Gas burner Multiple gas burners may be required for singeing, IR-driers or cylinder driers. Taking the AGI linear gas burner (see Fig.) as an example, a system of this kind can be explained as follows: the burner

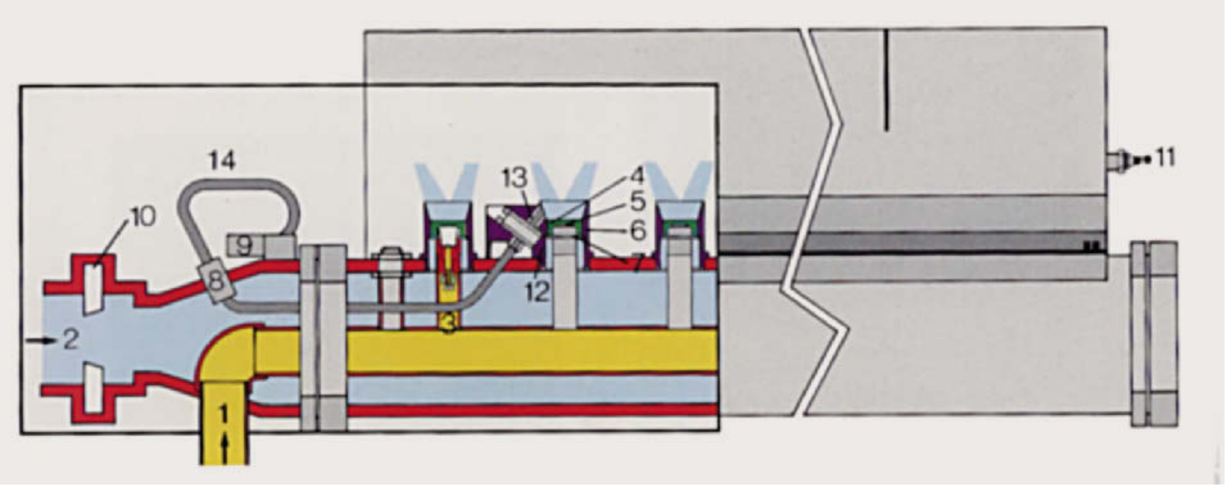

Fig.: "Gaz de France" (AGI) gas burner.
1 = gas; 2 = combustion air; 3 = calibrated opening; 4 = premix zone; 5 = open jet gas injector; 6 = observation port; 7 = turbulence ring; 8 = special glass fibre exit via stuffing box; 9 = signal converter (converting the optical into an electrical signal); 10 = pin diaphragm for limiting combustion air quantity; 11 = ignition plug; 12 = plug-in connection for ultra-violet flame detector; 13 = special glass fibre entry side; 14 = special ultra-violet glass fibres.

itself consists of two concentric tubes, the inner one for the gas supply and the outer one for the air supply. The openings in the outer tube for the individual burners are provided with impeller wheel turbulence rings for the combustion gas. In the middle of the turbulence ring is the injector which is supplied with gas from the inner tube. A mixture of gas and air is formed in the head of each individual injector.

The gas injectors are precision screw machine parts which ensure an extremely accurate throughput of gas. The injectors of the AGI burner are so-called "open-jet burners" and are manufactured under licence from the company Gaz de France, which also participated in the development of the linear gas burner. For flame monitoring purposes a special inspection hole is located in the burner itself, in which the entry end of a special glass fibre is mounted. From here the glass fibre cable is led through the air channel between the inner and outer burner tubes to a signal converter, i.e. it is protected from any mechanical damage. The UV radiation from the burner flame is converted by means of a UV cell into an electrical signal by the signal converter which is then further processed by a control unit.

Gas chlorination of wool Combed wool tops can be given an antifelting finish by chlorination when the chlorination process is followed by a polymer treatment. The chlorine bath (Hercosett process) has been developed for the chlorination of wool tops (see Fig.: Gas chlorinating bath) with chlorine water (chlorine gas dissolved in water) and bleach liquor (aqueous solution of sodium hypochlorite). All parts of the applicator unit in contact with this very aggressive liquor are constructed of glass-reinforced plastic (GRP), polyvinyl chloride, or the hydrochloric acid resistant Hastelloy C4 grade of stainless steel. The combed slivers are drawn from the entry zone through a separator grid and allowed to run parallel with a slight overfeed into the pair of feed rollers. The wool is opened by immersion in the liquor held in the nip of the rollers. An extremely uniform application of liquor is assured by a spray pipe with an inclined applicator plate on each side of the sliver. By this means, the chlorination liquor is able to reach each individual fibre through immersion.

The required quantity of chlorine gas is injected into the process water in an injector and a wetting agent added at a subsequent point before the liquor is uniformly applied to the sliver via the application system. On passing chlorine gas into water hypochlorous acid (HOCl) and hydrochloric acid (HCl) are formed in accordance with the following reaction:

$$Cl_2 + H_2O \rightleftharpoons HOCl + HCl$$

In this reaction, the pH of the bath is automatically set at approx. pH 2–2.5 and must not be further adjusted. Compared to sieve drum chlorination, there is no requirement for sulphuric acid to lower the pH; and cooling of the bath, which is typical of all other existing chlorination processes up to now, is also unnecessary in gas chlorination because of the precise and absolutely uniform application system. Even at process water temperatures of up to 30°C, a faultless and uniform chlorination of the sliver takes place. The reaction of wool with hypochlorous acid proceeds very rapidly and is essentially completed in the first third of the bath. With this treatment, oxidation takes place to a greater extent on the surface of the fibre so that the actual wool fibre receives less damage. The scales of the wool fibre are smoothed out by this process, the fibre surface becomes homogeneously hydrophilic and, at the same time, a negative (anionic) charge is produced which gives the fibre affinity for the subsequent resin treatment. The hypochlorous acid reacts very rapidly with the protein layer (exocuticle) of the fibre surface as a result of which the disulphide bridges are partially oxidized and the peptide chain partly hydrolyzed.

Gas chromatography (GC). This analytical technique is based on the sorption processes between a mobile phase and a stationary phase. Different components in the mobile phase move through the stationary phase at different rates due to their different distribution coefficients and so appear separately at the effluent end of the bed of packing where they are detected and measured by thermal consductivity changes, density differences, or ionization detectors. GC provides two results:

1. Retention time: the time taken for a substance to pass through the stationary phase. Under the same apparative conditions it is always the same; a substance may thus be indirectly identified by this means.
2. Signal response: in the case of ionization detectors the field under the detected signal is proportional to the concentration of the substance. This enables the concentration of a particular substance in a mixture to be determined with precision provided that substance-specific indication errors are taken into account.

The mixture of substances under investigation is passed through a column coated with a specific stationary phase by an inert carrier gas (e.g. helium). Thus the mixture to be separated is injected directly into the capillary column (i.e. "on column injection") and passes through the column by the gas current. By this means, a distribution of substances between the mobile (gas) and stationary (coating) phases takes place. Since the distribution coefficients of most substances are different, they will be retained for different lengths of time. Temperature-dependence of the distribution coefficients can be used to advantage in the separation of components at their boiling points provided the stationary phase layer has a similarly high affinity for all the substances present. Discrete bands (peaks) are formed which, corresponding to their different retention times, pass through the detector one after the other.

There are two possibilities for sample introduction:

1. Injection technique: the mixture under investigation is dissolved in a solvent and an aliquot of this solution (µl range) is injected and detected.
2. Gas sample injection (head space GC). The material on to which the sample under investigation is adsorbed (silica gel, textiles, etc.) is transferred to a head space vial that is sealed and placed in a thermostat at a preselected temperature to drive the desirable components into the head space for sampling. To achieve better desorption, the material is often covered with solvent and the resultant gas phase introduced into the GC system. The technique can also be used for the direct investigation of liquids such as textile auxiliaries for analysis of their readily volatile components.

The choice of stationary phase (column material) and its degree of activity is determined by the sample to be analyzed. To separate a polar mixture such as alcohols a different column material to that used for the detection of alkanes is used. In addition, different detector systems are also available. One of the most frequently used is the → Flame ionization detector (FID). For special applications, e.g. a photo-ionization detector (PID) by means of which substances are ionized and made detectable through the action of light may be suitable. A mass spectrometer can also be coupled to gas chromatography as a detector system (GCMS).

Gas chromatography is in very widespread use as an analytical tool, almost entirely for organic materials; the technique is rapid, simple, and can cope with very complex mixtures (100 or more components) and very small samples (nanograms); useful for both qualitative and quantitative analysis. Relative precision of 2–5%. Disadvantages: samples must be volatile and thermally stable below about 400°C; most commonly used detectors are non-selective; published retention data is not always reliable for qualitative analysis.

Gas fading A change in shade of dyed or printed fabric caused by chemical reaction between certain disperse dyes and gaseous contaminants in the atmosphere, chiefly acidic gases from fuel combustion (NO_x; SO_2). →: Colour fastness to atmospheric contaminants: nitrogen oxides; Burnt gas fumes.

Gas fading inhibitors → Inhibitors which offer protection against → Gas fading.

Gas fastness →: Colour fastness to atmospheric contaminants: nitrogen oxides; Burnt gas fumes.

Gas-flow transfer printing A further development of vacuum transfer printing technology.

The process uses a hot flow of gas directed on to a dye carrier medium (e.g. gas-permeable transfer printing paper) which it penetrates. The sublimed dye is carried along with the hot gas and deposited on the continuous web of fabric which rests on a gas-permeable conveyor belt. The direction of the gas flow passing through the dye carrier medium and the fabric is assisted by suction applied from beneath the conveyor belt. The choice of dye carrier medium, gas flow temperature, pressure difference between the upper and under sides of the fabric and the contact time are decisive parameters for control of the process. The degree of colour penetration achieved on pile fabrics by this process is far superior to that obtained by other transfer printing processes up to now. Since the dye carrier medium is only in light contact with the fabric being printed, no pile deformation occurs.

Gas fume exposure test → Gas fume fading.

Gas fume fading →: Colour fastness to atmospheric contaminants: nitrogen oxides; Burnt gas fumes.

Gas fume fading inhibitors Additives made to print pastes in order to prevent the reaction of nitrogen oxides (normally present in the atmosphere as contaminants, especially in industrial centres and areas of high population density) with disperse dyes belonging predominantly to the anthraquinonoid class.

Gas heating Used in textile driers, curing machines and stenters. Auxiliaries which are liable to volatilize or sublime must not come into direct contact with the flames in order to prevent their decomposition. Damage to the textile material can also occur.

Gas phase crosslinking A commonly used term for crosslinking reactions, e.g. with cellulose in the gas phase. →: VP3 process; Form V process; Cross-linking.

Gas phase processing Gases diffuse in fibres much more quickly than liquids (see Fig.). It is for this reason that attempts to promote gas phase processing have been made again and again in the recent past. For environmental reasons, however, the handling of gases is frequently problematic. Moreover, appropriate machinery for gas phase processing is expensive in many cases. However, in the case of heat transfer printing, gas phase processing, which involves the sublimation of disperse dyes, is quite simple.

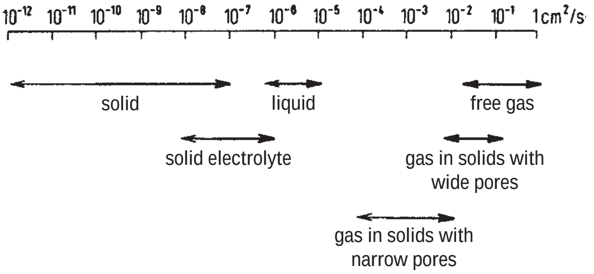

Fig.: Orders of magnitude of diffusion coefficients (D_0) as a prerequisite for gas phase processing.

The thermosol process (thermofixation) represents a special dye fixation technique for the continuous dyeing of polyester fabrics. It involves the following process stages: application of dye by padding, drying, thermosol treatment and afterwashing. The processing elements of immersion, squeezing-off and spraying predominate in the wet treatments whilst heating-up and cooling-down operations predominate in the thermal treatments. At the thermofixation temperature, only a few typically basic processes occur which, apart from coloration, would not be relevant. These can be described by the following primary functions: at 200–220°C, many crystals in the polyester fibre exist in the molten state, just as in heat-setting, and are therefore accessible to the dye. Depending on its molecular weight, the disperse dye actually sublimes under these conditions, i.e. it is converted from the solid state on the surface of the fibre to the gaseous state and diffuses rapidly and extensively into the fibre in the form of a gas before it becomes solid again at lower temperatures. On cooling, some of the dye co-crystallizes with the fibre polymer and thus becomes firmly anchored to give a fast dyeing.

Gas propulsion (in jet dyeing machines). In the Airflow system developed by Then, propulsion of textile fabrics is achieved by means of an inert gas so that movement of fabric without liquor load, or with a desired proportion of moisture is assured. The necessary dyes and auxiliaries are atomized and injected into the circulating gas stream where they are brought into contact with the fabric. Advantages: very short liquor ratios with consequent savings of water and energy. In adition to the dyeing and rinsing processes, fabrics can also be dried in the machine.

Gas sampling (pumps). In order to determine emissions in the laboratory qualitatively and quantitatively, the gaseous substances to be examined must first be adsorbed on to a suitable medium, preferably silica gel, activated carbon, etc. and then desorbed in the laboratory to facilitate measurement. To obtain quantitative measurements the pumps used to collect the gases must comply with certain conditions. For this reason, they are provided with automatic air flow control and can pump a specific volume minimum and maximum over a given time period. These parameters can be preprogrammed.

Gassing → Singeing.

Gassing machines (yarn singeing machines). Machines used for the singeing of yarns.

Gas testing tube A gas detector in the form of a small tube filled with a gas-permeable chemical which changes colour (due to a chemical reaction) when the air being tested is sucked through it. The length of the colour zone is a measure of the pollutant concentration. Accuracy of measurement ± 25%.

Gas trace analysis Analysis in the ppb or ppm range. Achieved mainly by means of electrochemical measurement.

Gas turbines in combined heat and power generation If it is assumed that the effective costs for electricity generation by electricity supply companies are too low since too many costs are externalized to the community, then the cost of electricity can be expected to rise further. These circumstances already dictate that production prices for electricity must reach appreciable levels. In many cases, therefore, in-house electricity generation can become viable within a short time. This is especially true if total energy plants and emergency power capacities can be combined, or existing emergency electricity generators can be converted to gas power or waste heat utilization. In principle, the use of gas engines for small total energy plants is to be recommended. Block-type thermal power station modules are available in the market for the generation of electrical power outputs from 90 kW with the entire waste heat exchanger system built into the base of the unit. These modules can be supplied with a complete control system ready for connection. For larger plants, especially where steam also has to be generated, gas turbines with a generating capacity of around 500 kW should be considered.

A gas turbine for combined heat and power generation operates as follows: the gas turbine compressor sucks in air for combustion via a sound muffler and compresses it to, e.g. 12 bar. This air is then heated in the combustion chamber of the gas turbine to approx. 1000°C. Combustion takes place with a large excess of air (lambda from 3.5 to 5). The pressure of the hot gas drops to atmospheric pressure in the turbine and the mechanical energy of the turbine is supplied to the compressor. The power requirement for the compressor lies considerably below the power output of the turbine. Consequently, the resultant excess power is converted into electrical energy in the generator. The exhaust gases are cooled down from approx. 1000 to 500°C by the pressure drop in the turbine and the heat contained in the exhaust gases is then converted, for the most part, into steam in the downstream waste heat boiler. The high vapour pressure, e.g. 10 bar, means that the exhaust gases are not cooled down to a desirable operating point level, i.e. the water vapour dew point of the waste gases, but only to considerably higher temperatures, e.g. 170°C.

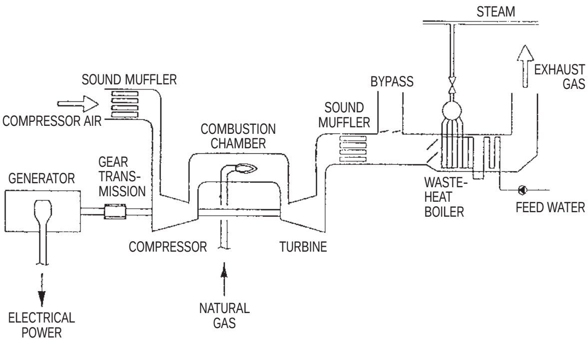

Fig. 1: Combined heat and power generation with a gas turbine.

The combination of a heat pump circuit with a gas engine is of interest if the gas heat pump is produced by heat recovery from the engine cooling water and the exhaust gases. On average, the energy saving achieved is in the region of 50%. If, however, waste heat is available from any other processes which would otherwise be released into the atmosphere, but can be used with the heat generated by the gas heat pump (Fig. 2) to the lower temperature level (exhaust gas heat recovery to the dew point) then, by including the former wastage due to non-utilization of waste heat in the calculation, energy savings of approx. 60% are arrived at. Gas heat pumps are economically interesting for outputs of about 400 000–600 000 kJ/h. Further additional energy-saving opportunities with industrial gas engines can be exploited because two shaft ends are available (simultaneous generation of electricity and heat). A particularly useful energy saving application of a gas heat pump, especially in textile processing plants with a high consumption of hot water during the summer, is to use the gas heat pump as a refrigeration unit for air conditioning systems or other cooling applications. Since waste heat is still produced by the engine despite application of the heat pump circuit as a cooling machine, its effective utilization must be ensured.

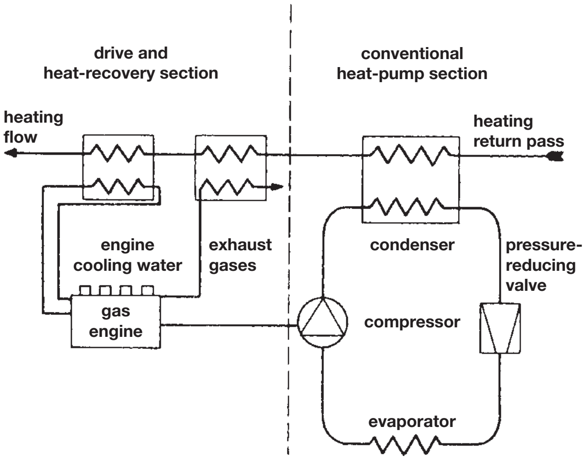

Fig. 2: Schematic diagram of a gas heat pump.

The open-cycle gas turbines are of the single-shaft type, i.e. compressor, turbine and power turbine are arranged on a common shaft. Major turbine components: air intake casing, two-stage centrifugal compressor, two- or three-stage axial turbine (depending on the turbine type) with exhaust diffuser, and single can combustor with central nozzle and high-energy ignition. The casing components are of ductile cast iron. The compressor wheels are of stainless cast steel, while the turbine's vane assemblies are precision castings of high-temperature steel. The turbine rotors consist of discs, with the rotor blades retained by a fir tree arrangement. The rotors and shaft components are centered with radial toothing and connected by a tie rod. The turbines designed for continuous duty are supported in plain bearings. Turbine cooling is by air taken from the air compressor. Cogeneration of power and heat or Combined Heat and Power (CHP) as it is called – the concept for efficient utilisation of primary fuel energy – is making vast inroads. Gas turbine generator sets (Fig. 3) provide electrical power at a location where it is needed, and at the same time produce useful heat for production and administration.

Gaufre (Fr.: *gaufre* = waffle, emboss). Flat fabrics in plain-weave, twill, or satin construction as well as plush materials and velvets with an embossed waffle-like pattern (→ Embossing) or a low lying pile

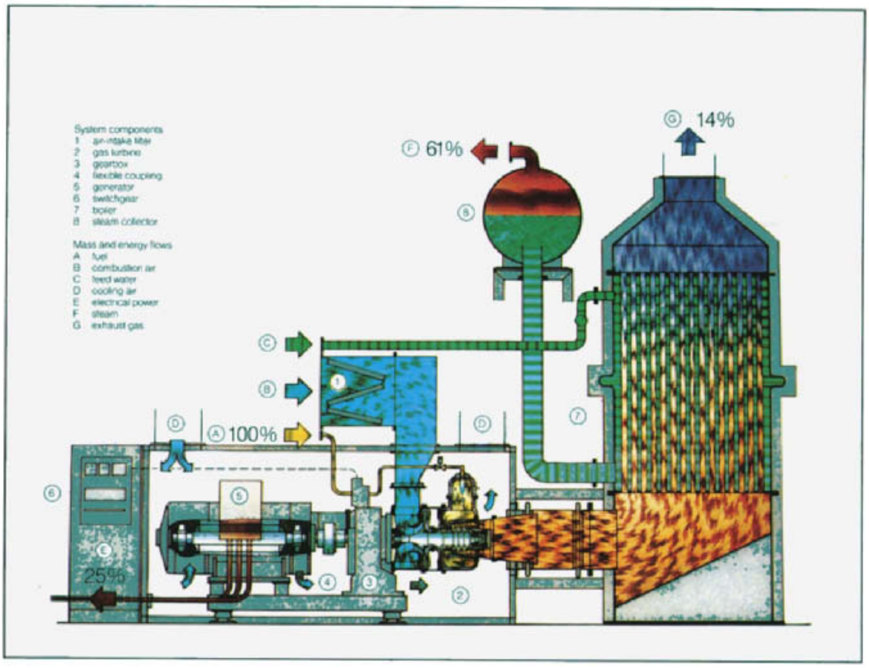

Fig. 3: Cogeneration System with M1A-13 Gas Turbine from Deutz MWM.

(= velvets). Gaufre fabrics include, e.g. →: Moiré fabrics; Reversible, etc.

Gauge (g),

I. A measure of the number of needles per unit length in knitting and hosiery. The greater the number, the closer and finer the knit. (e.g. raschel machine = 2 English inches; fully-fashioned knitting machine = 1.5 English inches; circular hosiery knitting machine = 1 English inch).

II. The number of wales per inch in a knitted fabric.

Gauze Lightweight, open-texture, net-like woven fabrics named after the Palestinian town of Gaza where they were originally used for veils. They mostly consist of thick yarns with a full finish or fine yarns with a veil-like appearance. Gauze fabrics (gauze weave) should not be confused with those produced by the leno weave, which is also a loose, open weave. Different types of gauze include: screen gauze (for screen printing), silk gauze, bolting cloth, cotton gauze (damask gauze, net curtains), wool gauze (→ Étamine, Marquisette), lining gauze, embroidery muslin, cotton muslin, etc. Cotton gauze is mainly used for surgical dressings.

Gauze weave A weave used in very thin fabrics, e.g. gauze, or for the production of woven effects (see Fig.). With a full leno weave, the warp threads are made to cross one another between the picks. In simple leno weaving, one warp thread (generally referred to as a crossing or leno end) is caused to lift alternately on one side and then on the opposite side of the neighbouring thread (usually referred to as the standard end) thereby producing “crossed” or “open” sheds. The leno ends are also drawn through a second heald which changes its position between the individual weft insertions. Advantage of the leno weave: the weft is anchored and therefore resistant to slippage.

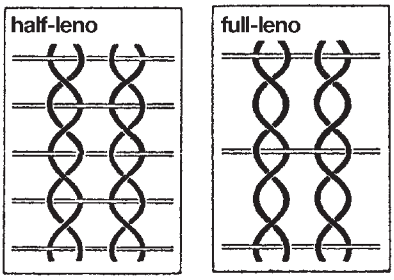

Fig.: Comparison between half-leno and full-leno weave.

GB, prefix for: British patent.

GC, abbrev. for: → Gas chromatography.

Gd, chemical symbol for gadolinium (64).

GDCh (Ger.), abbrev. for: Gesellschaft Deutscher Chemiker (German Society of Chemists).

Ge, chemical symbol for germanium (32).

Gear drives The stepless changing of the drive speed on process machinery can be facilitated by using mechanical gearboxes with constant motor speed or by directly adjusting the motor speed with electronic controls. Machinery with frictional drive gears and drive belts have no alternative electronic control of comparable price. For higher requirements, a mechanical ball/disk control mechanism has been developed, for outputs of up to 3 kW, which can regulate the speed down to a stop. Belt contact drives transmit outputs of up to 150 kW. Parallel to that, and for outputs which are higher still, three-phase current drives with a frequency converter are of interest (Fig. 1).

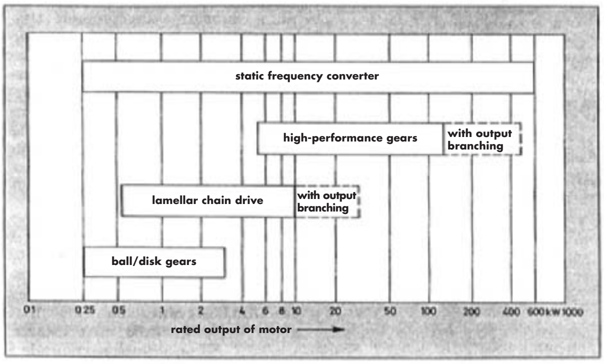

Fig. 1: Output ranges of infinitely variable drives.

Gears are torque converters. They consist of several machine elements and have the task of transmitting movements and forces, or of converting them. They transmit movements

a) by friction, i.e. actuated by pressure contact, e.g. belt drives, friction wheel drives;
b) via interlocking forms, i.e. with positive locking, e.g. toothed wheel gears, worm drive pairs, chain drives.

The speed change of drives can be regulated in steps (toothed wheel gears, chain gears) or in an infinitely variable manner (PIV drives, Variomat, etc.).

I. Toothed wheel gears consist of two or more gearwheels which work together. Depending on the type of teeth and the position of the gearwheels in relation to one another, we speak of:

- spur gears,
- spiral gears,
- bevel gears,
- worm drive pairs.

The speed change takes place step-wise through a train of gear wheels. The torque between two shafts or over a small distance are transmitted directly by gearwheels, in a positive locking manner. It is also possible to produce transmissions and direction changes. Transfer takes place when the projections of the one wheel – teeth – engage with corresponding gaps between teeth on the other wheel.

By "meshing" with one another, gearwheels transfer forces and movements. They are often combined to form toothed wheel gears. Here, it is important to permit only those that have identical tooth dimensions to mesh. The number of toothed wheels with their teeth must be in the same ratio as that of their reference circles. There are toothed wheels with spur teeth and also those with helical gearing. Helically-geared wheels demonstrate little play, little wear and run with less noise. Various gearwheel types are used in toothed wheel gears (Fig. 2), e.g.:

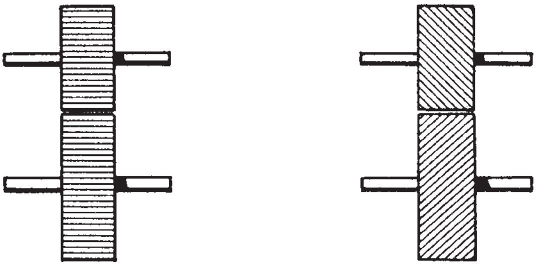

Fig. 2: Spur-toothed and helically-toothed gear pair.

1. Spur wheels: these have teeth on the frontal face.
2. Bevel wheels: they have teeth arranged in a conical manner. Bevel wheels are used when torque and forces of two non-parallel shafts are to be transmitted; in the case of spur gears, the shafts must lie parallel in order to transmit movement.
3. Helical gear wheels: these are spur gears whose teeth are cut in a helix. They are used in gears where shafts cross one another. Here there is also the possibility of transferring forces and torque of shafts which cross one another, by using a worm and worm wheel (worm gear pair, Fig. 3). If gearwheels are used as intermediate wheels, then they can be disregarded for the purpose of calculating the speed. Please note: Intermediate wheels can effect a change of rotation direction, but never a change of rotational speed.

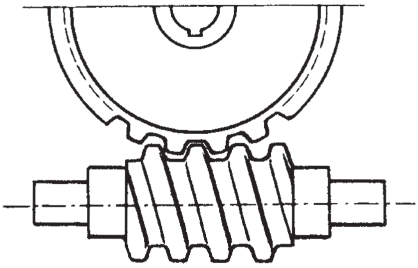

Fig. 3: Worm and worm wheel drive.

II. Chain drives (Fig. 4) transfer forces in a positive locking manner via two shafts, the distance between which cannot be bridged by means of gearwheels. Here, links of a chain engage into the teeth of chain wheels.

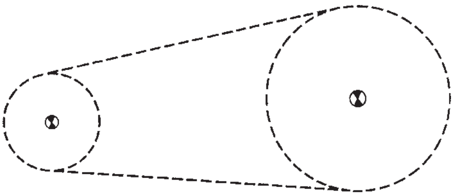

Fig. 4: Chain drive principle.

Gear drives

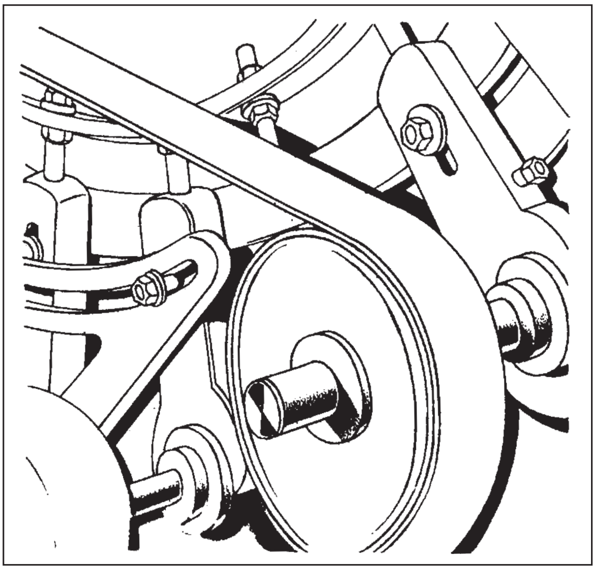

Fig. 5: Flat belt drive.

III. Belt drives (Fig. 5) transmit torque through friction. They transmit forces between shafts either via flat belts or via V-belts. Depending on the way in which the flat belt is guided (open or crossed), by changing the angle of belt contact, friction losses (slippage) can be avoided and changes in rotational direction can be achieved. V-belt drives (Fig. 6) have very low slippage. Here, a V-shaped belt runs in a groove of the pulley. The changes in speed are effected here in a step-wise manner through so-called step transmission, pulleys with varying disk diameters.

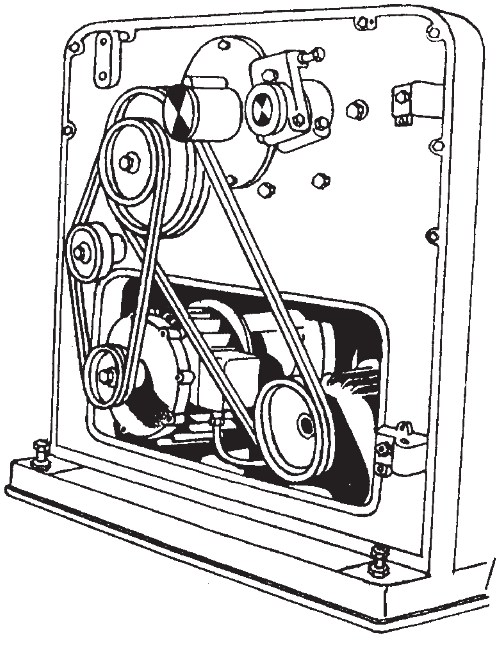

Fig. 6: V-belt drive.

IV. Friction gears (Fig. 7): If torque is to be transferred between two parallel shafts which cross or cut across one another, with only a small distance between them and with high circumferential speeds, frequent changes in speed and in direction, then friction gears are used. They can be regulated in an infinitely variable manner, by varying the position of the drive element relative to the driven element.

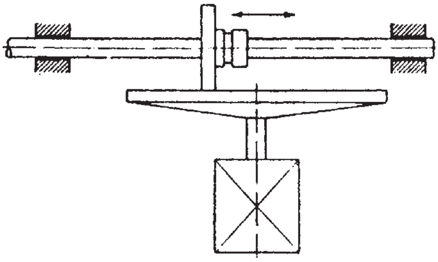

Fig. 7: Friction gears: crown gear with sliding gear wheel.

V. Infinitely variable gears: Infinitely variable drives run quietly and vibration-free; they can adjust the desired rotation range to the given working conditions. With them, speed changes can be effected whilst the machine is running. The following types are known:

1. PIV drives.
2. Würfel-Kopp-Tourator (balls control the adjustment range).
3. PC drive: (cones control the adjustment range).

In a PIV drive (Fig. 8), a V-belt or a link chain can act as a connector between the pulleys. The shaft (1) is the driving shaft; the power flows to the shaft (4) via toothed bevel disk pairs (2) and a wide lamellar chain (3). By means of a hand crank (5) via a rod linkage, the distance between the bevel disks can be changed and thus also the speed of the shaft.

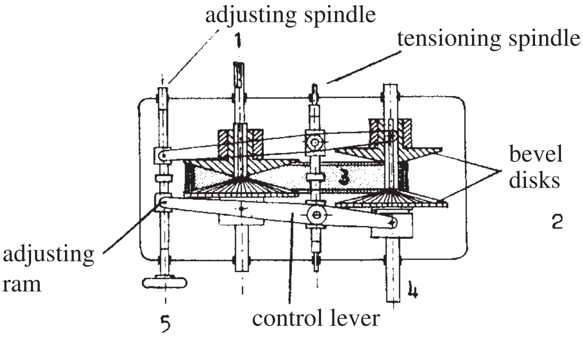

Fig. 8: PIV gears.

VI. Cam drives: If movements are to be converted, in modern textile machines increasingly the trend is to use cam drives. A cam (Fig. 9) (eccentric or cam disk) transmits the movement to the drive element (lever,

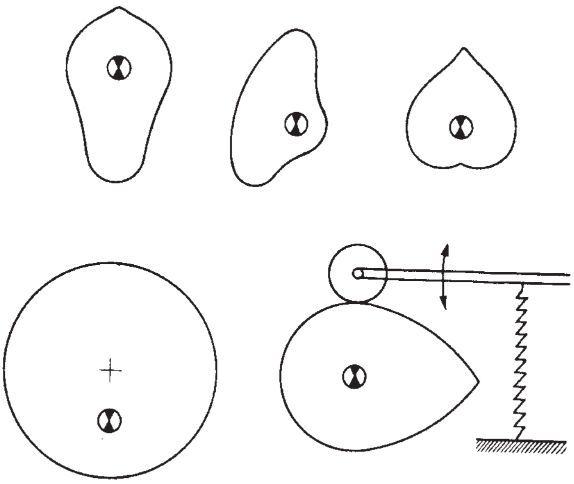

Fig. 9: Various cams for cam gears.

rod), usually by means of a roller. Transmission of movement is possible only when the cam follower is constantly in contact with the cam. There are two possibilities for this connection:

a) the cam contour is on the circumference (open cam gear), the cam follower is held down by means of springs,

b) the contour is milled into the cam as a groove; the cam follower is guided in this link by rollers.

Cam drives permit all types of movement, including movement intervals, but no movement of the cam follower can be achieved through arcs of the cam (dead position). Cam gears can be executed in open and closed forms.

Gedda gum → Gum arabic.

Gel A gelatinous, glassy, easily deformable mass comprising a disperse system of at least two components, i.e. of a colloidally distributed solid substance (e.g. →: Gelatin; Silicic acid) and a liquid (→: Lyogel; Xerogels). A gel can be prepared from a → Sol. Gels consist mainly of two components: the dispersed substance (gel binder) and the dispersion medium (solvent). Both components penetrate each other and join together. The coherence of both systems is the main characteristic of a gel, i.e. any point within the respective system can be reached from any other point without ever having to leave the system itself. The coherence of the dispersion medium is characterized by the fact that the diffusion of small molecules takes place at practically the same rate as in the pure solution. The gel structure consists as a rule of molecules which are connected to each other at adhesion points or adhesion zones depending on which type of energetic interactions between the (mainly) filamentary molecules exist. In the first case, they are referred to as primary valency gels: the chain molecules are bound by homopolar bonds into a three-dimensional network. In the second case, a secondary valency gel is present which is formed by the bonding of linear polymer chains by secondary valency forces (e.g. gelatin). It is in the nature of things that the second type of gels can be transformed into the solution state by changes in the environmental conditions whilst the primary valency gels are very stable under all conditions. If the solvent is removed from such a gel, or better, the swelling medium, it shrinks in most cases (xerogel), only to swell again on adding the dispersion medium. The size of the gel pores depends on the degree of swelling and this, in turn, depends on the solvent as well as the number of linkage points between the polymer chains. A range of porous polymers do not lose their structure, or only slightly, if the dispersion medium is removed (drying).

Gelatin The pure glue obtained by hydrolysis of collagen by boiling hides, cartilages and bones. Available as thin flakes or powder. Properties: transparent, glassy, lustrous material; colourless, odourless and tasteless. Water-soluble after prior swelling giving more or less viscous solutions. The addition of formaldehyde reduces water-solubility. Quality evaluation: 1 g in 100 ml water must still set to a jelly above 0°C. Uses: finishes, sizes and printing thickeners.

Gelatinizer → Plasticizers.

Gel dyeing (wet tow dyeing). Here, polyacrylonitrile fibres which have been produced by the wet spinning method are passed, still in the swollen state, through an aqueous dye bath (40–60%) during or immediately after drawing. A subsequent drying (heat treatment at 105–150°C) closes the pores of the fibre surface, by which the dye is fixed. Dark, intense shades are achieved with dye penetration and fastness equivalent to exhaust dyeing. Whilst polyacrylonitrile fibres are still predominantly dyed according to the exhaust method, it is apparent that gel dyeing has become the second most important dyeing method and has clearly overtaken continuous dyeing (pad-steam method). For its part, tow finishing (gel, spun dyeing, pad steam and exhaust methods) has been dominated by gel application for years. Wet tow dyeing is carried out following on from the extrusion spinning of the fibre, by the fibre manufacturer, and for this reason has a special position compared with other continuous dyeing methods with which the textile finisher is more familiar.

As is well known, polyacrylonitrile fibres are manufactured either according to the dry or wet spinning method. Whereas in dry spinning, the fibre is created from a solution of the polymer, predominantly in dimethyl formamide, by evaporation of the solvent, in wet spinning the fibre formation takes place in an aqueous precipitation bath with various additives. Besides dimethyl formamide, solvents include dimethyl acetamide, aqueous sodium thiocyanate, nitric acid, etc. The fibres produced in this way are initially present in a hydrated - i.e. swollen or gel-like - state, and show a particularly high affinity for dyestuffs. For this reason,

Gel dyeing

Tab.: Specific surface of wet-spun polyacrylonitrile fibres.

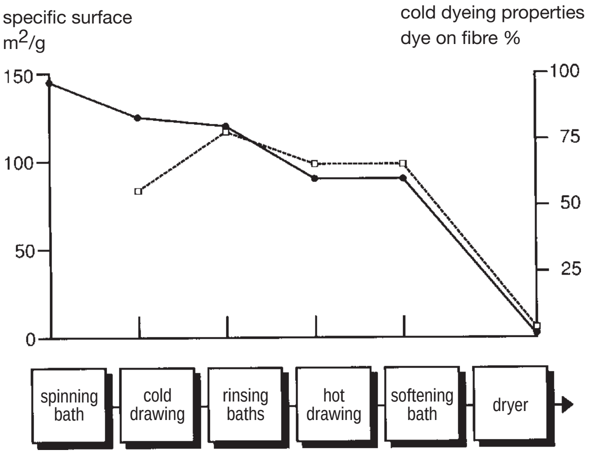

Fig. 2: Specific surface – cold dyeing properties in the course of the spinning process (as a precondition for gel dyeing).

dyeing can be integrated in the continuous process of fibre production (Fig. 1).

Depending on the spinning solution, precipitation bath composition and the working method, fibres are produced which often differ considerably in terms of their dyeing behaviour. For this reason, not all wet-spun polyacrylonitrile fibres are equally well suited for the wet tow process. The most important requirement for dyeing is sufficiently good accessibility of the tow, since only a few seconds are available for the contact between the wet tow and the dyeing liquor. In wet tow dyeing, diffusion plays only a subordinate role as compared with the dyeing of conventional polyacrylonitrile fibres. The dye absorption takes place via a pure adsorption mechanism which progresses very rapidly and is influenced very little by temperature. Gel application refers to dyeing or optical brightening in the spinning production line, namely after the rinsing section but before the drying unit. The dyeing mechanism is determined by the fibre structure - which is very open in this area - and the degree of orientation of the macromolecules, which is still relatively low. The amorphous structure means a high porosity of the fibres, and thus a very large specific fibre surface being available to the dye or optical brightener. It can be determined comparatively on freeze-dried tows in accordance with the Brunauer-Emmet-Teller method, and at room temperature it can amount to several times that of a dried, collapsed fibre of the same type (see Tab.).

How the specific surface of the fibre has changed in the course of the spinning process, and what this means for cold dyeing properties (an indicator of the dyeing properties under gel conditions), is shown by the block diagram in Fig. 2, which takes the example of a fibre type which has been wet-spun from DMF.

After fibre formation (145 m²/g), a constant slow reduction in the specific surface (90 m²/g) is to be observed over cold drawing, rinsing sections and hot drawing. Only after drying does this drop to the very low level. The so-called cold dyeing properties also move within a similar frame. In the present case, they were established by determining the relative degree of absorption of dyeing (3 seconds at 40°C) with C.I. Basic Red 46 (5 g per litre). Furthermore, the dyeing duration chosen here lies within the upper range of the actual ones customary in gel application, which are determined by the dimension of the dyeing unit and the run speed of the tow at the place of dyeing. Even though various hypotheses about the dyeing mechanism exist, it nevertheless seems to be clear that due to the strongly developed surface, the adsorption represents the dominant step in gel dyeing. Whilst most sources point to Langmuir's theory by way of explanation for this, there are also observations according to which the → Adsorption isotherms in equilibrium approximate more to those according to Freundlich. It must also be assumed that the mechanism extends beyond a normal ion exchange, and the gel fibre can, to some extent, also take up ion pairs.

The advantage of wet tow dyeing lies in the elegant inclusion of dyeing in the process of fibre manufacture, with a relatively rapid change of colour being possible. This makes the dyeing of even small batches worthwhile. In the case of bulk dyeing, on the other hand, batches of less than about 20 tonnes are usually regarded as economically uninteresting. The variety of the shades which can be achieved in wet tow dyeing is also larger, and corresponds approximately to that of exhaust dyeing. However, besides these advantages of wet tow dyeing, there are also certain problems. There can be difficulties with dye levelness. In view of the rapid dye uptake, it is not exactly easy to dye the tow – which consists of several hundred thousand individual filaments – evenly. The dyeing unit assumes particular importance. Dyeing can take place on a type of roller vat according to the counter-flow or co-current flow principle (source: Jenny).

Gelling machine Drying machine (suspension drier) for drying coated fabrics and nonwovens impregnated with a plastic solution (see Fig.).

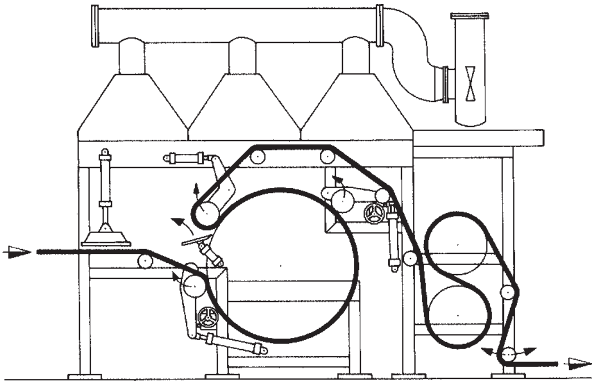

Fig.: WUMAG gelling machine for pre-gelling glass fibre matting (substrate for polyvinyl chloride floor covering).

Gel-permeation chromatography The principle of gel-permeation chromatography is the separation of materials according to molecular size and shape by passage of a solution through a column or across a surface consisting of a polymeric gel. The process is described as “gel-permeation”, “gel-filtration” or “exclusion chromatography”.

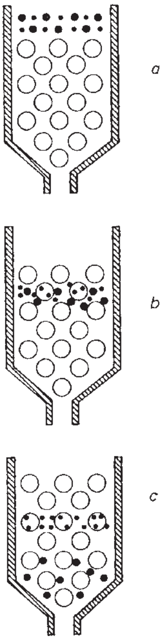

Fig.: Representation of gel chromatography in three phases.

If a macromolecular substance is introduced into a chromatography column (packing: dextran cross-linked with epichlorohydrin), the macromolecules are at first located outside the pores of the gel in the freely mobile solvent, but then diffuse into the pores until a distribution equilibrium is reached (see Fig.). The achievement of this distribution equilibrium depends on molecular size and shape and is, amongst other things, a function of molecular weight. Molecules which exceed a certain minimum size cannot penetrate inside the gel (upper exclusion limit) and are therefore eluted first. Medium-size molecules which could penetrate the pores, diffuse in the flowing solvent front in accordance with the concentration gradient. With decreasing molecular size (corresponding to a greater depth of penetration) an increasing quantity of solvent must be used to elute them. Within this “fractionation range”, an empirical linear relationship exists between the quantity of solvent necessary for elution (elution volume Ve) and the logarithm of the molecular weight:

$$Ve = K_1 - K_2 \log M$$

If the molecules fall below a certain size (lower exclusion limit), they will move unhindered throughout the entire volume of solvent and will not be separated by their size.

From a theoretical point of view, it is possible to imagine that when dissolved molecules of different sizes flow past such surfaces a separation takes place. The separation must be much more effective if the gel is granulated so that the interfacial surface area is increased many times, i.e. the time taken for a diffusion equilibrium to become established is considerably reduced. On allowing a solution of different sized molecules to trickle over gel particles filled with solvent in a vertical glass column, the molecules will be separated if the column is washed through with pure solvent. The procedure is reproduced schematically in the figure where only two sizes of molecule (represented by large and small dots) and the gel particles (represented by circles) have been shown for the sake of clarity. The gel offers no resistance to the diffusion of small molecules and they spread uniformly over the entire cross-section of the glass column whilst the larger molecules are unable to penetrate within the gel so that only the solvent between the gel particles (external volume) is available to them. During afterwashing with solvent, however, transport of these molecules only takes place in this external volume so that larger molecules are transported more rapidly than the smaller ones which, in the meantime, are delayed by diffusion in the (stationary) gel phase. If the mixture still contains medium size components, these would only occupy a certain part of the gel phase at diffusion equilibrium. Therefore, the components of a mixture will leave the column filled with gel particles in order of decreasing molecular weight corresponding to their diffusion-related retention times in the stationary gel phase.

Gel-permeation chromatography is used for the separation and desalting of high-molecular-weight materials and the determination of molecular weights.

Gel spinning The development of gel spinning for polyethylene began in the early 1980’s. With this technique it is possible to produce fibres with high tenacity and modulus from polymers with flexible molecular chains. The main characteristics of this process are the use of polymers having ultra-high molecular weights and the processing of dilute spinning solutions. The strength of the fibre increases with increasing molecular weight. The low concentration of the spinning solution allows a high draw ratio to be applied to the fibre. A linear increase in modulus with draw ratio exists (Fig. 2).

For a number of years now, several high-performance polyethylene fibres produced by gel spinning technology have appeared on the market.

The attainment of extremely high strength can be explained by so-called shish-kebab spinning (Fig. 1). High strength is more easily achieved the more the C-chains are statistically disoriented in the solution (or in the melt) and the less the shear forces acting on the extruded filaments so that complete orientation of the molecule chains is achieved by the drawing process only from a normal ratio of 30 : 1 to 100 : 1 (however, draw ratios up to 1000 : 1 are possible). The plates of folded molecular chains can be fully drawn. Polyethylene of MW ≥ $1.5 \cdot 10^6$ has been stabilized with 0.5% w/w di-tert-butyl-p-cresol (DBPC) at 150°C and then dissolved in 2% w/w decalin at 130°C, spun through 0.5 mm ∅ orifices, extracted and drawn in a hot air oven at 100–140°C. When drawn 32 times, the filaments had a modulus of elasticity of 90 Gpa and a tenacity of 3.0 Pa with 6% elongation at break. The relationship of the e-modulus to the draw ratio is shown in Fig. 2.

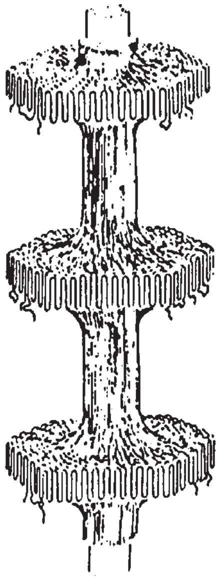

Fig. 1: Schematic representation of a micro-shish-kebab. The close relationship between the folded plates and the longitudinal fibre structure is to be emphasized here.

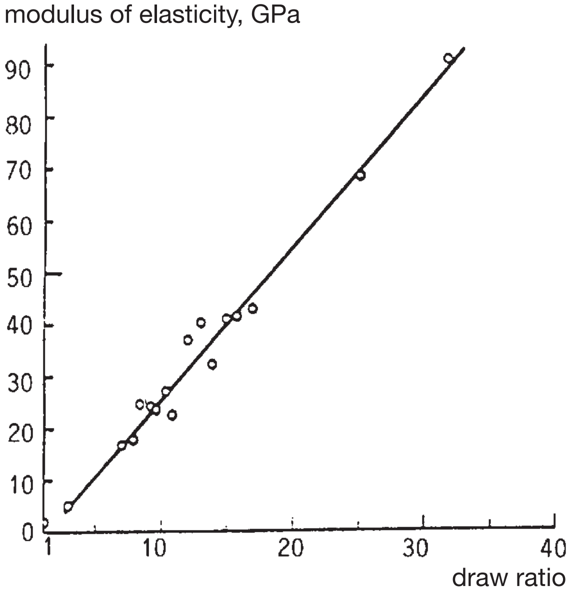

Fig. 2: Relationship of the e-modulus of gel-spun polyethylene filaments to the draw ratio.

In a similar manner to the gel spinning of polyethylene, the textile-mechanical properties of polyacrylonitrile are also improved by gel spinning with increasing draw ratios. The stress-strain behaviour of various highly drawn filaments spun from a 5% solution is shown in Fig. 3. The optimum drawing temperature is 160°C. At higher temperatures no further drawing appears possible; lower temperatures do not allow the application of high draw ratios.

The spinning solutions are produced by dissolving a polyacrylonitrile homopolymer (MW 540 000) in DMF. With the aid of a piston spinning machine, the spinning solution is extruded through a single hole spinneret into a spinning bath cooled to –30°C. Coagu-

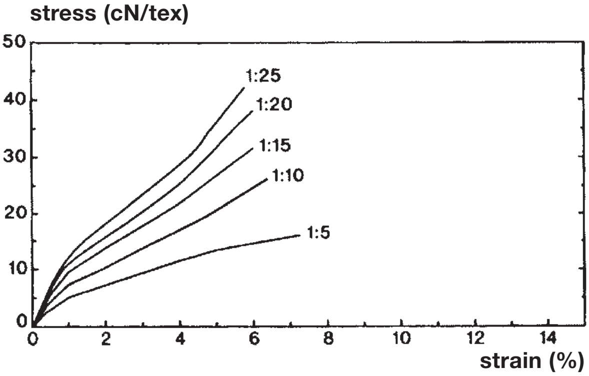

Fig. 3: Stress-strain behaviour of gel-spun polyacrylonitrile filaments in relation to draw ratio.

lation takes place in a spinning bath filled with n-butanol. The resultant gel filament is milky and translucent, extensible and soft. It is very tacky in this state and therefore cannot be wound immediately, but has to be passed through a second spinning bath filled with acetone (Fig. 4) where partial solvent exchange takes place. Acetone absorbed by the filament evaporates during the air passage between the acetone bath and the winder. During winding, the filament is externally dry and solid. The bobbins of gel filaments are stored in a DMF atmosphere until the drawing operation.

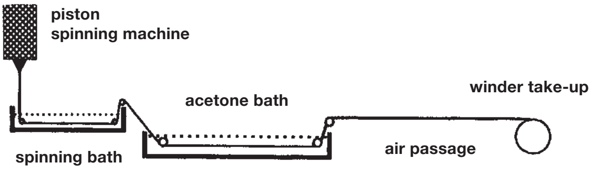

Fig. 4: Schematic representation of the gel spinning stage.

A xerogel is defined as a solvent-free gel. The discontinuous xerogel process consists of two stages: the production of a gel filament and its extraction, as well as the final hot drawing stage (Fig. 5).

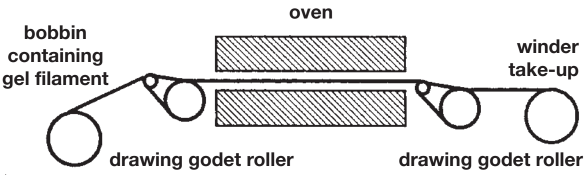

Fig. 5: Schematic representation of the gel drawing stage.

Gel time The → Processing time or potlife, i.e. the time during which a product remains sufficiently plastic to be workable up to solidification.

Gel, to When coatings are produced from polyvinyl chloride (PVC) without solvent, the polymer is made pliable by the addition of plasticizers. The material can then be coated before the compound begins to gel (set) during subsequent passage though the drying tunnel.

Generations of fibres In the somewhat rapid development of textile products, e.g. types of fibres, the respective stages of development for a particular family of products are referred to as generations. Thus, synthetic fibres for the tufted carpet sector have evolved through the following stages:

1st generation: normal fibre.
2nd generation: soil-hiding.
3rd generation: fibre + antistatic.
4th generation: fibre + fluorocarbon.
5 th generation: (1987): a) fibre + stainblocker + fluorocarbon; b) 4 th generation + stainblocker; c) fibre with built-in fluorocarbon.

Generative photography A photographic technique used for design creation based on the following technical possibilities: a) modification of existing motifs (figures, geometric shapes or crystals in UV light, polarized light, etc.) by translation, addition or rotation; b) exposures with a multiple camera (camera with several objectives, the shutters of which can be operated simultaneously or successively); c) by additive colour mixing; d) colour generation by polarized light; e) colour generation by filters.

Genetic engineering The example of insulin production by genetic engineering techniques is indicative of the enormous advances made e.g. in the field of protein synthesis. In 1963 Zahn succeeded in achieving the

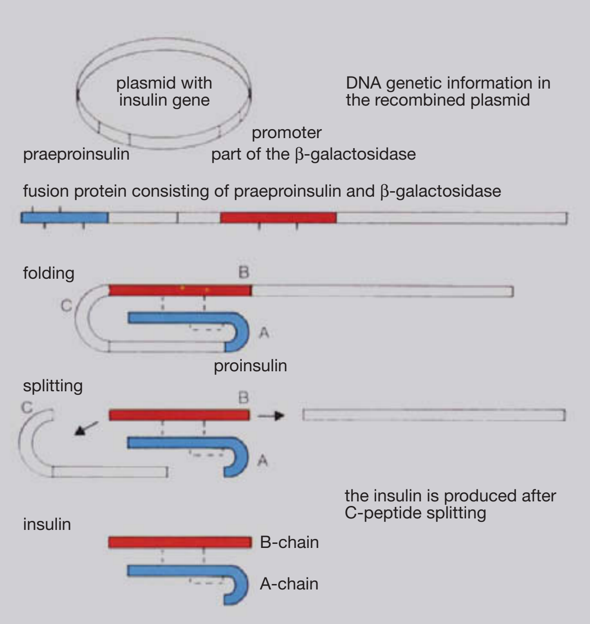

Fig.: Genetic engineering steps to biosynthetic human insulin.

chemical synthesis of insulin after years of studying the structure of this protein. Genetic engineering makes use of bacteria for synthesis purposes. Bacteria implanted into an animal or human gene will treat it as one of its own genes. If the appropriate genetic "code" is introduced it will produce proteins according to its own instructions. Moreover, the instructions for production continue to be given with each cell division. When a particular cell density is reached (usually two to three thousand million cells per millimetre of culture medium) the bacteria stop further growth. In the next stage, the bacterial culture can be "harvested": the cells are separated from the medium and "isolated". Insulin is then separated from the other components of the bacteria in a series of biochemical purification stages. Finally, the C-chain polypeptide must be separated from the molecule as a compound in order to convert the insulin from its precursor into its active form. The end-product is pure human insulin (see Fig.).

Genoa cord (→ Corduroy, Manchester velvet, corded velvet → Velvet). A velvet with characteristic weft ribs (1 warp + 2 wefts, ground weft and 2–3 long-floating pile wefts which are cut during finishing).

Genuine oriental rugs A quality label ("Echte Teppiche" in German) used for hand-knotted → Oriental carpets which was introduced in the middle of the 19th century as a protective label to distinguish them from machine-made carpets with "oriental" designs which were beginning to appear on the market at that time.

Geometric formula → Configurational formula.

Georgette A sheer, lightweight, somewhat transparent open-texture fabric with a fairly pronounced crêpe effect, usually produced in a plain weave with crêpe yarns from almost all types of fibres. It is generally woven with alternating pairs of S- and Z-twisted yarns in both warp and weft. The handle and appearance are characteristic, i.e. the fabric has a crinkly texture and is harsher and more opaque than chiffon. Georgette has a soft and flowing drape. It is mainly dyed in the piece or printed. These materials are very extensible and elastic due to the crêpe yarn twist, and are also highly permeable to air and virtually crease-free. Used for dresses, blouses, skirts, gowns and millinery.

In addition to the usual lightweight, more or less transparent georgette fabrics, there are also so-called winter georgettes, i.e. women's winter coat materials which have the typical georgette appearance on the face side, whilst the reverse side consists of a special backing fabric produced from carded yarns which is raised to confer better heat insulation.

Geotextiles A collective term for any textile material forming an integral part of civil engineering structures of earth, rock or other constructional materials. The use of these materials is rapidly increasing wherever cost savings in the use of other construction materials can be realised. The fields of application for geotextiles include the balancing of forces in road and rail construction, the reinforcement of embankments, filtration and drainage, agriculture and building construction (concrete floors during setting), sea bed protection, watertight structures/sewers (swimming pools), dam construction; coated and bitumen-impregnated materials. Geotextiles are produced from polyester, polypropylene, polyamide, polyethylene and blends. As a rule, geotextiles are, for the most part, water-permeable nonwoven filtration sheets (membranes) which have been manufactured by needle-felting and similar nonwoven bonding technologies. Their properties correspond to actual application requirements or must be adapted to the circumstances of use. Due to their porous structure (when introduced between the subsoil and upper ground strata) they ensure the successful separation and integrity of the bottom strata with most types of ground as well as the drainage of ground water and precipitation. Requirements: controlled quality, quick installation, water permeability, high tensile strength, good shear strength, toughness and a high modulus of elasticity. In addition, geotextiles should be resistant to rotting, mould, microbial attack and changes in temperature.

The profile of requirements dictates that only synthetic fibres can be considered as suitable materials for use in geotextiles.

Geotextiles fall into two important categories, i.e. "classic gotextiles" as typical products of the textile industry including fabrics and nonwovens, and "geotextile-related" products. The first stage in the fabrication of classic geotextiles involves the production of linear elements such as filaments, fibres, slit membranes (ribbons) and yarns. These linear elements are combined in the second stage to produce a permeable flat structure such as a woven fabric or nonwoven. Thus, typical, well-known processes employed by the textile industry are used in their manufacture. The geotextile-related products, on the other hand, have a coarser structure than classic geotextiles and include belts, mats, nets and lattices which are mainly used for the reinforcement of ground structures. "Composite geotextiles" are composed of several layers of geotextiles or related materials. A prefabricated drainage mat, in which an open core material is sandwiched between two nonwovens and mechanically bonded, is an example of this type of product. Synthetic polymers such as the polyolefins (polypropylene, polyethylene), polyester and polyamide are the main raw materials.

For the description and identification of a geotextile, details relating to the raw materials, among other things, are indispensable. Geotextiles have physical characteristics just as the ground conditions themselves. They are permeable and have certain mechanical properties which can change the environments where they are used.

Five characteristics, in particular, are typical for geotextiles used as construction materials:

1. The properties of the fibres, which are of a similar size to the fine components of the soil and exhibit considerable tensile strength in relation to their cross-section.
2. The nature of the bond between the soil and textile fibre: due to the incorporation of a continuous element into the loose stones, etc., the strength and deformation characteristics of the composite system are fundamentally changed.
3. Deformable structures based on poor building ground sensitive to subsidence, which can also suffer significant long-term deformation without their strength and stability being impaired, are of interest to the engineer.
4. Savings in transport, since geotextiles are considerably lighter and easier to handle than mineral construction materials.
5. The simple construction techniques as well as the reliability of geotextile building materials ensures the quality of building structures.

Geotextiles are used in all sectors of foundation and hydraulic engineering. They are employed in major construction projects such as earth embankments and motorways as well as in minor access roads or the construction of shafts. The four general fields of application for geotextiles in civil engineering are:

- transport engineering,
- hydraulic and dam engineering,
- land reclamation and environmental engineering,
- coastal defences.

The great majority of textiles incorporated into roadworks and highway construction are nonwovens. They are formed by bonding webs (mats) of continuous filaments, or 3–15 cm long staple fibres, laid flat on top of one another. The fibres are laid with or without a predominant direction. Depending on the type of fibre used, either staple fibre or filament nonwovens are produced. Mechanical, adhesive or thermal bonding techniques are employed to achieve the necessary bonding of the nonwoven structure.

A further classification of nonwovens, depending on the method of bonding employed, can also be made:

a) Mechanically-bonded staple fibre or filament nonwovens can be manufactured with the aid of special needles. Bonding with special needles provided with hooks or beards is achieved by interlacing the staple fibres and filaments. The fibre crossover points produced by mechanical bonding are movable, not rigid.
b) Adhesive-bonded nonwovens are obtained by impregnating or printing nonwovens with binder dispersions. Rigid bonds are formed at the fibre crossover points when the binder is cured.
c) Thermally-bonded nonwovens fall into three distinct groups: during thermal bonding with binder fibres, a small percentage of staple fibres or filaments with a low melting point assume the role of an adhesive binder after melting under heat. Core-sheath bicomponent fibres have a sheath (outer covering) with a lower melting point than the core which becomes tacky on heating. For thin nonwovens, made from fibres or filaments, thermal bonding can also be carried out by pressure and heat.

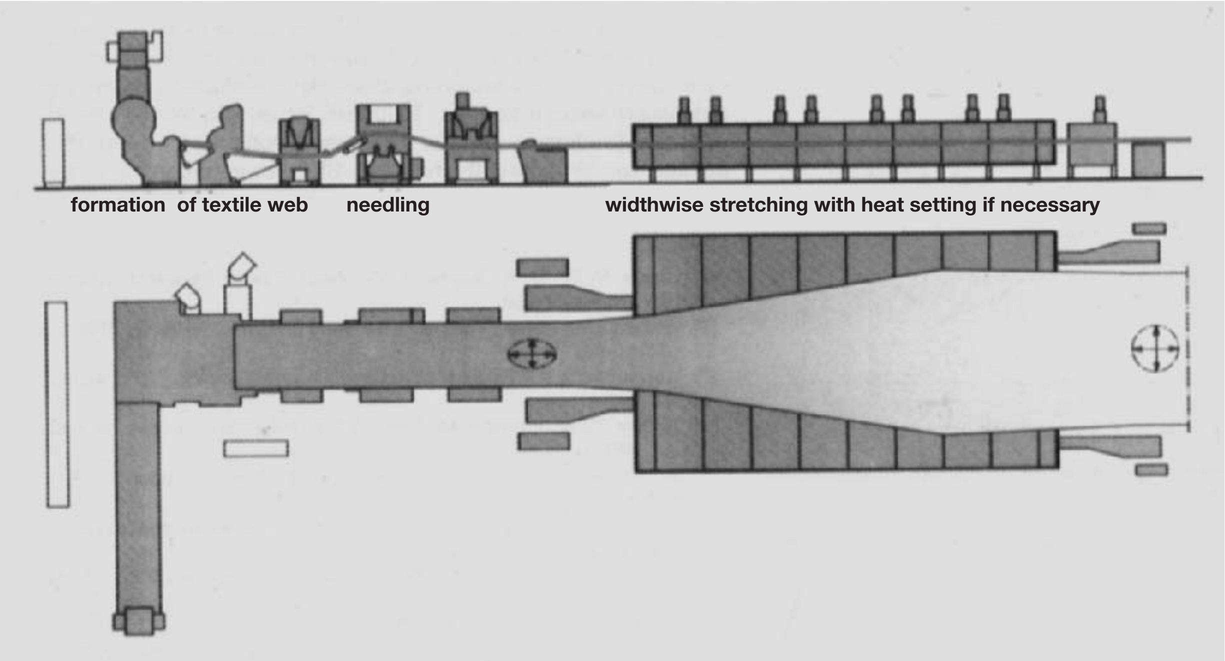

Fig.: Production plant for geotextiles.

Composite geotextiles consist of two-dimensional nonwoven, woven or other types of fabrics bonded together. A plant for the production of nonwovens is a high performance machine for the manufacture of two or three-dimensional random-laid webs. Working widths up to 5.4 m are achieved without the need for a crossfolder. Since stretching of the random web takes place with this technology, wide working widths can also be achieved. Random fibre orientation in the nonwoven is a fundamental requirement of this technology as the strength in the nonwoven before needling lies in the range of approx. 1 : 1 (lengthwise to widthwise direction). After needling, this ratio changes to approx. 1.5–1.8 : 1. However, values of approx. 1 : 1 can be achieved once again by subsequent stretching in the widthwise direction. For the geotextiles mentioned here, fibres with linear densities in the range of 3–7 dtex are well-proven in practice with staple lengths between 60 and 75 mm. The needling of geotextiles is carried out on both sides of the material. During this needling process, the strength ratio changes to approx. 15 : 1 (machine direction : widthwise direction). The ideal machine combination in this case is a pre-needling machine with a special feed system followed by a double-bed machine and a machine in which needling is carried out from the lower to the upper side. The final treatment is carried out on a stenter during which an increase in width of approx. 35% in relation to the initial width is achieved. During this stretching in the widthwise direction at a temperature close to the softening point of the synthetic fibre, an increase in overall strength is achieved both in the machine direction as well as in the widthwise direction which results in a final strength ratio of approx. 1 : 1.

Woven geotextiles consist of two perpendicular crossing yarn systems. Staple fibre yarns, multifilament yarns, ply yarns, monofilaments, slit film yarns or split yarns (as well as various combinations of these) are used in the warp and the weft. Woven fabrics also differ in type of weave, e.g. plain weave, panama weave, twill weave, the number of yarns per unit length and a possible additional bonding of the yarn crossover points. The thickness of yarns used in woven fabrics for foundation and hydraulic engineering applications range from 200–14 000 dtex.

German hardness degree (°d). An obsolete unit of measurement for water hardness. It is not an SI unit. Now replaced as a unit of measurement by mmol/l. → Water hardness units.

Germfree condition → Sterility.

Germicidal finishes → Antimicrobial finishes.

Gesamttextil (Ger.), abbrev. for: Gesamtverband der Textilindustrie in der Bundesrepublik Deutschland e.V. (Head Organization of the Textile Industry in the Federal Republic of Germany). → Technical and professional organizations.

Gesamttextil Research Council → Forschungskuratorium Gesamttextil.

Gesamtverband der deutschen Textilveredlungsindustrie e.V. (Ger.) → Technical and professional organizations.

Gesamtverband der Textilindustrie in der Bundesrepublik Deutschland e.V. (Gesamttextil; Head Organization of the Textile Industry in the Federal Republic of Germany). Representative top-level organization of the German textile industry; → Technical and professional organizations. The → Forschungskuratorium Gesamttextil is a branch organization, established in 1951.

Gesellschaft Deutscher Chemiker (GDCh). Society of German Chemists. A leading German professional organization which, since 1946, has taken on the tradition of the Verein dt. Chemiker. Publications include the journals: Angewandte Chemie, Chemie-Ingenieur-Technik, Nachrichten aus Chemie und Technik, Chemische Berichte, Werkstoffe und Korrosion. → Technical and professional organizations.

GF, → Glass fibres, → Standard abbrev. for textile fibres, according to DIN 60 001 T4/08.91.

G_F German system of assessing the toxicity of pollutants in relation to fish in accordance with the waste water levy act [ABwAG – Abwasserabgabengesetz]. Used to determine the dilution factor ($G_F = 2$ is the zero point), where tested effluent is no longer toxic to fish → Waste water evaluation.

g-factor Term frequently used in technical specifications for centrifuges: indicates how many times greater the centrifugal acceleration of the machine is than the acceleration due to gravity. In the absence of manufacturer's specifications, it can also be calculated from the drum diameter d(m) and the rotational speed n (rpm):

$$\text{g-factor} = \frac{d \cdot \pi^2 \cdot n^2}{2 \cdot 30^2 \cdot 9.81}$$

GH (Ger.), abbrev. for: Gesamtwasserhärte (→ Water hardness units).

Ghatto gum → Asiatic gums.

Ghiordes rugs Ghiordes rugs are the cream of Turkish manufacture. They are rugs of ancient origin and their design has affinities with the very beautiful and rare sixteenth century → Prayer mats. They are named after the town of the same name in western Turkey some 100 km from the port of Izmir. Ghiordes rugs are woven with 150 000–300 000 knots/m^2. Various colours are used for Ghiordes rugs. Firstly, these rugs must be divided into two categories: those over 150 years old which date from the court period, and those dating from the middle of the nineteenth century onwards. The first group have rather drab colours. The niche is in dark blue or ivory or, more rarely, dull green.

Also the number of colours used in the border motifs is limited and the shades used are quite light. The second group, however, have vivid colours. The niche is often red and the border motifs stand out in brilliant hues. Among the predominant colours are yellow, orange, red and ivory. In spite of their vividness, the colours used in this group of Ghiordes rugs harmonize perfectly with one another.

Ghosting effects A distinction is made between the following types of ghosting effects:

I. Abrasion ghosting: If the drying or cooling down of transfer paper after printing is inadequate, part of the dye film marks off on to the back side of the following layer of paper during roll batching. The effect is independent of time and is also described as short-term ghosting. Preventive measures: use of a suitable binder in the print paste.

II. Sublimation ghosting: Caused by the gradual sublimation of disperse dyes, especially those with a high vapour pressure, from the printed paper to adjacent layers of paper lying above or below in the roll during storage over several weeks or months (long-term ghosting). This type of ghosting is dependent on the storage temperature. Prevention: backcoating of the transfer paper with a thickening agent having no affinity for disperse dyes.

III. Migration ghosting: Caused by migration of disperse dyes in the print paste components in the dissolved form and results in the bleeding of dye around printed outlines (likewise long-term ghosting) which is temperature-dependent. Preventive measures: avoidance of solvent components in the print paste formulation which do not immediately evaporate.

Ghosting in transfer printing A defect in sublimation transfer printing due to inadequate storage stability of the transfer printing paper. During the storage of transfer printing papers, an undesired migration of dyes can occur which can cause disruptions in the sublimation transfer printing process and defects in the transfer printed fabric. The ghosting effects can be subdivided into 3 different categories: migration ghosting, abrasion ghosting and sublimation ghosting (Fig. 1).

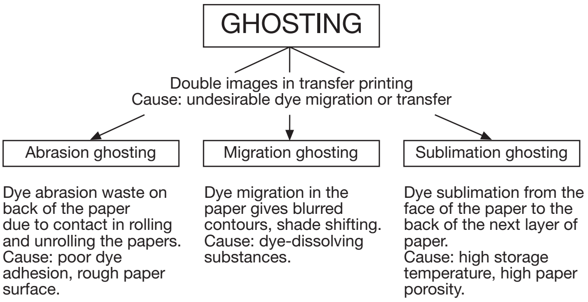

Fig. 1: Faults in transfer printing due to inadequate transfer paper storage stability.

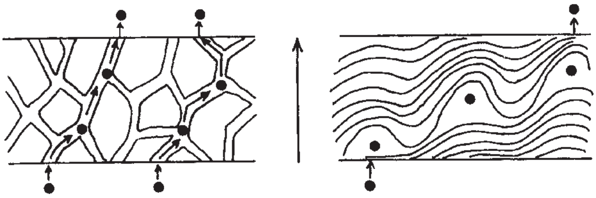

Fig. 2: Transfer dye migration (migration ghosting). Left: in the paper due to the cavity structure; right: in polyester film due to chain segment mobility.

Disperse dyes are able to move (Fig. 2) in transfer printing paper by pore diffusion (in contrast to polyester where dye movement takes place according to the model of free volume theory).

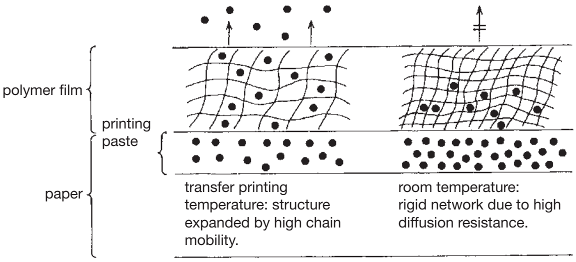

Fig. 3: Polymer properties necessary for preventing sublimation ghosting during face coating.

For this reason, sublimation ghosting (Fig. 3) should be preventable by coating the paper with a polyester film (Herlinger).

Ghost print A defect in transfer printing which takes the form of unwanted (usually paler) „ghost“ design images on the printed fabric due to the transfer of disperse dye from one layer of the rolled printed transfer paper to the layer of paper lying immediately on top of it. Such → Ghosting effects are dependent on the dye, thickener, paper quality and the storage conditions (temperature) of the printed transfer paper.

GI (Ger.), Ginsterfaser (broom fibres), → Standard abbrev. for textile fibres, according to the → EDP code.

gi, abbrev. for: → Gill.

Giant batch rolls Textile fabric is wound on to a movable batching unit in which a horizontal roller is supported by 2 A-shaped frames (A-frames). These giant batch rolls are used to wind fabric on or off in beam form for either intermediate storage or wet processing. Savings in fabric losses in piece end sewings favour a short payback period. In addition, the use of giant batch rolls considerably improves the efficiency of production (especially in continuous processes such as shearing, singeing, bleaching, dyeing, printing, etc.) due to the greater length of the batch (less batch changes/machine stoppages). Less batch changes means that processes are less labour intensive. An important innovation for more economical processing is the possibility to increase the size of batch diameters in jiggers to 1200 (1250) mm. With such batch sizes, increases in machine capacity of up to 40% may be realized and 4000–5000 m of lightweight poplin shirting qualities can be processed per batch (e.g. pretreatment and bleaching). Plant modifications necessary to handle giant batch rolls may mean that → Rising-roll batchers mounted at each side of processing machines must be replaced by special giant roll batchers or hydraulic centre spindle batchers. Squeeze rollers are substituted by a suction device. A particularly efficient system is the use of a non-stop giant batch changer at the end of a stenter (see Fig.).

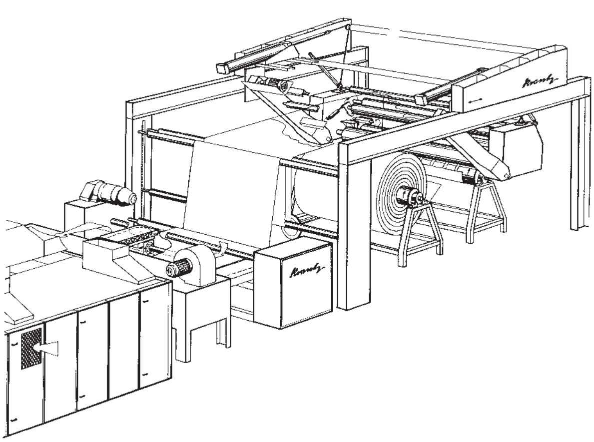

Fig.: Non-stop giant batch winder with no fabric store, A-to-A system (Krantz).

Gibb's Phase Rule Single-component systems normally exist as homogeneous and pure substances in a single phase. Multicomponent systems are mixtures which represent solutions of homogeneous phases. When liquids exhibit only limited mutual solubility, more than two liquid phases are present in equilibrium with a large number of components. A phase is that part of a system which is physically homogeneous down to the molecular level. Liquids are grouped into miscible and immiscible types and separate into two mixed phases which exist in thermal equilibrium with each other. Every solid substance with a uniform crystal structure, including mixed crystals, represents a single phase. Mixed crystals are built-up homogeneously like miscible liquids and represent a mixed phase. The point being emphasized here is that a single phase or mixed phase is characterized at the molecular level by its homogeneity.

A system is built-up from its components. The number of components is the smallest number of independent chemical compounds necessary to describe the composition of all phases of a system. The relationship of the phases, components and degrees of freedom involved is given by Gibb's Phase Rule. This describes equilibrium systems which always represent the lowest energy state. The rule was established empirically and is expressed by:

$$F = C - P + 2$$

F = the number of degrees of freedom in the system; i.e. the number of any varying state variables, temperature, pressure, concentration, which can participate in producing a state of equilibrium,

C = the number of components which determine the composition of each phase in the equilibrium system,

P = the number of physically distinct phases in the system.

The phase diagram (constitution diagram) gives a graphical representation of the relationship between solid, liquid and gaseous phases and their transitions over a range of conditions (e.g. temperature and pressure) at the same time. In an equilibrium system consisting only of a single substance (H_2O), the variables p and T are sufficient to establish the system.

Fig. 1 may be interpreted as follows: the curves A, B and C separate the temperature and vapour areas into three fields. Within the single-phase regions, p and T can be varied independently of each other without a new phase being formed = a divariant system. The curves describe two phases existing next to each other: the vapour pressure curve (C), sublimation pressure curve (A) or the melting curve (B). A single state variable is sufficient here to establish the system = a monovariant system. At point T, the three phases are in equilibrium with each other. This point is called the triple point. All state variables are fixed at this point = a nonvariant system.

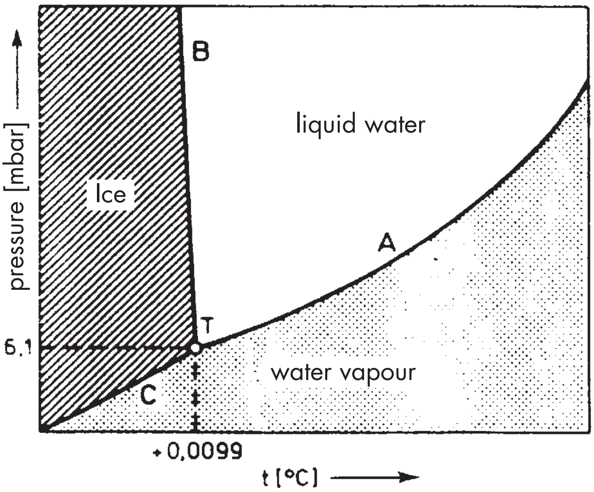

Fig. 1: Phase diagram of water (schematic).
A = vapour pressure curve (of water); B = melting curve (of ice); C = sublimation curve (vapour pressure curve of ice); T = triple point.

Emulsions are systems consisting of at least two phases of mutually immiscible liquids. Depending on the ratio of the components, either oil-in-water (O/W) or water-in-oil (W/O) emulsions are formed. In textile finishing, oil-in-water emulsions are used exclusively because there is no problem in diluting them with water. The basis for the emulsification of oils in water is a reduction in surface tension, so that dispersion of oil in the aqueous phase is made easier. The area, within which the emulsion exhibits maximum stability must be found in the emulsion triangle (Fig. 2). Only a very small area within this triangle is capable of forming micro-emulsions.

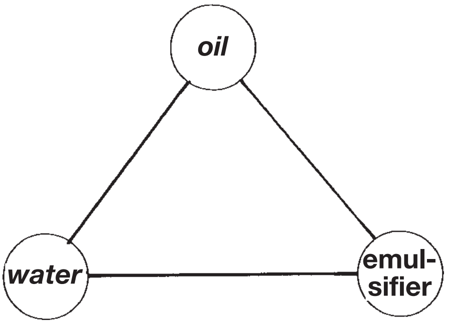

Fig. 2: Emulsion triangle (basic form of Gibb's three-phase triangle).

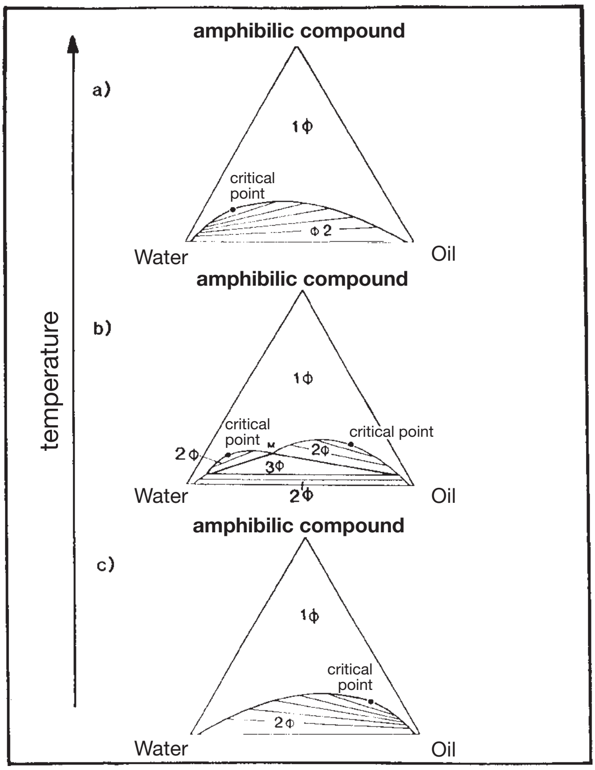

Fig. 3: Gibb's phase triangle (schematic) for a ternary system consisting of water, oil and an amphiphilic compound (source: Kahlweit and Strey).
n-Φ = n-phase area; M = coexistence point of the single-phase, two- phase and three-phase areas.

Any increase in the hydrophobic character of the oil, e.g. by increasing the length of the carbon chain, enlarges the three-phase area. On the other hand, hydrotropic electrolytes, or an increase in the hydrophobic character of the non-ionic surfactant, e.g. by increasing the number of carbon atoms in the molecule structure, and increased pressure, bring about a reduction in the size of the three-phase area until it disappears, i.e. at the tri-critical point of such systems.

Wash media used for textiles are normally single-phase multicomponent systems consisting of water, surfactant and the hydrophobic soil originally adhering to the textile. Such multicomponent systems exhibit different areas in the phase diagram which are dependent on pressure, temperature and composition. Consequently, single, two and even three-phase areas may occur which can be represented in the so-called Gibb's phase triangle (Fig. 3).

According to Danielsson and Lindmann, the optically isotropic, thermodynamically-stable systems of water, oil and one or more amphiphilic compounds, are described as micro-emulsions. At normal pressure, the phase relationships are largely independent of the pressure. Only during the transition to higher pressures does the position and size of the different phase areas in the ternary system change due to the influence of pressure on the binary system water/non-ionic surfactant. In addition to an extensive single-phase area, a two-phase area often occurs with the critical point on the side facing the oil side at low temperatures in the Gibb's phase triangle. With increasing temperatures, some systems have the following appearance: in addition to a single-phase area, three two-phase areas and one three-phase area is formed. A further increase in temperature leads to the disappearance of the three-phase area. The phase relationship resembles that at low temperatures but, in this case, with the critical point on the water-rich side (source: Schollmeyer).

Gifu dyeing process for polyester A Japanese dyeing method which employs phenol as a swelling agent and organic or inorganic acids at high concentration.

Giga (Gk.: *gigas* = giant). A prefix used to denote one thousand million times = 10^9; e.g. 1 GHz = 10^9 Hz.

Gilet black Used in the → Weighting of silk.

Gill A non-metric English and American unit of liquid measure equal to one quarter of a pint.

Gill box A device used for the production of fibrous webs to be subsequently printed with relief rollers. A prerequisite for → Vigoureux printing (printing of wool tops).

Gimp,

I. A helically wrapped core yarn in the form of a stiff cord. Often consists of cotton or wire wrapped with silk or viscose yarn for use in embroidery, lace or trimmings. Gimp can be used to sew buttons on clothing.

II. A narrow strip of fabric used in trimming furniture; often has a stiffening of wire or heavy cord running through it.

Ginning A process for separating cotton fibres from the seed in order that the fibres may be spun into yarns. Machines used for ginning may be either saw gins or roller gins.

GK (Ger.), abbrev. for: Grenzkonzentration (→ Limit concentration).

GL, → Glass fibre, → Standard abbrev. for textile fibres, according to the EDP code; → GF.

gl → Gill.

Glacé,

I. A term used for glazed yarn or polished thread.

II. Fabrics: a high-lustre fabric, a lining fabric with a lustre-imparting finish, a lustrous satin lining, etc.

III. A woven wool fabric.

IV. A lightweight British fabric with a cotton warp and mohair or lustre worsted weft produced in a plain weave.

Glacial acetic acid → Acetic acid.

Glacial acetic acid solubility test Action when hot: dissolves acetate, polyamide and silk. Action in the cold: dissolves acetate. In both cases triacetate also dissolves.

Glacial acetic acid test for dye class identification,

I. Vegetable fibres: boil the test specimen for 1–2 min in glacial acetic acid. Solution remains unstained: phthalocyanine dye (confirmation: nitric acid = violet; test for presence of copper or nickel). Solution is stained: vat or naphthol dyes.

II. Animal fibres: treat the test specimen in cold glacial acetic acid. Solution is stained: cationic (basic) dyes. Solution remains unstained: acid, direct and reactive dyes. → Dye class identification on fibres.

Glass An alkali calcium silicate. Fusion product of silica (silicon dioxide), calcium oxide (lime), and sodium carbonate (soda ash) = common lime-soda glass. Potash glass is obtained by substituting soda ash with potassium carbonate (potash). Glass is decolorized by the addition of manganese (principle: complementary colour). The addition of lead oxide (for flint glass, lead crystal glass) gives higher transparency and light refraction and is used inter alia for the manufacture of highly refractive lenses (especially convex lenses) for persons with acutely defective vision in order to obtain a thinner lens (aesthetic requirement); the disadvantages of such lenses include reduced sharpness of contours (higher prismatic characteristics) and greater weight than crown glass lenses. Glass is coloured with appropriate metal salts (dark glass and filters characterized by their transmission curves). The modern glass industry has made it possible to manufacture glass capable of meeting an ever increasing range of individual quality standards with the result that, over the past few decades, the applications of glass have become much more versatile. Special types of glass, such as borosilicate glass, are used in chemical apparatus and in heat exchangers for the heating and cooling of liquids and gases (i.e. for applications where extremely high resistance to corrosion against very aggressive products is required with virtually no sensitivity to temperature changes). Gasproof and moisture-proof glass is used for the inner lining of chimneys to prevent the aggressive condensates from flue gases pnetrating the chimney wall and destroying the chimney material. The condensate runs down the inner side of the glass lining where it is collected and disposed of by ecologically-

glass names	Ø-composition	softening temperature °C	properties
lead glass (lead crystal)	SiO_2 ....52% PbO ....35% K_2O 13%	400—500°	easily melted. Heat sensitive. Corrodible by hot water, hot KOH, $KMnO_4$ solution, salt solution
soda glass (standard glass; windows, bottles etc.)	SiO_2 ....75% CaO ....13% Na_2O 12%	600—600°	similar to lead glass but somewhat less corrodible
Jena equipment glass 20	SiO_2 .... 74.5% Al_2O_3 .... 8.5% Na_2O .... 7.7% B_2O_3 .... 4.6% BaO .... 3.9% CaO 0.8%	600—700°	difficult to melt, fairly insensitive to heat. Chemically hardly corrodible except by lyes and hydrofluoric acid
potassium glass (Bohemian crystal)	SiO_2 ....71% K_2O ....18% CaO 18%	700—800°	similar to Jena equipment glass 20
quartz glass	quartz 100%	1.700°	very difficult to melt. Completely insensitive to heat. Chemically non-corrodible except by hydrofluoric acid.

Tab.: Properties of the most important types of glass (all soluble in or corrodible by hydrofluoric acid).

acceptable means. Possibilities also exist for the use of special types of glass in filtration plants (see Table).

Glass batiste A glass-like, almost transparent and usually stiff batiste fabric. The character of this pronounced stiff and glassy material, produced by a special chemical treatment, is also resistant to washing. As far as cotton materials are concerned, which were formerly used exclusively for this purpose, the finish consists essentially of mercerization, bleaching, and a treatment in conc. sulphuric acid. Nowadays such fabrics are also woven from viscose filament yarns and, especially, fully-synthetic filaments. Organdie is a type of glass batiste fabric. The transparent character of such cotton fabrics produced by the acid treatment is often combined with a matt or milky patterning by preprinting the material with an acid-resisting thickener.

Glass buttons → Buttons.

Glass cement is magnesium oxide.

Glass fabrics Collective term for all textile fabrics produced from → Glass fibres.

Glass fibres Fibres may be drawn very easily from glass in the molten state. As spun yarns in wicks, ropes and woven fabrics, glass is an ideal insulation medium for continuous and short term exposure up to temperatures of around 300°C. Because of the relatively low price (10–20 DM/kg), glass textiles have, in the meantime, found wide application, e.g. in chemistry, chemical technology, insulation of machines, pipes and containers, in sound insulation and in electronics. Glass fabrics are used for interior furnishings wherever high demands are placed on safety, e.g. in ships, hotels, cinemas, wall coverings, etc. Estimated production capacities exceed 1 million t (1990) and are still increasing. In technically advanced countries, the production volume of glass filament yarns has reached approx. 10% of the production volume of synthetic fibres.

For over 30 years now, glass filaments have been produced mainly by the spinneret drawing process (Fig. 1) from spinning baths with drawing speeds of 3000–4000 m/min – a speed which only became practicable for some organic synthetic fibres a few years ago. It can be assumed that further significant progress has been made in recent years especially with regard to process reliability and increased productivity. Whilst, initially, only about 200 spinneret capillaries per bath were used, this has been increased in the meantime to 1200–2000 with corresponding increases in throughput quantities from 10 kg/h to, e.g. 55–60 kg/h.

The patent literature also contains references to experiments aimed at achieving further increases in the speed of glass filament extrusion from spinnerets by pressure spinning. Work has also been carried out on reducing investment costs by means of an electrochemical melting process in which the lining material of the spinning bath can be reduced in a ratio of almost 100 : 1 for the same melting performance. Greater technical flexibility is also achieved at the same time (Pochet oven).

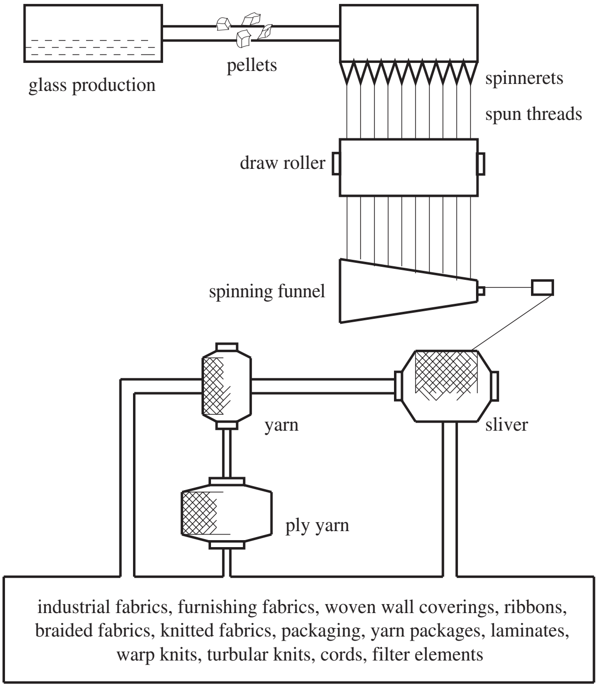

Fig. 1: Glass fibre production.

Although, initially, it had only been possible to apply the spinneret drawing process by a two-stage method, the single-stage process has, in the meantime, been widely adopted as was the case in organic synthetic fibre development (Fig. 2). A solid intermediate stage (glass marbles) is thereby eliminated which, in particular, brings about a reduction in the specific energy costs. It is common practice to melt E-glass (alkali-free glass) in spinning baths heated by natural gas with recuperative heat recovery to achieve melting capacities of 6–20 t/day. At present, experimental work is being carried out with all-electronically heated melts which,

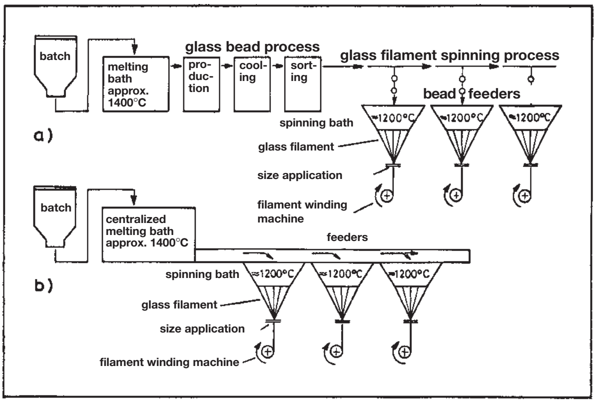

Fig. 2: Glass filament production.
a) discontinuous; b) continuous.

it is hoped, will bring a reduction of 20–30% in melting costs. In the meantime, spinning reliability has been considerably increased by process analysis. The knowledge gained with regard to the technological parameters forms the basis for process models with the aid of which computer-assisted process control will probably be achieved more easily for glass fibres than for organic synthetic fibres. The structure of glass filaments can only be compared with organic synthetic fibres to a limited extent, since subsequent drawing of the filaments is not possible. After cooling, glass fibres immediately assume a solid state. The more quickly cooling takes place (especially in the case of extremely fine individual filaments), the more their structure corresponds to that of the glass melt.

A "frozen-in induced orientation birefringence" exists in glass fibres which is, however, difficult to determine. Structural changes in the fibre are caused by ageing or reheating; disassociation (micro-heteregeneity), in particular, increases which, at the same time, causes the density to rise but also initiates contraction phenomena. The reasons for the fact that glass fibres can be 50–80 times stronger than the solid glass from which they were produced are also to be sought in the exceptional structure of the fibres (Fig. 3). The commercial exploitation of glass fibres is determined primarily by their properties and costs. Both depend essentially on the diameter of the individual filaments. For standard reinforcing materials, fibre diameters of 9–11 µm are generally employed although, for economic reasons, there is a tendency to increase the range to 13–15 µm.

No less important is the composition of the glass used in the production of reinforcing fibres. E-glass is used for general thermal and duroplast reinforcement applications. E-glass is an aluminium borosilicate glass with less than 0.8% alkaline oxides, which has a market share of 95%. HM-glass, on the other hand, is a glass containing titanium and beryllium oxides with a high modulus of elasticity. S-glass is an aluminium manganese oxide glass with increased linear strength. If the tensile strengths and e-modulus of current reinforcing fibres is compared, it can be seen that glass fibres occupy a middle position. In terms of mass-related parameters, those reinforcing fibres whose density lies considerably below that of glass fibres show up very favourably; this is especially true for aromatic polyamides (source: von Falkai).

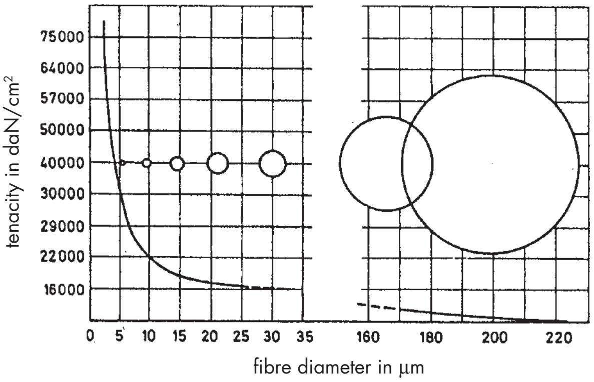

Fig. 3: Tenacity of glass fibres in relation to fibre diameter.

Glass fibre wallpaper, finishing of The treatment involves bonding the extremely loosely woven glass fibre fabric by coating. The fabric runs from batch rolls through a dispersion consisting of latex and starch as a filler. After passing through the finish applicator the liquor pick-up is reduced to approx. 150–190% by running slowly through the entire plant (production speed 5–15 m/min) and the nip between two horizontal padder bowls. The impregnated fabric then passes without contact through an infrared heating tower mounted above the padder where it is dried to a residual moisture content of approx. 15–30%. In order to flatten the protruding glass fibres the residual moisture is removed by a final passage over a cylinder drier. Overdrying at this stage must be avoided to prevent the starch turning brown since the glass fibre ground should be pure white.

Glass filament yarn → Glass fibres.

Glass plate test A commonly used test to check the correct vatting of vat dyes in dyeing as well as the rate of re-oxidation after dyeing (greening). Procedure: a glass plate is dipped in the prepared vat and immediately removed; if vatting is correct the dye liquor should remain clear as it drains off the plate without revealing any solid dye particles. Indigo vats should, e.g. drain off clear yellow and only begin to green after 20–30 s, i.e. colour change to blue.

Glass roving Consists of a multitude of parallel glass filaments without any significant twist.

Glass silk → Glass fibres.

Glass staple fibres Drawn or blown fibres produced from molten glass of finite length (staple fibre) of specific fibre diameter (→ Glass fibres).

Glass transition temperature (glass-rubber transition temperature; T_g). The temperature range within which an amorphous material (such as glass or a high polymer) changes from a brittle vitreous state to a plastic or rubbery state. The glass transition temperature does not occur at a single temperature but takes place over a short temperature range because real polymeric materials have a molecular weight distribution. The single point temperatures which are quoted in the literature etc., are obtained by interpolation. Unlike crystalline materials, amorphous materials do not melt when they are heated, but go through a glass transition. In the glass transition range, many physical properties of amorphous materials undergo a more or less drastic change. The most obvious change is that from a viscous or flexible material above T_g to a hard, sometimes brit-

Tab.: Glass transition temperature and properties of some monomers (RT = room temperature).

tle, solid below. On a molecular level, as the temperature is raised to the glass transition temperature and above, segments of the molecules are able to rotate. In high polymers, these segments consist of 25–50 chain atoms which may be estimated from the activation enthalpy of relaxation processes in semicrystalline or amorphous polymers. It is probable that trans/gauche transformations are involved here which proceed cooperatively over a wide range.The actual value of T_g for a polymer is clearly method- and rate-dependent; T_g is that temperature at which the molecular relaxation times are of the same order as the experimental times. From the structural point of view, the molecular arrangements in an amorphous material (or glass) below Tg possess the permanence of crystals and the randomness of liquids. As a crystalline arrangement of the molecules has a lower energy, for a glass to form on cooling from the melt there must be some barrier to crystallization. This may be caused by steric hindrances in the molecule such as bulky side groups, or, if the material is cooled quickly enough, by insufficient thermal energy, or by a combination of both. T_g is always less than T_m (melting temperature) since a crystal has a lower energy than an amorphous structure. T_g can be measured in a number of ways because most material properties change on going through it. For this reason, it is not sufficient to just quote a value for T_g; it is important to give the method and the rate of measurement. The glass transition temperature of high polymers is closely related to the effects produced on textile materials (see Table) and, for such polymers, is usually measured by differential thermal analysis.

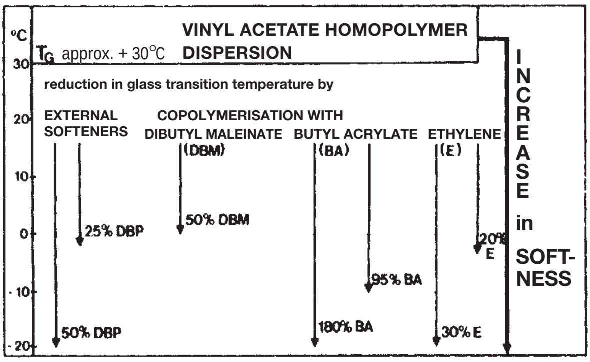

Fig.: Connection between softener quantities and glass transition temperature.

The Figure shows that the same quantities of various softener components produce different degrees of softening on textile materials which is why T_g provides a reliable measure of the softening effect of these components.

Glass-tube heat exchanger Heat can be recovered from polluted, aggressive exhaust air with such systems. Fresh incoming air can be heated in recuperative systems without an additional heat transfer medium, i.e. by air/air transfer only (separated by glass). Heat exchange occurs over the large surface area of small glass tubes through the heat content of exhaust air passing through them (used e.g. as internal heat exchangers in stenters). Condensation of water from the exhaust air is desirable since this raises the heat recovery capacity as the heat of condensation is conducted away and the heat transition coefficient is improved (see Fig.). Glass has smooth surfaces which are less susceptible to dirt accumulation (e.g. through fibre fly), does not corrode, and is relatively temperature-resistant. The thermal conductivity of glass is negligible. The only disadvantage of glass-tube heat exchangers is the fragility of the glass tubes.

Glass wool → Glass fibres.

Glass yarn A collective term for multifilament, spun and textured yarns produced in a range of different yarn thicknesses from → Glass fibres.

Glauber's salt → Sodium sulphate.

Glauconite A naturally occurring hydrated silicate of potassium, iron and aluminium. An intense green mineral found in marine sediments, especially greensands. After comminution and chemical stabiliza-

Fig.: Glass tube heat exchanger.

tion it is used as a natural base exchanger for water softening (e.g. as the former Neopermutit).

Glazed millboard → Pressboard.

Glazed yarn → Glacé.

Glaze finishing The production of lustre effects on textiles by certain finishing processes is followed, in most cases, by a mechanical treatment, e.g. chintz finishing. Processes which increase the lustre of textile materials include mercerisation, lustring and polishing. In the case of polyester blouse fabrics, another process used to achieve increased lustre involves a passage through a transfer printing calender.

Glaze finishing auxiliary These products are used to produce lustre effects on textiles with or without a subsequent mechanical treatment. For lustre effects where high requirements do not have to be satisfied, the usual finishing agents are satisfactory, e.g. paraffin wax emulsions, polyethylene glycols, etc. The production of permanent lustre effects resistant to water and washing (chintz and embossed effects) is achieved by mechanical means and the co-application of methylol compounds, urea or melamine resins and subsequent curing. Wash-resistant lustre effects can also be produced by the application of suitable plastics in the form of dispersions or solutions in organic solvents.

Glazing and flatting calender → Smoothing and calibrating calender.

Glazing calender → Friction calender.

Glen check (derived from Scottish: glan = tribe and check = chequered). In former times, Scottish families used different check patterns (tartans) to distinguish themselves from each other. Through subsequent generalization, the term glen check is now used to characterize materials with a typical block check pattern. The term is therefore only a description for a particular type of check pattern which is produced in a 2/2 twill weave with a 4:4 and 2:2 order of colouring in both warp and weft. This type of fabric is produced with worsted yarns as well as carded yarns from virtually all types of fibres. The former are normally closely cropped for men's suitings, womenswear and costumes. Besides the usual very muted tones, these designs are also available in more vivid sporty colourings. Glen checks with carded yarns are produced for men's fine suits and costumes (some of which are available in a Saxony quality, i.e. from fine merino wool with a flannel-like finish). Coarser qualities are also used mainly for men's suits and coat fabrics. Synonyms: glen plaid, glen urquhart plaid.

Glide rods Brightly polished rods or tubes positioned at right-angles to the direction of fabric transport instead of rollers to ensure faultless fabric passage in processing machines, etc. Used for centring the tightness in fabrics passing over the rod at a blunt angle by bending the fabric in a slightly downwards direction.

Glitter pigments A distinction is made here between polyester and polyoxide glitter pigments. They are produced by the comminution of metallized foils followed by sieving. Because of the risk of blocking screens or engraved rollers in printing, these pigments are only suitable for screens with a maximum of 9 threads per cm or engravings with a minimum depth of 30/100. Other problems may be caused by the print pastes separating out during printing. For this reason, the use of high viscosity, short print pastes is recommended.

Glitter threads Man-made fibres with a ribbon-shaped cross-section in coarse counts, mainly produced in a variety of spun-dyed colours.

Glitter, to This finish is achieved by angled inclination of the engraved lines on the upper roller in the schreiner or silk-finish calender.

Globular proteins Or simple → Protein, although in chemical terms often quite complex, are nonetheless structurally of spherical molecule form (e.g. egg albumin, globumin, haemoglobin); in contrast to the higher cell organisation of the chain proteins. (→ Pre-keratin).

Globulins Proteins insoluble in water, soluble in dilute salt solutions. Globulins are examples of simple proteins and occur naturally in milk, wheat and other cereal grains. The description, globulin fibres, is also used in connection with man-made protein fibres.

Gloria silk Smooth closely woven fabric; warp: cotton or (originally) organzine silk; weft: schappe silk or fine worsted yarn; in twill or satin weave for linings, umbrella cloth, etc.

Glossing A mechanical aftertreatment given to hanks of silk, linen, cotton and synthetic fibre yarns to loosen up the yarn structure, achieve increased lustre and a softer handle. Originally, wet hanks were placed over a wooden peg and wrung out.

Gloss value A measure of lustre for, e.g. textile filaments before delustring (e.g. 40) and with increasing delustrant additives (to below 4) or for raw cotton (15–17) before mercerising and with increasing density of caustic liquor after mercerization (up to 30°Bé = 76, after which it decreases again). It is also used for testing bleached materials (e.g. chlorine bleach on cotton = 59, oxygen bleach = 51, combination bleach = 58). The higher the lustre index, the greater the lustre. → Lustre, measurement of.

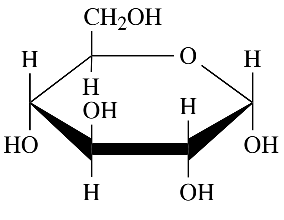
Glossy printing →: Chintz prints; Lacquer printing.

Glow Burning without forming flames, but with visible light.

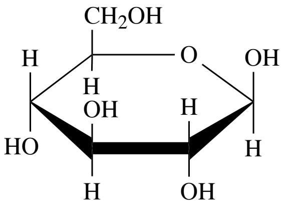
Glowing time → Flammability testing.

Glucopyranose Another name for cyclic → Glucose. The term is used because of similarity with the pyran structure. α and β-glucopyranose are stereoisomers of the same glucose modifications.

Glucose (dextrose, grape sugar, corn sugar, corn syrup), $C_6H_{12}O_6$, density 1.544. Colourless, transparent crystals, fine white powder, granular white lumps, or a viscous colourless syrup. Very hygroscopic, readily soluble in water up to 817 g/l at 15°C (anhydrous glucose) and up to 878 g/l (glucose containing water of crystallization). Glucose solutions have a sweet taste and a neutral reaction. Glucose is the end-product of the complete degradation of starch resp. desizing with diastases. The oxidation of glucose results in the formation of gluconic acid. A gallic acid ester of glucose forms tannin. Like all known → Sugars, exists in two isomeric α and β-forms, i.e. α-glucose and β-glucose. Both forms differ only in the position of the OH group relative to the 1st carbon atom, i.e. (α) below and (β) above:



α-glucose



β-glucose

During hydrolytic degradation with enzymes the respective isomeric forms are maintained. Under certain conditions, α and β-glucose easily become rearranged with one another. This occurs particularly rapidly in aqueous weakly alkaline solution. The new state of equilibrium is recognized by a change in optical rotation. The initial specific rotation of the β-form is 17.5° and that of the α-form is 111.2°, but the specific rotation of a solution containing both forms approximates to 52.5°. This change in rotation towards an equilibrium value is called mutarotation. Such a mixture of both forms is described as normal glucose or, frequently, as D-glucose (D indicates dextrarotatory = plane of polarization is rotated to the right); the same word root is likewise present in →: Dextrin and Dextrose.

β-glucose molecules form the basic building blocks of cellulose: 2 molecules each combine to form the disaccharide cellobiose; the resultant polycondensed macromolecules can form cellulose chains (polymers) through hydrogen bonds which represent the basis of all vegetable fibres (see Fig.).

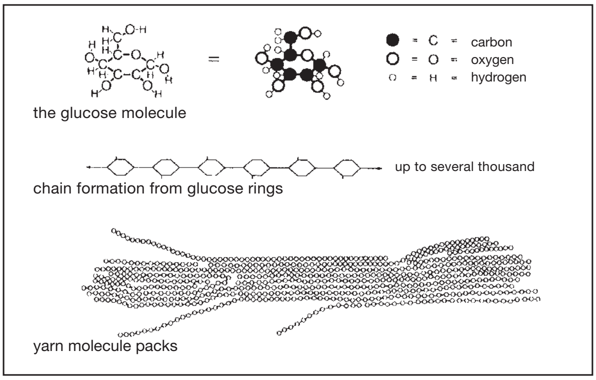


Fig.: From the molecule to the yarn.

Glucosidases A group of enzymes (belonging to the → Carbohydrases) which break down specific glucosides (into carbohydrate and aglycone) and as, e.g. maltase and cellobiase, also break down disaccharides (→: Maltose; Cellobiose) into glucose. Just as there are α and β-glucosides, there are also α and β-glucosidases which, in each case, react specifically only with the α and β-configuration.

Glucosides → Glycosides.

Glucosidic bond The chainlike linkage of cyclic glucose building blocks by oxygen bridges, e.g. starting from → Glucose via → Cellobiose to the high molecular weight cellulose chain molecule. → Cellulose.

Glue Most familiar are glues derived by boiling or steaming animal hides, tendons or bones which are high in collagen. Glues may be classified in order of quality as follows: isinglass, hide glue, leather glue, cartilage glue, bone glue and fish glue. Produced in various forms as (a) slabs (also Cologne glue), longest swelling time, poor core swelling, goes off quickly, small losses; (b) pearls (neutral bone glue, hide glue): (c) hide glue crumbs; (d) glue in plate form; (e) powdered glue. Advantages of glue in forms (b) to (e) include uniform quality, easy handling, easy solubility, (mostly) light in colour and acid-free, low water content, short swelling times, no losses, good yield and good keeping properties. (f) glue jelly (immediately soluble in boiling water).

The active constituent of glue is → Gelatin. Evaluation: comparative determination of softening points as a measure of adhesion power (hide glue : bone glue = 1.5 : 1). Uses: important sizing and finishing agent; protective colloid (dyeing); promotes better rub fastness and levelling in vat dyeing. Preservatives: nitrobenzene, salicylic acid, etc., (good quality glue can be kept for 1–2 days after preparation).

Glued carpets These fall into two categories:

I. Hand bonded: e.g. →: Appliqué carpets.

II. Machine bonded: e.g. → Flocked carpet as bonded bouclé carpets, bonded chenille carpets and similar products.

Glued composite fabrics Imitations in the style of woven → Cloqué fabrics are produced (→ Adhesive-bonded textiles) by, e.g. the superimposition of a crêpe fabric on top of a flat fabric (taffeta) and bonding them together locally. They can also be produced to a pattern, if desired, through application of the bonding agent by screen or roller printing. After damping, blister-like motifs appear in the upper fabric as in, e.g. adhesive-bonded cloqué. Fibre webs can also be included in a similar manner. The bonded areas are usually resistant to dyeing. Products based on nitrocellulose, rubber, chlorinated rubber, cellulose acetate, synthetic resins, etc., with the addition of plasticizers if necessary, stabilizers or mobile solvents, are employed. Adhesive-bonded cloqué is usually well dried in the air after bonding and dampened without tension to develop the crêpe effect. This is achieved by laying the material in layers in open becks (the upper layer is weighed down with a wooden grid) or the process can be carried out continuously in crêping machines. Finally, the material is centrifuged and dried without tension. Other important products of this type include, e.g. cheap blankets consisting of a jute fabric bonded on both sides with a wool web. Fashion variants of bonded fabrics include products produced by (→ Flocking), plush, velvet or velour effects, imitation suede, skins and furs, bonded coat fabrics, bonded pile carpets (on nonwovens) and laminates.

Glueing carriage Used to glue fabrics to screen printing tables for printing. The liquid glue is applied by means of a roller applicator and the fabric is brought into contact with glue film by means of pressure rollers.

Glueing systems for printing At the same time as the partial mechanization of the actual screen printing operation occurred, systems were also developed to mechanize and improve the efficiency of auxiliary operations such as glueing, removal of running fabric webs from the printing blanket, blanket washing, etc. The first stage was to mechanize the glueing of fabric to the printing blanket. For this purpose, a carriage with lifting and lowering functions carries the rolled textile fabric. This carriage is equipped with a glueing unit which applies a film of glue before laying the fabric and a pressure device to ensure complete contact with the glue film. In semi-automatic flat-bed screen printing the printing blanket is coated with a film of glue by a special glueing unit before the fabric is brought into contact with it. Various systems have been developed for this operation. Some systems are based on applicator rolls where the thickness of the glue film is controlled by a doctor blade. Another system uses a fully-engraved 1000 point roller which does not allow any variation in the thickness of glue film applied although it ensures an absolutely uniform application. Yet another method uses a brush roller for glue application and a rubber squeegee on the printing table itself to ensure even distribution of the glue film. Thermoplast adhesives, which only develop their adhesive properties under the action of heat, have also been used for some time. With this system, the fabric to be printed is pressed against the thermoplast film by a heated roller and the thermoplast film is heated by the fabric and becomes tacky as a result. Since the thermoplast adhesive is water-insoluble, it is not removed during blanket washing and can therefore be used for a long period of time before it needs to be renewed. To renew the thermoplast film, the old film is removed from the blanket with an organic solvent and a new film applied thereafter. In rotary screen printing similar glueing systems are employed to those used in semi-automatic flat-bed screen printing.

Glueing unit A device for the application of glue to printing blankets on screen printing machines.

Glutamic acid (2-aminopentanedioic acid). → Amino acids contained in wool and silk.

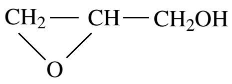
Glutine → Gelatin.

Glycerides Esters of glycerol, e.g. with low (acetin), or high molecular weight fatty acids resp. resin acids (→ Resin ester). The most common glycerides are based on fatty acids which occur naturally in oils and fats.

Glycerol (glycerine; glycyl alcohol; 1,2,3-propanetriol), $C_3H_5(OH)_3$, MW 92. A clear, colourless (pure 30°Bé, lightly coloured 20°Bé), odourless, hygroscopic and very sweet-tasting syrupy liquid. Combustible. Miscible with water, alcohol and acetic acid; insoluble in ether, white spirit, benzene and chloroform. Used as a universal solvent for salts, sodium carbonate (soda), sodium tetraborate (borax), potassium iodide, alkalis, alkaline earths, certain metal oxides, water-insoluble lime soaps, etc., tannin, St. John's bread, dyestuffs (especially cationic, acid, mordant and vat dyes; has a slight affinity-increasing effect); dyes which are insoluble in alcohol become soluble in alcohol if previously mixed into a paste with glycerol. Applications: as a hygroscopic agent (sizing; softening finishes), dye solvent in textile printing in amounts up to 100–130 g/kg of print paste. Component in print pastes for discharge printing (e.g. for wool and silk). Spotting agent (solvent action improved when warm).

Glyceryl phthalate resins → Phthalate resins.

Glycidol (2,3-epoxy-1-propanol). As a glycerol anhydride the simplest alcohol with an epoxy group. Very reactive, chlorine-free, with high purity and stability. Unlike halogen-containing analogues, no undesirable salt residues are formed in reactions with organic chemicals and, under careful conditions, higher yields are frequently achieved. Glycidol is 3-hydroxypropylene oxide 2,3-epoxypropanol and is a dehydration product of → Glycerol. Properties: colourless liquid, b.p. 162°C, soluble in water, alcohol and ether. Glycidol is used as a reactive solvent for epoxy resins, textile auxiliaries (levelling agents, dye-binding agents, etc.) and for the stabilization of halogenated hydrocarbons.



Glycidol vapour Reagent for improving the anti-crease properties of cotton.

Glycine → Glycocoll.

Glycine fibre → Regenerated protein fibre from the soya bean protein, glycine. Developed in the 1930s, but no longer relevant today due to the inadequate strength values (5–7cN/tex, wet strength 50%).

Glycocholic acid → Gall extract.

Glycocoll (aminoacetic acid, aminoethanoic acid, glycine). Glycocoll is the simplest of the amino acids (monoamino-monocarboxylic acid), $HOOC–CH_2–NH_2$, and is a substantial component of silk (42.3%) as well as wool (6.5%).

Glycol derivatives Chiefly the ethers or esters of → Ethylene glycol, such as ethylene glycol monoethyl ether (cellosolve), diethylene glycol, diethylene glycol ethers, thiodiethylene glycol (thiodiglycol), polyglycerols. Glycol derivatives of the above and similar types are excellent auxiliaries for dyeing and printing, especially for cationic, acid and vat leuco ester dyes, as well as for pasting vat dyes and, to some extent, also as penetrating agents in dyeing, and as substitutes for glycerol, etc. Other applications include: the manufacture of oxyethylated cellulose, polyglycol ethers, polyethylene glycols, cellulose glycolate.

Glycollic acid (hydroxyacetic acid, hydroxyethanoic acid), $HO–CH_2–COOH$; m.p. 78°C; colourless crystals, deliquescent, very soluble in water and alcohol. Decomposes below the boiling point. Glycollic acid has solvent properties for tannates (especially zinc tannate thereby making the preparation of basic (cationic) dye print pastes with tannin and a metal salt; the coloured lake only forms during subsequent steaming). Together with chloroacetic acid it dissolves cationic dyes (substitute for acetic and formic acids). Glycollic acid is also used for printing without steaming (ready-for-use print pastes, especially suitable for spray printing).

Glycosides Widely distributed group of compounds in plants as well as synthetic compounds consisting of carbohydrates and non-sugar compounds (aglycones). Glycosides are broken down (hydrolyzed) into these two components by boiling in water, action of enzymes or dilute acids, e.g.:

$$\underset{\text{methyl glycoside}}{C_6H_{11}O_5(OCH_3)} + H_2O \rightarrow \underset{\text{glucose}}{C_6H_{12}O_6} + \underset{\text{methanol}}{CH_3OH}$$

Hydrolytic cleavage of the glycoside bond into sugar and alcohol readily takes place with dilute acids (e.g. as in the acid tendering of cellulose). In contrast, glycosides are completely stable to alkalis. Besides →: Polysaccharides; Glycosides also include the compounds of complex alcohols and phenols with sugars. The various glycoside compounds exist in D-, α-, and β-glycoside forms.

Glyoxal (ethanedial, biformyl). The lowest dialdehyde:

$$\begin{array}{c} HCO \\ | \\ HCO \end{array}$$

Properties: yellow crystals, mild odour, readily rearranged into polyglyoxal, soluble in water (tetrahydroxydioxan), alcohol, ether and other solvents, powerful reducing action. Used in the manufacture of resin finishing agents, e.g. DMDHEU, tetramethylolacetylenediurea, glyoxal resins, as used in the Sanfor-set process for non-swelling and shrink-resistant finishes on regenerated cellulosic fibres. Glyoxal can also be used under mild curing conditions for formaldehyde-free finishes; catalyst: aluminium sulphate and polyhydric acids, shock catalysts. The addition of ethylene glycol prevents yellowing.

Glyoxal crosslinking agents A term in common usage for resin finishing agents which are representative of the reaction products of → Glyoxal with urea in particular, e.g. → Dimethyloldihydroxyethyleneurea.

Glyoxal resins → Glyoxal.

Glyptal resins → Phthalate resins.

Gminder fabrics Hard-wearing fabrics of various types (similar to linen/cotton unions) produced from cotton and cottonized hemp (process developed by the firm Gminder, Reutlingen, Germany).

GMW, abbrev. for: → Gram molecular weight.

Goat hairs The hairs of the common goat, Angora goat, Cashgora goat, Tibetan cashmere goat and the Persian goat can be spun into textile yarns. The quality of goat hairs varies considerably between the different breeds of goat. The hair of the common goat may be classified amongst the coarser animal fibres whilst the hairs of the other goats mentioned above may be grouped amongst the finer → Animal fibres. A distinction is also made between the finer wool-like, but mostly shorter undercoat hairs and the coarser outercoat hairs. Goat hairs are used in outerwear (wovens and knits) as well as for felts.

Gobelin French tapestry. Genuine Gobelin tapestries are hand-woven and have a similarity to → Rib fabrics with coloured designs (occasionally with gold and silver threads). Imitation Gobelin tapestries are produced with jacquard designs (3–5 warp and 3–4 weft systems) or by printing. Used as tablecloths, heavy upholstery and wallcoverings, etc.

Gold (Au), atomic weight 197.2; a golden-yellow (powder = brown), relatively soft, ductile, noble metal, density 19.3, m.p. 1062.5°C. Gold is resistant to air, water and alkalis; soluble in aqua regia (mixture of sulphuric and nitric acids) and potassium cyanide solution. Forms alloys with copper and silver. The carat is used as a measure of the proportion of gold in an alloy.

Gold bronze → Metal powders.

Gold purple reaction A very sensitive and specific test for → Oxycellulose. A test specimen is soaked in a weak acetic acid solution of stannous chloride (tin (II) chloride) and then placed in gold chloride solution. Oxycellulose absorbs tin (II) oxide as a result, and thereby assumes a red-brown colour.

Goldthwait test A differential dyeing test developed by Goldthwait *et al* as a practical method for estimating the maturity of cotton. The test is especially helpful in mill situations for detecting the presence of thin-walled or immature fibres which often cause problems in processing. The test employs a mixture of Chlorantine Light Green BLL (C.I. Direct Green 26) and Direct Fast Red 5B (C.I. Direct Red 81), two dyes with different dyeing properties and contrasting colours: Mature fibres absorb the red preferentially and immature fibres the green.

GOLEM (Ger.), abbrev. for: großspeicher-orientierte, listenorganisierte Erfassungsmethode. A method for the storage and rapid retrieval of an unlimited large quantity of documents and information by means of a medium-sized EDP system.

Golfers → Reclaimed wool from pullovers and knitted garments.

Gombo hemp → Gambo hemp.

Goniophotometer (Gk.: *gonia* = angle). An instrument for the → Photometric measurements of angles (see Fig.); e.g. as a measure in the evaluation of lustre on textile fabrics (measurement of the luminance factor).

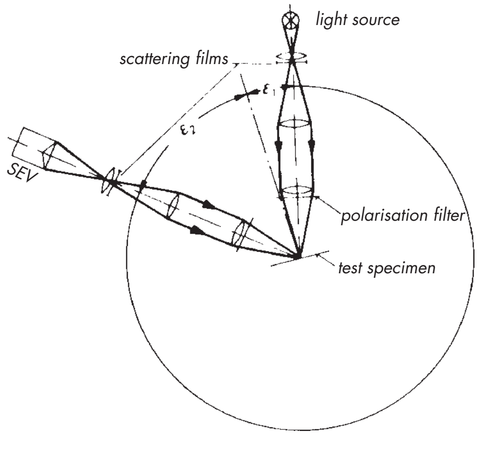


Fig.: Optical structure of the goniophotometer. ε_1 = entrance angle; ε_2 = angle of reflection.

Gore-Tex A water-repellent, windproof membrane with good water vapour transmission properties made from oriented polytetrafluoroethylene film. These properties are due to the presence of approx. 1.4 thousand million pores/cm^2, the size of which is so designed that although water vapour can diffuse through it, water drops are unable to penetrate it. Used as a laminate sandwiched between 2 fabrics for weatherproof clothing (see Fig.) as well as for technical purposes. Manuf. W.L. Gore & Associates.

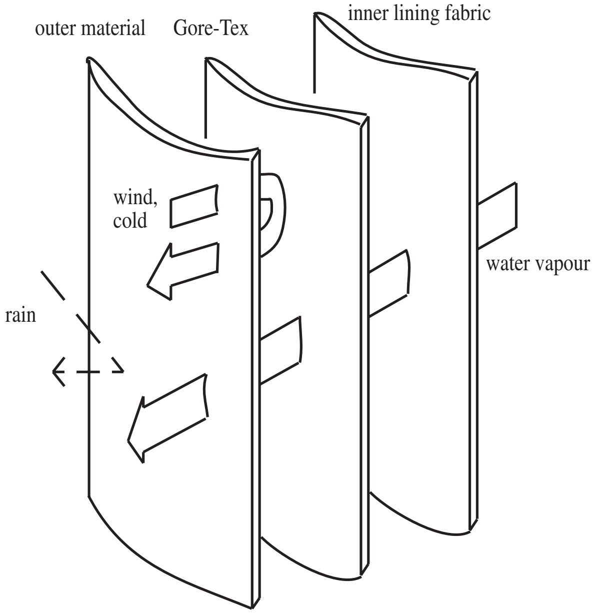

Fig.: Structure of weatherproof clothing with Gore-Tex membrane.

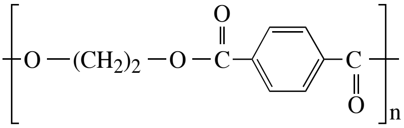
Görlitzer steamer A star steamer for the fixation of printed fabrics. In contrast to other systems in which printed fabric pinned to the star frame is positioned in the steaming chamber from above or below, in the Görlitzer steamer the star frame is loaded into the steaming chamber from the side.

GOST, abbrev. for: Gosudarstwennyi Standart (All-Union State Standard), Moscow, Russia.

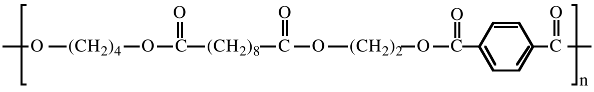
Gouache print A fashion print in the style of a water colour painting.

Gradel (Grad'l). Dense twill canvas, made using strong thread (of linen, as half-ticking), plain or multi-coloured; also cotton and linen cloths in herringbone weave, the latter often having a striped pattern.

Graduated-shrinkage fibres Polyester types which shrink progressively (→ Shrinkage fibres), as a form of chemical modification (co-polyester). The aim is to control and retard the shrinking processes, which by reducing the crystallization tendency in the linear polymer zone has the effect of producing progressive shrinkage, which is of benefit to the largely non-crystalline structure, i.e. after pre-shrinking at the lower temperature, when the temperature is increased, a further contraction phase can follow (in contrast to → High-shrink fibres).



The programming on the polyester molecule is brought about by inserting suitable co-monomers (di-functional compounds such as adipic acid, sebacic acid, etc.), which serve as a means for opening up the structure:



This chemical change to graduated-shrinkage fibres can be adjusted to meet requirements, thus for the knitting sector to somewhat more bulky yarns, which are mostly hank-dyed: with relatively large shrinkage at the boil and lower residual shrinkage during thermal after-treatment; on the other hand for the weaving sector with low shrinkage at the boil and very high residual shrinkage during setting at approx. 185°C, thus creating the desired voluminous fleecy handle. Side effects: Higher dyeing affinity, lower tendency to pilling. For graduated-shrinkage yarn mixtures (e.g. with wool, non-shrink polyester, regenerated cellulose), the non-shrink proportion in each case migrates to the yarn surface (influencing the handle); excessive interlacing of fibres should be avoided (= impeded contraction).

Graft copolymers → Graft polymers.

Grafting reactions When radical-creating media, e.g. electron irradiation or plasma, are allowed to act on olefinic fibres, e.g. polypropylene, fibre radicals are formed along the polymer chain. This behaviour enables grafting reactions to be carried out. Electron beams or electron accelerators are particularly suitable for the production of polypropylene radicals. Entirely different secondary reactions can occur depending on whether the irradiation is carried out in a nitrogen atmosphere (Fig. 1) or in the presence of oxygen (Fig. 2). Irradiation in a nitrogen atmosphere results in chain scissions and the formation of radical chain ends. Moreover, carbon radicals can be formed likewise at the tertiary carbon atoms by hydrogen abstraction. Crosslinking reactions can occur by the combination of two such tertiary carbon radicals. When the irradiation is carried out in the presence of polymerizable monomers, grafting reaction can take place which is accompanied by homopolymerization.

When the treatment is carried out with β-rays in the presence of oxygen, peroxide radicals, or peroxide groups, are formed from the resultant primary carbon radicals by the addition of oxygen molecules. These peroxide groups are stable up to approx. 60°C. If the polypropylene fibres pre-irradiated in the presence of oxygen are subsequently treated with monomers above 60°C, the peroxide groups break down with the formation of radicals which then initiate graft polymerization. With this procedure, there is only a limited likelihood of homopolymerization.

The mechanical technological properties of polypropylene fibres are negatively influenced by irradia-

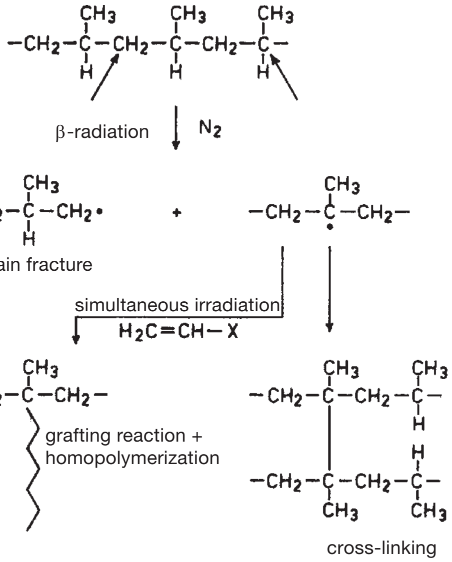


Fig. 1: Radical formation and follow-on reactions in polypropylene irradiated in nitrogen.

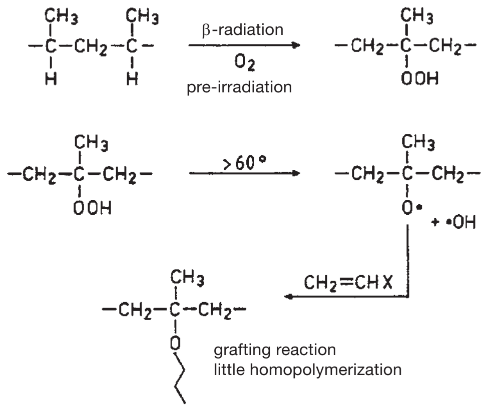

Fig. 2: Radical formation and follow-on reactions in polypropylene irradiated in air.

tion in nitrogen. Both the tensile strength and extensibility decrease with increasing dosages of radiation. At a radiation dosage of 100 kGy the tensile strength is still 80% of the initial value. A slight reduction in the degree of whiteness also occurs (Einsele).

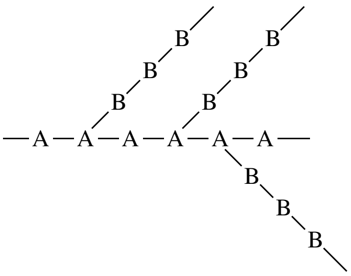
Graft polymerization of silk Amongst the chemical modification techniques, graft co-polymerization of vinyl monomers on silk fibres has proved to be an effective method of improving some original fibre characteristics. Grafting was proposed as a means of improving characteristics such as crease recovery, easy-care behaviour and light fastness, without impairing the handle and lustre of the silk fibre. A large number of vinyl monomers were applied to silk, and their effect on the fibre characteristics was investigated. A chemical modification of silk through reaction with epoxy resins was introduced in the early 1970s. This technique was mainly developed in Japan and was relatively well known, since it effectively improves the crease recovery in both dry and wet states, as well as light fastness, and laundering fastness of dyeings. The use of dibasic acid anhydrides as a modification agent was proposed; the modified silk fibres showed increased resistance to light decomposition. Furthermore, a slight chemical modification (carried out under mild conditions) led to a drastic change in the dyeing behaviour of silk.

The physico-chemical characteristics of the grafted silk depend heavily on the chemical nature of the functional side-groups which the monomer provides, but also on the degree of polymerization and the molecular weight of the chains which are polymerized in the interior of the fibre. Depending on the type of vinyl monomer used and the grafting conditions applied, the silk fibres undergo a slight or drastic change in their original characteristics. Graft polymerization of vinyl monomers on silk fibres can be effected by various methods, e.g. by irradiation, chemical or photo-induced initiation. The use of chemical redox systems in aqueous medium has played a large role for technical purposes. The chemical and photo-induced graft polymerization of polymethylmethacrylate (PMMA) was investigated in detail on silk. The influence of various parameters (such as monomer and initiator concentration, temperature, time, composition of the polymerization medium, additives such as salts and surface-active compounds) was investigated, in order to explain the kinetics and the mechanism of the graft reaction. The reaction mechanism includes the formation of free radicals on the basic structure of the silk fibroin. Carboxyl, amino and hydroxyl side chains of acidic, basic and hydroxyl group containing amino acid residues are regarded as the main reaction centres for vinyl monomers. The mean molecular weight and the molecular weight distribution of the poly-MMA which has been grafted onto silk depend on the selected initiator system and the reaction conditions. A linear relationship was found to exist between the weight increase and the mean molecular weight of the poly-MMA chains. Furthermore, the mol ratio between poly-MMA chains and the silk fibroin yielded a constant value. This suggests that after the initial stage of the graft polymerization, the growth of the grafted polymer chains plays a significant role in increasing the degree of grafting. MMA monomers and oligomers with a mean molecular weight of approx. 1000 form during the graft polymerization and appear on the fibre surface when the weight increase is 40–50%. They are not chemically bonded to the fibre, and can easily be removed by means of solvent extraction.

Alteration of the physical characteristics in the case of grafted silk can be summarised as follows: infra-red spectra clearly show the characteristic absorption bands of the silk fibre with the beta-conformation and the polymers grafted onto the fibre substrate. DSC measurements show that the decomposition temperature of the silk remains almost unchanged. Endothermal transitions were found which are attributable to the vinyl monomer in the silk matrix, with their intensities being approximately proportional to the degree of grafting.

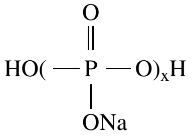
From these results, it can be seen that there is a low compatibility between the silk fibroin and the grafted polymer chains. Double refraction and isotropic refractive index show that the average molecular orientation and crystallinity of the grafted fibres decrease with increasing weight. X-ray diffraction curves have shown, however, that the crystalline structure remains unchanged even with high weight increases. This suggests that graft polymerization takes place primarily in the amorphous areas, as well as in the laterally arranged areas at the end of each crystalline segment, aligned along the filament axis (source: Tsukuda, Shiozaki and Freddi).

Graft polymers (graft copolymers). Polymers to which side chains from other building blocks are subsequently “grafted” on to the backbone of an already formed macromolecule (which may be obtained by polymerization, polycondensation or polyaddition, or as already existing polymers from natural sources resp. modified natural products). In principle, graft polymers have the following basic structure:



Such graft polymer structures are particularly suitable for modified fibres and textiles. Oxyethylated polyamide represents a typical example. The fibre backbone consists of polyamide 6.6. polymer on to which ethylene oxide polymer has been grafted. As revealed by infrared spectroscopy, the oxyethyl groups, or polyglycol chains, are actually attached to the amide nitrogen atoms of the polyamide chain. The graft polymer thus formed combines the individual properties of polyamide with those of polyethylene oxide to a greater or lesser degree. It is therefore possible to combine the desirable properties of both polymer components in the graft polymer. The graft polymerization process may also be applied to the combination of cellulosic molecules with synthetic polymers to form modified fibres with improved flame-retardant properties, dimensional stability, resilience, and bacterial resistance.

Graham’s salt Also known as sodium hexametaphosphate. A highly condensed, vitreous, sodium polyphosphate, i.e. a predominantly straight-chain condensed phosphate with the general formula $H(NaPO_3)_xOH$:



$$\mathrm{HO}\left(-\underset{\displaystyle \mathrm{ONa}}{\underset{|}{\overset{\displaystyle \mathrm{O}}{\overset{\|}{\mathrm{P}}}}}-\mathrm{O}\right)_x\mathrm{H}$$

in addition to a few percent of true metaphosphate (with cyclic structure). Readily soluble in water. Graham’s salt softens water without precipitation. It forms complexes with alkaline earths and metal ions.

Gram atom The quantity of an element numerically equal to the → Atomic weight expressed in grams, i.e. all gram atoms contain the same number of atoms.

Gram calorie → Calorie.

Gram equivalent The equivalent weight of a substance expressed in grams, i.e. the quantity of a substance by weight which corresponds to a gram atom of hydrogen. It may be calculated from the → Equivalent weight expressed in grams. →: Valency; Normal solutions.

Gram molecular weight (GMW). The → Molecular weight of a compound in grams.

Gram molecule → Mole.

Grams per litre The most commonly used measure of concentration in the textile bleaching, dyeing, printing and finishing industries and indicates the number of grams of a solid substance dissolved in 1 litre of a liquid.

Gram stain The most widely used differential diagnostic staining procedure for bacteria with cationic dyes (developed by the Danish physician H.C.J. Gram in 1884). This process divides bacteria into two major groups, gram positive and gram negative, depending on the structure of their cell walls. Procedure: The gram staining method involves first treating a dried and fixed film of bacteria with gentian violet (crystal violet) followed by a KI-I_2 solution to form a dark purple complex in the organisms. Subsequent treatment with polar solvents such as ethanol or acetone removes the complex from some species – the gram negative ones – but not others – the gram positive ones. The procedure involves 4 steps as follows:

Step Treatment Gram positive Gram negative

1. Initial stain Gentian violet for 30 s stains purple stains purple.
2. Mordant Iodine for 30 s remains purple remains purple.
3. Decolorization 95% Ethanol for 10–20 s remains purple becomes colourless.
4. Counterstain Safranin for 20–30 s remains purple stains pink.

Granite The name is probably derived from the mineral of the same name (granite = a coarse-grained igneous rock). In textiles, the term is used as a somewhat vague description for worsted cloth with a napless finish (chiefly in a 3/2 twill weave) often used for women’s dresses and costumes.

Granule A particularly finely ground product. The term is usually applied to disperse dyes in granule form which are non-dusting and easy to dispense in the dyehouse. → Commercial forms of dyestuffs.

Granule dyeing → Spin dyeing.

Graph A diagram depicting a functional relationship between two or more variables by means of a curve joining those points whose coordinates satisfy the relation. A diagrammatic representation of a series of measurements or calculated values, etc.

Graphic recorder Graphic output unit for graphic representation of work results from a digital computer.

Graphite (black lead, plumbago). An allotropic form of carbon, steel-grey to black, non-transparent plates or hexagonal crystals with a metallic sheen in various particle sizes. Density 2.1–2.3. Used in rust-protective coatings and paints, graphite printing, etc.

Graphite prints Dark printed effects with a metallic sheen dependent on the particle size of the graphite grade used. Fixed on textile fabrics to give prints with serviceable fastness properties.

Graphite stains Mainly dark, dust-like deposits on textiles frequently containing iron as well. The stains are removed in stages: any grease components are first removed with an organic solvent, benzene or white spirit after which the iron stains are removed with a mixture of oxalic acid, acetic acid and water.

Grass bleaching (grassing). A process formerly used for the → Bleaching of linen by spreading the linen out in the fields so that bleaching takes place gradually by exposure to the elements. The process has been almost entirely replaced nowadays by chemical bleaching.

Grass fibres → Esparto.

Grassing → Grass bleaching.

Grass stains Typically yellow-green or green in colour. Removal: a) hot fatty alcohol sulphate/sodium carbonate solution (for white goods); b) ethanol/ammonia in the ratio 10–15 : 1 (warm/hot); c) fatty alcohol sulphate/ammonia solution (warm) with the dropwise addition of hydrogen peroxide 3%; d) dilute lactic acid (warm) with addition of ethanol if necessary, and a treatment of up to 60 min for old stains, then treat with ammonia 5% (for coloured silks lactic acid/ethanol is particularly recommended); e) ethyl ether; f) ethyl acetate/chloroform/benzine soap 2 : 2 : 2, then white spirit. It is often necessary to repeat the treatments.

Gravimetric analysis (gravimetry). A method of quantitative analysis that depends on weighing. Principle: weighed quantity of the substance to be determined in solution + weighed quantity of a known substance in solution = precipitate of known composition from which, after filtration, washing, drying or ignition if necessary, and weighing, the quantitative composition can be calculated (→ Stoichiometry); e.g. according to the equation:

$$AgNO_3 + NaCl = AgCl\downarrow + NaNO_3$$

Although gravimetry usually offers a very high degree of accuracy, it suffers from the disadvantage that it requires careful and time-consuming procedures in comparison with other analytical methods (→: Titrimetry; Complexometry; Colorimetry, etc.). Moreover, the development of considerably less time-consuming quick tests of ever-increasing accuracy have led to a situation where recourse to gravimetry is only required in special cases.

Gravimetry → Gravimetric analysis.

Gravure printing An intaglio printing process using etched copper cylinders or plates. The Fig. illustrates a gravure printing plant for glass fibre matting. In order to achieve a perfectly smooth substrate surface as a prerequisite for gravure printing, it is necessary to apply a ground coat before printing (Ramisch-Kleinewefers), i.e. before print paste transfer takes place by contact between the inked roller and the substrate using an applied pressure (see Fig.). The process is also used for the production of high quality printed papers for → Transfer printing, e.g. for the sublimation transfer printing of polyester fabrics, etc. Very high printing speeds can be achieved (60–120 m/min) in gravure printing.

Grease content → Residual grease content.

Grease milling → Milling.

Grease stains Darker when fresh, generally lighter, and of a more matt appearance when old. In lightly coloured thin fabrics mainly transparent. Grease stains always have blurred edges. Removal: a) white spirit or, better, benzene or carbon tetrachloride, ethyl ether, ethyl acetate, carbon disulphide; b) chloroform/ether/carbon tetrachloride or chloroform/ether/alcohol; c) benzene/carbon tetrachloride 1 : 1.5; d) glycerol/benzene (carbon tetrachloride) 1 : 2 (especially for sensitive coloured goods); e) conc. benzine soap or solvent soap with alcohol if necessary and, possibly, trichloroethylene. Residues removed with benzene and, finally, chloroform; f) fatty alcohol sulphate/detergent solution (neutral) warm (if necessary with glycerol). In the case of particularly resistant stains, the use of increased temperatures, treatment overnight, or repeated treatments (e.g. a repeated drycleaning operation) is recommended.

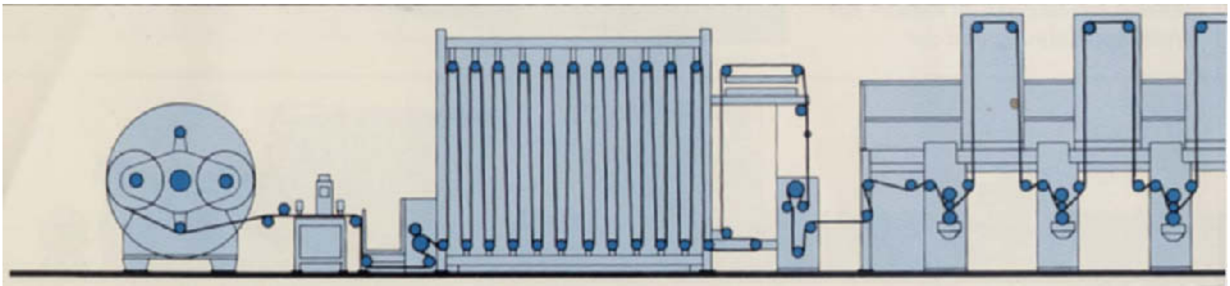


Fig.: Gravure printing plant for glass fibre matting (Kleinewefers KTM).

Greasy lustre Unwanted sheen on fabrics; results, e.g. due to rotary pressing (can be reduced by decatizing), wear “shine” in worsted fabrics, frictional “shine”, etc.

Greasy wool Unwashed → Raw wool.

Greek alphabet Individual letters of the Greek alphabet are frequently used in physical, physicochemical, and chemical terms and are also used as symbols in mathematical and chemical formulae.

Α α	alpha	Ν ν	nu
Β β	beta	Ξ ξ	xi
Γ γ	gamma	Ο ο	omicron
Δ δ	delta	Π π	pi
Ε ε	epsilon	Ρ ρ	rho
Ζ ζ	zeta	Σ σ, ς	sigma
Η η	eta	Τ τ	tau
Θ ϑ	theta	Υ υ	upsilon
Ι ι	iota	Φ φ	phi
Κ κ	kappa	Χ χ	chi
Λ λ	lambda	Ψ ψ	psi
Μ μ	mu	Ω ω	omega

Green Cotton A brand name for T-shirts produced in accordance with specific ecological requirements. Manufacturers of these shirts which are labelled with a number and the inscription “green” are bound by a self-obligation to fulfil the following conditions:

- only cotton grown under ecologically acceptable conditions may be used;
- only the most environmentally-friendly wet processing treatments are to be used.

The material may be washed, if necessary, in the greige state, ie. not scoured, bleached or dyed. The relatively good resistance to shrinkage in washing is achieved by drying in a special tumbler during finishing.

Green eater A characteristic of certain yellow vat dyes of poor light fastness which, in admixture with vat green dyes of high light fastness, promote → Catalytic fading of the latter. → Blue “eating” yellow dyes.

Green ground style A characteristic style of Africa print produced on cotton fabrics that have been prepared with Naphtol AS-G (Hoechst) in which red, yellow resists (Fast Colour Salts or Bases) and white resists are produced by overprinting with sodium thiosulphate as the resist agent. After printing and drying, the fabric is padded all over with an indigo blue dye (in the form of a vat leuco ester with sodium nitrite) and the colour finally developed in a sulphuric acid bath. (The characteristic green ground of these prints is produced by a combination of the yellow naphtol combination and the indigo blue component). → Africa prints.

Greenhouse effect Two environmentally-related phenomena are taking place in the earth’s stratosphere and atmosphere: thinning of the ozone layer (ozone depletion) and increasing amounts of CO_2 in the air (see Fig.). The so-called greenhouse effect, i.e. the gradual rise in average global temperature and the slower dissipation heat from the earth’s surface, is independent of the processes taking place in the ozone layer and is ascribed mainly to the burning of fossil fuels, especially coal, aided by aerosols and other contaminants. Atmospheric research has revealed that the content of trace gases, resulting from human activities, has increased constantly since the beginnings of the industrial revolution. These man-made trace gases include carbon dioxide from the burning of fossil fuels (coal, petroleum, natural gas), methane from the wet cultivation of rice, animal husbandry and poultry farming as well as waste disposal, nitrous oxide (laughing gas) from the earth’s nitrogen cycle, and chlorofluorocarbons (CFC’s).

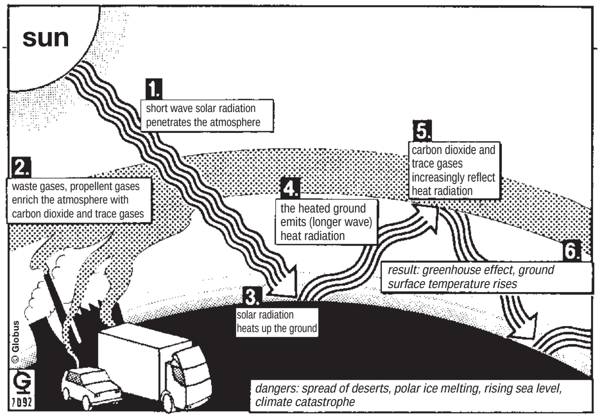

Fig.: The greenhouse effect and its origin.

Greening An unwanted “greening” of dyed and printed colours on textiles, especially blacks, during storage and in wear. The problem is mainly confined to sulphur dyes and aniline black.

Greensand → Glauconite.

Green unripe cotton Cotton seed hairs which have developed too late on the outer skin of the cotton seed or which originate from cotton bolls which have been harvested too early. These immature cotton fibres are thin walled and generally have only few convolutions, in contrast to mature fibres. Moreover, they still contain protoplasmic residues in the lumen. The natural green colour of immature cotton fibres cannot be destroyed by the usual bleaching processes. Cotton with a high proportion of immature fibres is therefore unsuitable for white goods.

Grège Raw silk; the raw silk strands or filaments (reeled from several cocoons), i.e. silk still covered by sericin (gum).

Greiz-Geraer fabrics (Greiz-Geraer ladies’ dress fabrics), obsolete German brand name for fine worsted fabrics made of merino wool, plain coloured or patterned, and in designs following Paris and Milan fashions. In the "Greiz-Geraer genre", 80% of the ladies' dress fabrics were woven in worsted spun yarns and 20% in pure silk.

Grenadine,

I. Silk yarn produced from doubled twisted → Organzine but with a higher degree of twist organzine silk).

II. A term used for various fabrics. That produced with a silk warp and worsted or mercerized cotton weft is called satin grenadine which is executed in a satin weave. The term also applies to a lightweight, almost transparent, type of → Étamine (silk/mercerized cotton) and fine loosely-woven women's dress materials similar to marquisette, or damask type fabrics. The term has also been used for fine stockings (viscose filament), from which crêpe stockings (yarns with a half voile twist) were developed (1933).

Grey goods inspection → Inspection of incoming goods.

Greying inhibitors for laundry detergents An explanation of the mode of action of these substances is as follows: soil in the wash liquor is first detached from the fibre and then prevented from redepositing on the fibre surface during rinsing by preferential adsorption on to the greying inhibitor. In the first phase of rinsing, the dissolved and dispersed soil is transported away and in the second phase, the adsorbate/synthetic fibre/greying inhibitor is broken down again so that these substances are also transported away in the rinsing water. Carboxymethylcellulose has proved particularly effective as a greying inhibitor for cellulosic fibres, whilst hydrophilic polyamide and polyester oligomers are recommended for polyamide and polyester fibres. The most effective greying inhibitors are mainly water-soluble high molecular weight compounds which are adsorbed strongly both by textile substrates as well as soil pigments. The adhesion of certain cellulose ethers is, e.g. so great that they are not even removed from garments by rinsing and such compounds have a soil-repellent action. Greying inhibitors have increased in importance due to the changes in detergent recipes and lower washing temperatures.

Greying of textiles in drycleaning The problem occurs mainly by redeposition of the previously loosely detached soil, dye particles or fibre lint (abraded fibres) in a now more finely distributed form from the solvent, or the small amounts of water in the drycleaning detergent (Fig. 1), on to the textile material, with the participation of electrostatic attraction forces between fibre and soil. Preventive measures include, e.g. filtration using filters of adequate dimensions, the use of drycleaning detergents with good soil suspending properties, efficient rinsing and, especially, the additional application of antistatic agents.

Excessively long drycleaning cycles, especially in soiled liquors, are to be avoided. Greying values (Fig. 2) between 30 and 50% relative humidity (RH) reach their lowest state at 50% RH and rise constantly again, under certain circumstances, until the point at which soil detachment is exceeded from approx. 75% RH. The range from 75–80% RH corresponds to optimum cleaning = maximum removal of water-soluble soils. A further increase in the RH results in pronounced yellowing; for the procedure used for measuring the degree of whiteness see → Yellowing during wear.

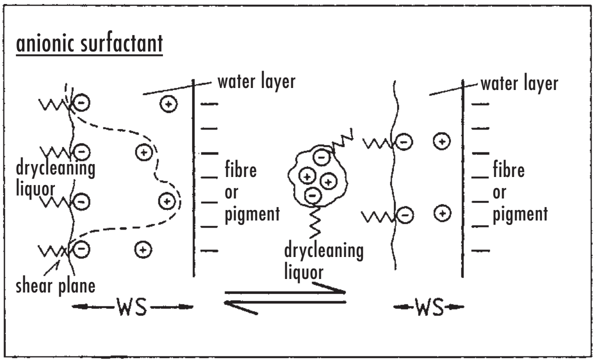

Fig. 1: Model presentation of the structure of surface charging in the adsorption layers (WS) of the water on the fibre surface and its shearing by the cleaning mechanics.

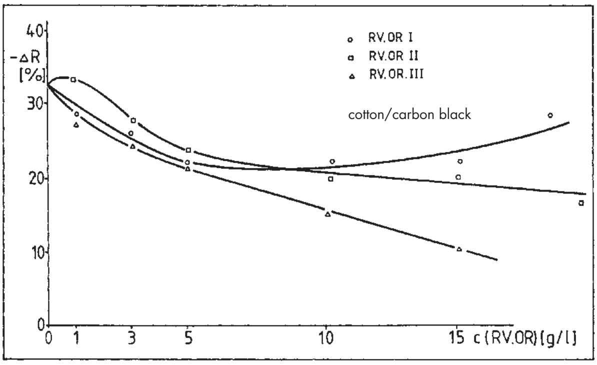

Fig. 2: Greying of cotton relative to type and concentration of drycleaning detergent.

Greying of textiles in washing A problem caused by the use of wash liquors with insufficient soil suspending properties, i.e. inadequate dosage of detergent. For the procedure used to measure the degree of whiteness see → Yellowing during wear.

Grey scales for colour fastness testing,

I. Grey scale for the assessment of staining (BS 1006 A03: 1990). Consists of a scale of 5 pairs of grey and white coloured plates in which each pair of plates indicates a different degree of contrast with the 5 full steps being arranged in geometrical progression. The degree of staining of the adjacent (undyed) fabric specimen subjected to a colour fastness test together with the dyed (or printed) textile specimen is assessed by placing the adjacent fabric next to the dyed (or printed) test fabric and comparing the degree of contrast against the grey scale. The number of the contrast pair in the grey scale (from 1–5) which corresponds as closely as possible to the degree of staining is noted and serves as the fastness rating. Half steps are provided in the grey scale to improve the accuracy of assessment:

1 = heavy staining,
2 = moderate staining,
3 = medium staining,
4 = slight staining,
5 = no staining.

II. Grey scale for the assessment of change in colour (BS 1006 A02: 1990). Consists of a scale of 5 pairs of grey-coloured plates in which each pair of plates indicates a different visible degree of contrast. In a like manner to that in (I) above, the visual difference between the grey scale and the test specimen is compared and rated as follows:

1 = very poor (severe change),
2 = poor,
3 = fairly good,
4 = good,
5 = very good (negligible change).

Besides the numerical rating for change in colour, the rating may be supplemented by a letter to indicate an accompanying change of hue or brightness, e.g. D = duller, Br = brighter, R = redder, Y = yellower, Bl = bluer, G = greener.

Grey series According to Ostwald, grey is that non-chromatic colour between black and white. The entire series of non-chromatic colours from white through grey to black is known as the grey series or grey scale. It consists of 8 colours referred to by standard letters, a (white), c (very pale grey), e (somewhat darker grey), g, i, l, n, p (deepest black), which can also be combined as a degree of → Saturation (greyscale) in the case of shades with the shade number of the chromatic circle. → Pure spectral colour.

Grey tufted carpets Tufted carpets, back coated only and held in store. Only after an order is received is the carpet cut to the required size, piece-dyed and dispatched.

Grinding burrs As a final stage in the grinding of doctor blades for printing, the grinding burrs which are formed along the edge of the doctor blade after it has been filed to the correct angle are removed from both sides of the ground edge with an oil stone.

Grinding machine,
I. → Sanding.
II. → Doctor blade grinding machine.
III. → Shearing blade.

Grinding machine for shearing knives A machine used for grinding and sharpening the helical shearing knive cylinders used in shearing (cropping) machines, i.e. precision sharpening of the upper cylinder and lower knife to ensure an absolutely uniform fit between the two (see Fig.).

Grinding mill In order to comminute disposable plastic materials (especially disposable plastic dye tubes) a shredder is first used for coarse comminution followed by treatment in a grinding mill for the production of small granules.

Grinding stone for printing rollers A special grinding stone used for repairing and polishing engraved copper printing rollers.

Grinning,

I. A term used in textile printing to describe a printing defect in the form of small, unprinted areas in a design caused by the printing of colours bordering each other with screens or printing rollers where the engraving allowance for the bordering colours has not been sufficiently generous to ensure an unbroken border between the adjacent colours thus allowing small white (unprinted) areas to “grin” through.

II. In dyeing: lighter appearance of a fibre type in dyeing mixed fibre fabric. In printing: irregular or light-coloured, unprinted places, poorly wetted out as a result of too highly concentrated thickener (→ Print definition).

Gripper Axminster A machine-woven velour carpet in which the differently coloured dyed yarns for

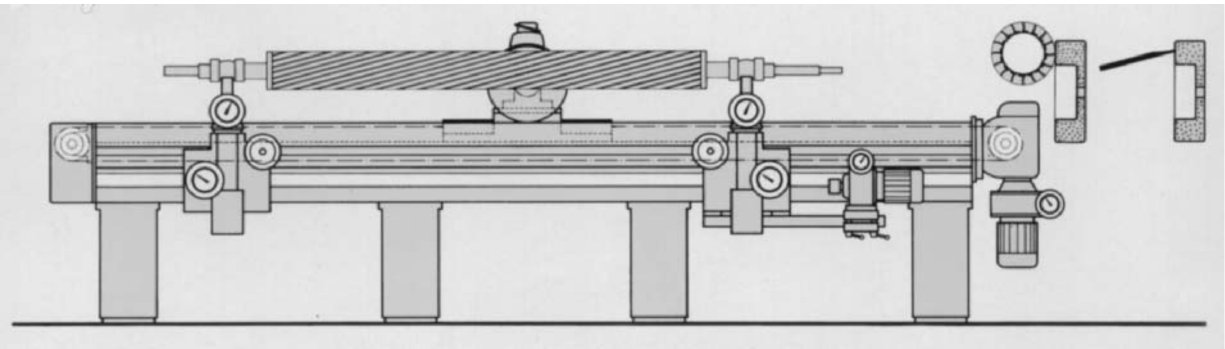

Fig.: ESB model grinding machine for shearing knives (Menschner); max. roller width 6000 mm.

the warp pile are supplied as required from bobbins carried on a creel behind the weaving machine. Jacquard-operated yarn carriers present the appropriate coloured yarns to the grippers which grasp the required length of pile, which is then severed. The grippers, holding the tufts, then swing down to insert the tufts of yarn at the point of weaving across the entire width of the carpet. The maximum number of colours is usually limited to 8 but may be as high as 12.

The design of a gripper Axminster is also clearly recognizable on the back of the carpet.

Gripping clamp in screen printing Serves to grip the screen gauze. Broad tabs faced with sandpaper hold the screen more effectively than can be achieved by hand tensioning.

Grooved embossing → Embossing.

Grooved roller Application roller with grooves. The depth and spacing of the grooves are dimensioned in such a way that one warp thread is assigned per groove. The main use is for sizing warp yarn. Warp yarn finishing processes are also possible.

Gross A unit of quantity equal to 12 dozen = 144.

Ground The background of a patterned textile which provides a contrast in weave, colour or profile (embroidery) to the design. In printed fabrics the ground is either the white (unprinted) background of a printed design or the coloured (printed) background of a multicolour design.

Ground colour (carpet). In true carpets, the colour of the area against which the pattern (motif) stands out in other colours.

Groundnut fibre → Arachin fibre.

Ground water Subterranean stagnant or flowing water which occupies cavities in the earth's crust in a coherent manner. Depending on their origin, different chemical constituents are dissolved out of the rock (minerals, alkalis, sulphates, chlorides, water hardening substances, iron, manganese etc.) or soil (nitrites, nitrates, humic acid etc.) as water flows through.

Ground white Substrate luminance (depth of bleaching) after pre-treatment and bleaching; its importance for max. luminance is shown in the Figure, taking cotton goods as an example.

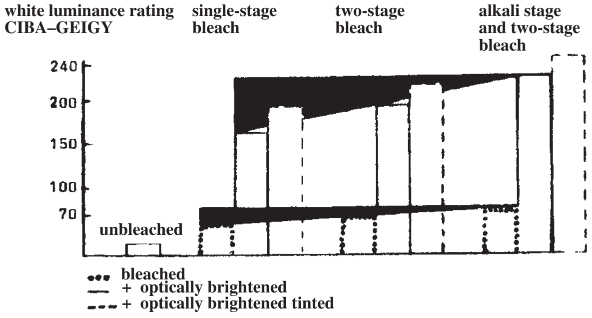

Fig.: Luminance on cotton goods which have been subjected to different pre-treatments.

The lower black wedge shape demonstrates the intensification from 1-stage bleach through 2-stage bleach to 2-stage bleach with prior alkali stage, with the luminance rising from 63 through 69 to 78. However, as can also be seen from the upper black wedge, the relatively low difference in the depth of bleaching has a much greater effect on the whiteness of goods which have already been brightened, for here the luminance rises from 164 through 194 to 222. Accordingly, here the increase in ground white through good pre-treatment or bleaching brings about a 4-fold increase in luminance in the case of optically brightened goods. As the corresponding columns in the diagram show, additional toning or blueing leads to a further increase in luminance. Even in the case of optimum bleaching and brightening, the luminance can consequently be increased some more by this means. Thus small increases in ground white have a very positive effect on the luminance of optically brightened goods. On the other hand, even slight deterioration in the ground white (e.g. through poor stability of the bleach) has a very noticeable negative effect on the final luminance. As a rule of thumb for prescribing toning additives for optical enhancement, one can assume that this can also be established on the basis of the reflectance curve (exception: samples with a strong yellow cast, frequently declining reflectance, a saddle point occurring after optical brightening in the green zone on the right next to the fluorescence point, which imitates the effect of a dye additive). In the case of optically brightened and toned samples, conclusions concerning the ground white can be drawn only from the reflectance level on the long-wave spectrum end (700 nm), but even that is no longer possible with heavy toning and in the case of turquoise dyes. For this reason, the aim is to achieve a high ground white or good bleaching, since then less blueing material is needed; greying and loss of brightness are thus to be kept as low as possible.

GSA (Am.), abbrev. for: General Services Administration; American Standards Organization.

GSB test Test for determining the maturity of cotton, otherwise called the Red/Green Test or simply → Goldthwait test, devised by Goldthwait, Smith and Barnett.

Gu → Guanaco, → Abbreviation according to DIN 60001 until 1988, as from 1991 now designated → WU.

Guanaco The yellow-brown hairs of the guanaco, a llama-like animal that roams wild over a large area of South America. Guanaco belongs to the group of → Natural protein fibres. Only the under hairs are of textile value. The fibre is extremely soft and silky, the finer hairs are approx. 20 µm and the coarse hairs approx. 75 µm in diameter. Guanaco hairs have about 118 scales/mm. The fibre is of little economic importance. → Animal fibres.

Guar gum (Guaran), Asiatic type of gum (Cyanopsis tetragonoloba), fraction of the endosperm ground from the seeds (diameter approx. 5 mm) of the guar plant, a grey-white powder comprising 65% mannose and 35% galactose (→ Galactomannan), aqueous-colloidal neutral solution, has an approximately 8-fold starch thickening power, and is used as a fine powdery thickener in carpet printing and dyeing processes, amongst other things (see Fig.).

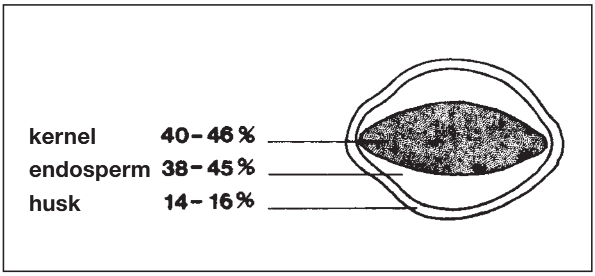

Fig.: Section through a guar seed.

Dispersibility: Hydrophilic guar gum is difficult to disperse (rectify by pre-mixing with alcohol or glycerine, as well as through more intensively-acting homogenizers), whereas easily dispersible guar gum derivatives in vigorously stirred water are considerably easier to handle. Such dispersible guarans require the addition of acid for hydration, through which complete dispersion is assured before viscosity increases. Hydration through the addition of acid must be initiated only after thorough dispersion; to avoid critical situations, possibly with initial adjustment with weakly ammoniacal water. Water temperature has a great influence on the hydration time: the colder it is, the slower the rise in viscosity; however at low temperatures, higher end viscosity can be achieved. For this reason, control/regulate the water temperature as precisely as possible. Once lumps have occurred they are insoluble, even when high shear forces and longer hydration times are used. Lumps can be caused by poor quality of guar gum, incorrect procedures, extreme water temperatures, pH too low. Avoid lumps by fast and even incorporation whilst stirring vigorously, monitoring the temperature and pH. The viscosity of guaran solutions is heavily dependent on temperature and on concentration (logarithmically, not in a linear manner), i.e. doubling the concentration can lead to a 10- to 15-fold rise in viscosity (small metering variations can cause large variations in viscosity). Fully effective increase in viscosity requires good dispersion. Under normal mixing conditions, with guar gum 95% of the maximum achievable viscosity is reached in 30 minutes, whilst guar gum derivatives hydrate even more quickly. Microbial attack can cause drastic losses in viscosity: for this reason, ensure absolutely clean working and storage conditions, as well as proper use of preservatives where printing pastes are stored for longer periods. Additives should best be added only after complete hydration; one must take into account the tendency of some dyestuffs to gel at high concentrations (possibly add counteracting agents), and also the fact that most guaran derivatives can even gel under alkaline conditions unless specific additives are used in accordance with the manufacturer's recommendations. In the alkaline range, guar gum can gel in the presence of borate ions and antimony ions, whilst oxides of lead, cobalt, antimony and chromium ions encourage gelling in the acid range. Guaran solutions are relatively stable in the presence of most acids at pH 2 and at room temperature, whilst oxalic acid in the presence of iron very quickly lowers the viscosity through acid hydrolysis. The oxidative breakdown of the galactomannan (and other water-soluble polymers) is catalysed by iron ions and tin ions, accelerated by sequestering agents (EDTA); for this reason, polyphosphates are more suitable than EDTA.

Guide pins Brass pins on the → Block for pattern repeats.

Guide rod Fixed rod for guiding the cloth.

Guide roller Device, fitted on textile machines, for guiding the cloth by means of an idler roller which rotates freely as the cloth is passed over it. The purpose of guide rollers is to ensure the correct passage of the cloth, i.e. at low tension, and free of creases (poor guide rollers are the main cause of creasing). With regard to low-tension travel, the weight of the roller is critical: a high dead weight impedes free running characteristics, since the frictional forces in the bearings are dependent on the load, and the inertia increases in proportion to the mass. As a result, high tensions occur as the cloth starts to run. For crease-free cloth guiding, the necessary conditions are achieved only with sufficiently rigid guide rollers. If a guide roller sags, then the cloth migrates to the centre and forms creases, with the material usually lying in three layers one over another. Here, the outer layer is stretched more than the inner one, and through stretch tension, compression forces arise which act on the cloth lying underneath, which can lead to lasting crease marks. The smaller the guide roller diameter, the greater the outer layer is stretched. Guide roller flexing is prevented by inelastic roller material (high modulus of elasticity) and by large diameter. With regard to the crease marks, a large roller diameter is thus the better solution.

Rollers with special steel coatings and special steel journals are predominantly used. A strong core barrel with a wall thickness of 6–7 mm in plain steel is the load-bearing element. This tube is encased in a no-knock stainless steel sheath 1.5 mm thick. The stainless steel journals are pressed-in hydraulically and welded to the stainless steel sheath. Guide rollers with diameters of 100/125 mm are specified as standard equipment. For more demanding requirements, i.e. at higher speeds, larger widths or more delicate fabrics, diameters of 125/150 mm are used.

Industrial trials of guide rollers with a steel barrel and those with a barrel of glass fibre reinforced plastic show that GFRP (glass fibre reinforced plastic) rollers offer advantages with regard to crease-free passage of the cloth, due to higher specific flexural strength (approx. 4–5 times higher than for steel and for larger diameters); as a result, higher loadings are possible in the short-term without permanent roller deformation. The surface roughness of smooth-ground GFRP rollers is superior to that of smooth-ground stainless steel rollers (the surface smoothness of GFRP rollers is particularly advantageous where there is any risk of contamination by dyestuff/finish). Currently, GFRP rollers can be used in dry/damp air at up to 120ºC, taking into account mechanical stress. When submerged rollers are used, the roller strength must be considered in conjunction with temperature and mechanical stress.

Guide roller bearings Guide rollers and their bearings are important components in open-width washing machines, since it is essentially on these that a crease-free and low-tension cloth travel depends. The dimensions of vats are independent of the guide roller diameter; rollers which are not submerged do not dip into the liquor and thus run dry (Fig. 1).

All machine types have carbon bearings for submerged guide rollers as standard equipment. These are mounted in pendulum bearings with zero backlash. Lubrication is via the liquid in the trough (Fig. 2). The stainless steel mount can be removed quickly and easily for replacing worn carbon bearings. The pendulum bearings merit special emphasis, thanks to the design (in contrast to horizontal bearings); one thus achieves automatic compensation without edge pressure (Fig. 3). Non-submerged guide rollers run in roller bearings in all cases. For more demanding requirements, external bearings are used, with the stainless steel journals being externally sealed against the vat wall by a rotating carbon slip ring (Fig. 4). This provides a roller bearing mount. This results in speedier replacement, smoother running, lower maintenance, acceptance of high tensions, perfect long-term parallel alignment of the rollers.

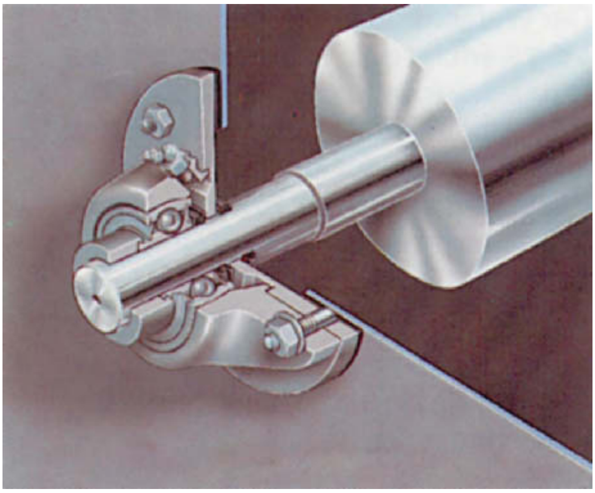

Fig. 1: Dry-running guide roller.

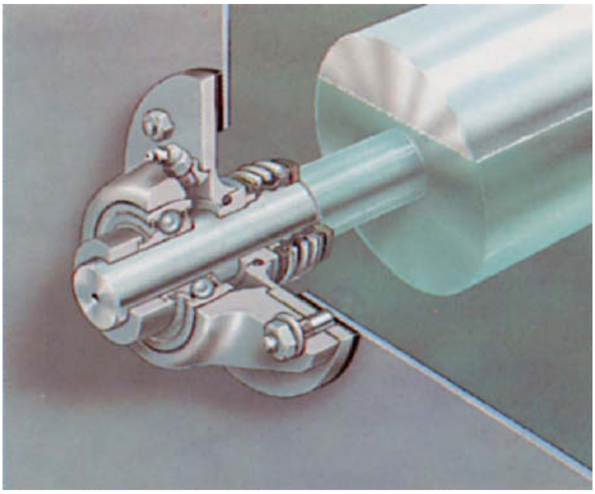

Fig. 2: Guide roller with under-liquor seal.

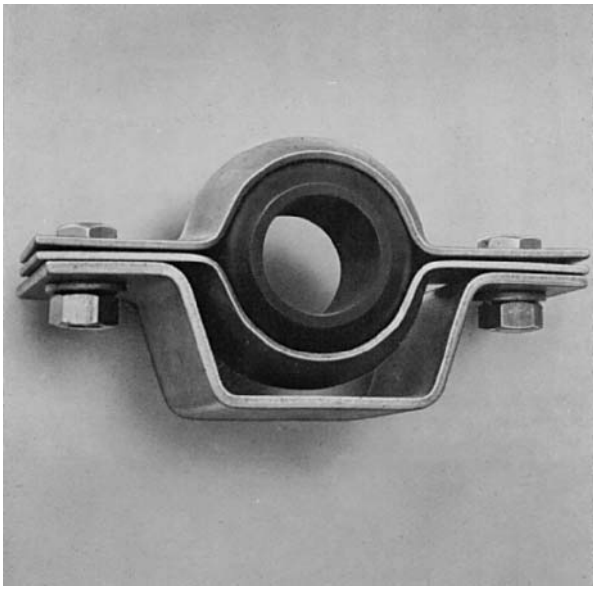

Fig. 3: Dry roller bearing, interior (carbon bearing).

Guide stops Guide stops are used in hand screen printing on tables to achieve more accurate register of difficult or very intricate designs. For this purpose, the

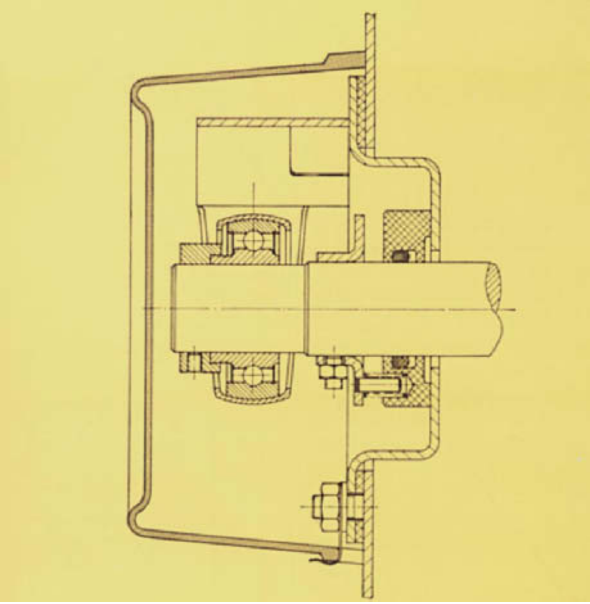

Fig. 4: In-vat roller bearing, exterior.

screen repeat is assisted on both sides of the printing table. Movable guide stops are attached to rails at each side. The stops for the design repeat (→ Printing screen locking units), which determine the repeat length as well as the transverse position of the screen frame, are positioned along one side of the printing table. The guide stops, which have the task of maintaining the screen at right angles to the fabric being printed, are fixed along the opposite side.

Guideline concentration → Technical guideline concentration.

Gum arabic Senegal gum, acacia gum, African vegetable gums which contain up to 80% arabic acid. Most highly prized is gum kordofan from Sudan (2 cm droplet length, slightly yellowish or of a deep amber colour, rarely colourless). Much less pure is Geddah gum from the area around Aden (grainy, deep yellow, brown to black; when dissolved leaves quite heavy insoluble sediment), similar in appearance and quality to Moroccan mogador gum.

General facts about gum arabic: the colour is pale yellow or brownish to reddish-brown/black, droplets 1-2.5 cm diameter, glassy on the inside, cracked and clouded on the outside, globular, longish, droplet-shaped, worm-shaped; fractions (grains) up to 1 mm diameter. Good gum (soaked overnight) is fully soluble in twice the amount of water (100 g per litre = approx. 5°Bé); solution almost clear, thick, slimy, rather sticky, weakly acidic. High adhesive strength requires high viscosity. The polarity of solutions is laevorotatory. Precipitations by sodium silicate, sodium tetraborate, albumin, ferric chloride, pure yellow with iodine solution; tannins do not cause precipitation. Applications: finishing auxiliary, printing thickening, for producing emulsions, etc.

Gum precipitate Isotropic electrolytic soap solution which may be separated from the neat soap after the finishing stage of soap production by either settlement or centrifuging.

Gums → Vegetable gums.

Gum tragacanth → Tragacanth.

Gütegemeinschaft für sachgemäße Wäschepflege (GG – Quality association for the proper handling of laundry). → Technical and professional organization.

Gütezeichenverband Textilveredlung e.V. (GüTV – Quality label association for the textile finishing industry). The purpose of this association is to promote the concept of quality in the textile finishing industry, to create quality labels and to set up rules for quality labels, with minimum requirements for the use of the quality labels, monitoring of the established minimum requirements with the involvement of independent public institutions, and initiation and implementation of corresponding promotional features.

Gütezeichen Weißmaßstab (White scale quality label). This quality label is awarded by the → Gütegemeinschaft für sachgemäße Wäschepflege e.V. and the Hohenstein research institutes, produced and issued on the basis of the Ciba-Geigy white scale (cotton). Aid for determining the degree of whiteness and shade variation.

Gutta percha (trans-polyisoprene). The name is derived from Malay getah = gum + percha = name of a tree from which it is extracted. A natural latex product, similar to rubber, from the latex of any of several tropical trees of the sapotaceous genera palaquium and payena. It can be vulcanized with sulphur. Gutta percha is brown to grey-white (purest grade: white) in colour. Pure gutta percha ($C_{10}H_{16}$) is a stereoisomer of polyisoprene). Properties: stiff, hard, and inelastic, but not brittle, when cold; thermoplastic, combustible; insoluble in water, soluble in chloroform, carbon disulphide, as well as in warm turpentine oil. Gutta percha is harder than rubber and is a better (electrical) insulating medium. It is obtainable in both liquid and dried forms. Applications: gutta percha bottles, container linings, formerly used for insulating electrical submarine cables before the introduction of plastics, also formerly used widely for golf ball covers. It may be used for painting on silk in the form of a solution with a honey-like consistency to produce resists on the fibre (it forms a film on drying which is impervious to water and dyes) and thus makes separation lines in coloured designs possible (similar effect to window leading in stained glass church windows). Gutta percha bottles are used, inter alia, for conc. hydrofluoric acid (spotting agent).

GüTV → Gütezeichenverband Textilveredlung e.V. Quality labelling association for the textile finishing industry.

Gypsum Hydrated calcium sulphate, ($CaSO_4 \cdot 2\,H_2O$). Gypsum has a low solubility in water (approx. 0.26% at 20°C). It is a component of permanent water hardness (→ Dried gypsum) and calcium precipitations in processing liquors as well as calcium deposits on textiles (→ Lime soap). It is also present in → Boiler scale.

Gypsum expansion Concrete cancer, the harmful effect of sulphates (→ Sulphate hardness of water) on mortar. This involves an initial formation of gypsum from the lime in the mortar, then to double bonds with the mortar (calcium aluminate), crystallises out in the presence of a volume of water (calcium sulphoaluminate). Consequence: strong crystallisation pressure, splitting of the mortar structure, structural damage. Penetration of a sulphate solution into concrete leads to a so-called "cancer" growing inside the hardened cement as aluminium compounds form calcium aluminium sulphate hydrate ($3\,CaO \cdot Al_2O_3 \cdot 3\,CaSO \cdot 32\,H_2O$), which, as ettringite takes up more space than any of the original compounds in the concrete ($3\,CaO \cdot 2\,SiO \cdot 3\,H_2O$; $3\,CaO \cdot Al_2O_3 \cdot 6\,H_2O$), and can lead to cracking and brittleness of concrete structures (e.g. in sewer pipes). This process of expansion is different to the simpler dissolving out of the concrete constituents, which can lead to a hollowing of concrete structures. A determination of maximum concentrations (e.g. 400 mg/l SO_4^{2-}) is therefore useful and can be met by diluting effluent containing sulphates and passing them through plastic pipes in the immediate vicinity of a textile finishing process, or until they achieve the required degree of dilution. Meeting relevant legislation may initially be costly and difficult to implement (e.g. installing plastic piping), but overall, the textile finisher is protected from the consequences, including those which may result from the polluter pays principle, if extensive sulphate damage is caused to the drainage or sewage systems.

H

H, chemical symbol for hydrogen (1).

h,

I. Symbol for → Hecto- (prefix indicating 100, as in hm = hectometre), factor 10^2.

II. Abbrev. for hour.

HA,

I. → Hairs, → Standard abbrev. for textile fibres, according to the → EDP code.

II. → Hemp, → Standard abbrev. for textile fibres, according to DIN 60 001 T4/08.91.

Ha, → Hemp, → Standard abbrev. for textile fibres, according to DIN 60 001 until 1988, from 1991 → HA.

Hackling A mechanical process given to flax stems after → Scutching. Its purpose is to remove short fibre, motes (or neps) and non-fibrous material. Hackling involves drawing the fibres through inclined steel combs, each successive comb being finer than the previous one. As a result, the coarse bundles of fibre are separated into finer bundles and the fibres are thereby aligned parallel to one another. The outcome is approx. 20–70% hackled flax (long fibre), 60–20% flax tow (short fibre) and remaining motes. → Flax processing.

Hair dye stains These stains vary in type and appearance; frequently brown to brownish-black in colour. In most cases, old stains cannot be removed. Removal: a) white spirit or solvent soap (warm), followed by ammonia 5%, and finally hydrogen peroxide 3% or dilute hypochlorite bleach liquor; b) Höllenstein brown (typical hair dye) can be removed as under a) above followed by the treatment recommended for → Silver nitrate stains.

Hair felt → Felt.

Hair fibres This group includes all animal fibres with the exception of wool (→ Natural protein fibres).

Hairiness A term used to describe the projection of free floating fibre ends or loops from the surface of a fibre assembly (Fig. 1). It is a desirable characteristic in raised, brushed, fleecy fabrics (confers good heat retention properties). However, hairiness reduces the strength of yarns. Undesired hairiness can be influenced within certain limits, i.e. in spinning and also by subjecting the material to various aftertreatments mainly by shearing, singeing and dressing. It is possible for hairiness to cause warp yarns to "cling" during movement in the shed of the weaving machine (warp yarn breaks). The German textile machinery manufacturer Osthoff has developed a hairiness tester (which determines the degree of hairiness on running webs by means of an opto-electronic scanning system (Figs. 2, 3

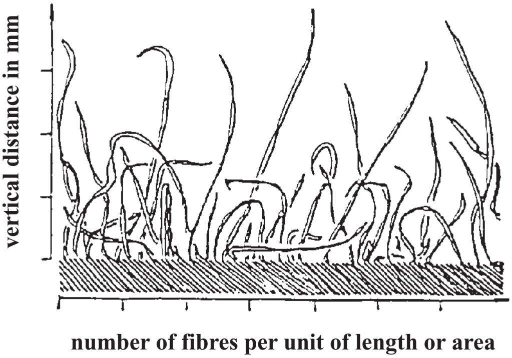

Fig. 1: Sketch illustrating hairiness on a fabric surface.

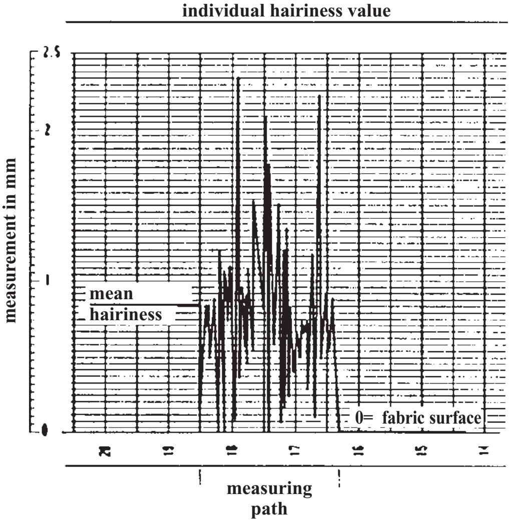

Fig. 2: Measurement curve of a hairy surface.

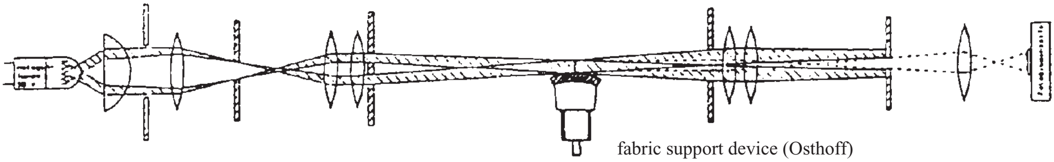

Fig. 3: Principle of the scanning beam system in the hairiness tester (Osthoff).

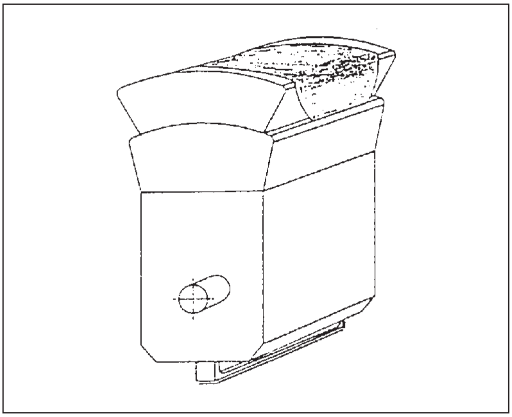

Fig. 4: Fabric support device (Osthoff).

and 4). This system was primarily designed to measure the hairiness of fabrics after singeing but can also be used to measure the pile height after raising or emerizing.

Hair linings Interlinings with a finish to give elastic resilience. The main purpose of the finish is to provide good recovery from deformation (highly dependent on the hair content of the weft). For these applications, horsehair in particular (→ Horsehair lining), goat hair, camel hair, mohair, alpaca as well as spun viscose in coarse counts are used. The hair fibres are often blended with wool or spun viscose. Wool, cotton, spun viscose or blend yarns are used in the warp.

Hair migration A disadvantage of → Hair linings caused by the hairs gradually working their way through the outer fabric after repeated dry cleaning thereby forming a nap which is visible on the fabric surface. It is particularly noticeable in dark materials. The problem can be solved by laminating.

Hair mordants (before milling), → Mordants for animal fibres.

Hair papilla → Human hair.

Hairs →: Natural protein fibres; Human hair.

Hai-Tao A variety of Asiatic algae with a flat fibrous structure, approx. 30 cm long. Swells in cold water and dissolves in hot water (as a mucilage); the solutions gelatinize again on cooling. Used mainly in Asia for the production of soft finishes, especially on fine fabrics (in combinations with starch or dextrine for cotton finishing).

Hajdu-method These include the Siotex process and the texylon process invented by Hajdu to improve the abrasion resistance of textiles. Principle: the deposition of silicon particles on textile materials.

HaKa A German acronym for “Herren und Knabenoberbekleidung” = men’s and boys’ outerwear. → DOB.

Half-bleach A term used to describe a bleaching effect which is adequate for goods to be subsequently dyed (but not for whites).

Half-dyeing, time of The time taken in minutes for a textile substrate to absorb 50% of the dye it will absorb at equilibrium under the same conditions. As a dye characteristic, it is less suitable for the selection of combination dyes for dyeing acrylic fibres with cationic dyes. In this case, the → Compatibility value K, is a much more reliable parameter.

Half emulsion Combination of an → Emulsion thickener and a conventional thickener (e.g. alginate). Used in direct printing for the application of most dye classes with the exception of indigo and oxidation dyes.

Half-milled hat bodies (half-planked felts). Premilled → Hat body for the production of felts.

Half resists →: Half-tone resists; Resist printing.

Half-shadow photometer → Colour measurement.

Half-tone Tone-in-tone effects in printing, i.e. a range of tones or tonal gradations in addition to the full depth tone with a sharp or gradual transition from the latter. → Half-tone process.

Half-tone autotype screens Half-tone effects in screen printing are produced with the aid of a cross-screen (autotype) grid which breaks up continuous tones into rows of dots of different sizes, i.e. large dots for darker areas and smaller dots for lighter areas. Since the human eye can no longer distinguish small dots below a certain size, they appear to merge into gradations of progressively weaker tones corresponding to the different sizes of dots. There is a certain relationship between the dot size and the viewing distance. In textile printing, half-tones between 20–40 are used, i.e. 20–40 half-tone dots per cm, where the spacing between the dots is dependent on their diameter.

When half-tones produced in this way are used to prepare printing screens, there is a risk of moiré formation (interference patterns) unless the angle of the half-tone positive is appropriately adjusted relative to the printing screen mesh.

Half-tone printing on textiles Unlike the continuous areas of colour in normal prints, half-tone prints consist of numerous closely spaced small dots which cannot be detected by the naked eye but give the impression of a shaded print surface. This is only possible if the dots do not collapse and are still present after fixation of the print paste has been carried out since otherwise the half-tone effect would disappear. Compared to half-tones on paper, which has a much smoother surface, textiles require a considerably smaller number of dots, i.e. a coarser cross-line → Screen with a maximum density of 30 dots/cm = 900/cm^2 or, for screen printing, only 12–20/cm = 144–400/cm^2. By interposing a cross-line screen of this type and colour filters, the negative of the original design is obtained with the reproduction camera and, after copying on to film, can be joined together to produce large diapositives from which the design may be transferred to the screen with a printing frame (for flat screen printing). By using different half-tones, variable print effects are obtained. For example, a seven-colour print effect may be achieved with just three printing screens if two of these screens contain, in addition to the full tone, a further two half-tone gradations in each case. Half-tone printing therefore allows the production of multicolour prints with various tonal gradations. It is, however, necessary to take into account the greater sensitivity of half-tone screens, e.g. with regard to mechanical damage, screen blocking, etc. To obtain more durable and, in particular, moiré-free screens, the mesh density (number of individual threads/cm) should be 1.5–2.5 times or 3–4 times greater than the half-tone density (Fig. 1). The angular position between the half-tones and the thread system of the screen gauze should be adjusted to 4–5° but never to 0°, 45° or 90° (which nearly always results in moiré formation). In 4-colour printing, the angle of the half-tones in the colour separations is adjusted to, e.g. 5°, 35°, 58° and 81° in relation to the printing screen mesh. Satin and taffeta weaves have proved particularly suitable for

	number of threads per cm	thread diameter	mesh size	free printing area	fabric thickness	volume of print paste in cm^3 / m^2
▲	68	43 µ	100 µ	49%	70 µ	34,2
▼	68/68	43 µ	60 µ	17%	82 µ	14

Fig. 1: Comparison between a normal screen gauze and a screen gauze with reduced open area for lower print paste throughput in flat screen printing.

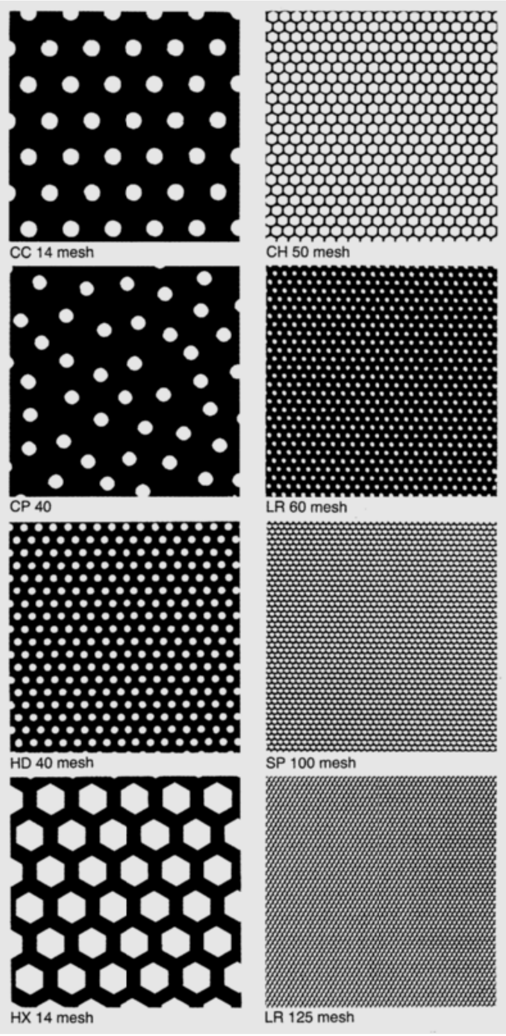

Fig. 2: Different screen mesh sizes of Stork rotary screens.

half-tone printing. In addition to the so-called cross half-tones, net half-tones (completely uniform mesh) are used for more precise shading, circular grain and worm grain half-tones (which produce an image in irregular dots with a “hammer blow” effect) are employed for somewhat coarser prints. Finally, structural effects may be achieved in printing if normal commercially available structural or half-tone films are also used in transferring the negative on to the screen. Thus, with the aid of the Idento(graphy) process, tonal gradations are achieved with transparent (Idento) film embossed with a grain effect and drawing over it or tracing with a black litho crayon. The colour difference is then reproduced in half-tone dots of varying size by the application of fairly intense pressure. The embossed film with the design can be used directly as a diapositive for copying on to the screen as long as the design repeat extends over the entire screen.

The production of designs on galvano screens demands considerable experience. In principle, there are two possibilities, the first of which is the least laborious. A uniformly thin light-sensitive coating is applied to steel mandrels of exactly the same diameter with smooth polished surfaces then, after drying, the half-tone colour separations obtained by photo-mechanical means are copied on to them (Fig. 2). During subsequent development, the light-sensitive emulsion dissolves out of the non-exposed areas. Nickel is then electrodeposited by galvanic means on to the steel mandrels, which are now covered with the design as half-tone dots, in a suitable rapid nickel deposition plant using appropriate nickel salt solutions. The cylindrical nickel covering which results from this process is then perforated in those areas wherever the half-tone dots in a colour separation are present. During the nickel deposition stage, care must be taken to ensure that uniform, homogeneous layers of metal are formed which should be as thin as possible.

In other cases, steel matrices which have been given a half-tone grid in dot form over their entire surface, taking care to position the half-tone at a suitable angle, are coated with a light-sensitive layer and the colour separations containing no half-tones are copied on to them. After development, the half-tones in the exposed areas are covered, but still remain in the unexposed areas so that during subsequent nickel deposition, perforations corresponding to the areas of the design are formed in the all-metal screens.

Half-tone process A process for the production of half-tone effects or tonal gradations. Two methods are used in practice, i.e. half-tone resists and half-tones produced with film. Half-tone resists are obtained either by using several screens with progressively weaker print pastes or by preprinting or overprinting → Half-tone resists on full depth print pastes. These resists affect the fixation of the preprinted or overprinted colour pastes thereby giving weaker printed shades in these areas. Half-tones produced with film achieve the tonal gradations by using screens which allow all the print paste to pass through for the full tone but which only allow part of the print paste to pass through the half-tones thereby breaking up the printed surface into smaller areas. By varying the proportion of white area lying between the printed half-tones, a reduction in the depth of colour is obtained. The individual elements within the printed areas can be uniform in shape, in which case they are known as autotype gradations, or irregular in shape with different grained effects (e.g. circular grain, worm grain or Idento half-tones). No special screen-making technique is involved in the half-tone process since the half-tone cross-screen grid is already present on the negative or positive and transferred in this form on to the screen gauze by the methods described.

Half-tone resists Resist effects produced by pre-printing a colourless print paste, i.e. containing no dye (with or without the inclusion of resist agents) followed by overprinting with a normal coloured print paste. A lighter colour is produced in those areas of the printed design where the second print paste falls on the first. Pre-printing with a high solids content thickener alone will already give a certain resist effect which can be further intensified by the addition of a white pigment (e.g. titanium dioxide, zinc oxide) or a white pigment incorporated into a plastics dispersion (= matt white).

Half-tone screen A half-tone screen is used to produce a range of tonal gradations by covering some parts of the screen’s printing surface with very fine mesh gauze and other parts with coarser gauze. Some parts of the screen are even covered with several layers of gauze in order to reduce still further the amount of print paste passing through the screen.

Halides Compounds of → Halogens (chiefly) with metals. The most important are the → Chlorides (e.g. sodium chloride, NaCl) which form salt-like halides in solid form. The halides of typical metals are ionic.

Halo,

I. A narrow pale (often blurred) outline surrounding a coloured discharge or resist print caused by the outward diffusion of the resist or discharge chemicals into the ground.

II. A ring surrounding the area of a stain on a textile material following attempts at stain removal by local application of a spotting agent (organic solvent). The ring or halo thus formed is caused by the outward diffusion of colouring matter, soil particles, grease, etc.

Halochromic effect Research around the triphenylmethyl radical led Baeyer to propose his theory of halochromy, whereby a colourless compound is rendered coloured on salt formation, e.g. → Oxonium compounds. The term “halochromism” is still used today to denote a colour change of a dye on the addition of acid or alkali. The effect is based on the formation of mesomeric resonance (→ Methyl sulphinyl carbanions).

Halogenated hydrocarbons Halogen derivatives of hydrocarbons. The most important representatives of these compounds in textile chemistry are the → Chlorinated hydrocarbons.

Halogens (Gr.: *halogen* = salt producer). The elements chlorine, bromine, iodine and fluorine. They react with metals to form ionic halide salts, e.g. iron chloride $FeCl_3$. Their hydrogen compounds are called hydrohalic acids, e.g. hydrochloric acid HCl. Halogens are represented as a summation parameter in pseudo formulae by the symbol "X", e.g. as in AOX (adsorbable organohalogens).

Halogen test lamp (haloid lamp). Gas detector and leakage indicator for chlorinated hydrocarbon and chlorinated fluorocarbon (CFC) solvent vapours according to the → Beilstein test. It is based on the principle of a propane/butane gas cooker detector which, in the presence of chlorine gas or chlorine compounds, reacts with a green flame colour. At higher concentrations of solvent vapours the colour of the flame changes from green to blue. The halogen test lamp should not be used too frequently since the gases formed in the flame are very detrimental to health and also attack metals and textiles.

Haloing (halo formation). Haloing takes the form of an uncoloured intermediate zone which develops occasionally between the printed colour and the ground in coloured discharge or resist printing. The effect is caused either by incomplete drying of the printed fabric, steam which is too wet during steam fixation of the printed colours, or excessive dosing of the discharging or resist chemicals. This printing defect is prevented by pre-padding the fabric with sodium m-nitrobenzene sulphonate (e.g. Ludigol) before discharge printing, adjusting the quantities of discharging or resist chemicals to suit the particular ground dyeing, the use of appropriate thickening agents in print paste preparation, and the use of less soluble or less hygroscopic substances in the discharge or resist pastes.

Halyde Meter A sensitive American measuring instrument used for monitoring the tetrachloroethane (perchloroethylene) content of the air, e.g. in dry cleaning plants.

It is based on the principle that a copper halide is formed from copper and tetrachloroethane in the heated arc of an electrode system. The spectral intensity of the resultant copper halide is measured by photoelectric means via an ammeter connected in the circuit. This provides a direct reading of the tetrachloroethane content in the workplace air environment in ppm. With this instrument, therefore, the air can be tested quickly allowing appropriate corrections to be made to the working conditions.

Hamadan carpets Especially hardwearing rustic → Knotted carpets from the region around Hamadan which rises above the Iranian tableland at some 2000 m above sea level. Hamadan and the villages of the province are the most important centres of carpet production in Iran. In the main, they have a typical brown natural colour from the wool and camel hair used in their production. Hamadan carpets are, on the whole, rather mundane as far as decoration and weave are concerned. The materials, by contrast, are of a very good quality. Approx. 250 000 Turkish knots per m^2.

Hammer blow A description usually applied to a silk fabric with a hammer blow appearance produced from warps with flat yarns and an irregular crêpe weave with alternating S and Z twist yarns, widely separated from each other (4–6 threads), in the weft. During subsequent washing and dyeing, the individual groups of weft yarns form blister-like areas on different sides of the fabric to achieve the desired effect.

Hammer blow effect A defect which occurs in various types of textile fabrics, e.g.:

I. A generally structure-related unlevelness of colour in cotton velvet, especially in the form of "lumps" caused by the presence of a large proportion of motes (these can be detected under the microscope as hard fibre tufts adhering to seed husk residues) which disrupt the pile uniformity.

II. A "hammered" surface appearance in crêpe fabrics produced from man-made filament yarns by the change of direction of highly-twisted yarns as well as changes between flat and crêpe yarns.

III. A moiré appearance in plain weave wool fabrics after crabbing.

Hammer clips → Clips.

Hand block printing The cloth to be printed is attached to the resilient surface of a strong and relatively short table (approx. 8 m long). The actual printing operation is carried out with → Hand printing Blocks on which the design is formed in relief. The printer presses the block on to the surface of a print paste contained in a vessel known as a "swimming tub" or "sieve" in two opposite directions to ensure an even coating of colour paste on the block. When the block is correctly positioned on the cloth, it is struck with the fist or a printer's mallet in order to transfer the print paste from the block to the cloth. This process is then continued as necessary by repositioning the printing block on the cloth each time in accordance with the design repeat.

Handcoater A simple and effective system for the manual production of colour strike-offs on paper (or textile material) with the aid of short stainless steel rods. The quantity of colour paste applied is determined by the circumferential grooves in the rod surface which range from fine to coarse.

Hand creasing test By means of the so-called fist method the fabric to be tested is crumpled, wrinkled, pressed or folded for a few seconds in the tightlyclenched fist and assessed, after opening the fist, whether the fabric recovers immediately from its creased state, or only after some time by hanging or lying, or whether the creases can only be removed after smoothing out or ironing.

Hand flocking device A flocking device for small articles which consists of a spherical sieve to hold the flocks and an electrostatic field to achieve flock alignment immediately prior to their application on the substrate surface. The device is operated manually. → Flocking, flocking coating.

Hand ironing test (→ Ironing test procedures). A simple procedure to determine the shrinkage resistance of outer fabrics and wool-containing fabrics (ready for making-up). Procedure: the fabric to be tested of 1 m measuring length is placed on an ironing felt and the entire test area covered with a prewetted (150%) cotton cloth. This is then ironed with a conventional iron (without sliding or shifting, only by lifting and repositioning etc.). The ironing temperature for outer fabrics and wool-containing fabrics is approx. 250°C (contact time 15–20 s); and 150°C for fabrics containing acetate or polyamide. Shrinkage measurements are taken after the fabric has cooled down directly on the smooth underlay in % from the measuring length.

Handkerchief printing machine (flat press machine). A semi-mechanical machine for the 4-colour printing of headscarves on a horizontal printing table (the size of the headscarf) which turns around its own axis with a colour box that can be raised and lowered containing two felts to which different colours are applied diagonally.

Hand-knotted carpets Carpets produced by the manual knotting of pile yarn tufts in a warp yarn substrate. → Knotted carpets.

Handle The handle of a textile fabric is determined by numerous different parameters. In commission finishing, the finisher is usually presented with a sample of finished fabric by the customer, in addition to a colour sample, which he is required to match in bulk production. Comparisons between the sample and the production batch are, however, subjective. It is for this reason that efforts have been made to find precise methods for the measurement of handle, e.g. →: Nozzle-test; Handle-Ometer, drape test. In Japan, attempts have been made to evaluate the handle of a textile fabric by measuring 15 mechanical and physical properties. →: Kawabata system of handle assessment; FAST system of fabric assessment.

Handle modifiers (hand modifiers). Descriptive term for a group of textile auxiliaries the primary function of which is to modify the handle of textile fabrics. They represent a sub-group of textile finishing agents. → Handle-modifying finishes.

Handle-modifying finishes Finishes applied to textile fabrics after bleaching, dyeing or printing for the purpose of achieving a particular handle which differs according to end-use. The following subjective descriptions are in common usage: full handle, wool-like handle, silky handle, soft handle, hard handle, stiff handle, fleshy handle, firm handle, scroopy handle, etc.

Filling finishes, which involve the application of cheap substances to increase the weight of a textile fabric (→ Weighting), may also be included in this category.

Handle of textile fabrics → Fabric handle.

Handle-Ometer An American instrument for evaluating the handle of textile fabrics including the determination of flexibility, compressibility, extensibility, elastic resilience, density, surface friction and thermal properties. The test procedure involves placing the textile material over a 6.35 mm wide slit where a rotating load arm brings pressure to bear on the sample in the slit. A load-measuring device determines the various resistance values of the fabric sample, the sum of which can be read off an electrical display.

Handling of hazardous substances A number of auxiliaries, dyes and chemicals used in textile wet processing are so-called hazardous substances. The handling of such hazardous substances in the textile finishing industry is a normal everyday activity. It is, however, not free of risk. The majority of hazardous substances used in textile finishing include, e.g. chemicals and auxiliaries with carcinogenic, toxic, corrosive or skin-irritant properties, or those which are combustible or present a risk of explosion. The German Ordinance on the Handling of Hazardous Substances (Gefahrstoffverordnung) sets out the statutory relationship in § 15 to § 18 between man and chemicals (= hazardous substances). This requires the proper handling of chemicals, the accurate labelling of hazardous substances, the precise instruction of employees on handling hazardous substances, and further requires that management are responsible for inspection and the provision of employee welfare. → Legislation on environmental protection.

The handling of hazardous substances is laid down in the “Technical Regulations on Hazardous Substances” (TRGS). These technical regulations are revised annually. In handling formaldehyde-releasing finishing agents, for example, a maximum workplace concentration (MAK-Wert = 0.5 ppm) has been laid down. Since the introduction of low-formaldehyde finishing, this value is hardly ever exceeded. In the TRGS 900, azo dyestuffs which contain amino components derived from benzidine are described as “substances suspected of having a carcinogenic potential”.

Data on substances necessary for work safety may be extracted from the Safety Data Sheet which contains a classification of the hazardous substance in the form of advice on particular hazards (R-sentences) together with symbols in concise form. The purpose of this information is intended to provide users of hazardous substances and preparations with advice on measures necessary to ensure health protection and safety at the workplace. The Safety Data Sheet must also contain, among other things, instructions on first-aid and fire-fighting measures, as well as particulars concerning toxicology, ecology and disposal. It is for this reason, that a Safety Data Sheet containing pertinent, correct and complete information on each chemical auxiliary used in the finishing plant must be readily available.

The nature and scope of the particulars required is given first of all by the specific working practices in the dye and chemical kitchen. Those employees engaged in the handling of hazardous substances must be instructed on the risks involved as well as the protective measures required by means of operating directives. Recommendations for drawing up such operating directives, and suggested instructional procedures, are given in TRGS 555. In order to avoid intimidation of employees engaged in handling hazardous substances, verbal instruction is to be recommended just as much as the instructions to be gained from reading a clearly produced operational directive limited to the essential points (Marzinkowski).

Handling time factor An individual element in the → Processing sequence for the time in which material is transported, processed or stored. The material handling time is subdivided into forming time (operation time, production time) and idle time (storage time as well as the idle time dependent on work flow, disruptions and labour factors).

Hand printing Blocks (printing blocks). For hand block printing the blocks are cut from wood which are then infilled with felt and, where necessary, copper strip and pins (depending on the intricacy of the design) are also incorporated. Fairly hard woods are used for all printing blocks, e.g. ash, box, lime, sycamore, holly and particularly pearwood. To facilitate registration in hand block printing, brass pins are driven in at the corners of the block to indicate the position of the next repeat (→ Block cutting).

Hand screen printing Textile printing carried out with flat screens on long tables up to 100 m in length. The process is mainly limited to the production of high-quality prints today as it is more labour-intensive and less productive than screen printing by machine. → Screen printing table.

Hand-sewing machines Used in wet processing departments for joining loose piece ends, e.g. after taking fabric quality control samples at various stages of processing, joining successive batches of fabric at processing machines etc. The majority of these machines produce a seam joined by the chain stitch.

Hanging black → Aniline black.

Hanging of velours carpets The hanging of velvet carpets and other pressure-sensitive fabrics in festoon accumulators (see Fig.) to achieve relaxation of the grey goods and prevent → Shading.

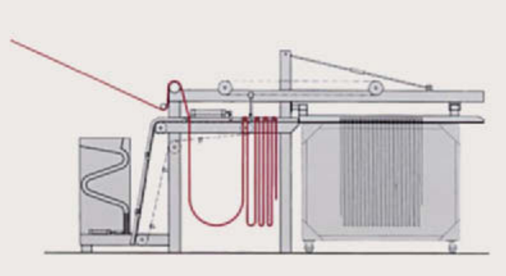

Fig.: Festoon accumulator for the relaxation of pressure-sensitive fabrics (Menschner).

Hank,

I. An unsupported assembly of yarn in coiled form (yarn hank, skein). The so-called round hank consists of 7 or 10 → Skeins for cotton and viscose (English counts: 1 hank = 7 skeins of 109.728 m = 768.096 m length of yarn. Metric counts: 1 hank = 10 skeins = 1000 m). The reeled hank yarn, which is bound with tie threads to hold the hank together, contains yarns which lie side by side (flat hank) or cross over each other to a large extent (cross yarn hank).

II. The so-called long hank composed of numerous 5000–20 000 m long (warp) threads. This form is convenient for wet processing in bleaching or dyeing and may be (a) wound into a ball (ball warping), (b) machine-wound on to a roller into a cross-ball cheese or (c) shortened into a link chain (chain warping).

Hank drying After dyeing, hanks are normally dried before further processing. The first stage, especially with natural fibres, is by centrifuging (hydro-extraction) in which the hanks of yarn are contained in a basket and subjected to high gravitational forces. Depending on whether high or low-speed centrifuges are used and the type of yarn (synthetic or natural fibres), centrifuging reduces the moisture content to levels of 4–35%.

Hanks of yarn based on natural fibres require further drying in hot air to reduce the moisture content to an acceptable degree. This is achieved either discontinuously by suspending the hanks on horizontal poles in a thermal chamber with hot air circulation, or continuously in modern thermal driers (hot air circulation) by suspending the hanks on rotating poles supported at either end on endless transport chains. → Festoon drier with rotating guide rollers. An alternative to this type of machine is a thermal drier based on the suction drum principle. In this case, hanks are processed individually on a belt feed. → Suction-drum drier. Radio-frequency drying (RF-driers) can also be employed for hank drying.

Hank dyeing machines The dyeing of yarn in hank form is the oldest method of yarn dyeing. Traditional rectangular-type machines (Fig. 1) in which the

Hank dyeing machines

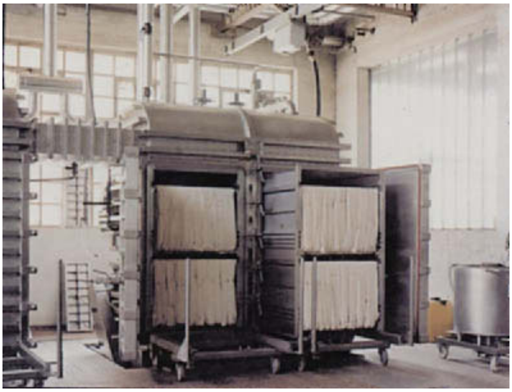

Fig. 1: *Minox hank dyeing cabinet.*

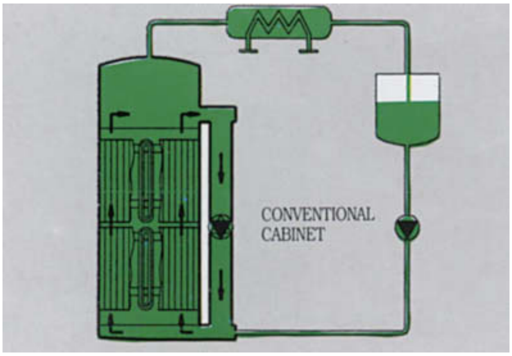

Fig. 3: Typical structure of a cabinet dyeing machine for hanks.

dye liquor is heated by open or closed-coil steam pipes, and the liquor is circulated over a weir and through the yarn by means of a reversible impeller mounted at one side of the machine, are still widely used for the dyeing of carpet yarns (hanks up to 5 kg and machine capacity up to 4000 kg).

More recently, vertical cylindrical dyeing machines (with or without pressure) in which the hanks of yarn are contained in special cages, represent alternatives to the rectangular-type machines (Fig. 2).

In Western Europe (with the exception of Italy), the dyeing of yarn in hank form has declined markedly (due to the labour-intensive handling involved) in favour of package dyeing. However, too little consideration has been given here to the experience of the knitter that hank-dyed yarn is more voluminous (has better bulk) than package-dyed yarn. The Italian machinery and textile industry have followed a different route, whereby the widely used rectangular-type machines, with relatively high liquor ratios and labour-intensive handling in hydro-extraction and drying, have been improved and extensively automated (Fig. 3):

- The hank carriers, in the form of transportable frames, are loaded externally.
- Due to the compact construction (low pressure up to 108°C with an air blanket) the liquor ratio has been reduced to between 15 : 1 and 18 : 1.
- Up to four machines can be coupled together in tandem.
- Fully-automated systems for hydro-extraction, drying and unloading, even up to the automated packaging of hanks in heat-sealed plastic bags, may be integrated into the hank dyeing operation.

In addition to rectangular-type and circular hank-dye-

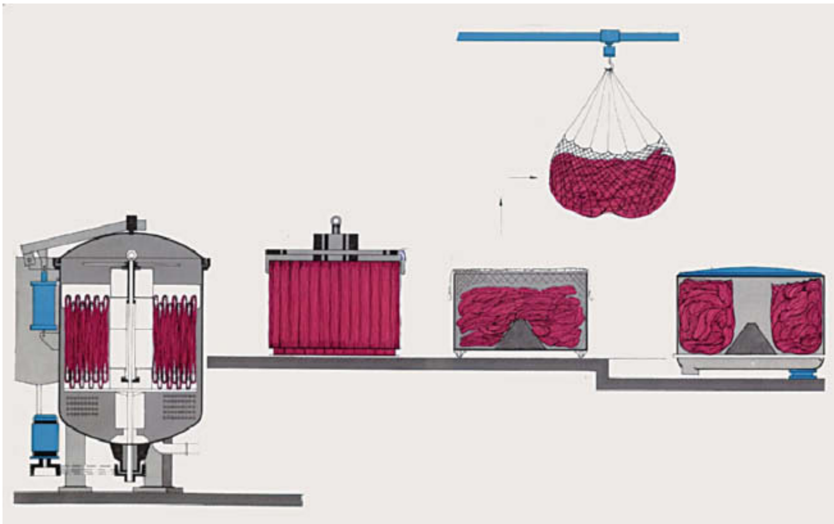

Fig. 2: Krantz dyeing machine with hank yarn material application plus centrifuge water extraction of the dyed yarn hanks.

Fig. 4: Mezzera spray dyeing machine for six yarn hank rows.

ing machines, the spray-dyeing principle has also been employed (→ Spray dyeing machine) in which hanks of yarn are suspended on slowly-rotating perforated pipes (Fig. 4) and flooded with dye liquor.

Hank loading Hanks of yarn for dyeing, drying, etc. are spread out and suspended on sticks or poles to ensure uniform treatment.

Hank mercerizing machines → Yarn mercerizing.

Hank, skein, reel The traditional unit of length for yarn in hank form. In metric notation, a hank (consisting of 70 turns, each of 1.428 m circumference) = $^{1}/_{10}$ of a standard hank = 100 m. For ply-yarns, different numbers of turns are used. In general, hanks are loosely fastened at various positions around the bundle of yarns with tie-bands to maintain the integrity of the hank and prevent tangling during processing. If the tie-bands are too tight, the yarn in these parts of the hank will resist the dye during dyeing thereby resulting in undyed places.

Hank spreading machine A machine used to stretch hanks of yarn intended, e.g. to be mercerized or treated in a stretched state.

Hank stretching Treatments applied to hanks of silk and mercerized cotton yarn to achieve increased lustre. The dry hanks are suspended between two rollers and the distance between the rollers is then increased by a controlled amount.

Hank tensioning An operation which involves tightening hanks of yarn on a trestle before suspending on poles prior to bleaching, dyeing, etc.

Hank test Test for fibre bundle strength. → Pressley-Index.

Hank yarn printing machine A machine used for flammé yarn printing on hanks made of wool, polyamide, staple fibre, cotton and silk. With the automatic Timmer hank yarn printing machine, printing is effected in four phases. In every phase, one quarter of the total circumference of the hanks is printed. Movement in longitudinal hank direction is automatic, so that the next quarter can be printed in the next phase. Movement in transverse direction and stopping are also automatic. This means that the hanks are passed four times through four pairs of rolls. These four pairs of rolls consist of four small rolls running through the colour troughs, and two counter-rolls. The print pattern depends on the colour combination and on the design engraved on the rolls. On account of the width of the rolls, which must be one quarter of the circumference of the hanks, and because of the longitudinal hank transport (which is also effected always by one quarter of the hank circumference) the machine is only suitable for a definite hank length (circumference).

Hansa-Mixer A mixer designed for the continuous foaming of latex coating compositions at a production rate of up to 6000 kg compound/h as fine foam containing 200 g/l. Foam density and metering are controlled automatically. The mixer is provided with a continuous-flow heat exchanger for cooling, heating, or maintaining the foam at a constant specified temperature, as well as a continuous-flow filter, etc. Manuf.: Hansawerke.

Hard boiler feed water → Boiler feed water.

Hard fibre matting Floor mats containing coconut or sisal fibres in warp and weft.

Hard fibres Leaf and fruit fibres of monocotyledonous plants (→ Vegetable fibres) obtained from the supporting tissue of large luxuriant leaves of tropical and sub-tropical plants. In contrast to the → Bast fibres (commonly described as “soft” fibres) hard fibres are much longer, i.e. between 110–250 mm long as technical fibres (only 1.5–4.4 mm long as elementary fibres), coarser and stiffer. Hard fibres are produced by treating the leaves in machines which scrape the pulpy material from the fibres, followed by washing and drying; retting is not necessary. The hard fibres include: →: Sisal; Henequen; Manila fibre; Abaca; Fique fibre; Phormium fibre; New Zealand flax; Alfa grass; Esparto. Hard fibres are used mainly for cordage, mats and rugs.

Hard lead An alloy of lead with 5–25% antimony. In contrast to pure lead, it is suitable for vessels used in peroxide bleaching.

Hardness of water →: Water hardness; Water softening; Water hardness salts.

Hardness ranges of water In accordance with the German Detergent Law, public water supply companies are required to suitably advise their consumers of the hardness range applicable to the drinking water supplied by them. Inscriptions on the packaging (in-

hardness range	German degree of hardness	mval total hardness/l
1	7	up to 1,3
2	7-14	1,3 - 2,5
3	14-21	2,5 - 3,8
4	over 21	over 3,8

Tab.: Hardness range of water.

cluding papers accompanying loose products) of washing agents and detergents must contain graduated dosing instructions for the respective water hardness ranges 1–4 (see Table).

Hardness scale (Mohs' scale of hardness). A scale introduced by Mohs to characterize the hardness of minerals, metals, etc., which is still in widespread use. This hardness scale provides only an approximate indication of the comparative hardness of materials but is nevertheless simple to apply. The 1–10 scale begins with the softest mineral talc (1) and ends with the hardest mineral diamond (10). Between these extremes are gypsum (2), calcite (3), fluorite (4), apatite (5), feldspar (6), quartz (7), topaz (8), and corundum (9). Thus corundum will scratch or abrade quartz but not vice versa. True hardness comparisons are, however, better indicated by a progressive numerical series (Rosiwal's attrition process) in which e.g. diamond is shown to be 140 times harder than corundum.

Hard rubber (ebonite). A hard form of → Rubber in which the latex molecules have been crosslinked with 30–35% sulphur by curing at 100–150°C. Lime or magnesia is used as activator. Properties: black, hard, brittle mass which on heating becomes sufficiently plastic to be moulded into shapes. Hard rubber is resistant to water, chlorine, alkalis, most acids, gasoline, oils and alcohols. Uses: tank linings, pipes, handles, cocks and valves, etc.

Hard segments The segments of polyurethane groups in elastane structures.

Hard soap (household soap). A → Soap with an approx. 60–70% fatty acid content used for domestic washing and cleaning, etc.

Hard stoneware Stoneware with particularly high mechanical strength and breakproof properties. Its resistance to corrosion is roughly equal to that of hard porcelain.

Hardware A general term for all the mechanical, electrical, electronic and magnetic components of a computer or electronic data processing system including peripherals. Hardware represents the physical part of a computer system which is supplemented by the → Software (programs).

Hard water →: Water hardness; Water softening.

Hare and rabbit fibres Apart from → Angora rabbit hair, these are more or less short hairs. Depending on the breed, hare and rabbit fibres are very variable. Preference is given to natural colours. In most cases the entire hair (excluding the cuticle) is pigmented (if red-brown often only the cortex, if brown also the medulla). Hare and rabbit fibres may be distinguished particularly by their respective felting and milling properties (see Table). Uses: very largely used for making felts, hatmaking, knitted goods such as cardigans, ladies' dresses, gloves and berets, usually blended with other fibres.

Harmful pollutants May be defined as all those substances introduced into an ecosystem which either harm the ecosystem itself or its value for living organisms to a measurable extent.

1. Harmful pollutants, in the ecotoxicological sense, are substances causing undesirable changes in affected systems which markedly exceed the usual ranges of population conditions.
2. Harmful pollutants, in the sense of emissions from the air pollution point of view, are substances which occur in higher concentrations at local, regional or global levels, and which can result in an acute indirect or direct impairment of the biosphere.

For many harmful pollutants the extent of harm is a concentration problem. In ÖTN 100 the term "harmful pollutant" is defined as follows: "In the sense of this directive, harmful pollutants are substances contained to a specified extent in a textile product or which, in normal expected usage, are formed to a specified extent, and have some kind of effect on the human population which, in the present state of knowledge, may be harmful to human health." The limitation that a substance is only regarded as a harmful pollutant if, in normal expected usage, it has some kind of effect on humans, excludes those substances which are chemically bound to a textile in such a way that they can neither migrate through the air we breathe nor through the action of water, perspiration (in clothing), saliva (chil-

	cystine content	swelling %	water solubility %	density	alkali solubility %	HCl absorption mval/g of hair
hare hairs	14—15.0	54—56	4—4	1.28—29	10.0—12,0	0.72—73
wild rabbit	11.5—12.0	58—62	4—5	1.25—26	12.5—14.0	0.75—76
tame rabbit	11.5—12.5	60—70	5—7	1.29—30	12.5—13.5	0.76—78

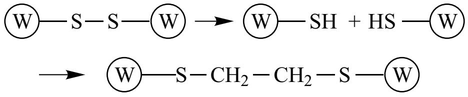
Tab.: Hare and rabbit hair parameters.

PROCESS	HARMFUL POLLUTANTS
grey fabric heat setting	fibre spin finishes, oils and their products of oxidation etc.
dyeing (incl. drying and heat setting; also thermosol)	carriers, auxiliary agents with affinity for fibres, levelling agents, emulsifiers, anti-foaming agents, organic acids etc.
steaming	acids, sulphides, sulphites
coating	solvents
textile printing	urea, very volatile additives
finishing (chemical finishing, soil release, flame-retarding finish etc.)	formaldehyde, acids, softeners, wetting agents, fluorocarbon compounds, phosphorus compounds etc.

Tab.: Harmful pollutant compounds in the textile processing industry.

dren's clothing) and skin contact. The limitation "in normal expected usage" is also very significant. This certainly excludes burning and the resultant formation of such combustion gases as CO and CO_2 (as occurs with all organic materials). The listing of those substances regarded as harmful pollutants (see Table) is given in product-specific standards (e.g. Ecotex). Such standards also specify the limit concentration above which a substance is regarded as a harmful pollutant within the scope of that particular standard. The standards also specify the test methods to be followed for the determination of harmful pollutants, or their emissions in air, in aqueous extracts, etc. These tests are selectively designed for the specific pollutants laid down in the standards (contributed by Herzog).

Harris stripping process A process for the regeneration of wool wastes which involves cleavage of the unstable disulphide bonds as a first stage, followed by the reformation of stable bonds with the introduction of methyl groups:



The wool keratin becomes more resistant to alkalies, oxidizing and reducing agents as a result of this chemical conversion. The process is first carried out at temperatures above 80°C and pH 7.5–9 with e.g. sodium dithionite and the addition of an emulsion of ethylene dibromide whereupon an intensive abstraction with sulphoxylates etc. takes place.

Harris tweed A woollen fabric formerly spun, woven and finished by hand (→ Homespun) in the Outer Hebrides of Scotland; the fabric is still hand-woven even today on the islands of Lewis, Harris, Uist and Barra. Harris tweed is made with carded yarns produced from pure Scottish virgin wool in twill or plain weave with a loose construction. There are two types: (1) fabric woven from handspun yarn and (2) fabric woven from machine-woven yarn. Harris tweed fabrics are relatively coarse and strong. Coloristically, melanges or designs with small areas of colour predominate. Finish characteristics: a light melton finish often with bristly effects. The fabric is used for sports jackets, suitings and coats.

Harsh wool Rough, hard, brittle wool of poor quality due to damp storage conditions usually accompanied by bacterial damage.

Hartshorn → Ammonium carbonate.

Hartshorn salt → Ammonium carbonate.

Hat blocking Used for shaping or stretching hats which, e.g. have been dry cleaned. As a rule, they consist of electrically heated cast aluminium moulds with a hand regulated stretching scale.

Hat body During the course of (wool and fur) felt hat manufacture, the following important forms of hat material are produced successively (see Fig.):

1. The body in the first stage of felting, which is roughly hat-shaped in the form of a hollow cone, and consists of fibres or hairs which are still only loosely bonded together, but which become mutually interlocked and further consolidated during premilling to give
2. a half-milled hat body which is about half the size of the body in 1 above. On continuation of milling until felting is complete, the next smallest form of the compact felt is obtained, i.e.
3. a fully-milled hat body consisting of a felt cone whose surface area has been reduced to approx. $^1/_8$ the size of the original form by milling and from which the desired final shape of the felt hat is achieved after further shaping steps (stiffening, stretching, decatizing, pressing).

In the hat body factory, preformed bodies for women's hats with a broad crown are known as cornet bodies. Hat bodies similar to men's hats with crown and brim are known as capeline bodies. If the latter have a raised fish skin and a horizontally aligned pile they are described as soleil bodies. Soleil is a lustrous fur felt with a shorter nap than velour.

Hatching Fine parallel lines resp. grooves on pad rollers or printing rollers (roller printing) set at an oblique angle to the direction of the running fabric which determine the depth of the engraved areas of the design. Their function is to hold the print paste, especially in large motifs, by preventing it from being scraped out of the engravings due to the action of the doctor

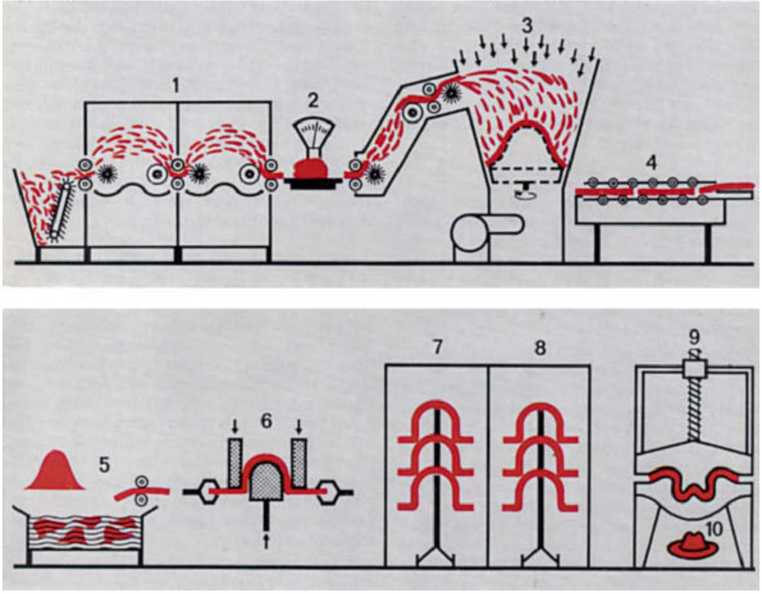


Fig: Schematic representation of hat production by the felt-bonding process.
1 = blowing machine (4–8 boxes); 2 = weighing scale; 3 = hat-forming machine with a whirling perforated cone and vacuum; 4 = multi-roller (milling); 5 = dip impregnation; 6 = pre-shaping with steam; 7 = drying (60–70 °C); 8 = curing (130–150 °C); 9 = after-pressing (80–120 °C); 10 = untrimmed hat (source: Bayer).

blade during printing, thereby ensuring a uniform print.

Hatching screen A screen with engraved hatching lines. It is used to engrave the hatched ruling lines into the printing roller and lies next to the design film. →: Engraving; Screen making.

Hatching tool A small engraving tool made of fine quality steel bar with a cutting point at one end which is driven by hand along the lines produced by the → Hatching screen on the printing roller.

Hat dyeing The high colour fastness of reactive and metal-complex dyes and fibre-protective dyeing methods in the isoelectric pH range, give the hat maker greater freedom in production technique. The hat maker can dye the material at any stage of manufacture and achieve good levelness. There are no problems of penetration and level dyeing with heavy fabric qualities in conventional dyeing machines. It is possible to dye loose fur qualities, half-milled hat bodies or $^3/4$ hat bodies without any risk of a noticeable decrease in the felting propensity of the material or change in shade.

Hat felt finishes – identification test → Finishing of hat felts.

Hat making form A loosely constructed cone of fur produced by drawing a specific quantity of blown fur on to a revolving perforated metal cone. The resulting form represents the first stage in hat manufacture.

Hat material Rabbit and hare fur, which has been mordanted by various means, used as raw material for the manufacture of fur hats (some are produced with different types of → Hair mordants). These materials differ from each other in shade and are chemically damaged to a greater or lesser extent; there are considerable differences in dye affinity.

HATRA, abbrev. for: Hosiery and Allied Trades Research Association (Nottingham, U.K.). → Technical and professional organizations.

Hazard classification of flammable solvents In Germany, the Verordnung über brennbare Flüssigkeiten, or VbF (Ordinance on Flammable Liquids) has classified organic liquids according to their flammability into 4 hazard classes. Distinguishing characteristics are the respective flash points as well as possible miscibility with water. The VbF regulates structural requirements for the storage of flammable liquids as well as the need for notification and licencing of plants where they are used:

Hazard Class A: Liquids with a flash point not above 100°C, which do not exhibit the properties of Hazard Class B with regard to water solubility.

Hazard Class A I: Liquids with flash points below +21°C (e.g. gasoline between –55°C and –25°C , ether –40°C, acetone –17°C, benzene –8°C, methanol +6°C, ethanol +11°C).

Hazard Class A II: Liquids with flash points between 21–55°C (kerosene, cleaning oils).

Hazard Class A III: Liquids with flash points between 55–100°C (diesel oils, heating oils).

Hazard Class B: Liquids with a flash point below +21°C which dissolve in water at 15°C in any ratio, or liquids containing flammable components which dissolve in water at 15°C in any ratio.

Hazardous substances act The hazardous substances act (Gefährstoffverordnung = GA) which came into force in the Federal Republic of Germany on 29.7.1980 includes various definitions of hazardous properties (→: Toxic substances; Legislation on environmental protection). In addition to the substances covered by the above definitions, a further category of so-called “particularly hazardous substances” has been introduced without any precisely defined criteria. The following data is based on the classification of the Deutsche Forschungsgemeinschaft (DFG) = German Research Council, and the Swiss Federal Health Ministry in Berne, as contained in the official Swiss Index of Toxic Substances (list 1):

1. Category IT = inhalation toxicity. Mean exposure limit < 4 ppm/h (e.g. phosgene, thionyl chloride).
2. Category Kw = probable human carcinogen (e.g. chloroform, dioxan, epichlorohydrin, trichloroethylene).
3. Category Ks = confirmed human carcinogen (e.g. benzene).
4. Category KT = carcinogenic in animal tests (e.g. hydrazine sulphate).

Hazen colour unit An American colour scale for determining the colour of chlorinated hydrocarbon solvents based on a platinum-cobalt stock solution designated as 500 Hazen units.

Hazen stock solution: 1.245 g potassium chloroplatinate + 1 g cobalt chloride ($CoCl_2 \cdot 6H_2O$) dissolved in 100 ml conc. hydrochloric acid and made up to 1000 ml with distilled water. Dilution of 1 : 100 with distilled water = 5 Hazen; 3 : 100 with distilled water = 15 Hazen. A chlorinated hydrocarbon control is contained in a small glass tube of the same diameter and filled to the same level with/without a comparative solution. The sample is viewed from above against a white background with the exclusion of side light.

HBL (Ger.), abbrev. for: Harnstoff-Bisulfit-Löslichkeit (→ Urea-Bisulphite solubility).

HB Yarn, abbrev. for: → High-bulk yarn.

HDPE, abbrev. for: high-density polyethylene.

HE, → Henequen fibre, → Standard abbrev. for textile fibres, according to DIN 60 001 T4/08.91.

He,

I. chemical symbol for helium (2).

II. → Henequen, → Standard abbrev. for textile fibres, according to DIN 60 001 until 1988, from 1991 → HE.

Heat absorbing dyes and dyeings → Infrared-absorbing dyeings.

Heat accumulator High performance thermal clothing made from, e.g. acrylic gel fibres containing microcapsules (see Fig.) which absorb and store heat then release it as required over a period of time due to their heat-accumulating properties.

Heat ageing → Ageing of textile materials.

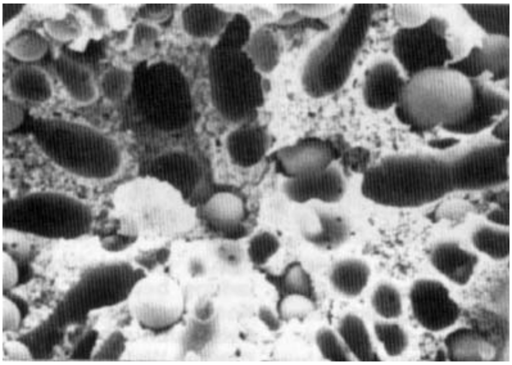

Fig.: Acrylic gel fibres with PCM microcapsules: magnification % 2000.

Heat and power generation The classic method which, in former times, was often used by many textile plants and may still be seen occasionally today, was based on the use of → Back-pressure steam turbine (Fig. 1). A high-pressure steam boiler generates superheated steam at 60 bar and, e.g. a temperature of 480°C. This steam is used to drive a steam turbine, the exhaust steam pipe from which is connected to the plant’s steam distribution line. Compared to a gas turbine, which gives a power output of 0.35–0.4 (kWh electric current/kg steam), a power output of only 0.15–0.2 kWh is achieved with a steam turbine process. This is one of the reasons for the decline of industrial heat and power plants equipped with steam turbines.

The schematic representation of heat and power generation from a gas turbine (Fig. 2) can be explained as follows: the gas turbine compressor sucks in air for combustion via a sound muffler and compresses it to, e.g. 12 bar. This air is then heated in the combustion chamber of the gas turbine to approx. 1000°C. Combustion takes place with a large excess of air (lambda from 3.5–5). The pressure of the hot gas drops to atmospheric pressure in the turbine and the mechanical energy of the turbine is supplied to the compressor. The

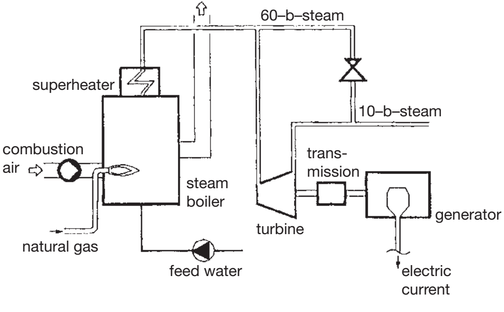

Fig. 1: Heat and power generation with a steam turbine

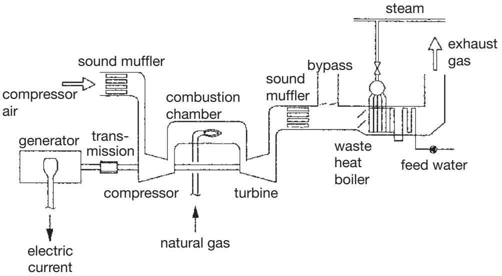

Fig. 2: Heat and power generation with a gas turbine.

power requirement for the compressor lies considerably below the power output of the turbine. Consequently, the resultant excess power is converted into electrical energy in the generator. The exhaust gases are cooled down from approx. 1000 to 500°C by the pressure drop in the turbine and the heat contained in the exhaust gases is then converted, for the most part, into steam in the downstream waste heat boiler. The high vapour pressure, e.g. 10 bar, means that the exhaust gases are not cooled down to a desirable operating point level, i.e. the water vapour dew point of the waste gases, but only to considerably higher temperatures, e.g. 170°C even if residual cooling takes place in a feed water preheater. It should therefore be possible to recover this residual heat by means of an additional downstream exhaust gas cooler for subsequent reuse in the textile plant or even in an external consumer's plant.

Heat balance (thermal energy balance). The word "balance" is derived from the Latin "bilanx", or scales, and means a comparison by weighing different factors or quantities against each other. A commercial balance sheet, in which assets are set against liabilities, enables us to assess the profitability of a company. In textile finishing, energy consumption is a critical yardstick for determining the operating costs and environmental impact of various processes. The energy balance of a process allows us to assess its cost-effectiveness, or that of the plant in which it is carried out. Such a balance compares the energy inputs used (assets) with the breakdown of their benefits for the process and the losses involved (liabilities).

We can now examine how this can be applied to two important finishing processes:

1. processes involving heat treatment, e.g. drying, and
2. the washing process.

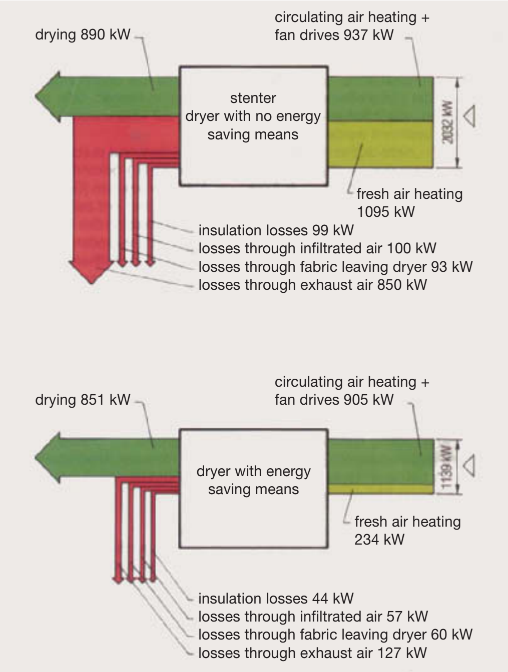

Fig. 1: Energy flow diagram of dryers with and without energy saving means (Babcock).

Fig. 1 shows two heat balances for the same drying task. In this particular process, a woven cotton fabric, 2 m in width, weighing 150 g/m^2, is dried from an initial moisture content of 80% to a residual moisture content of 8% at a production speed of 99 m/min. The upper diagram shows the performance of a conventional stenter as used everywhere and which is even found occasionally in new installations. From the 2032 kW input, only 890 kW, or 43%, is actually used to dry the

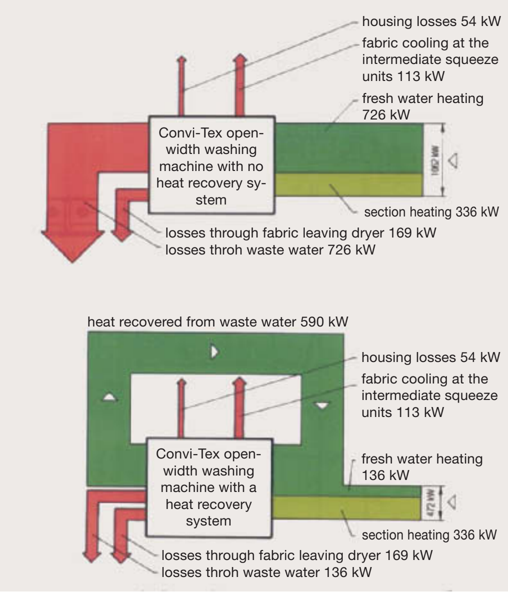

Fig. 2: Energy balances for washing processes with and without heat recovery (Babcock).

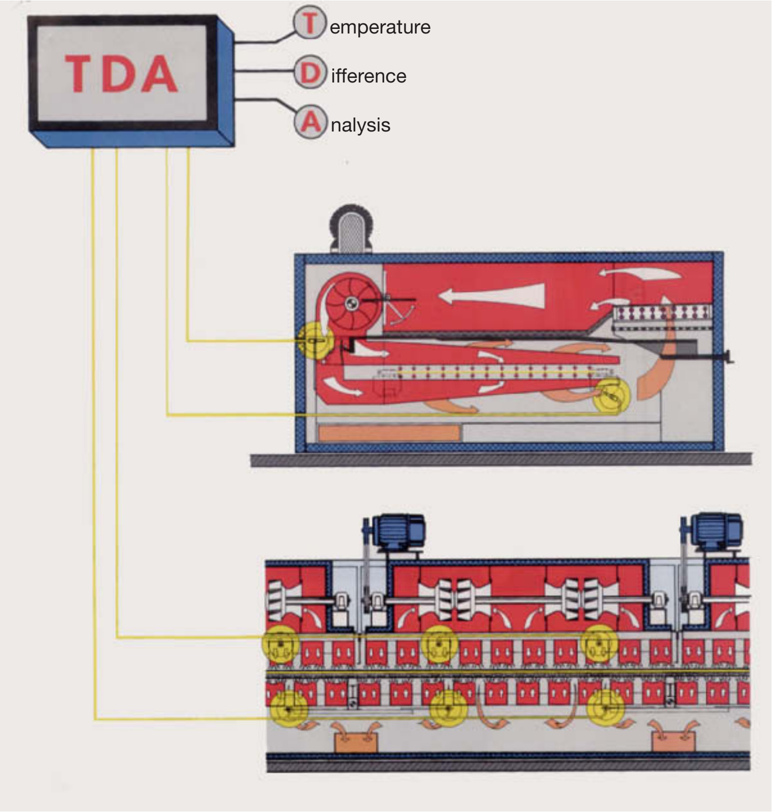

Fig. 3: Temperature difference analysis as a thermal balance of heated air and exhaust air containing water vapour (Krantz).

fabric. 57% is accounted for by various losses. A more modern, energy-saving process (lower diagram) uses only 1139 kW for the same task, and only 25% of this is lost. At a price of 0.04 DM/kWh for heat energy and 4000 hours annual production, the saving of 893 kW corresponds to a cost saving of DM 143 000 per annum. This fact, and the reduced environmental impact resulting from the lower energy consumption, cannot be ignored.

Even in continuous washing processes, a heat balance enables a better heat utilization to be achieved in the recovery of heat from the waste water. Fig. 2 demonstrates, with the aid of energy flow diagrams, the positive effects of a heat recovery system in a continuous washing range (Convi-Tex system of Babcock Textilmaschinen GmbH) for the same washing task. It assumes a closed heat exchanger system, with which an efficiency of approx. 80% can be achieved in practice.

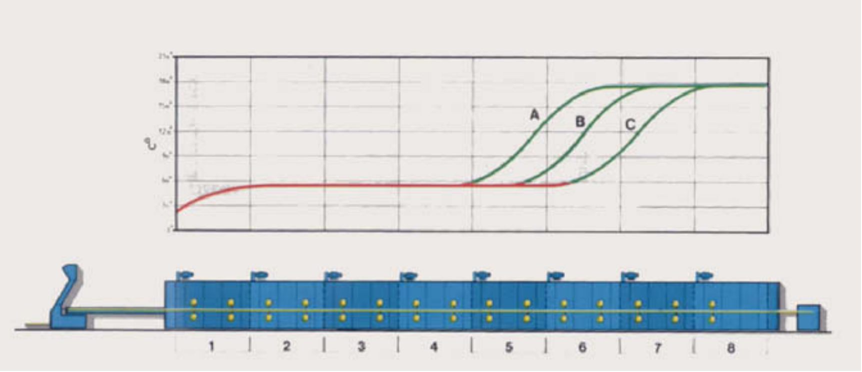

Fig. 4: Graph of fabric temperature during the drying (B + C) and heat setting (A) of mixture woven fabrics.

The energy balance shows that a washing range without heat recovery requires 1062 kW for the washing operation. As much as 726 kW of this, i.e. 68%, goes down the drain with the hot waste water.

The same washing range with a heat recovery system has an energy requirement of 472 kW which is only 45% of the previous requirement! Considering that a heat recovery system can pay for itself within approx. 6 months, it is remarkable that even today washing ranges are still operating in Europe without heat recovery systems. Both the energy balance and the payback period clearly demonstrate the need to fit heat recovery systems with a high degree of efficiency.

By comparing the temperature of circulating air in a stenter chamber as it leaves the blower with the temperature of exhaust air containing water vapour as it leaves the drying zone between the nozzle plates, with the aid of thermocouples (temperature difference analysis, see Fig. 3), the heat consumed in the drying process may be determined by calculation (with microprocessors). From the heat consumed, the surface temperature of the fabric may be deduced and a curve can be produced for the temperature of the fabric surface as it passes through all the stenter chambers (Fig. 4).

Heat balance diagram of a stenter drier → Exhaust air heat recovery.

Heat bonding of thermoplastics These are produced by the thermal bonding of thermoplastic materials, e.g. in the case of fabrics composed of polyvinyl chloride or polyethylene fibres by fusion at the thread crossover points. The welded seam can be so strong that it is not the seam itself that breaks down in a tensile test but the material adjacent to it. Various methods are employed in practice including, e.g. a) heat-impulse welding (an electrically-heated band, heated in short impulses, is pressed against the material being welded under pressure); b) hot wedge welding (the pieces of material to be welded are fed in direct contact over the upper and lower surfaces of an electrically heated wedge directly across the seam area then firmly bonded by passage through a pair of pressure rolls); c) hot air welding (a procedure involving a concentrated jet of hot air and a welding thread of the same material – this process is unsuitable for coated fabrics); d) high frequency welding (in this case, the maximum temperature develops in the centre of the welding zone within an alternating electrical field); e) ultrasonic fusing (fabrics are joined by focusing ultrasound waves to concentrate heat in the desired seam area).

Heat capacity,

I. Specific heat capacity (symbol c): the heat required to increase, or decrease, the temperature of 1 kg of a substance by 1°K (→ Specific heat). The word specific means per unit mass. Formerly, the specific heat capacity was derived from a mass of water = 1 kg at + 4°C and 1 bar = 1 litre.

The SI unit of specific heat capacity is given by:

$$\frac{\mathrm{J}}{\mathrm{kg} \cdot \mathrm{K}}$$

Conversion formula:

$$\frac{\mathrm{kcal}}{\mathrm{kg} \cdot \mathrm{K}} = 4\,186.8 \ \frac{\mathrm{J}}{\mathrm{kg} \cdot \mathrm{K}}$$

II. Combustion (heat potential, heat of combustion): the quantity of heat released by the complete combustion of a specific amount of textile material. Specific heat capacity: the heat energy released by the combustion of a specific quantity of textile material under specified conditions.

Heat conductivity (thermal conductivity, calorific conductibility, thermal conductivity coefficient), symbol λ, K or k.

I. General: the thermal conductivity of a substance is defined as the quantity of heat which will flow across unit surface area in unit time when the temperature difference across a unit thickness of the material is 1°K. The thermal conductivity of materials varies depending on the type of substance. It is particularly high in the case of metals which have good heat transport characteristics due to their molecular structure. For gases, on the other hand, it is particularly low since relatively few molecules are available for energy transport per unit volume. Textiles fall between these two extremes but also vary because of their different structures.

This parameter was formerly measured in SI units of thermal conductivity:

$$\frac{\mathrm{W}}{\mathrm{m} \cdot \mathrm{K}}$$

Conversion formulae:

$$\frac{\mathrm{W}}{\mathrm{m} \cdot \mathrm{K}} = 0.860 \ \frac{\mathrm{kcal}}{\mathrm{m} \cdot \mathrm{h} \cdot \mathrm{K}}$$

$$\frac{\mathrm{kcal}}{\mathrm{m} \cdot \mathrm{h} \cdot \mathrm{K}} = 1.163 \ \frac{\mathrm{W}}{\mathrm{m} \cdot \mathrm{K}}$$

II. Specific thermal conductivity of fibres: polypropylene fibres have the lowest thermal conductivity of all textile fibres. Consequently, clothing containing this fibre has good heat insulating properties (thermal textiles, blankets). The relative thermal conductivities of some textile fibres are as follows:

– air	1.0
– polypropylene	6.0
– polyvinyl chloride	6.4
– wool	7.3
– acetate	8.6
– viscose	11.0
– cotton	17.5

Heat creases → Running creaser.

Heat dissipation → Radiation heat losses from dye liquors and dyeing machines.

Heat exchanger A heat exchanger may be defined as any device that transfers heat from one medium to another. Heat exchangers which utilize steam are designed to transfer heat energy from the steam to another medium through a heated surface which keeps them physically separated. For dyeing machines, heat exchangers can be installed either externally (Fig. 1) or within the dyeing vessel (Fig. 2). External heat exchangers are of two types, i.e. the shell-and-tube heat exchanger (Fig. 3) and the floating head, baffled shell space, shell-and-tube heat exchanger (Fig. 4).

To determine the external dimensions of heat exchangers for textile driers, the form of the heating surface itself, as well as the air flow, is important. In the case of fully-integrated systems, the dimensions of geometrically smaller units can represent a convincing argument for their use. Unavoidable maintenance costs (= dismantling of dirty equipment, separate units for chemical auxiliaries, heating of wash liquors, etc.) are significant disadvantages of the recuperator in addition to the time involved. For the regenerator, however, these costs are much lower (automatic running with fixed units). A daily follow-up cleaning period is also necessary so that the stenter can be operated without interruption on the following day. In addition to the various types of heat exchanger already mentioned, heat exchangers with so-called heat pipes are also of interest. Water/water heat exchangers (Fig. 5) are available for collecting the waste heat from effluents.

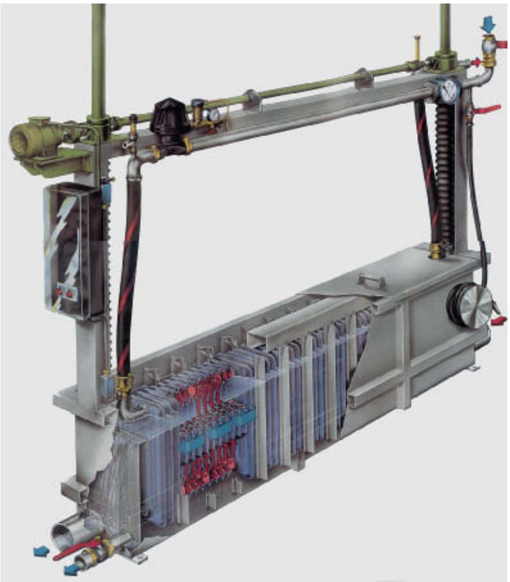

Fig. 5: Water/water heat exchanger (source: Brugmann).

Heat fixation → Heat setting.

Heat generation from primary energy Steam is used for heating purposes, as a source of motive power for machinery, and as a reaction and/or dissolving medium in many production processes. Depending on the particular application, the pressures, temperatures and quantities of steam required vary widely. For problem-free steam distribution, therefore, it is very important to install a correctly planned steam distribution system. A supply system for a steam using plant can therefore only be drawn up when the specific consumption requirements of all the various steam consumers are known. Steam consumers can be subdivided into three groups:

- direct steam consumers,
- steam consumers with indirect heating,
- steam turbines for electricity generation with subsequent steam condensation for the production of heat (increased efficiency).

1. Direct steam consumption: in such equipment the steam is in direct contact with the medium being heated. A typical example of such an application is the heating of water or aqueous solutions by means of perforated steam pipes. In general, it can be said that direct steam consumption involves the highest operating costs since the entire condensate (treated feed water) is lost. Such equipment has a high consumption of feed water which means high feed water preparation costs. There are some processes, however, where direct steam consumption is the most appropriate method since, e.g. the immersion of a heat exchanger unit in an autoclave

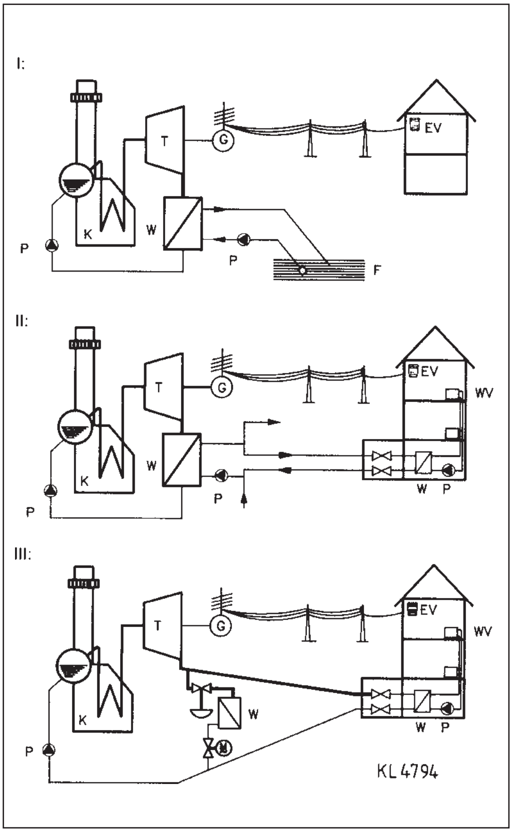

Fig. 1: I = basic power station for electricity generation, efficiency 33%; II = combined heat and power station for electricity generation and hot water distribution, efficiency 80%; III = combined heat and power station for electricity generation and steam distribution in a closed loop thermodynamic steam-condensate system with an efficiency of 80% (source: Baelz).
EV = electrical energy consumer; F = river; G = electricity generator; K = steam boiler with superheater; P = pump; T = turbine; W = heat exchanger.

would interfere with the function of the stirring mechanism. The low investment costs represent an additional advantage in view of the fact that no heat exchangers, steam traps, condensate return pumps and associated pipework are required.

2. Indirect steam consumption: this is the most customary method of using steam. In this case, steam is used to heat a series of pipes, heating banks, and double-jacketed vessels in order to transfer heat to, or evaporate, the medium on the other side. With indirect steam consumption, all the condensate is returned to the boiler house. The investment costs needed for containers, pumps, steam traps and pipework must be set in relation to the feed water preparation costs for direct steam consumers.

3. Steam consumption in steam turbines with subsequent condensation for heat generation: in general, power stations designed solely for the generation of electricity operate at an efficiency of only around 33%, whilst plants for combined heat and electric power generation achieve efficiencies of 80% and above. Three power plant concepts are illustrated in Fig. 1: a basic electricity power station, a combined heat and power station with hot water distribution, and a combined heat and power station with steam distribution.

When all the various steam consumers, with their required steam quantities, pressures and required temperatures have been determined, a steam distribution network (Fig. 2) can be planned. The various consum-

ers must be split into groups according to the required pressures and temperatures before the pipeline routing with the necessary desiccation stations can be established. The technology of the network has an important role to play here, and whether the network must remain operational around the clock or has to be shut down every evening and started up again the next day also needs to be known. In principle, it needs to be established whether the condensate lines can be installed for a 2-phase flow (steam and water) or water only. In Tables 1 and 2, some reference values and data on primary energy consumption according to steam usage have been given in order to provide a better understanding of the energy saving possibilities with modern steam technologies.

Steam is generated principally from primary energy sources. The high-pressure steam boilers for this purpose should be installed with a closed loop supply sys-

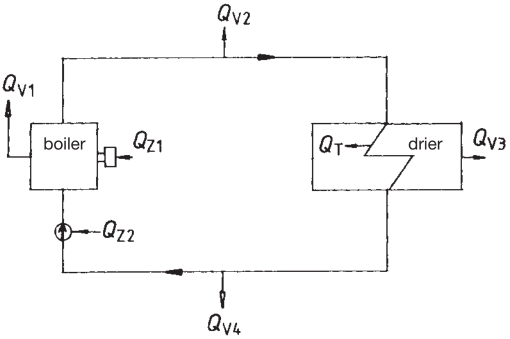
tem (Fig. 3). Such a system allows optimum energy recovery for boiler water conditioning and heating. Natural gas and light fuel oil (with dual fuel burners) are the optimum fuels for firing steam boilers. As with electricity, natural gas is supplied by the respective utilities under customer contracts which involve off-peak and peak time tariffs. For this reason, boilers should be fired with light fuel oil only during the periods of peak demand specified by the utility supply company, in order to avoid paying correspondingly higher tariffs for gas supplies during such periods. Depending on location, other fuels may, of course, prove more cost effective. The question of environmental protection must be included during all considerations and planning of energy generation and utilization. A complete steam supply system for a production plant consists of: water conditioning, fuel supply, high pressure steam boilers and burners, safety systems, containers, pumps and motors, pipelines and fittings, control and regulating systems. All such installations are subject to approval and licencing by the relevant factories inspectorate authorities (source: Baelz).

Heating efficiency The heating efficiency of a textile drier is the proportion of heating energy supplied to the machine during its production time in relation to the energy η_H fed into the heating system. Its definition and calculation may be represented by a schematic example of a steam and oil circulation heating system:



The heating efficiency is given by:

$$\eta_H = \frac{\Sigma Q_Z - \Sigma Q_V}{\Sigma Q_Z} = \frac{Q_T}{Q_Z}$$

$$= 1 - \frac{Q_{V1} + Q_{V2} + Q_{V3} + Q_{V4}}{Q_{Z1} + Q_{Z2}} \cdot \frac{Q_S}{Q_P}$$

where:
Q_P = energy consumption during production time,
Q_S = energy consumption during total time,
Q_T = energy consumption of the drier,
Q_Z = total energy supplied,
Q_V = energy loss.

Energy Q_{Z1} in the form of fuel, and energy Q_{Z2} used to drive the pumps, is fed into the heating system. The energy components Q_{V1}, Q_{V2}, etc. represent losses outside the system. The energy Q_T is supplied to the drier by the heating system. Energy losses are further influenced to a significant extent by the heating system during the heating up phase as well as during production stoppages. Under these conditions, the losses arising during production are further increased by a factor Q_S/Q_P. This factor is difficult to calculate but very easy to measure. Q_P is the energy supplied per unit product during continuous running production. In order to determine Q_S the energy consumption is measured over a relatively long period, e.g. one week, and divided by the quantity of product/s produced in that time.

Heating gas → Natural gas.

Heating rate Information on the following parameters is important for the customary heating up rate in dyeing processes for synthetic fibres and wool:

1. the start temperature T_{start},
2. the heating rate h,
3. the maximum temperature T_{max} ,
4. the necessary dyeing time t_{max} ,
5. if applicable, the exhaustion on cooling.

The maximum rate of absorption $\nu_{BE,max}$ for a dye in the exhaust process is virtually independent of the initial temperature T_{start} of the dyeing; on the other hand, $\nu_{BE,max}$ is proportional to the heating up rate and the activation energy E_D of diffusion:

$$\nu_{BE,max} = \text{const. } E_D \cdot h.$$

The question as to what % of available dye per min should be fixed by the rate of dyeing, i.e. the procedure for selecting the heating rate h [°C/min], is given by the formula:

$$h = \frac{\nu_{BE}}{r}$$

where r, as a constant of the activation energy, is proportional to the diffusion and indicates the % of available dye in the liquor that is absorbed per °C rise in temperature within the middle absorption range (between approx. 20–80% bath exhaustion). The value of r for different dye/fibre systems is as follows:

- 8% of av. dye/°C for acrylic fibres with cationic dyes,
- 4% of av. dye/°C for polyester fibres with disperse dyes,

– 2% of av. dye/°C for polyamide fibres or wool with acid dyes
(source: Hoffmann).

Heating surface A surface or partition (usually metal, glass or plastic) which physically separates a product being heated and the heating medium, e.g. as in a heat exchanger. By maximizing the area of contact under otherwise identical conditions, the greater the heating surface area, the greater the amount of heat transferred (→ Heat exchanger).

Heating-up energy Curves for heating-up textile material in dry air (drying) or in superheated steam (steaming) are different. The corresponding heat contents of textile materials to be treated may be represented by a J-X curve.

Heating-up of textile materials A specific heating-up time is necessary in order to bring a textile material to the required treatment temperature. During the drying of woven fabrics in stenters, the actual temperature (Fig. 1) approaches the target temperature asymptotically (e.g. the temperature of circulating air in heat-setting).

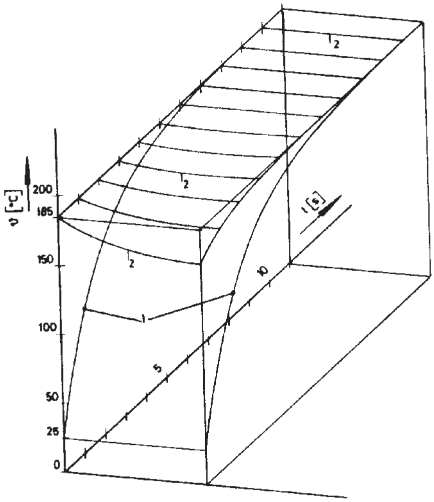


Fig. 1: Three-dimensional curve of air and fabric temperature during the heating-up of a textile fabric.

In this three-dimensional graph (Fig. 1) the abscissa represents the fabric width. The congruent curves 1 represent the heating-up of textile fabric. The group of curves 2 show the temperature curve of the hot air from the nozzles, i.e. before reaching the fabric (the incoming hot air temperature from the nozzles is constant at 185°C) and its cooling down after leaving the fabric. The fabric temperature is constant across the width. The temperature curve represented by the group of curves 2 indicates the change in temperature of the hot air before and after it has made contact with the fabric and must, under no circumstances, be related to the constant temperature curve across the width of the fabric. The t axis represents the time or, if multiplied by the fabric speed, the length of the stenter. Temperatures are in °C.

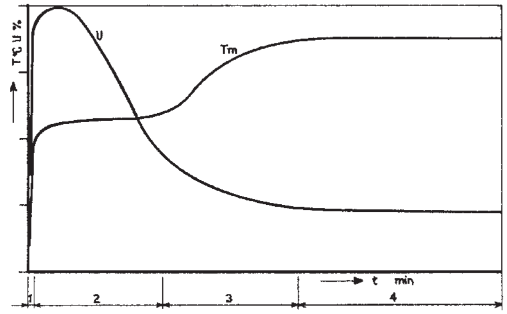

Fig. 2: Heating-up curve for a textile fabric in superheated steam.
t = time; T = temperature scale; Tm = temperature of fabric; U = moisture content of fabric.

During the steaming of a printed fabric, water vapour condenses at first on to the fabric as it heats up (Fig. 2) before the water evaporates again in the superheated steam later in the steaming process. Only then is the wet bulb temperature exceeded and the final temperature achieved on the fabric.

Heating-up time for exhaust dyeings To establish the bath exhaustion rate for an exhaust dyeing, the heating-up time (from start temperature to dyeing temperature) must be determined by the degree of levelness or unlevelness acceptable at the end of the heating-up phase, i.e. whether the levelling process is to

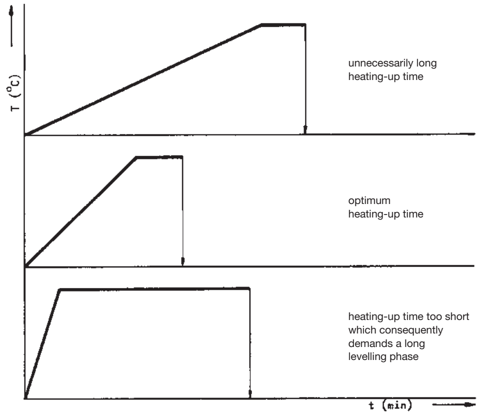

Fig. 1: Schematic representation of the minimum time required for a level dyeing, taking account of the heating-up and levelling phases.

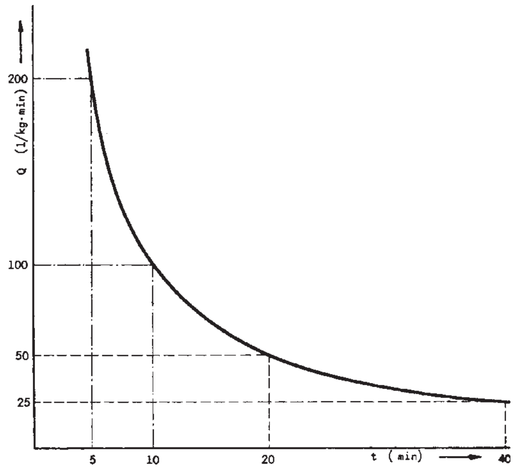

Fig. 2: Relationship between liquor throughput rate and the time required for the heating phase during the critical rate of dyeing.

take place at the dyeing temperature (Fig. 1). Normally, some degree of unlevelness at the end of the heating-up phase is acceptable in order not to prolong the heating-up time unnecessarily. A higher liquor throughput rate must be employed (Fig. 2) to save time in the critical temperature range.

Heating-up time for rapid dyeing systems The heating-up time is inversely proportional to the liquor circulation rate. Limits apply in practice, however, since textile material can be damaged at very high liquor circulation rates (e.g. package deformation), or the dye liquor may be insufficiently stable under such conditions.

Heat insulating materials Subdivided into three groups according to their structure, i.e. fibres, foams and filling materials. The actual heat insulating medium in these structures is air or, in the case of foams, the gas entrapped in the foam which was generated by a blowing agent during manufacture. Glass or mineral fibres, in particular, are used as effective components in various heat insulating materials. Natural fibres have seldom found application for heat insulation in the construction industry up to now.

Plastics such as polystyrene or polyurethane, as well as glass, are used as base materials for heat insulating foams. Glass foam is an ecologically sound product since the blowing agent, carbon dioxide, is formed by the oxidation of carbon monoxide during manufacture. The ecological safety of glass foam, as certified by the Association for Environmentally-Compatible Building Materials must, however, be qualified by the customary method of bonding foamed glass plates with bitumen during installation.

As filling materials, paper chips (cellulose granules) are the most widely used product and are blown into the cavities requiring insulation. Granulated cork may also be used. Cellulose granules are increasingly obtained from the recycling of waste paper. No reliable information on possible heavy metal contamination from the printing inks applied to paper is available up to now. As in the case of glass foams, other substances are added in the form of assistants to achieve specific characteristics during production (e.g. flame retardants), or to assist in making-up and installation.

Thermal conductivity λ, is an important parameter in the physical assessment of heat insulating materials. It provides a measure of the amount of energy transported away from the material per metre of insulating layer and per degree difference in temperature. The lower the value of λ, the better the heat insulation. A typical value for heat insulating materials is approx. 0.040 W/m°K (see Table) (source: Schenk).

Heat insulation (thermal insulation). To achieve a high degree of effective heat insulation, a garment must enclose as large a volume of static air as possible in order to create a microclimate. This means, however, that the size and number of garments worn in combination on the body must be optimally suited to each other. As illustrated schematically in Fig. 1 (left-hand side),

	fibres glass and mineral fibres	chemical foams	foamed glass	filling materials cellulose granules
hermal conductivity [W/m°K]	0.035–0.040	0.030–0.040	0.040–0.055	0.040–0.045
additives	3 % bakelite	0.5 %	not known	20 % boron salts
combustible	no	yes	no	yes
dioxin in combustion gases	no	yes	no	not known
health risk	carcinogen	suspected of evolving toxic gases	safe product, but bitumen used for installation	not known
handling	easy	easy	requires a specialist	applied by blowing
resources	unlimited	petroleum	unlimited	waste paper

Table: Classification and characteristics of heat insulating materials.

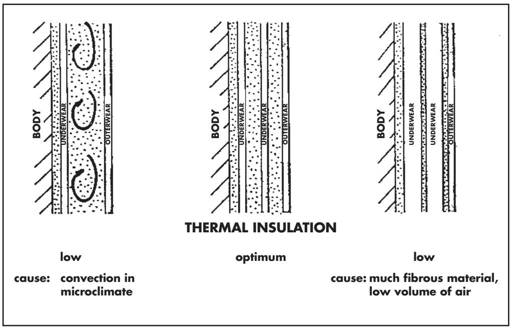

Fig. 1: Adaptation of outer and underwear to achieve optimum thermal insulation (source: Umbach).

an outer garment which does not fit closely in relation to the underwear leads to air convection in the microclimate which has the effect of reducing heat insulation. It would be false, however, to attempt to compensate for the loose fit of the outer garment by wearing a greater number of layers of thick under-garments. In effect, the resultant accumulation of fibre material would simply displace the heat-insulating air from the microclimate. By contrast, the optimum solution is to wear several items of underclothing (as in Fig. 1, centre), the thickness and size of which are adapted to the outerwear in such a way that as many small air voids are created as possible (but too narrow for convection, which reduces heat insulation). → Clothing physiology.

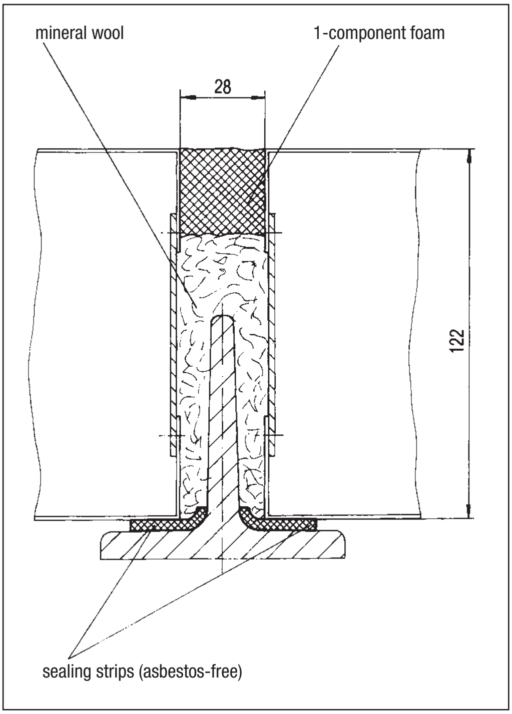

Fig. 2: Seal and insulation between framework and roof insulating plates on stenter.

Also in the case of machines consuming heat, e.g. stenters, good heat insulation from the surroundings is important in order to save energy (Fig. 2). Attempts to provide dyeing machines with heat insulation based on expanded foam materials have so far failed to bring any benefits.

Heat losses → Radiation heat losses from dye liquors and dyeing machines.

Heat-measuring papers → Thermometer papers.

Heat of a liquid The quantity of heat required to raise the temperature of 1 kg of a liquid from 0°C to the boiling point (expressed in J resp. kJ).

Heat of combustion → Heat capacity.

Heat of vaporization (heat of evaporation). The heat required in J/g to convert 1 g of a substance from the liquid to the gaseous state at the boiling point. The heat of vaporization for water is high, as is also that of alcohol because of the strong intermolecular forces (hydrogen bonds) in the liquid. By contrast, non-polar solvents have considerably lower heats of vaporization.

Heat pumps, reverse cycle heating systems A heat pump is a system for extracting heat from a fluid that is at a slightly higher temperature than its surroundings, i.e. it transfers heat from the low-temperature source to a high-temperature region by doing work on a working fluid which involves a reversible cyclic thermodynamic process. Compression heat pumps of this kind need mainly high-grade energy inputs such as electric current for electric motors or gas resp. oil for internal combustion engines to drive a reciprocating piston compressor. Possible primary energy sources include: ground water, water from rivers or lakes, soil, the atmosphere, waste heat in water and air. The heat pump (see Fig.) consists of a reciprocating piston compressor, a heat exchanger known as a condenser, an expansion valve and a second heat exchanger known as an evaporator.

The fluid, in vapour form, is compressed by the compressor so that its temperature rises. The vapour then passes through the condenser where it gives off heat to the heating medium (e.g. water for heating a finishing machine) and in doing so condenses to a liquid. This liquid, which is under high pressure, is then allowed to expand through an expansion valve. The evaporation of the fluid results in a considerable degree of cooling and, on passing into the evaporator it absorbs heat from the primary energy source, e.g. ground water, and becomes a vapour again before re-entering the pump. This cycle is repeated continuously. The efficiency of a heat pump is measured by the performance

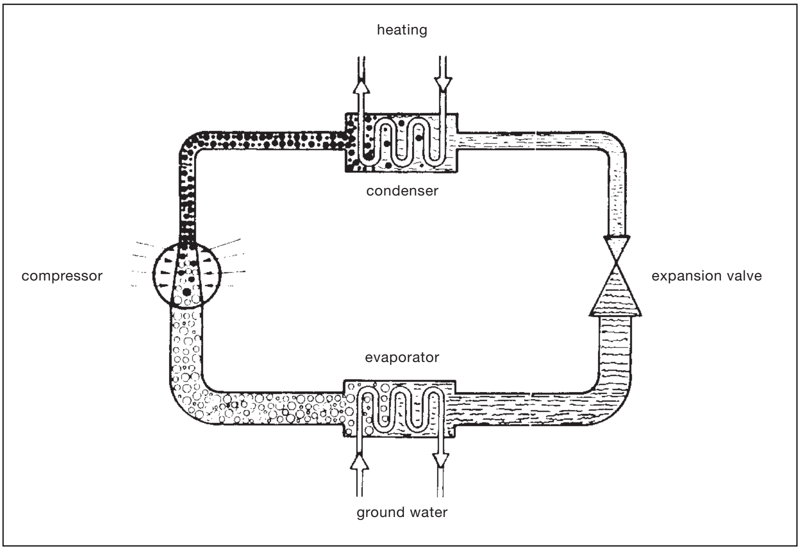

Fig.: Heat pump concept.

factor E. This gives the ratio of useful heat to the electrical energy consumed. Mean annual performance factors between 1.6 and 5 are usual. The theoretical maximum attainable performance factor is given by the Carnot cycle:

$$Ec = \frac{T_2}{T_2 - T_1}$$

where T_1 corresponds to the evaporation temperature (e.g. temperature of the ground water), and T_2 corresponds to the condensation temperature (flow temperature for heating). Performance factors which can be achieved in practice are approx. 0.5% the theoretical values. From the formula it can be seen that the smaller the value $T_2 - T_1$, the greater the value of Ec. The smaller the difference between the temperature of the heat source medium (e.g. ground water) and the flow temperature for heating, the higher the performance factor of the heat pump. The maximum temperature achievable with heat pumps is approx. 60°C. In the textile industry, heat pumps are particularly useful for utilizing the waste heat from effluents and exhaust air.

Heat recovery Hot exhaust air from driers or hot effluent from dyehouses can be used to preheat cold air or water. Heat exchangers based on this principle are designed to effect heat exchange between a) gas/gas, b) gas/liquid and c) liquid/liquid. The first requirement is the availability of a central hot water supply. The nature and scope of heat recovery depends on a variety of factors and therefore demands an in-depth evaluation of each individual case. In textile finishing plants, heat recovery from hot effluents and hot air from stenters, driers, hotflues, curing machines, etc. represent the most obvious opportunities.

Heat from hot effluents alone may be recovered from a variety of sources, e.g.: from wash liquors, from indirect cooling systems (e.g. dry cleaning machines and water-cooled compressors), from boiler desalination (reactor water) to maintain a specific conductivity of the boiler water, and finally from the waste water produced during boiler blow-down demineralization. The utilization of flue gases from boilers is only possible if the boilers are heated by natural gas. This source of heat from oil-fired boilers (light or heavy fuel oil), on the other hand, cannot be used because the Federal Emissions Protection Law in Germany (TA-Luft) does not allow a dewpoint below 185°C. Because of their heat content, exhaust air from textile driers can make a useful contribution to heat recovery (→ Exhaust air heat recovery).

If the above-mentioned heat sources are converted into kilowatt hour units and discharge temperatures of 32–35°C, as laid down in practically all communal regulations, are taken as a basis, the question arises as to how the recovered energy is to be reused in production processes through all seasons of the year if possible. A precondition for heat recovery is the availability of waste heat and a requirement for heat energy at the same time. Consequently, there is a necessity for a buffer which can store the waste heat and release it again as and when required. Since, however, there are considerable differences in the temperature ranges of various sources of waste heat, e.g. flue gas from 250–270°C, and water for indirect cooling from 40–45°C, the temperature gradients have to be taken into account. For

Heat recovery

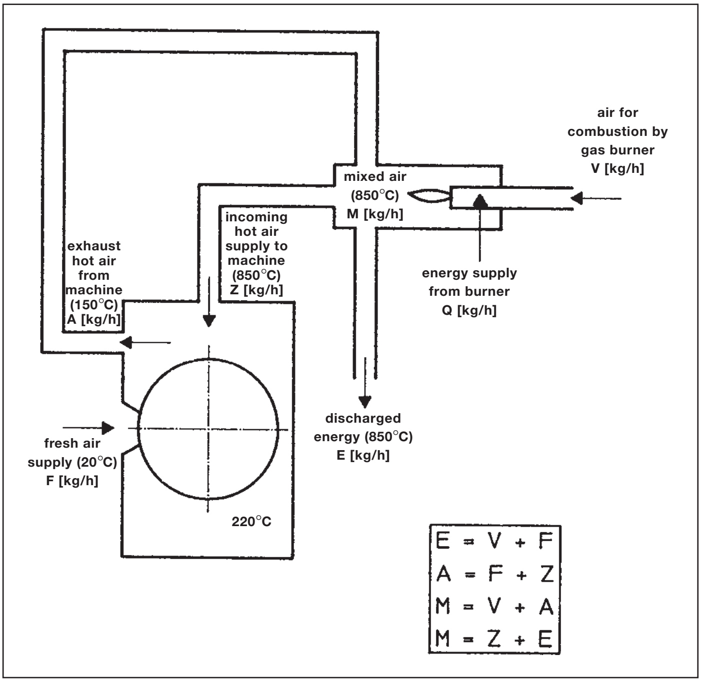

Fig. 1: Combined heat recovery and exhaust air cleaning system for a through-flow drier.

this reason, different buffer storage units are therefore required in practice.

Fig. 1 shows a typical heat recovery system in which different buffer storage units have been installed corresponding to the temperature gradients of the various sources of waste heat. In addition to these buffer storage units, circulation systems are provided in which water, circulating as a heat transport medium, is heated step by step and also cooled down again according to the temperature requirement.

In the heat recovery process, flue gas is cooled down in a flue gas heat exchanger (Fig. 2) from 130°C to approx. 35°C which means that the gas falls below its dewpoint at the same time. As a result, water present in the flue gas condenses in quantities of approx. 3 l min at a pH of 1.5–3 depending on the efficiency of the burner. This highly acidic flue gas condensate is collected and used for neutralization purposes. The flue stack, which is lined internally with stainless steel, is provided with a sump at the bottom to collect the flue gas condensate.

500 m of 40 mm diameter black PVC piping, as used for domestic water supply conduits, is contained in a typical waste water heat exchanger. This material, which is resistant to the alkalis, acids and oxidizing agents likely to be present in waste waters is, at the same time, resistant to temperature environments up to 50°C as well as pressures up to 5 bar. Although the temperature transfer is not as high as that achieved with,

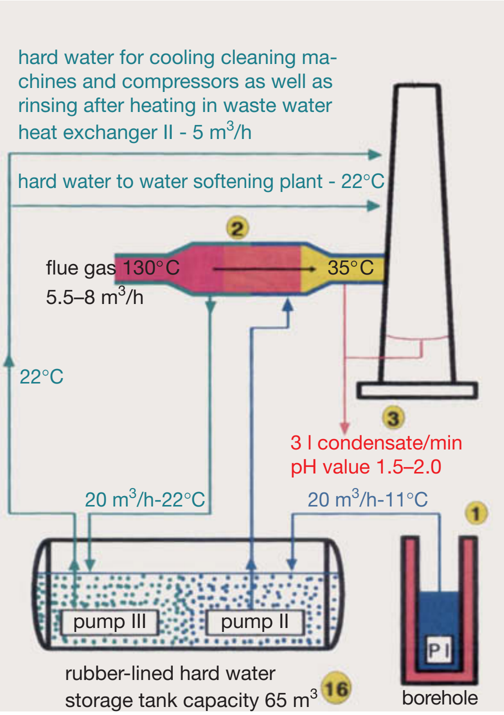

Fig. 2: Heat recovery in a flue gas heat exchanger (source: Kamm).

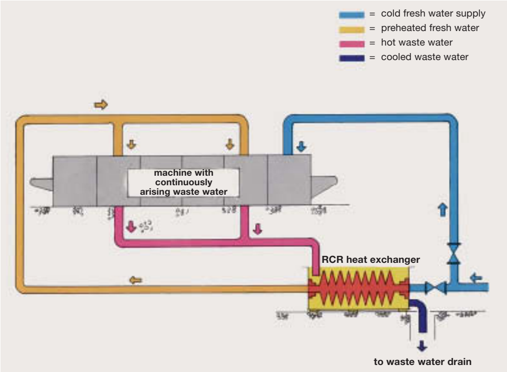

Fig. 3: Heat recovery in a continuous desalinator (source: Pozzi).

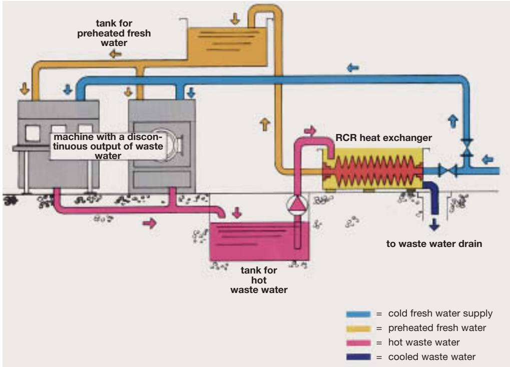

Fig. 4: Heat recovery with a discontinuous output of waste water (source: Pozzi).

e.g. stainless steel piping, it is considerably cheaper from a cost point of view. Since, however, a dwell time of 1 hour is involved, the disadvantage of a less efficient heat transfer can be disregarded in this case. Hard water, which is passed through the 500 m of PVC pipe and heated to approx. 38°C in the process, is then used for rinsing purposes. In the 65 m^3 capacity soft water tank, the soft water used for rinsing purposes undergoes a further rise in temperature. With heat recovery from the calender exhaust air and the flue gas heat exchanger, a circulation of rising and falling temperatures is involved. Heat recovery is also possible in a boiler feed-water treatment plant.

Heat exchangers can be used in heat recovery plants where effluents are produced continuously as well as discontinuously (Figs. 3 and 4).

For stenters, especially, the temperature gradient between the exhaust air and the incoming fresh air is so great that heat recovery is particularly worthwile.

Both integrated and external heat recovery systems are available for energy savings on stenters. The integrated systems are user-friendly, take up little space, and do not involve expensive installation (Fig. 5).

The highest efficiency is achieved with external systems (Fig. 6) which can be installed separate from, and next to, the stenter or above it. Operators are relieved of cleaning tasks by a fully automatic cleaning system which also ensures greater reliability in operation.

In principle, an external heat exchanger (Fig. 7) functions as a filtration system for the removal of harmful pollutants by cooling the exhaust air to such an extent that the pollutants condense to form droplets

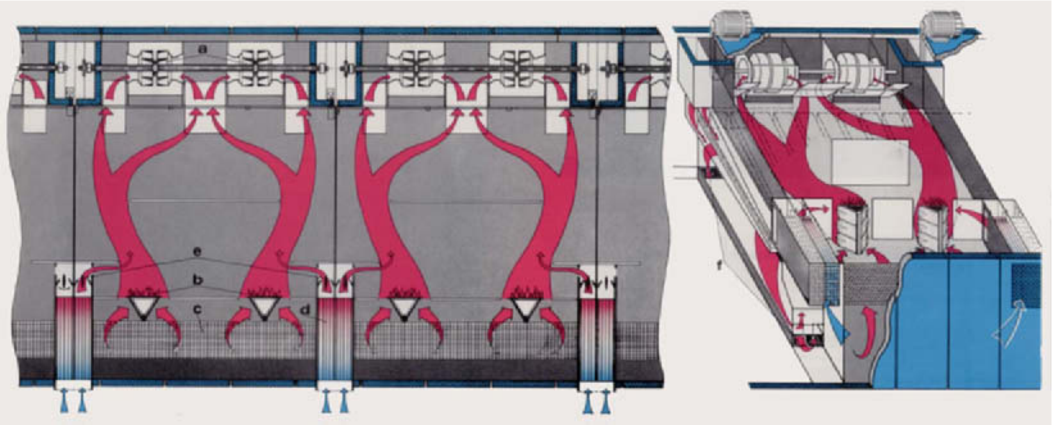

Fig. 5: Air circulation system with integrated heat recovery K.WI (Krantz).
a = 4 radial ventilators on a common shaft with external bearings; b = heating, example with direct gas heating; c = large air filters; d = bare tube heat exchanger in the exhaust air outlets; e = fresh air supply regulators; f = exhaust air extraction below the fabric web.

Heat recovery

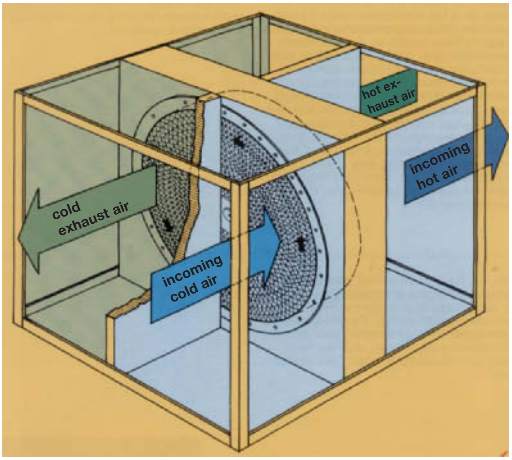

Fig. 6: Heat wheel (Babcock) used as an external heat exchanger for heat recovery.

which are then removed from the air through high-performance filters. The exhaust air from the machine is first passed into an external air/air heat exchanger. Fresh air impinges on the secondary side of this air/air heat exchanger (recuperative heat exchanger) which is then heated in the heat exchanger. This heated fresh air is then supplied to the machine so that heat is recovered from the exhaust air. The exhaust air is cooled down on flowing through the air/air heat exchanger. If possible, this pre-cooled exhaust air is passed through an air/water heat exchanger in a second cooling stage where process water is heated. After this air/water heat exchanger, or even after the air/air heat exchanger, the temperature of the exhaust air must have fallen to 60°C, at which temperature most pollutants condense to form aerosols (source: in part = H.A. Kamm).

Heat recovery from exhaust air is effected in three ways:

I. Regenerative: heat from the exhaust air is transferred in turn to a storage system and then to the incoming fresh air. Advantages: higher heat recovery. Disadvantages: complete separation of the exhaust and fresh air streams is not possible so that a risk of contamination exists if the exhaust air contains a high proportion of pollutants. For this reason, this type of heat exchanger is mainly employed in air conditioning applications.

II. Recuperative: heat is supplied and transported away continuously. There is a complete separation of both exhaust air and fresh air. Tubular or plate type heat exchangers constructed of metal, glass or plastic materials are used. In dyehouses it is possible to combine

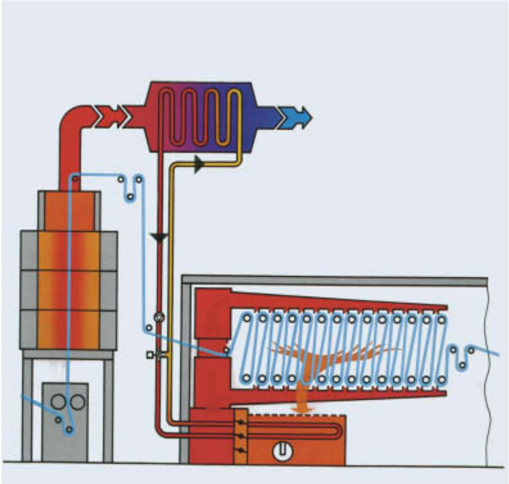

Fig. 8: IR predriers heat recovery (Monforts).

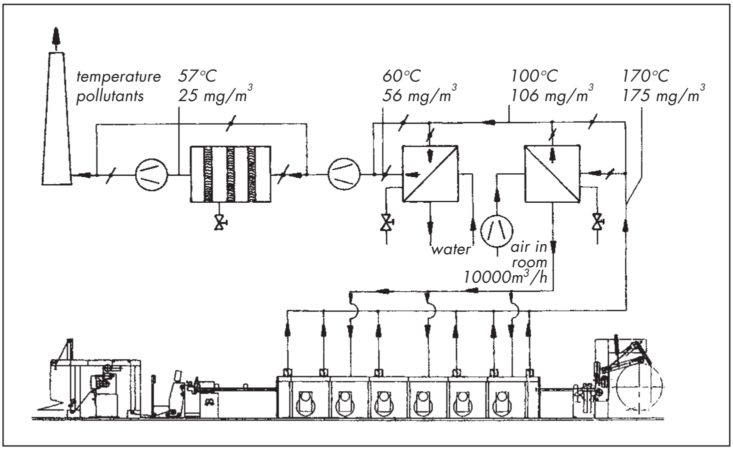

Fig. 7: Schematic diagram of an exhaust air cleaning system with heat recovery and filter (source: Behr).

the ventilation system with a heat recovery plant. The Hoval company has constructed a system of this kind which consists of a roof fan, air heater and a recuperative heat exchanger.

III. Babcock-Famatex heat wheel: specifically designed for stenters; heat exchange takes place via a metal body. The exhaust air is freed of condensate and completely cleaned by combustion.

The heat from the waste air expelled by the gas heated IR predrier is used to preheat the hotflue circulation air (Fig. 8). The transfer takes place in an air/oil heat exchanger system (Monforts).

Heat resistance → Thermal stability.

Heat resistance of cellulose This is primarily dependent on the degree of polymerization of the cellulose and becomes more sensitive to chemical and physical action with increasing stages of degradation. Also important is the content of oxycellulose and hydrocellulose as these forms are unstable at elevated temperatures. Changes resulting from the action of heat are dependent on the temperature and time of heat exposure. → Thermal stability of fibres.

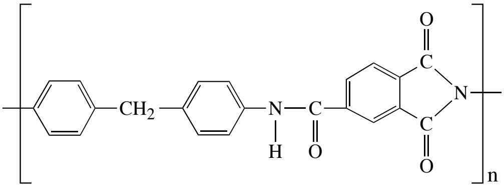
Heat-resistant fibres (thermostable fibres). The heat resistance of a polymer is characterized by three independent factors:

- the standard of general properties (mechanical and chemical),
- the retention of these properties for a given temperature range,
- the retention of these properties over a specific time and temperature.

For the special application of heat-resistant fibres in flame-retardant and heat-resistant protective clothing, three factors are decisive, i.e.:

- specific properties required for actual use in a garment (mechanical strength parameters and chemical resistance parameters),
- integrity of the textile surface during short-term exposure of the protective garment to radiant heat for possible protection against fire,
- retention of fabric surface properties during prolonged exposure to heat (firefighters' jackets generally consist of several layers of textile material for this reason, e.g.: wool cloth, nonwoven material, membranes or microporous linings).

Concepts for the specific thermal resistance of protective clothing to fire and heat are influenced more by the physical properties (functions of time and temperature involving a few seconds at 1000°C, or a few minutes at 250–350°C) of the raw material (e.g., melting point, second degree transition temperature) than the chemical properties such as, e.g. resistance to heat, hydrolysis or oxidation. These latter properties are important when thermostable fibres are used for the filtration of hot gases. Chemically, thermostable fibres are based on polyamide-imides (meta-aramid types), see → Aramide (fibres):



These fibres are manufactured by the polycondensation of trimellitic anhydride with di-isocyanatodiphenylmethane. The solutions, after incorporation of pigment, are wet spun into fibres followed by drawing at very high temperatures (this is necessary in order to achieve good resistance to light and washing).

Heat-resistant finishes Finishes which are intended to improve the resistance of textiles (strength, etc.) against the effects of high temperatures below the point of ignition. Such finishes are important for ironing cloths, paper machine felts and, possibly, tyre cords. Heat-resistant finishes for cotton include e.g. → Acetylation, treatment with dicyandiamide, etc.

Heat retention (thermal retention). This is an important serviceability characteristic of a garment (→ Wesel triangle). It follows from the → Thermal conductivity coefficient of textile fibres that all fibres, without exception, are better conductors of heat than air. Consequently, the heat retentivity of textile fabrics and similar materials is largely dependent on the respective pore volume and air content (→ Porosity). Since the thickness of the layer of air (= thickness of fabric % pore volume) is roughly proportional to total heat retentivity, an approximate estimate of the degree of heat protection of apparel fabrics to be expected can be obtained by determining the thickness of the layer of air. Determinations of this kind are, however, technically difficult, laborious, and also require special equipment. In order to avoid false conclusions, two methods which take into account the specific gravity are carried out at the same time:

- measurement of the → Air retentivity
- the so-called cooling measurement (with liquid at 37°C) on a copper cylinder wrapped with the test fabric. The percentual heat loss (kJ/°C) per unit time (h) and unit surface area (m^2) is determined by this means.

Heat retentivity → Heat retention.

Heat sealable paper A release paper, coated on the reverse side, used in the garment making industry to produce cutting layouts on textile fabrics. It adheres to any textile material with the aid of a hot iron and is easily removed again after cutting without leaving any residue.

Heat sealing A thermoplasticizing operation representing a primary stage in the bonding of nonwovens, collar interlinings and the fusing of fusible interlinings, etc. The temperature and duration of thermal bonding depends on the type of resin coating and the end-use of the substrate. Products suitable for thermal bonding see →: Melt-flow index; Sintering.

Heat-sensitive granules Small granules which have a precisely known melting point. Used for checking the temperature of steam pipes, calender bowls, ironing presses, etc.

Heat-set clothing → Heat-set garments.

Heat-set garments Heat-set garments are made from circular-knit fabrics where the desired body shape has been permanently set on heated three-dimensional metal mannekins. Collars and sleeves are welded to the main garment. This process eliminates the need for side seams and darts.

Heat setting An essential process in the pretreatment of man-made fibres which is also of importance in subsequent stages as intermediate setting or post-setting. The effect of heat setting is greater in fibres with an increasingly hydrophobic character and is carried out on polyolefin, polyester, polyurethane, polyacrylonitrile, polyamide, triacetate, acetate and viscose fibres (the fibres are listed in order of decreasing hydrophobic character). The objectives of heat setting processes include structure homogenization and the elimination of internal tensions within the fibre resulting in reduced shrinkage, improved dimensional stability, reduced creasing propensity and reduced edge-curl in woven and knitted fabrics. To this extent, the process may be better described as thermal relaxation. Heat setting changes not only the mechanical, but also the dyeing properties of man-made fibres. The principle is based on heating the fibre within a fibre-specific temperature range which is limited at the upper end by the melting point (softening range) and the respective glass transition temperature (necessary to break the secondary bonds) at the lower end.

The basic functions of heat setting are as follows:

1. Heating up the fibre with the evaporation of residual water and, with increasing material temperature, the “unblocking” of internal tensions and initiation of chain segment mobility.
2. Presentation of the material to the setting medium either under tension or tension-free passage as desired.
3. To subject the material to the setting medium for a specified period of time during which unstable crystallites melt and the polymer mass is partially recrystallized so that crystallites are formed the thermal stability of which is dependent on the parameters of temperature, dwell time and fibre tension during their formation.
4. On cooling, additional crystallization occurs in the crystallites of low stability and setting of the noncrystalline regions of the fibre takes place under the state of tension at the time of falling below the glass transition temperature.

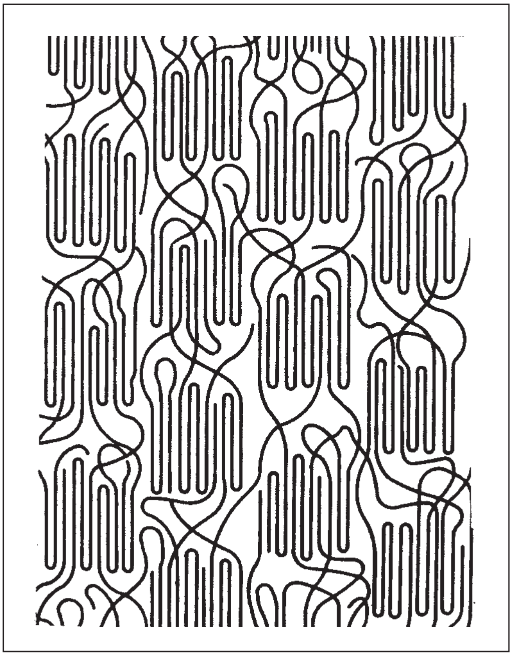


Fig.: Fringe fibril structure with chain back-folding according to Peterlin (1975). Shown in the vertical direction are four fibrils consisting of alternating crystallites with chain over-folding and amorphous areas. Between the fibrils lie the semi-crystalline, interfibrillar spaces.

The most important parameters of these functions are temperature, the given dimensions and the dwell time. A longer dwell time at the required temperature serves no useful purpose and therefore wastes energy. Heat setting processes within a temperature range of 130–220°C are possible; the selected temperature determines subsequent dyeing properties as follows: with increasing temperatures (e.g. in the case of polyester up to 200°C) the proportion of crystalline regions increases and, on exceeding this fibre-specific temperature, the proportion of noncrystalline regions increases (see Fig.) at the expense of the interfibrillar semi-crystalline interstitial spaces (→ Supramolecular structure of polymers). The greater the proportion of noncrystalline regions after heat setting, which is also influenced by the rate of cooling (rapid cooling reduces recrystallization), the better the subsequent dyeing properties. The temperature described as the “effective temperature” is that temperature which is necessary to cancel out the heat setting effect. Thus the heat setting temperature should be at least 25–30°C (for polyester 30–40°C) higher than temperatures to which the textile material will be subjected in subsequent processing or use.

Heat setting, determination of degree In the processing of synthetic fibres determination of the degree of heat setting is especially important since it contributes to the properties of the finished product. For polyamide fibres, swelling in sulphuric acid, and for polyester the critical solubility (phenol/tetrachloroethane) represent possibilities for determining the degree of heat setting.

Heat setting of carpet yarns Polyamide carpet yarns are set continuously in hot air at 205°C or in equipment where heat setting is carried out in saturated steam. See also → Carpet yarns, setting.

Heat setting of man-made fibres →: Fixation; Heat setting.

Heat setting processes Depending on the effective heating medium, heat setting processes include the following methods:

I. Hot air setting: the most common method of heat setting carried out on stenters or hot flue machines.

II. Contact heat: e.g. hot roll setting carried out on hot roll machines.

III. Saturated steam (steam setting): a method used for printed goods, socks, hosiery, woven and knitted fabrics, ply yarns, etc. since excellent resistance to shrinkage, creasing and high dimensional stability can be achieved. Setting is carried out discontinuously in vacuum or pressure steamers.

IV. Hot water treatment: under conditions below the boil the setting effect is not stable since the "effective temperature" is too low (these temperatures are already attained in making-up and in domestic washing). In the case of polyamide, on the other hand, effects which are equally as good as hot air setting are achieved e.g. at temperatures of 120–130°C in the beam dyeing machine (hydro-setting).

With polyamide and polyacrylonitrile fibres (no contact heat setting), the swelling properties are increased by setting in hot water or saturated steam and, by contrast, reduced by setting in hot air and contact heat. With polyester, the swelling properties are reduced in all three suitable media (I.–III.).

Demand is growing for seamless leisurewear and underwear (Fig. 1). Improved transverse elasticity and determined fabric weights are required. Presetting of knitwear with elastic fibre content just like heat setting of synthetic fabrics has, until now, been performed on stenter frames with the fabric cut open. Apart from the undesired sewing seams this process causes additional work and cost due to fabric slitting, fabric loss due to selvedge glueing and cutting, fabric doubling and sewing to avoid selvedge curling during dyeing, fabric reslitting etc.

The latest Dornier product – the Ecofix thermosetting range (patent applied) (Fig. 2) – is the first machine of its type on the world market capable of performing this heat setting operation on circular knits in their tubular form. With this solution, all the usual hosiery widths can be continuously and optimally steam-relaxed, thermoset with hot air and then treated with cold air. The patented automatically adjustable circular expander system – already thoroughly proven in the Dornier singeing, mercerising and bleaching ranges, ensures during the EcoFix treatment that the tubular

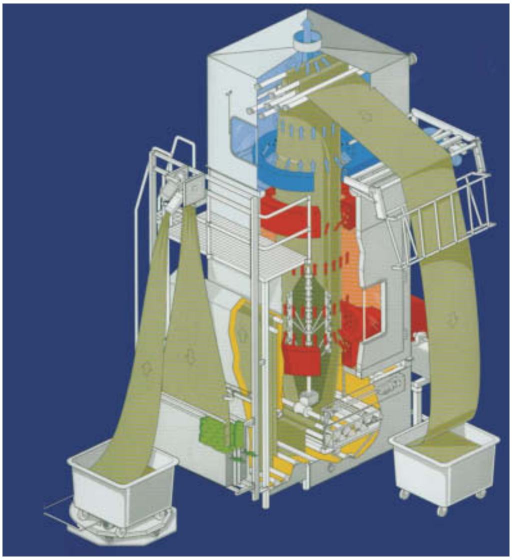

Fig. 2: Heat setting of tubular cotton/lycra knitted fabric; technical drawing of Dornier thermosetting range EcoFix.

fabric is held in its compressed condition with maximum control. Opening the stitches on the circular expander enables the hot air flow to pass uniformly around and through the tubular fabric. This system sets new standards in the field of heat setting, with shape stability, stretchability based on defined elasticity plus the required specific weight, all ensured on a reproducible basis.

Heat setting zone The dry zone in stenter driers for the heat setting of fabrics composed of synthetic fibres or their blends with special supplementary heating.

Heat, specific → Specific heat.

Heat stability The stability of dye dispersions/solutions to treatment temperatures in dyeing, for example especially when dyeing under HT conditions. The term must not be confused with dispersion stability since, under the action of heat, changes in the dye molecule can also occur which may result in reduced dye yields.

Heat transfer → Convection.

Heat transfer coefficient The capacity of a material (or combination) associated with heat transport to oppose the passage of heat through it with greater or lesser resistance (→ Heat transfer). A low heat transfer coefficient (k) corresponds to good heat insulating properties. In contrast to thermal conductivity, this parameter is not related to the length but to the heat flow per unit time through unit area.

The SI unit for the heat transfer coefficient is given by:

$$\frac{\mathrm{W}}{\mathrm{m^2 \cdot K}}$$

Conversion formulae for units no longer in use:

$$\frac{\mathrm{kcal}}{\mathrm{m^2 \cdot h \cdot K}} = 1.163\ \frac{\mathrm{W}}{\mathrm{m^2 \cdot K}}$$

$$\frac{\mathrm{W}}{\mathrm{m^2 \cdot K}} = 0.860\ \frac{\mathrm{kcal}}{\mathrm{m^2 \cdot h \cdot K}}$$

Heat transfer medium Heat transfer liquids for → Circulating hot oil unit used in the textile industry and as heat transfer fluids in → Heat exchanger. They are used exclusively in liquid form. Requirements:

– easily pumped at room temperature (20°C),
– boiling point must lie above the max. required temperature,
– non-toxic,
– non-corrosive in contact with machine components.

Raw materials for heat transfer agents include:

– mineral oil products,
– synthetic products (aromatics) with a max. operating range up to 350°C. Exceptions are diphenyl and diphenyl oxide (may be used up to max. 400°C, boiling range begins at 270°C, i.e. above this point, vapour pressures up to max. 13 bar must be taken into account), chlorinated hydrocarbons (no longer permitted).

The heating of machines, vessels, buildings, etc. with water or steam is a well-known application. In this case, water or steam serves as the heat transfer medium. At temperatures above 100°C, however, an increase in temperature is associated with a corresponding increase in pressure (saturated steam curve). For many industrial heating applications temperatures up to 300°C and above are required.

Whilst, in the case of water or steam, a pressure of 10 bar already prevails at a temperature of e.g. 180°C, and even 120 bar at 320°C, these temperatures can be achieved virtually pressure-free by thermal oil heating using suitable heat transfer agents produced by the mineral oil resp. chemical industry (i.e. such heating systems are not subject to the official regulations governing the use of pressure vessels).

Heating equipment based on the use of heat transfer oil is used to solve numerous industrial heating problems, e.g. for heating reaction vessels, mixing vessels, storage tanks, distillation columns and, not least, heat exchangers. With such heating/cooling systems, cooling can be carried out as well as heating. In principle,

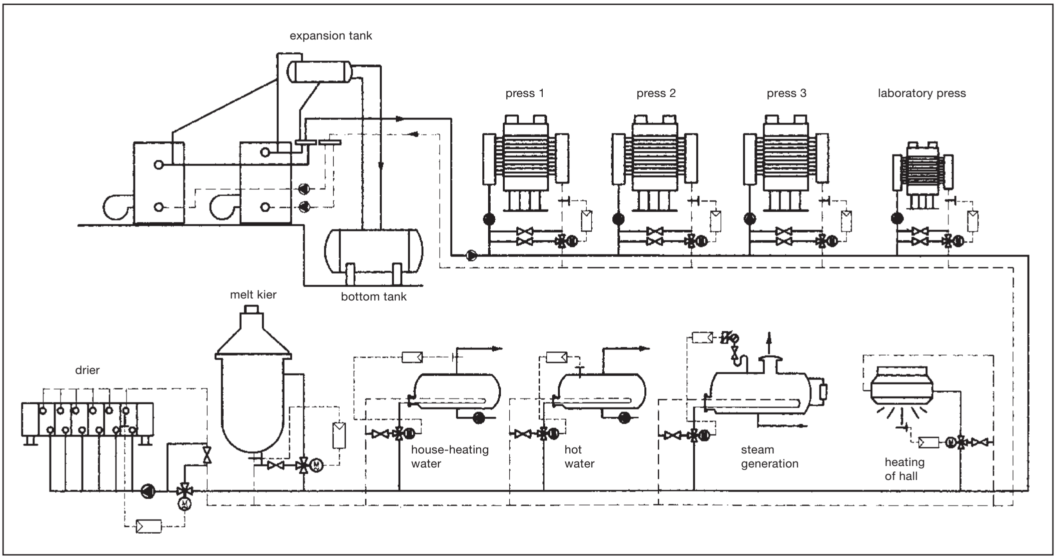

Fig.: Plant layout of a heat transfer oil system (source: Baelz).

indirect heating using oil as a heat transfer medium makes the gradual heating of machines possible since it is easy to control the temperature of the medium.

In plants where heat transfer oil boilers are already in use, it is usual for all the heat-consumers to be connected to this heat supply system; typical heat supply stations include:

- steam boilers heated by means of heat transfer oil,
- water heat exchangers for heating and the provision of hot water.

Since effective external sealing of such heat transfer oil systems is extremely important, glandless fittings are always employed.

A flow diagram of a heat transfer oil system used in the wood and plastic processing industries is shown in the Figure. This includes 3 large presses and 1 small press, 1 agitating mixer, 1 drier, 2 heat exchangers, 1 steam boiler and 1 air heater. The number of heat consumers may be increased or reduced exactly in accordance with requirements.

In general, a temperature difference of 10–30°C between the entry and exit of a heat consumer is sufficient to ensure the desired heating of the product as far as the thermal oil is concerned. Where precise control is desired, this can be achieved by means of a secondary circulation with a control accuracy of 1°C between entry and exit of the consumer in terms of thermal oil temperature. This control system is shown for the presses and the drier. A second circulating pump feeds the consumers with a large volume of thermal oil supplied through a secondary circuit. The temperature is controlled by a motor operated 3-way valve which controls the addition of hot oil as required. Programmable controllers may be used to meet special requirements. Fully-automatic control of pre-selected temperature/time profiles for heating and heating/cooling processes can be achieved with systems of this type (source: Baelz).

Heat transfer number A numerical expression of → Heat retention.

Heat transfer oil → Heat transfer medium.

Heat transfer oil circulation plant → Circulating hot oil unit.

Heat transfer printing → Transfer printing.

Heat transfer printing with cationic dyes Acrylic fibres, which only absorb sublimable disperse dyes at low colour yields, as well as cationic-dyeable polyester, can be transfer printed with transfer papers produced with cationic dyes in brilliant shades at acceptable colour yields. Improved colour yields are possible by means of a pretreatment with a 2% ammonium sulphate solution (3–5 min at 88–98°C) as a result of which the sodium ions contained in the fibre are exchanged by ammonium ions. → Transfer printing.

Heat transmission The heat transfer coefficient is that quantity of heat which can be transferred from a hotter to a cooler medium through a metal surface of 1 m^2 per hour per 1°C difference in temperature. Heat transfer plays a considerable role in, e.g. the thermosol dyeing process.

Heat and mass transfer from the air mixture to the material is determined by the volume of the flow directed parallel to the surfaces of the textile material. A laminar boundary layer is created along a textile surface by

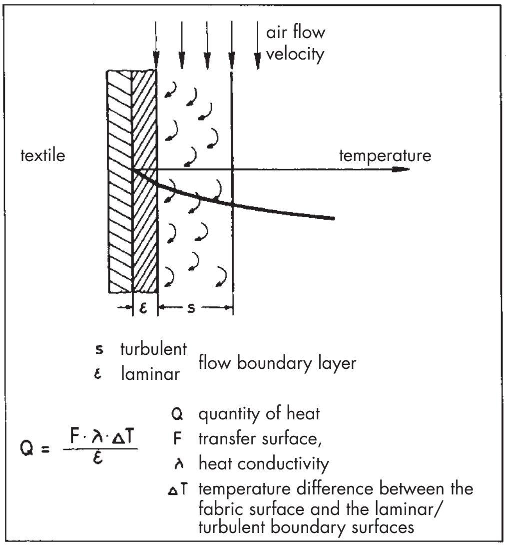

Fig. 1: Heat transfer to material with air flow parallel to the surface.

the air flow bounded by a turbulent flow boundary layer. The thickness of the laminar boundary layer with a flow parallel to the textile surface is determined by the speed of the flow. The transport of heat quantity Q from the medium flowing, over the textile within the laminar boundary layer (Fig. 1) by heat conduction into the turbulent boundary layer, is achieved by convection. Consequently, the heat conductivity of the boundary layer determines the rate of heat transport to the material.

In addition to the influence of temperature or vapour pressures, the → Heat transfer coefficient k plays a decisive role in the determination of the heating surface as demonstrated by the equation:

$$Q = k \cdot F \cdot \Delta T$$

The heat transfer coefficient k is influenced by three variable parameters (Fig. 2):

a) heat transfer from material A to the partition characterizes heat transfer coefficient α_i as defined by the equation:

$$Q = \alpha_i \cdot F_i \cdot (T_A - T')$$

b) continued conduction of heat through the material partition wall with a thickness S_W characterizes the heat conductivity value λ_W as defined by the equation:

$$Q = \frac{\lambda_W}{S_W} \cdot F_W \cdot (T' - T'')$$

c) heat transfer from the external partition to material B characterizes heat transfer coefficient α_a as defined by the equation:

$$Q = \alpha_a \cdot F_a \cdot (T'' - T_B)$$

Q = thermal output in kW,
α_i = heat transfer coefficient of the inner surface in kW/m²K,
α_a = heat transfer coefficient of the outer surface in kW/m²K,
F_i = internal surface area in m²,
F_W = partition surface area in m²,
F_a = external surface area in m²,
λ_W = heat conductivity value of the partition material in kW/m°K,
S_W = partition thickness in m,
T_A = mean temperature of medium A in °K,
T' = temperature of the internal surface in °K,
T'' = temperature of the external surface in °K,
T_B = mean temperature of medium B in °K.

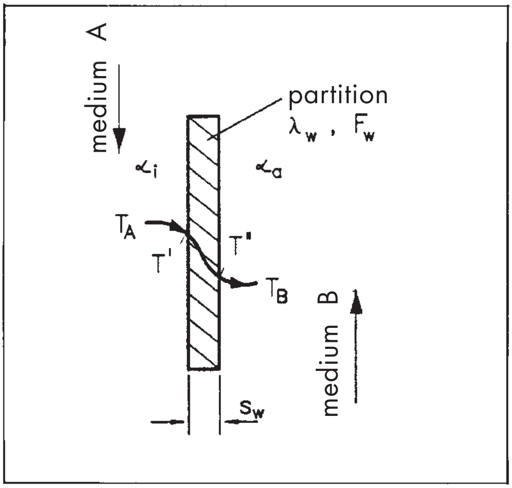

Fig. 2: Heat transition at a partition.

Heat transmission coefficient The heat transmission coefficient is a characteristic for the heat exchange or heat transfer between the boundary layer of a body and the adjacent medium (e.g. air). A high heat transfer coefficient corresponds to a rapid heat exchange. → Heat transfer.

Heat transmission resistance → Heat transfer coefficient.

Heat transmission surface → Heating surface.

Heat treatment zone (drying chamber). The heated sections in stenters and continuous drying machines in which textile fabric is subjected to increasing temperatures. Consists of a drying section (where moisture is driven off the moving web) and a dry heat section (in which heat setting or dye fixation, etc., is carried out at specified temperatures).

Heat tube roller A device to improve the heating of fabrics in thermosol dyeing ranges. The figure shows a heat tube roller installed in a Krantz hotflue which transfers heat to the fabric by contact with the uniformly heated roller as well as hot air circulated through recessed nozzles in the roller surface.

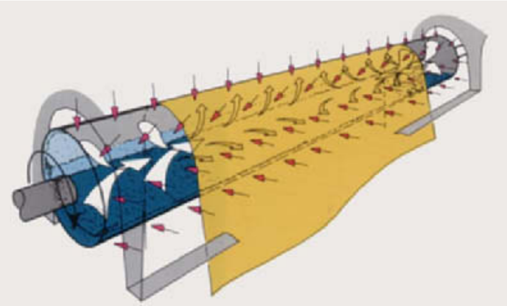

Fig.: Heat tube roller (Krantz).

Heat Utilization Ordinance When it is realized that the efficiency of converting energy sources into heat, even with the integrated power supply and recycling concepts known up to now, is at best only 50% and often considerably less, then a heat utilization concept specifically aimed at the energy-intensive textile finishing industry appears highly appropriate in view of limited global energy resources. A corresponding Heat Utilization Ordinance has been in existence as a draft statute of the German Federal Ministry of the Environment (Umweltbundesamt) since 5.9.1991. Under the terms of this statute, new plant and machinery, in particular, subject to licencsing for heat utilization will have to satisfy a relevant heat utilization concept within three years after a licence has been approved.

The law for protection against harmful environmental effects due to air pollution, noise, vibrations and similar nuisances, i.e. the Federal Air Pollution Control Act in Germany (Bundes-Immissionsschutzgesetz [BImSchG]) describes in § 5 the obligations of companies operating licensable plants. Among other things, § 5, clause 1, No. 4, states that plants subject to licensing must be constructed and operated in such a way that any heat generated has to be used for other plant operated by the company or else supplied to third parties who have already indicated a desire to make use of such surplus heat provided, of course, that this is technically feasible and reasonable having regard to the type and location of the plant (→ Environmental legislation).

The objective of the Heat Utilization Ordinance, HUO (see Fig. 1) is to achieve a reduction of air pollutants formed during the combustion of fuels by lowering energy consumption. This will achieve, above all, a reduction in carbon dioxide (CO_2) emissions in addition to a reduction of other airborne pollutants such as sulphur dioxide or nitrogen oxides. Under previous air pollution control legislation, the required reduction of airborne pollutants was largely achieved by taking retroactive measures. In the case of carbon dioxide, however, this is not possible due to the lack of appropriate technology. Consequently, in order to achieve a reduction in CO_2 emissions, a start must be made at the outset, i.e. by a reduction in the use of energy.

On the 7.11.1990, the Federal Government in Germany decided on a target reduction of at least 25% in CO_2 emissions which cannot be achieved without the legislative powers of the Heat Utilization Ordinance.

Audits of energy consumed by production plant and machinery result, as a rule, in significant energy savings without the need for high investment. From this it can be seen that a Heat Utilization Ordinance does not necessarily increase the costs of production, but probably reduces energy costs.

In this article, discussion of the published draft of the Heat Utilization Ordinance is restricted to its implications for the textile finishing sector and the relevant plant and machinery. The first part of the Ordinance, which comprises § 1 and § 2, contains general regulations. The scope of application of the Heat Utilization Ordinance is given in § 1. The Ordinance applies to the construction, condition and operation of plant and machinery subject to licencing as listed in Annex 1 of the Heat Utilization Ordinance. These items of plant are designated as being subject to compulsory heat utilization licensing. In Annex 1, the plant and machinery used specifically for textile finishing is included under paragraph 10.23, as already listed in the 4th BImSchV. This establishes the inclusion of textile finishing plant and machinery within the scope the Heat Utilization Ordinance.

The second part, comprising § 3 to § 5, describes fundamental requirements. Obligations with regard to the use of heat and energy are formulated in § 3. These are subdivided into the following categories: a) energy use within the plant itself (§ 3, clause 1), b) heat utilization within the company itself (§ 3, clause 2, No. 1), and c) heat supplied to third parties (§ 3, clause 2, No. 2).

As far as textile finishing plant is concerned, it is only the energy used by the plant itself and, possibly, the heat utilization within the company that are relevant in most cases. In order to satisfy the obligations relating to energy use within the plant itself, ten measures are listed in § 4, clause 1, which have to be taken into consideration. Of these, the following measures are important for textile finishing plant, (the numbers correspond to those given in the ordinance):

Heat Utilization Ordinance

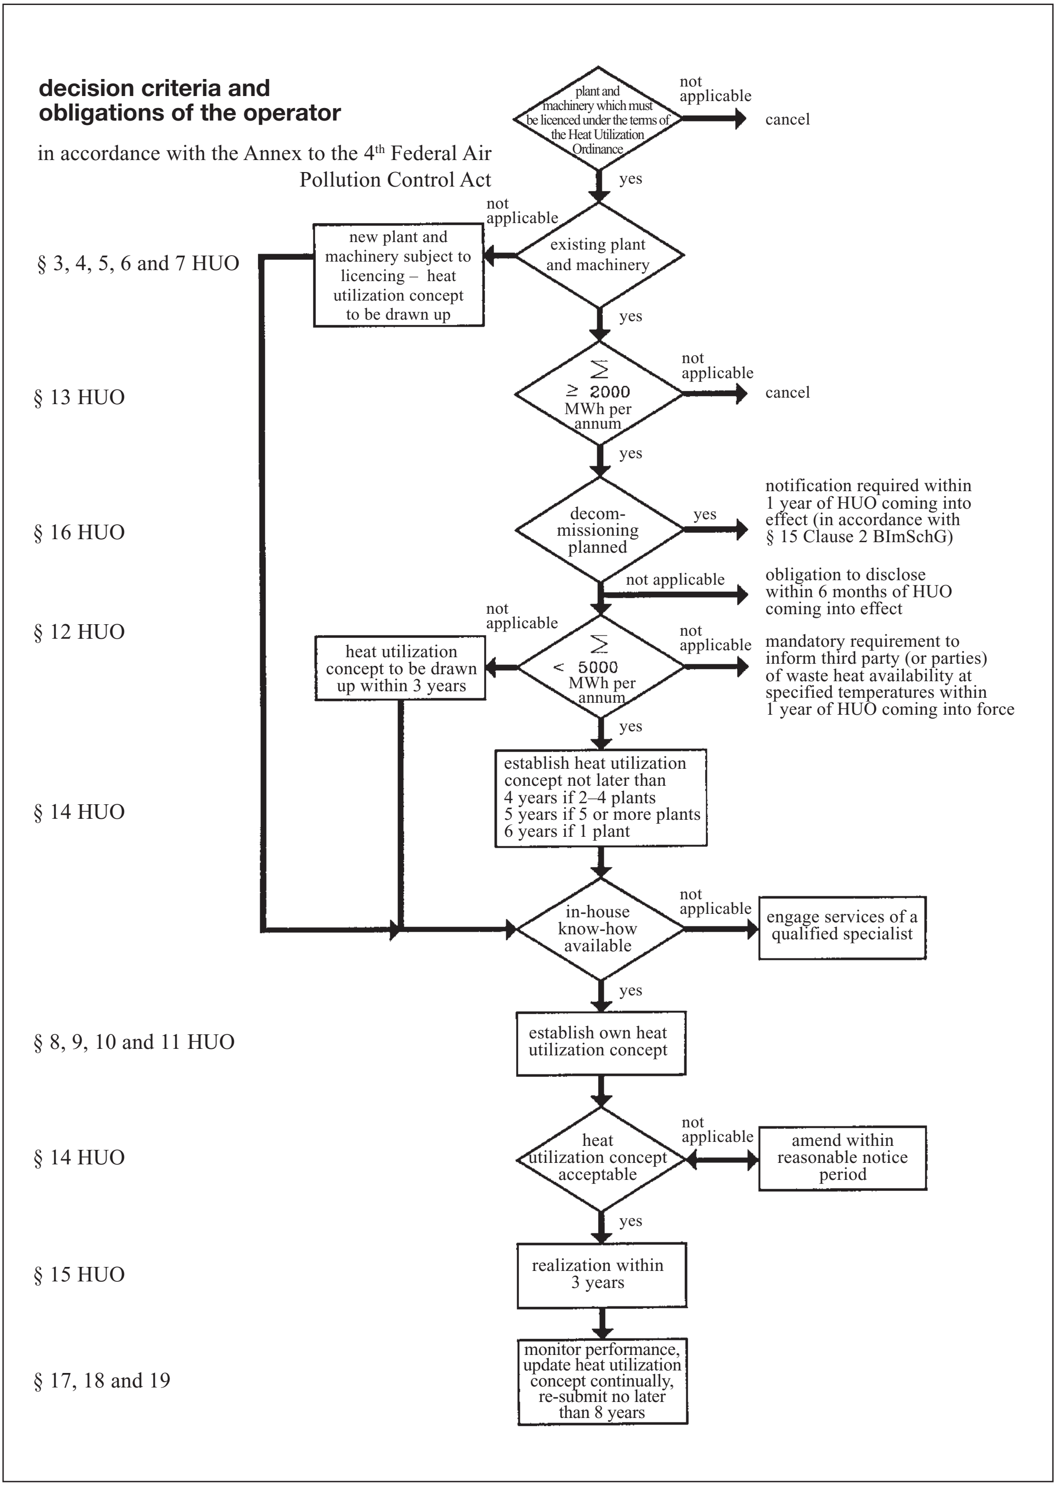

Fig. 1: Heat Utilization Ordinance (HUO), 1991 draft (according to PSB).

1. An energy-saving concept for the process sequence within the plant is required.
2. Provision must be made for the limitation of heat losses.
3. Realization of high energy efficiencies and a high degree of utilization.
4. Heat recovery within the plant.
5. Avoidance of waste heat.
8. Satisfy own requirements for mechanical work, electrical energy and heat by means of combined heat and power generation.
9. Energy-saving integration of energy supply to the plant within existing energy systems at the plant location.
10. An energy-saving concept for operation of the plant is required.

Measures which must be taken into consideration in order to satisfy the obligations relating to heat utilization are listed in § 4, clause 2. As far as textile finishing plant is concerned, the measure under No. 1 is important if the need should arise, i.e. 1. utilization of waste heat in plants operated by the company.

In § 5, it is stated when the measures required to satisfy obligations relating to energy and heat utilization are to be carried out. This stipulation must come as a shock to any business manager since it is laid down therein that measures are to be carried out if they are reasonable. In § 5, clause 1, measures are considered "reasonable" if the payback period is less than the serviceable life of a plant subject to heat utilization licencing and no other significant factors stand in the way.

$$n_a < n_N$$

where

n_a = payback period in years, and

n_N = serviceable life of the plant in years.

In Annex 1 to the Ordinance, compulsory figures are given for the useful life of the plant involved that have been taken from the depreciation tables of the Inland Revenue authorities. For textile finishing plant this corresponds to a serviceable life of $n_N = 10$.

In order to prevent the use of unauthorized economic formulae for the calculation, a simple formula to calculate the payback period n_a is given in Annex 2.

$$n_a = \frac{K_i}{E - 0.1 \cdot K_i}$$

where

K_i = investment capital necessary to carry out technically feasible measures relating to energy and heat utilization (in DM), and

E = savings and returns (in DM per year).

Further explanations are also given in Annex 2.

The third part, comprising § 6 to § 9, describes the required heat utilization concept. § 6, clause 1, describes the circumstances when the operator of a plant subject to the provisions of the Heat Utilization Ordinance is required to draw up a heat utilization concept. This becomes necessary where the energy supplied to the plant, in a proper and actually feasible scale of operation, is 2000 MWh/year or more. In clause 2 of this paragraph, it is stated which information the heat utilization concept must contain. This includes information on the energy supplied as well as the energy and heat utilized within the plant. It is explicitly stated that the operator must engage the services of outside specialists (e.g. engineering) if he is not in a position to draw up such a concept himself.

Information relating to energy utilization within the plant (§ 7) must contain the following:

- A description of the heat utilizing plant subject to the Ordinance in terms of its energy and process technology. To this end, energy flows represented by heat circuit diagrams, energy flow diagrams and process technology flow charts must be indicated and carbon dioxide emissions given.
- A presentation of additional or further measures for energy utilization within the plant which have been checked for carbon dioxide emissions and energy consumption.
- Reasons for decisions taken to adopt particular measures for energy utilization within the plant.

The fourth part (§ 10 to § 13), describes requirements for construction and operation and is therefore probably not relevant to the plants under consideration for textile finishing.

The fifth part (§ 14 to § 16), describes procedures for measurement and monitoring. § 14 is of relevance to textile finishing plant. It lays down that the operator of such plant must monitor energy consumption at regular intervals and take steps to counteract any increases in energy consumption. Where possible, a specific energy consumption should be given.

The sixth part (§ 17 to § 20), contains interim provisions. The duty to disclose details on existing plant according to the requirements of § 17 is important here. Operators of existing plant are allowed 1 year after the Ordinance comes into force to notify the responsible authorities of:

- the nature and location of the plant concerned,
- the energy supplied to the plant in a proper and actually feasible scope of operation.

In § 18 it is stipulated that a heat utilization concept has to be drawn up for existing plants consuming at least 4000 MWh/annum. It is further laid down when the concept is to be submitted. Depending on the amount of energy supplied, a notice period of 3–5 years has been set for this purpose. It is also mentioned

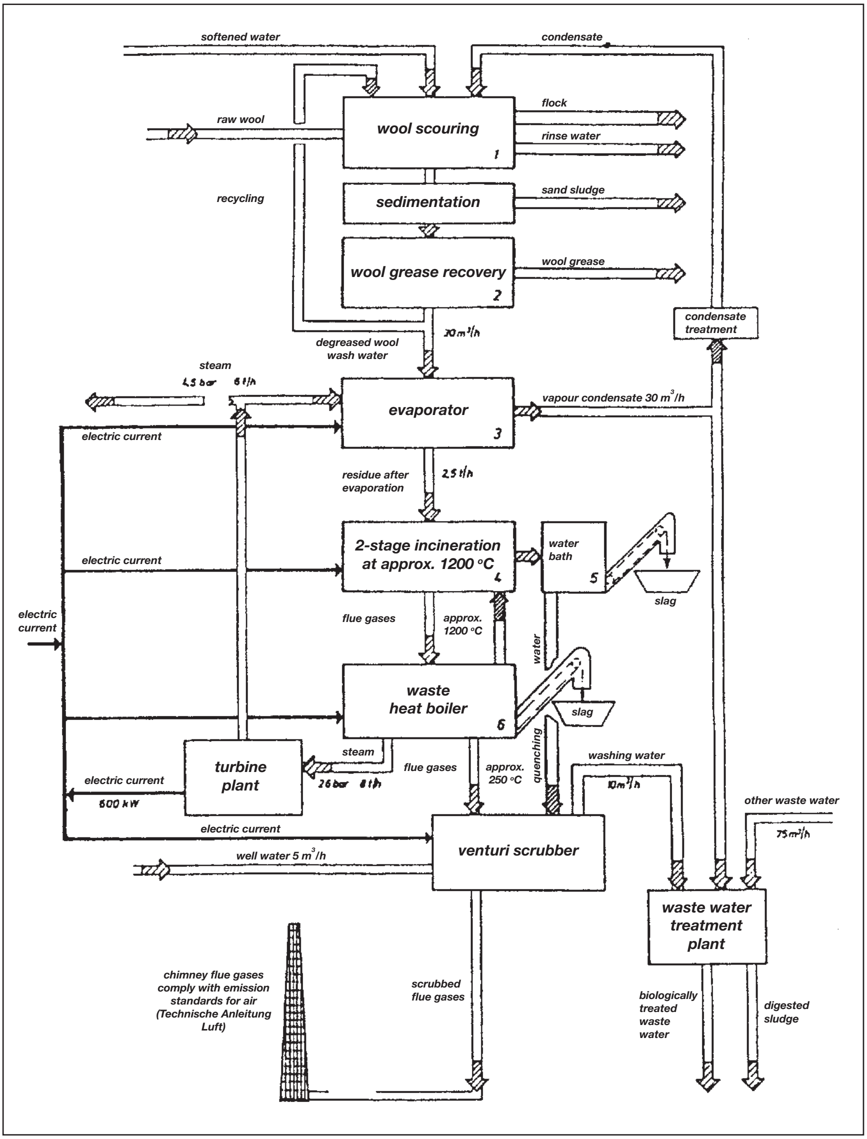

Fig. 2: Comprehensive heat utilization by cascade-form utilization of heat in the recycling of useful material (lanolin wool-fat) at BWK (Bremer Wollkämmerei AG) in Bremen.

that the remaining serviceable life of the plant may be notified.

The seventh part (§ 21 to § 25), contains general regulations, e.g. including breaches of the regulations (source: Fischer).

In order to comply with the Heat Utilization Ordinance, a survey of actual energy flows within a textile finishing plant is necessary. By taking this as a starting point, an integrated heat utilization concept (Fig. 2) can then be drawn up as a target standard.

Heat zone dwell system An open-width treatment for the scouring, bleaching and dyeing of woven fabrics composed of cellulosic fibres and cellulosic/synthetic fibre blends by the → Pad-Roll-Process.

Heavy chemicals Inorganic chemicals for industrial purposes produced in bulk quantities and often in a relatively impure state (technical grade), e.g. acids, alkalis, salts, chlorine, etc. See also → Fine chemicals.

Heavy coating → Heavy duty waterproof finishes.

Heavy duty detergent A universal detergent suitable for all washing processes and usually for all wash temperatures (→ Syndets).

Heavy duty detergent booster Intensifier for exceptional circumstances (difficult washing conditions) or where the laundry is particularly soiled, e.g. more intense soiling appearing locally, such as soiled edges on collars and wristbands. Generally pasty concentrate of suitable surfactants and compounds. → Detergent booster.

Heavy duty waterproof finishes A term used for waterproof finishes applied to tarpaulins and similar articles to provide resistance to water pressure. → Waterproof impermeability testing.

Heavy metals Effluents from textile wet processing plants can be contaminated with heavy metals such as copper, cobalt, nickel and chromium. They may be separated off by precipitation or the use of ion exchangers specifically designed for heavy metals.

The term “heavy metal” is understood to apply to metallic elements with a density greater than 6 g/cm^3. Both essential → Metals (iron, copper, zinc) as well as non-essential metals (not essential for the structure of the biosphere: cadmium, mercury, lead) can, at increased concentration levels (through bioaccumulation), result in growth inhibition and metabolic disturbances (by recomplexing, i.e. the exchange of essential by non-essential metals in metal-complexes). The chemical coordination behaviour of a heavy metal determines the distribution of a metal in nature. A-metal cations (calcium, magnesium, sodium) are present in water as free aquo ions; transition metal cations (iron, manganese, chromium) form hydroxo complexes in the solid or dissolved state; B-metal cations (mercury, cadmium, zinc, lead) form stable complexes with organic ligands. The residence time of a heavy metal in a biomass is inversely proportional to the affinity (tendency for adsorption, incorporation, precipitate formation) for the respective system. The toxic concentration range is highly dependent on the state of the heavy metal; thus the lethal copper concentration of a copper salt is convertible by the addition of an organic complexing agent such as EDTA in optimum (i.e. low) concentration. Mercury becomes more lipophilic (fat-soluble) by methylation and, in this form, can be more readily taken up by cells and enter the food chain.

Hecto- (Gr.). Metric prefix denoting 100 = 10^2, e.g. hectolitre (hl), a measure of capacity equivalent to 100 litres.

Helanca principle The classic resp. conventional Helanca principle or true twist process, developed by Heberlein & Co. AG, Switzerland, for the batchwise production of torque crimp stretch yarn from man-made continuous filaments, chiefly polyamide or polyester. The yarn is produced by combining highly twisted Z-twist and S-twist filaments, followed by heat-setting at high temperatures, and final untwisting:

1. S and Z-twist filaments are twisted with 2000–3500 turns/m and then combined as ply yarns with a few turns/m.
2. Steam setting: the ply yarns are heat-set on aluminium or cardboard tubes with overpressure or saturated steam in a vacuum steamer. The yarn packages are preheated dry, given a short steaming 2–3 times with as much vacuum as possible, then subjected to the action of saturated steam for 1.5–2 h (approx. 130°C) at 1.8–2 bar pressure (shorter steaming times = flabby handle, longer steaming times = stiffer handle) after which the yarn is finally allowed to cool and condition for at least 24 h. These conditions apply to aluminium tubes of 70 mm diameter for approx. 120 g of yarn material. Material damage during steaming in the form of stains or discoloration (not removable) is caused, e.g. by rust-contaminated condensate, interior paintwork in the steamer, twisting machine oil, spin finishes, etc.
3. Untwisting in the opposite direction at approx. 100 turns/m.

Helanca stretch yarns have mainly been used in hosiery, tights, underwear, lingerie, sweaters and some woven fabrics. The process has now been largely superseded by false twisting.

Helianthine Identical to → Methyl orange.

Helio-Klischograph An electronic engraving system used in the production of gravure printing rollers for heat transfer printing. Prints from Helio-Klischograph engravings produced by etching can be used to advantage on synthetic fibres, especially on fine woven fabrics with a smooth surface. This procedure is currently employed by printworks already in possession of a Helio-klischograph and/or those who produce paper for transfer printing with such engravings, and are also engaged in the printing of textiles themselves. In addition, the process is suitable for independent printers with appropriate design selections and colorations. – Manuf.: Hell.

Helix (wool, hair fibres). An elementary building block of the → Macrofibrils in animal fibres with a screw-like structure. According to Pauling, the microfibrils are formed with a central helix in the chain molecules of wool keratin in order to combine with others by means of a right-hand twist to form a unit. The helix has a high elastic recovery and can be pulled apart (breakdown of stabilizing hydrogen bonds) and relaxed again (reformation of hydrogen bonds), a property which is referred to as reversible denaturation. For a more recent account see → Intermediate filament.

Helmholtz colorimetric measures → Colorimetric measures.

Hem An edge to a piece of textile fabric (edge reinforcement) made by folding the raw edge under and stitching it to the body of the fabric. Hemming: the process of producing a hem. Hemstitch: a decorative edging stitch, usually for a hem, in which the cross threads are stitched in groups.

Hematine (hematein, haemateïn) → Logwood.

Hematoxylin (haematoxylin) → Logwood.

Hematron An electronic device for the control of rope length and milling shrinkage on rotary milling machines. A measuring strip sewn into the seam transmits an impulse to the sensor mounted at the entry to the machine which is then stored in the display unit and compared with a preselected value. As soon as this value is reached, the machine is stopped. The entire unit consists of a transmitter, speed monitor for the lower cylinder, a combined display and preselector as well as the electrical switching system.– Manuf.: Hemmer.

Hemicellulose Besides → Cellulose and lignin, hemicellulose is a component of wood and, to a slight extent, also of natural cellulosic fibres. It consists of an ill-defined group of various complex → Polysaccharides. Hemicellulose has a lower molecular weight than cellulose (degree of polymerization of 150 or less) and lower chemical resistance. It is only sparingly soluble or insoluble in water, and is broken down by plant ferments into sugars, but does not reduce Fehling's solution.

Hemicolloids →: Colloid; Macromolecules.

Hemp Flax and hemp are → Bast fibres. It is derived from the stem of the hemp plant (cannabis sativa) 50–250 cm tall, accompanied by a fair amount of woody matter.

The fibre is harvested and processed in a manner similar to that used for flax:

I. Mechanical process to separate hemp fibre from the straw (to give "green" hemp).

II. By → Retting to free the fibre from woody matter, then as in I above. (→ Flax).

III. By → Cottonizing.

Hemp fibres are greyish-white, matt yellow or greenish-black in colour, and have a greater or lesser degree of lustre. Strands of hemp are 1–2 m in length and 50–500 µm thick; individual fibres are 15–25 mm long and 10–50 µm thick. Tensile strength of the latter 3.0–7.0 cN/dtex, 10–20% greater in the wet state than dry. Extensibility is only 3–4 %. Hemp fibres are composed of approx. 9% water, approx. 78% bastose (cellulose-lignin compound), 0.5 % fats, waxes and colouring matter, over 9% deposits (impurities: pectin substances), approx. 1% mineral substances. The chemical properties of hemp are similar to flax (woody matter resp. lignin is soluble in hot alkali). Uses: Gminder fabrics, carpets, mats, sacking, cord, twine, etc. (→ Fibre identification).

Hemp line Fine, straight, parallel hemp strands produced by hackling long hemp fibres.

Hemp/jute discrimination tests,

I. → Phloroglucinol reaction.

II. → Aniline sulphate test.

Hemp stalk structure Comparable to → Flax stem structure. Differences: two bast bundle layers: a) primary bast fibres (combined in groups) of the outer layer as well as b) secondary bast fibres (individual bundles) of the inner layer formed on further growth of the plant to reinforce the skeleton structure. The first type are of greater value for obtaining long fibres than the shorter, coarser, secondary fibres which yield mainly hemp tow. The division of hemp bast bundles is considerably less than flax because of the higher lignification of the middle lamella. The fibre appears to be a mixture of cellulose and lignocellulose.

Hemp tow The short fibre stock of varying lengths removed in breaking, scutching, hackling, or combing. It is often very gnarled, matted, and very irregular.

Henequen A vegetable fibre, closely resembling sisal, belonging to the → Hard fibres group. Henequen is produced from the leaves of the Mexican plant (agave fourcroydes).

Henry's law The behaviour expected for a non-electrolyte solute of any dilute solution is obedience to Henry's law relating the solute vapour pressure p to the solute concentration c through an empirical constant k (G = free energy).

$$p = k \cdot c \cdot G = G_0 + RT \cdot \ln \frac{c}{c_0}$$

Derivation from the thermodynamic potential is analogous to that of → Nernst's distribution law.

Hercosett process (chlorine-Hercosett process). A process for the continuous shrink-resist treatment of wool which involves a prechlorination stage followed by the application of a preformed polymer resin, i.e. polyamide epichlorohydrin resin (Fig. 1), that is substantive to wool.

The process is carried out on wool tops in the backwashing machine. The first stage involves a weak chlorination in order to reduce the surface tension of the

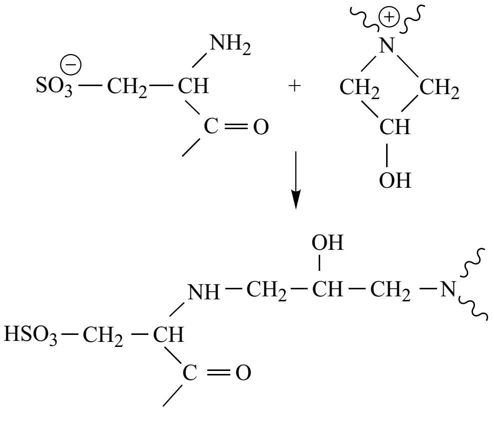

Fig. 2: Polymer bonding to the wool amino acid.

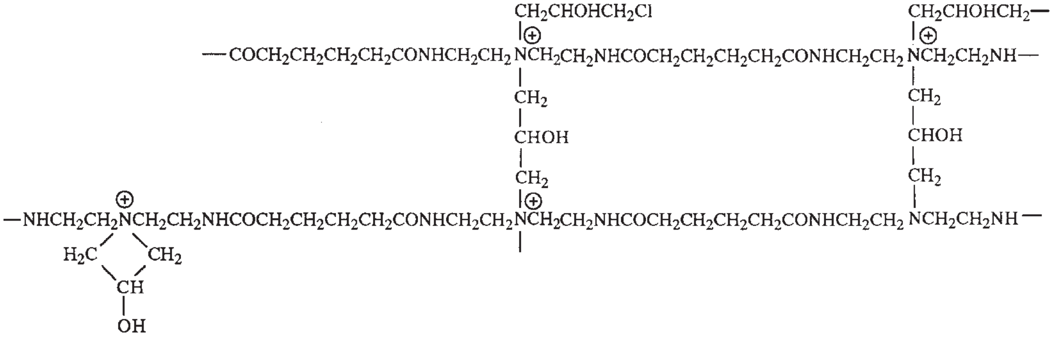

Fig. 1: Chemical structure of the Hercosett felt-free finish polymer.

wool fibre in order to facilitate subsequent wetting with the polymer resin. In the second stage, the positively charged polymer resin is applied and is attracted by the sulphonic acid groups (negatively charged) of the cuticle, the cystine of which has been partially oxidized by chlorination to cysteic acid. In the progress of finishing, the polymer becomes reactively bound to the amino groups of the wool keratin (Fig. 2).

The antifelting effect of the Hercosett process is probably due to the binding of a water film around the fibre by the charged polymer deposit thereby masking the scales and preventing fibre attraction.

Hereke carpets Especially valuable → Knotted carpets from the time of the last Turkish sultans (beginning of the 19th to the 20th century). The carpets are woven with a wool or silk pile on a fine cotton or silk ground fabric. 300 000–400 000 Turkish knots or over 1 000 000 Persian knots/m^2.

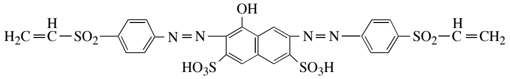
The design consists of tightly arranged strewn flowers as well as, to some extent, motifs inspired by the French rococo period.

Herringbone weave Herringbone is executed in a broken twill weave with alternating twill direction in a balanced chevron pattern that resembles the skeleton of a herring.

Hertz (Hz). SI unit of frequency, defined as the frequency of a periodic phenomenon that has a period of 1 second, i.e. 1 Hz = 1 oscillation/s.

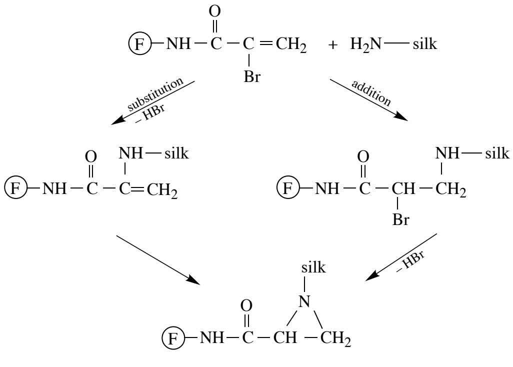
Hessian A coarse, heavy, plain-weave fabric of jute or similar yarn. Natural colour is brownish. Used for wrappings, wall hangings, etc.

Heterobireactive dyes Depending on their reaction mechanism during reaction with the fibre, reactive dyes with a single reactive group are subdivided into two types, i.e.:
a) substitution type
b) addition type.
Bifunctional reactive dyes such as C.I. Reactive Black 5 (20 505) can also react twice with the fibre (bireactive, bifunctional):



Reactive dyes with two different reactive groups, which can react according to both the addition as well as the substitution mechanism, are heterobireactive. They react both in the sense of a nucleophilic substitution as well as in the sense of a nucleophilic addition at a double bond.

Monofunctional reactive dyes of the α-bromoacrylamido type react according to both mechanisms and the same 3-membered aziridine ring is ultimately formed:



The use of bireactive dyes to improve selectivity and the degree of fixation is an old concept.

Let us consider a monoreactive dye (A) with a selectivity of around 60% (degree of fixation 60%) and a dye (B) with two reactive groups, both of which have a selectivity of 60%. From Fig. 1 it can be seen that dye (B) achieves a degree of fixation of almost 85% compared to barely 60% for the monoreactive dye (A).

Bireactive dyes conform to one of the three types schematically represented in Fig. 2 where R_1 and R_2

Heterobireactive dyes

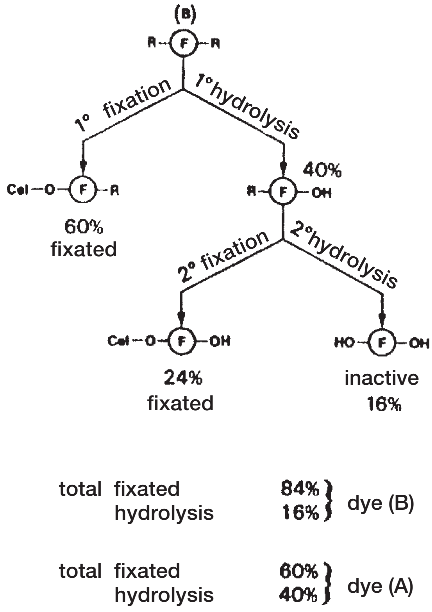


Fig. 1: Fixation and hydrolysis in their effect on reactive dyeing with heterobireactive dyes.

can be either two identical (bireactive dyes) or two different reactive groups (heterobireactive dyes). Exhaust dyes correspond mainly to types 3 or 2, although type 1 is also suitable.The type 1 dyes are, however, to some extent less substantive, less bulky, and are therefore often more suitable for textile printing or continuous dyeing.

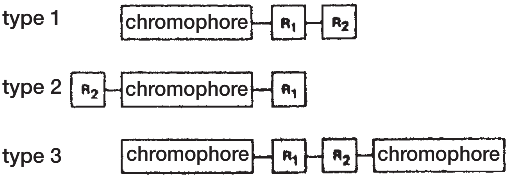

Fig. 2: Three types of heterobireactive dyestuffs.

Bireactive or heterobireactive dyes are already included is some commercial dye ranges:

- The most important representatives of the Cibacron E (Ciba-Geigy), Procion HE (ICI), Procion SP (ICI), and Basilen (BASF) ranges are bi-monochlorotriazine dyes of type 3.
- The Remazol range (Hoechst) contains some bi-vinylsulphone and monochlorotriazine-vinylsulphone dyes of types 1 and 2.
- Sumifix Supra (Sumitomo) dyes are monochlorotriazine-vinylsulphone dyes of type 1.
- The Cibacron F range contains some bifluorotriazine dyes of type 2.
- The most important representatives of the Cibacron C range are bivinylsulphone (type 2) or fluorotriazine-vinylsulphone dyes (type 1) illustrated in Fig. 3.

The second reactive group and the higher degree of fixation have a positive influence on reproducibility of shade since the degree of fixation is not only higher but also more constant.

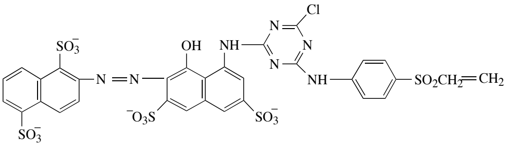

Fig. 3: Vinyl sulphone/monochlorotriazine (Cibacron C). Heterobireactive. Blue-cast red with good acid and alkali bonding stability.

If both different types of reactive group are positioned at each end of the planar dye molecule (Fig. 4) the question arises as to whether, e.g. in the bifunctional linking reaction with cellulose, the spacing of the hydroxyl groups are reached under dyeing conditions.

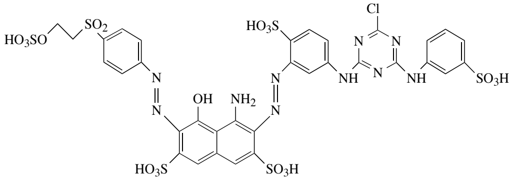

Fig. 4: Structure of a heterobireactive dyestuff.

The number of possible reactions and reaction products with multifunctional dyes is considerably greater than for monofunctional dyes. If the latter react both with the substrate as well as the water in the dye liquor, then two reaction products are formed and, at the end of dyeing, the dye is present as three variants altogether (including its unchanged reactive form). Two of these are present in solution and the third is linked to the cellulose. Taking a heterobireactive dye as an example, on the other hand, eight reaction products are possible and, by analogy with the monofunctional dyes, a total of nine dye variants can exist in this case (Fig. 5).

5 variants are linked to the substrate (c, f, g, h, i), and 4 remain in the dye liquor or can be extracted from the fibre with suitable solvents. The 5 fixation products are especially interesting. However, their analytical identification is difficult due, on the one hand, to their similarity, and the fact that they are not accessible by classical wet chemical methods in the solid state due to

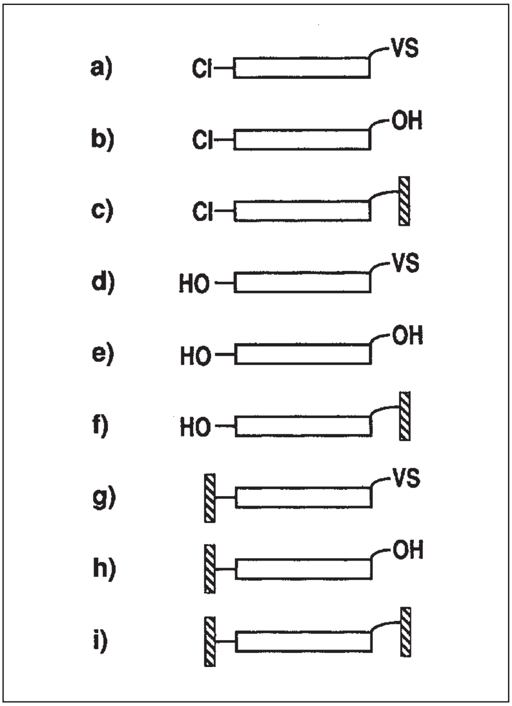

Fig. 5: Diagrammatic view of a heterobireactive dyestuff (a) and its possible reaction products (b-i) on stopping the dyeing process. Cl = monochlorotriazine; VS = vinyl sulphone; hatched = cellulose. The sulphuric acid ester of VS has not been illustrated, because it exists for only a very short time under alkaline conditions.

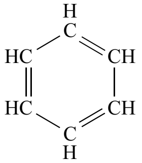
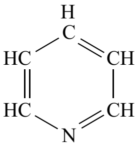
their linkage with the cellulose high polymer on the other (contributed by Meyer and Rys).

Heterocyclic compounds Cyclic compounds which, in contrast to isocyclic → Cyclic hydrocarbons, contain one or several other atoms (nitrogen, sulphur, oxygen, etc.) besides carbon in their ring structure. The most widely known type is represented by the compound pyridine which has structural similarities to → Benzene.



benzene

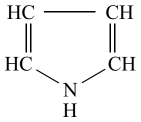


pyridine

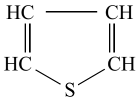
At the same time, pyridine represents the most important 6-membered ring heterocyclic compounds. In addition, there are numerous technically important 5-membered ring structures which are used in dye synthesis (principally vat dyes) as well as some textile auxiliaries, the comparative constitution of which is of interest.

Examples:

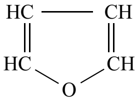
I. 5-membered ring structures with one hetero atom:



pyrrole (azole)

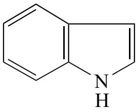


thiophen

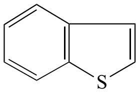


furane

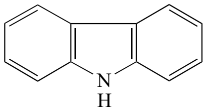
Condensed pyrrole ring systems form e.g. indole and carbazole, whilst thionaphthene (for thioindigo dyes) is derived from thiophene:



indole

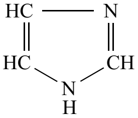


thionaphthene



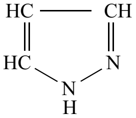
carbazole

II. 5-membered ring structures with two hetero atoms:

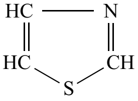


imidazole (glyoxaline)

(isomers)

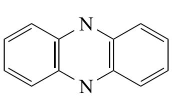


pyrazole

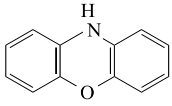


thiazole

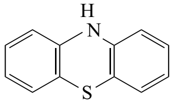
III. 6-membered ring structures linked by hetero atoms:



phenazine
(azine dye)



phenoxazine
(oxazine dye)



phenthiazine
(thiazine dye)

Heterofil fibres Core-sheath bicomponent fibres in which a core of polyamide 6.6 is surrounded by a sheath of polyamide 6. Due to their different melting points, nonwovens and needlefelt floorcoverings can be permanently bonded by a simple thermal treatment (the fibres being bonded at cross-over points through sintering of the outer sheath) without the need for a binder.

Heterogeneous Composed of dissimilar, unrelated or differing parts or elements; e.g. from a dyeing point of view, the wool fibre has heterogeneous properties since, in contrast to the cortical cells with high dye affinity, the outer scale cells have a very much lower affinity due to their different composition.

Heteropolar → Polar.

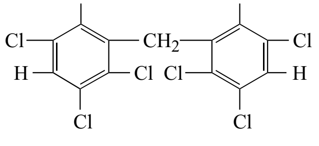
Heteropolar bond → Ionic bond.

Heteropolar compounds Compounds containing → Ionic bonds through the transfer of electrons as is particularly the case with salts.

Heteropolymerization → Polymerization.

Heteroyarns → Core-spun yarns, i.e. yarns produced from two filaments combined in spinning which, e.g. contract differently in thermal treatments to give a texturing effect (e.g. heteroyarns from triacetate and polyamide). Heteroyarns are not → Bicomponent fibres.

Hexachlorophene (dihydroxyhexachlorodiphenylmethane),



White, free-flowing powder; odourless; insoluble in water; soluble in alcohol, acetone, dilute alkalis and soaps. It does not cause skin irritation and is a powerful bactericide. Prevents bacterial decomposition of perspiration.

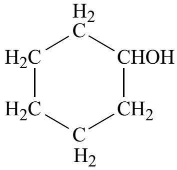
Hexachlorophene test (colorimetric method). A colour which can be measured in a colorimeter is produced from a solution of → Hexachlorophene in methanol with an ammoniacal-alcoholic solution of copper chloride. The test is likewise suitable for the detection of pentachlorophenol and trichlorophenol.

Hexafluoropropene, teflon.

Hexahydrophenol → Hexalin.

Hexahydropyrimidone resins → Propylene ureas.

Hexalin (hexahydrophenol, cyclohexanol),

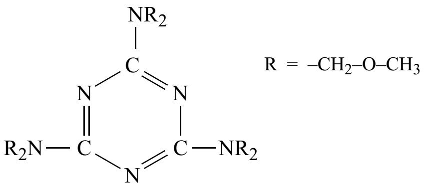


A colourless, oily liquid with a camphor-like odour, hygroscopic, sparingly soluble in water, miscible with most organic solvents and oils. MW 100, density 0.947, combustible. Hexalin is a good solvent for fats, oils, mineral oils, waxes, resins, asphalts, rubber, metal soaps. It also dissolves acetate filament/staple fibres.

Uses: in soap making for the incorporation of grease-solubilizing solvents; spotting agent; thinner for paints, lacquers and varnishes, etc.

Hexametaphosphate, sodium → Graham's salt.

Hexamethoxymethylmelamine → Methoxymethylmelamines:



Hexamethylene (cyclohexane, hexanaphthene, hexalhydrobenzene), $(CH_2)_6$; → Alicyclic hydrocarbons.

Hexamethylenediamine, $H_2N–(CH_2)_6–NH_2$; the chemically correct name is 1,6-diamino- hexane. In the synthesis of polyamide 6.6, hexamethylenediamine forms important base components which represent the main raw material costs. It is derived from the reaction of adipic acid (likewise a raw material for the synthesis of polyamide 6.6) with ammonia (catalytic vapour-phase) to yield adiponitrile, followed by liquid-phase catalytic hydrogenation as follows:

$$\begin{tikzcd} HOOC\text{—}(CH_2)_4\text{—}COOH \arrow[d, "2\ NH_3"] \\ NC\text{—}(CH_2)_4\text{—}CN \arrow[d, "4\ H_2"] \\ H_2N\text{—}(CH_2)_6\text{—}NH_2 \end{tikzcd}$$

adipic acid

adipindinitrile

hexamethylenediamine

Hexamethylenetetramine (hexamine; methenamine; urotropine), $(CH_2)_6N_4$. White, crystalline, hygroscopic powder. Soluble in 1.5 parts water and 10 parts alcohol, readily soluble in chloroform, insoluble in ether. Uses: e.g. metal powder printing.

Hexane, C_6H_{14}. → Saturated hydrocarbons.

Hexanol (hexyl alcohol), $C_6H_{13}OH$. → Alcohols.

Hexon bases A term used to describe amino acids containing a basic amino group of the diamino-carboxylic acid type, e.g. arginine, histidine and lysine.

Hexoses Carbohydrates with six carbon atoms →: Sugars; Carbohydrates.

Hexyl The straight chain group C_6H_{13}. → Alkyls.

Hexyl alcohol → Hexanol.

HF, abbrev. for: → High frequency current.

Hf, chemical symbol for hafnium (72).

Hg, chemical symbol for mercury (80).

Hierarchical fibre structure In their morphology, natural fibres in particular are characterized by a marked hierarchical fibre structure (Figs. 1 and 2).

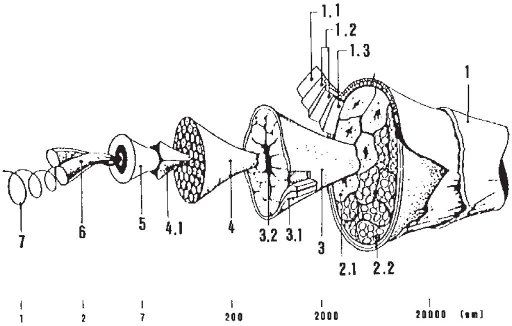


Fig. 1: Hierarchy of a fine merino wool fibre.
1 = cuticle; 1.1, 1.2, 1.3 = epicuticle, exocuticle, endocuticle; 2.1, 2.2 cell in the paracortex and orthocortex (cortex); 3 = cortex cell; 3.1 = cell membrane complex; 3.2 = nucleus residue; 4 = macrofibril (50–200 nm); 4.1 = interfilament material (matrix) of intermediary filament associated proteins (IFAP); 5 = intermediary filament (microfibril) of keratin (IF, 7–11 nm); 6 = dimer (left-handed double cord); 7 = right-handed a helix.

With cotton fibres, the individual layers of this hierarchy (see Tab.) can be reached with the aid of swelling agents having different action which makes them accessible for textile finishing processes. In the case of wool, as a biological composite, this accessibility is more difficult.

name of structural element	diameter	number of cell molecules in the cross-section	swelling agent	individually insulated after swelling	bonds still in existence after swelling
fibre	0.06 up to 0.2 mm	10^9	CsOH	convex and concave part (the latter swollen)	all in the convex part
macrofibril (crystallites)	0.4 µ = 400 nm	500 000	morpholine	microfibrils (i.e. crystallographically aggregated elementary fibrils)	crystals in elementary fibril bundles (no more intercrystalline interactions)
microfibril	200 up to 30 nm	2 000	$ZnCl_2$, ether	4 elementary fibrils	crystallisation and hydrogen bridges (cell I)
elementary fibril	3.5 nm	42	4 n NaOH	elementary fibril defects	cell I, intermolecular hydrogen bridges
elementary cell	0.6 nm	2	conc. NaOH (mercerising lye)	“sheets” (antiparallel)	intramolecular hydrogen bridges, cell II van der Waal’s interactions
molecule	0.5 nm	1	cuprammonia	polymer chain	transdiglycols form complexes, i.e. triggering the intramolecular hydrogen bridges and consequently rigidity and van der Waal’s interactions

Tab.: Hierarchical structure of cotton cellulose.

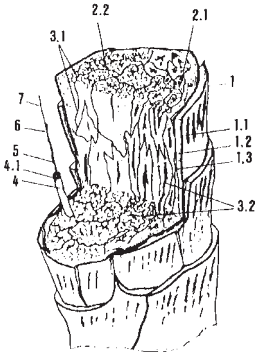

Fig. 2: Longitudinal and transverse cross-section of a fine merino wool fibre for explaining the hierarchical wool fibre structure (explanation in Fig. 1).

High-bulk yarn (HB yarn) → Textured yarns.

High capacity yarn packages
Yarn packages with a maximum diameter of 300 mm weighing up to 3.6 kg which are used particularly for wool and acrylic yarns. They offer advantages of shorter liquor ratios, e.g. down to 4.5 : 1, and a doubling of the dyeing machine capacity.

High concentration bleach A continuous bleach process in which high quantities of chemicals are applied by impregnation resp. padding, and bleaching takes place by a subsequent dwell stage or steaming.

High density polyethylene → Polyethylene.

High frequency current An alternating current with over 100 000 oscillations (frequencies) per second. Whilst the tension (volt) can certainly be high at these frequencies, the current (ampere) is greatly reduced.

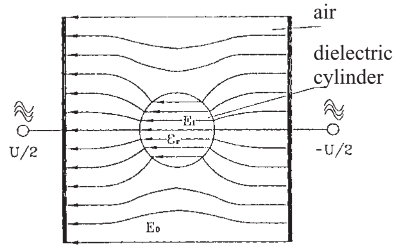

Fig. 1: Schematic field distribution between electrodes.

High frequency driers High frequency driers employ high frequency electromagnetic waves at frequencies from $v = 10^5–10^{12}$ Hz with corresponding wavelengths from $\lambda = 3$ km (radio waves) up to 300 μm (Hertzian waves). However, officially designated frequencies have been allocated for industrial applications in order to avoid possible interference with radio communications. Frequencies approved by inernational agreements for industrial use are:

13.56 MHz ± 0.05%
27.12 MHz ± 0.60%
40.68 MHz ± 0.04%

High frequency driers used in the textile sector are based on dielectric heating in the megahertz range since, in the microwave heating range, i.e. in the gigahertz range (10^9 Hz), there is a risk of yarn packages bursting due to excessive build-up of steam pressure in the wet medium. Most high frequency driers work with voltages of 10 000–30 000 V at an operating frequency of 13.56 or 27.12 MHz. High frequency generators have a power rating of 30 and 60 kW. The principle of dielectric heating is based on the fact that a dielectric material is either an insulator, i.e. non-conducting, or a very poor conductor of electric current. In high frequency drying, an electrical field is produced inside the dielectric material (e.g. yarn package) as a result of which the dielectric becomes polarized, i.e. a separation occurs between the positively and negatively charged sites in the molecule (Fig. 1). A dielectric material increases the capacity between the capacitor plates by a factor ε (the dielectric constant) compared to the capacity in the absence of the dielectric.

The arrangement of the yarn package as a dielectric cylinder in the originally homogeneous field between the plate electrodes represents a particularly favourable solution as far as an even distribution of high frequency field strength in the material being dried is concerned. In this case, the field distribution between the electrodes is to be understood as a homogeneous electrical field where a constant field strength E_i prevails:

$$E_i = E_0 \frac{2}{\varepsilon_r + 1}$$

where
E_0 = air field strength,
ε_r = relative dielectric constant of the material being dried.

The ruling field strength E_i which is responsible for the high frequency power density in the material being dried depends on the air field strength E_0 determined by the distance between the electrodes a and the electrode voltage U. When $\varepsilon_r = 78$, e.g. (pure water at 25°C), E_i is only 2.5% of the air field strength E_0 but when $\varepsilon_r = 3$ (dried material), the field strength at $E_i = 0.5\ E_0$ in the material would be 20 times higher.

The high frequency power density P/W cm^{-3} in the material being dried is given by:

$$P'' = E_i^2\ 2\pi f\, \varepsilon_0\, \varepsilon_r \tan\delta\ \mathrm{W/cm^3}$$

where
f = frequency,
$\varepsilon_r \tan\delta$ = loss product of the material (dependent on type of

material, moisture content, temperature and frequency),
ε_0 = $0.886 \cdot 10^{-13}$ As/Vcm.

By having the electrodes inclined in the direction of passage, the air field strength E_0, and thus the material field strength E_i, can be adjusted to the loss product $\varepsilon_r \tan \delta$, which changes during the progression of drying, in such a way that the power density P“ is adapted to the progression of drying (e.g. high power density during the heating up and initial evaporation stage, low power density towards the end of the drying operation). By ignoring any heat exchange with the surroundings, a good approximation of the total high frequency power requirement P_{HF} of a high frequency drier is obtained from the energy required to heat up the wet textile material to the evaporation temperature of water and from the energy required to evaporate the water:

$$P_{HF} = \frac{m_1}{t} c \Delta T + \frac{\Delta m}{t} q_{H_2O}$$

where
m_1/t = initial mass throughput,
c = specific heat,
ΔT = temperature increase to approx. 100°C,
$\Delta m/t$ = quantity of water evaporated per unit time,
q_{H_2O} = heat of evaporation of water.

This power requirement P_{HF} is given, on the other hand, from the mean value of the power density P” and the volume of material in the working capacitor:

$$P_{HF} = \bar{P}'' V_{Mat}, \qquad \text{i. e.}$$

$$\frac{m_1}{t} c \Delta T + \frac{\Delta m}{t} q_{H_2O} = V_{Mat} \bar{E}_i^2 \, 2\pi f \varepsilon_0 \, \overline{\varepsilon_r \tan \delta}$$

The higher the dielectric constant and the lower the conductivity, the greater the capacity of the capacitor. Examples of dielectric constants for a few technically important materials are given below:

vacuum	1.000000	benzene	2.3
air (18 °C)	1.00058	water	81.1
paraffin	1.7–2.3	ice	3.2
paper	1.8–2.5	glycerol	56.0

Separation of the positive and negative charges in the molecule or atom, i.e. the orientation of the molecules (dipoles) in the insulator is the reason why uniform heating is possible in each element of the yarn package volume. This uniform heating is created by oscillations of the molecules or atoms from the position of rest to 13.56 million times a second (at 13.56 MHz). This kinetic energy, and the frictional heat developed from it, is due to frictional forces formed by the uneven rhythm of the atoms or molecules. The intensity of molecular mobility is dependent on the polarity of the alternating field which is controlled by the generator frequency. Dielectric heating generates heat directly within the material itself, e.g. in a yarn package, there is no flow of air from inside to outside or vice versa, as in conventional through-circulation drying with hot air. The water inside the package is therefore evaporated by frictional energy and driven to the surface of the material in gaseous form from where it is transported away by the hot air system before condensation can take place. Since the intensity of drying is ultimately dependent on the dielectric constant, dry fibres absorb less high frequency energy than wet fibres so that a conditioned drying is possible. Since the turnover of heat energy is directly proportional to the water content, the conditioned weight is achieved to an accuracy of within ± 1%. The material itself is virtually unheated by the evaporation process since the yarn is only heated indirectly by the outflowing steam. In this case, the temperature barely exceeds 100°C. Consequently, migration of substances to the surface of the material does not arise since this can only occur in a wet medium.

In practice, material to be dried in a high frequency drier is, as a rule, hydro-extracted beforehand by centrifuging in order to achieve a low initial moisture content and therefore ensure an economical drying process (energy, time, efficiency, costs). Furthermore, high frequency drying is independent of the package density, size of package, the dyed shade or variations in the initial moisture content for the same height of package and the same material. Natural fibres such as wool, cotton and their blends can be dried without any problem, whereas polyamide, acrylics and their blends must be dried with care since spontaneous decomposition can begin due to the steep rise in the dielectric loss factor at higher temperatures. However, if the dwell time is correctly controlled, these products can also be dried without problem. This danger does not apply to polyester fibres. In the case of plastic polymers, heating does not take place by molecular movements and resultant fric-

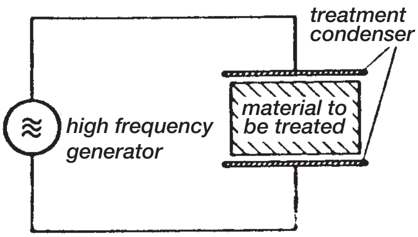

Fig. 2: Plate type electrode system.

tional heat, but by oscillations, rotations, etc. (directional transposition) of individual polarizable sites in the polymer chains which is then converted into heat energy. The frictional theory is not applicable in this case, since the molecules are firmly anchored within the chains.

1. Plate-type electrode systems (Fig. 2) are used in the drying of flat substrates and yarn packages, cheeses and the pre-warming of bales of fibre, etc.
2. Stray field and staggered field electrodes consist of tubular rod electrodes positioned at right angles to the direction of the moving web of material. The rods are staggered in relation to each other. The electrodes, positioned above and beneath the web of material, are connected in parallel in each case to one pole of the high-frequency generator. Compared to plate electrodes, the energy density produced by stray field electrodes (Fig. 3), in fibrous webs or similar materials is higher by a power of ten. They are used for drying open-width fabrics and yarn sheets.

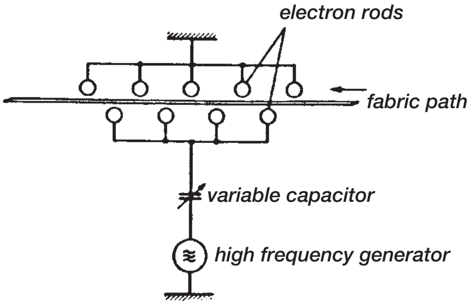

Fig. 3: Stray field electrodes.

In principle, a high frequency drier consists of three main components:
- the machine frame,
- the drying chamber with electrodes,
- the high frequency generator.

All necessary equipment for the operation of the drier is installed on and within the machine frame, e.g. the transport system, air heater, fan, air ducts, electrical control panel, cooling water vessel and pump, electrical heating, etc., which vary from one manufacturer to another. The drying chamber, usually of stainless steel construction, is built into the main frame in such a way that the entire machine is screened to prevent interference with radio and television transmissions. The drying chamber is a closed unit with openings at the entry and delivery ends. The installed electrodes are adjustable in height and the material being dried is passed between the capacitors continuously (continuous machine) or discontinuously (heating chamber). Water molecules in the material are set in motion and evaporated by a generated alternating current. The water vapour is absorbed by a supply of dry air and discharged into the atmosphere through exhaust air ducting before condensation can take place. The incoming air for this purpose is heated first of all in order to remove moisture since the drier the air, the more moisture it can absorb. Drying of the incoming fresh air is carried out in a heat exchanger in which fresh air is heated by the heat loss from the generator so that transformation losses are recovered. The electrode voltage must also be high enough for the electrodes to withstand any voltage surges.

The high frequency generator consists of the components illustrated in Fig. 4.

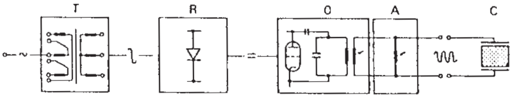

Fig. 4: High frequency generator wiring diagram principle.

The high frequency energy required for the heating process is produced by a high frequency generator in which the normal low tension of a three-phase network is converted into high tension by the transformer T. The static rectifier R converts the generated AC voltage into a DC voltage which is then converted into a higher frequency voltage by the tube oscillator O. The resultant high frequency voltage is then fed to an adapter unit A via a coupling coil where the working voltage can be regulated by hand or motor drive. Depending on the design and site of the drier, the high frequency generator is installed either above or adjacent to the drying chamber in a sealed metal housing (Fig. 5).

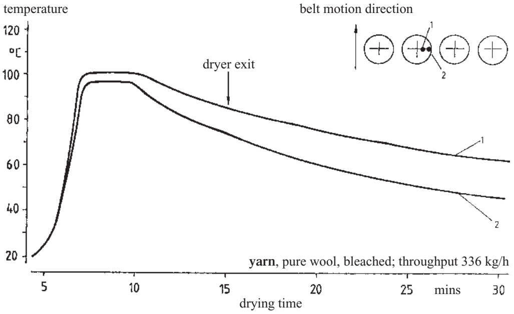

Fig. 6: Temperature curve in drying dye bobbins (100% wool) in an industrial high frequency drier.

In a high frequency drier for the continuous drying of yarn packages forced ventilation of the drying chamber is necessary. During the course of drying (Fig. 6), no temperatures higher than 110°C have been measured in yarn packages (source: Böhnke).

High frequency drying (HF-drying, RF-drying, dielectric drying). Drying takes place between two capacitor plates supplied with a constant high frequency AC voltage. The textile material is heated and dried by high frequency electrical oscillations whereby the depth of penetration is independent of material thickness so that HF-drying is particularly suitable for drying yarn packages. High frequency drying can also be used for warp sheets, tops, loose stock, hanks and garments. High frequency heating is employed in the bonding of polyamide-based nonwovens. →: High frequency driers; Drying systems.

High frequency dye fixation Dye fixation with the aid of high frequency energy. For high frequency applications the form of the electrodes is of decisive importance.

High gloss finish, high lustre finish → Embossing.

High grade synthetic resins. Synthetic resins free of fillers. Mainly → Phenolic plastics, used for a variety of applications.

High humidity measuring instrument Control systems for the contact-free continuous measurement of liquor content across the full width of fabrics during impregnation processes. These units are typically installed behind liquor application systems, e.g. padders, coating machines as well as for the control of predriers on thermofixation ranges, etc. Two different types of measuring system have been developed, i.e. a) direct measurement and b) difference measurement between dry and wet material. In all cases, however, the principle is based on the reflection of microwave or beta-ray transmissions.

Highly sulphonated oils → Sulphonated surfactants.

High modulus fibres → High wet modulus fibres (HWM fibres).

High performance liquid chromatography (HPLC). Like → Gas chromatography, HPLC is based on the separation of mixtures of substances by sorption processes between a stationary phase and the individual components of the mixture in the mobile phase. In HPLC a solution of the component mixture is pumped through a column containing the stationary phase under pressure. As a chromatographic technique, HPLC is always preferred to gas chromatography when the substances in the mixture are non-volatile (in general, substances with high molecular weights) or thermally unstable. For this reason, HPLC is used for the analysis of medicinal (pharmacological) materials, the determination of active substances in biological matrices and the analysis of synthetic polymers, etc. The obvious prerequisite for HPLC is that the mixture of substances, or substance, to be analyzed is soluble in a suitable solvent or solvent mixture. HPLC is also extensively used in the environmental protection field. Its main applications include the detection of polar non-volatile substances and the analysis of pesticides. Aldehydes may be separated and identified after derivation with 2,4-dinitrophenylhydrazine. An interesting application is e.g. the identification of formaldehyde in cigarette smoke. To this end, 30 ml of smoke are intensively mixed with 1 ml of reagent solution and eluted with water/acetonitrile at a flow rate of 1.5 ml/min. Detection is by spectrophotometer at 350 nm.

In dyeing investigations, HPLC permits the simultaneous separation and quantitative determination of reactive and hydrolyzed dye components, and is therefore particularly suitable for investigations into the course of reactions in reactive dyeing (→ Chromatography).

In addition to purely qualitative investigations, HPLC also enables quantitative comparisons to be carried out. Essentially, HPLC represents a more efficient further development of column chromatography with many separation layers in which newly developed packing materials (e.g. modified microparticulate silicas) are used, thus drastically shortening the material transport diffusion path. Constant flow rates are also achieved in HPLC with the mobile phase being pumped at pressures between 100–500 bar.

High polymers (macropolymers). Polymolecular mixtures of → Polymer homologues.

High pressure atomisers Atomisers used, e.g. for lubrication purposes, which employ centrifugal force high performance jets for lubricant emulsions subjected to liquid pressures between 50–150 bar and higher produced by high pressure pumps.

High pressure drier A drier for yarn packages in which the packages, supported on a carrier frame, are hydro-extracted/dried with high velocity hot air.

High pressure dyeing → High temperature dyeing.

High pressure hydrogenation → Fats, high-pressure hydrogenation of.

High pressure spray washing tower An open-width washing machine for viscose fabrics in which the goods are laid on rippled metal plates and sprayed with wash liquor through high-pressure nozzles. The working principle is the same as that employed in the → Spray washing machine with high-pressure jets. The liquor is fed to the nozzles by a centrifugal pump.

High pressure steam Steam at a pressure greater than 2 bar. Both → Saturated steam and → Superheated steam can be handled in this form. The difference between the two is given by the respective temperature.

High pressure steamer → HT pressure steamer.

High pure water Water of reagent quality. Produced from pure water with the following aftertreatments: prefiltration, activated charcoal adsorption, mixed bed ion exchange, sterile filtration. Highly pure water is low in ionized and organic impurities, free from germs and solid particles without the operating costs of the plant exceeding those of simple distillation.

High shrinkage yarns High-bulk yarns containing 30–40% → High-shrink fibres, also used in blends with wool. → Textured yarns.

High-shrink fibres Physically modified types of synthetic fibres which undergo shock shrinkage (by approx. 40–45%) in boiling water or hot air (heat-setting temperature 185°C). Normal acrylic and polyester fibres are used in blends with pre-shrunk fibres for the production of high bulk yarns (→ Textured yarns). The physical modification of, e.g. the homopolyester is concerned with texture only and is achieved by changing the degree of orientation and crystallinity of the polymers. Polyester high-shrink fibre types, which exhibit optimum molecular orientation after drawing but only a relatively low degree of crystallinity, shrink during heat-setting and are transformed into a crystalline system with a lower energy content which gives deeper shades after dyeing with disperse dyes. Moreover, polyester high-shrink fibres, for example, also undergo a boiling shrinkage of approx. 45% at dyeing temperature (98–125°C). Consequently, after dyeing in the form of loose stock, tops or yarn, the material is already fully shrunk and cannot, therefore, give rise to any further contraction in fabrics produced from such fibres during subsequent thermal aftertreatments (heat-setting).

High solids thickener → Low/high solids thickeners.

High-speed spinning The demands for higher quality, increased productivity and lower production costs which began in the 1970's, led to modifications in spinning technologies. In the classic → Melt-spinning process, filament extrusion speeds of approx. 1000 m/min are employed. The desired physical and textile properties are achieved in subsequent drawing. Initially, the combined spin-draw-wind process represented an alternative to this technology. Filament yarns produced by this method gave similar properties to those produced by the classic technologies. Consequently, high-speed spinning and winding technology was developed as an economically attractive variant. The properties profile of these filament yarns is, however, not identical to that achieved by conventional spinning technologies. For this reason, production of fibres by high-speed spinning methods has to be taken into account (especially by the textile finisher). Two-stage methods offer the greatest flexibility. Starting from partially-oriented yarn (POY), a fully-oriented flat yarn is obtained by simple drawing in draw twisting, stretch winding or stretch warping. The same POY serves as feedstock for the air-jet and false-twist texturing processes. Flat yarns may be produced by the particularly economical single-stage process. In this case, a distinction is made between spin drawing and high-speed spinning. In both cases, the product is a bobbin of fully-drawn yarn. In the spin drawing process, however, final orientation is achieved in two steps whilst in high-speed spinning, the polymer filaments are drawn only in the cooling zone below the spinnerets where they assume their final orientation.

Single-stage processes for the production of flat filament yarns are compared schematically in Fig. 1. The simplest process, in terms of machine technology, is shown in Fig. 2. In this case the polymer melt is extruded through spinnerets and, after the resulting filaments have cooled down, a spin finish is applied and they are wound on bobbins. In the two other cases, however, an additional drawing stage is interposed between cooling and winding by drawing the filaments through godet rolls or against air friction. Both these drawing variants are practically the same as far as the physical structure of the yarn is concerned.

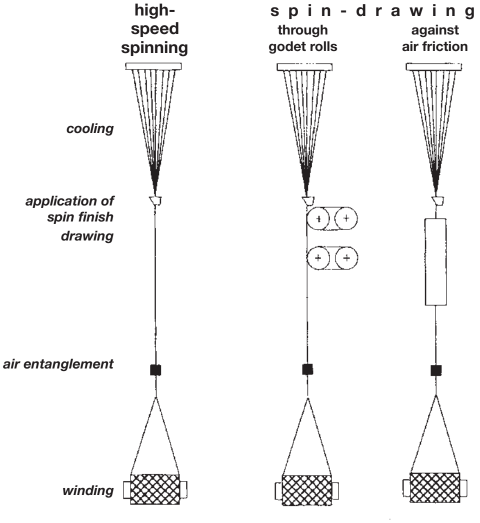

Fig. 1: Single-stage high-speed spinning processes (source: Tekaat).

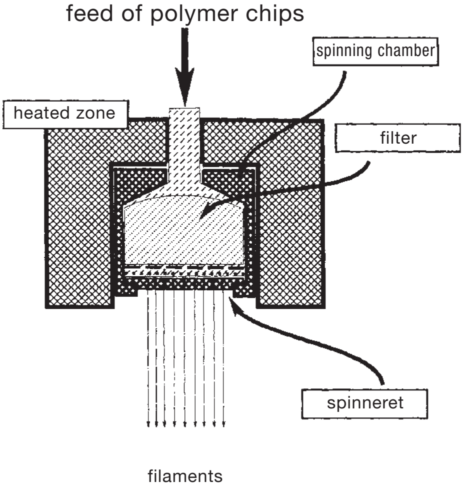

Fig. 2: Flow of molten polymer in the spinning chamber (source: Tekaat).

Stress-strain curves for filaments spun at different speeds are shown in Fig. 3. It can be seen that filaments spun at a speed of approx. 3000 m/min, which corresponds to that usually employed in draw-texturing, still have a delayed deformation (creep) of approx. 40%. It is only at speeds above approx. 5000 m/min that the first rise of the stress-strain curve is so steep that the filaments could be processed on normal textile machines. The precise drawing speed depends on the cooling conditions as well as the linear density of the individual filaments: the finer the filaments, the more quickly they cool down and a high orientation of the filaments is achieved at quite low drawing speeds which results in a steep stress-strain curve (source: Tekaat).

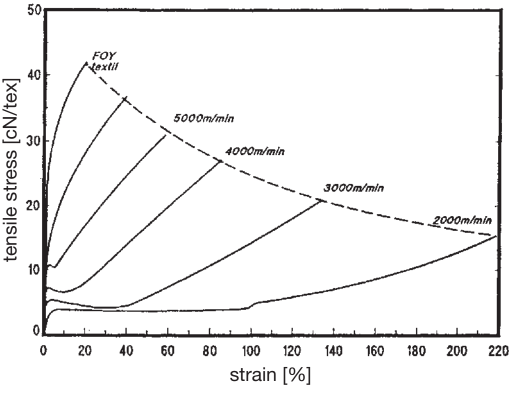

Fig. 3: Stress-strain curves for polyester filaments spun at different speeds (source: Tekaat).

High speed washer A rope washing machine for wool piece goods with increased throughput speed. Manuf.: Hemmer.

High-tech fibres The synthetic filaments and fibres with breaking strengths of 3–10 cN/dtex and E-modulus of approx. 35–130 cN/dtex, which are presently used in great quantities, achieve only approx. 10–25% of the theoretically possible strength or E-modulus. This is due, on the one hand, to irregularities in the partially crystalline fibre structure and the molecular weights of the fibre materials and orientation of the molecular chains on the other. By using materials with an extremely high molecular weight and drawing the filaments to the limits of possibility, a much closer approach can be made to the theoretically possible strengths and E-modulus. However, these procedures are only possible up to now for polyethylene and other linear chain molecules without large side chains (e.g. polytetrafluoroethylene, polyvinyl chloride and, perhaps, also polyacrylonitrile and polyvinyl alcohol). In the case of polyethylene, molecular weights of $2 \cdot 10^6$ with filament strengths of 30–35 cN/dtex have been achieved. Compared to the classical synthetic fibres, these so-called “high-tech fibres” are of increasing importance for technical textiles (geotextiles, filter materials, composites, protective clothing, etc.). The wide spectrum of chemical structures for such fibres can be summarized, in a highly simplified form, by the most important building blocks, i.e. the aromatics, as well as the temperature-resistant linkages and resultant polymer classes (see Table: Survey of technically used high performance fibre materials).

The properties of these fibres (with differences in relative importance) include high tensile strength, high thermal stability, low combustibility, high chemical resistance and good electrical resistance. The fields of application for these fibres demand a wide range of properties which are not adequately covered in generally available technological tests. Thus, for example, when such fibres are used in the filtration field they are subjected to short-term mechanical stresses in both longitudinal and transverse directions of the fibres due to the frequent cleaning cycles required (contributed by Falkay).

High temperature amylases A term used to define a new generation of desizing agents in the form of starch-degrading enzymes obtained by microbiological processes. These enzymes are still active at working temperatures of 100°C and above, thereby requiring extremely short reaction times.

High temperature contact process A process used for surface bonding of fibrous webs, coated and milled or needled felts, back-coated and tufted carpets on a contact drying machine. The process is based on the principle of direct contact drying between the coated side of the substrate and the cylinder surface at high temperature.

High temperature dyeing (HT dyeing). The dyeing of textiles at temperatures above 100°C in pressurized equipment → High temperature dyeing machines. The chief advantage is prevention of pump cavitation and consequent secure liquor circulation. High temperature dyeing has specific advantages for the dyeing of various fibres, especially the low-swelling or non-swelling synthetic fibres without reactive groups, i.e. above all polyester and triacetate fibres and their blends with other fibres. For cellulosic fibres, high temperature dyeing also offers advantages of reduced swelling and the de-aggregation of dye molecules, especially direct dyes, above a certain temperature with consequent improvement in dye penetration, more rapid levelling and therefore the possibility of reduced dyeing times. A strict selection of direct dyes and the addition of textile auxiliaries to prevent dye decomposition on boiling is necessary. New dyes have been developed for high temperature dyeing (Ditherm Fast dyes). Under HT conditions, vat dyes are better applied in the pigmented form only and then vatted in the usual way. Sodium dithionite (hydrosulphite) is not satisfactory as a reducing agent for dyeing under HT conditions, and a more temperature-stable reducing agent must be used. For wool, HT dyeing offers advantages of increased dye levelling and shorter dyeing times compared to dyeing at the boil. in order to maintain optimum wool quality, however, a maximum dyeing temperature of 106–108°C must not be exceeded. It has to be borne in mind that wool suffers the least damage under low temperature dyeing conditions at 80°C. For this reason, HT dyeing is less important for dyeing 100% wool articles than for wool/synthetic fibre blends. For synthetic and triacetate fibres, HT dyeing offers advantages of higher dye yields due to the increased dye diffusion rate, the achievement of deeper shades without carriers, a reduced tendency for stripiness in dyeing (modacrylic, polyester) and optimum dye levelling.

High temperature dyeing machines (HT dyeing machines). These machines offer the possibility of a closed dyeing system suitable for all dyeing temperatures under pressure (besides temperatures near the boil below 100°C) to achieve the objectives of → High temperature dyeing by raising the boiling point of the dye liquor and eliminating pump cavitation problems. In the dyeing process, which takes place under total exclusion of the external atmosphere, a static pressure prevails (produced by an auxiliary pump, water pressure, steam pressure, or compressed air) which either maintains the vapour pressure of the dyebath (static pressure) or lies above it in order to achieve the desired temperature above the boiling point of the liquor. Most high temperature dyeing machines use so-called expansion vessels (Fig. 1) which can be maintained at the same pressure as the entire dyeing machine to absorb liquor expansion and facilitate dyeing additions, or they may be open and can then receive the quantity of liquor which corresponds to the increase in liquor volume by means of a special valve. Other constructions provide space for liquor expansion underneath the cover of the autoclave or they also function without any expansion and overflow tank (Fig. 2). Such machines are subject to regulatory control (regional and state regulations often vary). The upper dyeing temperature limit of 130°C is not due to dyeing considerations but has been laid down by the German TÜV (Technische Überwachungsverein = Technical Inspection Association) as the material-specific upper limit for steel walls of high pressure vessels of normal thickness. Depending on the field of application, high temperature dyeing machines include the following types:

I. Pressure jiggers (→ HT-jigger).
II. Pressure star frames, give good results but suffer from low performance.
III. → HT beam dyeing machines (horizontal); most are also designed for yarn package dyeing.
IV. Automatic hosiery dyeing machines.
V. → HT dyeing machine for yarn and loose stock dyeing.
VI. HT jet dyeing machines.
VII. HT winch dyeing machines.

High temperature exhaust dyeing → Vat dyeing.

High temperature fibres Organic and inorganic fibres such as →: Ceramic fibres; Glass fibres; Aluminium silicates; Metal fibres. A collective term for especially → Fire-resistant fibres and heat-resistant fibres composed of organic macromolecular compounds which exhibit heat stable properties over a time-related

period whilst largely maintaining their technological characteristics and whose strength only falls to zero under normal atmospheric conditions at approx. 3000°C. The basic polymer molecule consists mainly of aromatic ring systems which are linked together by carbon, oxygen or nitrogen atoms, possibly via heterocyclic groups, and which contain only a few hydrogen atoms. High temperature fibres include a variety of macromolecular groups; linear macromolecules, ladder polymers, molecular networks up to the graphite fibre type (→ Carbon fibres), aromatic polyamides (→ Aramide (fibres)), polyimides (→ Arimide (fibres)), polyamide-imide fibres (→ Aramideimide fibres), polybenzimidazole (PBI), poly (bisbenzimidazobenzo) phenanthroline, polyterephthaloyloximidazol-metal chelate, polypyrone, poly-2,6-diphenyl-p-phenylene oxide.

High temperature heat transfer medium → Heat transfer medium.

High temperature light fastness Upholstery materials, glove boxes, parcel shelves, etc., in automobile interiors are subjected to relatively high temperatures due to the extensive area of glass in windows and windscreens. These conditions favour colour fading due to the action of UV radiation. A normal light fastness test is therefore not adequate for automotive textiles. An additional effect is due to the fact that absorbed light not only results in the photochemical degradation (of dyes and fibres) but also causes heating. UV light is primarily responsible for degradation reactions initiated by light. With dyes which are known to cause fibre tendering, visible light also contributes to accelerated degradation. Besides initiating photoreaction, absorbed light produces heat. Thus, in → High temperature light fastness tests for example, considerable differences in the test specimen temperatures can be found depending on the shade (see Table).

dyestuff	quantity (%)	absorbed radiation capacity (W/m²)	test specimen temperature (°C)
undyed	—	246	83
Irgalan yellow	0.05	379	84
GRL 200 %	1.05	620	
Irgalan Bordeaux	0.06	472	86

Tab.: Comparisons of absorbed radiation capacity with test specimen temperature in a hot exposure test (polyamide tricot; black body temperature 89 °C ; Irgalan dye = Ciba-Geigy).

High temperature light fastness tests In addition to the usual requirements (surface uniformity, shade conformity, rubbing fastness, fibre comfort), extremely high requirements have now been placed on the high temperature light fastness of textiles for automobile interiors. These requirements can differ quite markedly depending on the automobile manufacturer as well as the intended use in the automobile interior. It

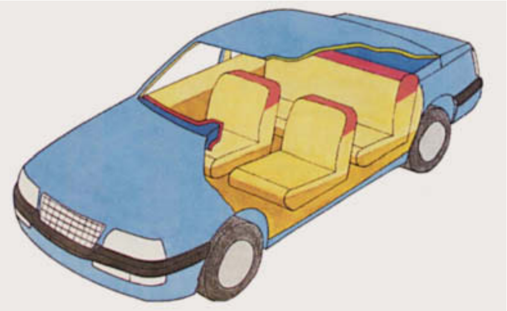

Fig.: Motor car textile light fastness requirements. brown = low; green = average; yellow = high; red = very high; dark blue = highest.

Specification/ description	Important criteria	Remarks
SN-ISO 105-B 02 „Xenon“	- Xenon radiator - light filtering: UV radiation < 310-320 nm remote IR radiation with glass or water filter 90% radiation in the 380-750 nm range - black body temp. < 45°C - rel. humidity ~ 60% - return run (light/dark 1:1)	- usual method of determining light fastness - numerical light fastness evaluation against blue scale 1-8
DIN 75.202 „Fakra“ Determination of the light fastness of motor vehicle interior fitting materials	- Xenon radiator - light filtering: UV radiation < 290 nm remote, rel. irradiation intensity of 290-400 nm, approx. 10% (relative to irradiation intensity 290-800 nm) IR radiation with glass or water filter - black body temperature 100-115°C } depending on type of equipment - test room temp. 40-72°C - air humidity 20±10% - same direction	- latest specification; hot exposure method particularly German car manufacturers; numerical light fastness evaluation against blue scale 1-8 (= single test cycle of 80 ± 16 hours), inaccordance with grey scale 1-5, if multicycle - all time data in this table relates to DIN 75.202, draft 11) 1984; i.e. single test cycle = 96 hours.

Tab.: High temperature light fastness tests.

is certainly possible for different automobile manufacturers to specify different colour fastness requirements even when following the same test specification. This means that the test specifications and the required results are to be regarded as fundamentally separate. In general, a clear trend towards even higher requirements can be detected where, in most cases, the same test specification is used, but with extended times of exposure. An overview of the strictness of the requirements, corresponding to the location of use of the textile material can be gained from the Figure.

At the beginning of the 70’s, a few automobile manufacturers switched over to newly developed test methods due to the fact that more and more glass was used in automobiles and the light fastness requirements were raised correspondingly. On the one hand, the light fastness tests introduced into the textile field many years ago were too slow and, on the other hand, the degree of correlation between laboratory results and the actual exposure under conditions of use was often unsatisfactory. Consequently, a great number of test specifications were drawn up requiring different types of apparatus and filter systems, besides specifying different conditions of temperature, humidity and time of exposure (→ Automotive textiles, light fastness testing). Comparisons between test results are therefore extremely problematic and is made even more difficult by the generally moderate reproducibility of the tests. This has led to a situation where certain dyes or their combinations give very good results in some tests and only moderate results in others. Correlation with conditions in practical applications are therefore questionable even when the ranking changes depending on the test method. It is clear that, in some tests, unnecessarily severe test conditions have obviously been specified for the raw materials to be used. With improved knowledge of the relationships involved a better, and to some extent, even more economical product selection should be possible. This unsatisfactory situation for all participants has led to efforts by various standards organizations to standardize the test methods.

In addition, efforts have been, and are being, made by various countries to a greater or lesser extent, to achieve better correlation of laboratory results with actual applications in practice (see Table).

The practical application of the high temperature light fastness test according to DIN 75 202 has been investigated in an interlaboratory trial involving 5 test centres. The results of the interlaboratory trial have shown that the wide tolerances of the test parameters and other factors can influence the test results considerably. With specified preconditions, however, it is possible to reduce the variation of test results and thus improve the reproducibility of the DIN procedure.

It has furthermore proved to be the case that, with increasing times of exposure, the Grey Scale is more suitable as an evaluation standard than the co-exposed blue standards.

High temperature resistant →: Thermal stability of dyes; Thermal stability of fibres.

High tenacity fibres (high tenacity rayon). Special fibres (filament or staple) with reduced swelling and increased dry/wet strength. They are mainly produced from viscose or partially-saponified acetate. The most important are → Viscose high tenacity fibres produced by a modified spinning process. Under the microscope such fibres are differentiated from regular viscose by their smooth-edged and mostly cylindrical outline with correspondingly fewer striations in longitudinal view. The cross-section is mainly cylindrical and smooth occasionally flattened on one side. (→ All-skin fibres).

High tension → Voltage ranges.

High vacuum metallizing A process for metallizing textiles (yarns, fabrics, knitgoods, plastic films, metal-effect yarns) from natural or synthetic fibres. Metal is deposited on the textile material in a high-vacuum vesselat a pressure of 1.33–0.0133 Pa. High vacuum metallizing can also be carried out continuously by drawing the material through a horizontal cylindrical vacuum chamber by a roller over the vacuum metallizing zone and batching on to a roller again. Many nonmetals and even organic compounds (certain dyes) can be deposited on textile surfaces using the same principle. The better the high vacuum, the higher the lustre and adhesion of the deposited films. In principle, all materials which do not release large quantities of volatile substances (e.g. moisture) and disruptive gases under these conditions, which would break the vacuum or impair adhesion of the film, are suitable for high vacuum metallizing. Scorching or burning of the material being processed is prevented by screening the radiant heat at the high vacuum deposition zone. On the other hand, the slight amount of condensation heat on the material is insufficient to cause burning.

High wet modulus fibres (HWM fibres). Modified regenerated cellulosic fibres of the → Modal fibres group. The strength and wet modulus of these fibres are similar to cotton. They have lower strength but higher extension than → Polynosic fibres. Used alone or in blends for easy-care textiles, etc.

High wet pick-up The use of liquor ratios which are too short can result in too little water, as a medium for the necessary diffusion processes, being available for the dyeing of pile fabrics by continuous methods as well as in the pretreatment of cotton fabrics. With conventional padding techniques, however, it is difficult to exceed a maximum pick-up of 70–90%. Higher applications of liquor are described as high wet pick-up (wet on dry) or addition impregnation (wet on wet). The following processing machines are available:

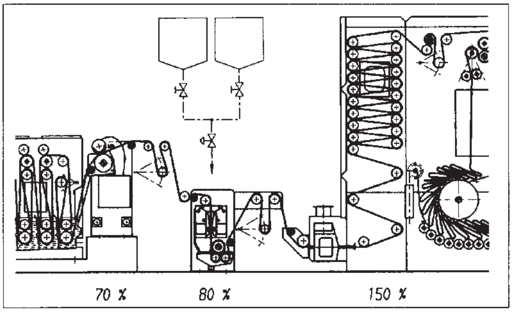

Fig. 1: Single-stage continuous pretreatment line. (detail): 70% squeezing effect after the pre-scour section, bleaching liquor addition of 80% by "Flexnip" (centre of diagram), fabric reaches steamer with 150% liquor content (Küsters).

I. Küsters have introduced an efficient pretreatment technology with the integration of a "Flexnip" unit (maximum pick-up of bleach liquor) into a continuous bleaching range (Fig. 1). Compared to conventional saturators, a number of advantages are realized with the "Flexnip" application system:

a) higher liquor application and therefore lower concentration of chemicals;
b) by dispensing with a separate scouring stage, a single-stage process can be used thus reducing fibre damage;
c) liquor strength factors of only 1 : 1.2–1.5 compared to the former 1 : 3–5;
d) only the liquor is added, without any liquor exchange, thus ensuring a constant chemical concentration on the goods;
e) less caustic soda solution is required compared to conventional scouring processes and there is considerably less residual liquor to be drained (saturator 500–600 l, Flexnip 8–10 l), i.e. considerable reduction in effluent pollution;
f) smaller machine concept with a consequent lower energy consumption and space requirements, simpler operation (titration no longer required).

II. Babcock have introduced the "Super-Sat" saturator unit as an alternative to internal or external boosters with which the application of chemical liquors is possible (Fig. 2). The liquor content of this saturator unit is only approx. 5 l/m fabric width. The liquor volume in the pipework and distribution system is included in this Figure. The liquor content of the dedicated metering system "Polycomat" amounts to an additional 5 l approx. The "Super-Sat" unit, which is located just before the steamer entry, is capable of providing liquor loads on textile fabrics up to the limits of their liquor-carrying capacities. To this end, liquor is not only applied, but also compelled to penetrate the fabric. Due to the large quantity of liquor, the concentration of the im-

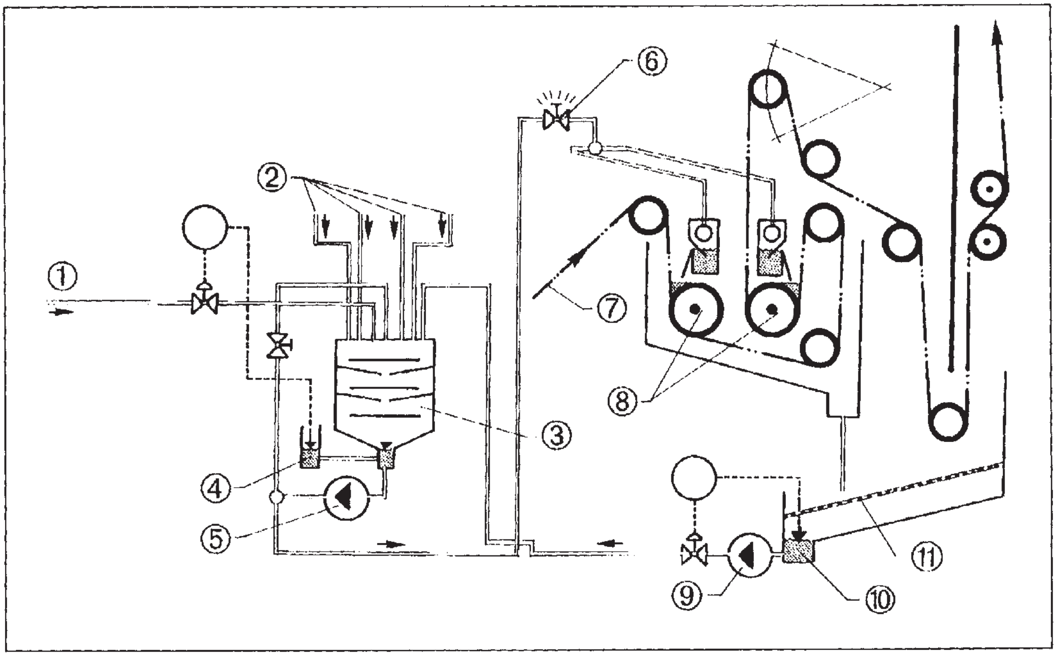

Fig. 2: "Super-Sat" (Babcock) impregnating unit.
1 = fresh water; 2 = chemical solutions; 3 = mixing tank; 4 = level control; 5 = circulation pump; 6 = quantity adjusting valve; 7 = fabric; 8 = impregnating rollers; 9 = recirculating pump; 10 = escaped liquor; 11 = lint filter.

pregnation liquor is only approx. 10–30% higher than the concentration on the fabric. As shown in Fig. 2, the unit consists of a double nip trough with liquor distributors (similar to the "Econ-Tex" open-width washing machine). Liquor distribution is achieved by means of pouring channels above the impregnation rolls.

Impregnation of the fabric and the resultant approx. 50% exchange of water in the fabric with the chemical liquor is achieved by forced penetration in the liquor wedge between fabric and saturator roll on both sides of the fabric one after the other. The higher liquor exchange achieved with the "Super-Sat" ensures a uniform bleach effect even with different fabric weights. The quantity of liquor is controlled and limited by the amount of liquor fed to the saturator rolls and an adjustable spar above the saturator rolls. Excess liquor is collected in a trough below the steamer entry and recirculated. The excess liquor flowing from the sides of the saturator rolls is also collected and recirculated. Liquor losses are avoided by the proven principle of weight-proportional metering which ensures economical processing. Even application of the liquor in and on the fabric is completed by guide rollers in the steamer entry zone. This can be used as a supplementary measure, i.e. by applying a slight overfeed (up to 5%) to the rollers, further penetration is promoted by rubbing against liquor adhering to the surface of the fabric. The liquor pick-up of the fabric, limited only by the carrying capacity of the fabric itself, is so high that, on the one hand, the risk of crease marks is minimized and the prerequisites for effective cotton seed removal are optimized on the other.

III. With the "Raco-Yet" system (Figs. 3–6), Kleinewefers KTM have developed a high wet pick-up process based on a different principle. By means of a two-component mixing nozzle an aerosol is formed by the combination of chemicals (dissolved in water) and steam (both streams meet at the outer nozzle tip which ensures that the liquor is simultaneously heated and at-

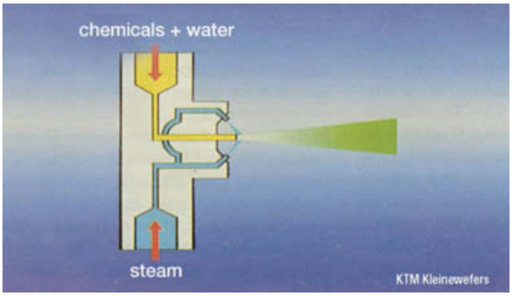

Fig. 3: Two-substance mixing nozzle with external mixing (Raco-Yet, Kleinewefers KTM).

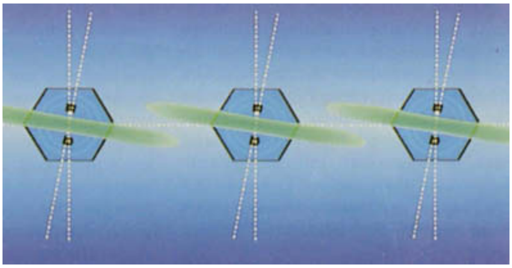

Fig. 4: Nozzle jet overlapping in the Raco-Yet (from Kleinewefers KTM).

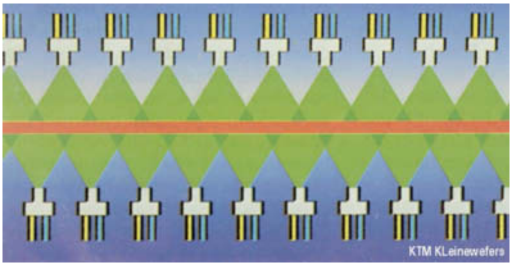

Fig. 5: Offset nozzle banks on the face and reverse of the fabric in the Raco-Yet.

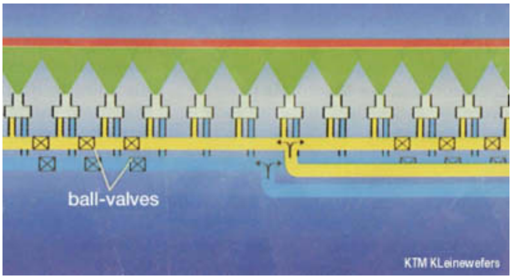

Fig. 6: Liquor and steam feed across the fabric width.

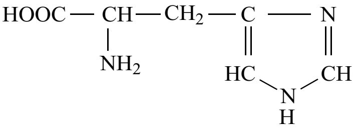
omized to form an aerosol), and the micro-droplets are able to penetrate well inside the fibre with the aid of thermal and mechanical energy. With this aerosol a product application of 130–150% (liquor pick-up) is achieved. Since the aerosol penetrates deep into the fibre structure and the reaction is not controlled by diffusion, short reaction times in the subsequent steaming stage are sufficient.

Through the application of "Raco-Yet" process technology in cotton pretreatment with tight-strand fabric passage, desizing (starch is broken down by oxidative degradation), scouring and bleaching (alkali and hydrogen peroxide) are achieved in a single-stage process with average steaming times of 2 min to give a degree of white suitable for dyeing. In cases where size recovery is to be carried out, a wet-on-wet prewash stage can be incorporated.

H ions → Hydrogen ions.

Hirschburger process A → Space dyeing method for yarn sheets similar to the → Hörauf process, except that in this case 2 threads can be wound at the same time on to a carrier with only one winding head. The working speed of the winding head is between 600 and 1000 m per min, and can be varied in three stages. The dwell time in the steamer is 1–5 min and depends on the kind of winding as in the Hörauf process (close winding or widely spaced winding), i.e. it depends on the speed of winding and transport as well as the thickness of the material. During the transport of material through the steamer, the carrier rotates five times around its own axis to ensure uniform steaming.– Manuf.: Maschinenfabrik E. Hirschburger KG.

Histidine An amino acid (α-amino-β-imidazole-propionic acid) contained in wool (0.7%) and silk (0.47%):



Historical development of textile fibres Until about 1900, natural fibres such as wool, silk, cotton and the hard fibres were the principal raw materials for the manufacture of textiles. In the 20th century the relative proportion of natural fibres has declined (with the same rise in natural fibre production) to approx. 55% (see Table) due to the development of man-made fibres (from natural and synthetic polymers). On the other hand, provision of the world population with textiles (without synthetic fibres) would now be unimaginable since the capacity for growth of the raw materials (natural fibres and wood for regenerated cellulosic fibres) is limited.

In the case of man-made fibres, the market today is split between 58% staple fibres and 42% continuous filament fibres. At the end of the 1940's, the synthetic fibres were only used as continuous filaments at first until today's equilibrium between staple and filament was reached by gradual stages. Although at the beginning of man-made fibre development, polyamide fibres were the most important raw materials, the market today is broken down into 54% polyester fibres, 24% polyamide fibres, 15% polyacrylonitrile fibres and 7% other fibres (e.g. poly-propylene, etc.)

HLB-temperature → Phase inversion temperature.

HLB value The HLB system (HLB = hydrophile-lipophile balance) was introduced by Griffin, as an empirical scale from 1–20, to characterize the balance between the hydrophobic and hydrophilic moieties in sur-

year	cotton	wool	silk	hard fibres	man-made fibres	total
1900	3 162	730	10	1 500	1	5 403
1910	4 200	803	k. A.	k. A.	5	–
1920	4 629	816	k. A.	k. A.	19	–
1930	5 870	1 002	k. A.	k. A.	208	–
1940	6 907	1 134	k. A.	k. A.	1 132	–
1950	6 647	1 057	19	3 000	1 677	12 400
1960	10 113	1 463	31	5 152	3 358	20 117
1970	11 784	1 659	56	4 865	8 397	26 761
1980	13 884	1 599	64	4 800	14 182	34 529
1989	17 582	1 936	65	4 900	19 057	43 540

Tab.: World production of textile fibres 1900–1989 in 1000 t (k. A. = no data).

face-active textile auxiliaries (surfactants, emulsifiers) and is independent of their constitution (but highly temperature-dependent). A low HLB value (< 10) signifies a predominance of hydrophobic groups indicating that the surfactant is lipophilic, and a higher HLB value (> 10) that more hydrophilic properties predominate. The HLB describes the ratio of relative intensity between polar and apolar portions of a surfactant molecule. The HLB value is therefore determined by the type and size of the hydrocarbon chain as the apolar representative and the strength of the dipole in the polar portion. Consequently, a long straight-chain hydrocarbon portion has greater intensity than a short branched hydrocarbon chain. In the polar range, an ethylene oxide group is less, and a carboxyl, phosphate, sulphate, sulphonate group (in order of increasing effect) more intensive. The following properties are determined by the HLB value:

a) surfactant solubility,
b) emulsifying properties of a surfactant,
c) soil suspending properties of a surfactant.

In simplified terms, the 1–20 scale of the HLB system has the following significance:

1 – 3	solvent soluble, water insoluble
3 – 7	solvent soluble, water dispersible
7 – 10	solvent soluble, water soluble
10 – 13	water soluble, solvent soluble
13 – 18	water soluble, solvent dispersible
18 – 20	water soluble, solvent insoluble

From the above classification, the fields of application of individual surfactants are determined. Thus, for example, general-purpose detergents and textile washing agents are found in the range from 13–18, whilst highly-active washing agents with fat-dissolving properties as well as pre-spotting agents for drycleaning with especially high activity against wet soiling are found in the range from 10–13. Drycleaning detergents, which can also be used as pre-spotting agents, are included in the range from 7–10. Drycleaning detergents with, for the most part, finishing properties as well, are found in the range from 3–7. On this basis, for example, an emulsifier for a particular purpose can be selected. Hydrophilic groups include, e.g.: $-OH$, $-NH_2$, $-SO_3Na$, $-OSO_3Na$, ethylene oxide, etc.

Application fields of surfactants according to their HLB values:

1.5 – 3	antifoaming agents
3 – 6	drycleaning detergents
4 – 6	W/O emulsifiers
7 – 9	wetting agents
8 – 13	O/W emulsifiers
13 – 15	wash-active surfactants
15 – 18	solubilizers.

Methods of determination:

I. Emulsion comparison method (oils with known HLB values are used as reference parameters).

II. Cloud point determination on heating (precipitation of water soluble surfactants with HLB values from 12–18).

III. Turbidity titration with water (by differential solubility in benzine/water and water).

IV. From the → Spreading coefficient for HLB values of 7–15.

V. Chromatographic methods (influence of the migration capacity by HLB values of 0–18).

VI. Rapid calorimetric method according to Orben.

VII. Titration.

The practical value of the scale lies in the fact that the required HLB value for the preparation of an emulsion with emulsifiers of known HLB values can be ascertained from simple emulsification tests, and other emulsifiers of known HLB values can be selected. Moreover, the HLB value of a mixture of emulsifiers is proportionate to the HLB values of its components, which makes possible the preparation of an emulsifier mixture of known HLB value. Unfortunately, despite

$HLB = \frac{H_M}{G_M} \times 20$ H_M = hydrophilic molecule content G_M = total molecular weight		$HLB = \frac{H}{5}$ H = % hydrophilic content		$HLB = 20\left(1 - \frac{VZ}{SZ}\right)$ VZ = emulsifying agent saponification number SZ = fatty acid number

100	0	20		18		18

Tab.: HLB values and calculation bases.

the clarity and usefulness of the HLB system, in practice its value is limited by the fact that the emulsion type is frequently also affected by numerous other parameters, e.g. the water/oil ratio, temperature and viscosity, so that optimum HLB values for the preparation of a particular emulsion must be determined experimentally in every case (→: PIT; Cloud point index). Calculation is possible for emulsions whose structure and molecular weight are known. The HLB value is accordingly a function of the weight ratio of the hydrophilic portion to the total emulsifier molecule.The table shows such possibilities for calculation (according to Griffin), together with properties dependent on the HLB values.

HL-process A process for dry cleaning establishments in which a dry cleaning detergent/water emulsion may be added directly to the cleaning liquor with a dry cleaning detergent concentrate.

HM process (H = Habis Textil AG, M = Monforts). A plant for the curing of finishes and fixation of prints on woven fabrics in textile finishing. It combines a rapid heat-up phase in hot air and a short dwell time in a steam atmosphere.

Ho, chemical symbol for holmium (67).

Hog's bristles (pig bristles). Depending on the method of slaughtering, the approx. yield is 300 g of stiff, coarse bristles per pig by scraping. Special fermentation processes are used to remove skin particles. Uses: apart from brooms and paint brushes, hog bristles are also used as a padding material and in fur hats.

Holbein rugs Oriental rugs or carpets mainly from the Bergama area in western Turkey and named after the painter Hans Holbein the Younger, who portrayed some examples in his pictures.

Hole etcher A variant of the burn-out print style. This process was already being carried out during the middle of the 20th century before synthetic fibres appeared in the market, and should therefore be described as the classic burn-out style. Print pastes containing an acidic component are applied to 100% cotton in order to burn holes out of the fabric in specific areas corresponding to the printed design. Fraying of the burned out holes in the fabric during washing is avoided by selecting tightly woven fabrics for this style of printing. The problem does not arise if the burn-out areas are surrounded by a border printed with pigment colours since, in this case, the polymer film of the pigment binder prevents frayed edges by bonding the exposed fibres.

Hole in milling A technical term for a fabric defect (hole) caused by sudden high pressure or impact during fulling or milling (rotary cylinder, perforated roller).

Hollow cop (tubular cop). A → Cop of yarn with no internal support, i.e. a form of yarn package consisting of wound yarn only without any bobbin or tube. The yarn is unwound from the inside of the hollow cop.

Hollow squeegee (→ Double squeegee). A squeegee system used on flat-bed screen printing machines consisting of a pair of parallel rubber squeegee blades mounted in a single support. The print paste held between the two blades is transported across the printing screen by the rear blade only during each pass, the leading blade being raised at the same time. Thus, the leading blade for the first pass becomes the rear blade for the subsequent pass.

Home furnishings Together with household textiles, home furnishings account for approx. 30% of all textile fibre consumption. Apart from woven articles such as upholstery materials, carpets and bed covers, various special techniques are also used for the manufacture and finishing of home furnishings, e.g.:

- stitch bonded fabrics (Malimo): textile wallcoverings;
- knitted fabrics: upholstery materials;
- flocked fabrics: textile wallcoverings, net curtains, furnishing fabrics;
- layers of superimposed yarns: textile wallcoverings;
- nonwovens: textile wallcoverings;
- tufting technique: upholstery materials, carpets;
- coated fabrics: glassfibre wallcoverings.

Homespun Plain-weave coarse fabrics originally produced in the British Isles from hand-spun Cheviot wool, generally undyed and characterized by their uneven quality which was due to the hand weaving and spinning. Today, homespun is frequently used as a general term for loosely woven fabrics produced from very coarse, rough-haired, mottled or even slubby woollen yarns mainly in plain-weave constructions, often with a light melton finish. Used for lightweight suits, men's jackets, costumes and coats.

Homogeneous Composed of similar or identical parts or elements. A composition in which the components are of the same kind. A homogeneous system consists of a single phase, e.g. a common solution such as a salt or sugar solution. Homogenization: intimate mixing, e.g. of importance in the preparation of particularly fine emulsions.

Homogenizers High-speed mixers in which coarse and polydisperse emulsions are transformed into almost monodisperse systems by subjecting the liquid to high shear forces.

Homologous series A series of related chemical compounds in which each successive member has one more CH_2 group in its molecule than the preceding member. For instance, CH_3OH (methanol), C_2H_5OH (ethanol), C_3H_7OH (propanol), etc., form a homologous series.

Chemical compounds forming a homologous series have great physical similarities, especially neighbouring members. Other examples are: methane, ethane, propane, butane, etc., and benzene, toluene, xylene.

Homopolar → Polar.

Homopolar bond → Atomic bond.

Homopolymers Natural or synthetic → Polymers derived from a single type of building block (monomer) in contrast to → Copolymers.

Honeycomb backing (embossed foam, structured foam) → Backcoating of carpets with foam having an embossed honeycomb-like pattern.

Honeycomb fabric Cotton fabric in which the warp and weft threads form ridges and hollows to give a cellular appearance which may be evident on one or other, or both faces of the fabric. The honeycomb weave is achieved with groups of short running warp and weft floats.

Honeycomb screen An arrangement with a honeycomb grid used in the transfer of designs on to rotary printing screens during exposure to a light source in which oblique incident rays from all directions are, for the most part, screened out by the honeycomb grid so that they have no effect on the copying process.

Honeydew A descriptive term for secretions on cotton hairs caused by whitefly or aphids during cotton growing. The sticky deposit is composed of various sugars. The spread and intensity of honeydew infestation almost always has a direct correlation with the use of various insecticides. In the selection of suitable insecticides for cotton plants, it is important to protect the natural enemies of the aphids. Besides problems caused by insecticides, cotton contaminated by honeydew causes processing problems in spinning and frequently impairs the quality of yarns spun from such cotton. It is known that the honeydew components (i.e. sugars and various proteins) corresponding to the non-enzymatic (brown) reaction scheme, form brownish-black pigment stains. This reaction proceeds even at low temperatures, albeit relatively slowly, and is accelerated by the action of heat. The presence of additional substances such as organic acids can likewise contribute to the reaction as well as stimulate the formation of sugar caramel structures which results in similar yellow-brown pigments.

Hörauf process A → Space dyeing process for yarn sheets in which yarns from cross-wound packages/cops are passed through a dye liquor applicator. The amount of dye applied to the yarn can then be reduced to the desired liquor pick-up by means of a patented procedure (which is similar to the OPI method). The yarn is then conducted to a winding machine (Buddecke system) to obtain a continuous, hank-like wound package consisting of individual layers of yarn held by four endless conveyor bands. These layers are transported along a bar over a distance of 2.7 m through a steamer in a tension-free state to fix the dyes. The winding rate can be varied between 400 and 1200 rpm. The dwell time in the steamer is 7.25 min for yarn which is generally closely packed (16 threads per cm), the winding speed being 600 rpm. The dwell time is only 3.6 min if the yarn is spaced wide apart during winding (4 threads per cm) at a winding speed of 300 rpm. After steaming, the yarn is drawn off from the carrier and wound on bobbins.– Manuf.: M. Hörauf.

Horizontal emerizing machine For woven fabrics, with emerizing rolls and a dust bag filter for dust extraction from the machine. Fabric feed and delivery via batch rolls.

Horizontal flammability test → Flammability testing.

Horizontal HT-beam dyeing Machine → High temperature dyeing machines.

Horizontal jet drier → Jet air circulation driers with an electrically-driven wash unit for the fabric conveyor. Universally applicable for thin fabrics which can be subjected to powerful repeated suction pressure. Adhering water is removed by suction.

Horizontal migration Selective horizontal migration is due to the different migration rates of the components in a dye combination. It causes → Dichroism which results in an irregular and uneven appearance of the dyed fabric.

Horizontal open-width washing machines (→ Horizontal washing machines). This design of washing machine has wash compartments in which the guide rollers are arranged in vertical banks between which the fabric passes upwards in the open-width state in a series of almost horizontal loops with liquor flowing from top to bottom (see Figs. 1 and 2).

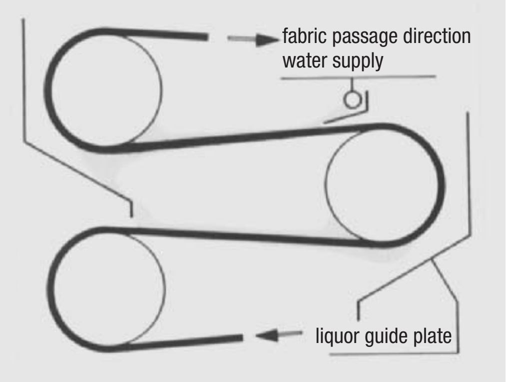

Fig. 1: Schematic fabric path in horizontal passage open-width washing machines.

Horizontal package dyeing machine → High temperature dyeing machines for yarn packages and spinning cakes with a horizontal dyeing chamber to accomodate dye tubes each containing approx. 10 individual packages. Short liquor ratios of around 4 : 1.

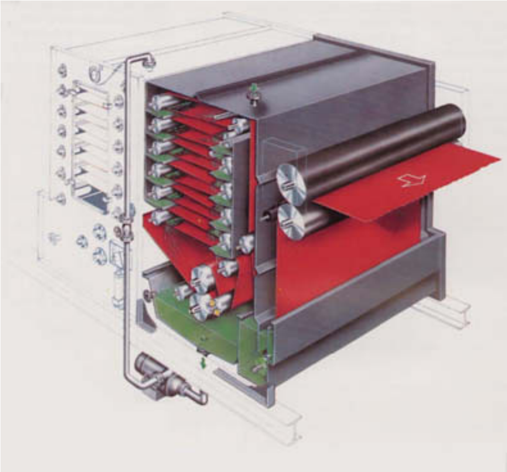

Fig. 2: Küsters horizontal passage open-width washing machine.

Horizontal padder (horizontal foulard). A → Padder, without a liquor trough, in which fabric is padded through a wedge of liquor held in the nip between two horizontally arranged padder rolls. → Horizontal two-bowl padder.

Horizontal rope washing machine → Horizontal washing machines.

Horizontal star dyeing machine A → Star frame in which the frame loaded with fabric is rotated through the dyebath.

Horizontal stenter A stenter with an air-cushion nozzle system for the drying and heat-setting of textile fabrics (see Fig.). The machine can be incorporated into an integrated finishing line for the finishing of wovens and knits and is provided with a double batching system on giant batch rolls at the delivery end for fully-continuous operation.

Horizontal test → Flammability test.

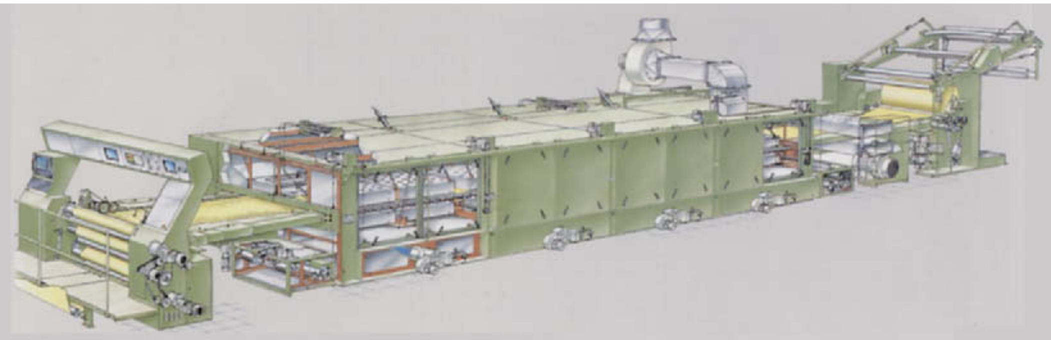

Fig: Horizontal stenter (Babcock).

Horizontal two-bowl padder A padder in which piece goods are run vertically downwards through the nip of a horizontal padder containing the liquor (see Fig.).

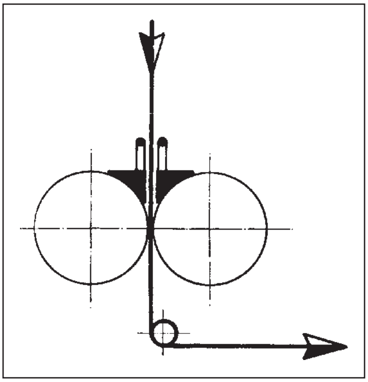

Fig.: Horizontal two-bowl padder.

Horizontal washing machines (tangential washing machines). Industrial long drum washing machines mostly with Pullman divisions (horizontal separators) for larger units and a lengthwise (tangential) opening for loading/unloading.

Horizontal washing machines for piece goods These machines are based on a horizontal fabric passage from the bottom to the top of the wash compartments and are used for washing piece goods in rope form or open-width depending on the particular design (→ Horizontal open-width washing machines). Liquor flow is from top to bottom thereby providing an ideal countercurrent flow washing system.

Horsehair Coarse, stiff, elastic hairs, usually white, brown and black in colour. Natural horsehair is obtained from the tail of the horse (60–80 cm in length, ∅ 80–400 µm) or the mane (25–45 cm in length, ∅ 50–200 µm). Synthetic horsehair consists of coarse viscose, acetate, polyamide and other monofilaments as well as partially dissolved and re-solidified cellulose threads. Horsehair substitute: apart from synthetic horsehair, so-called vegetable horsehair from leaf bast fibres (agave, manila, sisal), as well as glazed yarns, are also used. Yarn: chiefly of horsehair wrapped with cotton or other fibres, also as ply yarns with cotton (horsehair ply yarn). Uses: → Horsehair cloth, and as weft in stiff interlinings for jackets, skirts, upholstery fabrics, hat trimmings, etc.

Horsehair cloth Fabrics woven from pure horsehair are used as hair sieves. Haircloth, which consists of a cotton or wool warp and → Horsehair (natural or synthetic) wrapped with two fine cotton yarns (alternate S and Z-twist) to produce so-called horsehair ply yarns in the weft is used in → Horsehair linings.

Horsehair lining A half-horsehair fabric, i.e. usually with cotton or wool in the warp and horsehair in the weft used as a stiff interlining in coats and suits to retain the shape, and in women's hats. The crosswise elasticity of the material is determined by the number of horsehair yarns in the weft.

Hosiery finishing machines, automatic Integrated production lines for the cleaning, dyeing, plastification (heat-setting), softening and drying of hosiery.

Hosiery goods Textile knitgoods produced by the intermeshing of loops of yarn from one or more yarn systems in which the loops may run in a horizontal, i.e. widthwise (weft-knit) or vertical, i.e. lengthwise (warp-knit) direction. → Knitted fabrics.

Hosiery setting (boarding). A process carried out on (polyamide) hose or other knitted garments to achieve a desired shape or size which involves the action of heat under moist or dry conditions whilst supported on formers (Fig. 1) in so-called boarding machines (with steam hoods) or pressure steamers, as well as in special continuous machines (→ Boarding).

Fig. 1: Heliot machine for the continuous setting of hosiery.

To shape and set stockings or socks after circular knitting and making-up, they are therefore transported through the steaming and drying zone on aluminium boards or templates (Fig. 2).

Hospital textiles Since organic materials are subject to microbial attack and are eventually broken down, various products and methods have been developed to protect everyday articles and equipment from this kind of damage. Textiles used in the medical field, above all, are exposed to the damaging effects of microbial attack which, in the absence of preventive measures, would undermine general hygiene in hospitals. Consequently, the antimicrobial treatment of textiles employed in the medical sector serves a dual purpose:

- to protect the textile material against damage,
- to maintain a high standard of hospital hygiene.

A variety of methods are used for this purpose:

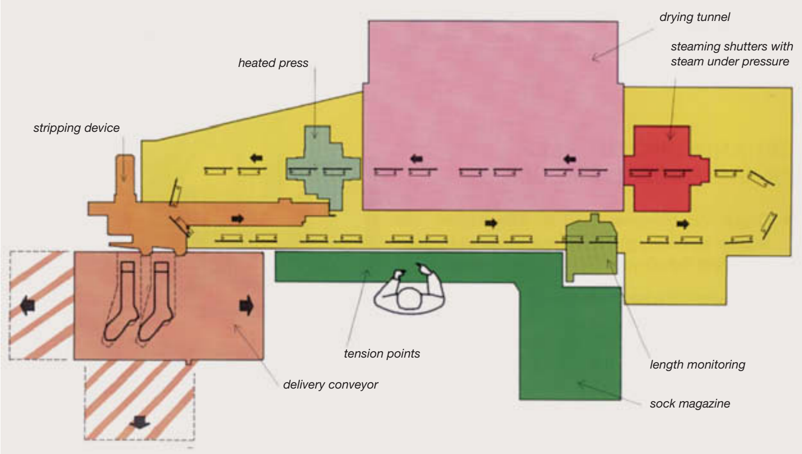

Fig. 2: Process flow in a hosiery setting machine (Heliot).

1. Sanitation: processes to control the number of microorganisms at low levels with the aim of (i) preventing the risk of uncontrolled proliferation of undesirable microorganisms, (ii) achieving an inhibiting effect and/or (iii) counteracting any damage due to microbial attack. Whilst efforts are made to destroy microorganisms as far as possible by disinfection, the aim of sanitation is to keep the number of microorganisms as low as possible by microbistasis, which is why such methods are referred to as having a fungistatic or bacteriostatic action. The gradual, uncontrolled reproduction of microorganisms is prevented by these measures. Undesirable microorganisms, in this context, include those microorganisms which give rise to problems in the usual application of a particular material (e.g. mildew on shower curtains or unpleasant odour formation in socks as well as certain kinds of damage to materials).

2. Inhibition: this term specifically refers to the antimicrobial finishing of articles in daily use. The effect of these processes is that odours caused by the products of microbial metabolism cannot arise in the first place if microbial metabolism is prevented. Inhibition differs from deodorizing by preventing the development of microbial odour in the formative phase, whereas deodorizing only covers up such odours (use of fragrances), i.e. by masking or chemical blocking (so-called neutralization).

3. → Antimicrobial finishes: the treatment of materials with antimicrobial substances to control the number of microorganisms at low levels. This form of finishing is directed exclusively towards the matrix and not its surroundings, e.g. human skin. Depending on the serviceability of the article, this type of finish should be bonded to the substrate to a greater or lesser degree, and therefore exhibit a growth-inhibiting action to provide the material with the required protection.

Hygiene requirements for the various risk categories in a hospital demand specific precautionary measures. In addition to general cleanliness, precautions also have to be taken with regard to cleaning, disinfection and sanitation. Depending on their field of use, these textiles have to meet different requirement specifications with regard to quality and hygiene, e.g.:

a) Textiles in the sickroom, such as bedsheets, covers, blankets and towels, as well the patient’s clothing. These articles are required to be:
- skin-friendly,
- absorbent,
- hygienically clean.

Textile fibres capable of satisfying these requirements include cotton in particular, as well as wool with certain limitations. Cotton has a high absorbency for liquids of all kinds. Cotton textiles are, in many cases, reinforced with polyester fibres to improve their mechanical properties which, to some extent, results in a loss of absorbency. The fabric construction should be specified to ensure good launderability. Wherever possible, long staple fibres should be used and the finish applied should give rise to minimum dusting. Disinfection must, of course, also be possible. Certain laundering processes in which oxidizing agents such as peracetic acid are used, can damage the cotton component in the sense that the absorbency is reduced due to degradation of the cellulose. Finishes with crosslinkable resins can likewise cause a partial loss of absorbency and, in the case of resins containing nitrogen, also give rise to chlorine retention.

b) Clothing for nursing and hospital staff as well as textiles used in the nursing and catering fields: the following requirements specification applies to these materials:
- skin-friendly,
- hygienically clean,
- soil-repellent,

- non-dusting,
- antistatic,
- limited absorbency.

Complete absorbency is not a requirement for textiles in this category. On the other hand, good soil-repellent properties which can be achieved, e.g. with a fluorocarbon finish, are important. A resin-based hydrophobic finish combined with soil-repellency is a particular requirement to prevent splashes of blood or secretions penetrating clothing worn by medical staff. In addition, these textiles must be easily laundered. As most of these materials are made from cotton/polyester blends, they cannot be laundered at the boil. In the main, such textiles are laundered at a temperature of 70°C to prevent creasing which, of course, does not achieve the same quality of hygiene as laundering at the boil. The remedy to this problem involves thermochemical laundering processes, although oxidative degradation of the cellulose by peracetic acid cannot be ruled out in this case. This has a negative impact on the wear comfort and absorbency as well as the tear strength of the material. For certain textiles in the catering sector, special requirements must be fulfilled, e.g. high absorbency in the case of tea towels, hand towels and wipes. Since these are mainly composed of 100% cotton, laundering at the boil is possible.

c) Clothing worn by doctors as well as other textiles exposed to risk areas (operating theatres) such as surgical gowns, covering sheets, screens, face masks, headgear, etc. The highest requirements with regard to hygiene and special finishes are placed on materials exposed to these risk areas. Such textiles must have the following characteristics:

- skin-friendly,
- hygienically clean,
- capable of sterilization,
- soil-repellent,
- low absorbency,
- non-dusting,
- antistatic.

These requirements are necessary both for the surgical gowns as well as for all other textiles used in high risk areas. Special precautions must, of course, be observed with regard to cleaning and laundering of such finishes. Since woven polyester fabrics or polyester/cotton blends are mainly used for these applications, laundering at the boil is not possible. Other means must therefore be resorted to in order to achieve an optimum standard of hygiene in laundering. Although thermochemical laundering methods achieve a satisfactory level of hygiene, degradation of the cellulose occurs at the same time with consequent breakdown of the finish. Moreover, oxidizing agents can also lead to the formation of protein coagulates which prevents optimum cleaning (source: Mebes). → Antibacterial textiles.

Hostaphan film A physiologically harmless polyester-based film without plasticizer. The film is transparent, extraordinarily resistant to tearing and impact with excellent abrasion resistance; it is soft and flexible in thinner qualities. Good fatigue strength at elevated temperatures and suitable for insulation. Resistant to heat at temperatures up to approx. 150°C and to cold at temperatures down to –60°C. Also resistant to water, common organic solvents, fats and oils. Virtually unlimited application for lamination with fabrics of all kinds or vacuum coating with metals. Hostaphan film is also used in the production of metallic yarns.– Manuf.: Kalle.

Hot On care labels refers to hot water (54-60°C).

Hot air bonding plant Spraying device as a → Spray bonding plant for binder-free bonding using fibre bonding: an appropriate percentage of fusible fibres is mixed with the main fibre material. Bonding is carried out in the one or two-way circulating air drier. Nonwoven fleece lies loose on the conveyor belt. Air temperature up to 220°C.

Hot air drying chamber → Drying chamber for printed goods.

Hot air drying machine → Hotflue.

Hot air fixation → Heat setting.

Hot bath flat setting Collective term for work stages in the finishing of wool such as boiling, crabbing, potting, decatizing, etc.

Hot cutting process The greater use of synthetic fibres and the constant trend towards improved performance has led increasingly to the use of the hot cutting process, which has the advantage of better performance whilst simultaneously sealing the cut edges. The hot cutting process is separation by means of thermal contact: the textile being separated is melted in a narrow cutting area by means of a hot blade and separated under slight pressure. This is limited to thermoplastic textiles. It can also be used for sealing the selvedges of woven fabrics made of thermoplastic fibres.

The hot cutting process can be used whenever:

- thermoplastic fibres are used,
- fabric is being processed,
- selvedges are able to bear the increased loading.

In addition to the question of the material and the quality demands made on the cut, an essential aspect is the economic efficiency of the cutting process. In small industrial enterprises with a low cutting requirement, manually operated equipment can be successfully employed. However, larger enterprises with many metres to process and, in particular, industrial plants with continuous manufacturing processes are dependent on machine cutting systems.

Hot dissolving method Dissolving method for naphthols in piece dyeing and in printing for generating insoluble azo compounds on the fibre material. The naphthols are made into a paste with, for example, Turkey-red oil and caustic soda solution and then made into a solution with boiling water. Other classes of dyes in powder form, such as direct, acid, reactive and cationic dyestuffs, are applied according to the hot dissolving method.

Hot-dyeing dyes Vat dyes which exhibit their highest affinity for cellulosic fibres at 50–60°C and are applied by the → IN dyeing method. They are referred to as hot-dyeing dyes to distinguish them from so-called cold-dyeing vat dyes which have the highest affinity for cellulosic fibres at 25–30°C and are applied by the → IK dyeing method.

Hotflue Hot air drying machine for fabric, preferred for intermediate drying. Passage of fabric is usually either vertical, alternating up and down through a drying area with circulating hot air, or diagonally in an up and down zig-zag fashion with double-sided air flow (air jets) from above and below.

With the “Quadro Dry” from Babcock (Fig. 1) each section has 2 circulation fans in the top and the bottom of the system. In the direction of the fabric movement, these fans are top left and bottom right, then top right and bottom left. The 4 fans of a section are therefore 4 times reversed.

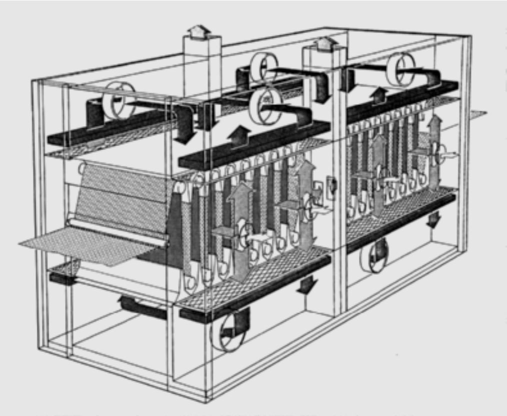

Fig. 1: Babcock dyeing hotflue Quadro Dry.

The 2 air circulating fans (1) per modular unit with the „Thermex“ from Monforts (Fig. 2) are symmetrically arranged and, aligned with whichever heating system is installed, suited to drying, thermosol dyeing and curing processes. Before the air conveyed from the two fans reaches the jets (2), it is brought together in a chamber (3). The controlled exhaust extraction occurs through a shaft (4) built into the processing area. Heat recovery (5).

With the Krantz hotflue, the heat flow on the process rollers (Fig. 3) is directed by a special metal slot.

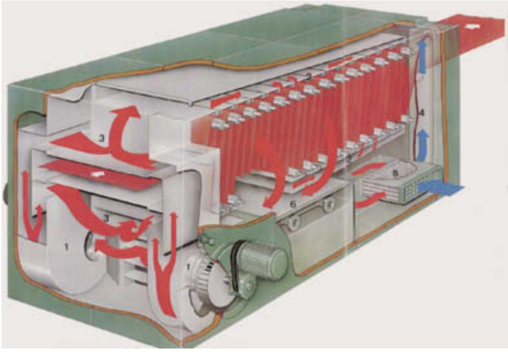

Fig. 2: Thermex from Monforts.

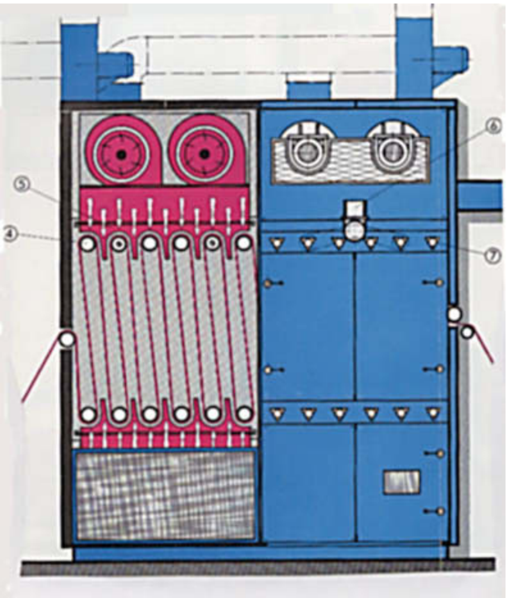

Fig. 3: Hotflue from Krantz.
4= Deflecting roller with special drive (6 + 7); 5 = metal slots for intensifying the heat flow.

Hot impregnation process For selected synthetic resins and additives. Impregnation of hot finishing liquors gives increased efficiency of the squeezing, spin drying or dewatering processes. The viscosity of the water falls with increasing liquor temperature. The water penetrates the fibre better at a greater temperature and it may also be removed better through the operation of mechanical forces.

Hot melt adhesives The use of thermoplastic hot melt adhesives in the manufacture of composites is an environmentally friendly method of processing, which makes use of thermally activated melt adhesives based on copolymers. These high-grade polymers are employed chiefly in the coating of interlining materials, which are used widely in the clothing industry. Besides this traditional market, the products increasingly have a technical application, e.g. in the car industry for manufacturing composites for door panels, roof canopies, headlinings, masking fabric, decorative PVC materials, etc. Copolyamide and copolyester hot melt adhesives are also gaining in importance in the manufacture of laminates.

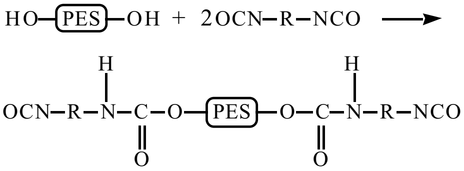
Hot melt adhesives bond the components of the sandwich in the laminate. Adhesives can generally be classified according to the setting mechanism (physical and chemical hardening):

I. physical:
- hot melt adhesives
- plastisols
- contact adhesives
- tack adhesives
- solvents/dispersion adhesives
- glues

II. chemical:
- unsaturated polyesters
- cyanacrylates
- methacrylates
- reactive PU systems
- polymethylol compounds
- silicone adhesives
- polyimides/polybenzimidazolines

Active adhesives are referred to as physical when the setting process follows physical methods and chemical systems are cross-linkable and based on a chemical reaction.

Hot melt adhesives are physically setting systems which normally are not cross-linked. They are activated by means of temperature. Developments are at a laboratory scale to cross-link hot melt adhesives on the basis of copolyamides. These serve to improve the properties of such products in relation to their thermal stability and their resistance to washing treatments and solvents. The cross-linking may occur thermally, photochemically or by means of moisture; certainly, only inline laminations are possible with finishing on the appropriate coating equipment, whereas with thermoplastic melt adhesives bonding may occur independent of time and place. A typical hot melt formulation reacts as follows to the further reacting polymers:



$$HO-\boxed{PES}-OH + 2OCN-R-NCO \longrightarrow$$

$$OCN-R-\overset{H}{\overset{|}{N}}-\underset{O}{\underset{\|}{C}}-O-\boxed{PES}-O-\underset{O}{\underset{\|}{C}}-\overset{H}{\overset{|}{N}}-R-NCO$$

The Table shows a classification of hot melt adhesives. Hot melt adhesives result from the manufacture of copolyamides in granular, powder and film form. In addition hot melt adhesives are supplied on the basis of copolyesters, ethenvinyl acetate, and high and low-pressure polyethylenes. The advantages of copolyamides are specifically:
- thermal shock resistance from – 40°C to + 120°C
- resistance to ageing
- resistance to petrol, oils and fats of all kinds
- 100% adhesive paste, unplasticised and environmentally neutral
- stable in storage
- high bonding speed, rapid availability for further processing
- good adhesion to textiles, leather, foam, plastics, phenol resin bonded mouldings, metal, etc.

The choice of suitable hot melt adhesive type is based on an understanding of the requirements profile of the composite in order to obtain an optimum coating result.

Common applications are based on:
- the powder dot method (woven and knitted fabrics)
- the paste dot method (nonwoven fabrics)
- the scatter coat method (wovens, nonwovens, foams, etc.),

which require the use of fusible powders. There are a series of mechanical innovations based on the application of granulates.

The following are three important processes:

	Polyamide	Polyester	EVA	PU Hot Melt Adhesives	Block Polymers
Manufacture	dicarboxylic acid + diamine	dicarboxylic acid + diols	radical polymerisation	polydiols + diisocyanates	styrene + isoprene or butadiene
Possible variations	molecular weight of end groups	end groups	molecular weight of vinyl acetate content	molecular weight of end groups	molecular weight of monomers
Melting viscosity	generally low	medium to high	mostly very high	thermoplast. PU: low	medium to high
Thermal stability	good to very good	good	weak	thermoplast. PU: weak reactive PU: very good	weak

Tab.: Classification of hot melt adhesives

- application with gravure-printing embossing cylinders (meltprint process, Rototherm),
- hot melt application via rotary print screens (Villars, Caratsch),
- hot melt application using slot extruder (Hardo).

The scatter coat method is very important for the manufacture of composite materials. There is the classical scatter coat system consisting of scatter head, IR channel, laminating calender; and the more recent variant of scatter head, IR field, flow press, laminating calender. In both cases lamination or coating only may be carried out with these systems. For scatter coating, copolyamide and copolyester powders in the particle size range of 200–300 µm or 300–500 µm are used. With coating from the melt, the granulate is melted on directly and applied either via engraved rollers/screens as a design or as a sheet by means of slot extruders.

Dry laminating calenders are designed for the use of environmentally friendly adhesive systems. Suitably equipped, they permit the application of thermoplastic materials in film, mesh, nonwoven, hot melt and powder form. There are two systems distributed on the market:

a) flat-bed laminating systems (Fig. 1),
b) dry laminating calenders.

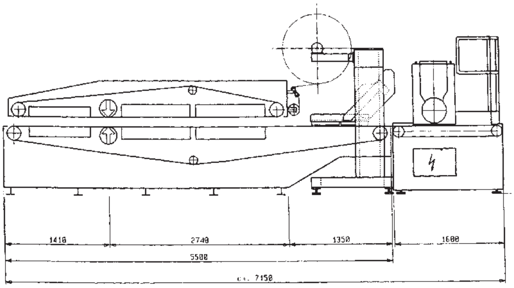


Fig. 1: Laminating system with IR radiator and powder distributor (Elf Atochem, Germany).

The following represent a selection of examples for the manufacture of composite with nonwovens using thermoplastic hot melt adhesives. In addition, there are more possibilities for combining nonwovens with other materials than those given.

I. Nonwoven laminate for “breathable” interliner systems: laminate structure (Fig. 2). Laminate production: 1st stage: dot coating of pastes by means of rotary printing on nonwovens or film. 2nd stage: composite manufacture on continuous dry laminating systems. Properties and use: water vapour permeable interliner systems are often used for the manufacture of rain and sportswear and protective clothing. They are sewn between the outer fabric and the lining and thus allow the garment manufacturer to give free form to the outer material. In addition, interliner constructions have a softer handle than membrane film directly laminated onto the outer fabric. The composites have good resistance to washing and cleaning.

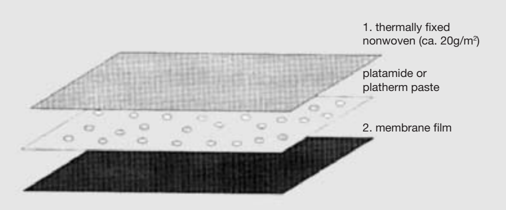

Fig. 2: Nonwoven laminate for “breathable” interliner systems: laminate structure.

II. Roof linings for minibuses: laminate structure (Fig. 3). Laminate production: 1st stage: lamination of the nonwoven with film on a dry laminating system or continuous flow press. 2nd stage: reactivation of the hot melt adhesive film by means of temperature and binding with the basic material in a mould. Properties and use: instead of the hot melt adhesive film, a spunbonded nonwoven or powder could be used. In this particular instance, the film is used because it serves simultaneously as a “dust barrier” (delivery van). Hot melt adhesives in the form of spunbonded fabric or powder would be more advantageous with regard to the acoustics; dependant on the air permeability at the non-covered places, the dust might collect there, which would lead to irregular soiling.

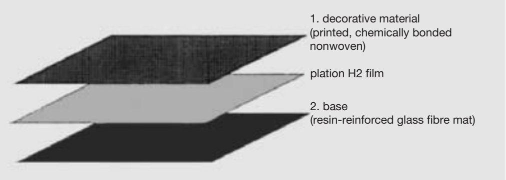

Fig. 3: Laminate structure for minibus roof linings.

III. Roof linings for cars: laminate structure (Fig. 4). Laminate production: 1st stage: spunbonded fabric made of granulate is applied/extruded directly onto the base nonwoven. 2nd stage: pressing of the nonwoven/spunbonded with a premoulded, hot base material in a cold mould. Properties: the copolyamide spunbonded fabric has very good adhesive properties and, at the same time, a high degree of thermal stability. The direct application of the spunbonded onto the decorative fabric saves one operation: no thermal loading through additional lamination.

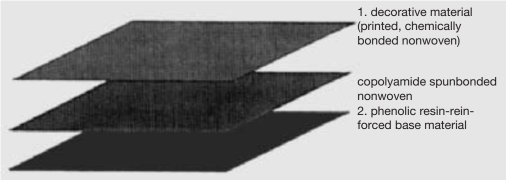

Fig. 4: Laminate structure for car roof linings.

IV. Sound insulation elements, upholstery materials: laminate structure (Fig. 5). Laminate production (inline process): coating of the nonwoven with powder on a scatter system, which is connected to a dry laminating system. The powder is sintered with IR radiators. The PU foam is conveyed in front of the flow press and bonded with the nonwoven fabric. The heating is made from the nonwoven side. Properties: copolyester hot melt adhesives have good adhesion properties to polyether and polyester urethane foams. Depending on the requirements, copolyamides hot melt adhesives may be used (according to Jahn).

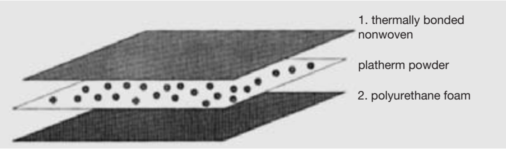

Fig. 5: Laminate structure for sound insulation elements and upholstery materials.

Hot melt adhesives as interliners and stiffening materials (iron-on materials, ironing fabric). In the form of fabric, tape or non-woven as modern, work-saving interliners and stiffening materials (instead of, for example, linen interlining, stiffening cloth and the like). Hot melt adhesives are used in the most important interliner materials. They are either woven or nonwoven fabrics that are coated with thermoplasts. Cotton, viscose, polyamide, polyester or polyester/cotton blend fabrics can be used as the ground fabric, whilst polyethylene, polyurethane, polyvinyl chloride, polyvinyl acetate, etc. are used as the coating materials. Cellulosic fabrics are given a pretreatment with urea based resins. Coating follows by various methods and usually involves covering most of the fabric surface in something like a film extrusion coat. To avoid a stiff handle with larger surfaces, e.g. with garment front interlining, the adhesive paste is applied in dot form. Here scatter coating machines are used to apply the adhesive as a powder. The material may also be applied as a paste by means of rotary screen printing machines. Modified rotary screen printing machines also permit powder application (→ Powder point process). Gravure printing machines are also used for this purpose, while another type of machine allows the thermoplast to be applied in the melted state.

Hot melt coating,

I. Hot adhesive finishing, surface or spot-form coin laminating of interliners (see Table: thermoplastic materials for hot melt coating), especially for front fusing with thermoplasts (copolymers vinylacrylic, polyester urethane). →: Laminating technology; Hot melt adhesives.

II. Indirect application (transfer coating) on such fabrics as the backs of tufting carpet by means of hot melting (hot melts, plastic dispersions, →: Elastomers; Latex), also highly filled plastic masses used in blade coating (heavy coating). With the polyurethane transfer process, the foaming reaction mixture is applied to a hot drum, steel band or release paper and then the back of the carpet is placed in the resulting foam. Hot melt coating systems normally cause more air pollution than water pollution.

Hot melt laminating Laminating process as an alternative to flame bonding. The fabric being laminated is bonded with melted polymer, which is heated up in the appropriate form (Fig. 2) and transferred to the web shortly before the sandwich is formed (Fig. 1).

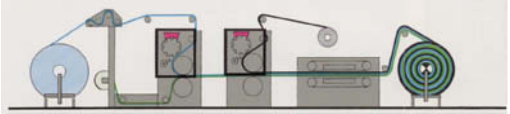

Fig. 1: Powder dot application (Villars) in hot melt laminating.

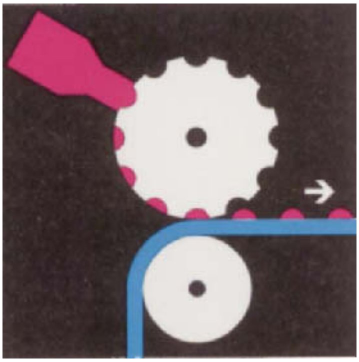

Fig. 2: Powder dot application (schematic).

The hot melt technique of Stork (Fig. 3) is based on the following principle: finely atomized, heated polyurethane glue is applied to one of the two substrates

Hot melt laminating

	melting point or softening point °C	resistance to chlorinated hydrocarbons	washing fastness	main field of application	form of application
copolyamides	75—103 depending on copolymer			men's and boys' wear, women's outerwear (laminating)	powder dot, paste dot and powder scatter process
high pressure polyethylene	100	capable of swelling	fast to mild washing	ribbons interlinings, women's outerwear	film extruder, paste and powder scatter process
low pressure polyethylene	128	good	fast to boil washing	shirt collars, cuffs, temperature-sensitive outerwear, leather,	ditto paste printing
polyvinyl acetate	75—90	—	—		paste printing
ethylene vinyl	60—85	very moderate	fast to mild washing	leather	paste printing powder scatter, powder dot process
copolymers (saponified)	90—115	good to moderate	fast to 60°C washing	leather	paste printing powder scatter, powder dot process
PVC copolymers (plasticised)	120—160	good	good	laminating siliconised woven fabrics, stabilising soft nonwoven and knitted fabrics	dot coating

Tab.: Thermoplastic materials for hot melt coating.

being laminated by means of spray heads (Fig. 4). The second substrate is then pressed onto the first. The glue hardens due to the air moisture content and after 8 hours the substrate can be processed again. The glue reaches full adhesion after 24 hours.

This laminating technique (Fig. 5) has the following advantages:

- environmentally friendly since no solvents involved;

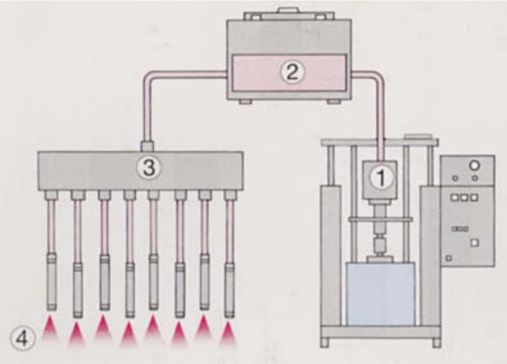

Fig. 3: Heating, conveying and aerosol system for polyurethane (Stork).
1= polyurethane melting unit; 2= conditioner; 3= dosing pump; 4 = spray nozzles.

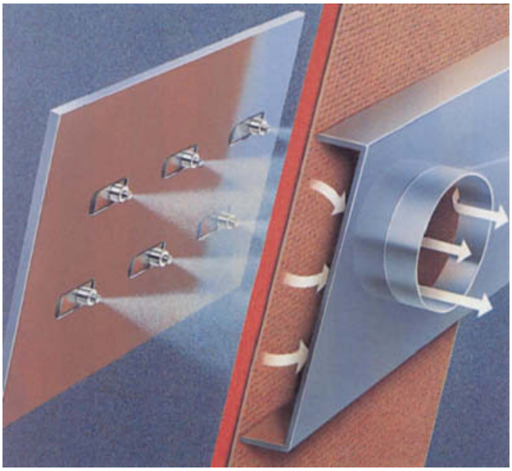

Fig. 4: Spraying of melted polymer (Stork).

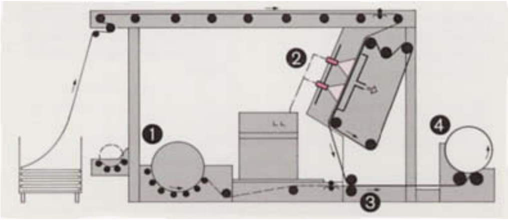

Fig. 5: Hot melt laminating (Stork).
1 = feed unit; 2 = hot melt spray unit; 3 = laminating unit; 4 = winding unit.

- energy-saving since only the glue is heated;
- sensitive substrates can be processed;
- the laminate continues to “breathe” since the glue does not form a closed layer;
- the laminate retains its good feel and remains soft since the quantity of glue is small;
- minimum glue consumption (up to 1.5 g/m^2).

Hot melt lamination Flame lamination is questioned for environmental reasons. Hot melt lamination (using hot melt adhesives) is a possible alternative. This involves the use of thermoplastic polymers, which wet out the substrate in a very short time, in the molten form without significant fabric penetration. Thus the melt viscosity is significant. Three temperatures are important:

- T_M = melting temperature
- T_A = processing temperature
- T_F = temperature of thermal stability

For hot melt adhesives acting as physical binders, the relation of these temperatures should be

$$T_F < T_M < T_A$$

If a cross-linking hot melt adhesive is used, however, this relation changes to

$$T_M < T_A < T_F$$

A typical processing situation is depicted in Fig. 1. The hot melt adhesive is melted in the coating head and extruded; at the same time, the engraved roll takes up the low-viscosity molten material and releases it upon contact with the first substrate on the transfer cylinder onto the fabric as a design. The coated substrate on the laminating roller comes into contact with the IR preheated second substrate in a sandwich form over the entire width and the hot melt adhesive binds the substrates together in the nip of the two rollers. The laminate that results is cooled in a subsequent ribbon calender. Instead of the hot melt adhesive applied by the dot-print method, hot melt film may be used to bond the laminate. Perforated film that remains air permeable is made by the deliberate shrinking of longitudinally cut film in the IR field (Fig. 2).

Hot melt sizing Process developed by Burlington/USA for sizing with a thermoplastic, water soluble polymer (hot melt), which is applied via a roller at 135–155°C. Each individual warp thread runs in a groove. Advantage: energy saving on conventional methods. Disadvantages: high investment costs, expensive sizing material, non-recoverable, additional operation of assembling.

Hot mercerisation Mercerisation with an alkaline solution of approx. 60°C on raw goods causes less change in dye up-take on dyeing. Swelling of the fibres is less, and thus hot and cold mercerisation is often combined. Since swelling is an exothermic process, the

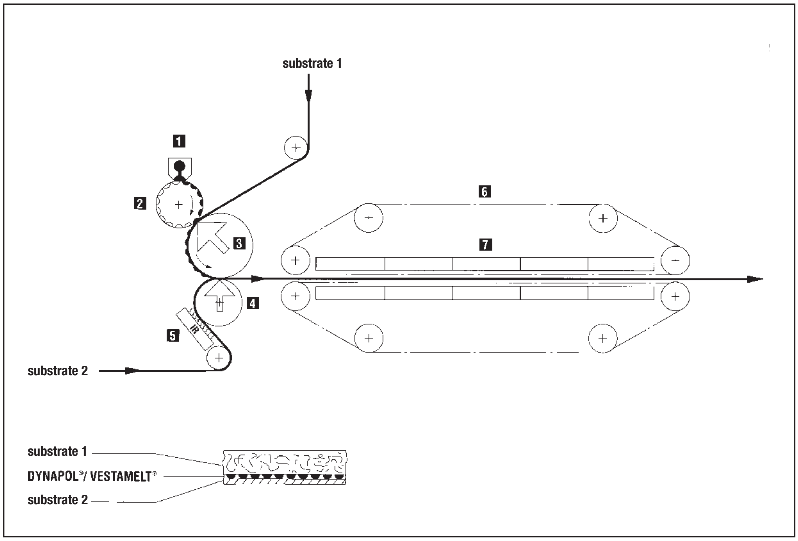

Fig. 1: Typical laminating system for hot melt adhesive application (Hüls).

E = shrinkage; IR = infrared heat source.

hot impregnation of cotton fabrics promotes the even penetration of the less swollen mass of fibres with caustic soda solution, while a subsequent reduction in temperature initiates the swelling process. With an increasing concentration of the caustic soda solution, cotton will swell increasingly at 80°C and very rapidly independent of the concentration. If the used liquor in the test apparatus is replaced by a mercerising liquor of – 10°C, then the pre-wetted cotton will swell substantially more, and demonstrates that an exothermic reaction is involved in this swelling process of two-stage mercerisation.

Hot plate press Used for → Transfer printing of textiles and fully fashioned goods. As a rule a protective paper sheet is laid across the lower of the two plates, on top of which the textile substrate is then laid together with the transfer printing paper. A pedal mechanism is used to press the upper plate down onto the lower for a period of 20–30 seconds, during which time a constant temperature is maintained under the control of a thermostat.

Hot roller fixation →: Heat setting; Hot roll fixation machines.

Hot roll fixation machines Hot roll fixation machines are used for thermal fabric fixation through contact with hot metal rollers. The rollers are double-walled and usually heated from inside by gas. Final fixation through passage over air- or water-cooled rollers. Also combined with hot air fixation.

Hot sand drying process → Fluid-bed process.

Hot seal laminating →: Hot melt coating; Heat sealing.

Hot system optical brightener White tint with optimum effect at boiling temperature. → Cold system optical brightener.

Hot unit American term for an enclosed dry cleaning system (so-called WR types = washer-recovery driers), in which the goods are cleaned, spun, dried, aired, whilst solvent is recovered simultaneously. Opposite → Cold unit = transfer system.

Hot water development Continuous dyeing process for vat dyes. Reduction of the padded vat pigment occurs in a 75–95°C hot blank vat. Light tones are developed without any intermediate drying. Process today has no practical signficance because colour conformity and levelness fail to satisfy all standards.

Hot water reservoir Appliance for preparing and storing hot water up to 80°C, equipped with an adjustable two-position controller.

Hot wetting agents → Wetting agent.

Houndstooth check (dog's-tooth). Pattern description of fabric with similarities to a houndsfoot. In terms of technical design, two forms are found based upon colour and weave; however there is no precise commercial definition thus all types are recognised e.g. coarse designs → Shepherd's check designs (especially with coarser woollen yarns) are described as houndstooth check.

House dust mites Mites cause allergies, 3 to 4% of the population suffering from them, and therefore the antimicrobial finishing of household textiles for example in "the allergy age" is always important. If microorganisms are prevented by suitable means from multiplying, there is a resultant break in the mites' food chain, and consequently a massive population reduction. The best known allergies are caused by the excretions of spider types like mites for example, or by microorganisms like mould spores, and by pollen, animal hair or certain foodstuffs or many other materials. The number of affected persons varies a very great deal depending on the method of investigation. In the case of mould allergies, figures from 5 to 8% of the population are quoted, and 3 to 4% for mite allergies in the household. Altogether 12 to 16%, which is a not insignificant part of the population, are treated medically – and the trend is rising. There are various reasons for this: on the one hand, doctors are paying increasing attention to allergy problems, no longer regarding them as just impairing the quality of life, but as genuine diseases. On the other hand, the increasing demand for comfort and the requirements for new buildings, e.g. insulation, produce a moist, warm climate in living accomodation, providing ideal conditions for mites, fungi and bacteria to breed in.

Mites prefer the same climatic conditions as fungi and bacteria, this is to say warm and moist. These creatures which belong to the spider family, are very unpleasant for many persons, and endanger their health. They are only 0.1 to 0.5 mm in size (Fig.), and are virtually invisible to the naked eye. They live between the textile fibres, and are not dependent on any particular substrate. In the course of their lifetime, they produce excretions equivalent to 200 times their net weight. Only in the sixties was the allergen responsible for this

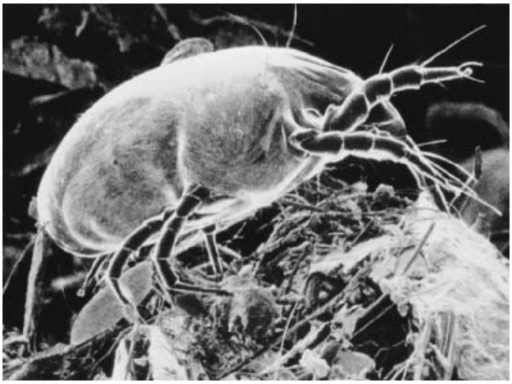

Fig.: The average size of house dust mites is 0.3 mm. About 10 mites could fit inside the dot at the end of this sentence. (Picture: David Scharf, Los Angeles, USA).

kind of allergy discovered. About 3 to 4% of the population, but 50% of asthmatics, suffer from this allergy, which is characterised by dizziness, sneezing, red and watering eyes, shortage of breath, asthma attacks etc. Mildew allergies can give rise to the same symptoms. The weight of skin particles shed daily by a person is about 1.5 g, and is sufficient to provide sustenance for over a million mites. Moulds contribute to this by breaking down the fat layer of shed skin, thus rendering the mites' food more digestible. A temperature of 20 to 30°C and a relative humidity of 65 to 80% are the right conditions for rapid mite population growth. In one generation, i.e. in 3 to 4 months, an original population of 1000 units can easily develop into a colony of over 40 000. Mites are to be found everywhere in a house or flat. Their number depends largely on the climatic conditions.

Household laundering → Domestic washing.

Household laundry → Fastness to washing.

HP, high pressure (→ High pressure steam).

HPD dyeing process for sulphur dyes A hot-pad-dry continuous dyeing process for lightweight cotton or regenerated cellulose fabrics. The liquor contains dye, sodium sulphydrate, caustic soda, glucose and thiourea. After padding, the material is dried or steamed then aftertreated.

HT beam dyeing machines → High temperature dyeing machines, in which piece goods can be treated horizontally at temperatures above 100°C (up to 140°C). The fabric is wound on perforated beams; the liquor is pumped through in either direction. Can also be used for cheeses with special carriers. The heart of all HT beam dyeing machines is the pump. Its output has to adapt to frequently different operating conditions (fabric thickness, winding density). Tailing and shade difference of the selvedge is better on a HT beam dyeing machine than on a winch or jigger.

HT bleach Peroxide bleaching at temperatures of 110–120°C on HT machines (autoclaves) or in special → Pressure steamer for cotton piece goods.

HT bleaching process By using pressure reaction chambers, e.g. Vaporloc (Mather & Platt) with hydrogen peroxide, it is possible to obtain a good bleaching effect on cotton and cotton/polyester blends in 2 min.

HT dyeing machine → High temperature dyeing machines.

HT-Fabric Beam Dyeing Machine → High temperature dyeing machines.

HT-jigger A jigger for the high temperature dyeing (HT-dyeing) of textile fabrics in open-width under pressure (at pressures up to 4 bar). Now largely replaced by HT beam dyeing machines.

HT loop steamer Used as a universal → Continuous steamer. Characteristic features are: low-tension cloth guide, high productivity and the facility for operating with both saturated steam (100°C) and superheated steam (up to 180°C). This allows synthetic fibres (such as polyester, triacetate) to be continuously steamed. In addition, HT loop steamers are ideally suited to setting fabric that is sensitive to tension, such as knitted fabrics made of textured polyester.

HT pressure steamer → Pressure steamer in which woven and knitted fabrics are steamed on a continuous basis with saturated steam at temperatures up to 140 °C and can thus be used for pad dyeings/print development.

HT rapid draining device Assists in polyester HT dyeing in removing oligomers. Controlling the HT rapid draining device on any HT dyeing machine allows the liquor draining temperature to be adjusted as preferrred, e.g. to 130–140°C and in a range where oligomers are not attached to the fibre and can be discharged to drain. The hot dye-liquor is mixed with used, cold process water under controlled conditions and eventually led into the effluent discharge system when the temperature is suitable.

HT steam Steam at a higher temperature (→ Superheated steam) can also exist under normal pressure and be further used at atmospheric pressure (→ High pressure steam).

HT steaming This takes place in continuous → HT loop steamer. Hot steam above 100°C is the heat transfer medium. Specially suitable for fixing polyester or triacetate when printing with disperse dyes. It is possible to work tension-free so they are especially suited for processing tension-sensitive knitwear. Opertaes at temperatures between 160–180°C for 6–8 min. Higher fixation temperature and dwell time require careful selection of dyestuff (above-average fastness to sublimation); as a rule, printing paste contains a fixation accelerator. They are also used, with suitable dyestuff choice and fibre type, with saturated steam (100°C) so these steamers have a temperature range between 100–180°C.

HT steam process → Reactive dyes in direct printing.

Huckaback A hard-wearing cotton, linen or linen/cotton fabric with a characteristically rough-surface effect and very firm handle. The huckaback weave is produced on a plain ground texture by (usually) two regular short floats, warp on one side and weft on the other. The weft yarns are slack twisted to aid absorbency. The small weft floats give the fabric a "barleycorn-like" appearance on the face of the fabric which also causes it to be more absorbent. Huckaback hand towels are produced from cotton, linen and linen/cotton unions. Borders and designs may be woven with coloured yarns. Better qualities are produced with finer yarns and are occasionally woven with warp sateen stripes. Some of the pure linen and linen/cotton union qualities, which contain red pattern stripes woven with cotton, are sold unbleached whilst other qualities are supplied to the market in the fully-bleached state only.

Hue (shade, tint) → Colour.

Human factors engineering As a branch of → Ergonomics, human factors engineering deals with the relationships of man-machine systems with the aim of achieving the best possible combinations of man and machine in terms of overall compatibility. Efforts are made to achieve this objective by the optimum adaptation of machines to the size and proportions of the human body (e.g. through the provision of visual display units, user-friendly devices and anthropometric process control systems).

Human hair Hair is formed by hair follicles (Fig. 1) found in the dermis. At the ends of these follicles, mitotically active tissue forms cells from which the hair is ultimately composed. While the cells are pushed to the skin's outer surface, keratinisation takes place and cells will differentiate into cuticular, cortical and medullar cells. In general a distinction is made between two parts of the hair: the hair shaft emerging from the skin and the hair root hidden in the skin. The latter develops as a pocket-like inlet in the outer skin from the third embryonic month onwards. Its lower wider end (bulb) sits on an upturned projection of the connective tissue, the papilla. This is shot through with smaller blood capillaries, which transport the nutrients necessary for hair renewal. The cells immediately surrounding the papilla are called matrix cells. Through constant cell division they continue to produce fresh hair substance, which pushes upwards and gradually forces itself out of the skin as visible hair.

The freshly formed cells will already differentiate in the bulb of hair. They divide in a spatially characteristic way, change their form and take on various functions, forming the cortex, cuticle and the individual root sheaths. The root sheaths serve, on the one hand, to anchor the hair firmly in the skin while, on the other, they form a kind of "conducting tube" for the developing hair. The hair root sits in the skin at an angle. On the side of its obtuse angle to the skin surface, it is connected with a small muscle (hair-raising muscle), which pulls together in the cold or with a shock and, in doing so, causes the hair to become upright. Just above the hair-raising muscle are the sebaceous glands, arranged like grapes around the hair root. They lead into the follicle funnel and produce a white tallow-like secretion, sebum. A network of fine nerve fibres envelops the hair root below the sebaceous glands, making it sensitive to pain. Hairs do not grow incessantly, but rather are subject to growth and rest cycles. Here the individual body hairs will behave differently. Head hairs grow the longest in terms of both time and elongation. They actively grow for 2–6 years and reach lengths of 70 cm and above. With the transition from the active growth state to the rest phase, the bulbs of hair will recede, shorten

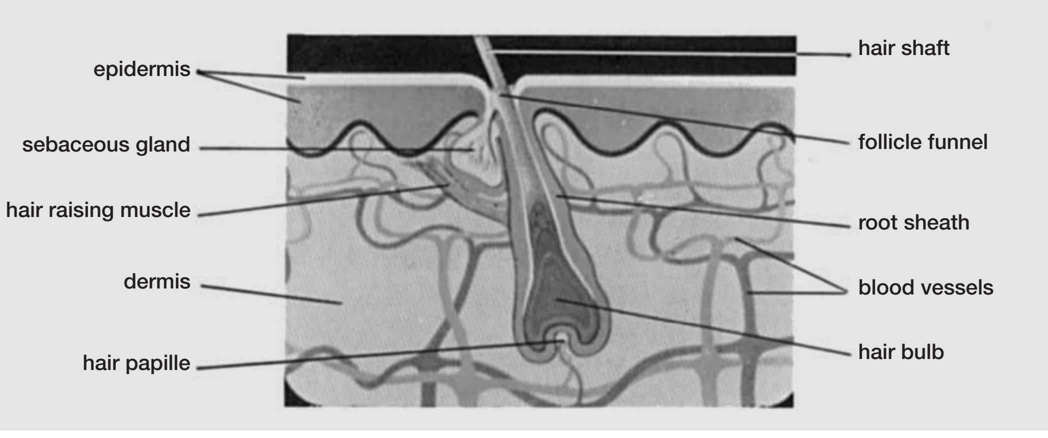

Fig. 1: Diagrammatic view of hair structure in the hair follicle.

keratinise, become bristly and lose the cohesion with the hair papilla. The hair with an atrophied root of this kind can be easily and painlessly combed out. After some time, the hair root will recover again, grow down and form a new hair. The cells responsible for producing the pigmentation melanin, the so-called melanocytes, decrease in number and efficiency of synthesis with progressive age. The hair, which is no longer uniform and pigmented throughout, appears grey and, in extreme cases when no pigment is present at all, white.

The initial material from which the melanin is synthesised is tyrosine, an amino acid. Synthesis occurs in four stages according to the diagram:

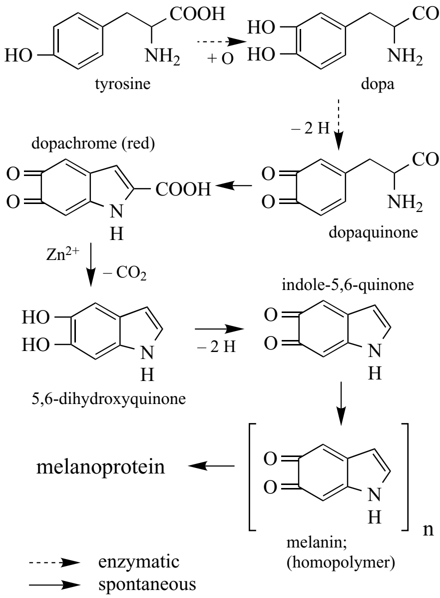

Fig. 2: Melanin synthesis diagram.

1. A series of enzymatic oxidation reactions (dependent on the genes) initially results in dihydroxphenylalanine (DOPA) and then in dopaquinone.
2. Another series of intermediate reactions (molecular rearrangements in conjunction with a cyclisation, without the involvement of enzymes, but in the presence of metal ions) results in indole 5,6 quinone (eventually also other indolequinones).
3. A non-enzymatic polymerisation results in great melanin molecules.
4. These three-dimensional polymers form, together with proteins, complexes that represent the final pigment. A distinction is made between:
   a) the eumelanins, which provide colourings ranging from black to brown; they have a high molecular weight and are insoluble in alkali;
   b) the pheomelanins, which provide yellow colourings; they contain sulphur, which stems from the combination of cysteine and dopaquinone (cysteyl dopa); their molecular weight is lower and they are soluble in alkali;
   c) the trichochromes, which produce lively red and purple colourings; they likewise constitute sulphurous melanin, but have a low molecular weight.

A large part of present knowledge about human hair has been handed down from research into wool. The structure principle (Fig. 3) of a multiple composite system can be found with all keratin fibres. The outer cover is formed by the cuticle, which surrounds the inner strand, the cortex, in the centre of which an axis of medullar cells can be found. The individual morphological components are:

1. Cuticle: outermost layer of the hair, consisting of 6–8 layers of flat, superimposed cells, which make up a 20% share of the weight of the hair. The cuticle is the first part of the hair which comes into contact with environmental influences. In accordance with its protective function, it is very hard and chemically resistant.
   a) Exocuticle: resistant to enzymatic decomposition and heavily disulphide bonded. Since it contains relatively few polar groups, it works as an

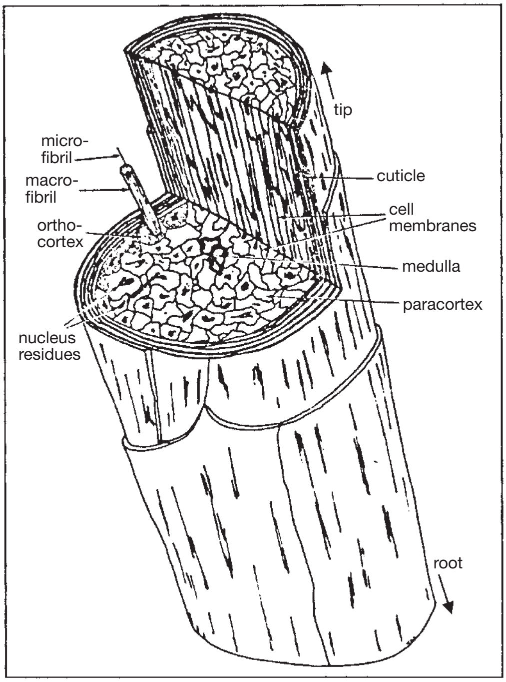

Fig. 3: Diagrammatic view of the internal structure of a typical Caucasian human hair.

effective barrier for the diffusion of hydrophilic substances.

b) Endocuticle: is not as resistant and is solubilised by proteolytic enzymes. In it is found cell detritus from the cytoplasm of the formerly living cells.

2. Cortex: makes up the largest part of the human hair and consists of dead cells and intercellular connective material. The cell membranes of cuticle and cortex are connected here. The network of membranes of all former cuticular and cortical cells are described as a cell membrane complex (CMC). The cells of the cortex are approx. 100 µm long and contain primarily the macrofibrillae, important for the mechanical properties of the hair.
3. Pigment granules containing the hair colouring melanin are found both in the cuticle and between the macrofibrillae.
4. The material between the macrofibrillae, the intermacrofibrillar cement, consists of residue from cytoplasm and nuclei of earlier active cells.
5. The macrofibrillae themselves are made up of microfibrillae, highly organised fibrillar proteins and matrix, a supposedly less organised structure, which sheathes each macrofilament. The great resistance and flexibility of the fibre is due in the main to this microfibrillae-matrix complex. Its strength is chiefly guaranteed by the number of disulphide bridges, which (it is believed) develop within and between the proteins of the macrofibrillae. These proteins are described as keratins (partly according to Hüsken).

Humidity measuring instrument (→ High humidity measuring instrument). With modern processing technology in textile finishing it is important to be able to measure the moisture content of running webs continuously and contact-free (→ Residual moisture content). The measuring range of the system should be as wide as possible since moisture content levels can vary between extremes of 1–150%. Various measuring techniques are used in practice (Figs. 1 and 2).

To control the moisture content of steam, a system based on measuring the oxygen content of the steam can be employed, e.g. by measurement with a zirconium element.

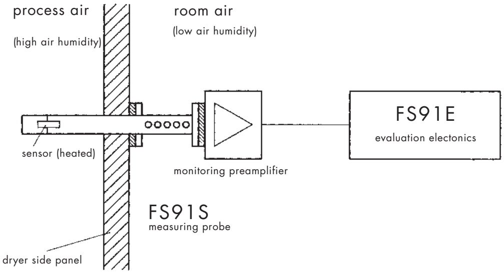

Fig. 1: Block diagram of a humidity measuring instrument (Pleva).

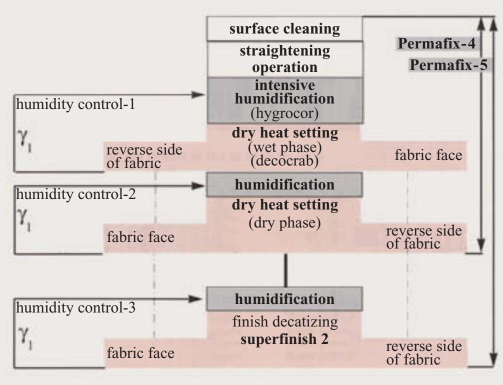

Fig. 2: Processing cycle of the Permafix-4/5 humidity measuring instrument with zirconia element (Menschner).

Humidity monitors → Humidity measuring instrument.

Humification Decay caused for example by → Moulds and bacteria.

Hungry cloth Loose, transparent knitwear. Not always faulty production. Such cloth is deliberately manufactured according to fashion trend demands in a suitable character (e.g. fine, extremely thin lisle stockings).

Hunter coordinate system This occurs through converting the → CIE tristimulus value to the illuminant D65/2° observer according to the following relations:

$$L = 10\sqrt{Y},$$
$$a = 17{,}5 \cdot (1{,}052\,X - Y) : \sqrt{Y}$$
$$b = 7 \cdot (Y - 0{,}919\,Z) : \sqrt{Y}$$

L is the luminosity axis (achromatic axis) analogous to the Y axis in the standard valency system. a and b characterize the chromaticity (and can have positive and negative values). The physical ideal white here has the coordination L = 100 and a = b = 0.

Hup dyeing apparatus Serves to dye fully milled (not well balanced) hat bodies in a floating liquor: relatively low liquor ratio (max. 1 : 30); liquor is circulated by a propeller which automatically changes its direction of flow; the dye liquor is pushed and drawn through the mass (Fig.). Attainable dyeing temperatures with closed apparatus around 98°C. Best results with level dyeing acid dyestuffs.

Hurdle drier Box drying machine for flock, hank yarn and cross wound spools, with perforated floors (cabinet drier).

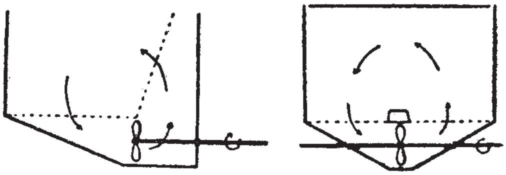

Fig.: Hup dyeing apparatus (Obermaier).

HVI, abbrev. for: High Volume Instrumentation System. A series of integrated semi-automatic electronic instruments for the classification of cotton quality. The system is being used on an increasing scale and has already replaced the subjective conventional classification system in many countries.

HVM → High wet modulus fibres (HVM fibres).

Hyamines Quaternary ammonium type bactericides, algicides and fungicides, available in the form of water-soluble crystals or aqueous solutions.

Hybrid bond, hybrid structure → Mesomeric resonance.

Hybrid composites These may be engineered for a great variety of dynamic effects. A light-weight composite with a higher degree of stiffness and at the same time higher burst strength may, for instance, be required. A hybrid of aramides for high tensile strength and carbon fibres load bearing zones is constructed. Hybrid materials made of aramides and carbon fibres give an optimum balance between mechanical properties and adequate tolerance to damage in many types of application. Often the dynamic load distibution demands a high interlaminar shear strength and, at the same time, optimum flexing behaviour, which can be achieved by a hybrid of these fibres. Property changes can be created with texture variance, too. Hence, for example, a clear loss in tensile strength due to moisture absorption will occur with 90° laminates, whereas this is not noticeable with 0°–45° laminates. A similar effect can be shown with the modulus. Swelling elasticity coefficients and thermal elasticity coefficients can be affected by composites of layers with various angles of fibre position. In addition, besides the two-dimensional fibre arrangement, the 3-D structure can be selected (e.g. three-dimensional woven fabric, needled nonwoven fabric, etc.), allowing important composite properties to be determined. Besides these examples of multilaminar hybrids, there are also intralaminar multiple-fibre materials with which different fibres are combined within one plane, e.g. a fabric with aramide in the warp and glass in the weft.

Hybrid computers Computers consisting of a coupled analogue and digital computer, a digital computer complemented with analogue elements or an analogue computer complemented with digital elements. They combine the advantages of both analogue and digital computers and find application in process computers.

Hybrid fibres Fibres based on polymer blends. The extrusion spinning occurs from a common solution (or melt) of at least two fibre-forming polymers, of which one is a native polymer, e.g. cellulose or casein. Ideally hybrid fibres may be regarded as filament composites. Examples of hybrid fibres (polymer blends and solvents) are:

PAI/Cell	$(HCHO)_X$/DMSO
PAN/Cell	$(HCHO)_C$/DMSO
Cell/PAN	N_20_4/DMF
	LiCl/DMA_C
PAN-Co/Cell	$ZnCl_2/H_2O$
PAN-Co/Fib	NaSCN/H_2O/DMSO
PAN-Co/CA	DMF

(PAI = polyamidimide, Cell = cellulose, PAN = polyacrylonitrile, Co = Copolymerisate, Fib = fibroin, CA =acetate).

Hybrid yarn manufacture Since the development of new high-temperature resistant thermoplasts, interest in using these materials as a matrix with high-performance composites has increased particularly in the air and space travel industry. The techniques illustrated above (see the following Fig.) are principally available for the manufacture of suitable prepegs.

Hydracids, hydrogen acids Oxygen-free acids, such as halogen acids (typically hydrochloric acid HCl).

Hydrate (Gk.: hydor = water), molecular compound formed through → Hydration with bound water molecules.

Hydrated cellulose → Regenerated cellulose.

Hydrated terpene Mixture of tetraline and pine oil (hydrated terpene) as oil of turpentine substitute.

Hydration Reaction of the dipole with ions forming stable "hydrate sheath". Each negatively charged ion (anion) attracts the positive end (H^+) of adjacent water molecules and endeavours to bind certain water molecules, a phenomenon which the usually smaller positively charged ions (cations) show to a greater degree. Each cation attracts the negative ends (O^-) of ambient water molecules and binds some of these to the hydrate sheath, which can have considerable stability, particularly with 3 to 4 valent ions. This property already characterizes the hydrogen ion, which is known to be constantly present as a hydronium ion H_3O^+ ($H_2O + H^+ \rightarrow H_3O^+$). Similarly, water molecules bond together with other ions, too, to form hydrated ions, on which the characteristically good dissolving power of salts is based. The same explanation also applies to colloidal electrolytes. Forces of attraction between cations and water molecules may be so strong that in many cases cations, upon insertion into a crystal, will trap and mo-

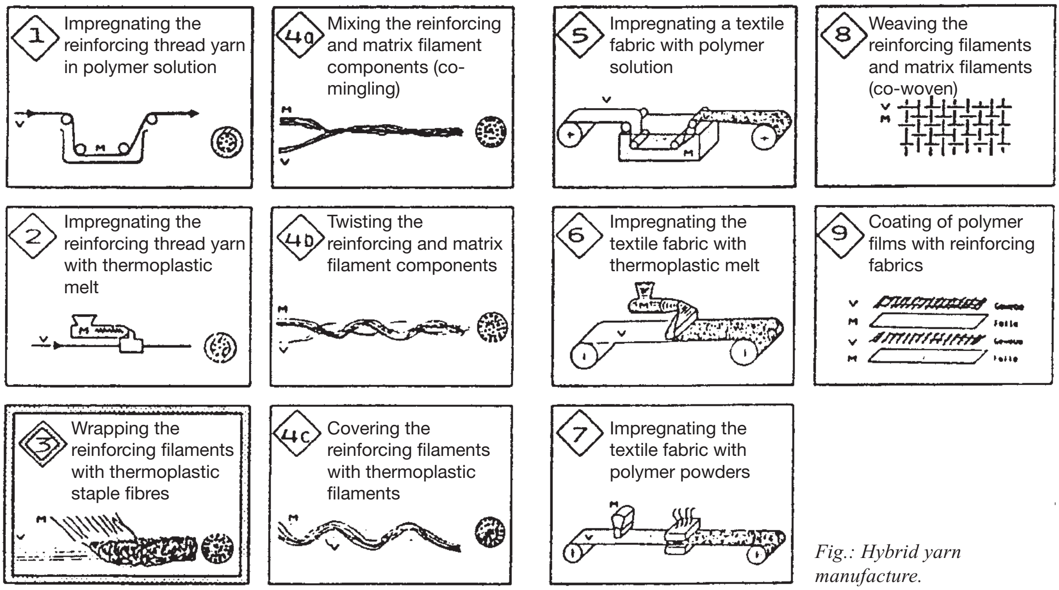

Fig.: Hybrid yarn manufacture.

lecularly bind a sheath of water molecules as so-called hydrate water (hydrates). Polyvalent ions have this ability more so than monovalent ions. Hence larger ions like Mg^{2+}, Al^{3+}, Fe^{3+} will even bind a plurality of water molecules. Such hydrate complexes are found in the following salts and also in the solutions:

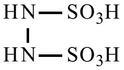
$A1C1_3 \cdot 6\ H_2O$
$CuSo_4 \cdot 5\ H_2O$
$FeCl_3 \cdot 6\ H_2O$
$Kal(SO_4)_2 \cdot 12\ H_2O$
$MgCl_2 \cdot 6\ H_2O$
$MgSO_4 \cdot H_2O$ / $MgSO_4 \cdot 7\ H_2O$
$Na_2CO_3 \cdot 10\ H_2O$
$Na_2SO_4 \cdot 10\ H_2O$

Hydraulic (Gk.) moved by the pressure of fluid (pumped); e.g. high-pressure atomizers for increasing air or fabric humidity (jets) or mechanical drives for step-less speed control (control devices) consisting of driven oil pump and driving fluid motor.

Hydrazides Derivatives of → Hydrazine. Carbohydrazide or fatty acids find their use in the flame-retarding and permanent-press finishing as formaldehyde acceptors. Carbohydrazide is not regarded as being particularly toxic and has a considerable antibacterial effect in finishing.

Hydrazine (Diamide), $H_2N–NH_2$. Fuming, caustic alkaline fluid, reducing agent. Application: inter alia as oxygen binding agent with boiler feed water preparation in the form of hydrazine hydrate $N_2H_4 \cdot H_2O$ in 25% aqueous solution; protects against corrosion. Caution: overdosage in laundering causes yellowing and poor wash effects. Activated hydrazine for boiler use (oxygen binding already occurs at room temperature under the release of nitrogen).

Hydrazine sulphate (Diamide sulphate),



$$\begin{array}{l} HN-SO_3H \\ \,| \\ HN-SO_3H \end{array}$$

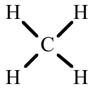
Density 1.38. Colourless crystals, low solubility in cold water, readily soluble in hot water. Separates free metal from noble metal salt solution. Application as a reducing agent in analytical chemistry and cupro-ion dyeing process.

Hydrocarbons Compounds of carbon and hydrogen derived principally from petroleum, natural gas, coal tar and plant sources.

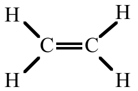
Subdivided into the following groups:

I. Aliphatic hydrocarbons (fatty compounds) with open chains (straight or branched)

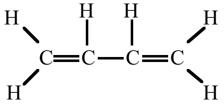
a) → Saturated hydrocarbons, e.g. methane:



b) unsaturated:
- with one double bond (olefins), e.g. ethylene:



– with two double bonds (dienes), e.g. butadiene:

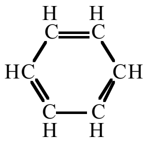


– with a triple bond (acetylenes), e.g. acetylene:

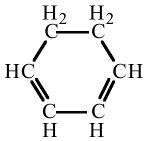
$$H-C\equiv C-H$$

II. Aromatic hydrocarbons (cyclic hydrocarbons)

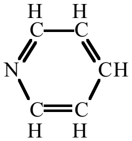
a) with C-rings (isocyclic) (→ Cyclic hydrocarbons), e.g. benzene:



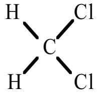
b) as IIa, but with an increased number of hydrogen atoms (alicyclic) (hydroaromatic hydrocarbons), e.g. cyclohexene:



c) hybrid ring structures (heterocyclic compounds), e.g. pyridine:



III. → Chlorinated hydrocarbons, e.g. dichloromethane:



Hydrocellulose Mineral acid damage to → Cellulose is shown through water absorption and splitting of oxygen links bewteen glucose building blocks. Properties: reduced strength, increased reducing power, modified dye affinity. Detection: hydrocellulose alone →Ammoniacal silver nitrate solution. Also with → Prussian blue reaction, Turnbull's blue reaction, Fehling solution, methylene blue and solubility test (which also indicate → Oxycellulose). No staining with Diamine Blue 2B, Congo red or Benzopurpurine.

Hydrochloric acid HCl; molecular weight 36.46. Salts → Chloride. Colourless (highly concentrated) to slightly yellowish liquid, fuming in air, often impure (sulphuric acid, arsenic, ferrous salts: then yellowish); pure hydrochloric acid is volatile, aggressive to the skin, strong acid, miscible with water and alcohols, acetone, etc. Application: acidification after chlorine bleaching or washing, diazotization, stain removal (for rust and ink stains), descaling. Residue in cotton fabrics have a carbonizing effect with drying or ironing.

Hydrochloric acid test For → Dyestuff group identification on fibres, especially for cellulose dyeing of genuine red and black dyes. Method:

I. For red: boil test fabric and concentrated hydrochloric acid = colouring and solution light yellow. After addition of caustic soda solution = both violet = Turkey red (→ Paraffin test).

II. For black: saturate the test fabric with concentrated hydrochloric acid, colouring and solution turn red. After addition of sufficient ammonia and allowing to stand longer, a bluey black sediment will form with a colourless supernatant solution = logwood black.

Hydrodynamic processes in printing The explanation of the mechanisms found in printing is not only of theoretical interest, but also practical relevance since processes are involved which can positively affect the quality of print and the economic process management. From a hydrodynamic standpoint, such an explanation means investigating those factors which affect the size and distribution of pressure on the paste and in the printing zone, as well as an analysis of the hydraulic loss occurring during the printing process, namely through the paste diffusing through the screen openings. In practice, this means first and foremost:

1. Calculating the pressure generated in the nip between doctor blade and screen.
2. Determining the width of the printing zone in which the paste diffuses through the screen opening.
3. Calculating the hydrodynamic resistance to which the printing paste is subjected during diffusion.
4. Ascertaining the effect of the geometry of the doctor blade, the printing speed and the rheology of the printing paste on these processes.
5. Determining the connection between the paste pressure and the quantity of printing paste applied to the material.

In practice, the paste begins to flow when its pressure reaches values that overcome the screen's resistance and guarantee its diffusion at a particular speed. The rate of diffusion of the paste is very low at the edge of the printing zone; it will increase gradually as the contact line between doctor blade and screen is approached. Thus an even film of printing paste is formed on the material as it passes through the printing zone, whose thickness is dependent on the printing conditions, the printing paste properties and the capillary forces of the material.

Hydroentanglement Spunlace technology has been applied for bonding of nonwovens for years already. In the middle of 1995, Messrs. BBA Inc., USA developed the Interspun process and applied for its patenting. This process is used for treating textile-structure surfaces by means of water jets and has a positive influence upon structure and properties of woven fabrics. Contrary to the spunlace technology for bonding of nonwovens where free-moving individual fibres are subject to high energy water jets (Fig. 1), fibres of woven and knitted goods are firmly integrated in the yarn resulting in a distinct change of inner structure.

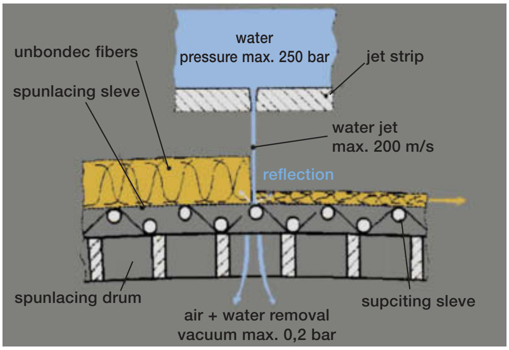


Fig.1: AquaJet Spunlace System.

In 1998, BBA and Fleissner signed a cooperation agreement making Fleissner the exclusive machinery supplier for this technology. Thus the years of experience in the field of nonwoven hydroentanglement through the AquaJet system (Fig. 2) developed by Gerold Fleissner can now also be applied to fabric treatment in an ideal manner. Fabric finishing can no longer be imagined without the AquaTex system for fabric enhancement which will have a lasting influence upon fabric treatment. Enhancement here means a textile finishing process that, besides improvement of the product's quality, is especially linked to saving of costs and energy, environmental protection and reduction of textile finishing steps such as washing processes etc.

The Interspun process uses micro water jets of 0.1–0.15 mm impinging from perforated nozzle strips with 60 jets/inch in form of a curtain onto the cloth with a pressure of 150–250 bar and speeds of up to 300 m/s. This water is sucked off by means of a suction slot arranged underneath the injector and is led to the high pressure pumps passing an air/water separator and filtration system in this circuit before being pressed through the high pressure jet heads again. During this passage, part of the water (depending on the type of fibre between 3 and 5%) is constantly added as fresh water to compensate for the loss by fabric moisture evaporated in the dryer, water drops in the air/water separator, and back-wash water in the filter system. When subject to the water jets, the material is transported either on a suction drum or a conveyor belt. The fabric can be hydroentangled on either one side or both sides.

By high energy water impinging on the cloth, the yarns blossom and the loose ends of the fibres both within the individual yarns and between adjacent yarns

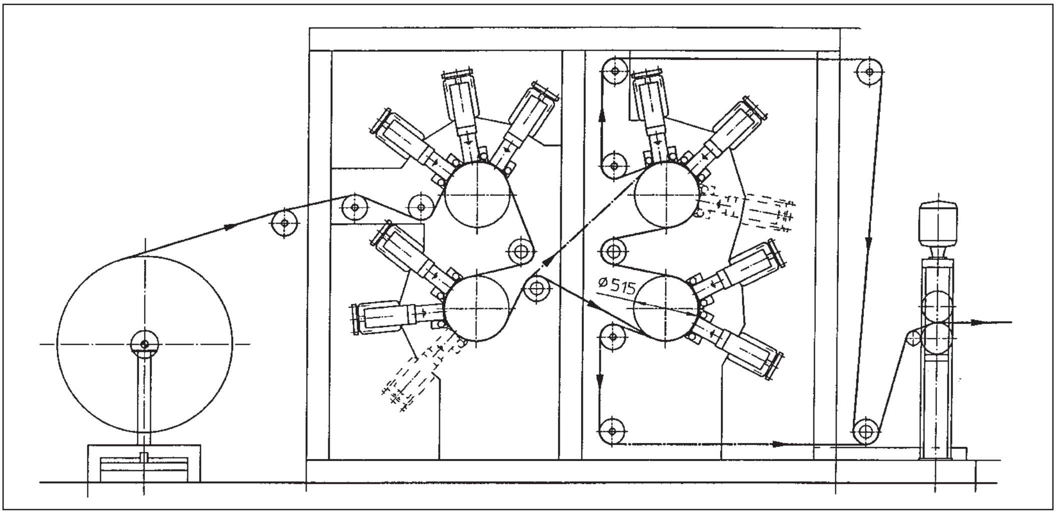

Fig. 2: Water jet for nonwoven bonding (AquaJet from Fleissner).

entangle. With the water being pressed through very fine jet nozzles, an impure, turbulent jet caused by turbulence in the jet head or particles/soiling at the jet nozzles may result in uneven treatment of the fabric, in turn leading to streaky effects. The AquaTex system jet heads are designed such as to distribute the water over the width evenly and at uniform pressure thus ensuring each water jet delivers the same energy. The belt or drum(s) to transport the material during water treatment is used for exhausting excess water in a vacuum slot before the next water curtain. Too much water on the fabric surface during impingement of the water jet may cause uneven enhancement or a Moirée effect. The vacuum in the suction slot at the same time keeps the material in place. The slot is arranged directly underneath the jet curtain to achieve efficient enhancement.

Hydroextracted goods → Centrifuge hydro-extraction.

Hydroextraction by centrifuge (spinning), → Water extraction by → Centrifuges.

Hydroextraction effect (centrifuging effect). A measure of the amount of liquor remaining on a textile material after hydroextraction (centrifuging), expressed as a percentage based on the weight of dry material.

Hydroextraction index → Hydroextraction effect.

Hydrofixation → Heat setting of polyamide piece goods in HT beam dyeing machines using hot water (up to 140°C), mostly combined with bleaching, scouring or dyeing.

Hydrofluoric acid Hydrofluoric acid (HF) is a 40% aqueous solution of hydrogen fluoride (a colourless gas) in the form of a fuming liquid. MW 20.01. Salts of hydrofluoric acid are known as → Fluorides. Both the fumes and the solution are strongly acidic. Hydrofluoric acid is highly corrosive and toxic by ingestion and inhalation. It dissolves virtually all metals (except gold, platinum and lead) and attacks glass and porcelain (by the formation of silicon [tetra]fluoride) on heating. The potassium salts are only sparingly soluble in water or dilute acids whilst the silver salts are readily soluble. Uses: for etching glass; its salts are used as a substitute for antimony potassium tartrate (tartar emetic); as a spotting agent (e.g. for removal of iron stains) as an alternative to oxalic acid, etc.

Because of its corrosive properties, hydrofluoric acid is handled in monel, PTFE or platinum equipment.

Hydrogel → Gel.

Hydrogen Chemical symbol H (Lat.: hydrogenium). Atomic weight 1.01 → Non-metals, a gas; colourless, odourless, tasteless; lightest gas (14 times lighter than air); combustible (pale blue flame) under intense heat development and formation of water; 2 parts with 1 part oxygen form an explosive mixture. Only slightly water-soluble, hydrogen extracts the oxygen from oxides (especially in the presence of catalysts) (→ Reducing agent). As a dissociated component (→ Hydrogen ions H^+) of water-dissolved compounds, hydrogen is the carrier of acidic reaction (hydrogen ion reaction). It is produced through the action of acid on base metal (Zn + HCl), whereby liberated H atoms escape from the solution and the metal dissolves as ion. ($Zn + 2H^+ + 2Cl^- \rightarrow Zn^{2+} + 2Cl^- + H_2\uparrow$).

Hydrogenated hydrocarbons → Alicyclic hydrocarbons.

Hydrogenated phenols Hydroaromatic compounds of the type hexaline and methyl hexaline play a significant role in solvent-containing textile auxiliaries of many kinds solvating assisitants (→ Hydrotropic property), where they serve as solvents for fats, oils, resins, waxes, tar, linoxyn, etc.

Hydrogenation (Hydrogenium = hydrogen), to attach hydrogen, e.g. with carbon liquefying (Bergius process). Principle: hot splitting of the carbon molecules (under pressure) and simultaneous hydrogenation (hydrogen gas) produces paraffin, petrol, etc. → Fats, high pressure hydrogenation of; Fat, hydrogenation of.

Hydrogen bonds A hydrogen bond is a type of electrostatic interaction between groups in molecules that have hydrogen atoms bound to electronegative atoms (e.g. so-called → Donor, such as oxygen, nitrogen, sulphur, chlorine, fluorine). Hydrogen bonds may therefore be regarded as electrostatic bonding forces between dipole molecules with a high dipole moment, in which the hydrogen atom is at the positive end of one polar group and forms a linkage with the electronegative end of another polar group. (→: Secondary valency forces; Dipoles).

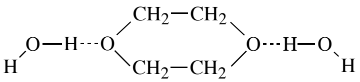
$$\overset{\delta-}{X} \longleftarrow \overset{\delta+}{H} \cdots\cdots \overset{\delta-}{Y} \longleftarrow \overset{\delta+}{Z}$$

Hydrogen bonding is responsible for the self-association of H_2O molecules in water and ice. In this structure, the hydrogen of one molecule is always bound to the oxygen of another molecule through a shared electron pair which, however, lies somewhat closer to the oxygen so that the oxygen atom is at the negative end, and a hydrogen atom (or, more correctly, a H^+ [proton]) is at the positive end of a dipole.

Hydrogen bonds are characterized as relatively loose bonds which are usually completely disassociated again in the vapour phase since the H^+ is generally more strongly attached to one of the two electronegative atoms than the other. From the foregoing, it can be seen that the hydrogen bond is relatively weak and certainly weaker than the usual → Ionic bond and → Atomic bond. Hydrogen bonds are, in fact, only about one tenth to one thirteenth as strong as normal covalent bonds but have pronounced effects on the properties of substances in which they occur. Such bonds are therefore readily broken and re-formed again, which is one of their important features. They are, however, stronger than → Van der Waals forces.

The electrostatic intermolecular dipole interaction involved in hydrogen bonding is of considerable practical importance in almost all branches of textile chemistry:

I. Solvation: water is a good solvent for electrolytes or polar solvents such as dioxane through the action of hydrogen bonds:



Highly polar liquids are suitable as solvents for synthetic polymers if the bonding energy between solvent and polymer is greater than between solvent and solvent.

II. Fibre structure: in many cases, hydrogen bonds play a decisive role in fibre structure. They are formed in virtually all fibres through functional OH and/or NH groups between the chain molecules, thereby creating structural elements that are of considerable importance for the crosslinking and elastic resilience of the macromolecular fibre structure. Good orientation of the fibre molecule is due to the close proximity of polar groups and the electrical interactions created by hydrogen bonding. This, in turn, is largely proportional to the degree of crystallinity and is therefore more or less responsible for the close packing of the molecules which is not only manifest in the specific strength of the fibre but also, e.g. in dyeing mechanisms and in the interstitial inclusion of synthetic resin particles (in cellulose), etc. The temporary breakdown of hydrogen bonds is also responsible for the swelling processes, the thermoplastic properties and, with subsequent re-formation of hydrogen bonds, the heat-setting of textile fibres.

III. Dyeing: hydrogen bonds are often involved in dye/fibre attractions and can participate in dyeing mechanisms in many ways, especially in the case of synthetic fibres. Typical examples include, e.g. bonding between direct dyes (azo groups) and cellulose (OH groups) where the linear and planar structure of direct dyes is largely responsible for their attraction to cellulosic fibres by allowing close alignment between the dye molecule and the cellulose chain molecule, which makes it easy for hydrogen bonds to form. The bonding between disperse dyes (NH-, NO- groups) and polyamide fibres represents another important example.

Hydrogen halides Oxygen-free, acid compounds formed between hydrogen and → Halogens, e.g. HF, HCl, HBr and HI. Hydrogen fluoride differs from the other hydrogen halides because of its strong hydrogen bonding and consequent association.

Hydrogen-ion concentration (H^+ concentration). Chemically pure water reacts neutrally since both types of ions (H^+ and OH^-) are fully dissociated in practice. Since according to the law of mass action the product of the concentration of H and OH ions must always be the same (10^{-14} g/l), it is sufficient to only specify the H-ion concentration each time. Should this increase, the solution becomes more acidic, causing the OH ion concentration to fall and vice versa if the reaction shifts towards the alkaline. For the purposes of simplification, only the respective exponential of the tenth power without minus signs are used. Applied to the H-ion concentration, as a generally valid yardstick, instead of 10^{-7} g/l "7" is written as an expression of the H ion concentration or → pH (from "pondus hydrogeni" = weight of H), written pH 7.

From this it follows for pH and solution reaction:

0–3	highly acidic
4–6	weakly acidic
7	neutral
8–10	weakly alkaline
11–14	highly alkaline

The change in a full pH degree corresponds to a tenfold (900%) increase or reduction in action each time. According to this, the pH is the measure for the reaction strength, not for the particular amount of acid or alkali in g/l.

Hydrogen ions (H ions, hydronium ions, hydroxonium ions), H^+ or H_30^+. Electrically positively charged particles of hydrogen atoms, which cause the acidic reaction of acids and acid salts to occur.

Hydrogen methyl polysiloxane (HMPS), is used in silicone finishing in the textile industry. It is reactive and can react with itself to form cross-links. It then forms a polymolecular, coherent film around individual fibres of a yarn bundle or fabric. Chiefly emulsions made of dimethyl polysiloxane (DMPS: does not react with itself at normal concentrations) and small parts of HMPS (for increasing the viscosity) are incorporated. In order to obtain good water repellancy and a soft handle, the fabric requires a hydrophilic support layer of heavy metal hydroxides, e.g. zircon hydroxide.

Hydrogen peroxide (Hydrogen superoxide, hydroperoxide → Peroxide), H_2O_2, structure H–O–O–H. Molecular weight 34.016. Besides water, hydrogen and oxygen form hydrogen peroxide H_2O_2. In its anhydrous state, this is a liquid whose physical properties are very similar to those of water. The boiling point is at 150.2°C, the freezing point –0.43°C. The molecule is diamagnetic; its structure is reproduced in Fig. 1. The metastable original state of H_2O_2 is separated from the product water in the model (Fig. 2) by an energetic barrier, the "activation peak". This makes the decomposition of hydrogen peroxide thermodynamically possible:

$$H_2O_2 \rightarrow H_2O + {}^1/_2\, O_2;\ \Delta G^\circ = -96\ \text{kJ/mol}$$

However, at room temperature only a few molecules are so rich in energy that they reach the free activation enthalpy (ΔG^*) of 76 kJ/mol. Decomposition may be greatly accelerated by heating, whilst catalysis speeds up the reaction rate (catalytic activity of simple metal ions).

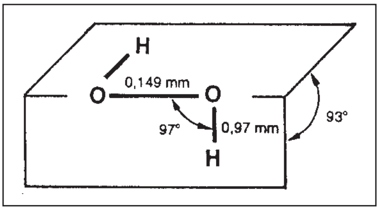


Fig. 1: The structure of H_2O_2.

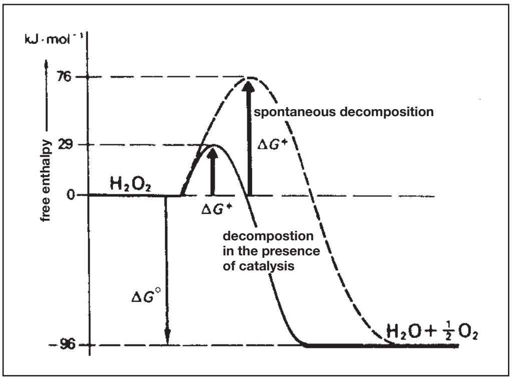

Fig. 2: Activation energy (ΔG^*) with spontaneous and catalysed decomposition of hydrogen peroxide (besides ΔG° = exothermic energy gain).

Hydrogen peroxide salts: peroxides, solid hydrogen peroxide: → Carbamide peroxide. Forms: 3–40% Vol. Hydrogen peroxide is water-clear, colourless and odourless, weakly acidic (normally stabilised with sulphuric acid). The more concentrated (apart from anhydrous hydrogen peroxide), the more readily it decomposes. Store in a cool, dark place and, for use, preferably in partially filled bottles with drilled corks. Dust contamination can cause severe decomposition. Storage: receptacles made of glass, stoneware, porcelain, special steel, super-pure aluminium etc. Strong oxidation and bleaching agent (→ Bleaching agent, hydrogen peroxide). Catalyst presence in water or on fabric (rust, iron, manganese, brass, copper, etc.) causes premature decomposition (fibre damage). Effect of heat and light and the presence of dust, heavy metals, enzymes and alkalis (also alkali leached from glass) cause decomposition to water and oxygen.

Should H_2O_2 encounter greater oxidation agents, it acts reductively, e.g.:

$$2\ KMnO_4 + 3\ H_2SO_4 + 5\ H_2O_2 \rightarrow$$
$$K_2SO_4 + 2\ MnSO_4 + 8\ H_2O + 5\ O_2$$

Louis-Jacques Thénard first introduced the hydrogen peroxide molecule in 1818. This symmetrical molecule forms a dihedral with the base of the oxygen atoms O–O, to each of which a hydrogen atom H attaches itself in both directions below an angle of 96°. Modern physics characterises this molecule through various, quantifiable movements of the electrons visible in the spectroscope (rotations and vibrations Fig. 3).

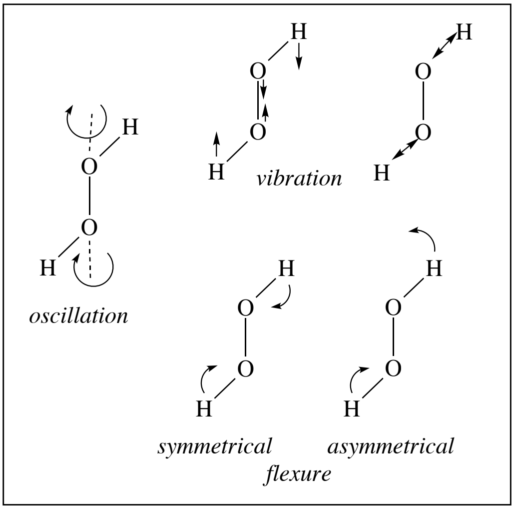

Fig. 3: The hydrogen peroxide molecule can be stimulated to produce vibrations in various ways.

The intramolecular vibrations represent oscillations of the atoms around their equilibrium state, comparable to a mass suspended on a spring (chemical bond) (Fig. 4). Since a molecule with n atoms (n = 3–6) shows the same types of vibrations, there are for H_2O_2 six types of vibrations (Figs. 3 and 4).

Application: bleaching agent for wool, cotton, silk, linen, viscose filament yarn/staple fibre, synthetic fibres, viscose, hair, bristles, feathers, animal hair (with oxygen stabilisers), furs, wood, straw, sponges; glue, gelatine, fats, wax; oxidation agent for sulphur and vat dyeing. Desizing agent for viscose fabrics. Disintegrating agent for starch (sizes). Scouring agent (scorch marks, blood, dye, coffee, tea and sweat stains, etc.).

Hydrogen peroxide bleaching

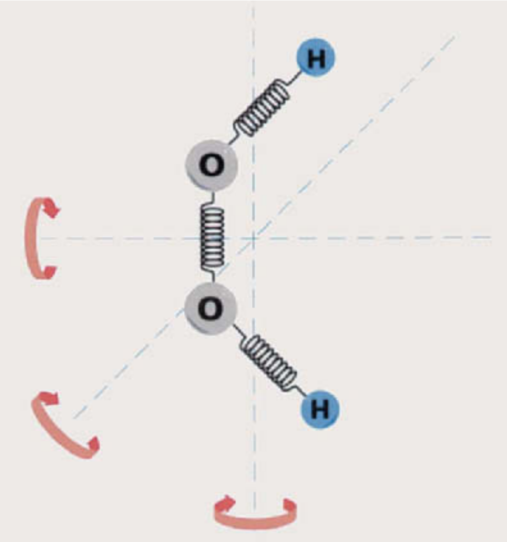

Fig. 4: Rotational axes around the atomic bonds of the hydrogen peroxide molecule (according to Fornelli).

Concentrated hydrogen peroxide solutions have a damaging effect on virtually all materials.

Hydrogen peroxide bleaching In a three-stage preparation range for cotton fabric (Fig. 1), the following demands are made on the process chemicals in the hydrogen peroxide bleaching stage:

- swelling effect (H_2O)
- wetting and washing
- emulsifying
- dispersing
- complexing
- peroxide stabilisation
- activation (NaOH)
- fibre protection

Depending on the type of fabric, rope bleaching (Fig. 2) or under-flow bleaching (Fig. 3) is used. New kinds of bleaching systems for hydrogen peroxide make use of high-moisture application (Fig. 4).

Flexnip (Küsters, Fig. 4): Starting with a moisture content of around 70%, the fabric enters from top to bottom into a 10-litre trough in which the bleaching bath is replaced every few seconds. At the lower exit, the fabric passes between two flexible squeeze rollers, which control the application to 150%, hence guarantee a liquor uptake of 80%. A seal prevents the loss of fluid. The liquor is replaced automatically to keep a constant liquor level. The entrance to the steamer is horizontal to prevent liquor spotting. Wet-on-wet impregnation (Fig. 5) is possible in this system. Very precise control of the bleaching chemicals is necessary (Fig. 6).

Optimax system (Menzel, Fig. 7): High pressure on the fabric is followed by a strong decompression,

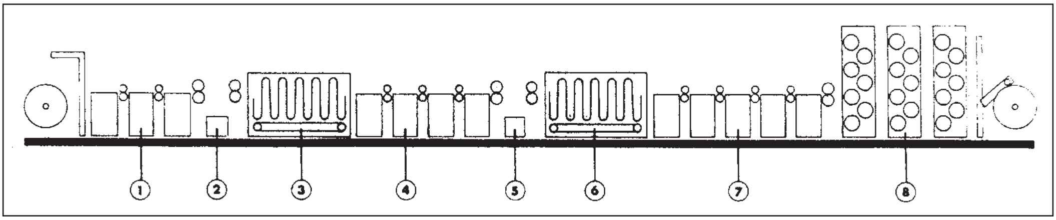

Fig. 1: Classic 3-stage pretreatment system for desizing, boiling and bleaching. 1= desizing; 2–4 = boiling; 5–7 = H_2O_2 bleaching; 8 = cylinder dryers.

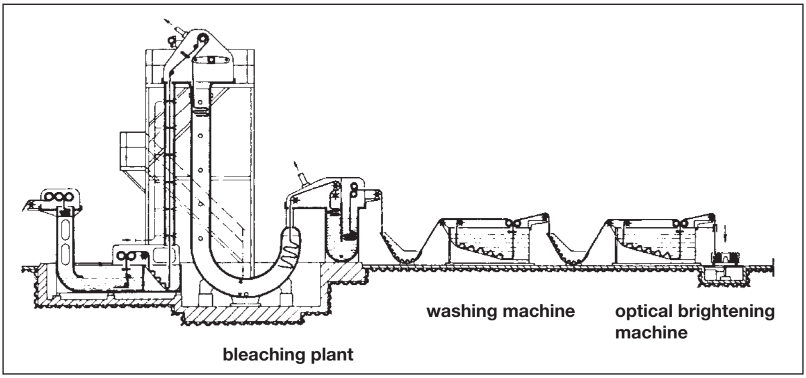

Fig. 2: Rope bleaching system of Friedrichsfeld GmbH.

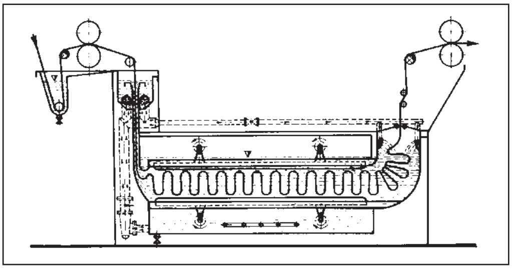

Fig. 3: Menzel under-flow bleaching system.

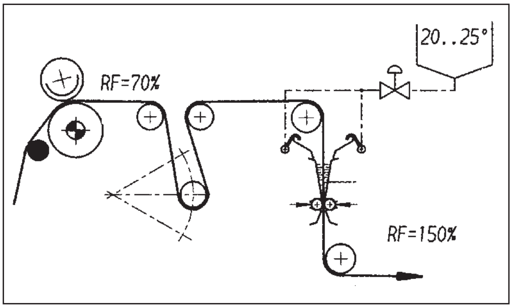

Fig. 5: Flexnip wet-on-wet application (Küsters).

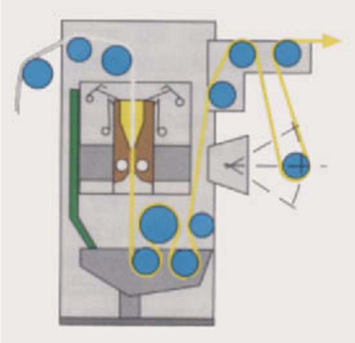

Fig. 4: Flexnip by Küsters for pretreatment.

which effectively acts like a suction of the liquor, similar to a sponge. The desized and warm-scoured fabric is squeezed between two Rowatex rollers; then it absorbs the liquor found in the nip formed by the two rollers. Two small rollers prevent any loss of fluid. The fabric circulates from under to over. In front of the entrance to the steamer, two rollers regulate the maximum liquor application. The system is flexible because it allows minimum and maximum application values.

Super Sat system (Babcock, Fig. 8): The special aspect of this system is its use of the nip for the passage of

the fabric between the rollers. The desized, warm fabric squeezed to 70% expression passes through the 5-litre Super Sat system to enter the steamer with maximum application. The system is characterized by an automatic inflow of liquor direct to one side of the fabric, then out the other side. The liquor uptake reaches the absorption limit, promoting the penetration of the bleaching chemicals. The excess liquor is re-circulated. Continuous dosing through the polykomat ensures constant chemical concentration.

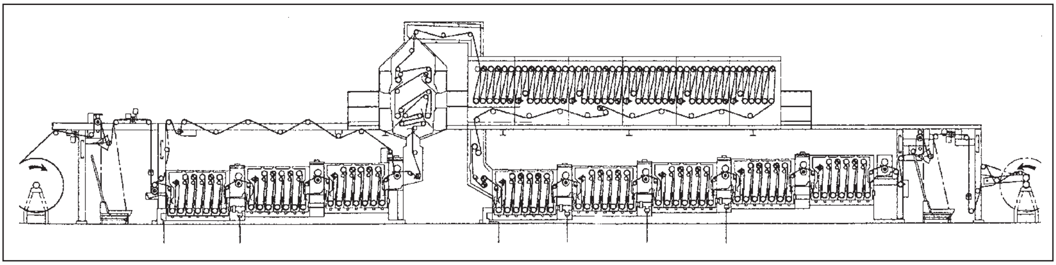

Fig. 12: System design for dry-on-wet and wet-on-wet processes according to the Raco-Yet principle of Kleinewefers KTM.

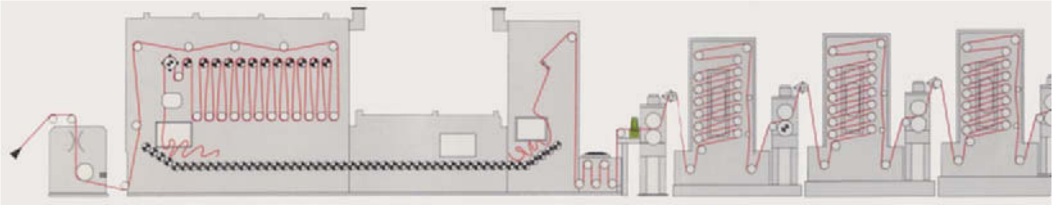

Fig. 13: Küsters Flexnip with processing time = 15 min in the steamer for bleaching with hydrogen peroxide.

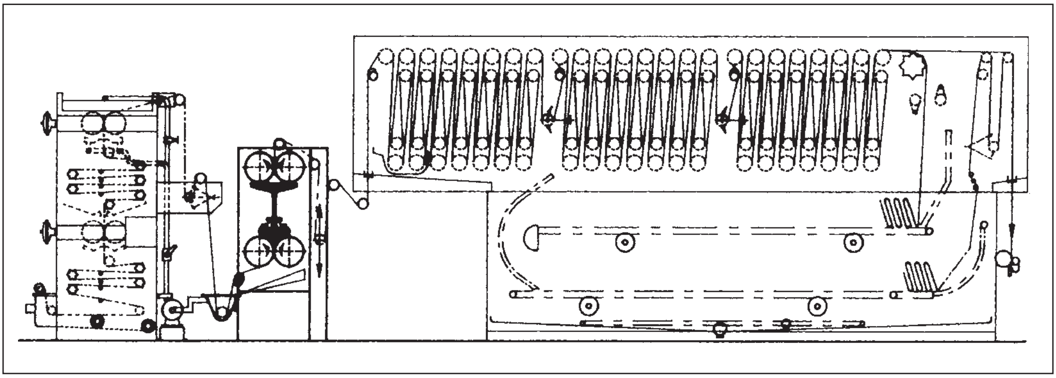

Fig. 14: Elementary diagram of the universal application system Optimax in a pretreatment system (Menzel).

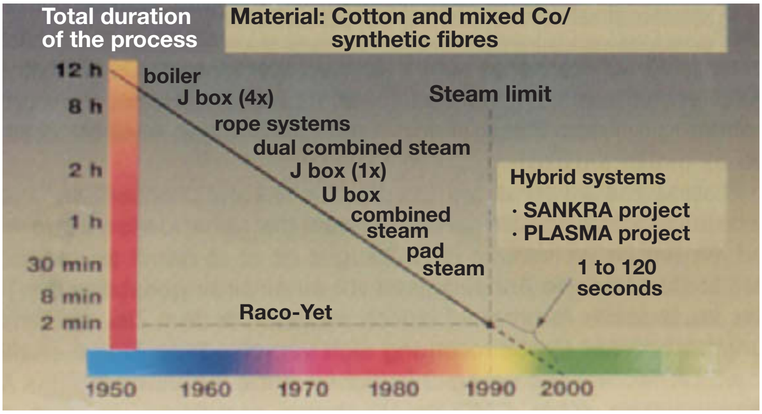

Fig. 15: Shortening of the bleaching times by changing the process engineering (Fornelli).

of the chemicals. The fabric passes in this way through the Dip Sat system (10 l capacity) with a moisture of 60%, then horizontally into the steamer with a maximum application of around 140%.

Raco-Yet (Kleinewefers KTM, Fig. 10): Steam and bleaching liquor are mixed in a binary nozzle and sprayed onto the passing fabric. Only 2 min steaming are then required. Pretrials for determining the bleaching formulae are possible on a Raco-Yet simulator (Fig. 11). Because of the short steaming time, a Raco-Yet bleaching system can treat the fabric in the steamer entirely in a fixed fabric guide (Fig. 12). This is impossible with other types of high-moisture content hydrogen peroxide bleaching due to the need for longer steaming times necessitating combined steamers with fixed and free fabric guides (Figs. 13 and 14).

If the aim is to achieve even shorter reaction times than the Raco-Yet by means of hybrid systems (Fig. 15), as with the Sankra process, which is not yet state of the art, or with Plasma applications (research project), then in short it is necessary to create a reaction-controlled process from the diffusion-controlled bleaching process.

Hydrogen peroxide bleaching mechanism Hydrogen peroxide is the most frequently applied textile bleaching agent. If fibre damage is to be limited, then it is essential to fully understand the mechanism of the bleaching process. Although numerous studies have been carried out, there is no conclusive evidence whether an oxidative and/or a radical decomposition of the yellowness occurs. The predominant opinion is that ionic decomposition products of the hydrogen peroxide have a bleaching effect and radical decomposition products cause damage. Dannacher and Schlenker postulate, on the other hand, a direct involvement of the perhydroxyl radical ion as a bleaching agent.

Several mechanisms are considered possible with regard to the bleaching effect of hydrogen peroxide:

a) Because bimolecular oxygen has no bleaching effect, oxygen "in statu nascendi" (in the nascent state) is assumed to be an intermediate stage of decomposition from H_2O_2 to O_2, and atomic oxygen (O) is actually produced. Since normal atmospheric oxygen has no corresponding bleaching effect, it is conceived that a reactive progenito is formed in decomposition and then converted into harmless oxygen. This aggressive stage which the oxygen molecule passes through at "the hour of its birth" is happily accorded the term "active oxygen" in older literature.

There is no experimental indication of atomic oxygen under bleaching conditions. An examination of the energy released in the decomposition reaction also contradicts this hypothesis:

$$H_2O_2(fl) \rightarrow H_2O(fl) + {}^1/_2\, O_2(g)$$

For the components in their standard state, the energy balance of this reaction is exothermic. The standard state of oxygen, however, is molecular oxygen. If the reaction is formulated with atomic oxygen, then there is an energy deficit, which results from the bonding of the oxygen molecule. The reaction becomes strongly endothermic. Oxygen in statu nascendi is liberated as active oxygen for thermodynamic reasons.

b) As with straw bleaching, → Singlet oxygen is formed in the redox reaction of H_2O_2 with hypochlorite. When used as antichlor in the intermediate stage bleaching, H_2O_2 is oxidized as follows:

$$H_2O_2 + ClO^{\ominus} \xrightarrow{pH\ 10} H_2O + Cl^{\ominus} + O_2$$

The balance of the hydrogen peroxide bleaching, on the other hand, remains exothermic if molecular oxygen is not formed in its normal electronic state, but rather in the initial electronically activated one, a singlet. This singlet oxygen can actually be generated under washing conditions and proven by catching with a trap compound.

A common method of forming singlet oxygen in an aqueous medium is oxidation of alkaline hydrogen peroxide solution with hypochlorite. Whether the singlet oxygen produced in this way actually bleaches can only be verified by means of experiment. Bleached cotton fabric dyed with black tea has served as standard staining. This staining is often used with bleaching tests for domestic detergents.

The chosen method for producing singlet oxygen has one disadvantage: the educts themselves are bleaching agents. At room temperature, the bleaching effect of hydrogen peroxide within the chosen test peri-

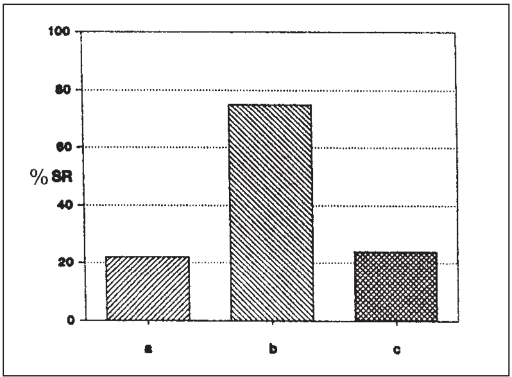

Fig. 1: Overall cleaning effect of tea staining at room temperature (according to Dannacher and Schlenker).
a = $4.6 \cdot 10^{-3}$ mol/l H_2O_2; b = $9.2 \cdot 10^{-4}$ mol/l HOCl;
c = $9.2 \cdot 10^{-4}$ mol/l ${}^1O_2$ and $3.68 \cdot 10^{-3}$ mol/l H_2O_2.
% SR = relative soil removal.

od of 30 min is slight. The concentration of hypochlorite used, however, will produce a good bleaching result. To inhibit a direct bleaching effect of the reactive hypochlorite, hydrogen peroxide has been used at five times higher concentration (according to Dannacher and Schlenker).

The bleaching effect obtained under these conditions with singlet oxygen ranges within the limits of experimental error. The result is no better than it is with hydrogen peroxide alone, which is still present in great excess (Fig. 1). Singlet oxygen is obviously not the “active oxygen” of hydrogen peroxide bleaching.

Hence, no bleaching effect has been obtained using this system where hydrogen peroxide is used in excess.

c) Perhydroxyl anion: hydrogen peroxide is a weak acid with an affinity constant in water at 20°C of $K = 2.4 \cdot 10^{-12}$. If alkali is added to an aqueous hydrogen peroxide solution, perhydroxyl anions are formed.

$$H_2O_2 + HO^{\ominus} \rightleftharpoons H_2O + HOO^{\ominus}$$

The characteristic decomposition according to

$$HOO^{\ominus} \longrightarrow HO^{\ominus} + [O]$$

increases with rising pH of the liquor. Although the perhydroxyl anion formation as the characteristic decomposition is exothermic, the activation energy is relatively high, however, with the result that aqueous solutions of hydrogen peroxide itself are metastable at boiling temperature; decomposition, though, is catalysed by heavy metals and readily oxidizable substances. The activation energy of the characteristic decomposition is reduced in alkaline liquors.

Cellulose is broken down via radical mechanisms, preferably forming keto groups in the process. The chain scission will then occur via a nucleophile substitution by the perhydroxyl anion. However, a reaction chain is conceivable which commences with a hydrogen peroxide adduct; Fe^{3+} will increase the speed of this process, but produce the same end products.

The bleaching reaction can be initiated by nucleophile substitution by means of the perhydroxyl anion. Conversely, chromophores also act as free-radical scavengers, with the result that, besides the bleaching effect of the radicals, the breakdown of the cellulose by dyes is generally prevented.

Perhydroxyl anion HO^{-}_2 functions as a nucleophile and can therefore be added to an electrophile carbonyl group. The peroxidation mechanism may correspond to a Dakin rearrangement (Fig. 2).

The decomposition of the hydrogen peroxide develops according to the equations

$$H_2O_2 + HOO^{\ominus} \longrightarrow H_2O + HO^{\ominus} + O_2$$

or

$$H_2O_2 + HOO^{\ominus} \longrightarrow {}^{\bullet}OH + H_2O + {}^{\bullet}O_2^{\ominus}$$

The perhydroxyl anion is the conjugated base of the weak acid hydrogen peroxide. In the strongly alkaline pH range, this anion is present in considerable concentration. With a pH that is greater than the pK of the acid dissociation, its constituent part will exceed that of the non-dissociated hydrogen peroxide. This is borne out by the observation that the bleaching effect of a hydrogen peroxide liquor visibly increases with alkali addition.

There is some indication, however, that this so-called “alkaline activation” may be taken too far and then change into its opposite. Test stains were bleached by Dannacher and Schlenker under very mild conditions, 60 min at 60°C, using hydrogen peroxide in a buffer solution. The result was a pH dependency with a

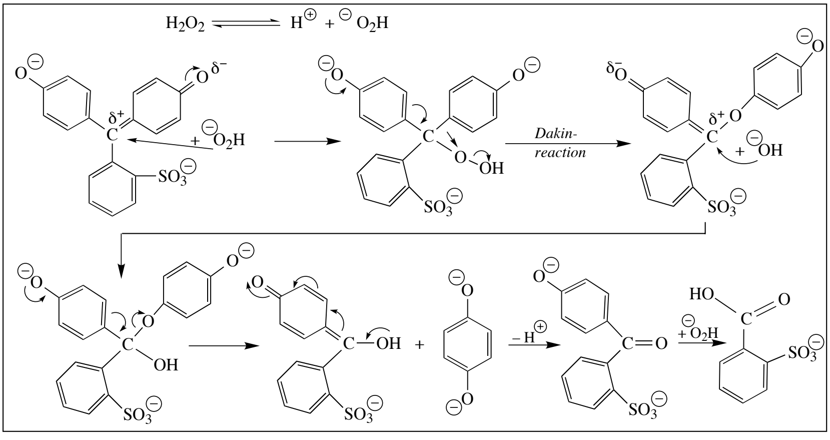

Fig. 2: Oxidation mechanism involving the perhydroxyl anion.

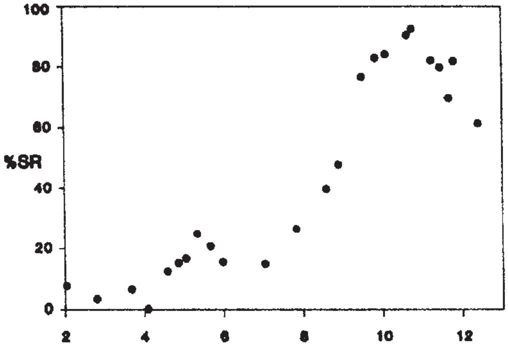

Fig. 3: Relative soil removal (% SR) after 60 min bleaching at 60°C (according to Dannacher and Schlenker). 6.5 · 10^{-3} mol/l H_2O_2 in a buffer solution.

considerably marked maximum (Fig. 3). The similarity with the concentration progression of the perhydroxyl anion is conspicuously slight. Precisely where the hydrogen peroxide is dissociated to more than 50%, the bleaching effect will decrease again. This finding is utterly incomprehensible if the perhydroxyl anion is assumed to be the sought-after "active oxygen".

d) Hydroxyl radical is formed with radical decomposition of H_2O_2. The pH dependency of the bleaching effect recalls the speed at which the decomposition of hydrogen peroxide develops. It is assumed that this decomposition occurs in a radical chain reaction. This reaction is started by the transfer of an electron by an electron donator to hydrogen peroxide. The closed loop of hydrogen peroxide decomposition is interrupted by the recombination of two radicals.

$$\begin{array}{lll}
\textit{start:} & H_2O_2 + \text{donator} \rightleftharpoons & HO^{\ominus} + HO^{\bullet} + D^{\oplus} \\
\textit{chain:} & H_2O_2 + HO^{\bullet} \longrightarrow & HO_2^{\bullet} + H_2O \\
 & H_2O_2 + HO_2^{\bullet} \longrightarrow & H_2O + HO^{\bullet} + O_2 \\
\textit{termination:} & 2\,HO^{\bullet} \longrightarrow & H_2O_2
\end{array}$$

The intermediate radicals here (the hydroxyl radical and the perhydroxyl radical) have likewise been postulated to be the species of hydrogen peroxide bleach active in the bleaching. Dannacher and Schlenker attempted to prevent this bleaching reaction with suitable free-radical scavengers. The test conditions were chosen according to the maximum pH dependency, where a deterioration in the bleaching effect is the most discernible. First of all, free-radical scavengers were selected whose rate constants of reaction with the hydroxyl radical are several orders of magnitude above the reaction with the perhydroxyl radical. Hence the aim was to selectively prevent the reaction of test-soiling with hydroxyl radicals. The experiment shows (Fig. 4) that these free-radical scavengers are not in the position to affect the bleaching result in the least. This bears out the numerous critics of a radical bleaching mechanism: the active species of the hydrogen peroxide bleach is not the hydroxyl radical.

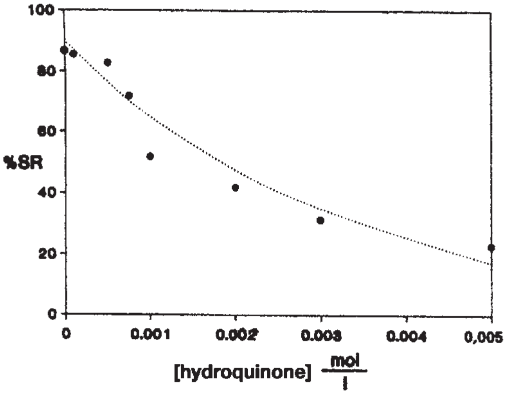

Fig. 4: Suppression of the bleaching reaction of hydrogen peroxide with hydroquinone (according to Dannacher and Schlenker). Relative soil removal after 60 min with 6.5 · 10^{-3} mol/l H_2O_2 at 60°C and pH 10.5.

e) Perhydroxyl radicals are very acidic, comparable with acetic acid: they are therefore almost totally dissociated in the pH range of the bleaching maximum (Fig. 3). The conjugated base is known under the name superoxide. Dannacher and Schlenker chose hydroquinone as a free-radical scavenger for this and, analogous to the tests with hydroxyl radical scavengers under the conditions of the bleaching maximum, waited for a deterioration in the bleaching. With increasing hydroquinone concentration, the bleaching effect is in fact increasingly suppressed (Fig. 4). This radical is obviously immediately involved in the bleaching reaction.

$$HO_2^{\bullet} \xrightleftharpoons{pK_A\ 4.8} {}^{\bullet}O_2^{\ominus} + H^{\oplus}$$

With a pK of the perhydroxyl radical of 4.8, one would expect to find the observed rise in the bleaching effect with a basically lower pH. According to this view, a decrease in the bleaching effect, once an optimum pH has been exceeded, should not be seen. Such a view of the equilibrium, however, completely ignores the kinetics of formation and decomposition of the radicals involved in this equilibrium. Most kinetic constants of the individual reactions of this chemical decomposition mechanism of hydrogen peroxide are known. As for the rest, an upper limit can be specified. These values allow the pH dependency of the superoxide concentration to be estimated. A comparison with the development of the bleaching effect of hydrogen

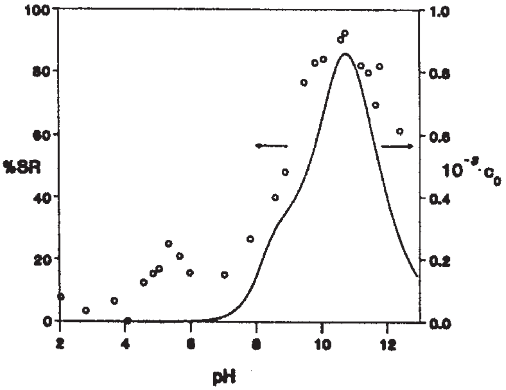

Fig. 5: Interpretation of the pH dependency of the bleaching effect (according to Dannacher and Schlenker).
0 = experimental values using a buffered hydrogen peroxide solution ($c_O = 6.5 \cdot 10^{-3}$ mol/l) after 60 min bleaching at 60 °C, left ordinate: estimation of superoxide concentration, right ordinate and drawn-through line.

peroxide reveals clear similarities according to Dannacher and Schlenker (Fig. 5).

The radical anion "superoxide" is the only one of the species observed to consistently account for all the experimental findings.

Hydrogen peroxide bleaching regulators With bleaching, hydrogen peroxide is used for

- increasing the degree of whiteness
- avoiding chemical damage to the fibre
- degradation of impurities
- suppressing the release of oxygen;

the particular portion is system dependent.

Bleaching systems contain regulators to reduce fibre damage and oxygen release. Buffers are used to maintain the correct pH for activation since alkali is required to neutralize the cellulose breakdown products. In addition, complexing agents are required to chelate any heavy metals present. Bleaching systems with built-in catalyst present do not inevitably cause a corresponding breakdown of cellulose: the catalyst also needs to be activated.

In the two-phase system of fibre with yellowing impurities and bleaching liquor, then different reactions need to be considered: Firstly the yellowing impurities remain in the fibre and are peroxidised there. The oxidizing agent is adsorbed onto the fibre surface and builds up a chemical potential gradient and diffuses into the fibre, reacts there in the core of the fibre with the yellowing impurities and breaks down its chromophore system. The resulting chemical products may then remain in the fibre or they may be small enough to diffuse to the fibre surface and eventually into the bulk phase.

In the second case, the yellowing impurities diffuse into the bulk phase and may be oxidized there. For a real bleaching system one can assume that both processes take place. A real model must take account of the diffusion coefficients of the different species and will mainly occur in a diffusion-controlled manner.

The objective of the pretreatment should not be overlooked; these are, for cotton and polyester/cotton piece goods in particular:

- high degree of whiteness dependent on the subsequent processes;
- freedom from seed husks;
- good rewettability;
- low ash content;
- free from size and preparation;
- optimum removal of the impurities in the native cellulose.

Besides the chemico-technological demands on the pretreatment, there also needs to be a guarantee that the pretreatment effects are absolutely uniform (edge/middle/edge, beginning/end) (Fig. 1). Good production safety, reproducability, flexibility with regard to the range of fabrics, and the least possible effluent loading should also be ensured (Table).

Whiteness: measured as % reflectance on the Elrepho apparatus (Zeiss), filter R 46 or by means of colour measurement as a numeric value → Whiteness formulae. Absorbency: by DIN 53 924 mod., measured as height in mm on 20 mm wide strips of fabric from the warp after 2, 15, 30, 60 and 120 s. Desizing: according to the TEGEWA violet scale; DP (fluidity) value: in accordance with the EWNN method, DIN 54 270-T 3-77, on warp yarn. The seed husk content is determined by count per 10 cm^2.

The objective of the bleaching of textiles consists of achieving a satisfactory or, in the extreme cases, high degree of whiteness with the least possible fibre damage. This last requirement is particularly important insofar as already partially damaged cellulose is known to be successively broken down in subsequent processes including care processing, with the result that ulti-

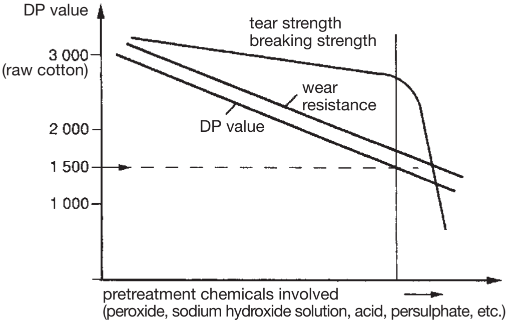

Fig. 1: Dependency of DP value, breaking resistance, tear strength and wear resistance on the pretreatment method.

Hydrogen peroxide bleaching regulators

fabric	raw	desized	boiled

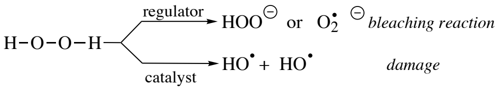
Tab.: Measurements of quality factors.

mate strength may be too low. That is also the reason why fibre damage caused by catalysts, especially localised form, may not be recognized until the post-bleaching treatment stages or even in use.

With peroxide bleaching in an alkaline medium, the following are the main reactions:



$$H{-}O{-}O{-}H \xrightarrow{\text{regulator}} HOO^{\ominus} \text{ or } O_2^{\bullet\,\ominus} \quad \textit{bleaching reaction}$$

$$H{-}O{-}O{-}H \xrightarrow[\text{catalyst}]{} HO^{\bullet} + HO^{\bullet} \quad \textit{damage}$$

The bleaching reaction takes place at the same time as the decomposition reaction so that the concentration of peroxy anion sinks with increasing decomposition, while the bleaching effect decreases. At the same time, active species are formed. Heavy metal compounds catalyse the peroxide decomposition by forming free radicals, which statistically attack the cellulose fibres, leading to a reduction in the DP value. It is conceivable that the coloured impurities are also broken down by the peroxide decomposition so that an increase in whiteness is achieved. Owing to the expected reduction in the DP value, peroxide decomposition initiated by heavy metal compounds must be avoided during the bleaching.

Peroxide decomposition in bleaching liquors occurs by an ionic mechanism that can be described as a reaction of the 1st order. Here is actual decomposition reaction

$$HOO^{\ominus} \longrightarrow HO^{\ominus} + [O]$$

the so-called activation reaction as a rate-controlling step is shown as:

$$H_2O_2 + HO^{\ominus} \rightleftharpoons H_2O + HOO^{\ominus}$$

$$-\,dc/dt = k \cdot c$$

The reduction in the peroxide concentration is therefore proportional to the peroxide concentration itself.

After integration in the limits c_0 and c_t according to the peroxide concentration at the start and the time t, there follows:

$$\ln \frac{c_0}{c_t} = k \cdot t$$

If one therefore applies $\ln c_0/c_t$ to the time t, straight lines result, whose gradient corresponds to the constant k for the rate of peroxide decomposition. These values are shown graphically in Fig. 2 for a buffered system.

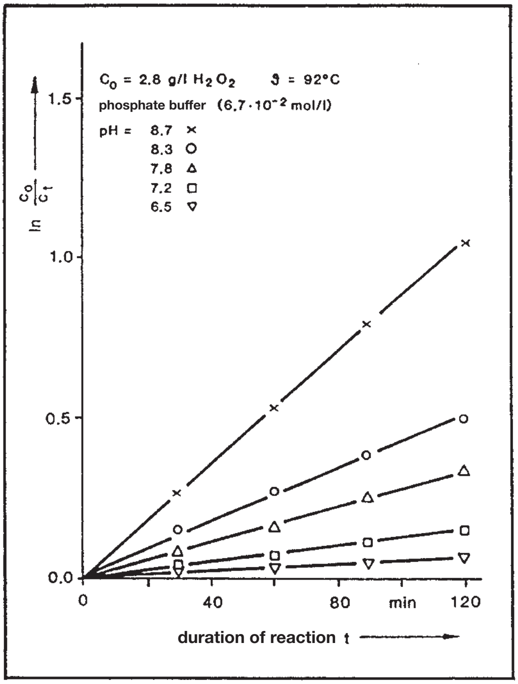


Fig. 2: Peroxide decomposition with a change in the pH without textile material (according to Heidemann).

This produces the familiar, distinctive dependency of the peroxide decomposition on the pH of the medium, which is to be expected due to the activation reaction mentioned. The rate of peroxide decomposition is already relatively high even in the weakly alkaline range for bleaching processes at the typical temperatures, with the result that the use of regulators is advisable. As shown in Fig. 3, in the presence of magnesium polysilicate under the limits of a standard bleach for a pH of 12, even with a high peroxide concentration the expected decomposition is minimized. As expected, decomposition occurs at a given temperature, again

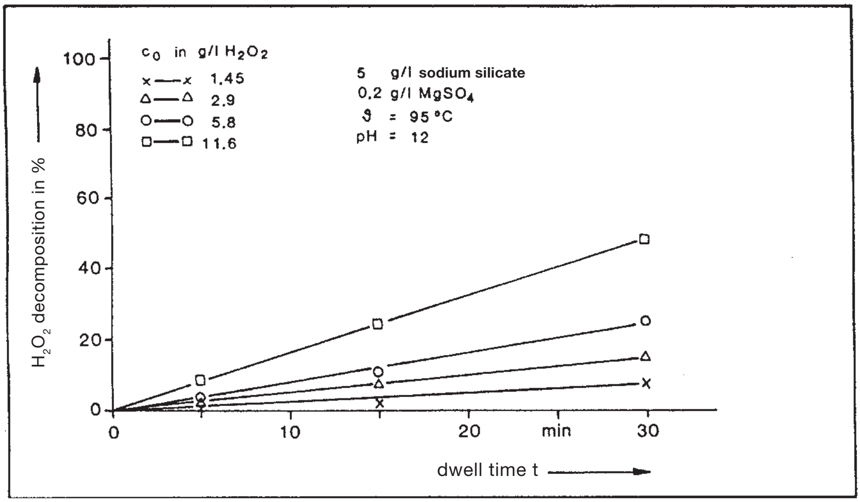

Fig. 3: Peroxide decomposition in bleaching liquors without textile material (according to Heidemann).

proportional to the original concentration, i.e. as a 1st order reaction. While in virtually catalyst-free systems the relations are relatively easy to see, this does not apply to radical peroxide decomposition initiated by heavy metal compounds. Hence, in the presence of iron (III) ions, for example, a complex sequence of decomposition reactions develops, which is triggered by the formation of a hydroperoxy radical:

$$Fe^{3+} + HOO^{\ominus} \longrightarrow Fe^{2+} + HOO^{\bullet}$$

The Fe (II) ion formed reacts with peroxide by forming hydroxyl radicals and represents, from the well-known Haber-Weiss mechanism, the start reaction for the development of further decomposition reactions in the form of radical chains. Here iron (III) ions may continue to react not only with the peroxy anion, but also with the free H_2O_2 itself in line with the Haber-Weiss mechanism. It is to be assumed, therefore, that the peroxide decomposition found in catalyst-containing bleaching liquors is of a complex nature, the properties of the regulator used also playing a role here.

The following demands are made of the auxiliary agent system:

- good wetting action on raw fabric also at impregnation temperatures < 20°C,
- non-foaming,
- good soil-suspending property,
- good electrolyte tolerance,
- stable to the bleaching agent,
- good dispersing and emulsifying ability even at low temperatures,
- good scouring,
- good silicate dispersing ability,
- good rinsing ability.

The stabilization of the peroxide bleaching liquor with sodium silicate and magnesium ions with semi- and fully continuous processes offers clear advantages: on the one hand, costs are considerably lower while, on the other, the risk of catalyst damage is much lower. In addition, the optimum stabilizing quality leads to a better use of peroxide in the bleaching process, a fact which is likewise reflected in cost savings. The very mild action of the bleaching process (optimum ratio of stabilization to activation) is qualitatively beneficial too.

The disadvantage of inorganic stabilization to date has been the fact that the exclusive use of sodium silicate in hydrogen peroxide bleaching has meant a deposit of silicate on machine parts and the bleached material. Especially critical points (with continuous systems) are the initial lead rolls in the reactor unit and the initial washing stage. These deposits have an extremely disruptive effect since a creaseless passage of the cloth can no longer be guaranteed. They continue to cause chafe marks, which may become visible in the subsequent dyeing. It has only been possible so far to remove these obstinate impurities mechanically with a great deal of expense, whereby a drop in production due to the machinery being idle had to be accepted.

Addition sequence: H_2O, Mg salt, organic stabilizer, surfactant, (sodium silicate), NaOH, H_2O_2.

The most common stabilizer is sodium silicate in colloidal polymer form (water glass). Its stabilizing ability is increased by the presence of the hardness-producing substances of the water. Colloidal Mg silicate is together with a dispersing agent the most effective stabilizer.

$Si(OH)_4 + H_2O \rightleftharpoons H_3O^+ + SiO(OH)_3^-\ {}_{2-}$ (pK = 9.46)
$Si(OH)_3^-\ {}_{n-} + H_2O \rightleftharpoons H_3O^+ + SiO_2(OH)_2^-$ (pK = 11.8)
$SiO_n(OH)_{4-n} + HO_2^- \rightleftharpoons SiO(OH)_{3-n}(OOH)^{n-}$ (n = 0; 1; 2)

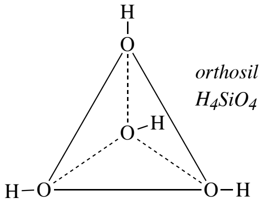
Hydrogen peroxide bleaching regulators

Magnesium is indispensable as a co-stabilizer. The effect of Mg salts as stabilizers is due to a complex being formed involving the superoxide radical $^{\cdot}O{-}O^{\ominus}$, where the radical chain reaction is interrupted by immobilisation.

$$Mg(OH)_2 + {}^{\bullet}O{-}O^{\ominus} \longrightarrow HOMgOO^{\bullet} + HO^{\ominus}$$

The main disadvantage of the silicate stabilizers consists in them forming deposits on the fabric and the machine, which is particularly critical in continuous processes; hence the trend for substituting the stabilization with sodium silicate. Frequently, oligophosphates and polyphosphates are used, their application being limited to the weakly alkaline range on account of their hydrolysis. Organic stabilizers are based on sequestering agents, organically substituted phosphonic acids, proteolysis products and their condensation products with fatty acids, and free-radical scavengers each with dispensing agents.

Stabilization with silicate is described as inorganic stabilization.



orthosilicates
H_4SiO_4

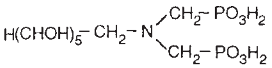
What is usual is the mixture of a salt formed from the weak acid SiO_2 and the strong base Na_20. The NaOH concentration is crucial for activation: 1 min steaming = 20–30 g/l NaOH; discontinuous = 1–2 g/l NaOH.

Sequestering is understood to mean the effect of complexing agents, which should be distinguished from the anticatalytic effect, when ferric ions are deactivated in the peroxide bath without magnesium being found. Organic complexing agents such as EDTA, NTA or pyrophosphate work as stabilizers.

The "threshold effect" refers to the inhibition of calcium carbonate precipitation (boiler scale) or chelate formation of Fe^{2+} in the peroxide bleach with greater efficiency than should be anticipated from the plausible coordination possibility. Thus there is very good dispersing ability per constituent of weight of complexing agents.

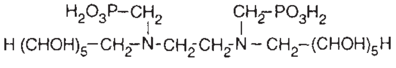
The crucial processes for radical peroxide decomposition are, on the one hand, the rate of dissolution of contamination of the cotton and, on the other hand, the interaction between the dissolved heavy metal ions and the regulator. These findings can no doubt be derived from the studies of peroxide decomposition with the addition of iron hydroxide and of dissolved ferric ions and, in addition, can be applied to the cotton contaminated with iron hydroxide with regard to the bleaching result (Fig. 5).

The following compounds, among other things, are used as regulators:



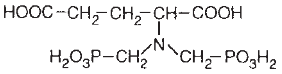
GDP

$H(CHOH)_5-CH_2-N(CH_2-PO_3H_2)_2$



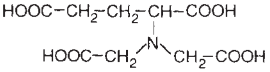
DGEDDP

$H(CHOH)_5-CH_2-N(CH_2-PO_3H_2)-CH_2-CH_2-N(CH_2-PO_3H_2)-CH_2-(CHOH)_5H$



GSDP

$HOOC-CH_2-CH_2-CH(N(CH_2-PO_3H_2)_2)-COOH$



GSDA

$HOOC-CH_2-CH_2-CH(N(CH_2-COOH)_2)-COOH$

$(HOOCCH_2)_2N-CH_2-CH_2-N(CH_2COOH)_2$ EDTA

DTPMP

$(H_2O_3PCH_2)_2N-CH_2-CH_2-N(CH_2PO_3H_2)-CH_2-CH_2-N(CH_2PO_3H_2)_2$

Their effect compared with different cations is depicted in Fig. 4.

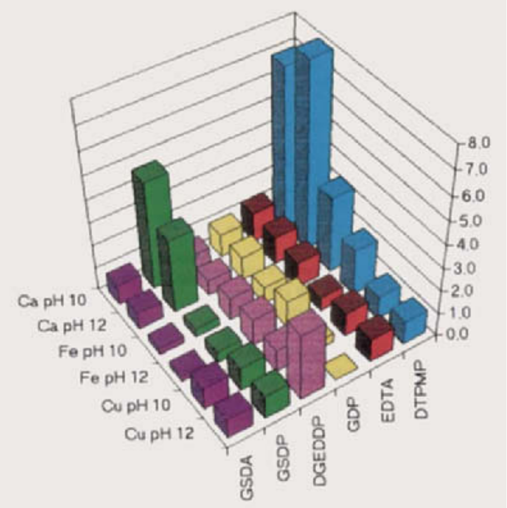


Fig. 4: Bonded cations [mol] per complexing agent [mol].

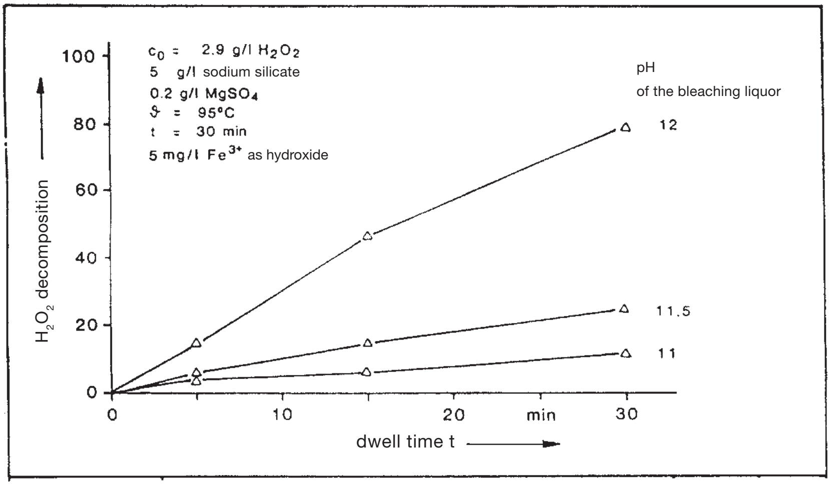

Fig. 5: Peroxide decomposition in bleaching liquors without textile material.

Hydrogen peroxide decomposition May occur homolytically and heterolytically.

In an acidic medium, heterolytic splitting will occur

$$(HOOH_2)^+ + H_2O_2 \rightarrow 2\ H_2O + O_2 + H^+$$

or peroxy acids which have a bleaching effect will be formed

$$(HOOH_2)^+ + RCOO^- \rightarrow RCO{\cdot}OOH + H_2O$$

Homolytic splitting in the acidic range $H_2O_2 \rightarrow 2\ (^{\cdot}OH)$ would require too high an activation energy. In the alkaline environment, decomposition occurs in accordance with Fig. 1.

For anti-catalysts to stabilise hydrogen peroxide solutions in commercial conditions, barbituric acid, urea and phosphoric acid (for complexing Fe^{2+}) are used.

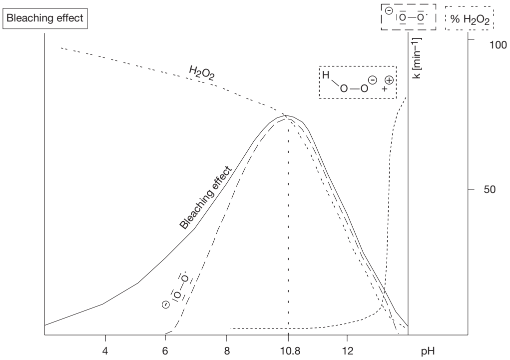

Fig. 1: Decomposition of H_2O_2 dependent on pH.

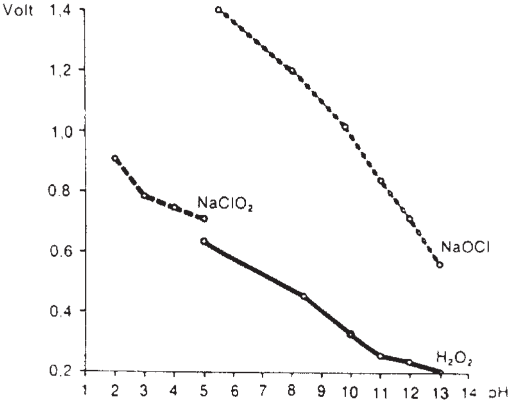

Fig. 2: Redox potentials of bleaches specific to the normal hydrogen electrode.

The redox potential (Fig. 2) of H_2O_2 is smaller in comparison to hypochlorite or chlorite. The quantitative analysis occurs in a redox process:

$$MnO_4^- + 2\ H_2O + 3\ e^- \rightarrow MnO_2 + 4\ HO^-$$
$$H_2O_2 \rightarrow O_2 + 2\ H^+ + 2e^-$$

Hydrogen peroxide is also enzymatically decomposed. Blood contains the enzyme peroxidase. This accelerates the reaction between hydrogen peroxide and the organic molecule benzidine so much that a blue pigment results almost instantaneously in the presence of the smallest quantities of peroxidase and acid. The reaction itself, therefore, serves to establish proof of blood traces. Peroxidase consists of a protein body to which a so-called porphyrin group is attached. This porphyrin group is geometrically in a single plane and contains at its centre a ferric ion Fe^{3+}. Perpendicular to this molecular plane, a H_2O_2 molecule can now make its approach and be bonded with the Fe^{3+} ion (Fig. 3).

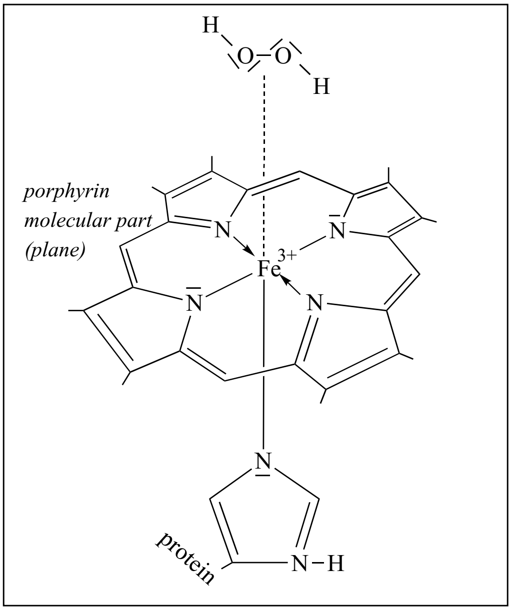

Fig. 3: Attachment of H_2O_2 to the porphyrin remnant of peroxidase.

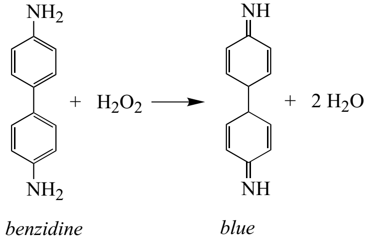
Two hydrogen atoms are now given off in succession from the benzidine, from which two molecules of water, the blue pigment and the regenerated catalyst are formed:



benzidine

blue pigment

The peroxidase fails to appear at all in this reaction equation, but the reaction requires a basically smaller activation energy when the H_2O_2 is attached to the porphyrin group of a peroxide molecule.

The radical decomposition starts a chain reaction as follows:

$$H_2O_2 + {}^\bullet O_2^- \rightarrow {}^\bullet OH + HO^- + O_2$$
$$HOO^- + {}^\bullet OH \rightarrow H_2O + {}^\bullet O_2^-$$
$$H_2O_2 + {}^\bullet OH \rightarrow H_2O + HOO^\bullet$$

This chain reaction can also be initiated by heavy metal ions in line with the Haber-Weiss mechanism:

$$H_2O_2 + Fe^{2+} \rightarrow {}^\bullet OH + HO^- + Fe^{3+}$$
$$HOO^- + Fe^{3+} \rightarrow {}^\bullet OOH + Fe^{2+}$$

Hydrogen peroxide has a smaller oxidation potential than ozone under normal conditions. Owing to the catalytic effect of iron or other heavy metal ions, a radical reaction mechanism is set off, in the course of which OH radicals are produced, which have a greater oxidation potential (Fig. 4). The combination of hydrogen peroxide and ferrous salt is known as Fenton's reagent. The hypothetical reaction mechanism is reproduced in Fig. 5. In the initiating reaction, the hydroxyl radical is produced from the divalent iron and hydrogen peroxide. Besides its oxydizing effect due to its greater oxidation potential, the hydroxyl radical in a subsequent chain reaction enters into radical reactions with hydrogen peroxide and organic compounds, which cause, among other things, their oxidation and breakdown.

$$O_2 + 4H^+ + 2e^- \longrightarrow 2H_2O \qquad E_o = 1.229\ V$$
$$H_2O_2 + 2H^+ + 2e^- \longrightarrow 2H_2O \qquad E_o = 1.776\ V$$
$$O_3 + 2H^+ + 2e^- \longrightarrow 2H_2O_2 + O_2 \qquad E_o = 2.07\ V$$
$${}^\bullet OH + H^+ + e^- \longrightarrow H_2O \qquad E_o = 2.28\ V$$

Fig. 4: Oxidation potentials of some oxygen compounds.

$$H_2O_2 + HOO^\bullet \longrightarrow H_2O + O_2 + OH$$
$$RH + OH^\bullet \longrightarrow H_2O + R^\bullet$$
$$>C=C< + OH^\bullet \longrightarrow HO-\overset{|}{\underset{|}{C}} - -\overset{|}{\underset{|}{C}}{}^\bullet$$
$$Fe^{2+} + HOO^\bullet \longrightarrow Fe^{3+} + HOO^-$$
$$Fe^{3+} + HOO^\bullet \longrightarrow Fe^{2+} + O_2 + H^+$$

Fig. 5: Radical reactions with Fenton's reagent.

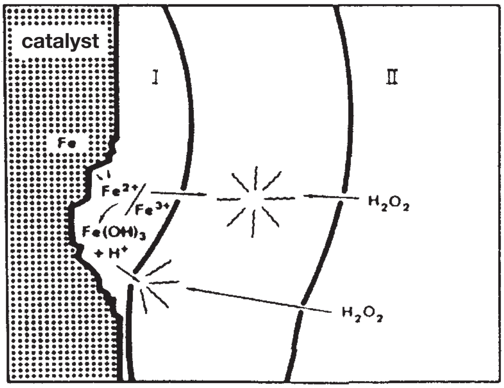


Fig. 6: Catalyst damage to cotton caused by iron (according to Meier).

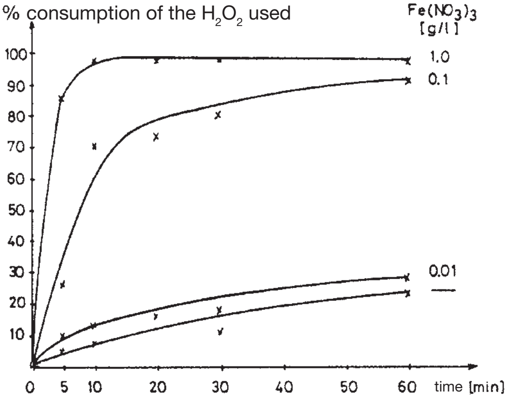

Fig. 7: Decomposition curve of the H_2O_2 present in the bleaching liquor with various $Fe(NO_3)_3$ concentrations.

The attempt to explain catalyst damage might take the following form (Fig. 6): oxidation causes ferric ions to become detached from iron particles which become attached to the fabric. Resulting Fe^{3+} ions catalyze "locally" the peroxide decomposition and, with it, the over-oxidation of the cellulose because in the stagnant area of liquor (I) high concentrations of Fe ions exist and unused peroxide is transported to it by the moving liquor (II).

Tab.: Metal content of the raw cotton fabric of various batches (1–6) in mg metallic ions/kg fabric. dl = virtually undetectable (identification limit with Ni 1 mg/kg and with Pb 3 mg/kg).

Because cotton takes up traces of metal from the finishing bleach process, the decomposition in the presence of iron is important (Fig. 7). At the same time, iron is converted into ferrous ions according to the mechanism depicted in Fig. 8 and then has a catalytic effect on the hydrogen peroxide decomposition as a ferrous ion.

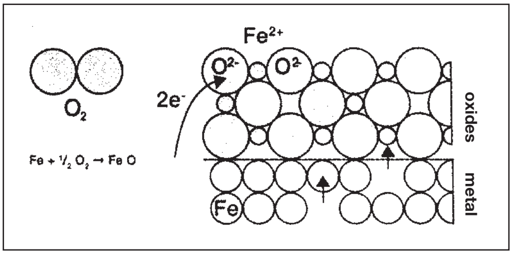

Fig. 8: Conversion of iron into ferrous ions (according to Fornelli).

Studies of Heidemann describe peroxide decomposition by using three regulators common in practice, whose chemical composition is shown in Fig. 9. In Figs. 10 + 11 and in Fig. 12, the time characteristic of the peroxide decomposition is shown at a given temperature, each time in a pH range dependent on the ferric ion concentration, in comparison to a virtually catalyst-free liquor. The concentration range selected up to 10 mg/l ferric ions corresponds here to a practically relevant loading of the liquor when the contamination with iron compounds completely dissolves. Accordingly, a content of 100 mg/kg for a liquor ratio of 1 : 10 and of 10 mg/kg for a liquor ratio of 1 : 1 results, which represents the usual ratios for batch and pad-batch processes.

The findings reveal a different characteristic of peroxide decomposition depending on the type of regulator, which cannot be described by a simple function. For this reason, to represent the dependence of peroxide decomposition on the pH and ferric ion concentration in the bleaching liquor, the decomposition with the same dwell time and temperature is used. As Heidemann's findings, illustrated in Figs. 13–14 and shown in Fig. 15, the peroxide decomposition increases sharply above a regulator-specific, critical pH. As is shown in the example of the magnesium polysilicate regulator, even minimal concentrations of ferric ions of 1 mg/l are

Hydrogen peroxide decomposition

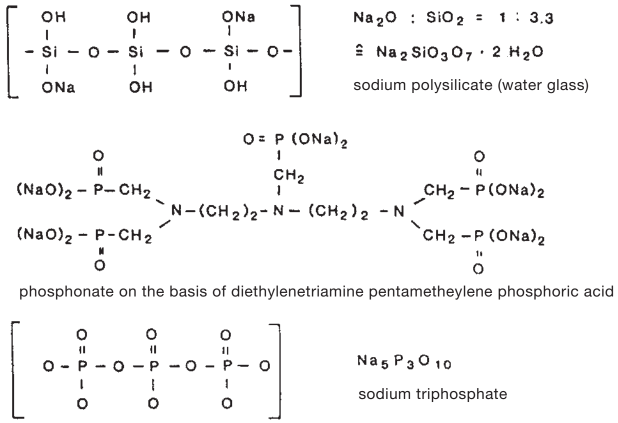

Fig. 9: Regulators used in the peroxide bleach.

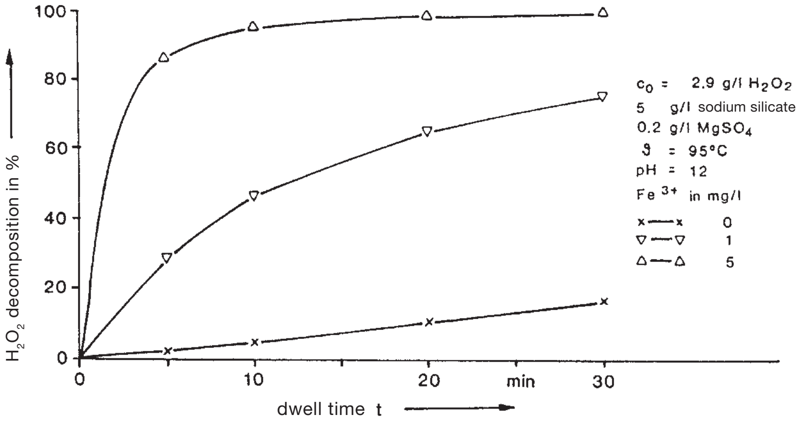

Fig. 10: Peroxide decomposition in bleaching liquors (with sodium silicate) without textile material dependent on the dwell time (according to Heidemann).

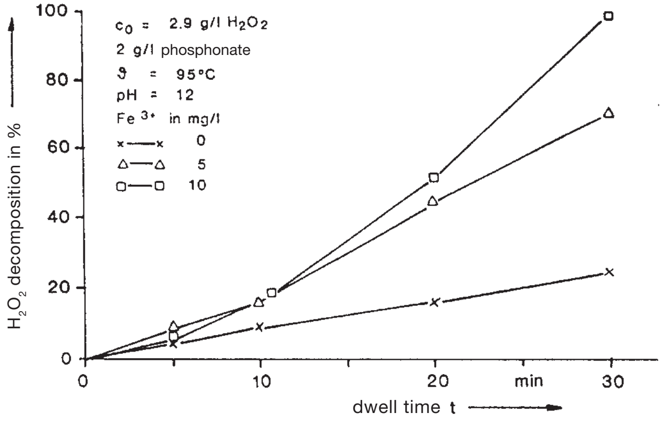

Fig. 11: Peroxide decomposition in bleaching liquors (with phosphonate) without textile material dependent on the dwell time (according to Heidemann).

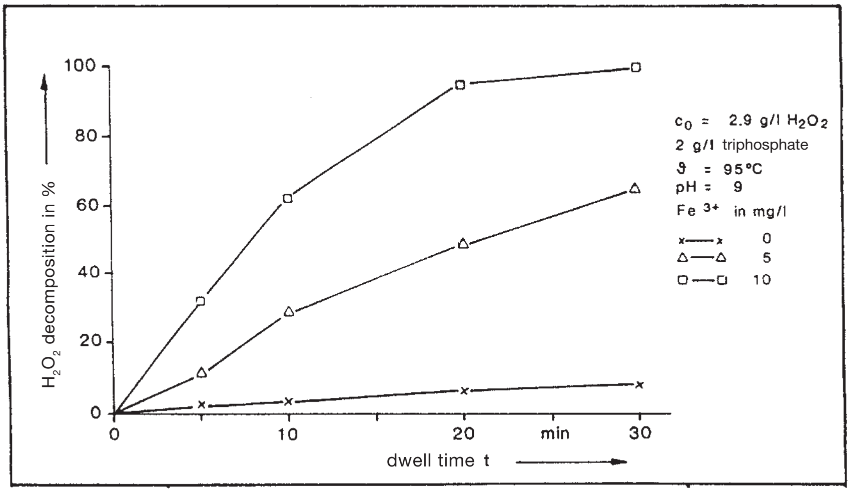

Fig. 12: Peroxide decomposition in bleaching liquors (with triphosphate) without textile material dependent on the dwell time (according to Heidemann).

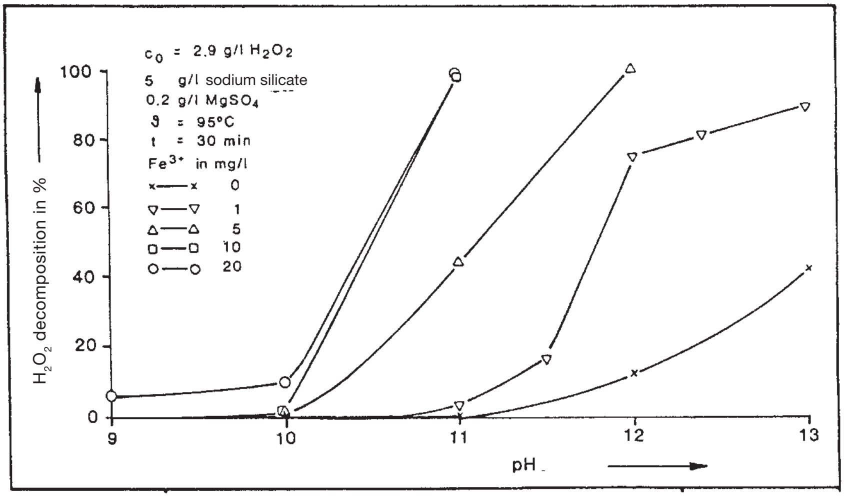

Fig. 13: Peroxide decomposition in bleaching liquors (with sodium silicate) without textile material dependent on the pH (according to Heidemann).

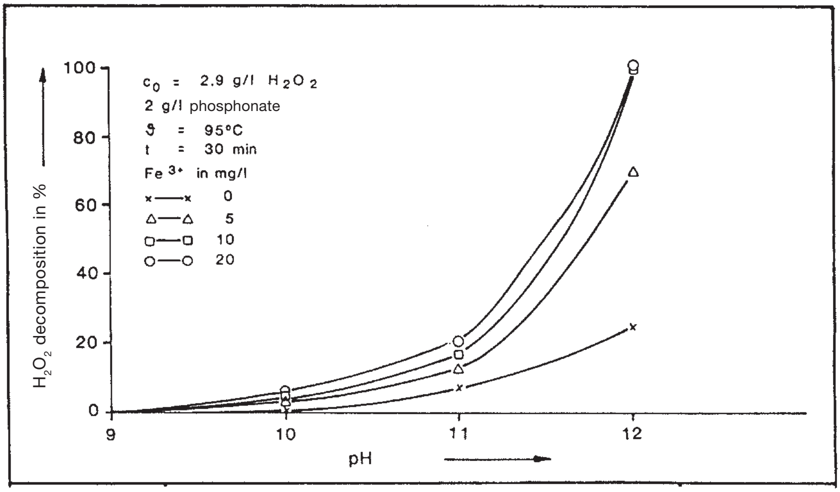

Fig. 14: Peroxide decomposition in bleaching liquors (with phosphonate) without textile material dependent on the pH (according to Heidemann).

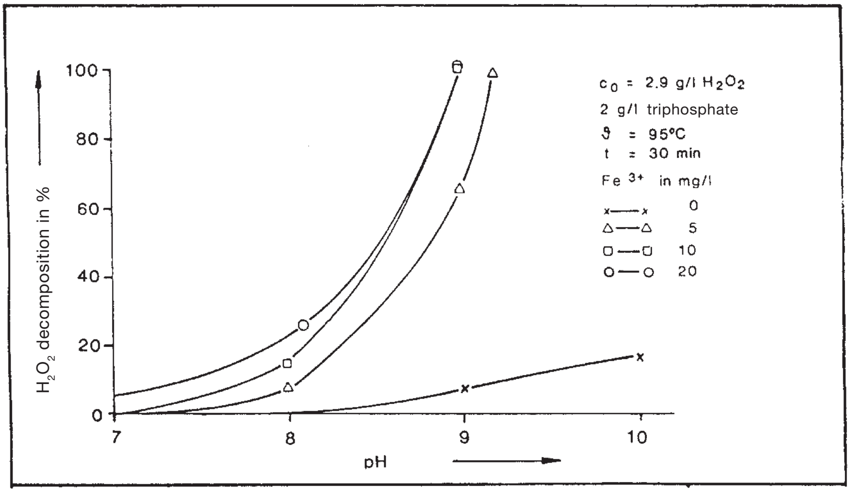

Fig. 15: Peroxide decomposition in bleaching liquors (with triphosphate) without textile material dependent on the pH (according to Heidemann).

enough to trigger greater than average peroxide decomposition above pH 11. The complexing ability of the individual regulators is therefore distinctly pH-dependent. Since complex formation, etc. depends on the concentration of the reaction partner, it is to be expected that, through increasing the concentration of regulators, peroxide decomposition is reduced with a given concentration of ferric ions.

Hydrogen peroxide dry-in process (blanchiment rapide). Since the end of the 1920s, continuous H_2O_2 bleaching of wool has been used, mainly for the brightening or bleaching of loose wool or combed top and occasionally yarn. Operating principle: impregnation with various H_2O_2 solutions, squeezing off and drying, with temporary H_2O_2 concentration, H_2O_2 decomposition and bleaching occurring in the course of the drying process. The degree of whiteness is naturally dependent on the quantity of H_2O_2 present on the fibre. The amount of H_2O_2 per unit of weight of wool used is limited by the levels that lead to damage to the wool. As a working liquor, either a weakly alkaline, weakly acidic or neutral solution of e.g. 20 ml/l H_2O_2 35% w/v is used, depending on the neutral or alkaline quality of the scoured wool.

Hydrogen sulphide test for sulphur dye identification The fibre specimen under test must be freed from substances containing sulphur (sodium dithionite, etc.) by boiling in water with a few drops of sodium carbonate solution. Rinse and boil again with diluted hydrochloric acid until dampened lead acetate paper no longer turns dark. Remove hydrochloric acid. Add stannic chloride/hydrochloric acid solution and warm slowly. If the lead acetate paper is now coloured between brown and black with simultaneous change of colouring to yellow, then sulphur dye is present. Only thioindigo derivatives of vat dyes show a weak reaction to this test after prolonged boiling.

Hydrolases The most extensive main group of → Enzymes which catalyze the hydrolytic cleavage of C–O and C–N bonds in the breakdown of large molecules.

Hydrolysis Chemical reaction of molecules or ions with water to form more molecules or ions. A typical example is the hydrolysis of cellulose, i.e. hydrolytic splitting of cellulose, known as → Hydrocellulose.

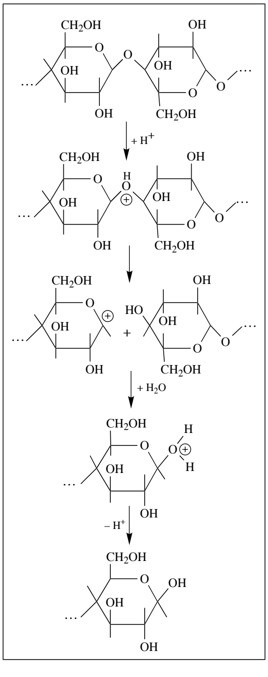

Fig.: Acid-catalysed hydrolysis of cellulose.

The glucosidic bonds in cellulose are split by acid catalysed hydrolysis (see Fig.), where a high yield of d-glucose is created. It is assumed that some glucosidic bonds in which the oxygen atom is initially protonized are weaker towards hydrolysis (compared with the rest of the glucosidic bonds) because an aldehydic or carboxyl group is found near them.

Partial hydrolysis on solution in water occurs with many salts with a slightly acidic or slightly alkaline reaction in water. An excess of H ions (acidic reaction) or OH ions (alkaline reaction) is seen:

salts from			hydrolysing with solution action	type-example
acid		base		
strong	+	weak	→ acid	$Al_2(SO_4)_3$, $ZnCl_2$
weak	+	strong	→ alkaline	Na_2CO_3
strong	+	strong	→ neutral (no hydrolysis!)	NaCl.

Hydrolysis, reversible The effect of water on the ions of a dissolved salt, lead to a state of equilibrium where ions and molecules of the acid or base forming the salt exist together. If the conditions change, acid or base molecules may change back into ions. This is especially significant with salts of weakly organic acids or weakly organic amines with large hydrophobic tails.

Hydrolysis, sensitivity to In the USA, it is normal to neutralise alkaline laundering of resin finished goods with the addition of acidic reacting salts (e.g. zinc silicone fluoride) in the final rinsing-bath, in order to prevent yellowing that can easily occur as a result of hot tumble drying. Overdosing of the acidic salt will create acidity on the fabric, which will affect the finished effect. Hence, fabrics destined for the American Market require the best hydrolysis stability.

Hydrolysis, stability to Resistance of a type of finish, particularly an easy care finish or the resin-finishing agent itself, to acidic or alkaline → Hydrolysis. With insufficient stability to acid hydrolysis, splitting of the cross-linked resin-finishing agent may occur, which considerably impairs the finishing effects; there is no risk with resin finishing in the alkaline range.

Hydrometer A device for measuring the density of liquids consisting of a sealed cylindrical glass tube with a density scale at the upper end and weighted with mercury or lead shot at the lower end. When placed in a liquid, the hydrometer floats upright with the tube partially immersed, the degree of immersion depending on the density of the liquid which can be read off directly from the scale at the liquid/air interface. Hydrometers are based on the principle that the density of a solution corresponds to a particular concentration so that they provide a rapid means of determining the percentage of a dissolved substance in water, e.g. sodium hydroxide, sulphuric acid, etc. The presence of foreign substances leads to incorrect measurements. The lower the density the deeper the hydrometer sinks and vice versa. Different hydrometers are available for liquids with a higher or lower density than water. The scale may be calibrated directly in specific gravity or in arbitrary units such as, e.g. °Bé (Baumé scale) in France and Germany, or °Tw (Twaddell scale) in England.

Since the densities of different substances dissolved in water differ from one another, hydrometer readings have to be compared against tables of densities for the particular substance being measured. In some cases, this can be avoided with special hydrometers for a specific application only, e.g. the alcoholometer, which gives a direct reading of the alcohol content.

Hydrometers do not provide a reliable means for measuring densities of solutions in the following categories: a) old liquors below 1°Bé (specific gravity 1.006), b) chlorine bleach baths (especially used baths), c) solutions containing mixtures of different substances and d) to determine the alkalinity or acidity of a solution.

Hydronium ion → Hydrogen ions.

Hydrophile-lipophile balance → HLB value.

Hydrophile-lipophile ratio The hydrophile-lipophile balance is a measure of the ratio between the hydrophobic and hydrophilic components of a surfactant, i.e. between the → Nonpolar group (lipophilic) and the → Polar group (hydrophilic) and is related to surface activity. It determines the affinity of an emulsifier to water or to weakly polar organic solvents. See → HLB value.

Hydrophilic group Group of molecules whose behaviour towards water is → Endophilic.

Hydrophilic groups – effectiveness comparison Approximate quality classification for practical evalua-

tion of textile auxiliaries. The Table shows comparisons based upon the following values: 0 = no effect, demonstrably bad; 1 = clear effect, acceptable; 2 = Effect notably better, good; 3 = effect pronounced, very good.

Hydrophilic properties of textiles Consideration of the criteria which the consumer uses to make their choice of textiles and their relationship to hydrophilic and hydrophobic properties, gives the following critical properties:

- moisture absorption and transport,
- static charge or discharge of the static charge resulting from friction,
- soiling (dry, wet),
- soil removal with washing and cleaning.

Processes such as water vapour absorption, migration and capillary transport are decisively influenced by the surface characteristics, with a hydrophilic surface being positively assessed from a physiology of clothing perspective. Microporous "breathable" multilayered types (e.g. Gore-Tex, Sympatex) are increasingly gaining in importance. Permanently hydrophilic body contact layers also increase the wearer comfort in such cases.

Definition of the most important terms:

1. Moisture absorption: amount of water on and in the fabric after establishing the equilibrium between the fibre and standard climate humidity (20±2°C, 65±2% relative humidity).
2. Water retention: amount of water retained in the fibre after a defined centrifuge process.
3. Capillary height: measure of the rate at which water is transported in textile fabrics against the force of gravity.
4. Water absorption ability: amount of water (in %) which a textile fabric, adapted to the standard climate, absorbs from immersion in water.
5. Wetting: primary: surface spreading of a fluid; secondary: associated with deep penetration. Wetting may also be expressed as a function of time and surfactant concentration. It is also controlled by interaction of the surface tension at the limits of the fixed and fluid stage.
6. Penetration: ability of a fluid (e.g. water) to completely penetrate a textile material (effect below the fibre surface).
7. Heat of hydration: the heat that is released with the hydration (wetting) of dry fibres with water and is regarded as a measure of the hydrophilic property. Apart from the actual fibre's hydrophilic property, it is also dependent on the moisture content of fibres prior to wetting. A fibre whose moisture content reaches the saturation limit, produces a heat of hydration which is equal to zero. Some values of dry fibres:
    - wool 113.1 kJ/g
    - polyamide 31.8 kJ/g
    - polyester 3.4 kJ/g
8. Fibre wettability: wettability of the fibre capillaries.
9. Hygroscopicity: swelling capacity (sorption) of the fibrous material in water.

The wettability of the fibres depends on the chemical groups found on their surface that are able to accumulate water (e.g. by means of hydrogen bonds, ion and dipole forces). A distinction is made between:

- strongly hydrophilic groups $-S0_3H$
  $-COO^-$
  $-SO_3^-$
- weakly hydrophilic groups OH
  OR
  $-NH_2$
  $>C=O$

In addition, the wetting is also dependent on the surface tension of the wetting fluid, as well as on the physical parameters such as temperature, time and surface character. The assessment of hydrophilic property is either direct or indirect:

Direct methods:

- test of water retention ability (in %),
- test of moisture transport and moisture bonding power,
- calorimetric test of the heat of hydration of dry fibres.

Indirect methods:

- wetting values of fibres (time),
- capillary rise (time and height),
- wicking time (water spreading time in s),
- test of the static charge and discharge (e.g. field decomposition half-life [F_{HZ}] in s),
- soil release and soil redeposition behaviour.

A single methods as listed is not enough to permit a reliable evaluation of the hydrophilic property. This requires at least the following tests:

- moisture bonding power at a constant temperature,
- water retention ability.

The indirect methods are influenced above all by the wetting effect of the products, which does not develop parallel to the hydrophilic property. Hence a wetting agent may, for example, significantly improve the absorbency and capillary rise without, however, affecting the moisture transport.

Hydrophilic property Tendency of a material, to take up water (opposite → Hydrophobic).

Hydrophilic rendering property Ability to make soluble, e.g. with textile auxiliaries the elimination of water insoluble of hydrophobic hydrocarbon groups and increase of → Hydrophilic group which, owing to their great affinity with water, enable hydration and dispersion of the textile auxiliary to take place. This occurs in auxiliaries with ionic or non-ionic groups.

Hydrophilic treatment process Process for increasing the absorbency of textiles made of synthetic fibres. Through improved absorption of moisture and perspiration, the treated garments, stockings etc., are more pleasant to wear. Principle: e.g. impregnation with a dispersion of polyamide derivatives.

Hydrophobic Property of a material to have a water-repellent effect (opposite → Hydrophilic property).

Hydrophobic finishes, evaluation of To assist in determining the hydrophobic properties, there is:

I. Rain test according to Bundesmann (DIN 53 888): Here a test specimen is held under tension whilst a fixed quantity of water is "rained" upon it. At the same time, a device rubs the fabric from the underside with a turning motion. Any water passing through the cloth is collected in a glass beaker and its volume measured. Any surface water is removed by centrifuge and any weight increase for the test specimen is determined. The amount of water absorbed by the sample and passing through the sample serve as a measure of its performance. In addition, the water-pearl effect is determined visually by comparing the appearance of the specimen with a series of standard appearance pictures.

II. Spray test (following AATCC 22-1971): This assesses the water-pearl effect. The test device (Fig.) allows a gentle spray of water to fall on a pre-tensioned test specimen at an angle of 45°. 250 ml of water is sprayed during 30 s, the test specimen is then struck twice to loosen surface held water and any remaining water and wet-out area is assessed. A value from 0 (worst) to 100 (best) is rated by visual comparison with standard appearance pictures.

III. Tegewa drop test: Method for determining the absorbency. The fabric under test is held without tension whilst defined size droplets (0.050 ml ±10%) of a 2% solution of patent blue V are applied from a height of 40 mm. The absorption time of the drops and the diameter of any staining is recorded.

Hydrophobic group Group of molecules whose behaviour towards water is → Exophilic.

Hydrophobic interactions If non-polar molecules such as hexane are introduced into water, then they will tend to congregate to form larger units. At the same time a "cavity"is formed in the water that was previously homegeneous, in which a number of hydrogen bonds of the water (→ Iceberg structure of water) are temporarily broken. The water molecules suppressed in this way reorientate themselves to form a maximum number of hydrogen bonds again, even if the opportunities for doing so are limited in the immediate vicinity of the hexane micelle. The water molecules around the hexane micelle are inevitably arranged higher than otherwise in the homogeneous solution, while the entropy of the solution decreases due to the absorption of the hexane. Non-polar molecules do not associate in the water because they have a greater affinity to each other, but because water molecules are forced into more bonds with each other due to their presence. Polar interactions (e.g. in salts) are weakened by water (salt dissolves in water).

Not only salt linkages or ion-pair bonds, but also hydrogen bonds are weak in the presence of water (e.g. in a protein solution or in a swollen fibre protein such as wool). It is in the presence of water, however, that the hydrophobic interactions have a stabilizing effect. These come about because the numerous non-polar side chains with a paraffin or benzole structure also

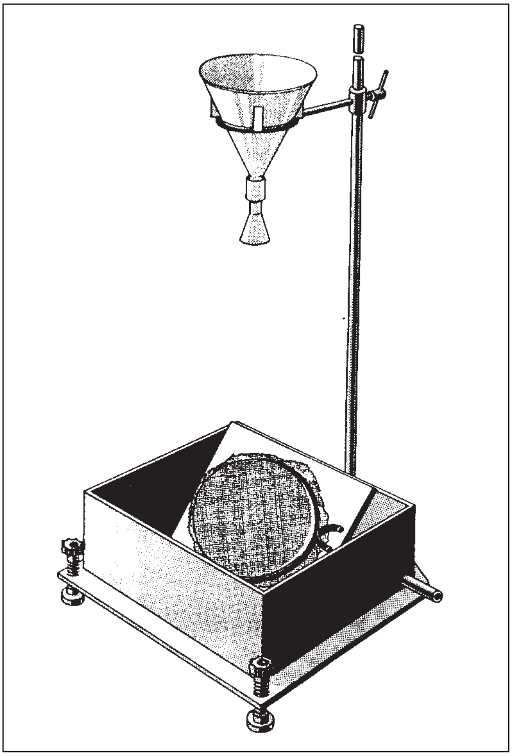

Fig.: Spray test apparatus for hydrophobic effect evaluation.

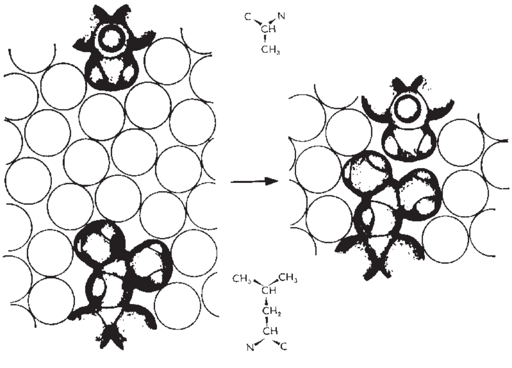

Fig.: Approximation of protein-bonded methyl groups due to hydrophobic interactions in water.

built into the wool congregate in a micelle-type manner inside the protein molecule, in order to withdraw from the aqueous environment of the solvent or swelling agent. As a result of the agglomeration of the non-polar groups, the contact area between the non-polar groups and the solvent water is reduced to a minimum (see Fig.). Hydrophobic interactions, on the other hand, are weakened in alcohol.

Hydroplastic Deformable in the wet state, e.g. cotton through hydrate formation of the cellulose OH groups, where even slight quantities of water in humid air are enough to break the hydrogen bonds produced by OH groups. → Thermoplastics.

Hydroplasticity factor The wearing properties of textiles made from regenerated cellulose fibres depend, among other things, on the wet and dry crease angles. Both should be in a certain ratio to each other. A good dry crease angle in itself is not sufficient.

Hydropneumatic fabric guiding system This may have, for example, 4 control rollers and a width-adjustable scanning head (for non-contacting control of the material's edge), which emits a control impulse for the hydrocylinder via a hydropneumatic relay, which then in turn moves the 4 control rolls in an appropriate way to control the fabric.

Hydropulsation Perforated drum-Pulsing-Open width washing machine especially for process-sensitive and extremely loosely constructed fabric. With dwell section (over immersed incline that lays the cloth onto a perforated conveyor belt) and pulsation perforated drum. Fold height and layer thickness controlled by belt speed. Overflow height and liquor flow rate. – Manuf.: Hemmer.

Hydro salts e.g. → Sodium dithionite.

Hydrosol → Colloidal solution in water.

Hydrosulphite → Sodium dithionite.

Hydrosulphite discharges (→ Reductive discharges), sodium dithionite has not completely replaced tin salt- and zinc-dust stripping (too rapid decomposition in alkaline solution). Against it, → Formaldehyde sulphoxylates strips are widely used (better stability and protection of cellulose fibres).

Hydrosulphite-glucose vat This is used mainly with → Sulphoxylates together with glucose, resulting in increased reductive capacity and stability.

Hydrosulphite vat Reduction vat used in vat dyeing and in indigo-sodium dithionite vats. Sodium dithionite reduction baths prodcue sulphate as an end-product (concrete-aggressive).

Hydrosulphuric acid → Thiosulphuric acid.

Hydrotimeter Special burette with graduations according to German degrees of hardness for (total) → Water hardness, determination of, after Boutron and Boudet.

Hydrotrope Registered trade name for a group of substances which show → Hydrotropic property and are used in the detergents industry.

Hydrotropic property The ability to improve the solubility of compounds which are either of low solubility or insoluble, e.g. to turn completely water-insoluble hydrocarbons, chlorinated hydrocarbons, mineral oils, fats, etc. into an aqueous solution or at least an emulsion form, as required by many fat-dissolving soaps, stain removers, emulsions, etc.

compound	solubility in dist. water	100 ml with 25 °C 40% sulphonate sol.
ethyl acetate	8.80 ml	42.60 ml
benzole	0.16 ml	0.37 ml
toluene	0.04 ml	1.20 ml
calcium sulphate	0.22 g	0.48 g

Tab.: Hydrotropic dispersion of the strong hydrotrope meta-xylosulphate-Na (after Booth/Everson).

Hydrotropic property is therefore the ability to confer solubility, where a low solubility substance dissolves or has improved solubility when the added substance is not a solvent for the dissolved substance (Table); such substances, are known as hydrotropic agents (hydrotropes). If the substance is an interfacial active compound, one also talks of → Solubilisation. The solvency is based on a strong reduction in the surface tension of the water and the dispersion effect on the poorly soluble substance. The hydrotropic substances work as

- wetting agents, dispersing agents, penetrating agents or detergents, or as
- emulsifiers, stabilisers.

The dissolved substances in the solutions, emulsions, dispersions may be subsequently separated by dilution. The modes of action of the auxiliary substances are very varied. However, no chemical reactions take place between the components. If the auxiliary agent is a surfactant, for example, the reason for the improved solubility is to be found in the fact that the solubility of the poorly soluble substance is greater in the surfactant micelles than in the aqueous phase of the individual surfactant molecules. "Structure breakers" are substances such as urea and short-chain acid amides, especially N methyl acetamide. They break down the water structure around the hydrophobic group of a poorly soluble substance. It is assumed that these substances are only found for geometric reasons in unstructured areas of water and that they reduce the chemical potential of these areas. At the same time, they break down three-dimensional water structures just as an iceberg melts ("iceberg hypothesis"). An increase in the solubility may also be achieved in some cases by the poorly soluble substance forming mixed crystals with the auxiliary substance. Hydrotropic substances are usually strong electrolytes with a polar hydrophile molecular part, e.g.

carboxyl groups, hydroxyl groups, sulpho groups, sulphide groups, and with an apolar organophile hydrophobic molecular part such as aliphatic, aromatic, saturated cyclic, alicyclic and heterocyclic hydrocarbon groups. Aqueous solutions of the alkaline and alkaline-earth salts of these compounds are used. The substances dissolved are, for example:

- phenols
- high-molecular alcohols
- nitrobenzene
- aniline
- proteins
- carbohydrates.

Hydrotropic solutions are used in chemical reactions such as hydrolysis and condensation, in the manufacture of detergents, cosmetics, azo dyes (coupling of diazonium compounds with amines that are poorly soluble in water), and in electrolysis. Compared with organic solvents, hydrotropic solutions are, among other things, non-volatile, non-flammable, readily capable of being regenerated. They demonstrate good electrical conductivity and their solvent effect is independent of the pH.

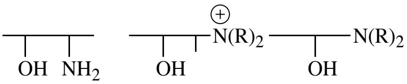
Hydroxides Compound or radicals with → Hydroxyl group. They usually form alkalis (or bases) with metals, alkaline metals, alkaline-earth metals; exceptions: permanganic and chromic acid. With non-metals, on the other hand, they form acids (boric, silicic, sulphuric, etc.). Organic hydroxides are described as either → Alcohols (non-ionising OH) or → Acids (hydrogen ion-eliminating hydroxyl → Phenols).

Hydroxonium-ion → Hydrogen ions.

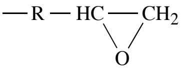
Hydroxy- Name for complex-bound hydroxyl (→ Hydroxyl group).

Hydroxyacetone Rarely used reducing agent for water-soluble sulphur dyestuffs.

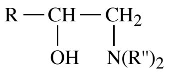
Hydroxy amines (hydroxyalkylamines), class of → Fatty amines:



through complex industrial processing as longer chain olefin epoxides:



through replacement of the reactive H atom to:



$$R-\underset{\displaystyle OH}{\underset{|}{CH}}-\underset{\displaystyle N(R'')_2}{\underset{|}{CH_2}}$$

The resultant hydroxy amines are similar to the fatty amines in their properties and may replace these in their classical areas of application. Tertiary hydroxy amines can be alkylated to quaternary ammonium compounds and convert to betaines or sulphobetaines or oxydised to amine oxides. They have surface active properties, some with anti-microbial action and are used in the manufacture of textile auxiliaries, rinsing, disinfecting and softening agents.

Hydroxyethyl cellulose Non-ionic, water-soluble → Cellulose derivatives (cellulose ether) in various states of viscosity.

Hydroxyethyl or hydroxypropyl starches Important → Starch ethers as conversion product of starch with ethylene or propylene oxide (in presence of alkali). Degree of etherification of 0.3–0.5 produces good water-solubility and avoids any tendency to reversal of the reaction.

Hydroxylapatite Phosphate water softening (→ Phosphate process for softening and silicate removal) usually based on tricalcium phosphate, results in calcium-rich complex salts.

Hydroxyl group (OH group), typical component of → Bases (→ Hydroxides), alcohols and acids (as an auxochrome in dyestuffs), caustic soda liquor, phenol. As a dissociated component of water-soluble compounds, the hydroxyl group is the source of the alkaline reaction and degree of alkalinity (→ Hydrogen-ion concentration).

Hydroxy methylation reaction of synthetic resin compounds The reaction kinetics of the manufacture of reactant resins are believed to occur via the hydroxy methylation reaction on the ionized form of the basic compounds. It is important that the marketed products contain the least free formaldehyde possible so that both the direct cross-linking of the cellulose with formaldehyde and chlorine retention by free NH groups are avoided. Understanding the mechanism of the reaction allows control over the equilibrium of the reaction mixture and prediction of the finishing process results. When the intermediate products are considered, there are two basic mechanisms possible.

With the acid catalysed hydroxy methylation reaction (Fig. 1) formaldehyde is activated by the addition of a proton (1). The carbonium ion reacts with the NH group-containing compound (2) until a protonized N hydroxy methyl compound is formed, which deprotonizes at the next stage (3). The alklaine catalysed reaction starts with the NH group-containing compound (4). The reaction rate is determined by the bimolecular reaction (5) and leads to the formation of the hydroxy methyl anion. The latter reacts quickly with the protonized base, causing a hydroxy methyl compound to be formed (6).

Another view of the trimolecular mechanism is reaction mechanism 2 (Fig. 2). Here two relatively stable

ACIDIC CATALYSIS:

$$CH_2O + H^+ \rightleftharpoons {}^+CH_2OH \qquad (1)$$

$$>NH + {}^+CH_2OH \rightleftharpoons >{}^+NH{-}CH_2OH \qquad (2)$$

$$>{}^+NH{-}CH_2OH \rightleftharpoons >NH{-}CH_2OH + H^+ \qquad (3)$$

BASIC CATALYSIS:

$$>NH + B \rightleftharpoons >N^- + BH^+ \qquad (4)$$

$$>N^- + CH_2O \rightleftharpoons >N{-}CH_2O^- \qquad (5)$$

$$>N{-}CH_2O^- + BH^+ \rightleftharpoons >N{-}CH_2OH + B \qquad (6)$$

Fig. 1: Reaction mechanism 1.

addition products are formed, and the addition of the third participant in the reaction proceeds according to the scheme of the general acid-alkaline catalysis without proton transfer, avoiding the trimolecular mechanism.

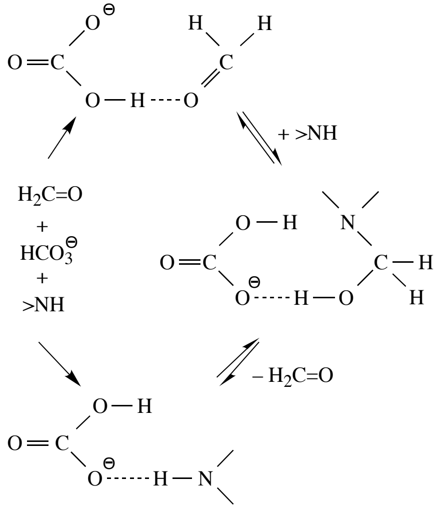


Fig. 2: Reaction mechanism 2.

The reaction mechanism is the same for both pure compounds and for mixtures: the catalyst probably participates to a small extent, with the transitional state representing the ionized form of the basic compound. The presence of acetyl di-urea does not affect the process kinetics, nor the production suitability. The speed of the hydroxy methylation reaction for 4.5 dihydroxyimidazolidone and acetyl urea as well as the activation energies vary, which is probably attributable to the non-comparable energy state of the non-active molecules. The weak N-C bond probably favours the redistribution of the formaldehyde in that the second NH group of the 4.5 dihydroxyimidazolidone is hydroxy methylated. However, the synthetic resin manufactured from the market production of the three substances should not affect the suitability of the textile product any worse than resin finishing using product on the sole basis of 1.3 to (hydroxy methyl) 4.4 dihydroxyimidazolidone 2.

Hydroxypropylmethyl cellulose Methyl-hydroxypropyl cellulose, a mixed cellulose ether used as a greying inhibitor.

Hygienic laundering care Laundering of textiles, a) in accordance with the guidelines laid down by the Bundesgesundheitsamt (Federal Ministry of Health) in Germany for the disinfection of laundry and b) according to the guidelines laid down by the → Gütegemeinschaft für sachgerechte Pflege (Quality Mark Association in Germany) for appropriate laundering care.

Hygienic state Extensive removal of pathogens from the textile material, e.g. with → Textile care.

Hygral expansion Change in length per 1% change in the moisture content. Has a fundamental effect on shrinkage values. Hygral expansion and relaxation shrinkage are the two main causes of the dimensional instability of woollen fabrics, a further cause being ironing shrinkage.

1. Relaxation shrinkage is irreversible. It occurs through the relaxation of prior temporarily set tensions that develop during the fabric processing. Such tensions occur most frequently during the finishing processes, particularly with dry finishing such as shearing, pressing, decatising (especially roller decatising).
2. Hygral expansion effects, on the other hand, are the dimensional changes that occur through changes to the (woollen) fabrics. The amount of hygral change depends chiefly on the fabric structure and the degree of fixation. The more the yarn is crimped by the cross-linking, the greater is the hygral expansion. With stronger fixation in finishing, higher hygral expansion values are found in comparison to a lower degree of fixation. Hence a reversible dimensional change occurs with the hygral expansion, which is determined by the fluctuating moisture content of the woollen fabric (→ Hysteresis).
3. Ironing shrinkage occurs on the steam press. The dimensional changes here may consist of the addition of relaxation and hygral changes.

Hygrometer Indicating device for relative humidity. The most important is the hair hygrometer, with a measuring element consisting of specially degreased and prepared human hair or a bundle of hair. Under the influence of changing humidity, these hair elements will show a change in length that is converted into changes on a scale calibrated in % relative humidity. With the larger hygrometers, used for monitoring relative humidity in factory areas, the measuring element is only used as an indicator and the values are converted via an electromechanical control device and an electric motor drives the display unit (unit connection 220 volt a.c.). Contact hygrometers are hygrometers with an electrical contact device for measuring relative humidity. Built-in hygrometers, with a rear-ventilated mounting, are inserted into air ducts, dry rooms, etc. for taking measurements.

Hygroscopic agents Water-absorbing products as additives for finishes, printing pastes, sizes, to balance the air and fibre moisture and influence the fabric weight and handle.

Hygrotester German appliance for electrical → Moisture content measurement.

Hyperfiltration → Reverse osmosis.

Hyphomycetes → Moulds.

Hypo- (Gk.), prefix with the meaning of “under, beneath, below”. In chemistry it is used to identify compounds in which the central atom is found in a lower state of oxidation than is normally the case.

Hypochlorite bleach Bleaching with sodium hypochlorite is seldom used as a single bleaching stage. The chief importance of this process is based on the following facts. Since peroxide bleaching is associated with a tendency to cause catalytic damage to cellulosic fibres in the presence of heavy metal ions, the inclusion of a prior hypochlorite bleach in the continuous bleaching of woven fabrics has made it possible to employ milder conditions in subsequent peroxide bleaching. This measure thus ensures a high degree of white with a greatly reduced risk of catalytic damage. At the same time, a reduction in chemical costs is realized for the production of full whites with this combined process in comparison to a pure peroxide bleach. The combined sodium hypochlorite/hydrogen peroxide bleach offers the following advantages for the continuous bleaching of woven fabrics:

a) high process reliability,
b) low risk of fibre damage,
c) uniform whiteness (which is, to a large extent, independent of the cotton fibre provenance),
d) cost-effective process.

As a disadvantage, however, is the fact that chloroform has been identified in effluents from bleaching plants originating from the hypochlorite bleach. Such waste waters therefore give rise to increased → AOX values.

The reaction mechanism of hypochlorite bleaching proceeds as follows:

hydrolysis:

$$NaOCl + H_2O \rightleftharpoons NaOH + HOCl$$

bleaching agent release:

$$HOCl \longrightarrow HCl + O$$

max. HOCl development:

$$NaOCl + HCl \longrightarrow NaCl + HOCl$$

formation of free chlorine:

$$HOCl + HCl \rightleftharpoons H_2O + Cl_2$$

The actual bleaching agent is not the sodium hypochlorite (NaOCl) itself but the hypochlorous acid (HOCl) produced from it (see Fig.). The concentration of the actual bleaching agent HOCl in bleach liquors is greatly dependent on the pH. In order to ensure mild bleaching conditions, a pH range between 9–11.5 must therefore be selected. Since, under practical conditions, pH levels below 10 are difficult to keep constant, an initial pH beween 11–12.5 is selected as a rule in order to take into account consumption of caustic soda by the cotton. → Chlorine bleaching; Sodium hypochlorite bleaching.

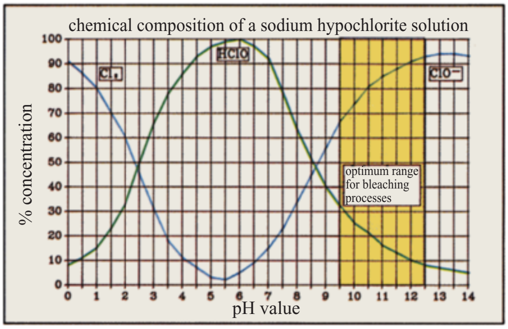

Fig.: Chemical composition of sodium hypochlorite bleaching liquors at different pH.

Hypochlorite bleach fastness Resistance of the shade to hypochlorite bleach.

Hypochlorite oxy acids → Chlorine oxoacids.

Hypochlorite-Peroxide Bleach → Chlorine-Peroxide bleach.

Hypochlorites Salts of the hypochlorite → Chlorine oxoacids.

Hypochlorite wash fastness → Fastness to washing.

Hypocotyl Botanical description for part of the embryo plant, e.g. with → Bast fibres, the transitional stage from the root to the stem. Hypokotyl fibres: bast fibres already existing in the hypocotyl below the cotyledon axis, individual fibres up to 15 mm long, still very uneven, wooden, brittle, low strength, technologically without value. Mechanically destroyed in fibre extraction.

Hypohalide Compound form: Hypo and → Halides.

Hypophosphites → Phosphoric acids.

Hyposulphite → Sodium hyposulphite.

Hypothetical As yet unproven scientific assumption, e.g. listing of hypothetical structural formulae.

Hypsochromic group Substituent group that causes a hypsochromic shift in dyestuff synthesis. Opposite of the → Bathochromic group.

Hysteresis (Gk.: remaining behind), elastic aftereffect, i.e. the change in form by which some (e.g.

rubber-like) substances do not recover fully or only recover slowly once the elastic stress has ceased to be applied (see Fig.).

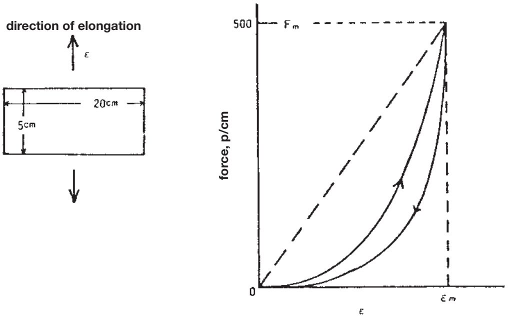

Fig.: Curve of the determination of tensile elastic properties of a textile fabric.

1. Fibres with different loading and subsequent unloading show varied functions f (fibre behaviour) = (type of loading). The diagram shows a typical hysteresis curve, for the load:un-load cycles, where the curves are not identical.

2. In the Kawabata handle evaluation system, any hysteresis recorded is evaluated in relation to
- shearing hysteresis width of load:un-load curves
- recovery ability with elasticity of elongation measurement
- bending hysteresis width
- hysteresis with compression measurements.

3. The hygral expansion or contraction of woollen fibres also follows an hysteresis. Hygral expansion, a special property of all fabrics made of hygroscopic fibres, can be observed most often with woollen fibres due to their specific swelling properties. The scale of this only temporary dimensional change depends in part on the degree of fixation, though chiefly on the fabric structure, and can be predicted in most cases. Relaxation shrinkage and hygral expansion may overlap, which is why the hygral expansion can only be determined from test specimens which are completely relaxed, i.e. through repeated immersion in warm water, and dried free from tension. Each moisture content corresponds to a particular length and width, whereby the hysteresis needs to be taken into account: with a definite moisture content, the dimensions are somewhat larger if the moist state is reached by evaporation from the wet side than they are by adsorption of moisture from the dry side. This effect is really small with normal worsted fabrics, but may become quite marked with fabrics that have an open structure.

The hygral expansion has its origin in the fibres themselves: if the moisture content of a practically dry, crimped woollen fibre (moisture content approximating 0%) is increased, then swelling of around 16% will occur in a radial direction even before the saturation limit is reached, while the swelling simultaneously taking place in a longitudinal direction is slightly more than 1%. The consequence of the radial swelling is that the fibres stretch or straighten, which is equivalent to an enlargement of the span of the curl geometry or to an extension of the arc radius. Theoretically, the radius of the arc should increase by 16% as the fibre changes from the dry to the moisture-saturated state, which has actually proved to be the case with coarser fibres such as Lincoln wool. With finer wools, such as merino fibres, the change in the arc radius is on average 52% higher. Orthocortex and paracortex are arranged side by side in such fibres. If a fibre is bent with this cortex arrangement, then it will turn in such a way that the paracortex lies on the inner side of the curvature and the orthocortex on the outer side. In the same orientation, both cortex segments are located in the growth-based curves of the natural fibre crimp. Hence, the differences in the distribution of the cortex parts seem to be chiefly responsible for the greater changes in the arc radius found with finer fibres. If the moisture content of the fibre again drops to its original value, then in all cases the radius of the arc also returns more or less to its previous value, with the result that the fibre regains its original length. Consequently, whenever the moisture content of the fibre is either increased or decreased, an expansion or contraction will occur in a longitudinal direction, but on two different "paths" in the diagram "Moisture content expansion".

Hz, symbol for → Hertz.

Iceberg structure of water Of all known liquids water has the highest heat of vaporization per gram. The reason for this particularly high value is the network of hydrogen bonds which still hold the structure of water molecules together even in the liquid state. In the iceberg or cluster model of the structure of liquid water, more or less small clusters of of water molecules are held together by hydrogen bonding in an ice-like structure. The hydrogen bonds are constantly disintegrating and reforming (Fig. 1) so that at one instant a certain molecule can be bound to another and in the next instant become freely mobile again. These bonds must be broken if the liquid is to evaporate. To achieve this, energy is necessary, which results in a higher heat of vaporization than for liquids without hydrogen bonds (e.g. tetrachloroethylene).

Hydrogen bonds between O- and H- atoms in different molecules are closed and broken again over time. On average, the percentage of H atoms participating in the hydrogen bonding remains constant although individual bonds are continually changing. At a particular moment, perhaps one group of molecules forms an ice-like cluster, and a moment later, another group is bound in a cluster (Fig. 2), or an individual water molecule (e.g. at room temperature) momentarily as such before becoming bound in the cluster again.

Ice colours Produced directly on the fibre by preparing cotton with beta-naphthol followed by development with ice-cooled diazotized aniline. Obsolete process; now substituted by Naphthol AS types.

Iceland moss This is the name given to islandicus lichen or Cetraria islandica, a lichen from the northern countries which is exported from Iceland, Norway and Sweden. Phenotype: Fruticose, bushy, lobed upwards, with bark on both sides, base tapered, drop-like, tubular, leathery, 10–15 cm in height; colour: olive green to light, otherwise grey-white. Reddish base, dried; top greenish brown, underside grey. Approx. 60% mass is released from the powdered lichen during boiling with very diluted sodium hydrogen carbonate solution, and a gelatine is formed when the solution is cooled. The extract consists of a polysaccharide mix of lichenins and isolichenins, a range of lichen acids (fumaric protocetraric acid, protocetraric acid and cetraric acid) and protolichesterinic acid which is converted into lichesterinic acid during processing. Usage: for sizing, proofing and printing thickeners.

ICR (Ger.), abbrev. for: Informationsstelle Chemischreinigung, Stuttgart, Germany (German Information Office for Drycleaning); → Technical and professional organizations.

Ideal black (physical). A black which absorbs 100% of the incident light at all wavelengths, i.e. the reflection amounts to zero. See also → Ideal white.

Ideal white (physical). Also described as normal white; closely approximated with barium sulphate with a reference point ≅ 100. In colour space it corresponds to the → Achromatic point, to which a colour approximates after bleaching. Ideal white is a borderline case insofar as 100% of the incident light is reflected at each wavelength (counter term: → Ideal black). The commonly used term "100% reflection" corresponds to the spectral energy factor β = 1 (also described as the luminance factor β).

Idle machine time → Useful life of working.

Fig.: Ignition points (*) of samples in standard flammability tests (arrow = direction of combustion).

Ikat The word "ikat" is derived from a Malaysian word *mengikat*, which means to tie, knot, bind or wind. In this technique, attractive designs are produced by the successive localized application of dyes to threads before weaving. The technique was also highly developed in Indonesia, India, Madagascar, Central and South America, etc. In ikat dyeing, predetermined sections of the threads are bound tightly, knotted, or otherwise made resistant to dye penetration, e.g. as may be seen in the bundle of cotton yarn shown in the figure in which the areas bound with one knot are for a white resist, and those with two knots are for a red resist. Depending on how the dyed resist yarns are woven, there are warp ikat, weft ikat and double ikat (in which both warp and weft yarns have been resist dyed) variations. Careful control and planning results in the typical and characteristically attractive designs of ikat dyeing. When the yarns are woven, the edges of the design motifs have a blurred or soft effect caused by bleeding of one colour into another (some dye always penetrates underneath the edges of the resist areas) or when the coloured areas do not coincide exactly in weaving. Ikat is a laborious dyeing technique involving the application of several colours often still carried out with vegetable dyes.

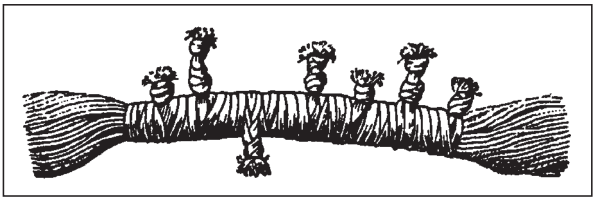

Fig.: Knotted substrate for the Ikat technique.

IK dyeing method Dyeing method for vat dyes (IK dyes) which have the highest affinity for cotton at 25–30°C. Because of inferior fastness properties the so-called cold-dyeing vat dyes which can only be applied by this method have diminished in importance. → Vat dyeing.

Illuminating colours An old term for textile colours used in resist and discharge printing. Illuminating colours are produced mainly with brilliant dyes from a different dye class to supplement the shades missing from a particular dye range.

Illuminating dyes In textile printing, illuminating dyes are those dyes which are used to substitute the missing shades in a particular dye class, e.g. vat leuco ester dyes as coloured resists under naphthol and aniline black dyeings. In discharge printing, a distinction is mades between white discharge printing and coloured discharge printing. In coloured discharge printing, coloured grounds (produced with dischargeable dyes) are printed with discharge printing pastes containing dyes resistant to the discharging agent. Since these dyes are required to produce shades which stand out coloristically from the ground colour, dyes which yield particularly brilliant shades are used for reasons of optimum design effect and these may also be considered as illuminating dyes. If vat dyes are used for the production of coloured discharges, the reducing agent not only has the task of destroying the ground dye but must also, at the same time, convert the discharge-resistant vat dyes into their leuco form to facilitate their exhaustion on to the fibre:

$$\begin{aligned}&HOCH_2SO_2Na + H_2O + O{=}dye{=}O \rightarrow\\&HOCH_2SO_3Na + HO{-}dye{-}OH\end{aligned}$$

During further processing the vat dyes are reoxidized on the fibre where they are ultimately restored to their original chemical form again. On a Colour Index system dischargeability scale of 1–5 (where 1 = virtually undischargeable and 5 = readily dischargeable to white) only those dyes classified as 1 or 2 are suitable as illuminating dyes in coloured discharge printing. Discharge-resistant dyes may be found among various dye classes, e.g. direct, acid and cationic (basic) dyes, as well as vat and vat leuco ester dyes (see Fig.).

A few acid dyes, especially certain blue and green types, are anthraquinone derivatives which, in some cases, are very difficult or impossible to discharge, so that they can be employed in the production of coloured discharges. Greens and other shades are obtained by

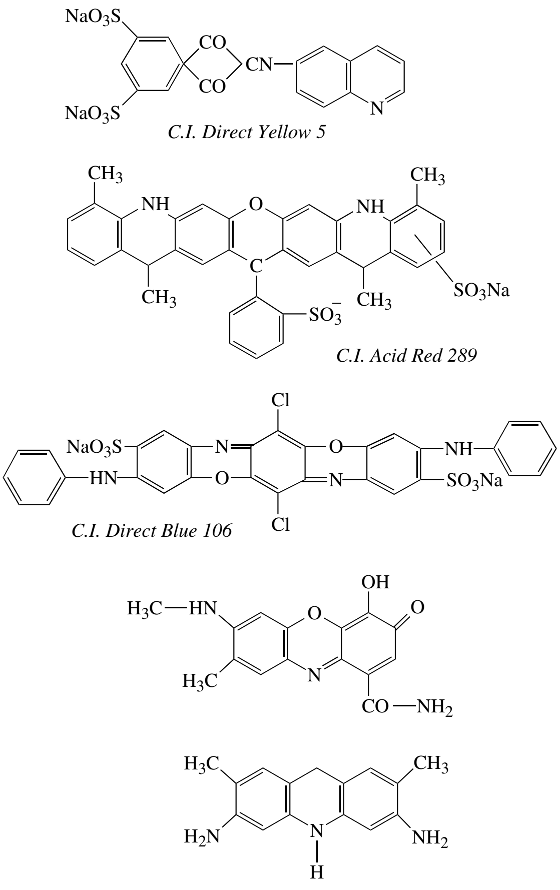

Fig.: Examples of illumination dyes for wool and silk discharge printing.

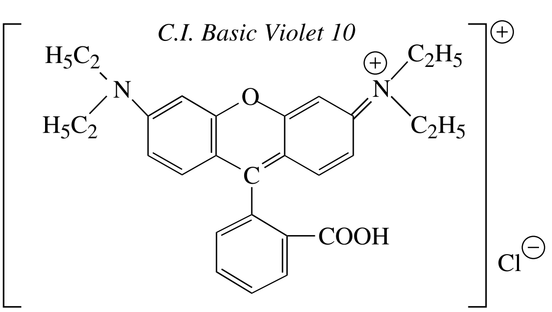
using mixtures. It is advisable to limit the dyes used in mixtures to one dye class; mutual precipitation of acid and cationic dyes can occur in mixtures resulting in losses. Diphenylmethane and triphenylmethane dyes are, in some cases, either not decolorized, or decolorized only with difficulty by reduction. With some of these dyes, the original colour returns on exposure to air or after treatment with oxidizing agents. A few direct, acid and cationic dyes belong to the group of triphenylmethane dyes, e.g. rhodamine, and are also known as xanthene dyes since they may be derived from xanthene.



These dyes yield exceedingly vivid, clear and brilliant prints which are virtually impossible to achieve with other dyes. Rhodamine B is a brilliant bluish-red dye. On esterification with ethanol, Rhodamine 3B is formed which yields an even bluer red shade than Rhodamine B. The discharge-resistant Rhodamine 6GP is a dye with a similar chemical constitution. The two discharge-resistant acid dyes, quinoline yellow and rhodamine are only used because of their stability to zinc formaldehyde sulphoxylate since their fastness properties leave much to be desired. The discharge-resistant rhodamine acid dyes are obtained by sulphonation of the basic rhodamine. Other discharge-resistant xanthene dyes include the resorcinol dyes such as eosin and Bengal pink.

Discharge-resistant dyes of different dye classes include, e.g.: C.I. Acid Yellow 5, C.I. Direct Yellow 28, C.I. Acid Yellow 99, C.I. Acid Red 87, C.I. Acid Red 52, C.I. Acid Blue 59, C.I. Acid Blue 102, C.I. Basic Blue 3, C.I. Acid Violet 90.

Illumination The quantity of light or luminous flux falling on unit area of a surface. Illumination is inversely proportional to the square of the distance of the surface from the source of light and directly proportional to the intensity of the light. The derived SI unit of illumination is the lux (symbol lx). 1 lux is defined as the uniformly distributed illumination of 1 lumen of luminous flux over an area of 1 m^2, i.e.

$$1\ \text{lx} = \frac{1\ \text{lm}}{1\ \text{m}^2}\ ;$$

Since 1 lm is equal to 1 cd · 1 sr (cd = candela; sr = steradian; lm = lumen), it follows that:

$$1\ \text{lx} = \frac{1\ \text{cd} \cdot 1\ \text{sr}}{1\ \text{m}^2}$$

As a comparison: 1 phot = 10 klx = 10 000 lx.

The Hefner candle (light intensity 0.903 cd) radiates a power of 95 µW in a horizontal direction on 1 cm^2 of surface at a distance of 1 m. The steradian is the SI unit of solid angle.

ILMAC (Ger.), abbrev. for: internationale Fachmesse für Laboratoriumstechnik, Meßtechnik und Automatik in der Chemie (German Technical Fair for Laboratory Technology, Metrology and Automation in Chemical Applications). Held annually and concurrently with the Schweizer Mustermesse (Swiss Trade Fair).

Image analysis in fabric inspection On-going quality requirements must be translated into measurable terms in order to control the fabric quality during production. Sensors and measuring methods must also be developed. Optical sensors will play an important role. The use of photodiodes, laser scanners and video cameras is conceivable. The signals from these sensors must be processed in order to obtain relevant product properties. Where images are concerned, this is referred to as image processing (see Fig.). Image processing is predominantly used for video images. A distinction can be made between applications where the images are merely improved and those where the images are analysed, producing one or several values as an end result. With industrial applications, values are generally derived from the images. Robots with "vision" systems determine the position and orientation of individual components. In such cases, reference is made to "pattern recognition". Image processing is used for textural analysis to describe an image using one or more parameters without describing all the objects within the image in detail.

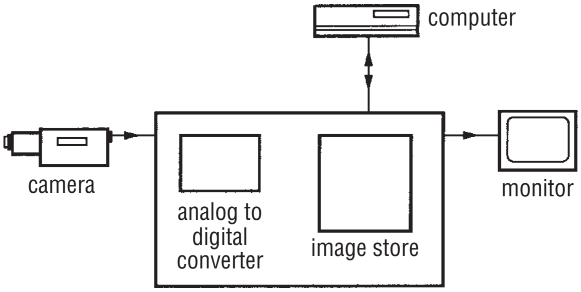


Fig.: Diagrammatic view of an image processing system as a basis for image analysis in fabric inspection.

A video camera is generally used to record the images. An analogue to digital converter is used to digitise the information concerning an image and this is then stored in part of the computer memory which is known as the visual storage. The image then consists of e.g. 512 x 512 image elements, each of which reproduces the average picture grey scale value of a small part of the original image. This image may now be processed using a computer. The changes can be tracked on a second screen which continually reproduces the contents of the visual storage. The computer is able to alter the grey scale values of the image elements. It is therefore possible to add a value to all the image elements in order to make the image lighter as all the grey scale values are changed. It is however more interesting to make the new value of an image element dependent on the values of its adjacent image elements. Such operations are referred to as "window" operations as the new grey scale value is dependent on the image elements within a specific window. By repeating the application of such operations, images can be enhanced for the eye and specific features can be derived from an image. If an image is to be characterised using several values without the objects within the image being described in detail, methods can be used to analyse the texture of an image. The texture can be defined as a surface composed of smaller parts without it being necessary to describe the precise form of these individual parts in more detail.

Image processing The automation of visual test and inspection processes for textiles poses a range of complicated tasks for digital image processing. Solutions which have been drawn up for the interactive mode of the test laboratory can be transferred gradually into the areas of production, finishing and making-up. A basic prerequisite for this is that the computer operates sufficiently quickly. Fault analysis on a moving length of cloth using a CCD matrix camera gives a rough estimate ($b = 2m$, $v = 60$ m/min, resolution $\Delta x = \Delta y = 0.2$ mm, 20 operations/image spot) of at least 10^9 operations/s. This value is not achieved by many computers. Steps are being taken to find new types of working principles and computer architectures and to advance into the region of 10^9 operations/s. One of the key terms used is "parallel computer technology", a concept which has been realised in transputer and neuronal networks. The basic concept is that the programme is broken down into blocks which are transferred to be processed on computers which operate in parallel to one another. Another option is to use algorithms in parallel. Acceleration factors of 10–100 can be expected overall.

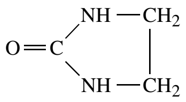
Imago effects → Transparent and opal finishes.

Imbibition A measure of the liquid or water-holding capacity of a textile material.

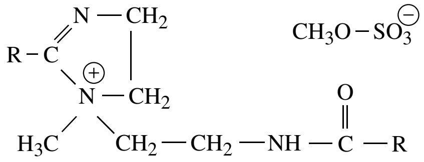
IMDG/IMCO, abbrev. for: International Maritime Dangerous Goods code/Inter-governmental Maritime Consultative Organization. Hazard symbols and warning signs for dangerous goods or substances.

Imidazole → Heterocyclic compounds.

2-imidazolidone Trivial name for (cyclic) ethylene urea. As dimethylol compounds (e.g. DMEU, DMDHEU) 2-imidazolidone resins and derivatives are important reactant resins for textile finishing.



Imidazolinium compounds A classical raw material for fabric softeners and tumbler auxiliaries is the tallow-alkyl imidazolinium salt:

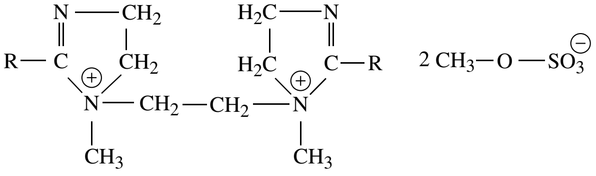


1-methyl-1-fatty alkylamidoethyl-2-fatty alkyl-imidazolinium methyl sulphate

R= glyoxaline

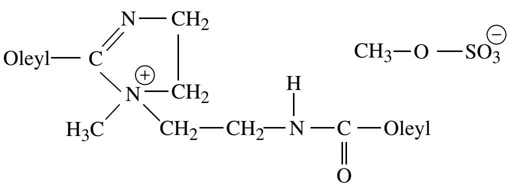
which is dispersible in cold water as a fabric softener. It is produced from fatty acids and diethylenetriamine to obtain a ring-closed condensate with dimethyl sulphate via ditallowalkyl.

Another interesting di-quaternary softener additive is derived from the series of bis-(imidazolinium) compounds:



1,1-Ethen-bis(-1-methyl-2-talgalkyl-imidazolinium)-methylsulfat

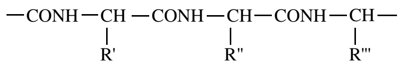
An imidazolinium methyl sulphate with oleyl groups as alkyl substituents is also a very suitable compound in many respects:



1-Methyl-1-oleylamidoethyl-2-oleyl-imidazoliniummethylsulfat

Imido, imino groups (NH groups). Imines are compounds containing the group –NH– (the imino or secondary → Amino group) joined to two other groups. Imides, on the other hand, contain the imido group –CONHCO–. From a dyeing point of view, these groups represent the most important components of the peptide bond, e.g. in protein (wool, silk) and polyamide fibres:

WO-type:



$$-CONH-\underset{R'}{CH}-CONH-\underset{R''}{CH}-CONH-\underset{R'''}{CH}-$$

PA 6-type: $-CONH-(CH_2)_5-CONH-(CH_2)_5-CONH-(CH_2)_5-$

PA 6.6-type: $-CONH-(CH_2)_6-NHCO-(CH_2)_4-CONH-(CH_2)_6-$

Imines Compounds containing the group –NH– (the imino group) joined to two other groups; i.e. secondary amines.

Imitation fur (simulated fur, imitation skin). A collective term for numerous imitations of natural furs and skins. Synthetic fibres are predominant as raw materials for the production of simulated fur pile fabrics with increasing use being made of hollow fibres. Imitation fur fabrics are often foam-backed.

Imitation lambskin Materials of this kind are, as a rule, woven from wool as → Double plush, and can be white, piece-dyed or mottled. The wool tufts, as so-called pile loops, are unevenly distributed in different sizes. These imitations achieve their characteristic appearance through milling. Imitation lambskin fabrics are also produced as knitgoods and are then softer and more elastic.

Imitation skin → Imitation fur.

Imitation suede (imitation suede leather). These materials may be subdivided into the following categories depending on the manufacturing process:

I. Imitation suede 1st generation: → Artificial leather produced mainly from textile random webs, woven or knitted base fabrics: a) either by flock coating or b) artificial leather coatings (mainly polyurethane and polyvinyl chloride).

II. Imitation suede 2nd generation: available commercially since the middle of the 1970's as special fibre laminates in e.g. polyurethane resin compounds. The special fibres are produced as matrix/fibril (M/F) bicomponent fibres from several polymers with different solvent solubilities. If the matrix phase is extracted or dissolved from such M/F systems (e.g. with dimethylformamide) the microfibril composite fibres are left as the fibril phase whilst, if the reverse procedure is followed by dissolving out the fibril phase, the matrix phase remains behind as a multiple hollow fibre with a longitudinal porous structure (Figs. 1 + 2).

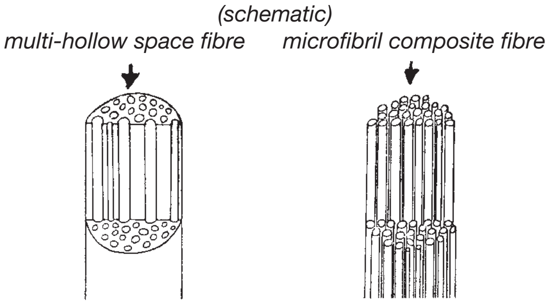


Fig. 1: Microfibril fibres for imitation suede.

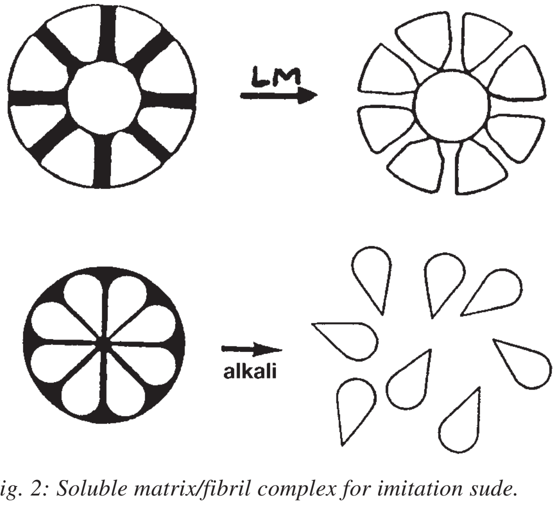

Fig. 2: Soluble matrix/fibril complex for imitation sude.

The technical manufacturing principles involve a) the extraction of at least one fibre component from the pre-bonded M/F random fibre web, followed by impregnation with a binder (e.g. a polyurethane elastomer) and coagulation of the system; or b) impregnation of the pre-bonded random fibre web followed by coagulation of the system and then the extraction of one component of the fibre material. Finally, the slubby surface of the bonded elastic laminate is subjected to a mechanical treatment, e.g. emerizing. c) Bicomponent fibres of polyester/polyamide in knitted fabric form are subjected to a thermal treatment, or a treatment in sulphuric acid, followed by emerizing.

Properties: depending on the needle felting conditions, average fibril count (approx. 20–400) and fibril Ø (approx. 1.3–2 µm. An increase in the number of bundled fibres increases the tensile strength and resistance to tear propagation/unit weight, but also reduces dyeability and results in decreased elasticity at the same time (= a less rubber-like handle). On closely examining the surface of an emerized imitation suede fabric it is found that more than 80 fibrils or those with a Ø of approx. 2 µm or less are responsible for the characteristic leather-like lustre and considerable chalking effect. → Synthetic velours.

Imitation yarn Soft-twisted, bulked coarse cotton yarn consisting of short fibres spun in the manner of carded yarn (→ Condenser yarn).

Imi-Wax An abbrev. for imitation wax print. The purpose is to imitate real wax prints by avoiding the laborious wax resist printing process. The crackle or veining effect in Imi-Wax Africa prints is produced by direct printing and the indigo of real wax prints is imitated by printing blue diazo fast colour salts on naphtholated grounds. In the vast majority of cases, the same typical designs and colours are used as for real wax prints. The production of Imi-Wax prints is mainly carried out on roller printing machines. → Indigo styles in Africa prints.

Immature cotton Cotton picked before it is fully mature. The fibres are not properly formed and the yarn made from them is generally weaker and inferior. Immature cotton tends to form small neps in the spinning process. In contrast to → Dead cotton, the fibre contains a considerable amount of protoplasm and therefore has changed dyeing properties. → Cotton maturity index.

Immersion (Lat.: *immergere* = to dip or submerge). A term used, for example, in the sense of immersing cotton yarn during mordanting for Turkey red. The term is also used in microscopy with immersion objectives, i.e. immersion of the plane surface of the front lens of an objective in a drop of water or oil on the cover glass of a microscope slide to reduce refraction at the front lens at higher powers. Besides aiding aplanatism the numerical apperture of the objective is increased by this process, which therefore increases resolving power. → Immersion fluid.

Immersion accumulator An intermediate storage compartment in a continuous pretreatment range in which, e.g. a cotton fabric impregnated with a peroxide bleach liquor is allowed to dwell for several minutes in a reservoir of hot bleach liquor to allow sufficient time for reaction to take place. The fabric is transported slowly through the compartment at a relatively long liquor ratio by means of a conveyor which ensures that the treatment is carried out entirely below the surface of the liquor (see Fig.). This type of unit has proved popular for the bleaching of weft-knit cotton fabrics.

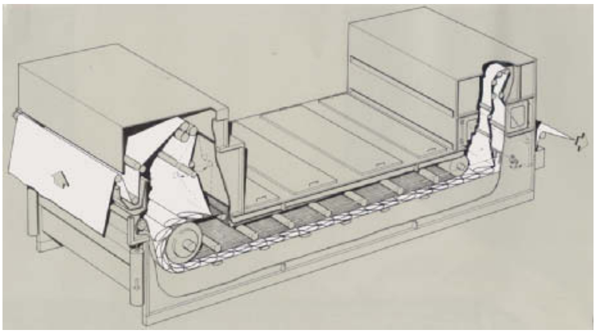

Fig.: Immersion accumulator "Steepmaster" (Küsters).

Immersion bleach process With these processes, the material being bleached remains submerged in the liquor for a specific period of time, e.g. in a "wet" J-box (or sump) in contrast to other continuous bleaching processes where the fabric is simply impregnated with bleach liquor and plaited down in a storage unit. The under-liquor treatment is a technology for wet processing of textile piece goods which represents both a breakthrough in the process technology of "discontinuous exhaust methods" towards continuous treatment as well as an extension of existing continuous treatments towards the use of "longer liquor ratios". The advantages of providing a greater supply of liquor, even in typical continuous treatments, have been known for a long time as amply demonstrated by the use of:

- sumps in J-box installations for fabrics in the rope and full-width state,
- boosters in pretreatment steamers,
- immersion zones in HTP steamers (high-temperature and pressure) as e.g. in the plaiting system shown in Fig. 1.

From a process technology point of view, considerable advantages have been achieved by this means, e.g.:

- more complete removal of impurities from the substrate,
- greater uniformity of the achieved effects and the prevention of crease and rope marks,

Immersion bleach process

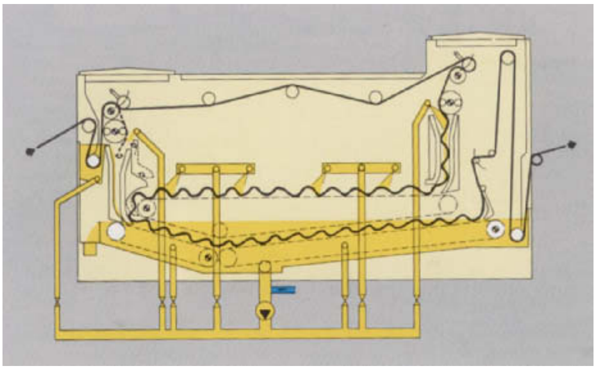

Fig. 1: Wicoflex immersion tray system allowing band material to reside both in a steam chamber and immersed in liquor in the same system (Kleinewefers KTM).

- development or preservation of particular fabric characteristics,
- reduced chemical concentrations with consequent protection of the material against excessive chemical damage and sensitivity.

On the other hand, efforts have continually been directed towards the substitution of relatively time, water and energy-intensive discontinuous (batchwise) long-liquor processes such as the jigger, winch and, more recently, overflow and jet treatments, by continuous methods without sacrificing the advantages of the former, e.g.:

- use of long treatment times with low chemical concentrations on the goods,
- allowing the material to float with consequent possibilities for the goods to relax at long liquor ratios.

Machine designs incorporating the following concepts are used in practice:

- spiral passage of material through winch becks,
- immersion of open-width material in suspended loops (e.g. Mezzera system)
- washing and shrinking machines for polyester textile materials which have also followed this trend.

In 1976, Bayer developed a bleach process known as the PKS process (i.e. the “Peroxid-Kontinue-Schnellbleiche” in German), a continuous rapid peroxide bleach in which the principles of both methods of treatment have been intentionally combined. From considerations of process flow, discontinuous and continuous long liquor systems differ considerably.

In discontinuous (batchwise) processes, the chemical reaction usually begins at a maximum concentration of the particular chemicals used and a minimum treatment temperature. The system is gradually brought to the maximum temperature within a certain time and maintained at that temperature for a specified period. The chemical concentration undergoes continual degradation so that the maximum temperature and maximum concentration do not normally coincide which simplifies the recipes for such processes and, in the case of hot peroxide bleaching especially, is also favourable for peroxide stabilization and control. The reaction products are removed in rinsing operations and the detached impurities are carried away. In the next treatment cycle, processing is carried out in “clean” baths again.

With continuous processes, on the other hand, the reaction is carried out in a “standing” bath at a constant temperature and chemical concentration on continuously running fabric. After a certain treatment time, a dynamic equilibrium establishes itself between chemical consumption, liquor input and output, chemical supply and the asymptotic maximum of bath impurities resulting from detached fibre contaminants and their reaction products with the treatment chemicals. Since exposure of textile materials in continuous under-liquor baths (Fig. 2) involves considerably longer standing times, this can lead to harmful degradation and saponification reactions proceeding much further than in discontinuous processes causing unwanted precipitation reactions. Precipitations of lime-soap-like stain

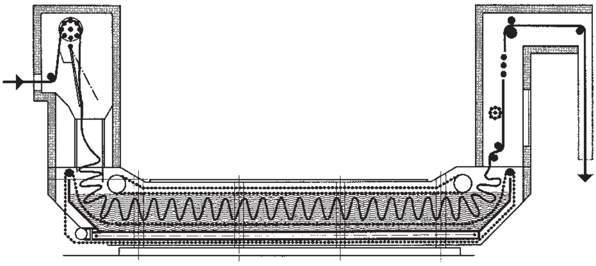

Fig. 2: Typical steeping machine (Menzel).

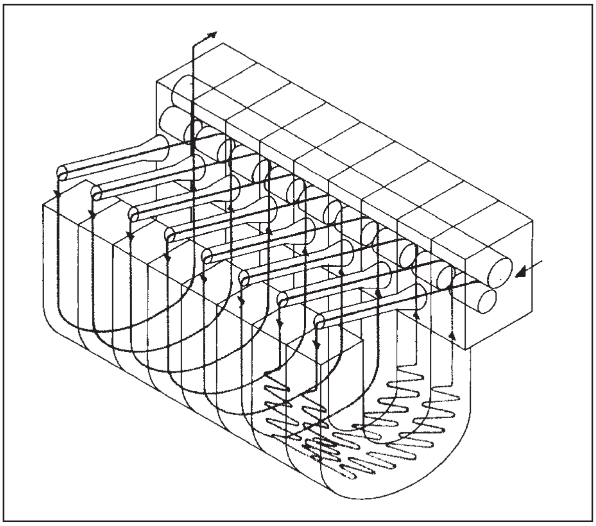

Fig. 3: Typical immersion tray system for strands of material.

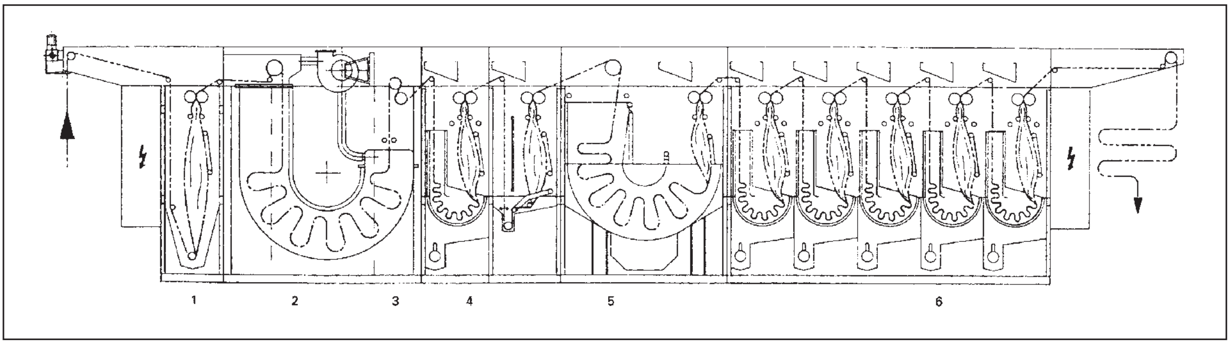

Fig. 4: PKS immersion bleach system in the Brückner continuous bleaching facility for broad tubular fabric.

forming substances are examples of such reactions. Since the maximum temperature (80–90°C) in continuous peroxide bleaching coincides with the considerably higher chemical concentrations, self-decomposition of the peroxide also reaches considerably higher levels than in discontinuous processes which becomes manifest as a higher specific peroxide consumption. These peculiarities make it necessary to employ special recipes for continuous long liquor processes, especially in the peroxide bleach.

Continuous treatments, especially those based on J-boxes (Fig. 3) and the conveyor belt bleach, are well-established in practice. These are steaming processes combined, in some cases, with cold pad-batch treatments.

Another alternative which gives better whiteness and better fibre protection (e.g. higher DP values) is the PKS process developed by Bayer. This under-liquor bleaching system (Fig. 4), gained importance in the past since suitable machines for its application were already available. Many machine makers now offer appropriate machines for the treatment of knitted fabrics in rope and open-width form (open-width tubular and slit goods), e.g. Brückner, Thies, MCS, Goller, Argathen, KTM Kleinewefers and Jemco, etc.

These multifunctional processing ranges (precleaning, bleaching, extraction, afterwashing of dyeings and prints) have led to a greater acceptance of processes based on “under-liquor treatment” in practice. The liquor temperature and dwell times, as well as the chemical concentrations and choice of stabilizer and surfactant are of decisive importance in these processes (source: Guth, Broglin and Günther).

Immersion centrifuge Textile material is wetted out in the basket of a particular type of → Centrifuges and subsequently centrifuged. An immersion centrifuge is used to saturate or impregnate textile materials with liquors by centrifugal force as well as for rinsing, souring and neutralizing. Processing liquors may be collected during centrifuging and re-used.

Immersion fluid A liquid used for immersion objectives in microscopy, e.g. water, monobromonaphthalene, cedar-wood oil, to reduce the refraction at the front lens of the objective.

Immersion jigger A type of jigger which was often used in the past for dyeing with vat dyes. In this type of jigger the draw rollers are not mounted above the liquor as in a normal → Jigger but below the surface of the liquor so that the problem of atmospheric oxidation of the vat dyes during dyeing is prevented.

Immersion length The total length of the immersion zone in, e.g. the impregnation troughs of padders and other machines in order to ensure satisfactory and uniform wetting out of textile piece goods.

Immersion squeezing In order to intensify the liquor exchange in wet-on-wet processing or the wetting out of textile fabrics in wet-on-dry treatments at high production speeds in a padder trough with a low liquor content (i.e. with a short immersion path), squeeze rollers are also employed below the level of the liquor in addition to the usual squeeze rolls mounted above the trough (see Fig.).

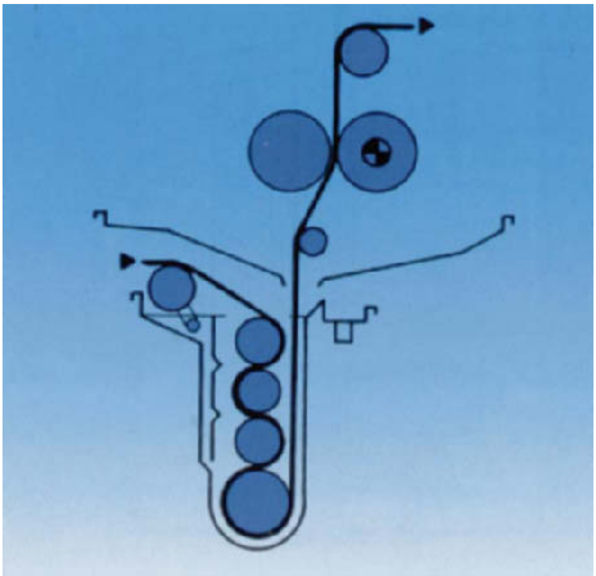

Fig.: Immersion squeezing in a padder of Kleinewefers KTM.

Immersion test A test method for water-repellent impregnations on textiles (especially for yarns and knitted fabrics). Procedure: The textile test specimen is weighed then submerged in a sieve for 5 min under 10 cm of water (the sieve is jerked a few times to remove collected air). The specimen is then taken out of the water, allowed to drain for approx. 10 min, weighed again and the water uptake calculated.

Immersion wettability test Determination of the → Wetting power of a surfactant with the aid of a standard cotton specimen which, as a round-cut dry substrate hung on a thread, is pulled by a hook under water. The time required for this specimen to sink to the bottom is measured. With the aid of this test, the wetting power of different surfactants can be compared by determining the respective concentration required to achieve a wetting time of 25 s. This value (log C_{25}) can be entered against the abscissa value for the chain length of the surfactant to obtain straight lines in homologous series. In the immersion wetting test, branching in the chain molecules and longer chain lengths lead to a reduction in the "C_{25}" value. For a specific wetting action, however, a minimum concentration is always required irrespective of the molecular structure of the surfactant.

Immunization A chemical process for the surface modification of fibres to achieve a different affinity towards dyes, e.g. in connection with processed untreated fibres in order to obtain two-colour effects, fancy edges, local printed effects, etc. Since the introduction of acetate and triacetate fibres the importance of such processes has declined or has led, on the one hand, to the development of so-called resisting agents and to the numerous animalized fibres on the other.

The immunization of cotton fibres results in a reversal of their affinity for direct dyes in favour of acid, cationic or disperse dyes. The process is carried out by e.g. esterification of the cotton fibre with acid chlorides or p-toluene sulphochloride:

immunize

or with isocyanates, acetic anhydride = passive yarns (→ Acetylated cotton).

The immunization of wool and similar fibres results in a loss of affinity for acid and chrome dyes in favour of cationic dyes. The oldest process of this kind was based on the action of tannic acid solution and subsequent fixation with metal salts. Such immunized wool can be produced as white or dyeable fibre, but has poor stability to boiling acidic liquors. For this reason, numerous other treatments have been developed, the practical results of which are based on the application of resisting agents.

Immunized yarn → Immunization.

Impinging flow Within the medium surrounding the fibre, a distinction should be made between the diffusion boundary layer and the flow boundary layer on the surface of the fibre. A state of equilibrium arises between the material concentration in the fibre surface and the diffusion boundary layer. The time it takes for this equilibrium to be reached is dependent on the substrate. The concentration gradient between the diffusion boundary layer and the flow layer, however, is determined by the rate of the flow layer. Where the impinging flow rate is constant, the so-called hydraulic diameter, which is composed of pores of various sizes in the yarn and fabric, or the modification to this profile during flow governs the rate of the flow layer and thus the material exchange. The blending of the 2 liquor layers is encouraged by a turbulent flow which arises at specific impinging velocities, as well as by the profile of the pores in the textile.

The macro-kinetics of dyeing processes which occur on impinged surfaces can be described using the convective diffusion model (Fig. 1).

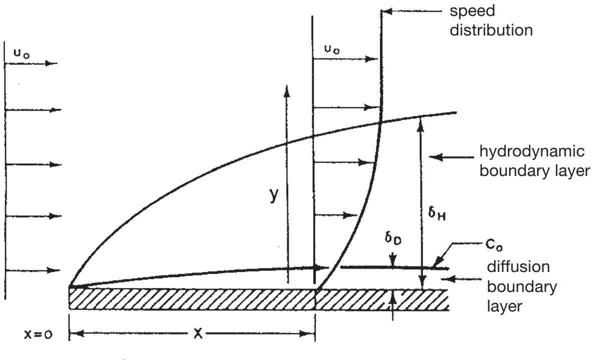

Fig. 1: Impinging flow profile on substrate surfaces. The convective diffusion model combines the impinging flow profile of the liquor with the concentration declivity of the dye on the substrate surface. The bondary layer dimensions are defined for the 95% value of u_o and c_o.

In a stationary liquor across a fibre surface, the adsorption velocity of the dyestuff will fall as the diffusion boundary layer δ_D increases. In the event of a tangential flow of dyestuff across the substrate surface at a velocity of u_0, the diffusion boundary layer which has been depleted in dyestuff is cleared and replaced with fresh liquor, with the result that dyestuff with increased velocity can once again be combined with the substrate by a considerably reduced diffusive boundary layer.

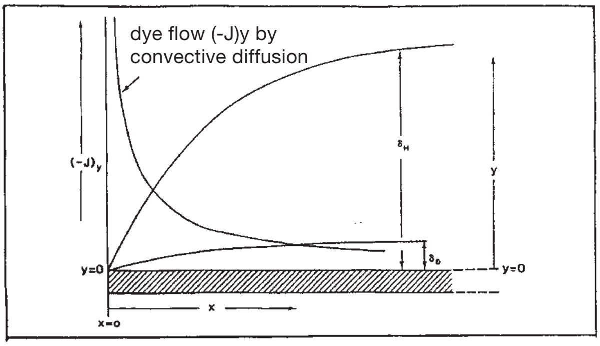

Fig. 2: Dye flow by convective diffusion.
The dye flow J, maintained by convective diffusion on the substrate surface, tapers off after passing the starting section x to a constant value characteristic of the dyeing system.

The effective mass flow on the fibre surface required for the adsorption of dyestuff (Fig. 2) is given as the result of the contrasting convective and diffusion flows. These determine the thickness of the hydrodynamic or diffusion boundary layer. As shown in Fig. 3, dyeing in a liquor which is only circulating slightly is characterised by a relatively thin hydrodynamic and an extended diffusion boundary layer. In a liquor which is flowing strongly, the relative ratios of size of the two boundary layers are reversed. The characteristic equilibrium required for the absorption of dyestuff on the substrate surface is therefore achieved more quickly by impinging flow.

Loose stock, yarn packages, nonwovens and multi-layered fabric batches as well as single layered sheet textiles are regarded as textile waste. These are amassed randomly, and this, together with the different fibre geometries, result in complex flow mechanisms. This type of textile waste can be regarded as a branched channel system. When the impinging flow velocity is increased, turbulent flows arise in addition to the laminary flows.

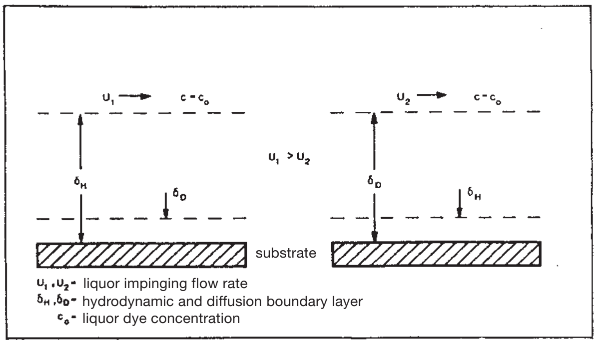

Fig. 3: Boundary layer impinging flow.
The dye absorption on the substrate surface causes a dye concentration gradient in the liquor layers adjacent to the surface, reducing the diffusion-controlled dye flow. The dye deficit occurring can be balanced by increasing the liquor flow.

When a fluid flows upwards via a granular or a powdery fill, a vortex occurs (i.e. the particles are suspended) if the loss of pressure in the fluid is equal to the surface pressure of the fill (loosening point). With solid/gas vortex layers demixing occurs as the rate at which the tube empties increases (formation of bubbles and channels) because the homogenous vortex layer does not represent the most stable state at high gas velocities (as the gas is not sufficiently dense) or when the impulse to be transferred is large (due to the significant difference in density). As the flow velocity continues to increase, there is a tendency towards a reciprocating vortex layer, i.e. a layer is raised like a piston. Particles fall away from the underside of this once again and form a new layer.

One characteristic of these individual channels is that they cannot be assigned a uniform tubular cross section q, nor consequently any uniform flow mechanisms. Fig. 4 shows by way of an example the ratios with a sudden expansion of a pipe with the radius r to a larger cross section. It is observed that the impinging fluid with the (laminary) velocity distribution w (r) does not flow as a closed jet from the narrower into the wider cross section. There is a contraction of the incoming flow before the flow expands to follow the wall of the pipe after a certain distance. A dead water zone with a vortex build-up forms between the contracted jet and the wall of the pipe.

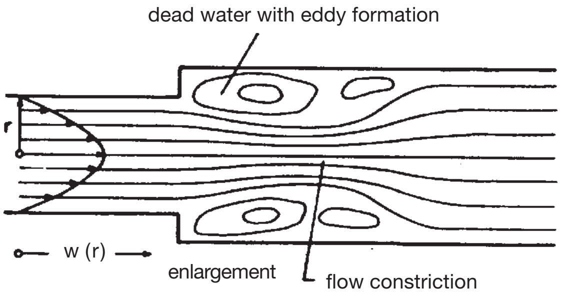

Fig. 4: Flow conditions after sudden pipe widening in the case of laminar flow.

By mixing the contracted jet with the dead water surrounding it, there is a loss in flow energy. The flow mechanisms for a sudden narrowing of the pipe are shown in Fig. 5, and Fig. 6 shows these mechanisms where a stop plug is used by way of example causing the jet to taper off. A channel system does not represent

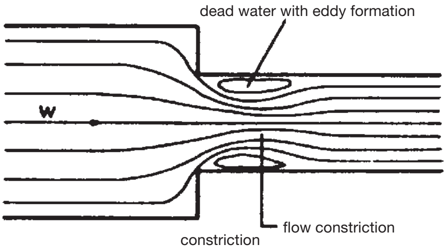

Fig. 5: Flow conditions after sudden pipe narrowing in the case of laminar flow.

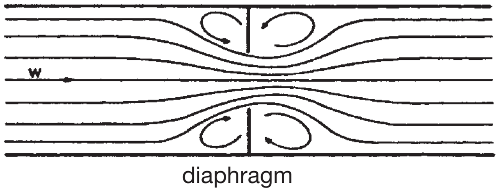

Fig. 6: Flow conditions caused by sudden pipe narrowing in the case of laminar flow.

a standard pipe combination and moreover this kind of system is characterised by a number of dead water areas, caused by sudden changes in cross-section. (Source: Schollmeyer).

Even on the immediate surface of a fabric passing through a wash liquor in open-width, there is an adhesive layer which displays unfavourable flow properties and which significantly reduces the washing off properties of the fabric. This layer contains some of the impurities already removed from the fabric itself or from the surface of the fabric, the diffusion coefficients of which increase as follows:

soluble substances > colloidal systems >
insoluble pigments.

The viscosity of the adhesive layer is correspondingly high, and can increase to a semiliquid state. The adhesive concentrate is surrounded by a water film which consists of detergent solution and which is entrained depending on the velocity of the moving length of cloth as a laminary boundary layer (i.e. it "flows" with the length of cloth).

The following methods can be used to effectively break through the two barriers, i.e. the adhesive concentrate and the laminary boundary layer, so that the detergent solution can pass through the length of cloth:

- reducing the surface tension of the boundary layers by means of surfactants;
- washing mechanics to move the fabric;
- construction of concentration gradients by means of squeezing off and adding fresh water;
- longitudinal flow and predominantly cross-currents;
- increasing the temperature.

A distinction can be made between laminary and turbulent impinging flow by measuring if the differential pressure is plotted against the flow velocity in a flow system. Straight lines with slightly different gradients are formed (Fig. 7).

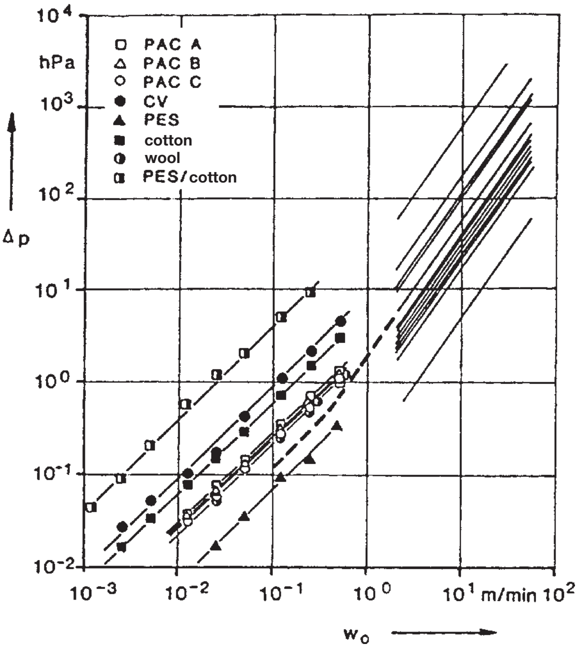

Fig. 7: Pressure losses p relative to the impinging flow rate wo of woven fabrics in the log-log system for distinguishing laminar (left) and turbulent (right) flow (Heidemann).

Impregnating machine Roller vat or rope device with squeezing unit used for wetting with bleach concentrates in rope bleaching and open-width continuous bleaching, e.g. → J-box.

Impregnation (Lat. Impregnare = to soak, saturate). In a general sense, impregnation refers to treatment of textiles by impregnation with solutions, dispersions or emulsions. Impregnation is one of the most important operations in finishing, less for yarns than for fabrics and knitwear. It is required for all continuous and semi-continuous processes including boiling off, bleaching and dyeing (Fig. 1). Impregnating fabrics with various chemicals is the most common process in textile finishing. It forms an integral part of desizing, washing, mercerizing, bleaching, dyeing and proofing. The effect of impregnation on the quality and the economic success of a finishing process is therefore of considerable importance.

Impregnation is understood to refer to the passage of a fabric through an impregnating solution, after which the fabric is mangled evenly across its width and length. In dry-on-wet impregnation (Fig. 2), dry goods are fed into the impregnation bath. This process is es-

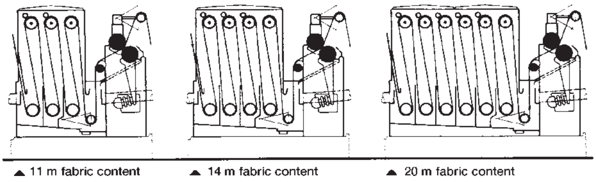

Fig. 1: Different versions of a roller vat for impregnation in cotton pretreatment (Babcock).

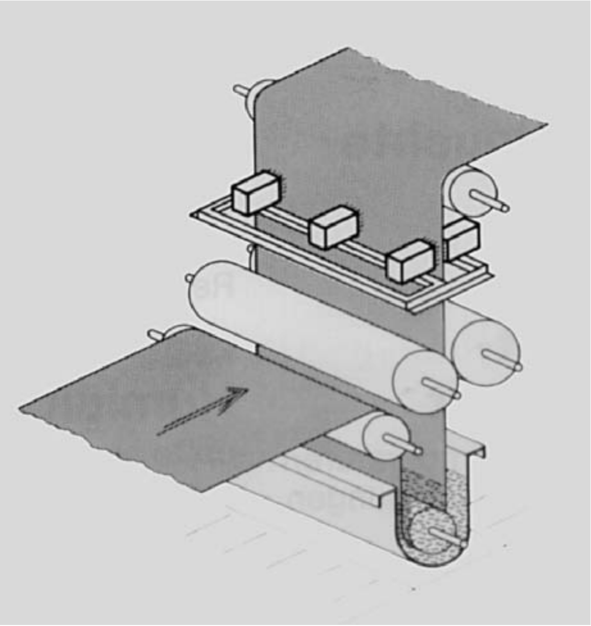

Fig. 2: Dry on wet impregnation of a textile fabric running in open-width into the trough with squeezing of excessive liquor and measuring of the liquor coat (Pleva).

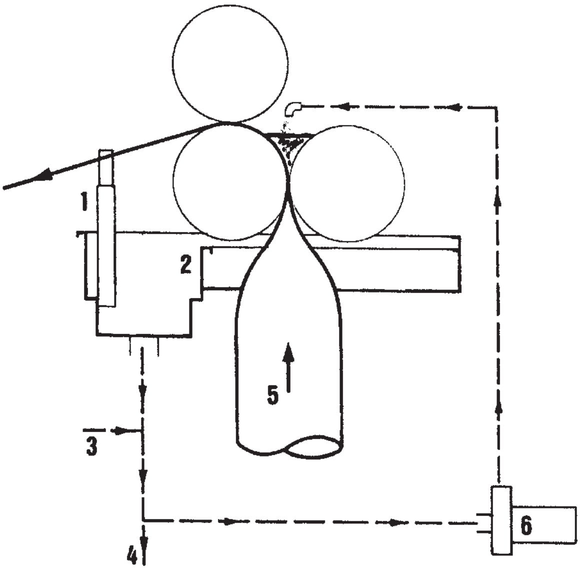

Fig. 3: Wet on wet impregnation of a tubular knitted fabric (Fabcon).
1 = level sensor; 2 = liquor trough; 3 = liquor supply; 4 = liquor drain; 5 = inflated knitted fabric; 6 = circulation pump.

sentially a wetting process during which the impregnating solution is absorbed by the fabric. There is no exchange of concentrations and substances. Where non-refined chemicals are used, the concentration of the impregnating solution remains unchanged. Wet-on-wet impregnation (Fig. 3) signifies that moist or wet fabric is introduced into the impregnation bath. No significant further wetting can therefore take place, although the impregnating solution is absorbed further if the fabric which enters the impregnation bath is drier than when it exits. A characteristic feature of wet-on-wet impregnation is that a greater or lesser proportion of the fabric moisture is exchanged for the impregnating solution, which gives rise to a change in concentration in this solution. The term impregnating solution is given to the liquor which passes through the fabric for the purpose of impregnation. The concentration of this solution is given in g/l. The concentrated chemical solution which is continually added to the impregnating liquor during impregnation is referred to as a feed or stock solution. As this is added, the chemicals absorbed by the fabric are continually replaced thus maintaining a constant concentration of impregnating solution. In practice, the feed or stock solution is 5–10 times more concentrated than the impregnating solution. The concentration is given in g/l. The ratio of the moisture content added to the weight of the fabric when dry is expressed as a % of the weight of the fabric when dry (liquor pickup). The proportion of the moisture content deposited by the fabric in the impregnating solution which has been exchanged for an equal quantity of impregnating solution is referred to as the exchange. The exchange is given as a % of the total moisture content deposited by the fabric and is a factor which only arises in wet-on-wet impregnation. When expressing the exchange, the difference in the liquor pick-up before and after impregnation is not taken into consideration. The exchange must not be confused with the total moisture content which the fabric has removed from the impregnating solution.

$$\text{exchange factor F} = \frac{\text{exchange in \%}}{100}$$

The current chemical consumption is given in g/kg of the weight of the fabric when dry or as a % of this weight. In contrast, the concentration of the impregnating solution or feed solution should never be given as a %.

The impregnation of dry goods generally takes place in pre-washing, desizing, dyeing and proofing.

Dry-on-wet and wet-on-wet impregnation occur equally frequently in mercerization. Dry-on-wet impregnation is very seldom used in bleaching as the fabric has generally already been subjected to a wet treatment before bleaching. The prerequisite for an effective dry-on-wet impregnation is that the fabric has been thoroughly wetted . The reaction time is relatively short as impregnation occurs extremely quickly and the impregnation temperature cannot always be set at the desired level. Consequently, a good wetting agent must be used. If the thorough wetting of a fabric can be guaranteed, the desired concentration of the impregnating solution can easily be calculated as a function of the liquor pick-up and the desired chemical concentration on the fabric. An example follows:

With a liquor pick-up of 80%, 1% (10g/kg) of chemicals should remain on a specific fabric. The concentration of the corresponding impregnating solution is calculated as follows:

$$\frac{10 \cdot 100}{80} = 12.5 \text{ g/l} \quad \text{or} \quad C_1 = \frac{C_2 \cdot 100}{FA}$$

C_1 = concentration of the impregnating solution,
C_2 = desired chemical concentration on the fabric in g/kg,
FA = liquor pick-up.

During dry-on-wet impregnation, the liquor is continually reduced as moisture is being absorbed by the fabric. The concentration of the liquor does not change, however (this does not apply where non-refined chemicals are used). In dry-on-wet impregnation, the feed solution therefore has the same concentration as the impregnating solution. The calculation and control of the impregnation bath is more complicated in the wet-on-wet process. In dry-on-wet impregnation, only the liquor pick-up needs to be taken into consideration as a calculation factor, whereas in the wet-on-wet method, three factors need to be recorded:

- the liquor pick-up of the incoming fabric (input moisture content) = FA_1,
- the liquor pick-up of the outgoing fabric (output moisture content) = FA_2,
- the exchange.

In theory, there are three options relating to the liquor pick-up:

1. $FA_1 > FA_2$: The fabric releases more moisture into the impregnating solution than it removes after impregnation. Consequently, the impregnation bath will soon overflow. This option is therefore impractical.
2. $FA_1 = FA_2$: The fabric releases just as much moisture into the impregnating solution as it removes. Where the bath volume remains constant, the concentration of the solution would soon be exhausted as a result of the exchange. The addition of more chemicals would also result in the bath overflowing. It is therefore not possible to use this option in practice.
3. $FA_1 < FA_2$: The fabric releases less moisture into the impregnating solution than it removes. The decreasing liquor volume can be compensated by the addition of more chemical solution. This addition also maintains the concentration of the impregnating solution which is decreasing as a result of exchange. This is the only option which can be used in practice. The greater the difference between the two liquor pick-ups, the better the results which will be achieved. FA_1 must in any case be at least 15–20% lower than $FA_{2.}$

If the definition of exchange is also considered, all the factors and ratios are significant for the calculation of the concentration of an impregnating solution .

Impregnation agents → Water-repellent finishing auxiliaries.

Impregnation centrifuge Centrifuges for loose fibre or single yarn packages in which the textile material is impregnated with a treatment liquor by pumping and centrifugal force.

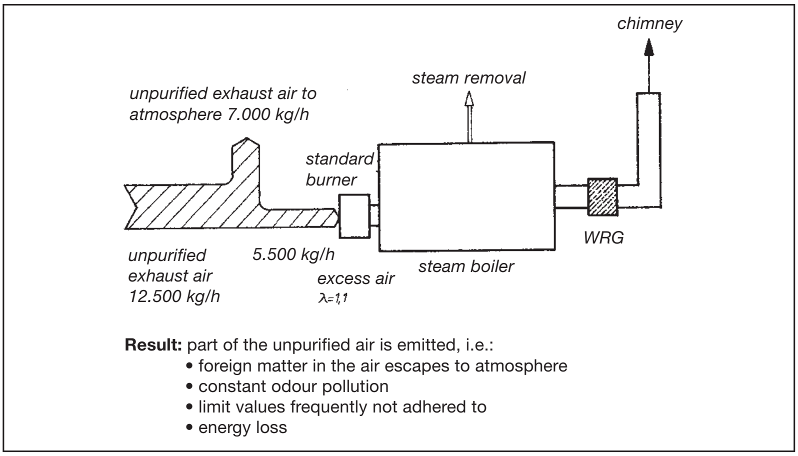
Impressioning machine A single-colour roller printing machine for the production of test prints as a means of checking the engraving quality of engraved printing rollers, or to produce strike-offs of new designs, as well as small samples.

Imprimeuse Samuel A machine which began the development of partial mechanization in block printing. The pattern in relief was not applied to a flat wooden block but to the surface of a roller rotating on bearings. Print paste transfer was provided for by means of an endlessly running felt blanket. The process is now of historical interest only.

In, chemical symbol for indium (49).

Incineration for waste disposal The combustion of exhaust air from finishing processes such as singeing, heat-setting and, in certain circumstances, drying, eliminates combustible pollutants and noxious-smelling foreign matter from the exhaust air whilst allowing energy recovery at the same time. In order to cope with large quantities of exhaust air, the combustion must be carried out, as a rule, with a high excess of air. The elimination of pollutants and energy recovery are only partially achieved in processes which do not employ a high excess of air in the boiler (Fig. 1).

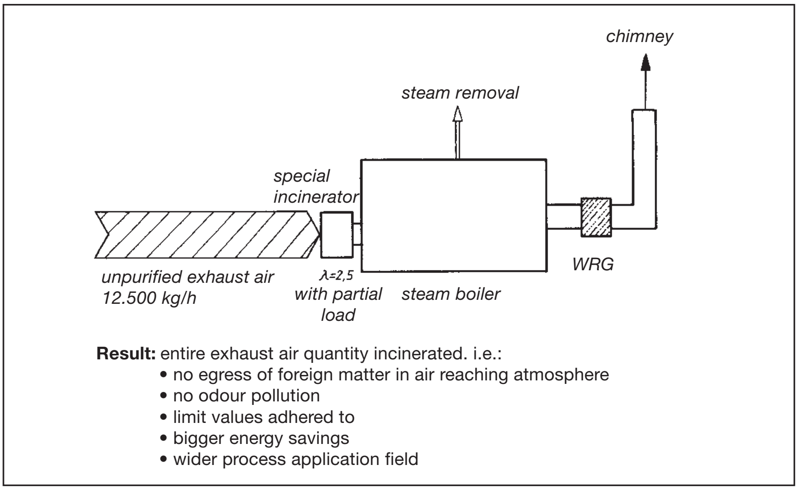
One method used in practice combines the incineration of airborne pollutants in existing steam or hot water boilers with a high excess of air, and energy recovery from the boiler flue gases (Fig. 2). This method is thermally viable when the temperature of the exhaust air before reaching the boiler is higher than the cleaned and cooled exhaust gases in the chimney. Even in the case of low exhaust air temperatures, however, this still represents a relatively favourable method although the energy saving is no longer particularly significant.



Result: part of the unpurified air is emitted, i.e.:

- foreign matter in the air escapes to atmosphere
- constant odour pollution
- limit values frequently not adhered to
- energy loss

Fig. 1: Normal excess air operation.



Result: entire exhaust air quantity incinerated. i.e.:

- no egress of foreign matter in air reaching atmosphere
- no odour pollution
- limit values adhered to
- bigger energy savings
- wider process application field

Fig. 2: Operation with large quantities of excess air (Sparal).

In the case of effluents containing low concentrations of pollutants, incineration after a preceding multistage evaporation treatment can represent a worthwile method of treatment. In this way, even low concentrations can be made accessible. Whether this method offers a viable solution depends on the calorific value of the effluent which can be estimated from the COD value ($1\ g\ O_2/l = 13\ kJ$) and the concentration range. This method is applicable within the range of 100 000–200 000 mg O_2/l.

The Bremer Wollkämmerei in Bremen, Germany, incinerates the residues from its raw wool scouring process with gas as an added fuel in a two-stage combustion chamber at 1200°C. The ash is withdrawn via the flue gas dust collector as well as in the convection zone of the boiler plant. The flue gases are cooled down from 1200°C to 250°C in the downstream waste heat boiler. The energy from the flue gases is utilized for the generation of steam at 26 bar, the pressure is reduced to generate electricity, and the steam is then used in the evaporation plant. In general, incineration should be regarded as an alternative option; the higher the concentration of inorganic components in the effluent, the more worthwile the recovery of useful substances is likely to be. →: Waste disposal; Waste management; Recycling.

Inch (abbrev. as in. or "). The commonly used non-metric unit of length in Anglo-Saxon countries. 1 inch = 2.5399956 cm. In industry the usual conversion is 1 inch = 2.54 cm; 1 cm = 0.3937 inches. 12" = 1" (foot).

Incoming goods inspection (incoming fabric inspection). The preliminary inspection of all textile goods received by a textile finishing plant for processing in order to check conformity to specification, quantity of goods supplied, quality as received (especially defective goods) before the goods are accepted for processing. → Quality control.

Incompatibility reactions of the skin This problem has attracted increasing public interest. Possible interactions between the skin and particular items of clothing are to be associated with the health disorders resulting from them. Pre-eminent among these are the allergic and non-allergic types of eczema, as well as intolerance allergies, pseudo-allergies and other reactions of the skin (→ Skin diseases). Physical irritation and chemo-toxic effects are considered as probable causative factors here. Among the most frequent contact allergies are those induced by substances based on formaldehyde, specific disperse dyes in particular, metallic compounds, materials containing rubber, as well as textile preservatives and/or detergent components.

The methods used to isolate and identify individual allergenic materials deserve great attention especially with a view to the epidemiological detection of textile-induced skin disorders and the preventive measures which can be derived for them. The great number of irritative textile and, above all, wool intolerance reactions of the skin are not infrequently attributed erroneously to the allergy phenomenon. They arise principally in cases of individual increased skin sensitivity, i.e. in patients with atopic skin conditions which leads to the triggering or worsening of eczematous reactions (source: Klaschka).

INCONOR (Sp.), abbrev. for: Instituto Colombiano de Normas, Bucaramanga, Colombia (Columbian

Institute of Standards); → Technical and professional organizations.

Incorporation (Lat.: *incorporare* = to embody). In the widest sense all processes in which non-reactive compounds are applied by conventional means to (incorporated in), synthetic fibres especially, via the melt spinning process (in the spinning dope) or during finishing processes (dyeing, wet processing). Taking polyester as an example, the figure shows the conventional incorporation of a fluorescent brightener in spinning on the one hand, and the reactive incorporation on the other.

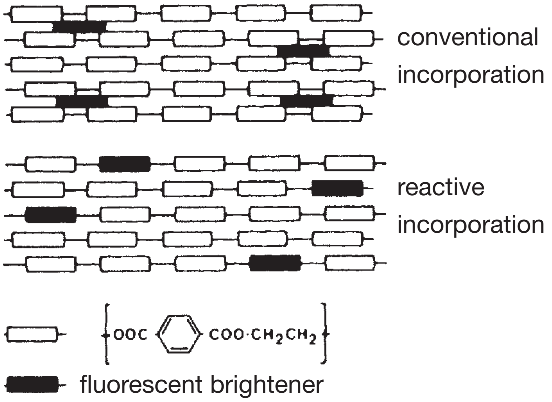


Fig.: Classic incorporation of spinning fluorescent brghtener in comparison with reactive incorporation.

For incorporation phenomena all the free sites in the fibre interior are not necessary and a non-continuous distribution is sufficient for finishing effects since according to the law of mass action the concentration of finishing chemicals on/in the fibre is uniformly adjusted during incorporation. Such "islands in the sea" distribution of finishing chemicals on fibre surfaces can be detected in practice by stereoscan photographs.

Incubation In the context of textile chemistry this is a term used in enzyme chemistry, i.e. the time of reaction between an enzyme and a substrate. Degradation of starches to water-soluble dextrins begins as soon as an enzyme solution comes into contact with the size. A satisfactory degree of degradation is only achieved, however, if the enzyme concentration in the impregnation bath is correctly adjusted to the incubation time and temperature. A long incubation time (as for plaited goods) permits the use of a low enzyme concentration whilst short incubation times require a combination of higher enzyme concentrations and higher incubation temperatures (e.g. as in pad-steam desizing). If desizing is carried out in the jigger, incubation (on the roll) alternates with impregnation in the bath; in this case the entire duration of the desizing treatment is determined by the number of passages (ends).

Indanthren dyeing Cellulosic textiles can be dyed with → Indanthren dyes in the form of yarn and knitted or woven fabrics. Indanthren dyes are applied by continuous, semi-continuous and batchwise methods as follows:

1. Batchwise methods (exhaust process):
   - leuco process,
   - semi-pigmentation process,
   - pigmentation process,
   - high temperature process (HT process).
2. Semi-continuous method (pad-fixation process):
   - pad-jig process.
3. Continuous methods:
   - pad-steam process,
   - wet-steam process.

The pad-steam process is the most important continuous dyeing method for Indanthren dyes and was developed by Dupont in the 1940's. The technology is geared to the specific properties of vat dyes. The water-insoluble non-substantive vat dye pigment is first applied to the fabric on a padder. After intermediate drying and impregnation with the reducing chemicals, the dye is reduced and fixed on the fibre in an air-free atmosphere of saturated steam in a steamer. Depending on the depth of shade, only 30–60 s are required for reduction and fixation of the dye. Restoration of the dye to its original water-insoluble pigment form is usually carried out by oxidation in a continuous open-width washing range. After oxidation, a hot soaping treatment is given as near to the boil as possible in order to achieve the final shade and high level of colour fastness. Continuous dyeing with vat dyes has been successfully practised for many years. Through further technical developments in machinery, including electronic control and metering systems, this method is now capable of meeting most requirements with regard to optimum utilization of natural resources (water, energy, etc.).

On the other hand, the situation in batchwise dyeing is markedly different. Innovations in machinery and process technology are still being sought. The pigmentation process, above all, has established itself for the dyeing of vat dyes by exhaust methods. In this process, the dye, in its non-substantive pigment form, should be distributed as uniformly as possible at a high percentage on the textile material. It is a well-known fact that the degree of pigmentation can be increased by raising the bath temperature. This can be attributed to the formation of aggregates of dye pigments. It has also been established that, despite the formation of coarser dye pigment particles, uniformity of pigment distribution on the textile material can likewise be improved by raising the temperature.

The high affinity of vat dyes in the reduced state can lead to uneven exhaustion of the dye in the initial phase of dyeing. It is therefore common practice to level out this initial unlevelness again by increasing the dyeing temperature and adding levelling agents. The question arises, of course, as to whether this initial unlevelness can be avoided or limited by a controlled vatting of the dye. As a consequence of the introduction of metering systems in reactive dyeing, suitable metering devices are available in many dyehouses. It seems reasonable to suppose that this technology could also be used for metering the reducing agent in the dyeing of vat dyes. However, the metered addition of sodium dithionite can only influence the bath exhaustion curves of these dyes to an insignificant degree. The metered addition of sodium dithionite does actually slow the rate of exhaustion to a certain extent but does not produce the desired flat exhaustion curve. → Vat dyeing.

Indanthren dyes In 1901 René Bohn succeeded in producing an insoluble blue dye by fusing 2-aminoanthraquinone in alkali to which he gave the name Indanthren. Besides anthraquinone derivatives and more highly condensed aromatic ring systems there are only a few representatives of other chemical classes among the Indanthren dyes. The precursors and chains of synthesis of these dyes may be classified according to production lines: the α-chemistry of Bayer and the β-chemistry of BASF.

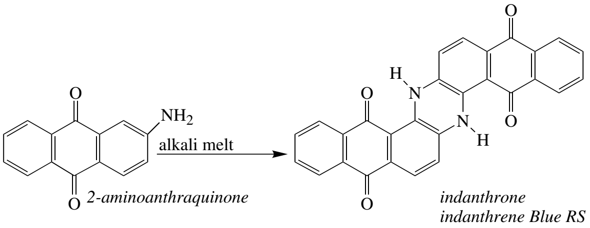

Fig.: Indanthrene Blue RS, Bohn synthesis.

Before 1914, Bayer, Agfa and BASF as well as Hoechst, Cassella and Kalle collaborated in the manufacture of Indanthren dyes. Bayer built the α-chemistry production line and BASF the β-chemistry line. Until the First World War a range of fast vat dyes was available. Production lines were developed from the patent applications of the dyes and essential precursors which are still valid today for dye manufacturers. Many of the dyes discovered up to the time of the IG Farben Amalgamation are very important members of vat dye ranges. Their proportion still amounts to approx. 40%. By comparison, the dyes which were developed in the IG Farben period, i.e. from 1925 to 1939 still represent 45%. The proportion of new individual dyes introduced since the Second World War is relatively small at 15%.

1. Indanthrone is characterized as a hot dyeing product. It is the basis of important dyes in the blue sector. Their high tinctorial strength, high affinity and good fastness profile resulted in the first success of vat dyes, e.g. Indanthren Blue RS.
2. Violanthrone and iso-violanthrone are classical dyes in the navy-blue, dark blue and green sectors, e.g. Indanthren Dark Blue BOA and Indanthren Brilliant Green FFB. Their levelling properties and affinity are of a similar order to the indanthrones although on average, however, their colour fastness to light and weathering are somewhat poorer.
3. Pyranthrone dyes such as e.g. Indanthren Gold Orange G, are classical representatives of β-chemistry. Further dyes such as Indanthren Orange RRTS, as well as Indanthren Direct Black RB and RBS are derived from the pyranthrone dyes in the imide group. Flavanthrone and anthraflavone are of no importance.
4. The carbazoles are an extensive class of dyes. They belong to the category of IW dyes, have average rates of exhaustion and good to very good levelling properties. The fastness properties, especially colour fastness to light and weathering, are of a high order, e.g. Indanthren Brown LBG.
5. Thiazole and oxazole compounds are IW dyes with good fastness properties. They are manufactured by complex synthesis, e.g. Indanthren Red FBB. (contributed by Nahr and Ruppert).

Indanthren IW dyeing process → IW dyeing method.

Indanthren label A trademark of BASF for certain vat dyes of the anthraquinonoid series (→ Indanthren dyes) as well as selected Naphtol AS combinations (Hoechst) and certain Phthalogen dyes, provided these are able to meet specific colour fastness requirements such as light, washing and/or weathering fastness. The name is attributed to Indanthren blue which was synthesized in 1901 by Bohn in Ludwigshafen and is a contraction of indigo and anthracene. Bohn considered this dye to be an indigo derivative at first. Since the dissolution of the → Indanthren Trademark Association, the trademark rights have been taken over by BASF; beneficiary licencees also include Bayer, Cassella and Hoechst.

Indanthren normal-dyeing process → IW dyeing method.

Indanthren reaction A test used for the detection of benzene hydrocarbons in white spirit and other solvent mixtures. Indanthren Violet RT is added to the mixture: the dye dissolves only in the absence of benzene (or homologues).

Indanthren Trademark Association (Indanthren-Warenzeichenverband e.V.). An association founded on the 15th May 1952 and dissolved in 1974 (former headquarters: Frankfurt) to which the dye manufacturers BASF, Bayer, Cassella, Hoechst, Produits Chimiques Ugine Kuhlmann (today: Pechiney Ugine Kuhlmann) as well as the head organization of the German textile finishing industry (Gesamtverband der deutschen Textilveredlungsindustrie) belonged. The association made available to its members the labelling requirements which must be met by the dyes, dye components and the dyed and printed textiles produced from them for the use of the registered trademark. The registered trademark is composed of the word "Indanthren" and the pictorial trademark with the letter "I" (initial letter of Indanthren) flanked by the sun's rays on the left and a rain shower on the right to indicate resistance of the dye to weathering, etc. The printing and dyeing conditions, purity and test criteria were summarized in handbooks and loose-leaf folders with dyed patterns, etc. accompanied, in some cases, by foreign language texts. Since the dissolution of the association, BASF is the registered owner of all rights relating to the Indanthren trademark.

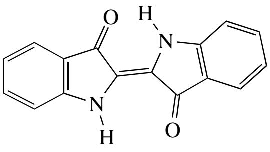
Indanthren yellow paper (vat yellow paper). Yellow indicator paper (strips) coloured with indanthrene yellow. Indanthrene yellow paper is used to test vats in vat dyeing. If the vat conforms to regulations, then the yellow visibly changes colour to cornflower-blue within 3 s. If however the resultant dyeing is yellow olive-greyish blue (dirty) in colour to any extent, the vat is not composed correctly, i.e. there is insufficient sodium hydrosulphite and/or caustic soda solution.

Indentation Permanent pile deformation in upholstery velour fabrics visible as pressure marks resulting from the normal everyday use of upholstered chairs and seats.

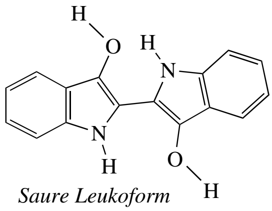
Indicator (Lat.: *indicare* = to point out, compare). A reaction-sensitive substance which allows the progress of a chemical change to be followed, but generally a substance which marks a precise stage in certain chemical reactions, e.g. acidic, alkaline, neutral reaction, by a characteristic change in colour. The determination of pH is a typical application for indicators of this kind. Thermopapers which show when a particular temperature has been exceeded represent another type of indicator.

Indienne Indienne was formerly a term used to describe printed cotton fabrics from India. Today it is used as a general term for lightweight cotton prints achieved by specific printing techniques.

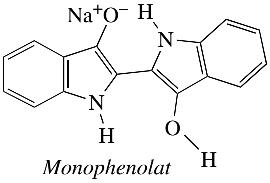
Indigo Originally a natural blue vat dye extracted from plants, especially of the *Indigofera tinctoria* genus grown principally in eastern India and China. It represents the oldest blue vat dye (Fig. 1).



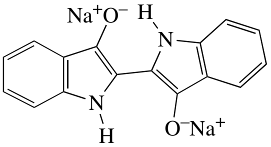
Indigo



Saure Leukoform



Monophenolat



Biphenolat

Fig. 1: Spherical indigo model (BASF).

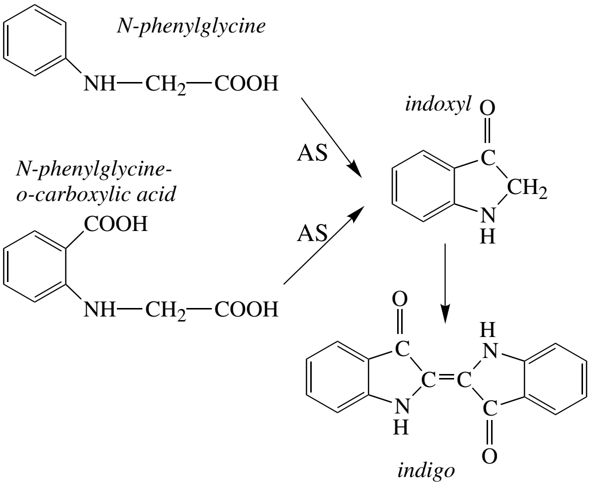


Fig. 2: Indigo synthesis (AS = alkali melt).

The active component, indigotin, is obtained by fermentation, oxidation and boiling the dried plant leaves; in this process 100 kg of dried plants yields 1.5–2 kg of indigo dye. The initially colourless compound is converted into the yellow vatted form by fermentation and various alkaline additions in the form of plant and bark juices. The blue colour develops only after exposure to air by oxidation through the action of atmospheric oxygen. After its first arrival in Europe in the 16th century, indigo entirely superseded the formerly used woad because of its higher tinctorial power. Natural indigo quickly declined in importance with the development of synthetic indigo in 1880 (Fig. 2).

Indigo carmine (sodium salt of indigo disulphonic acid). A blue water-soluble powder. Very sensitive to oxidizing agents. Uses: test for nitrates, chlorates, wool damage.

Indigo carmine reaction Used as a test for wool damage. Wool hairs are allowed to lie in a small amount of a cold saturated solution of → indigo carmine mixed with a little sulphuric acid.

A microscopic preparation is made in conc. glycerol. Damaged areas of wool hairs are stained blue. A 1% aqueous solution of Benzopurpurin 10B (cotton red) produces a similar reaction; treat at the boil.

Indigo detection → : Wash test; Paraffin test; Indigo test.

Indigo dyeing In exhaust dyeing, it is necessary to maintain the correct pH (Fig. 1) besides ensuring sufficient additions of reducing agent. If cotton is dyed with indigo by continuous methods, the dyeing has to be carried out in a series of several dips, i.e. in several stages. A distinction is made between machines for the continuous dyeing of yarn in cable form (ball warps) or in the open-width state. The dyeing of cable began in the USA whereby 300–400 individual warp threads are combined to form a single cable (ball warp). Later, in Europe, the dyeing of full-width warp beams was developed in which the yarn was dyed, dried, sized, and wound directly on to weaving beams ready for weaving in a single operation (Fig. 2).

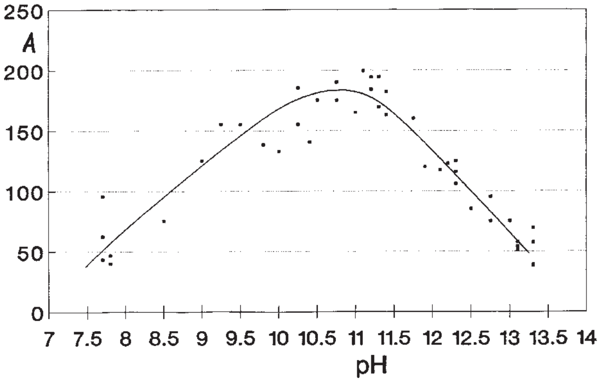

Fig. 1: Dye yield (A) in dyeing cotton yarns with indigo vat at different dye liquor pH values.

I. Cable dyeing (ball warp dyeing): the dimensions of machines for cable dyeing are quite striking since plants of this type can be up to 60 m in length. Yarns for the warp cable are taken from cross-wound packages and batched on so-called ball-warpers as ball warps. The length of the cable can be up to 25 000 m. These ball warps, with 300–400 threads per cable, are displaced by a distribution system before the machine so that on running the cable into the first wetting bath the entry angle between individual cables differs as little as possible. By this means different tensions in the threads are prevented. Continuous dyeing without machine stoppages for batch changing is possible since the cable containing the warp lengths of the new ball warp can be tied to the end of the first ball warp. Particular attention must be paid to thread tension since, in indigo dyeing, different thread tensions lead to differences in yarn coloration which results in warp stripiness. Usually, 3–4 wetting troughs are provided in ball warp dyeing ranges. Depending on the desired degree of precleaning, an additional boil off must be given for which purpose a further 4 troughs are necessary because of the need for after-rinsing.

In ball warp dyeing, approx. 10–18 kg of warp/min can be dyed. Mainly OE-spun cotton yarns are used from which impurities such as hemicellulose, waxes, as well as calcium and magnesium salts are partially removed in the pretreatment. These substances sometimes form a layer several centimetres thick on the surface of the wetting baths which would cause soiling of the yarn as it leaves the bath. Here it is appropriate to remove this layer of dirt by intensive hot rinsing with overflow. Not all plants are able to meet the technical prerequisites for adequate rinsing baths and heat energy. From the machine technology point of view, optimum conditions for a uniform overflow across the width of the troughs are not always available since some machine makers do not have a complete understanding of the physico-chemical processes involved in yarn treatment. After pretreatment and wetting, the ball warp enters the dyebaths. The dye vats are designed in such a way that immersion times of 20–25 s are achieved. In order to prevent an excessively high consumption of reducing agent, relatively deep troughs with a small liquor surface are used. The liquor volume is approx. 2000 l per day. A very long air passage (up to two floors high) is necessary to ensure the complete oxidation of dye including that within the ball warp itself. In ball warp dyeing plants the oxidation time is approx. 1–2 min.

Formerly, 6 dye vats were used. New cable dyeing plants are, however, equipped with 8 vats. Their advantage lies in the fact that, for the same depth of shade, the indigo bath concentration is lower. This results in the formation of finer layers of indigo on the yarn. Two advantages are gained from this, i.e.:

- Less indigo penetrates into the interior of the yarns in the first dipping operation which is consistent with the desired high proportion of white in the core of the yarn.
- The finer layers of indigo result in somewhat better colour fastness to rubbing and washing.

After dyeing and oxidation, the ball warp passes through 2–3 rinse baths. Usually, it is sufficient for the rinsing operation to be carried out at room temperature. It is, however, important to ensure that at least 3–4 l of water per kg of warp yarn is energetically sprayed against the warp; this applies to each of the rinse baths. If rinsing is carried out at temperatures in the region of 50°C, stripping of the dye is unnecessarily high. Ball

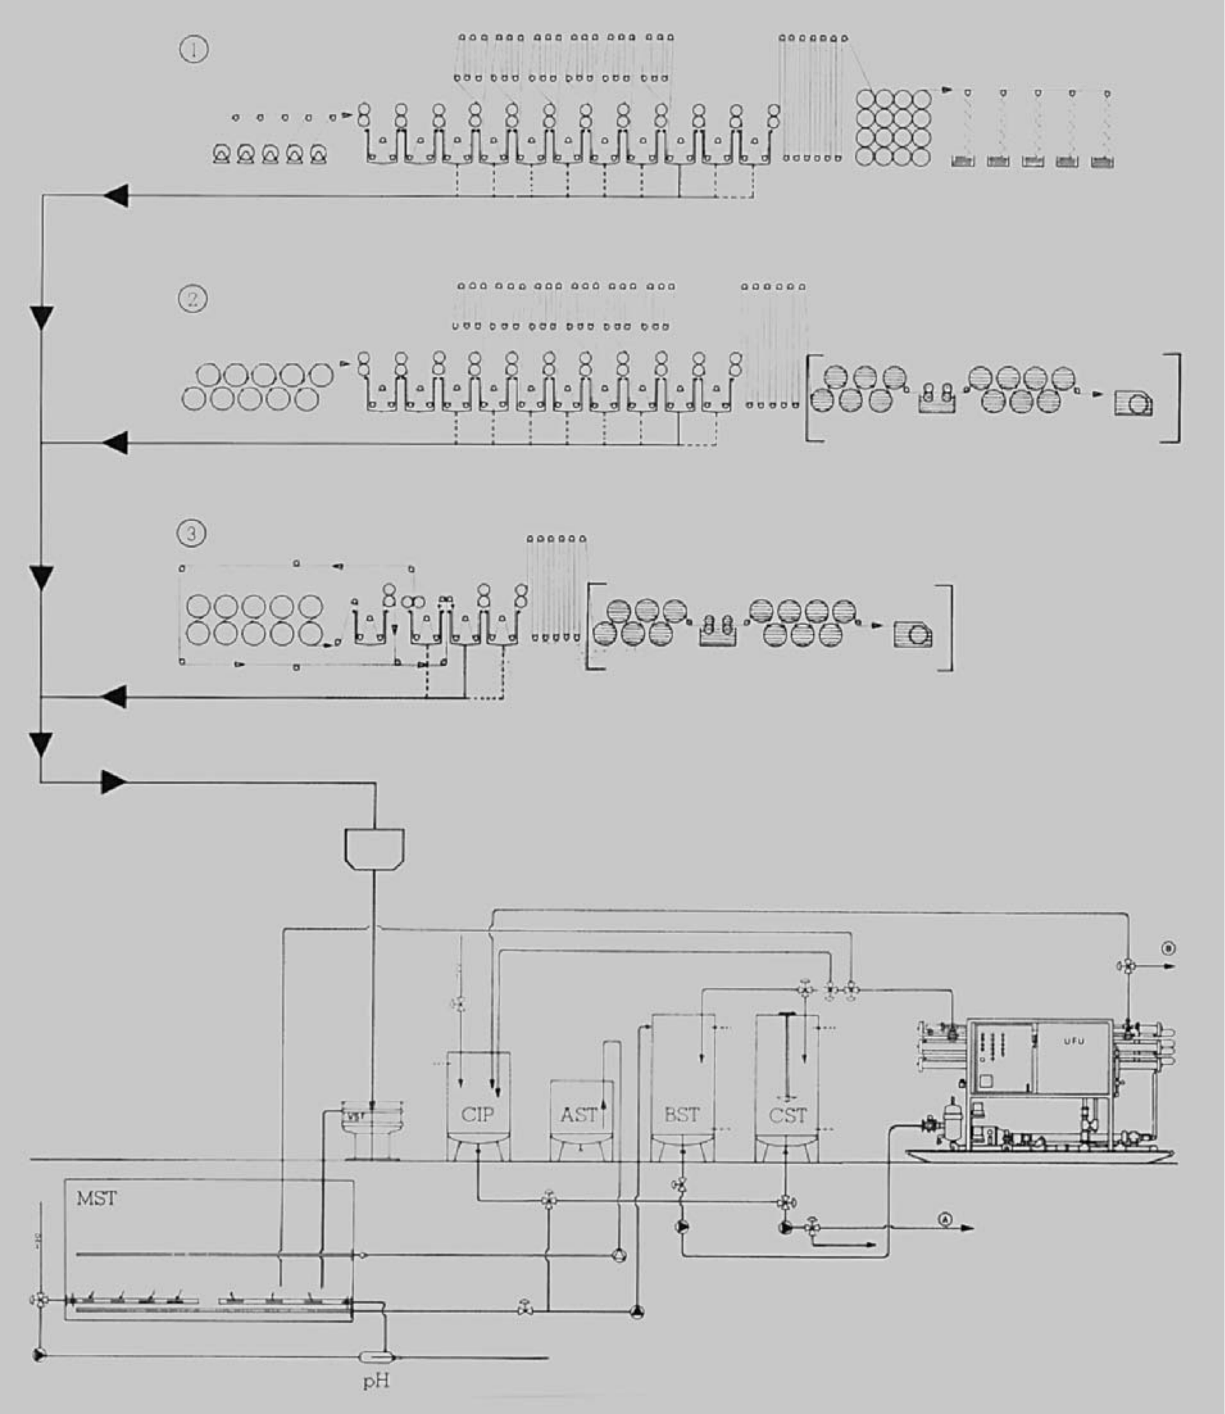

Fig. 2: Comparison of tow dyeing (1), open-width dyeing (2) and so-called loop dyeing (3) by the dyeing methods usual in the USA for indigo with effluent preparation.

warp dyeing does not end with the rinsing operation and the cable passes through a following softener bath in which 0.5–1.0% (based on dry substance) of a cationic softener is applied to the yarn. This softener application facilitates a better opening of the cable in the long-chain beamer. The cable is opened to such an extent at this stage that the individual threads are brought into parallel alignment with the aid of a comb so that they can be wound on to beams for sizing. Even with perfect yarns and an effective softener, the operating efficiency of such beamers lies below 50% in some cases.

Depending on size and width, the capacity of ball warp dyeing machines is between 12, 24 and 36 cables of yarn. If the number of threads in a dyeing machine in which the yarn is dyed in the form of a full-width warp beam is compared with that in a ball warp dyeing machine, the following comparison figures are obtained:

1. Open-width dyeing machine: 3800–4200 threads,
2. Ball warp dyeing machine: 4800/9600/14 400 threads.

With 36 ball warps, material throughput is more than 3 times higher than that from an open-width machine. In ball warp dyeing machines the squeezer rolls are of appropriately large dimensions. Rubber against steel rolls are employed in the squeezer units. The applied pressure is dependent on the particular function of the squeeze rolls. If, e.g. squeezing is carried out after the last wetting bath at 10 bar, a somewhat lower pressure setting is used for the following squeezes in order that the yarn can take up dye liquor. A pressure of 10 bar is used to express the rinse liquor from the last rinse bath before the ball warp enters the softener bath. All other squeezer pressures are set to 4–6 bar. In Fig. 3 the liquor pick-up along the vertical axis of a graph is plotted against the squeeze pressure along the horizontal axis. From this it can be seen that liquor pick-up becomes uniformly less with increasing pressure (up to approx. 4 bar). Above 5 bar, however, the curve flattens sharply. High pressures are required to exert a mechanical influence on the ball warps. Under these conditions the yarns are squeezed apart better and can open out up to 20 cm in width. This promotes more uniform dyeing and a somewhat quicker oxidation.

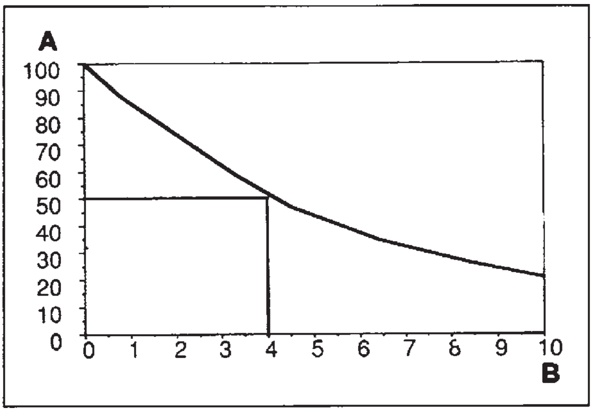

Fig. 3: Liquor uptake (A as a %) relative to squeeze pressure (B in bar).

II. Open-width dyeing (slasher dyeing): after 1970 a second type of dyeing machine was developed in Europe in which the warp threads are run parallel to each other, instead of in cable form, followed directly by sizing. These dyeing machines are also known as “slashers” like the sizing machines. This may be due to the fact that sizers had probably already experimented with size dyeing on their machines. Trials were carried out with pigment colorants as well as indigo. If indigo is applied as a pigment in sizing, only a dull bluish grey colour is obtained. The obvious solution was to approach the machine makers with the desire to develop a separate dyeing machine which could be installed in front of the sizing machine. Today, practically all well-known manufacturers of sizing machines include open-width indigo dyeing machines in their product ranges. As in the case of ball warp dyeing machines, slasher machines also have advantages and disadvantages.

Advantages:

- The open-width dyeing machine is smaller than a ball warp dyeing range so that investment costs are also lower;
- The opening of ball warps (cables) is by-passed;
- Because of the parallel warp threads, the wetting stage is shorter and a single wetting trough can be sufficient;
- The adjustment or stabilization of dyebaths is quicker;
- The liquor content of the vats seldom exceeds 800 l.

Disadvantages:

- In contrast to cable dyeing, no friction occurs between the threads in the region of the guide rollers during dyeing of warps in the open-width state. As a result, a comparable level of colour fastness to rubbing and washing to that obtained in cable dyeing is often not fully achieved.
- The consumption of sodium dithionite is significantly higher due to the greater surface area of the textile material.

Nevertheless, more slasher machines are in use world-wide than ball warp dyeing machines. Since 1989, on the other hand, it appears that more ball warp dyeing machines are being installed once again. This applies especially to countries in the Asian region.

Consideration of the individual treatment stages in the slasher machine reveals the following machine requirements and process times:

1–2	wetting vats,
4–8	dyeing vats,
3	rinsing vats.

Dipping and oxidation times are 10–20 s and 45–60 s respectively.

III. “Loop-dye 1 for 6” dyeing machine: a variation of the open-width machine is the “Loop-dye 1 for 6” machine which was developed in Switzerland and built by Küsters (Fig. 4). In this machine, the warp continually runs back into the same dyebath after dipping and oxidation. As a result, the machine is considerably shorter and sodium dithionite consumption is appreciably less. The warp is passed through the dyebath several times. After the last dipping, a separate air passage is given and the warp is subsequently rinsed and sized. Due to the superimposition of dye in 5–6 dips, a dyed effect similar to that achieved in cable dyeing is ob-

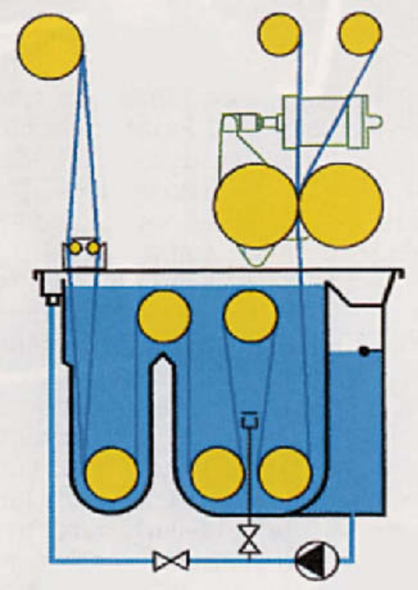

Fig. 4: "Twin-Pad" application in indigo dyeing (Looptex).

tained. Slight friction between the warp yarns also occurs in this case with similar advantages to those described earlier (contributed by Haas).

Indigo dyeing/sizing machines Continuous plants for dyeing warp yarns with indigo in full open-width followed by sizing. A continuous plant of this kind from the warp beamer is illustrated in the Figure. The entire plant consists of: 1–2 wetting troughs for wetting out or pre-dyeing/rinsing; 4–5 dye troughs, approx. 100% residual liquor with subsequent air passages (vertical); 1–2 rinsing troughs; cylinder pre-drier (approx. 30% residual moisture content); accumulator/compensator (for approx. 40 m warp length); sizing machine (various models, single or double size box, running speed approx. 20 m/min; final drier. All the dye compartments are provided with individual pairs of squeeze rollers (infinitely variable pressure setting), effective pressure indicator, pneumatic lifting of guide rollers and upstream adjustment mechanism (compensator control for yarn tension). Dip times in the dye vats from 1–6 s. Vertical air passages for oxidation approx. 4 m in height; each of approx. 2 min with a final passage of approx. 3 min.

Indigo print (blue print). Cotton fabric with white motifs on a blue ground. The existence of blue prints in Egypt had been reported by Pliny the Elder (c. 23–79 AD). The technique was first introduced into Europe at the end of the 17th century by Jeremias Neuhofer of Holland via Augsburg in Germany. The technique is still occasionally practised today in Westphalia and Bavaria and more extensively in Slovakia. It involves the production of a white or coloured resist as an illuminating colour under indigo blue. The printing operation is carried out with the aid of wood blocks. Because of its high solids content (mechanical resist action = paste resist), high adhesion, good chemical resistance and its easy removal during washing off, crystal gum, which has ideal viscosity characteristics, is used as thickening agent for the print paste. Dye fixation is prevented in the printed areas by metallic salts with oxidizing or acidic properties added to the print paste. After application of the resist paste, the fabric is dried and dyed in the dipping vat. The paste develops its action only in the vat and has the disadvantage of having a high lead content ($PbSO_4$, $Pb(NO_3)_2$,

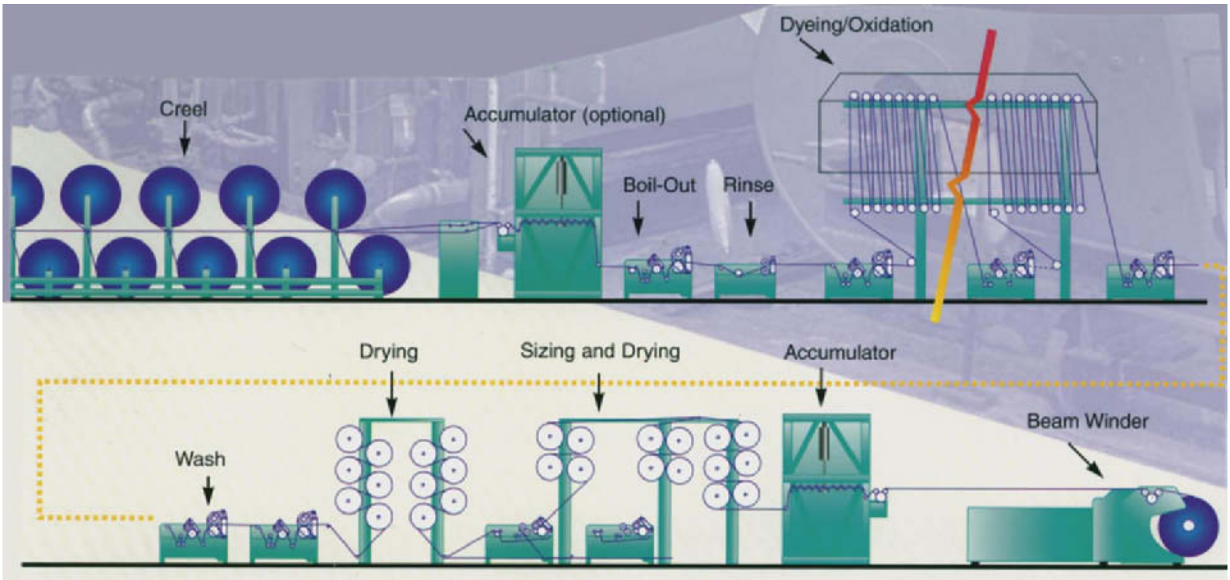

Fig.: Open-width dyeing-sizing with indigo more suitable for lightweight denim than the traditional rope system (from West Point).

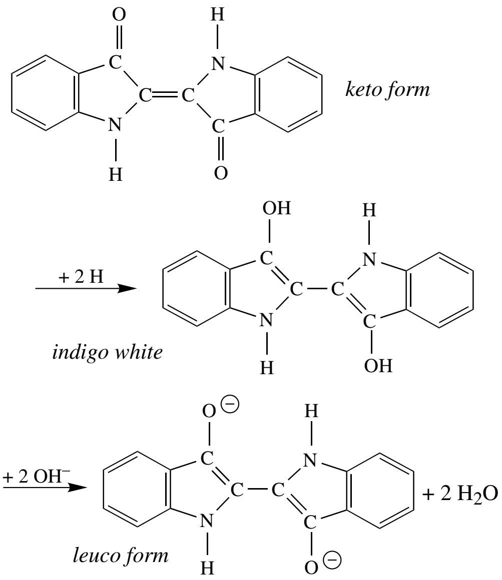
$Pb(OH)(CH_3COO)$, PbO). A so-called “copperas vat” brings about the following chemical reactions:

$$FeSO_4 + Ca(OH)_2 \longrightarrow Fe(OH)_2 + CaSO_4$$

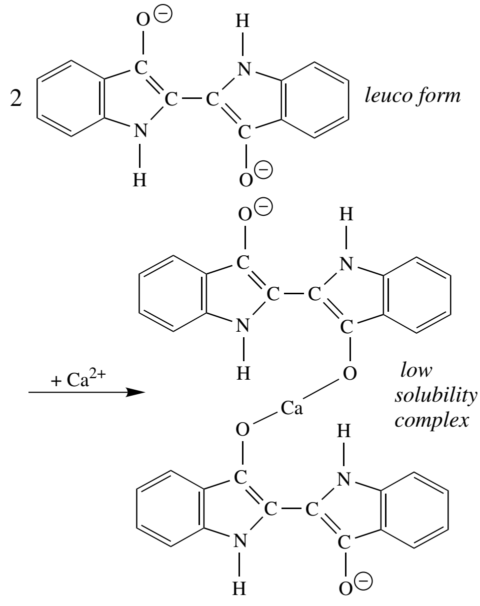
$$2\,Fe(OH)_2 + 2\,H_2O \longrightarrow 2\,Fe(OH)_3 + 2\,H$$

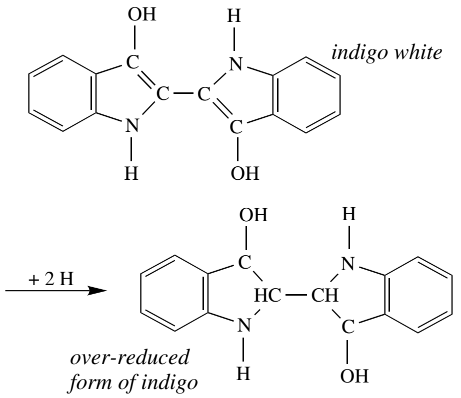
$$Ca(OH)_2 \longrightarrow Ca^{2+} + 2\,OH^-$$



In the “copperas vat” additional, and undesirable, side reactions also take place: these are mainly precipitations of calcium carbonate and over-reduced indigo as well as indigo precipitated by calcium. Besides reoxidized indigo and fibre impurities, these precipitations contribute to the formation of vat sludge.

$$Ca(OH)_2 + CO_2\ \text{(air)} \longrightarrow CaCO_3\!\downarrow + H_2O$$





The chemical resist is produced by the oxidative and alkali-binding action of the metal salts with the aid of catalysts. The indigo vat formed by alkaline reaction is thus destroyed locally by the applied resist. In this process, semi-permeable films of metal hydroxides and reoxidized indigo are formed which prevent the penetration of colloidally dissolved indigo in the liquor. In addition, the thickener itself, together with added printing oils, also has a mechanical resist action.

$$2\,Pb(NO_3) \rightleftharpoons PbO + 4\,NO_2 + O_2$$

catalysts: PbO, $PbSO_4$

$$CuSO_4 + 2\,H_2O \rightleftharpoons Cu(OH)_2 + H_2SO_4$$

$$Pb(OH)(CH_3COO) + H_2O \rightleftharpoons Pb(OH)_2 + CH_3COOH$$

The released oxygen oxidizes the leuco form of indigo and the acids liberated neutralize the alkali present in the vat.

Indigo recovery and reuse Substances present in effluents, wastes or exhaust air can certainly be described as valuable substances, after recovery and cleaning, when they can be used again without any detriment compared to the original finishing agents, dyes, etc.

The draft of the German 38th Administrative Regulation contains precisely defined limits on the discharge of dyes into waste waters which, in most cases, demands compulsory treatment of such waste waters. This also applies, e.g. to the rinse liquors which accumulate during indigo dyeing. As a rule, these have a dye concentration of 0.2–0.4 g/l and contain between 12 and 20% of the original amount of dye used depending on the particular dyeing process.

Ultrafiltration membranes are ideally suitable for the elimination of this dye. In practice, inorganic (dynamically formed ZrO_2 coated) or organic membranes are used which are capable of retaining up to 90% and more of the indigo molecules (as long as these are present in the oxidized state). As a result, a practically dye-free permeate is obtained.

In the case of indigo recycling, elimination of the "pollutant" can be combined with recovery of a "valuable substance". After reduction, the dye concentrate produced by ultrafiltration (50–80 g/l) can be used for dyeing again without any problem. The permeate is at least partially recycled and used for pre-wetting or prewashing even when it contains sulphite due to the use of sodium dithionite as a reducing agent. The percentage of unfixed dye and the indigo price obviously play a major role in the economics of indigo recycling. On the basis of several analyses, payback periods of between 2 and 3.5 years are typical. → Recycling.

Indigo styles in Africa prints,

I. Real Wax: the oldest and most artistic technique involves covering (resisting) parts of the textile material with a wax-colophony mixture. The design is produced by subsequent dyeing with indigo. Since the wax resists are fairly brittle, irregular and extremely fine cracks are formed which results in the typical veining or crackle effects. After dyeing, the wax is removed (e.g. by saponification) and the remaining colours are applied either by repeating the wax resist treatment or by block or screen printing. Sequence of operations:

- wax printing,
- indigo dyeing,
- wax removal,
- application of colour pastes (e.g. substantive dyes, reactive dyes),
- fixation,
- washing/drying.

II. Imi-Wax: the industrial production of Real Wax prints is extremely laborious and costly. For this reason, a technical imitation under the name Imi-Wax has been introduced in practice. The Imi-Wax technique is based on the same designs and colours typically used for Real Wax prints. However, Imi-Wax prints are mainly produced on naphtholated grounds in order to imitate indigo with diazo fast colour salts which are also used to obtain all other shades that are technically possible. Other dye classes are used to obtain shades which cannot be achieved with diazo fast colour salts. Sequence of operations:

- application of naphthol ground,
- printing (diazo fast colour salts supplemented with e.g. Phthalogen blue, reactive dyes, etc.),
- fixation,
- washing/drying.

III. Real Indigo: for this style, the white cotton fabric is printed directly with indigo followed by fixation and washing off. This technique is used to produce high coverage blue/white prints often supplemented by other colours. Sequence of operations:

- printing with indigo,
- fixation/washing/drying,
- overprinting (e.g. reactive dyes),
- fixation,
- washing/drying.

IV. Imi-Indigo: the Real Indigo style described above is also imitated industrially. In this process all the dyes are applied in a single operation and then fixed. Mainly vat leuco ester dyes are applied alongside fast colour salts on naphtholated grounds by direct printing. Sequence of operations:

- application of naphthol ground if required,
- printing (e.g. vat leuco ester dyes, diazo fast colour salts, reactive dyes),
- fixation,
- washing/drying.

V. Fancy-Print: in this style traditional effects applied in Africa are brought together. The style involves discharge and resist printing techniques which were common in Europe from 1900–1955 but which have since gradually disappeared on that continent due to the rationalization of production methods (e.g. aniline black resists, indigo resists, etc.). No general sequence of operations.

VI. Plangi: this is a very old technique for the production of resist effects by gathering, folding, or rolling the fabric, usually held with stitching, to form specific patterns on subsequent dyeing. The plangi technique is an ethnologically-based and artistically valuable craft. It is, unfortunately, seldom practised today. In this case also, the resist effects obtained can also be supplemented with additional colours applied by direct printing. Like the other handcraft techniques described above, very attractive plangi imitations have also been developed. Sequence of operations:

- binding the textile material,
- dyeing with indigo,
- washing/drying,
- printing (e.g. reactive dyes),
- fixation,
- washing/drying.

Indigo test The most commonly used test for the identification of indigo dyeings. Spotting with conc. nitric acid produces a yellow stain surrounded by green edges (= oxidation of indigo to the yellow coloured isatin).

Indigotin, sulphonated indigo as an acid dye.

Indirect polluter → Waste water pollution sources.

Indirect steam → Steam as a liquor heating medium.

INDITECNOR (Sp.), abbrev. for: Instituto Nacional de Investigaciones Tecnólogicas y Normalización, Santiago, Chile (Chilean Standards Institute); → Technical and professional organizations.

Individual fibrils (elementary fibrils, basic fibrils, microfibrils, protofibrils, capillaries). This refers to the initial developmental stage of the next highest cell organisation of the fibril bundle or → Fibrils and is constructed of micelles or crystallites in parallel bundles. Approximate diameter in wool: crystallite 0.005 µm, individual fibril 0.01–0.04 µm, fibril bundle 0.1–0.3 µm.

Individual value The individual value is the statistical term for the characteristic value of a unit (sample) in a → Populations or random sample.

Indole → Heterocyclic compounds.

Induction (Lat.: *inducere* = to introduce). Electromagnetic induction is the generation of an electric current or voltage in a conductor.

Induction forces → Secondary valency forces.

Industrial cleaning This refers to the cleaning of industrial textiles, industrial clothing of all types, uniforms, machine cloths, etc.

Industrial gloves → Protective clothing.

Industrial gum (printing) → Industrial gums.

Industrial gums (industrial printing gum, crystal gum, labiche gum, sheet rubber, drying rubber). Industrially manufactured → Vegetable gums, preferably from Asia. Gum and → Rosaceae rubber which is dissociated under pressure or using oxidation methods, as a result of which the gum is already cold water soluble and suitable for sprinkling in powder form to thicken print dye pastes. The gum is available in irregular pieces, uncoloured (bleached) through to deep red and brown. Generally preferred as a powder (poss. modified using starch gum or starch). Type reaction (according to Grafe) as follows: Tannic acid does not give a precipitate (as with gelatin/adhesive). An alkaline copper solution at 70°C does not give a red deposit (as with starch gum). There is no typical discolouration with iodine solution (starch = blue, starch gum = red). There is no blue colouring (as with starch gum) with molybdic acid ammonia and a little nitric acid.

Industrial hygiene In order to reduce the risk of handling textile finishing agents as far as possible, both in production and in use in terms of their carcinogenic and allergy-inducing effect on humans, industrial hygiene measures are intended to limit the effect of dyes and chemicals on both staff and the environment. The risk results from the harmful effects of the substance and exposure to it (effect). The following measures are required:

1. well planned and safe work stations; partition of the colour kitchen from the other areas; good ventilation in the colour kitchen (4 changes of air/hour), slight overall negative pressure so that dye dust does not escape outside; dust extraction from scales and areas where dyestuff has been handled - this should be carried out from top to bottom using a low flow rate; good facilities to clean floors and walls with water should be available (no packing units should be stored directly on the floor); the packing units should be transported to the scales for collection and there should be short transport paths for products regularly used.
2. extensive automation (weighing and setting up stations) and robotisation (dyestuff stores).
3. suitable working equipment: long-handled withdrawal blades, one for each packing unit opened; drum pumps with separable motor section; no paint brushes, even to clean the weighing scales; no brooms should be used – special vacuum cleaners, jets of water or mops should be used instead; large quantities of dyestuff which have been spilled should not be disposed of with the waste water.
4. suitable recreation and wash rooms; eating, drinking and smoking should be prohibited in the colour kitchen.
5. protective clothing, in particular protective glasses and gloves must be worn as per guidelines (safety data sheets for the relevant chemical products); compliance with guidelines should be monitored.
6. staff training, particularly in all aspects of safety. Information should be made accessible to everyone involved; working procedures and safety regulations must be formulated in writing.

The following is expected of the workers:

7. order and cleanliness at the workplace.
8. observance of all safety regulations; wearing protective clothing; initiatives to prevent accidents, unnecessary exposure and considered, appropriate handling of dyestuffs and chemicals.
9. good personal hygiene, regular washing of hands and face; protective clothing and work clothing must not be taken home; dyestuffs on the skin should not be removed with hypochlorite or reducing agents as these may damage the skin and cause toxic decomposition products to be absorbed.

Industrial noise pollution (industrial noise). Industrial noise pollution refers to general noise in or from the workplace which is sustained for any length of time. Industrial noise pollution may affect the general well-being of the workers (even resulting in permanent damage to hearing) and cause interference within the company or disturb neighbouring communities. Industrial noise pollution must therefore be kept to a minimum. The industrial noise pollution situation is generally complex and is dependent on a number of variables which to a certain extent can only be understood empirically, e.g. from the type and number of machines in use, their stress and load, the position of those exposed to noise and from the space considerations. Industrial noise pollution is very rarely at a constant level. In the textile finishing sector, industrial noise pollution is essentially determined by the technical status of the machinery and the type of heating systems in use. To assess the workplace (see Fig.), sound levels with sound pressure level values in dB (decibels) are used.

The Figure shows how procedural measures can be used to actively combat industrial noise pollution: acoustic emissions of 95–105 dB (A) are given off when the baths are directly heated. The sound pressure level values can be reduced to 78–85 dB (A) however if the baths are filled with hot water or the heating process

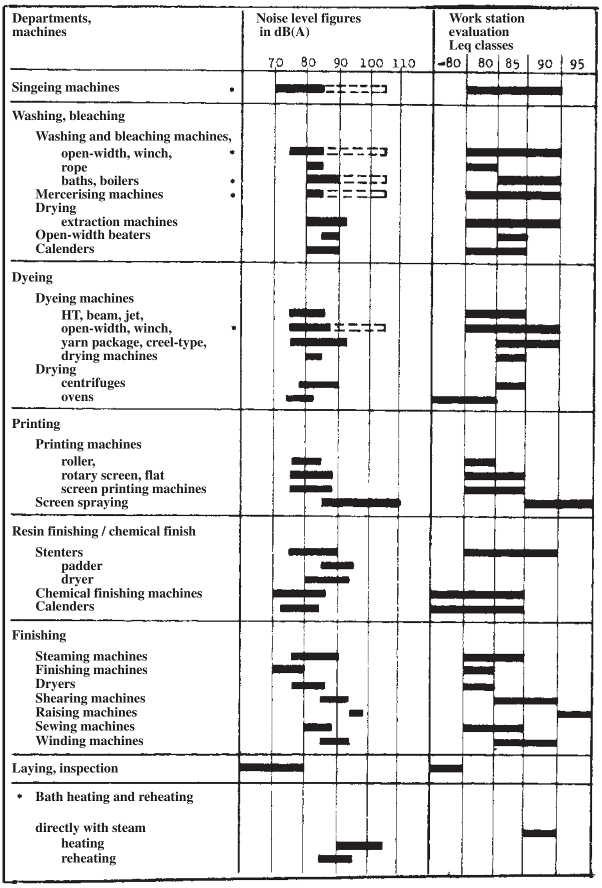


Fig.: Noise pollution at textile finishing work stations according to SUVA (Swiss Accident Insurance Company, Accident Prevention Department).

is carried out using sealed systems (e.g. using the HT process). A similar improvement can be achieved by installing special steam nozzles or mixing zones. In flat screen printing, film screens are still occasionally cleaned using spray guns and blow guns, which results in noise pollution of between 95–110 dB (A). In comparison, a screen cleaning machine operates at approx. 80 dB (A). Technical working measures to combat this are already in place. These include acoustics, architectural acoustics, process technology and mechanical engineering. The following concrete considerations are also possible: separating compressors, circulating pumps, vacuum pumps, and hydraulic units (with divided working areas) or where there is insufficient space, soundproofing these machines. If the vibrations from these machines affect the foundations, pipework and casing, insulation elements should be incorporated. This type of targeted measure may reduce the average industrial noise pollution level by approx. 3–8 dB. In certain circumstances, hearing protection such as ear plugs, ear cushions and ear muffs are available for those exposed to noise, although this does not offer an ideal solution. → Noise protection.

Industrial organization (management). Industrial organization is the task of optimising industrial processes and is directly linked to increasing productivity and production figures. This involves looking into specific aspects such as control/measurement and the bearing of this on costs by deployment of personnel or technical qualifications.

Industrial protective clothing Workwear which must be worn for certain tasks (e.g. the industrial safety shoe). The employer must provide this clothing. → Protective clothing.

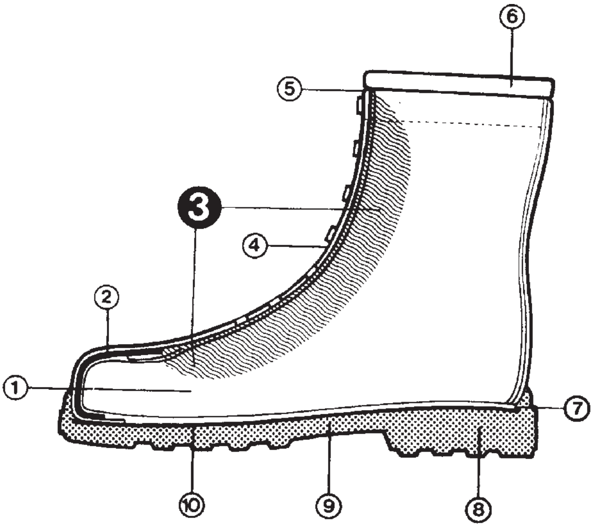

Fig.: Industrial protective shoe.
1 = top quality cowhide; 2 = integral steel cap; 3 = aramid fibre interlining; 4 = closure; 5 = protective strap; 6 = upholstered edging; 7 = leather insole; 8 = elastic heel; antiskid, solvent and temperature resistant sole; 9 = steel sole (protection against nail penetration etc.).

Industrial salt Denatured common salt (made inedible for human consumption). As denaturants the following products are used, e.g. petroleum, dyesuffs, etc. Industrial salt is free of salt tax.

Industrial soaps (technical soaps). Special soaps used for particular technical applications, e.g. textile soaps, etc.

Industrial standards Until a few decades ago, industrial standards were primarily the domain of engineering departments in most medium and large companies. With the arrival of "profit-centre concepts", however, the predominance of pure engineering became less marked. From its conventional objective, interest in standardization at company level was chiefly limited to works standards. Aspects such as efficient production, interchangeability, limitation of products and simplification of stock-keeping were predominant for the company; industry-wide co-operation in this field was initially restricted to the national level. The ever-increasing division of labour in the economy, intensified technology transfer and the further expansion of international integration in the global economy have brought increasing demands for nationally and internationally agreed standards. The aspects of standardization are numerous and, among these, the traditional ones such as e.g. the collective use of available know-how, the limitation of variety by standardization and the classification of sizes and dimensions, the easing of relations through increased uniformity of organizational structures, modes of behaviour and expression both within and outside the company, are to be emphasized. Implementation of these measures results in simplified stock-keeping, greater rationalization and, above all, a contribution to quality assurance and increased safety (e.g. as provided in the draft of DIN ISO 11 111 for textile machines). The effects of these aspects on the environment and their compatibility for human beings are also the objectives of standardization. These latter aspects contribute considerably to the protection of consumers as well as their health and habitat, which are particularly important from the point of view of the state.

Standardization has been defined by → ISO as “the laying down and application of appropriate rules in order to realize, within a given field of activity, a systematic order to the benefit of, and the participation of, all interested parties and especially to achieve optimum economies throughout, taking functional circumstances and safety into account.” The declared objectives of the EC, namely the dismantling of technical obstacles to trade, the abolishment of national borders in commerce, the achievement of transparency in the European market, has not only triggered a hitherto unknown, almost frenetic level of activity, but has also led to a full-blown revolution in standardization. Consequently, the safety of people and machines, health, consumer protection, environmental protection, quality assurance, as well as activities in conformity to standards certification for example, the mutual recognition of testing laboratories etc., merely represent stages in the new direction of advancement in European standardization. An international standard (with worldwide validity) can be contemplated if national standards (on the same subject) already exist in various countries. Such a harmonized standard has as its objective the conformity of frequently contradictory national standards. In certain cases, the standard may also be completely new, especially if no national standard on this particular subject exists yet. Such a standard can be regarded as a preview of the future, since the standard can exist before the product for which it has been designed. The

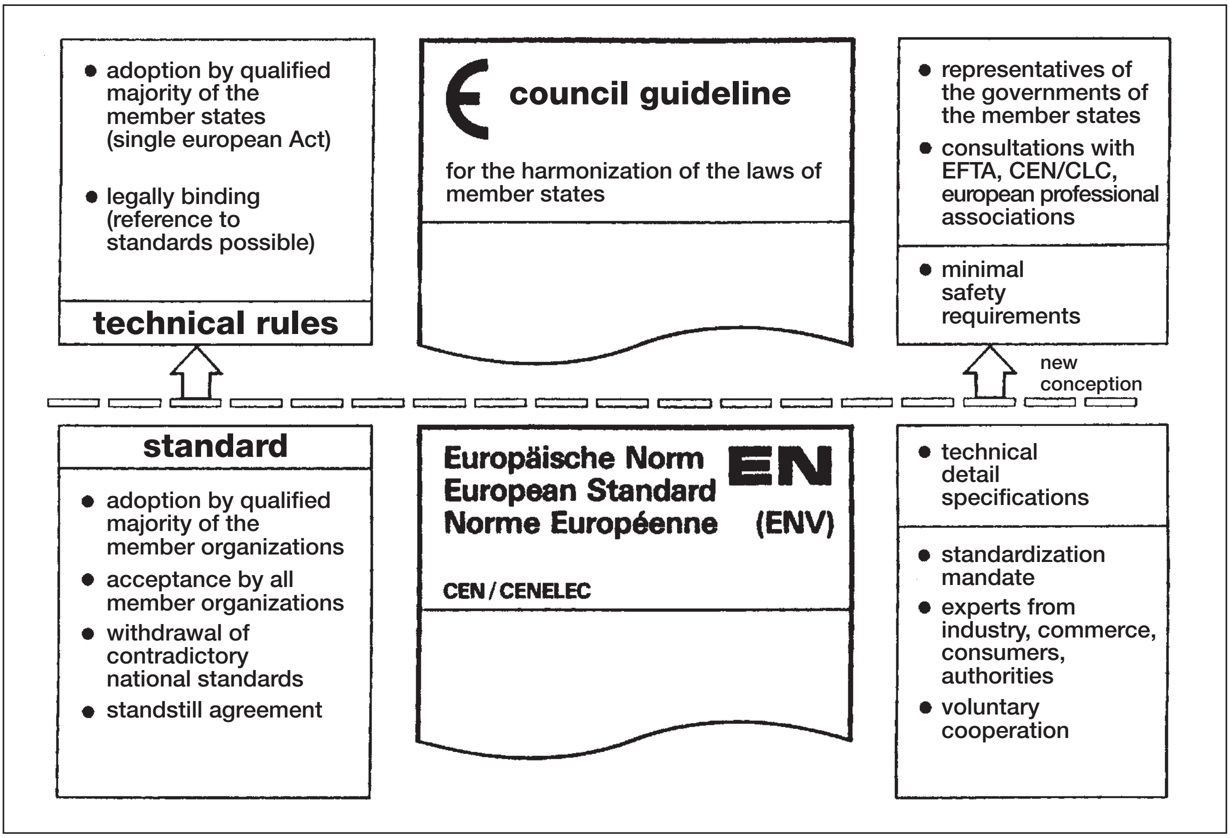

Fig.: Concept for industrial standards.

importance of an internationally harmonized standard is obvious especially in the case of products which are used as various components in a finished product, or as interchangeable elements for finished goods in numerous countries. A new concept (see Fig.) from now on is the formal separation of the technical specification and the private standard. The legally binding technical specification should contain only the necessary minimum of essential safety requirements, whilst the formulation of the technical details should be entrusted to the well-proven procedures of private industrial standardization by CEN/CENELEC (source: Thiévent).

Industrial textiles,

I. In Anglo-Saxon countries and the Netherlands a term used in the sense of → Technical textiles which are not always used for industrial purposes but also for consumer goods with a technical function.

II. A term used for → Rental linen.

Industrial workwear Materials for industrial workwear belong to a category of textiles which have to meet particularly high requirements. They must have high stability and outstanding durability in order to withstand the high mechanical stresses to which they are subjected in most fields of use. Since industrial workwear in many fields is provided by employers under leasing arrangements, mechanically stable and therefore particularly hard-wearing clothing materials are of great importance. Inextricably linked with the cost performance of industrial workwear are also the requirements placed on easy-care properties and wash-and-wear resistance. The specific application conditions or soiling to which industrial workwear is subjected in the field means that it is not possible to clean or wash such articles effectively and hygienically in household equipment but only in commercial laundries and drycleaning establishments. The materials used for industrial workwear must correspond to the latest state-of-the-art technology as regards their suitability for a particular field of use. For good cost performance it should not be necessary for articles of industrial workwear to require a time-consuming and expensive steam pressing after washing and cleaning, but should rather achieve a good external appearance after final treatment in the so-called “tunnel finisher”.

In addition to these requirements, industrial workwear must also protect the wearer from climatic influences at the workplace. Despite the often highly variable climatic conditions and work load during the course of a working day, industrial workwear must be capable of supporting the human body’s temperature-regulating processes so effectively that an agreeable „microclimate“ develops close to the skin in order to achieve good wearing comfort. Only under such conditions can the working man develop his full performance capacity. By contrast, industrial workwear with poor physiological wear properties not only impairs the well-being of the person and thereby increase the stress at the workplace, but also reduces the physical performance of the wearer and can even prove harmful to health under certain circumstances.

Industrial workwear materials have been developed principally to meet the first-mentioned technological requirements of durability and wash-and-wear properties. In view of the fact that synthetic fibres, especially polyester, are able to meet these requirements, e.g. high abrasion resistance and tensile strength, dimensional stability, high luminosity with fluorescent safety colours, cost-saving finish possibilities after laundering/ cleaning treatments, etc., comparatively better than natural fibres, industrial workwear used under leasing contracts consists almost exclusively of blends with a predominant proportion of polyester (contributed by Umbach).

Industrievereinigung Chemiefaser e.V. (IVC). Industrial Association of Man-Made Fibre Producers in the Federal Republic of Germany. Affiliated to → CIRFS; → Technical and professional organizations.

IN dyeing method A method for dyeing those vat dyes (IN dyes) which have the highest affinity for cotton at 50–60°C. → Vat dyeing.

Inert (Lat.: *inertia* = inactive, sluggish). Slow to react, unreactive, indifferent, passive. Polytetrafluoroethylene, for example, is practically inert to all organic solvents and common chemicals.

Inert gas drier Coatings with explosive solvents are dried in driers in which an inert gas (nitrogen) is used as the circulating gas (circulating air in conventional driers) when solvent-containing coating compounds, e.g. adhesives, are applied. The drier housing is completely gas tight and the separating partition be-

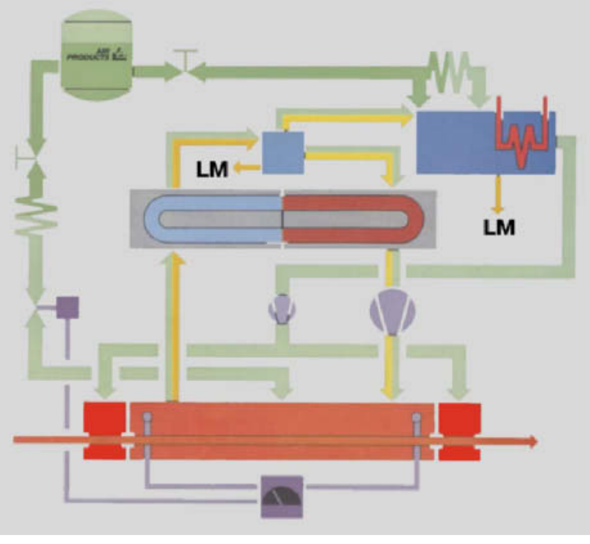

Fig.: Drier (bottom) for solvent coating with inert gas operation (green = N_2 flow) and nitrogen recovery after condensing solvent (LM) out (top).

tween the upper and lower sections of the drier is sealed with an endless seal to exclude ingress of oxygen and prevent explosions. Both the entry and exit slots of the drier are provided with air locks with separate inert gas systems which also prevents the ingress of oxygen into the system. A continuous loss of inert gas occurs in these air locks which is, of course, minimized by the special design of the air locks.The concentration of oxygen in the drier is continuously monitored and automatically maintained at ≤ 6%. In this way, the circulating gas can be loaded with solvent up to its theoretical saturation point so that solvent-recycling in a condensation plant is an economic possibility. For this purpose, a definite quantity of circulating gas is withdrawn from the individual drier zones by means of a circulating gas fan (exhaust air fan in conventional driers) and conducted into the condensation plant where the solvent condenses out and the purified inert gas (fresh air in conventional driers) is again recycled to the drier zones (see Fig.) (contributed by Olbertz).

Infeed frame An infeed frame is a frame above a skein or a carriage at the infeed of a continuous plant consisting of tubes (in its simplest form made from timber) in order to feed the web into the plant at full-width and as smoothly as possible. → Variable-tension rolls or Slatted expanders are often connected to infeed frames.

Information flow in textile finishing The introduction of information technology into a textile finishing mill is extensive and demanding due to the variety and complexity of the manufacturing processes which are subject to continual rapid changes. In many places, the necessary experience is not yet available which is, among other things, to some extent an expression of the still inadequate training of textile practitioners in information management. Moreover, there is a lack of information technologists in the textile finishing industry. Many mills are therefore in a transitional phase from the introduction of a few computers (e.g. for recipe prediction based on colour measurement in the dyehouse laboratory or the automation of batchwise dyeing processes) to a comprehensive application of information technology which not only covers the manufacturing processes but also the entire organizational structure of the company. The application fields for information management etc., can therefore include the following areas (Fig. 1):

- Modern measurement and control technology, in conjunction with microprocessors as universal control and monitoring elements, is used to an increasing extent in all stages of textile finishing for batchwise as well as continuous processes.
- The control of processing operations, recipes and

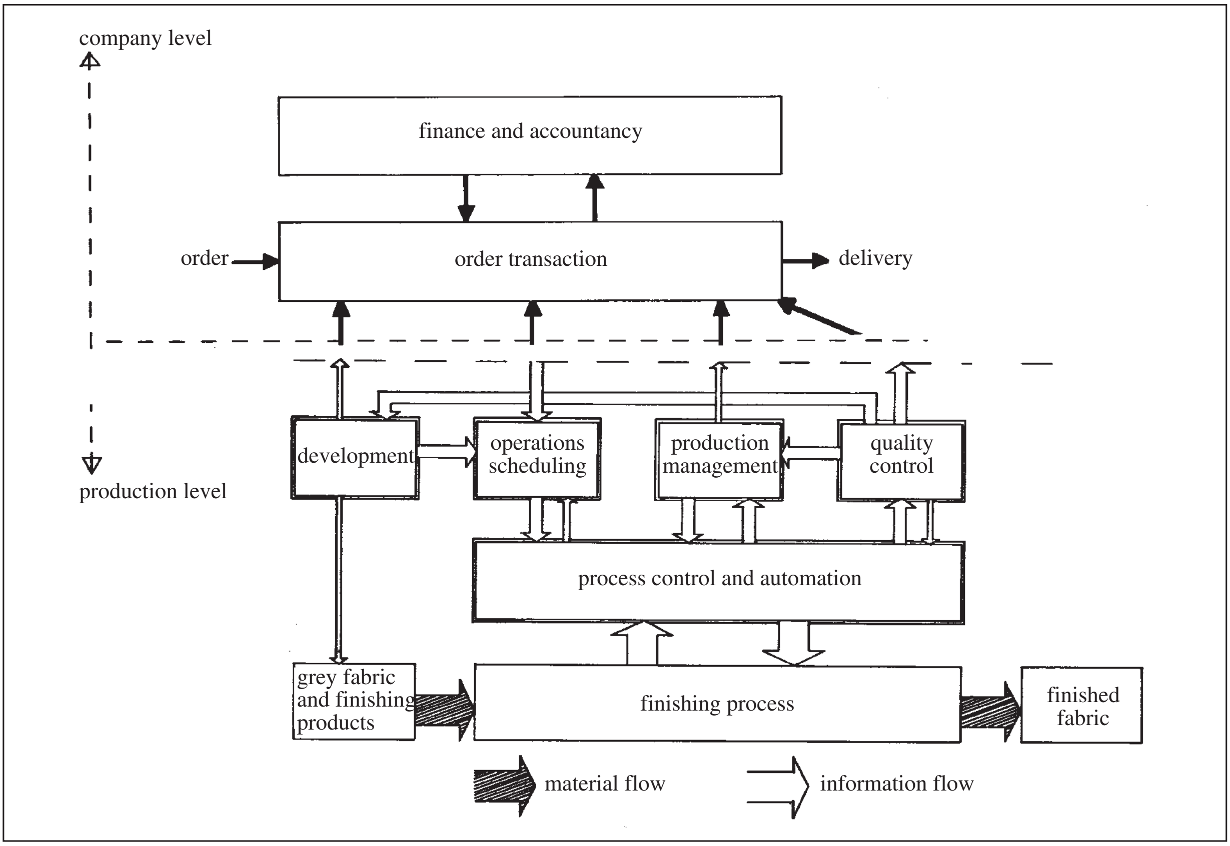

Fig. 1: Information flow (vertical) and material flow (horizontal) in the textile finishing operation.

Information flow in textile finishing

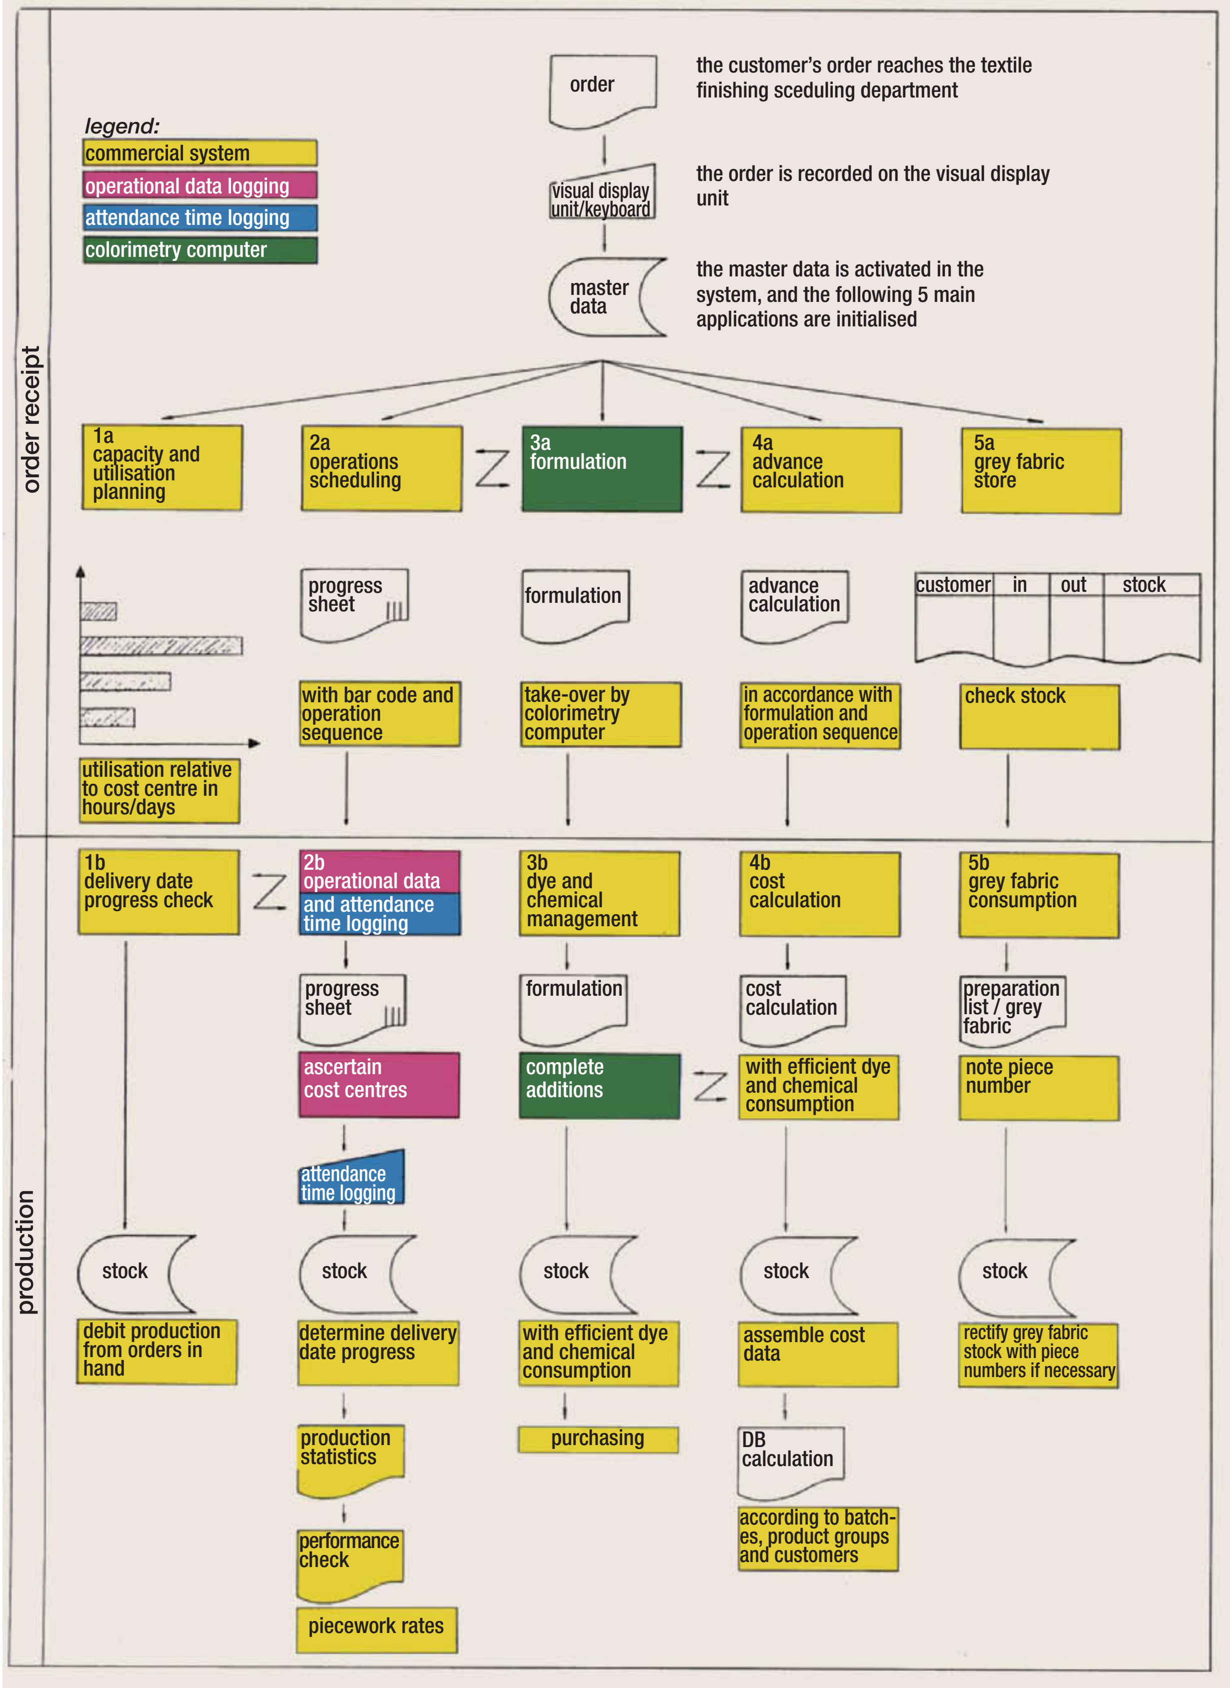

Fig. 2: Data processing in textile finishing.

entire processes can be carried out much more efficiently by computer. The necessary forms and process documents are produced easily, quickly and error-free by this means.
- Computerized data processing provides the most accurate possible information for planning capacity utilization and delivery deadlines, pre- and post-calculation of process costs, as well as the optimized storage of greige fabrics, dyes and chemicals. The computer-aided logging of operational data monitors the progress of each individual batch through all stages of finishing and provides accurate figures on machine times, consumption data and quality characteristics.

It is clear that the smoothest possible interlocking of the sub-domains of such a comprehensive information concept (Fig. 2) should be aimed for by carefully matching one to another.

Information systems Information or communications systems are generally available when information is acquired by the exchange of data. In the IT sector, an information system refers to an underlying database system which has been expanded to include a query system which enables the user to access the data interactively. The database system is the part of the information system which deals with the description of the data available, the data management, and handling of and access to this data. It consists of the database, which includes all of the relevant data, and the database software, which organises the management of and access to the data. In order to carry out specific requirements of a database system, in particular physical and logical independence, it is necessary to view the data in 3 different levels (Fig. 1):
- The conceptual level comprises the logical overview of the data,
- The internal level is concerned with the physical organisation of data,
- The external level deals with the view of individual user groups or application programmes.

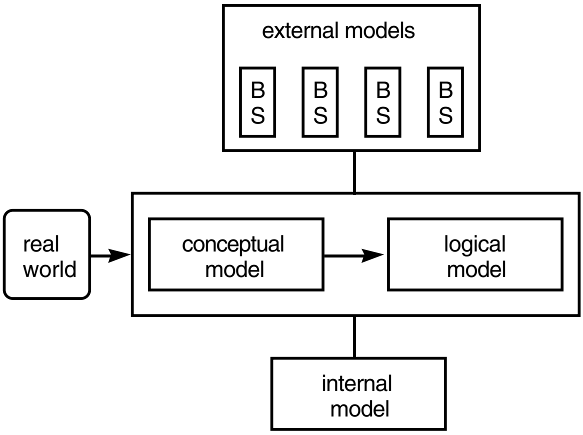

Fig. 1: Architecture of a databank system (BS = user viewpoints).

These 3 levels form the so-called architecture of a database system. The essential components are the conceptual, internal and external models.

The conceptual model describes the data of a system to be represented on a logical level, independent of the data processing perspective. For this purpose, the real world must be mapped on a suitable model by abstraction and grouping. The model is formed as follows: Certain things from the real world are described as objects, so-called entities, between which there are specific relationships (Fig. 2). Such entities can be any real and abstract things which are of interest when describing the area to be analysed. In order to reduce the actual complexity of the subject area in the model, entities are examined for certain similitude criteria in order to summarise them into categories. Entities are of one type within each group. Certain features, so-called attributes, are required to describe entities. In turn, each attribute may be assigned values from a specific range of values. The formation of categories is also characterised in that each entity type or category has a combination of attributes, i.e. each entity type is associated with a corresponding combination of attribute values. Concrete relationships between entities can be classified, in that quantifiable relationships, so-called relationship types, arise between entity types. Entities and their abstract relationships can be shown as an E-R diagram (entity-relationship diagram). Entity and relationship types are defined with the conceptual model and attributes and their values are specified.

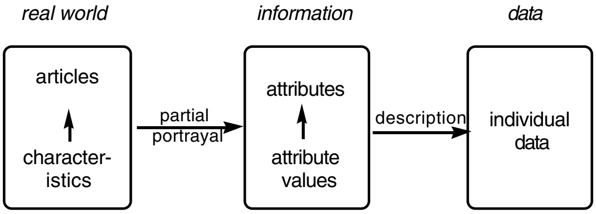

Fig. 2: Portrayal and description of the real world by data and information.

The external model describes the user groups' view of the logical overview of the data. Different user views are necessary as each user (or each user group) has his own view of the data stored in the database, adapted to the individual problems. This means e.g. that someone who only wants a general overview has a different view to someone who is looking for specific information within the database. Each user group therefore has their own external model. The external model must be derived from the overview of the logical data, the conceptual model. An external model is described by a data manipulation language (DML). A DML can either be an extended programming language or a specific query language. The external model is not only created by the actual user, but by someone with a knowledge of both the conceptual model and the user's field of application who is therefore aware of what data is relevant for the user.

The internal model comprises the physical data organisation, i.e. the structure of the stored data, its memory organisation and its access capabilities. An entity type describes a category of objects (entities) with similar features. Each entity type, E, is assigned a specific attribute quantity, A, with a finite number of elements, a.

$$E: < A >$$

$$A = \{a_1, a_2, ..., a_n\}$$

Each attribute $a \in A$ possesses attribute values w_a of a specific range of values. Each entity e of type $E: < A >$ is uniquely defined by its combination of attribute values, i.e. A is an identifier for E. This characteristic may however already apply to a subset of A. If no attribute may be omitted from the identifier subset in order to identify E, then the subset is described as a key for E. In general, there are several keys for each entity type. The primary key, which characterises a specific object using an attribute value, is differentiated. If the value is altered, this would signify a change in the object. (The attributes of the primary key can be identified by underscoring). Each combination of attributes except for the primary key functions as a secondary key. This enables a number of entities of type E with specific properties to be selected.

Entities which are actually available are connected together by concrete relationships, which in turn can be classified as abstract relationships between entity types. A relationship type can have attributes, the concrete relationships between entities have relevant attribute values. Entities and relationships are stipulated by an observer of the real world and can be totally different for different observers. It is possible when displaying the same facts to regard a relationship also as an entity or to define an attribute of an entity type as an independent entity, with a specific relationship arising between these two entity types. If the entity types have been selected, however, attributes and relationship types are also stipulated. In addition to relationships between two entities, relationships between three or more entities of the same type are possible: a relationship type, f, is characterised by the number, e, of entity types involved; the number of entity types corresponds to the size of f.

$$f: \{ E_1, E_2, ..., E_n\}$$

$$\text{size}(f) = n.$$

Where relationships have the same entity type, these must be given so-called role names so they can be identified within the associated entity types. The complexity of relationships gives information on how many other entities can, may or must be concretely related to an entity of a specific type. This is expressed by the degree of complexity (f). There are various notations available to represent the degree of complexity, which will not be detailed further here.

In view of the typologising of information systems, databases can be classified from various perspectives. The typology used to classify databases in one of the best known database managers "Directory of Online Databases" of Cuadra Associates, works on the basis of functional features (Fig. 3). In contrast, the databases are organised from structural perspectives. The different views affect the classification of databases.

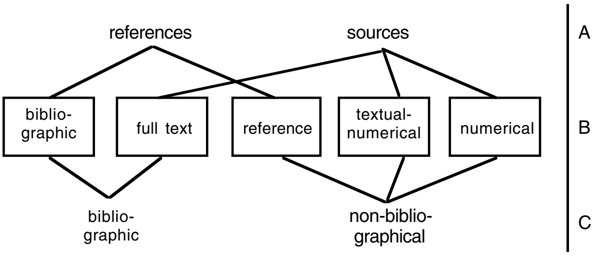

Fig. 3: Classification of information systems under different aspects.
A = functional feature; B = databank types; C = structural feature.

Reference databases are characterised by secondary knowledge, i.e. the data stored refers to sources of information such as literature, organisations, companies etc. Bibliographical databases, also commonly referred to as literature databases, such as BIBLIODATA, include bibliographical data concerning books, dissertations, congress reports, reports and periodicals from all subject areas which have been published in German language literature both at home and abroad since 1945. There are however literature databases such as the textile technology database, TITUS, which consists primarily of articles in periodicals, which are also structured following bibliographical criteria. The individual documents are generally available in the form of abstracts which convey the contents of the document in a concise and succinct manner thus expanding the significance of the literary reference.

Infotex International Abbrev. for Information Textile International. A cooperation between 7 leading international technical journals in Germany, France, Spain, USA, Switzerland and Hong Kong. Purpose: support in market observation, sharing of experience and reciprocal representation. German representation: Melliand Textilberichte International.

Infrared (Lat.: *infra* = below, beneath). Infrared (IR) radiation is long-wave radiation which is not visible to the human eye. The entire IR-spectrum extends from 780–400 000 nm of which only the smaller component of the vibration spectrum between 780–3000 nm is of most interest (see Fig.).

The transition zone between red in the visible spectrum and infrared lies within the range 700–860 nm. All bodies emit IR-radiation, even in the cold, although the radiation becomes more intense the hotter the body. Infrared radiation produces the sensation of warmth from non-glowing hot bodies which is why IR-radiation is also called heat radiation. In order to produce artificial IR-radiation of adequate intensity (e.g. for infrared drying), temperatures above 500°C are necessary. At such temperatures visible radiation is also produced to a notable extent although this can be eliminated by IR-filters in locations where it is not desired.

Effect: as in the visible spectrum, IR-rays are also subject to absorption to a greater or lesser degree. The spectral IR-absorption is greatly dependent on the atom groupings and chemical bond characteristics of the irradiated substance. According to this, most organic compounds have an absorption maximum in the wavelength region between 2500 and 15 000 nm (by comparison the absorption maxima of thin films of water are approx. 3000 and approx. 6000 nm). IR-radiation is capable of setting the atomic nucleus in motion, i.e. vibrating, positively-charged atomic particles in molecular association (dipole moment in cis-form) are formed as charge carriers (not electrons in the shells of the atom as is the case with visible light) which transfer the absorbed radiation energy to neighbouring atoms as so-called collision energy thus having the practical effect of causing bodies to heat up by thermal conduction. Chemical changes can only be caused indirectly by this heating. Only the short-wave IR-radiation can be made use of photochemically by the blackening of previously sensitized plates or films where radiation up to 850–900 nm is mainly involved in practice. IR-radiation is furthermore able to excite phosphors to accelerated phosphorescence which rapidly subsides again, and cause some metal alloys to emit electrons (similar to photocells in visible light). The latter opens up the possibility for direct detection of IR-radiation as well as reflection. The so-called image converter works according to a somewhat modified principle, whereby invisible IR-radiations or images are made visible indirectly. Lightproof IR glasses, which use an appropriate barrier filter, limit IR-visibility to the near IR-transition spectrum. IR-photography and highly sensitive temperature-measuring instruments of the thermoelement and bolometer type, etc., offer further detection possibilities.

Infrared-absorbing dyeings Such dyeings are particularly suitable for heat-retaining winter clothing. Since approx. 50% of sunlight is made up of infrared radiation, dyes which have a pronounced absorption capacity for infrared (IR) offer the possibility to convert absorbed radiant energy into heat. According to findings by the Philadelphia Section of the AATCC, increases in temperature of 14°C were measured on dyeings produced with such dyes on the same textile fabric with shades of similar appearance to those produced with ordinary dyes. Dyes of this kind are also described as “warm dyes”. Such dyes with over 70% absorption

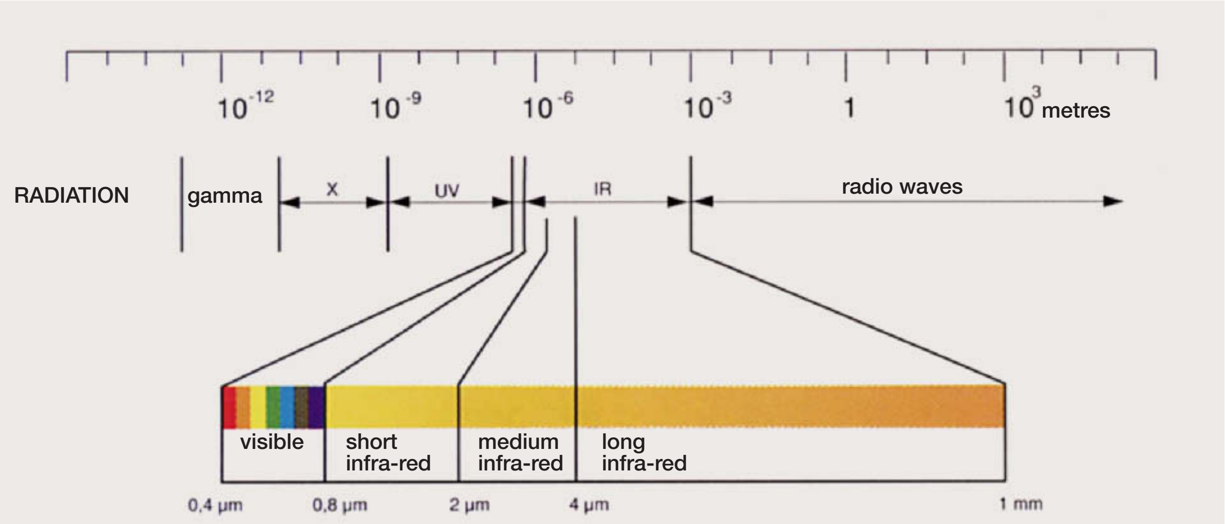

Fig.: Wavelength spectrum of visible and IR-radiation.

(monochromatic energy at the 1000 nm line) mainly include sulphur dyes as well as some vat, acid and chrome dyes where selected blue, navy blue and black dyes have predominated. In the nature of things, it is the chemical constitution of the dye, and not the visible colour, which is decisive here. Where lower demands are placed on absorption (approx. 40%), brown (40%) and green (45%) may also be included among sulphur dyes as well as brown (45–47%) in the case of chrome dyes. The above-mentioned dye classes also contain some other blue and black representatives with considerably lower absorption values. If necessary, reliable information on these properties can only be obtained from the dyestuffs industry. All other dye classes and the shades obtainable from them yield absorption values below 30%. The absorption capacity may be greatly increased by metal salts. By means of simple absorption determinations based on photographic exposures of dyeings irradiated with 300 watt incandescent bulbs (with the interposition of appropriate filters if necessary), inferences can be drawn from the density of prints taken from plates which are especially sensitive to IR regarding the extent to which total IR-absorption (black prints) or total reflection (white prints) is approached, or on which side the predominant intermediate values lie (grey prints). This method can be further refined by taking into account the time factor of exposure to IR radiation, and by measurement of the white or black content (grey standard) quantitative evaluations can also be made.

Infrared drying In drying technology, the invisible IR-radiation from electromagnetic wave radiation, referred to by physicists as infrared radiation, is used by preference. In terms of drying technology, the most significant spectral range is 700–3000 nm. In this range, the particles are displaced in more rapid, random vibrations, thus warming the product. The radiation emitted is referred to as the emission, and the radiation, converted into another form of energy when the material is penetrated, is referred to as absorption. The radiators or radiation receivers which emit the greatest possible flow of energy at a given temperature are referred to as "black bodies". Their radiation has a continuous spectrum and follows "Planck's radiation formula". According to the Stefan Boltzmann law, the following applies to the heat exchange between two large parallel surfaces of different temperatures:

$$Q = \frac{C_s}{\frac{1}{\varepsilon_1} + \left(\frac{1}{\varepsilon_2} - 1\right)} \cdot \left[\left(\frac{T_1}{100}\right)^4 - \left(\frac{T_2}{100}\right)^4\right]$$

C_s is the radiation constant of the "black body" (5.67 W/m^2K^4); ε_1 and ε_2 are the so-called emission ratios of the bodies involved in the radiation exchange; T_1 and T_2 are the absolute temperatures of the bodies. If the so-called radiation exchange coefficient C_{12} is formed from the expression outside the brackets in the above equation for bodies with known emission ratios (material constants) and a defined temperature factor

$$a = \frac{\left(\frac{T_1}{100}\right)^4 - \left(\frac{T_2}{100}\right)^4}{T_1 - T_2}$$

and a heat transmission coefficient of the radiation is defined using $C_{12} \cdot a = \alpha_{radiation}$, then the heat transmission during radiation can be represented in the form

$$Q = \alpha_{radiation} \cdot (t_{radiator} - t_{fabric})$$

and the evaporative capacity via radiant heat can be calculated using

$$G_D = \frac{Q}{r}$$

The radiation exchange coefficient C_{12} is formed from the radiation coefficients C_1 and C_2 of the bodies 1 and 2 as follows:

$$C_{12} = \frac{1}{\frac{1}{C_1} + \frac{A_1}{A_2}\left(\frac{1}{C_2} - \frac{1}{C_S}\right)}$$

The radiator coefficients can be read off from the emission ratio:

$$\varepsilon = \frac{C}{C_s}$$

In practice in textile drying, C_{12} can be set at 4.0. The temperature factor (for $t_{goods} = 100°C$) for various common radiator temperatures is:

T_{STR} (°C)	400	500	600	700	800
a (grd³)	6.19	8.44	11.3	14.62	18.66
$\alpha_{STR} = a \cdot C_{12}$	~25	~34	~45	~58	~74

It should be noted that in this definition, $\alpha_{radiator}$ is particularly temperature-dependent. Thus for a radiation pre-drier with a radiator temperature of e.g. 700°C (radiation on both sides and with an area ratio of $A_1/A_2 = 1$) for the quantity of heat exchanged the following applies:

$$Q = 58 \cdot (700 - 100) \cdot 2 = 69\,600 \text{ kcal/m}^2 \cdot \text{h}$$

and for the evaporative capacity per hour:

$$G_D = \frac{Q}{r} = 128.8 \text{ kg/h} \cdot \text{m}^2$$

The pure radiation exchange is counteracted here by convective influences which arise in particular with gas-operated IR-predriers as a result of the warm flue gases. This also causes a further convective heat exchange. Radiation driers are generally only used in the first stage of drying. As they have a high power density and achieve a high spec. evaporative capacity with well balanced emission and absorption ratios, there is a risk of surface damage to the goods if the wet bulb temperature is not adhered to. This depends on both the emissivity and the “correct” spectral range. In order to achieve a high level of profitability when heating materials, IR radiators with emissions essentially within the area around 3000 nm must be used. As the absorption ratios of textile fabrics (Fig. 1) and water (Fig. 2) are also very favourable in the order of 3000 nm (virtually 100%), radiation temperatures of 500–800°C are preferred.

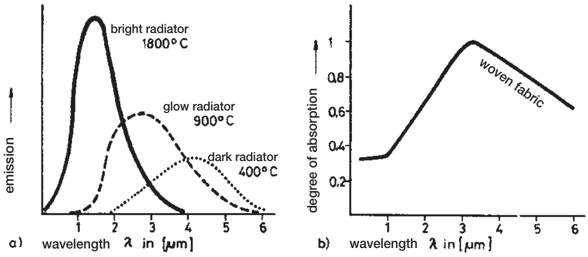

Fig. 1: a) Spectral emission distribution; b) Spectral absorption distribution on infrared radiation driers (1 μm = 1000 nm).

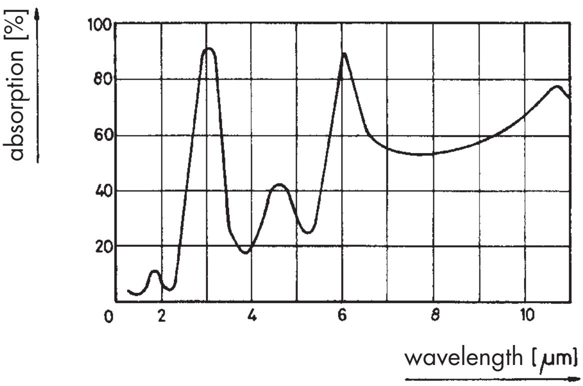

Fig. 2: Absorption spectrum (water 0.01 μm).

The radiator, the most important component of the IR-radiation drier, can be categorised (Fig. 3):

1. depending on the type of energy used to heat the radiator. Electrical and gas-heated radiators are most common.
2. depending on the portion of visible light; radiators which emit light, which noticeably illuminates the surrounding area in addition to invisible rays, are known as bright radiator driers. Invisible rays are emitted from dark radiators. Emission of light starts at temperatures above 500°C.
3. depending on the temperature of the radiator.
4. depending on the composition of the radiation.

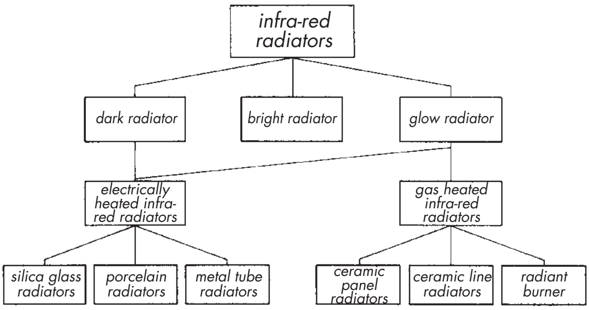

Fig. 3: Infrared radiator classification (Monforts).

Dark radiators
T = 200–500°C, max. emission 3700–6100 nm
Incandescent radiators
T = 500–1200°C, max. emission 1900–3700 nm
Bright radiator driers
T = 1200–2500°C, max. emission 1000–1900 nm

The electrically heated IR-radiators most commonly found in the textile industry are:

- Flat top IR-radiators made from porcelain
- Quartz glass twin pipe IR-radiators.

Flat top IR-radiators (Fig. 4) are integrated ceramic radiators with a heating spiral which has been firmly fired on, and are manufactured using a special process. The heating spiral is made from high temperature resistant nickel-chromium alloy. The glazed surface of the radiator protects the heat conductor from attack by atmospheric oxygen and thereby prevents premature oxidation and corrosion. The wires are arranged in such a way that it is only possible to have a slight temperature difference between the wires and the surface and that heating only takes a few minutes (Fig. 5). Radiating elements at 650–1000 W are used for textile IR-predriers. These radiators absorb surface temperatures of 300–750°C and radiate over a range of between 3000–10 000 nm.

Setting on a clamping fixture (tenter) is advantageous in that it is possible to control shrinkage of both the warp and the weft. On the other hand, these ma-

Infrared fixation

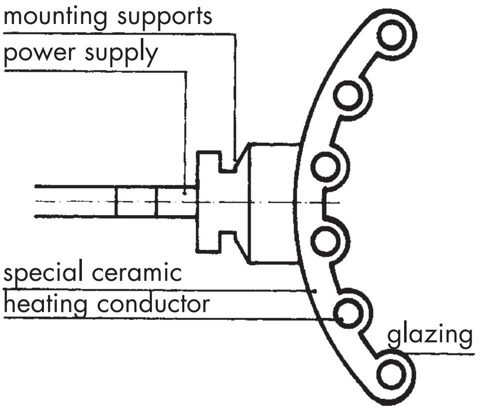

Fig. 4: Infrared panel radiator (Monforts).

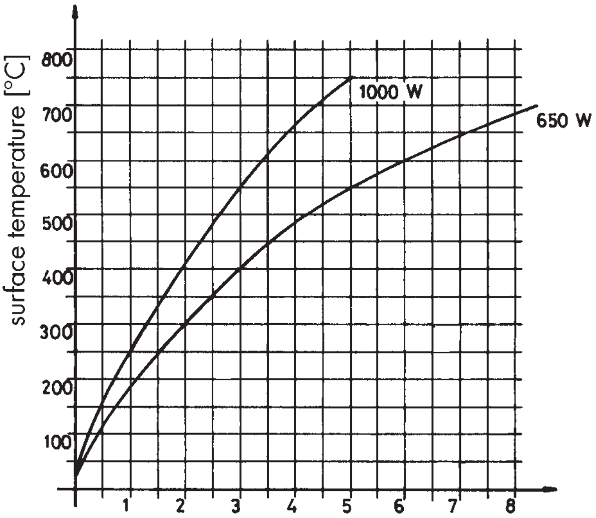

Fig. 5: Heating-up curves for infrared panel radiators (Monforts); abscissa = time [min].

chines require a large amount of space as sufficient production is only possible with long frames. Where short frames are used, the setting time can be reduced and production increased by integrating IR radiators with short-wave radiators (tungsten quartz burners). Electric and gas heated IR-predriers are known. Gas heated systems have heat recovery (Figs. 6 and 7). IR-driers can also be used before steaming machines.

Infrared fixation, e.g. the two-phase infrared process (Hoechst): printed fabric is padded and rapidly heated up without steam. No condensation occurs so there is less tendency for the printed fabric to mark-off or bleed. The recommended wavelength is 1300 nm at which a maximum radiation absorption of 80–85% is achieved.

Infrared laboratory dyeing machines The use of a liquid heat transfer medium (e.g. glycol) in laboratory dyeing machines can be substituted by heating the rotating dye beakers with infrared radiation; a particu-

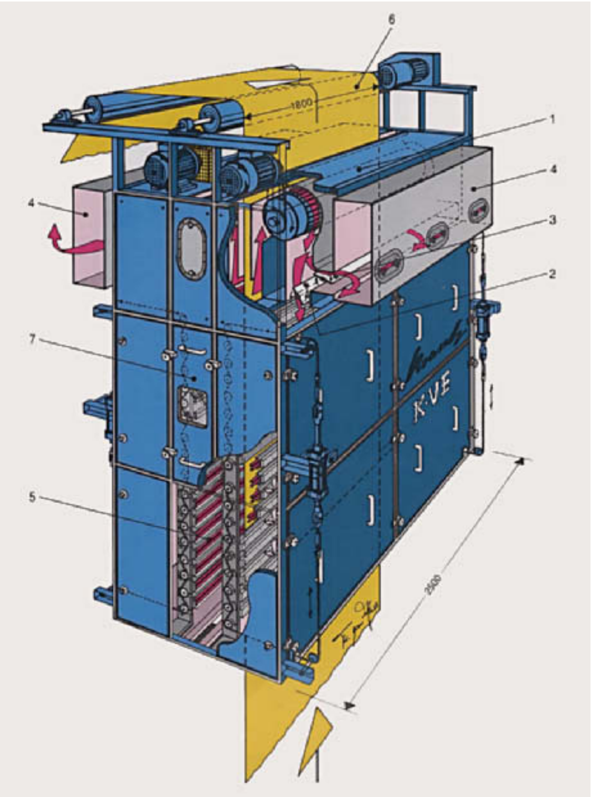

Fig. 6: Electrically heated infrared predrier (Krantz). 1 = circulating/exhaust air fans; 2 = circulating air regulating flaps; 3 = exhaust air regulating flaps; 4 = exhaust air ducts; 5 = gold vaporised IR-radiators, tiltable; 6 = driven deflecting rollers; 7 = flap with viewing window.

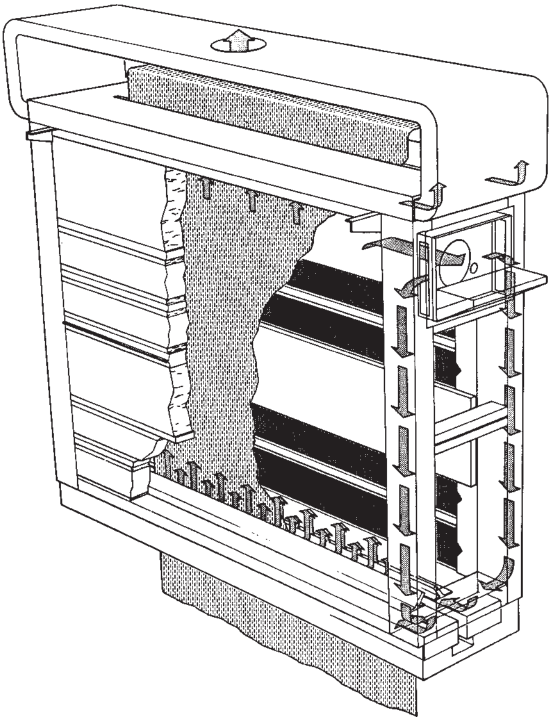

Fig. 7: Gas heated infrared predrier (Babcock).

larly intense absorption of heat is achieved with black beakers by this means.

Infrared moisture measurement Infrared light (IR) is absorbed to a different extent by various surfaces depending on wavelength. Water also absorbs IR energy of a certain frequency. If monochromatic IR light of one wavelength, at which moisture is particularly intensively vaporised, and another wavelength where there is virtually no absorption, is alternately irradiated onto a measuring device and the energy reflected in each case is compared, this will give the amount of moisture in the goods being tested. The so-called differential light process, i.e. alternately emitting a measuring beam and a comparative beam through the same beam entry point, is characterised by the fact that influences which affect both signals equally, i.e. structure of the goods to be tested, density, degree of reflection, ambient light, are largely insignificant.

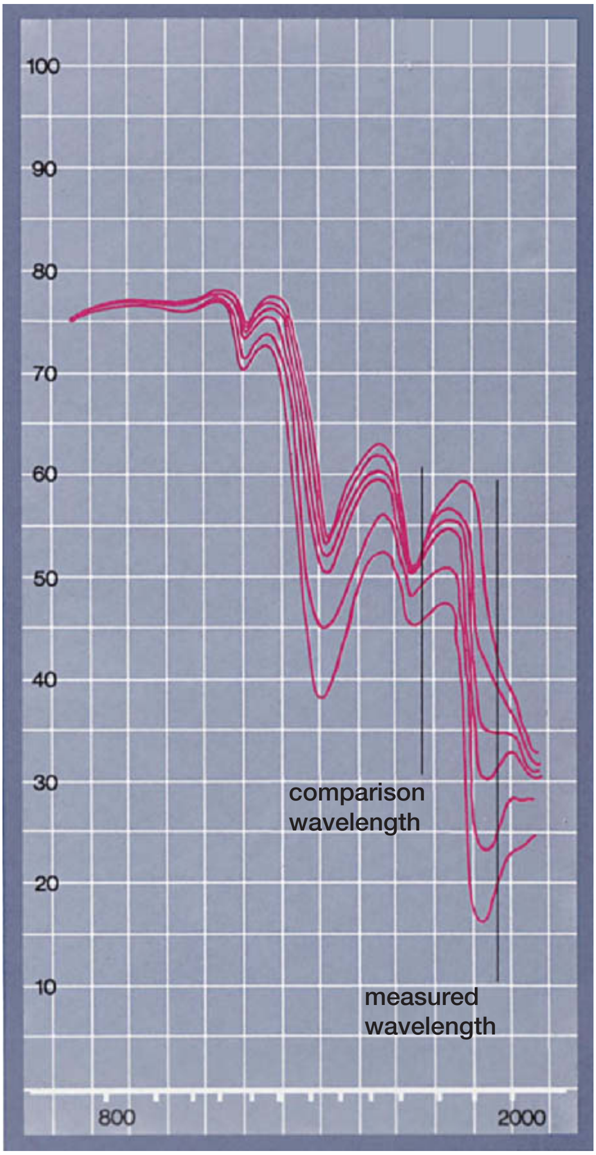

Fig. 1: Wool spectral curves in the infrared range.

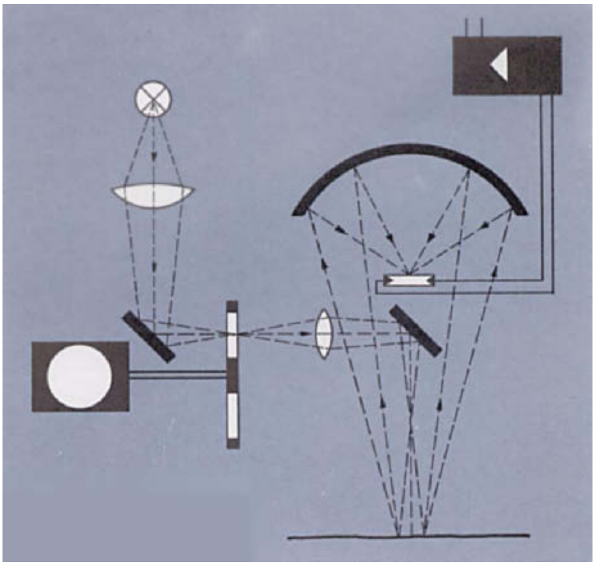

Fig. 2: Path of infrared radiation from light source to material to be tested and back (Mahlo).

The various wavelengths (Fig. 1) are obtained by two optical filters which are directed successively on a rotating filter wheel in the path of the rays. Monochromatic filters only transmit a very narrow section of the overall width of the infrared light. Different moisture measuring ranges may use different filters if preferred (exchanging the filter wheel). The distance of the reflective sensor to the goods to be tested is typically 100 ± 10 mm and is therefore relatively not critical. The ray of light should impinge both vertically and obliquely. The measuring point has a diameter of approx. 25 mm; in spec. cases it is thus possible to achieve an extremely well-defined reading (Fig. 2).

Infrared predriers Watertight infrared radiation fields in working widths up to 6 m are employed especially as predriers in printing, dyeing and finishing applications (Fig. 1).

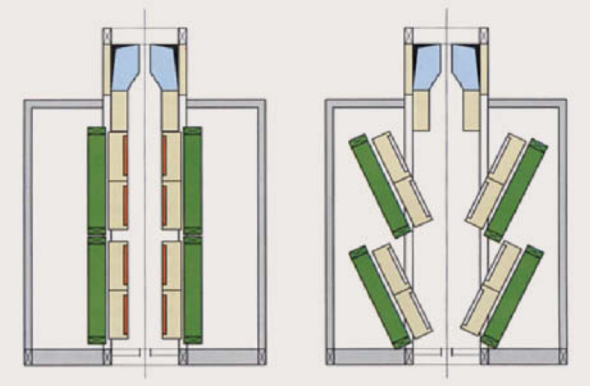

Fig. 2: Tilting electric infrared predrier (Matherm).

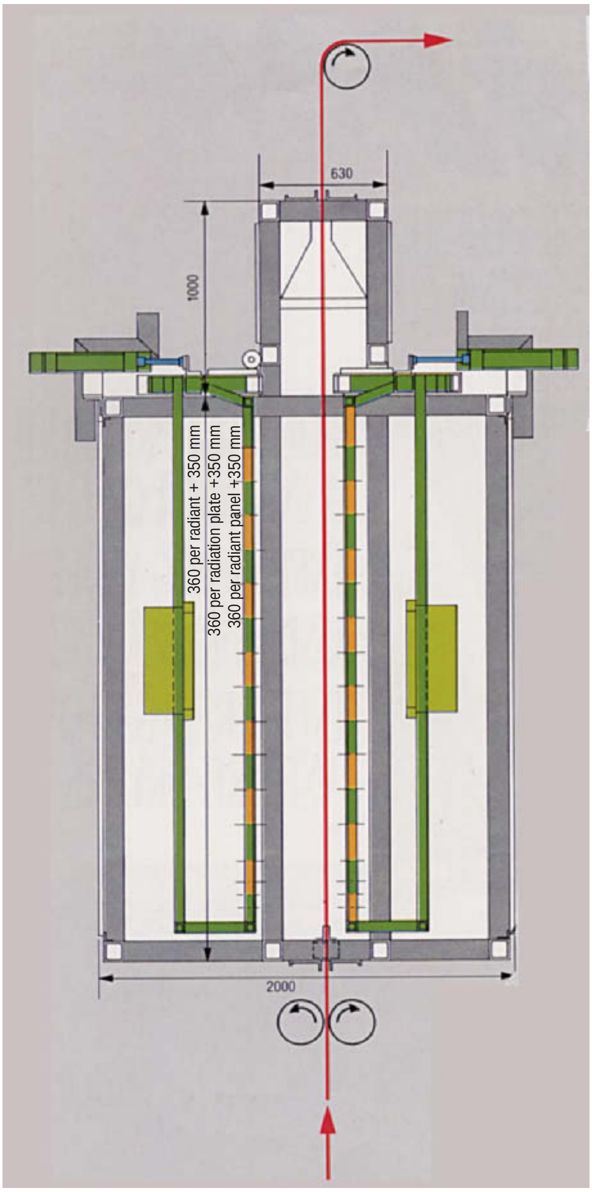

Fig. 1: Infrared-based AGT predrier.

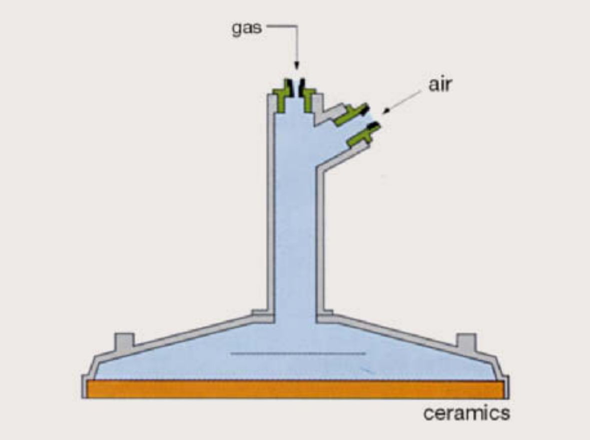

Fig. 3: Gas-heated infrared predrier (Matherm).

Both electrically-heated and gas-heated radiators (Figs. 2 and 3) are available.

Infrared reflectance As far as textiles are concerned, infrared reflectance is, in general, the diffuse reflection of light rays with wavelengths between 700–1200 nm. Infrared reflectance plays an important role in → Camouflage dyeings and prints.

Infrared-reflecting dyeings These dyeings represent the opposite of → Infrared-absorbing dyeings. Such dyeings are particularly suitable for cooling summer or tropical wear. Selected dyes with a pronounced reflecting capacity for IR-radiation, which are also described as “cold dyes”, are used for this purpose. A very extensive colour range, including almost all shades, is available for which most dye classes contain a relatively wide selection of individual representatives with over 70% reflection (monochromatic energy at the 1000 nm line). The IR-reflection of dyes used in the production of camouflage dyeings and prints for military purposes is of greatest importance here.

Infrared sensor Entry device for contact-free and mechanical sensing fitted to stenter driers, especially for sensitive fabrics and the detection of uneven edge migration with fine fabric qualities.

Infrared spectroscopy (IR-spectroscopy). An optical technique for measuring the absorption spectra of solid, liquid or gaseous organic compounds in the IR-region. The technique is also used for the determination of isomers and homologues. The IR-absorption curve obtained is compared with the known curves in a catalogue (e.g. Landolt-Börnstein) which permits a rapid identification of constitution. In IR-spectroscopy, transitions between molecular states, especially the vibrational and rotational states, are recorded. In order to record the absorption continuously, a beam of IR-light in the spectral region of 200–4000 nm is passed through the sample. From the resultant absorption peaks functional groups such as ketones, esters, etc., can be easily and precisely identified.

It is possible to carry out both qualitative as well as quantitative analysis by means of IR-spectroscopy. The “fingerprint” region of the spectrum in the range from 650–1 450 nm is particularly suitable for qualitative analysis. With very few exceptions, molecules have characteristic vibrations (skeletal vibrations) in this range which enable the analyzed substance to be identified. The Fourier-transform IR spectrometer (FT-IR) is particularly important for the quantitative analysis of low concentrations. In contrast to conventional IR-spectrometers, the IR-ray is not resolved spectrally at different angles in FT-IR instruments, a stream-splitter as well as a fixed and movable mirror are used for interference. Mirror movement is controlled by a helium/neon laser. The interference signal is digitally recorded and subjected to Fourier transformation. The FT-IR spectrometer is not only capable of recording IR-spectra, the investigation of material surfaces is also possible with appropriate accessories.

Besides the analysis of environmentally-relevant substances, the qualitative and quantitative analysis of textiles, with regard to their fibre composition, is also possible by means of IR-spectroscopy. IR-spectroscopy also offers the possibility to determine weaving and spinning assistants, e.g. sizes, quantitatively after extraction and the preparation of a calibration curve.

Infusorial earth → Kieselguhr.

Ingrain dyes An imprecise description formerly used for all colorants which were produced *in situ* on the fibre by the development or coupling of one or more intermediate compounds.

Inhibitors (Lat.: *inhibere* = to restrain). Substances which retard or stop specific chemical reactions or processes, e.g. →: Antioxidants and Corrosion inhibitors. In the so-called swelling treatment (→ Inoculation) of water conditioning, use is made of the inhibiting action of small amounts of sodium metaphosphate (0.5–2 g/m3) which amounts to only a fraction of the required quantity to prevent the formation of calcium carbonate crystals.

Initiator A reaction accelerator or promoter, e.g as in radical polymerization. Its action is similar to that of a → Catalyst, except that it is usually consumed in the reaction whilst a catalyst remains free.

Injector A device used in the colour kitchen of a printing plant for the preparation of e.g. thickeners. The substance to be dissolved is sucked into the injector by low pressure. The low pressure is produced by spraying water through nozzles with an overpressure. By this means, the substance is wetted out at the same time. The concentrate thus formed then passes from the injector into a mixer turbine.

Ink Coloured inks are aqueous solutions of coal-tar dyes with suitable additives. Both cationic dyes (e.g. rhodamine, fuchsin, methylene blue) and acid dyes (e.g. eosin, ponceau, nigrosine, acid blue) are used. Black inks consist mainly of a mixture of gallic acid, tannic acid and an iron (III) salt (iron gall ink). Uses: dyeing, drycleaning, varnishes.

Inking couple Dye paste trough with transfer roller and printing roller in the roller printing machine.

Ink jet A stream of liquid in the form of a dye solution produced by a spray nozzle.

Ink jet colorant application A contact-free application system for colorant solutions. → Ink jet colorant application.

Ink jet printing In the ink jet process (Fig. 1) there is no contact between a dye applicator (e.g. engraved roller or screen) and the material being printed as in conventional methods of printing. Rather, dye liquors (inks) are squirted through fine microprocessor-controlled jet nozzles. This operation is carried out almost silently at high speed on surfaces which can be in any form: e.g. eggs, wadding, metal cans, etc. Special requirements are placed on the inks and their additives both for the ink jet techology itself as well as for the various media to be printed. The inks must be of low viscosity, have adequate fastness to light and water, and a pH as close as possible to neutral. They must also be rapid-drying without, at the same time, drying-out in the printer head, and must also be non-corroding and possess a certain surface tension.

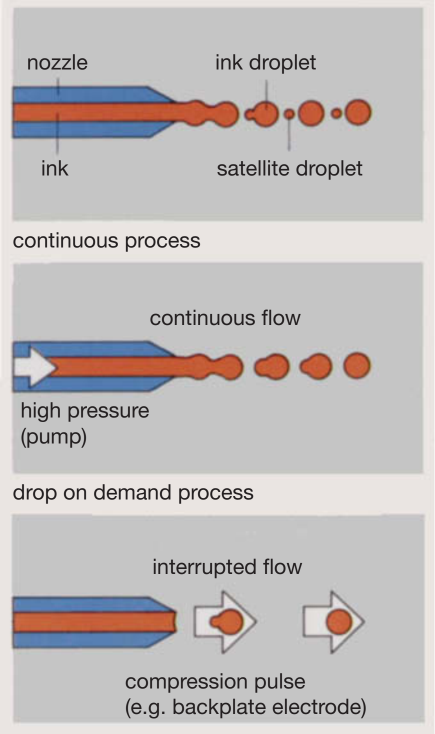

Fig. 1: Ink jet process functional principle.

The first functionally-reliable apparatus for ink jet application was an oscillograph. In this apparatus the rotary magnet of a galvanometer system is located on a fine glass capillary which functions simultaneously as a torsion thread. The upper end of the capillary is bent at an angle of 90° so that the flow of ink from the end of the capillary produces an ink stream in the direction of the substrate. The stream is deflected in rhythm with the galvanometer current. Modulation is achieved by rotation of the jet nozzle opening and continuous translation of the substrate. This apparatus, named “Oszillomink”, was developed in 1948/51 by Elmquist.The upper operating frequency is 1000 Hz.

By using special inks, formed into ink droplets (according to either the piezo-electric or the thermal “bubble-jet” principle), substrates with appropriate reactive groups (protein or cellulosic fibres) can be “printed” or better, patterned, with chlorotriazine reactive dyes by the ink jet process if the fabric has been pretreated with a colour intensifying auxiliary.

Ink jet printing may be conveniently subdivided into two types, continuous and drop-on-demand. The

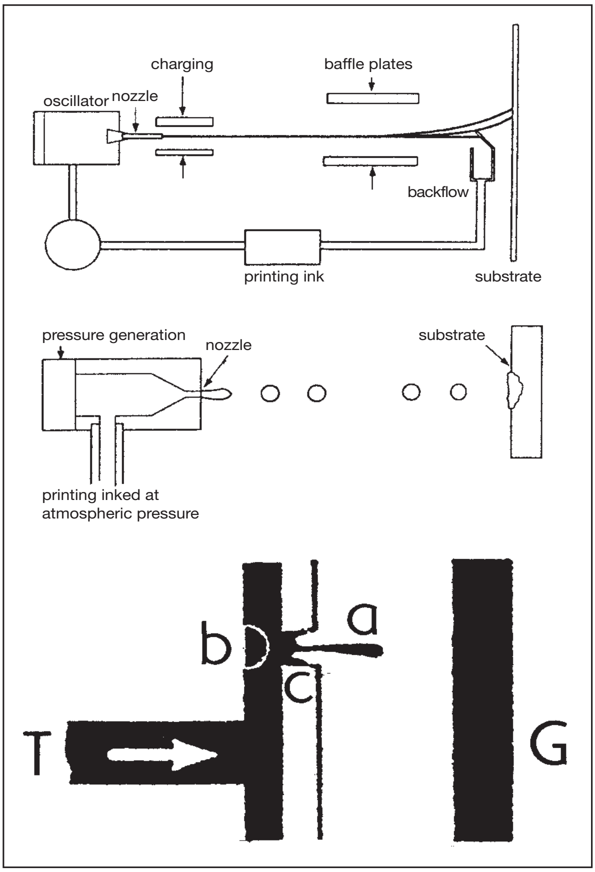

Fig. 2: Continuous ink jet process (top) in comparison with the periodic drop on demand piezo process (centre) and in comparison with the periodic drop on demand bubble jet process (T = ink feed; a = ink droplet; b = evaporating ink; c = nozzle; G = substrate).

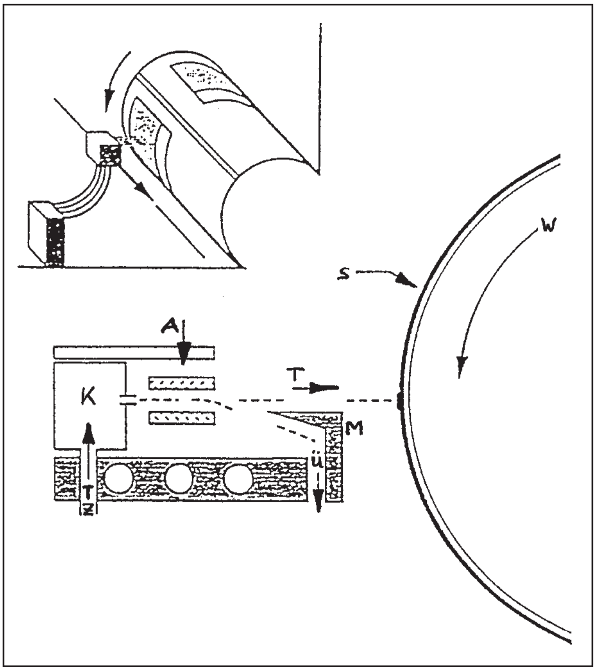

Fig. 3: Principle of IRIS-Graphics and Stork ink jet printing. Ü = diverted excess ink (is discarded); M = knife; W = roller; TZ = ink feed; A = cover plates; T = sprayed ink; S = substrate.

main difference between the two lies in the means by which the ink droplets are formed. In the continuous process (Fig. 2) ink is accelerated at moderate pressure through a jet nozzle and formed into droplets by a piezo-electric head which oscillates at high frequency. The droplets are electrically charged and deflected on to the substrate electrostatically.

In the drop-on-demand (DOD) method, a distinction is made between the piezo-electric and the bubble-jet process. The first process also uses a piezo-electric element but without a control mechanism. The speed of the droplets is slower and only sufficient droplets are formed as are actually required. The bubble-jet process (developed by Canon) uses a computer signal to produce an electric current on a non-conducting layer within the jet nozzle which reaches a temperature of around 400°C in 5 µs. This causes local vaporization of the ink and the shock wave from the expanding bubble ejects a drop of ink from the jet orifice at high velocity.

Stork has been particularly concerned with developing the application of ink jet technology as a printing alternative for cotton fabrics with reactive dyes (Fig. 3). Stork Screens BV has developed the TruColor Jetprinter 2500 (TCP-2500), based on Hertz technology, for the rapid production of colour-fast samples on textile fabrics. The conventional sample printing machine and sample table can be largely substituted by this system. The TCP-2500 works according to the Hertz continuous stream technology. A special valve for textile dyes as well as the necessary software (to control the printer from a CAD station and allow design information to be printed) have been developed for the practical application of this technology.

In continuous jet printing, a continuous stream of dye droplets is formed which is directed on to a substrate by a jet nozzle. This is achieved at a frequency of 625 kHz (625 000 droplets per second per colour). These droplets are selectively charged with a negative electric charge. The charged droplets are deflected in an electrostatic field and returned to a dye storage tank. The uncharged droplets are directed on to the substrate where the design is built up in the desired colour way. The system is based on four-colour printing (i.e. cyan, magenta, yellow and black).

A special type of reactive dye had to be developed in order to achieve optimum colour reproduction on the textile substrate since all the printing colours formerly used for the jet printer were unable to meet the requirements of the textile market. In collaboration with Zeneca Colours UK, therefore, new reactive dyes, based on the Procion P range, have been developed.

Ink jet printing technology,

I. Continuous ink jet printing. In this form of ink jet printing, the continuous stream of dye liquor forced out of a fine jet nozzle is controlled either by deflection or superimposition of a deflector plate (Electrocolor process) or deflection by means of compressed air (Millitron process). The excess dye liquor is collected and returned to the storage tank.

II. Drop on demand ink jet printing. In this case, discrete drops of dye liquor are jetted by switchable electromagnetic valves located in the dye liquor feed tubes in a predetermined sequence determined by the pattern being printed (Chromotronic process).

III. Quantitative control of the ink jet as in the Agfa ink jet process, etc. → Ink jet printing in the non-textile sector.

Inlet-controlled water heater In this type of water heater, stored water in a boiler is heated by excess steam which thus serves as a heat accumulator for the plant. The accumulator temperature can reach up to approx. 95°C. Heating of the stored water is entirely dependent on times when excess steam is available. The lower boiler is provided with a steam damper. The upper boiler functions as an instantaneous water heater, i.e. incoming cold water absorbs heat and is then supplied as hot water to the point of use. The boiler works without pressure and is in constant balance with the outside air. Even when used with high pressure steam there is no risk of explosion. Boiler scale and corrosion are hardly a matter for concern since the stored water is reused without interruption. With appropriate heat insulation there are practically no heat losses. This flow-through heating system for the production of hot water represents an economical process at a low investment cost and is much more advantageous than storage tanks and boilers which function solely as hot water accumulators.

Inlet material, bed ticking Inlet material is a thick cotton or viscose fabric in a 3-shaft twill weave which has a down-proof (feather-proof) weave and finish; generally red, but is also available in other colours. Use: for bed ticking.

In-line measurement This refers to the measurement of values without taking a sample, e.g. in the production system. → On-line.

Inner drum Rotating cylindrical drum of the → Double drum machine serving as repository for the treatment of items in washing, cleaning or dyeing and having agitator ribs, a segmented drum and perforations in its periphery. The inner drum is mounted axially either on one side with the loading door in the front face (front loading washing machine) or on both sides (for capacities exceeding 50 kg) with a top loading door (tangential). There is also a free axis inner drum which is suspended from stainless steel chains which are themselves actuated by a reduction gear drive. Every type of inner drum is enclosed within the robust → Outer drum. Washing machine inner drums of up to 90 cm diameter are usually not segmented but may have vertical dividing walls. Drum segmentation usual if the diameter exceeds 90 cm.

Innovation Conversion to forward-looking solutions, e.g. to technical production or processing problems. Perfection of existing, and the introduction of new, technologies, methods, experiences, new markets, etc.

Innovation time The time span required for the → Innovation of a product or process from the beginning of development to the commencement of industrial production or introduction to the market.

Inoculation Minimum dosage process for the prevention of boiler scale in boiler feed water by the complexing of hard water salts. The process is also commonly used for the removal of already-precipitated scale sediment in cooling water. A distinction is made between:

1. Acid addition, preferably with sulphurous acid which is less corrosive and also binds atmospheric oxygen at the same time.
2. Phosphate addition: 2–5 g/m^3 (e.g.) for the prevention of scale in cold and hot water piping systems.

Inorganic chemistry A term for the branch of chemistry concerned with the chemical behaviour of all elements and their compounds with the exception of those carbon compounds which fall within the province of → Organic chemistry. Today approx. 50 000 compounds are known.

Inorganic fibres Also described as → Mineral fibres. More exacting requirements in the field of environmental protection, the performance of materials, or the productivity of existing systems also calls for the development and use of newer types of fibres. The importance of inorganic fibres of oxide or non-oxide basis is due, above all, to the extremely high temperature resistance of various physical or chemical properties up to temperatures greater than 1100°C. Due to this outstanding property, this important generation of fibres will be of interest in the future for the solution of problems where resistance to high temperatures in processing or application is demanded. Yarns produced from mineral fibres are suitable, e.g. in the form of woven fabrics or braids, for heat insulation purposes as well as the reinforcement of specific electrical and thermal composites.

An increased environmental awareness, especially in the field of energy conservation and exhaust gas filtration, the higher requirements placed on material properties such as strength or stiffness even at high temperatures (the future-oriented development in the field of fibre-reinforced metals and ceramics is a striking example here), and the higher performance of e.g. fabric-reinforced printed circuit boards (for the electronics industry), are examples of tasks which will be solved by the use of special inorganic fibres in future.

Inorganic fibres are characterized especially by their high temperature resistance combined with higher specific strength and stiffness or their special physical or chemical properties. Complex requirements in various fields of application make the careful selection of appropriate types of fibres or yarns essential. Amongst the special inorganic fibres, products based on silica yarns have aroused particular interest as well as the extremely temperature-resistant Al_2O_3 and SiC fibres and yarns which are also used for the reinforcement of metals and ceramics.

INRA (Fr.), abbrev. for : Institut National de la Recherche Agronomique (National Institute for Agronomic Research). A French textile research institute. → Technical and professional organizations.

Insecticide A substance used to kill or destroy insects in the form of:

a) an oral poison (acts as a stomach poison provided it is taken with the insect's food),
b) a contact poison (which acts on the nervous system),
c) a respiratory poison (which acts on the respiratory organs). → Mothproofing.

Insecticide chemicals Chemicals which provide protection against insect infestation and are able to protect textiles from destruction by insects such as moths (→ Mothproofing), termites, silverfish, etc. Such products are based on e.g. fluorides, organic phosphonium, ammonium and sulphonium compounds as well as triphenylmethane and urea derivatives.

Insect repellent An odoriferous substance (repellent) for insects which is particularly effective against flying insects (insect protection). Insect repellents are used to produce → Insect repellent finishes on textiles which are effective for a limited period of time. Not to be confused with → Insecticide.

Insect repellent finishes In contrast to the use of → Insecticide (oral or contact poisons, etc.), special odoriferous substances (repellents) are employed for the purpose of repelling insects. These substances are unpleasant or unbearable to insects and therefore have a repellent effect as far as insect bites are concerned whilst, for humans, they have only a slight or even a pleasant odour. Repellents of this kind find widespread use as skin creams, body oils, etc. Experience has revealed that such insect repellency is rather non-specific and a relationship between chemical constitution, physical data and insect repellency appears questionable. Useable repellents are, as a rule, neutral, viscous oils of low volatility or crystals with low melting points and, almost without exception, a bitter taste. In order to maintain the longest possible activity, such substances must, in addition, not give rise to skin irritations or cause damage to textiles. Suitable products for textile impregnations include, e.g. indalone, undecenoic acid, mandelic acid hexyl ester, N-cyclohexyl-2-(butoxyethoxy)acetamide, etc. A patent for the production of insect repellent hosiery recommends saturation with quaternary ammonium compounds followed by subsequent drying and heating to approx. 100–150°C.

Insible interlinings → Interlinings.

In-situ reactive dyeing In order to shift the reaction equilibrium of a reactive dyeing on cotton to the right (see equation)

$$\mathrm{CellOH + ClRBF} \rightleftharpoons \mathrm{CellORBF + HCl}$$

to achieve a reduction in the pollutant load of the effluent (with unbound reactive dye), attempts can be made to increase the fixation yields on dyed cellulose , e.g. in the cold pad-batch method by appropriate process technology. Better yields are thus achieved in the Babcotherm drier (by the Ecoflash process or with Remazol dyes; Fig. 1). In the case of in-situ reactive dyeing, however, an entirely different approach is also possible by synthesizing the azo dye step by step on the fibre.

Under suitable conditions, reactive dyes will react with the hydroxyl groups of the cellulose fibre. As is well-known, however, this reaction does not proceed quantitatively since a certain proportion of the dye reacts to form the dye hydrolysate. In order to achieve high colour fastness, therefore, this hydrolysate must be removed from the completed dyeing as completely as possible. In some cases, a considerable amount of washing is required in order to achieve satisfactory removal of the dye hydrolysate. The amount of washing required depends, amongst other things, on the particular shade and the depth of dyeing and is also greatly influenced by the substantivity of the dye; ease of hydrolysate removal in washing is much more difficult with dyes of high substantivity than those with low substantivity. The alternative idea for a "two-stage" formation of dye on the substrate is not a completely new concept and has already been discussed in a publication by B. Bröcker and D. Fiola, where a reference by H. Rath in his Textbook on Textile Chemistry (*Lehrbuch für Textilchemie, 1st edition 1952, published by Springer-Verlag*) describes the reactive bonding of naphthols to cellulose in order to improve colour fastness. The present idea for a new, unconventional method of reactive dyeing without the undesirable generation of coloured effluents is based on the following procedure (according to Hilden, Grütze and H. K. Rouette: a colourless reactive component of small molecular size is applied to the cellulose fibre and covalently bonded to it by means of a reactive anchor under customary textile reaction conditions. After this reaction is complete, the unfixed hydrolysate of low substantivity (due to its small molecular size) is washed off. Then, in order to form the final dye (i.e. the chromophore system), a colourless diazonium salt (e.g. diazo-

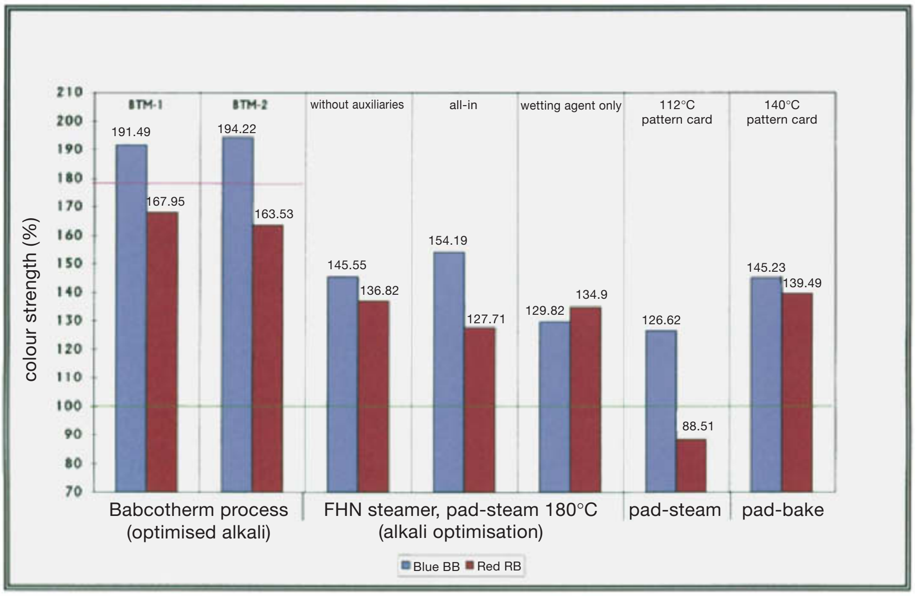

Fig. 1: Comparison of colour strengths (Remazol dyes) achieved in different processes. Reference = cold pad-batch process, washed/ pattern card = 100% colour strength. (source: Voth, Krix and Rouette).

tised o-sulphanilic acid) is coupled to the covalently-bonded reactive component during a so-called "illumination" stage. The sole function of the final short wash-off treatment is to remove excess o-sulphanilic acid. This procedure is described as the "ISR method", (i.e. in-situ reactive dyeing). Because of the large number of possible reactive components known, and the use of a single illumination compound, the colour range which can be achieved by this means covers over 80% of textile shades. In addition, a wide variety of reactive anchors may be employed. The outstanding feature of the new "ISR process" is the use of small molecular size reactive components of low substantivity which gives excellent levelness, good covering of structural differences in the fibre, as well as high rates of reaction. Of prime importance, however, is the relative ease with which the small molecular size hydrolysate can be removed during washing-off and the associated savings of water, energy and time (Fig. 2).

Because of the low substantivity of the individual components already mentioned, preference is given to applications on the pad. If a horizontal padder (with liquor application in the wedge between the padder bowls) is used for the cold pad-batch process in order to bond the reactive anchor to a cotton twill fabric during subsequent batch rotation then, after an appropriate dwell time, illumination can be carried out subsequently in the jigger. The build-up capacity of a typical red colour with this dyeing method (compared to a corresponding conventional reactive dye) of 453% at 0.05 mol/kg is good compared to a 100% colour strength at 0.01 mol. If the cold pad-batch fixation yields of these red dyeings after washing-off are compared with one another by means of reflectance measurements at 20 mmol/l in each case, then maximum fixation yields are already achieved with the "ISR method" after dwell times of 10 hours (Fig. 3). Based on the respective reactive content, fixation yields for the ISR components and the conventional dyes achieved in cold pad-batch dyeing are well over 90% (Fig. 4).

A more rapid reaction is achieved in the pad-thermofix-wash process. In this case, maximum colour

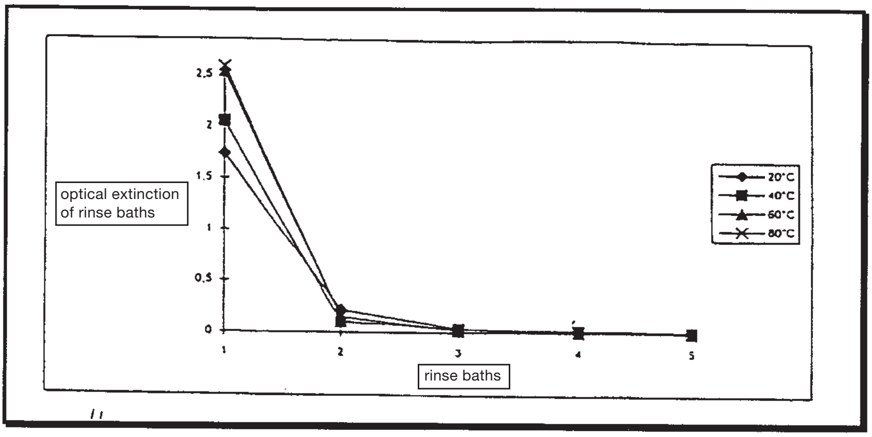

Fig. 2: Ease of washing out the reactive hydrolysate.

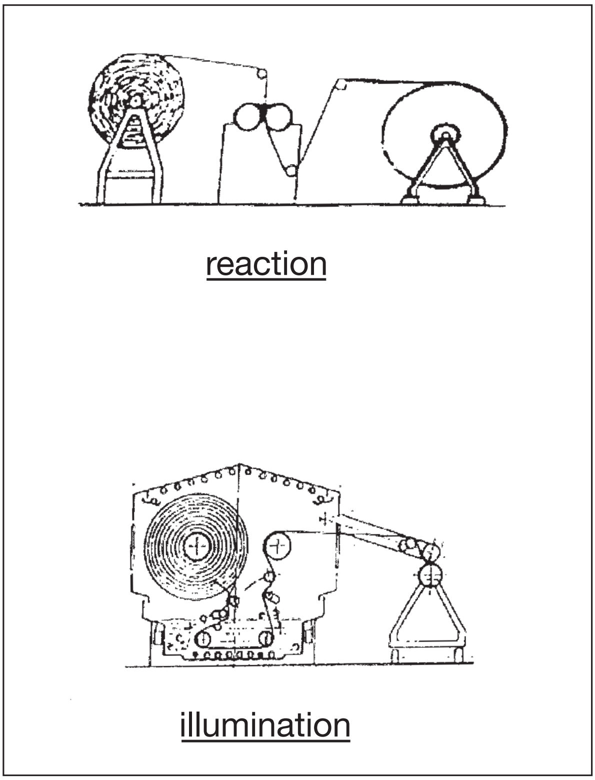

Fig. 3: Reaction and illumination.

strengths are already obtained after a reaction time of 1 minute at 150°C (Figs. 5 and 6).

For the diazotization reaction in the illumination stage, an approx. quadruple molar excess of activated o-anthranilic acid is required with deep dyeings when coupling is carried out in an alkaline liquor for only 5 minutes (LR = 10 : 1) (Fig. 7).

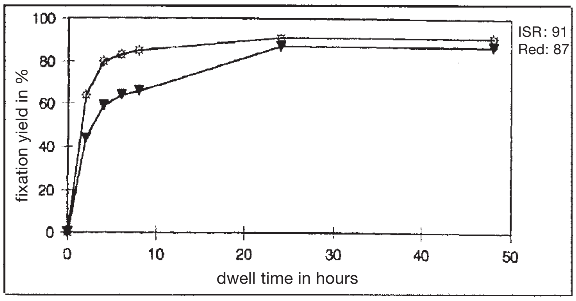

Fig. 4: Fixation yields in the cold pad-batch method ("ISR method" = 91%, conventional = 87%).

If four different cold pad-batch reactions are treated in a jet dyeing machine as a single batch and illuminated with a maximum of 2 mol (1 mol excess) of o-sulphanilic acid, then four colours are developed in-situ

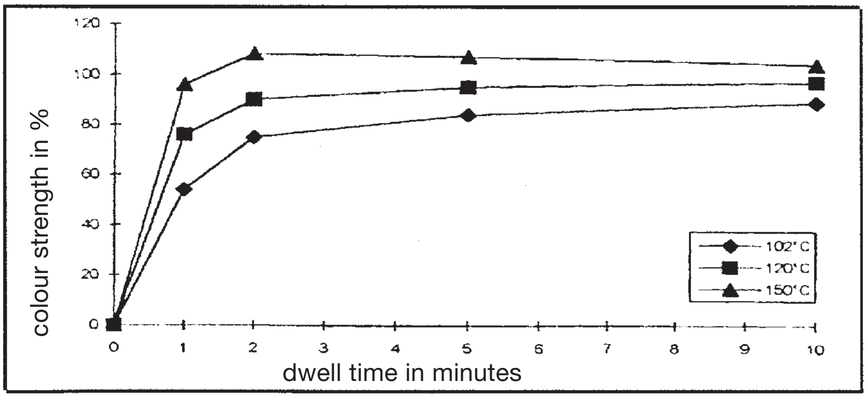

Fig. 5: Fixation yields in the pad-thermofix-wash method by the "in-situ reactive method".

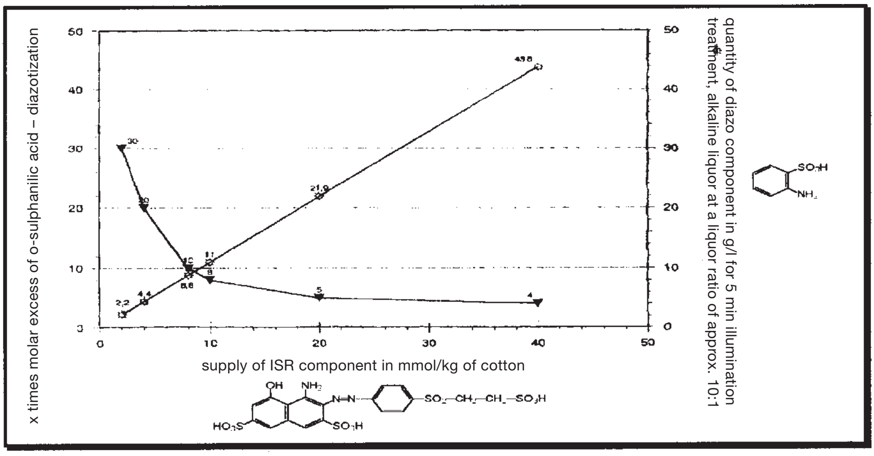

Fig. 7: Coupling ratios.

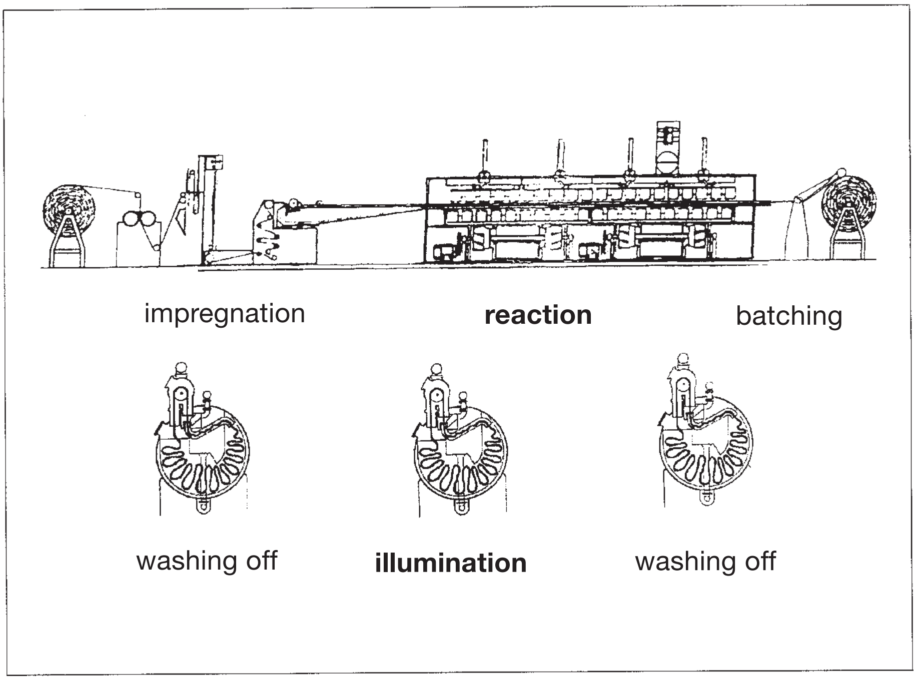

Fig. 6: Process stages involved in the "in-situ reactive" dyeing method.

simultaneously in the jet (Fig. 8). The rinsing and illumination stages take about an hour. The COD values of the effluent from overflow rinsing after 25 minutes are practically zero mg O_2/l for the 4 reaction fabrics; these values rise again during the illumination stage to a maximum of 500 mg O_2/l since the system has been dosed with 2 mol of activated o-sulphanilic acid, but the values fall again to around 100 mg O_2/l after 60 minutes and after the 1st rinse.

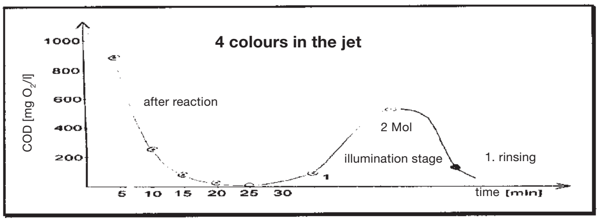

Fig. 8: "In-situ reactive" effluent COD values.

The essential characteristics of the "ISR method" derived from the foregoing can be summarized as follows:

1. the method is limited to applications on the padder,
2. it involves a 2-stage process, i.e. padding/exhaust process,
3. diazotization is carried out "in-situ",
4. the chemical process stages have been transferred from the dye maker to the customer.

The low substantivity of the reactive cold pad-batch/or pad-thermofix components already described above, which is the underlying principle of this method, limits their application to cold pad-batch and pad-thermofix processes only due to the fact that fixation yields in exhaust processes are unsatisfactory since the necessary substantivity for such processes is lacking. This means that "in-situ reactive dyeing" must be concentrated on certain important market sectors of reactive dye application: 20 000 tonnes/annum for cold pad-batch and 18 000 tonnes/annum for continuous processes, compared to 70 000 tonnes/annum for the exhaust process. The stability data for the particular diazonium salt of the o-benzene sulphonic acid used here, which has been precisely investigated, requires that the diazotization stage has to be undertaken immediately before dyeing, which means that the active chemical procedure is now carried out by the customer which is not very popular nowadays. In connection with these chemical limitations of the "ISR process", it is important to realize that brilliant yellow, golden yellow, orange and red shades are actually achieved from colourless reactive components, which is the basic precept of the process, i.e. the conversion of colourless dye precursors on the fibre into coloured dyes. The necessary change in wavelength required to produce a blue shade from two colourless dye precursors by means of an azo bond has unfortunately not proved successful; rather, the shade range requires a coloured reactive component which would unavoidably result in coloured rinsing water. Trichromatic dyeings produced from the individual components of yellow, red and blue are too reddish. The colouristic sectors of the market for brilliant blue, light-fast combination blue, turquoise and brilliant green are unfortunately not covered by the "ISR process". An innovative dye manufacturer has placed a wide spectrum of customer-oriented products and an innovative process at the disposal of the textile industry. The results are being tested by DyStar for market relevance and customer benefit in collaboration with various partners. At the present time, therefore, the example given in the foregoing report on the "ISR process" does not appear to justify further active development under the current technical and economic conditions relating to textile wet processing in the reactive dyeing of cellulose.

Inspection and mending The repetition of a previously carried out material treatment (i.e. as an aftertreatment). In the case of hosiery, the repair of defects such as ladders, small holes, etc.

Inspection machine Textile fabrics are examined on inspection machines after completion of the final finishing process. The fabric inspector carries out the following tasks: quality inspection, detection and recording of faults, defect marking. The fabric runs at full width over an inspection table, an inclined table top which, under certain circumstances, is illuminated from below towards the fabric inspector (matt glass plate). In some cases, defects detected visually can be manually entered direct into a fault marking and recording system. For many articles, such defects can be marked and recorded in this way whilst the goods are running which considerably increases the efficiency of the machines. Inspection machines are adapted to handle all forms of textile fabrics, i.e. from plaited goods on to rolls, rolls into plaited goods, and roll to roll. For tubular knitgoods, inspection machines are available for checking both sides of the fabric in a single operation.

Inspection tables → Inspection machine.

INSTA, abbrev. for: Inter-Nordiske Standardiseringsarbejde, Denmark (Scandinavian Standards Association); → Technical and professional organizations.

Intaglio A method of printing in which the design is engraved beneath the surface of a printing plate or cylinder, e.g. as in roller printing.

Integrated finishing A form of textile finishing in which textile material purchased by the finisher is finished and then re-sold, in contrast to → Commission finishing.

Integrated heat recovery A system in which heat recovery elements are integrated into the doors of stenter driers. Heated exhaust air is already cooled down in the drying chamber via a countercurrent heat exchanger thereby heating up the incoming fresh air which is then mixed with the circulating air.

Integrated pollution control In addition to downstream pollution control measures, "production-integrated" pollution control has assumed increasing importance. This involves the operation of plants in which environmentally-polluting emissions are reduced on a decentralized basis and, in ideal cases, prevented or in which the residual products can be re-used within the production processes. With the utilization of residual products as feedstocks in another process within the production plant or even in another plant, the term production-integrated pollution control has taken on a wider importance. The objectives of research and development in process technology will in future be particularly aimed at:

- the optimization of reaction conditions with regard to yields,
- the recycling of unreacted starting products and assistants within the plant,
- the separation of by-products and their use in another process,
- the reprocessing and cleaning of exhaust air and waste water.

An example of integrated pollution control in which the recovery of starting products and the cleaning of exhaust air and waste water are combined is the process employed for manufacturing polyester. In this process, environmental pollution has been almost entirely avoided. For the synthesis of polyester, para-xylene, ethylene glycol, atmospheric oxygen and methanol are required. The methanol used in the process can be recovered and recirculated. The formation of by-products results in slight losses of methanol. Only these quantities of methanol need to be freshly added in the process. The catalyst used in the process is likewise separated off and recycled. Only a small quantity of catalyst therefore needs to be freshly added. In addition to the desired polyester chips, only carbon dioxide and small amounts of carbon monoxide are formed as waste materials from the raw materials used, due to skilful process control and waste water/exhaust air combustion. In this process, therefore, it appears that apart from negligible amounts of pollutants, only the desired end-product leaves the manufacturing plant in practice.

Integrated pollution control solutions In an ideal situation, textile processing takes place in a closed system, i.e. the production material, "water", which is loaded with additives in the form of chemicals, is fed in a cycle without the sludge having to be disposed of externally. The energy required for waste water treatment is used as the middle stage of an exergy-cascade in the form of exhaust air combustion energy after the energy supplied to the plant has been optimally used for production purposes. Where surplus heat is produced in the closed operating system, the integrated concept should be extended to external consumers by using the excess for local heating. The intention is therefore to achieve textile finishing operations orientated towards recycling the working materials - water, dyestuffs and textile auxiliaries - at the same time as optimally utilising the process energy used without externalising ongoing costs related to removing by-products in a way which is detrimental to the economy as a whole. As the necessary internal electricity is produced using a gas turbine, $^2/_3$ of the energy converted in this should be used as process heat (in the form of steam for dyeing and finishing processes for textiles and to dry these at high-frequency current). The residual energy in the form of steam ensures the distillation of all waste water concentrates. The resultant distillate is reused as process water.

A plant may have sufficient energy in the form of heat from high temperature exhaust gases from the combustion of textile exhaust air.

a) to clean critical exhaust gases in a combined heat and power generation system by cleansing the NO_x content from after combustion products with catalysts using ammonia dosing; these are incorporated via a recuperation system;
b) to concentrate critical process heat in cascades after it has been usefully separated into partial streams and concentrations so that harmless ash can be dumped after the following processes have been carried out: evaporation by excess waste heat, partial recovery of potential recyclable dyestuffs and textile auxiliaries from the sludge formed, the biological degradation of the sludge in putrefaction basins in order to produce methane as a combustible gas and combustion of non-recyclable residual substances. Attempts are also being made to isolate surfactants with a new type of Cavitand technique and to process residual dyestuffs to form synthetics;
c) to convert the environmentally harmful carbon emissions into an environmentally-friendly energy carrier by releasing excess waste heat which is transferred during condensation of the evaporated distillate via recuperators to a local heating cooperative.

The integrated concept is comprised of the following:

1. The focus on the primary energy, gas (and to a limited extent the exhaust gas, methane, produced from the putrefaction basins when refuse is processed) which is used in gas turbines to produce internal electricity and to utilise the waste heat converted in the form of steam in the waste water distillation process (by using the waste heat in a waste heat boiler to produce steam). Gas is also used to provide vapour for production. Although the use of the primary energy, gas, increases the CO_2 emissions from the plant, the concept reduces the CO_2 production seen as a whole, if the production of external power (using coal, oil and atomic energy) is taken into account when assessing the overall CO_2 emissions. The entire old boiler house system used to produce steam by burning primary energy is no longer required.
2. Combustion plants in production (particularly certain dyeing and drying plants) are, in the long term; being converted to high-frequency drying. These operate on the basis of “power” without CO_2 emissions, thus reducing the emissions of critical waste gas, which affects decomposition products of chemicals evaporated during drying.
3. External electricity is used when the plant is overloaded. If excess electricity is produced, electricity is supplied to the general electricity grid.

Integrated process The combination of several elements in a system, e.g. the combination of individual finishing machines in a continuous processing plant.

Integration dyeing The method involves maintaining the concentration of dyestuff in the dye bath at the lowest possible level throughout the dyeing process. This is achieved by gradually introducing a dyestuff to the dye bath in accordance with the known diffusion rate of the dyestuff or dyestuffs in question. Integration dyeing is of particular advantage when dyeing using dyestuffs which have a high affinity to the fibre but a low diffusion rate, which makes possible the use of direct and vat dyes with which level dyeing is difficult. Diffusion measurements have confirmed that the aggregation is dependent upon concentration and (more significantly) the temperature, these therefore being factors which underlie integration dyeing (from Vickerstaff).

Integration of CAD systems CAD and drafting systems must be capable of integration into the production stages of textile manufacture. In order to follow market trends as quickly as possible (quick response), CAD systems used in the plant (e.g. for textile printing) must be integrated into a network. A designer does not have the technical expertise of the dyer just as a dyer does not have the experience necessary for the creation of new products. Both should be able to extract the data for their work from the same database, i.e. the designer obtains the exact colours for the creation of his product and the dyer/printer obtains exact data for dye recipe generation and the coloration process.

When systems for designers and colourists are installed on different computers and these are integrated with one another via a network, a common database can be accessed from any work station, i.e. using the same data source. Depending on the particular manufacturing stages in the plant, individual systems can be connected to this network so that any combinations of individual systems are possible (Fig. 1).

I. Colour system (CS): with this system it is possible to represent all popular colour specifier systems, and use them to produce electronic collection portfolios for subsequent product simulation. The advantage of this procedure lies in the fact that the colour coordinates of all colours defined in this way are known. These values can then be transferred to the CAD system for colour mixing or to calculate dyeing or printing recipes by computer colour matching (CCM). With this system it is also possible to generate in-house colour systems. The possibility also exists to determine particular shades by interpolation whereby the respective colour coordinates are also calculated each time.

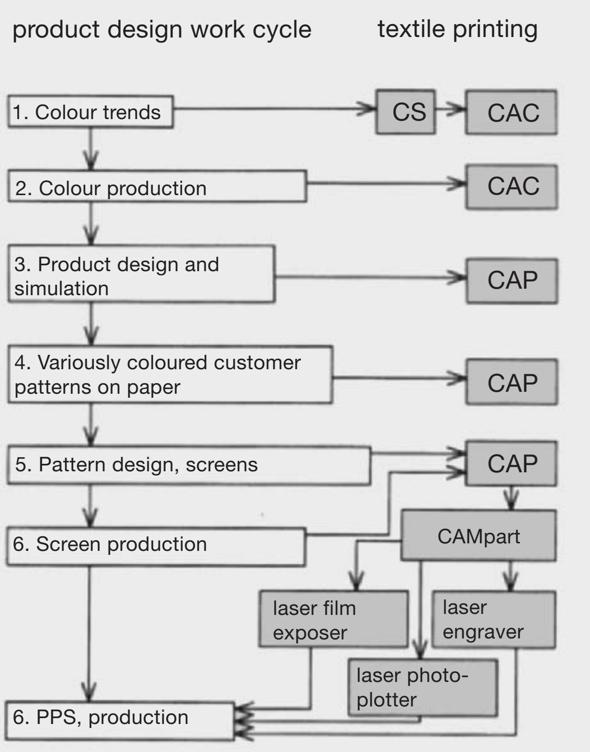

Fig. 1: Integration of textile industry CAD systems.

II. Computer Aided Colouring (CAC): in this system, colours are mixed with the aid of actual calibration dyeings. In compiling the range for these calibration dyeings, all product-specific conditions can be taken into account at the outset, e.g. so that only those dyes are selected which

- are actually suitable for application on the dyeing machines in the particular plant;
- are capable of meeting the required colour fastness to light or washing for the product in question;
- lie within the cost limits for the particular product.

By means of this procedure, it is possible to ensure that the colours selected to match a particular product can actually be produced subsequently under the given conditions already at the initial colour matching stage. A further significant advantage of this system is the fact that it can be integrated with Datacolor's "Osiris" computer colour matching system. Thus, CAC colour suggestions can be established first, followed by dye recipe generation with Osiris, and subsequent visualization of the recipes again on the CAC system under a wide range of conditions, all on the same computer.

The function of the CS and CAC systems is to establish colour collections for subsequent product design.

By building on the results of these colour collections, products can be designed on the display screen up to the actual simulation of a finished product depending on the particular textile manufacturing process. With all three systems, therefore, the data necessary for the product is automatically reproduced.

III. Computer Aided Textile Printing (CAP) is a system which enables all the processing stages as far as production of the final textile print to be carried out with computer assistance.

IV. Computer Aided Weaving (CAW) is a system which enables all the design work involved in dobby weaving to be carried out with computer assistance. In this case also, all the production stages, provided they can be connected to the computer, are linked to the system.

V. Computer Aided Jacquard Weaving (CAJ) is a system which covers all the various operations from designing through figure drafting, weave, construction pattern drafting to fabric simulation as well as machine control in jacquard weaving.

All these systems can be interlinked with one another and exchange information. This is achieved physically via a network (LAN = local area network) based on Ethernet hardware for PC networking and a common database. Various experts often carry out specific tasks at individual work stations since only a part of the information for the next manufacturing stage is necessary. All these systems are linked to the production (Fig. 2).

In Fig. 2, the work flow involved in product design for textile printing is represented schematically. Consideration of the six work stations involved in this

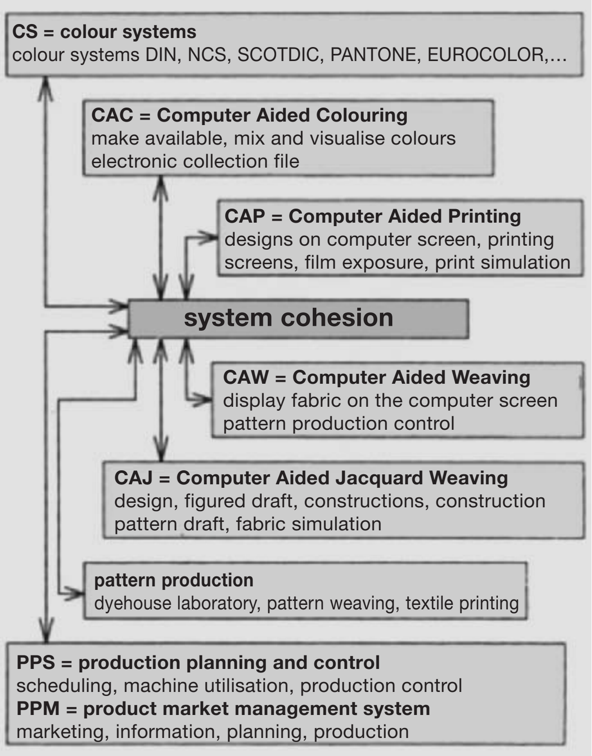

Fig. 2: Production stages and integration.

scheme immediately reveals that all these operations are not carried out by one and the same person. Even in this specific sector of textile manufacturing, it is also necessary for a variety of experts to make their own contribution to the success of the entire operation. The networking possibilities resp. the individual work stations of the system must therefore be made available to all the various functions involved in textile print production such as coloration, product design, product planning, engraving, sampling, film and screen making, and the colour kitchen (source: Fieles-Kahl).

Interactions Interactions between polymer chains (in fibres) are based on hydrogen bonds, salt linkages, hydrophobic bonds or chemical crosslinkages (see Fig.). Interactions also occur between polymers and compounds of low molecular weight (e.g. dyes).

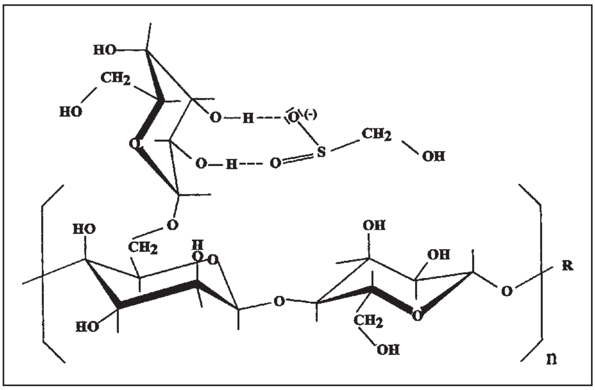

Fig.: Schematic diagram of possible interactions between alginate and formaldehyde sulphoxylate.

Intercellular A term meaning between cells, and refers to the non-crystalline (amorphous) regions, e.g. in fibres (→ Crystallites).

Intercellular cement An intercellular binding material which holds the cortical cells together in → Wool structure. It is analogous to sericin in → Silk structure.

Interchange impregnation Interchange impregnation refers to the impregnation of wet fabric on a padder or in a roller vat (see Fig.). During this process, there is a partial exchange between the water introduced by the fabric and the impregnating solution. Contrast → Additive pick-up.

Interface The surface of e.g. fibres, soil particles, etc., in contact with water, auxiliary solutions and wash liquors (→ Surface tension). In the case of porous solid substances especially, the (micellar) surface with its numerous macroscopic and submicroscopic channels must also be taken into account, besides the externally visible surface, which presents (with its air occlusions) a considerable interface for internally diffusing substances (dyes, auxiliaries). Thus, the micellar surface of 1 g cotton cellulose, for example, is approx. 5000 m^2.

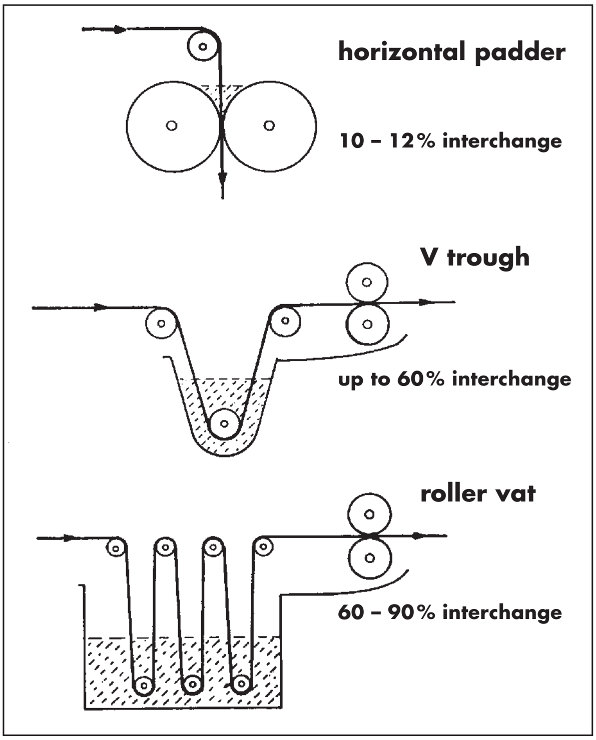

Fig.: Interchange effects of different impregnation processes.

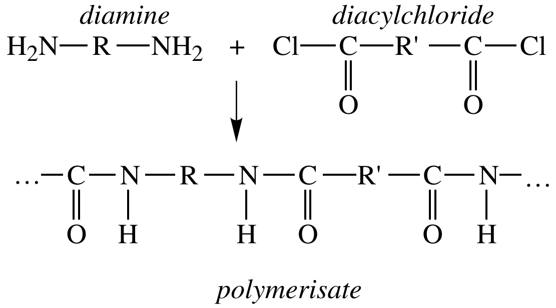
Interfacial layer in tenside solutions This is the layer which extends across an → Interface. The thickness of this layer is determined by the fact that the concentration of the adsorbed substance is higher in this layer than in either of the two adjacent phases.

Interfacial phenomena Phenomena in the form of mechanical, electrical, optical effects, etc., which occur at the → Interface between two phases (liquid/gaseous).

Interfacial polymerization (IFP). Polymerization in which two reactive monomers, each dissolved in different solvents that are mutually immiscible, react at the interface between the two solutions. As applied to the antifelting shrink-resist finishing of wool, interfacial polymerization occurs at the contact zone between an aqueous alkaline solution of a diamine and an inert solvent (e.g. 1,1,1-trichloroethane, carbon tetrachloride or toluene) containing an acid chloride. In semi- or fully-continuous processing, an ultra-thin film of polyamide is formed on the fibre surface. In the Bancora process, for example, 1,6-diaminohexane and sebacic acid dichloride are used for this purpose. The process can be combined with mothproof and crease-resist finishes thereby improving serviceability properties. Neither the dyed shades nor the colour fastness of the dyeings are affected by the treatment.

The principle of this interfacial polymerization is as follows:



$$H_2N-R-NH_2 + Cl-\underset{\underset{O}{\|}}{C}-R'-\underset{\underset{O}{\|}}{C}-Cl \longrightarrow \ldots-\underset{\underset{O}{\|}}{C}-\underset{\underset{H}{|}}{N}-R-\underset{\underset{H}{|}}{N}-\underset{\underset{O}{\|}}{C}-R'-\underset{\underset{O}{\|}}{C}-\underset{\underset{H}{|}}{N}-\ldots$$

Interfacial tensiometer (according to Lecomte du Noäy and Seelich). An instrument for measuring the surface tension between two liquids. Applications: for testing the effectiveness of wetting agents, emulsifiers, soaps, etc.

Interference (Lat.: *inter* = between, *ferire* = to strike). Superimposition. A term used in physics for superimposition phenomena caused by the coincidence of waves (radiation) having a certain phase relationship to one another which can be observed in the region of overlap.

Interference filters These are composed of a suitable combination of thin films having different properties in which specific wavelength regions of light are supressed or allowed to pass through by interference (superimposition). The most common are metal interference filters produced by successively evaporating e.g. semi-transparent silvered films of suitable thickness on glass plates between which is a thin film of magnesium fluoride.

Interionic bonding forces → Ionic bond.

Interior lighting The aim is to create an environment which contributes to the well-being of the workers, prevents both accidents and fatigue, improves quality and minimizes waste. Several quality features directed at lighting in the various areas of the product process are significant in order to optimally fulfil these conditions.

The nature of the visual task to be carried out determines the level of illumination used. Minimum values as prescribed in DIN 5035 must be adhered to. These values refer to the relevant working planes. Compliance with the minimum values is monitored and required by the employer's liability insurance association and industrial supervisors during plant inspections.

Interlace Interlace is a mechanical yarn cohesion of (carpet) yarns which are manufactured with zero twist and formed by the interlacing of the individual filaments. → Intermingling.

Interlining More or less heavily finished → Interlinings such as →: Buckram; Linen interlining; Horsehair cloth; Nonwoven material, etc. as well as →: Wadding; Shoulder padding, etc. which is fused or sewn inside specific parts of a garment (i.e. between the inner and outer layers) to improve shape retention, strength, warmth or bulk.

Interlinings (linings). Interlinings are the "skeleton of clothing" which ensure a lasting fit. They are sewn to the outer fabric in the form of fabrics, knitwear or nonwovens or combined directly with these (fixed). Natural and man-made fibres, animal fibres and blends are processed. Sophisticated finishing methods provide the interlinings with specific properties depending on their intended purpose. Types of coating, adhesive compounds and add-ons in particular make it possible to adapt the various interlinings appropriately to all outer fabrics, from the finest batiste to silky jerseys, poplin, carded and worsted yarns to fleecy coating, leather and fur. Interlinings correspond to the outer fabrics in terms of their tendencies to shrink, wear comfort and care characteristics. They support and enhance these characteristics.

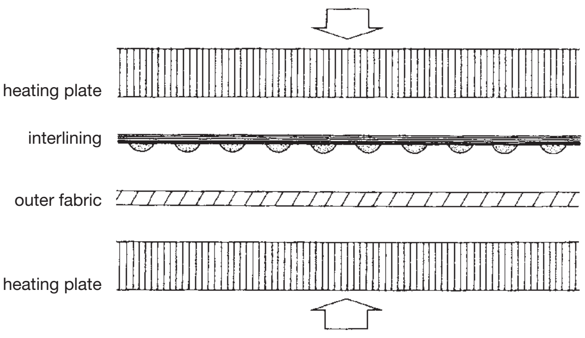


Fig.: Interlining heat setting operation.

In the past, interlinings were laboriously sewn into items of clothing in single or multiple layers as wadding, but today, the processing of fixable interlinings is predominant. These can be permanently bound to the outer fabric rationally using setting machines and pressing. This bonding, which is resistant to washing and dry-cleaning, is achieved by the influence of temperature, time and pressure.

A number of fixing points (meltable polymer applied to the interlining as a dot coating in mesh = number of setting points per inch) are used to bind the interlining and outer fabric (see Fig.) in the steam press (fusing temperature) between two steam platens. This is also referred to as front fusing.

Classification:

1. Elastic interlinings (the weft material is decisive for wrinkle recovery): hair linings, nonwovens, woollen wadding.
2. → Stiffened fabrics including hot melt adhesives.
3. → Interlining.

Some basic requirements: weight and ability to hold shape should be tailored to the outer fabric and intended purpose (no losses during wear), characteristic elastic recovery, no undesired deformations when sitting, good air permeability (no heat build-up or bothersome perspiration), total shrink resistance and resistance to repeated moisture and heat (during tensionless drying and pressing) and resistance to dry cleaning. The quality of the interlining has a significant impact on the serviceability of the garment. A high level of resistance to washing is required for shirt interlinings. High and low pressure polyethylene are suitable for this. These interlinings can be applied using the powder dot, dot or scatter coating method; the dots have an aqueous base. Interlinings display shrinkage conformity if any residual shrinkage alterations mirror those of the outer fabric.

Interlock materials Interlock materials are fine-meshed knitgoods produced on the circular knitting machine which are used for close-fitting undergarments etc. An alternative form of this is referred to as cross tubular goods. Interlock is the combination of two 1/1 rib knits. Only plain stitches are visible on either side of the fabric as the reverse stitches are found inside the knitted fabric.

Intermacrofibrillar cement Intercellular cement in → Wool structure.

Intermediate drying in textile printing Intermediate drying is carried out between the printing of each colour in a multicolour design in hand screen printing in order to prevent marking off during printing with the individual screens. In mechanized flat and rotary screen printing, as well as roller printing, intermediate drying is carried out between printing and steaming in order to preserve the sharpness of the print and avoid marking off. Intermediate drying is omitted in carpet printing.

Intermediate filament According to current nomenclature in protein chemistry, the microfibrils in the → Wool structure are formed from a type of low-sulphur proteins which are referred to as intermediate filament (IF) proteins. The matrix consists of proteins containing glycine and tyrosine, as well as proteins containing sulphur, known as intermediate filament associated proteins (IFAP).

The smallest link in the hierarchy of the wool structure is the α-helix (see Table). These combine to form protofibrils. These in turn combine to form microfibrils, which then result in macrofibrils, surrounded by the matrix. The α-keratins, as the main chemical constituent of wool are insoluble, hard substances which are highly elastic. They are present in the macrofibril in the form of two components, the microfibril and the matrix. The matrix consists of tyrosine and sulphur proteins, whereas the low-sulphur proteins are assigned to the microfibrils. The macrofibrils on the other hand form the cortex cell, embedded in the intermacrofibrillar cement. Chemically, the intermacrofibrillar cement is a non-keratin protein consisting of cytoplasm and residual nuclei.

Fibril type	Build-up in cross-section	Diameter (nm)	Length (nm)
Macrofibril	approx. 700 microfibrils	300	10 000
Microfibril (intermediate filaments)	8 Protofibrils	10	1 000
Protofibrils	4 Polypeptide chains	2	1 000
Individual intermediate molecule	2 Polypeptide chains		50
Polypeptide chain α-helical	1 Polypeptide chains	1	50

Tab.: Build-up and dimensions of fibrils in wool (all figures are approximate values).

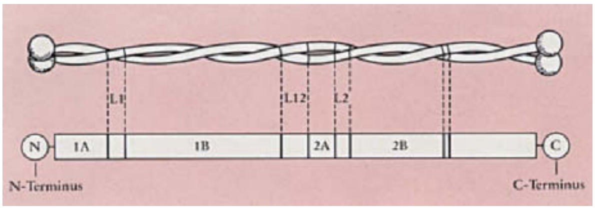

Fig. 1: Two entwined intermediate filaments.

During biosynthesis, dimers (Fig. 1) are formed as a result of parallel pair generation from a basic and an acid keratin (intermediate filament). The individual keratin has a rod domain consisting of α-helices. There is a double-strand super helix or coil in the dimer. The stability of the dimers depends on this particular double-twist quaternary structure which involves hydrophobic interactions. The next intermediate product is the “four-chain complex” which consists of 2 antiparallel dimers and represents the structural component of the protofilaments. It has been assumed for some time that there are protofilaments with a diameter of 2–3 nm in wool and hairs from microscopic electron tests. Earlier hypotheses on the number of protein chains in the cross-section of a protofilament have now been outdated, and the current theory is that tetramers supply a protofilament by means of longitudinal associations. Another theory is that 8 (as opposed to 9 + 2, as quoted in earlier literature) protofilaments combine to form one complete intermediate filament (Fig. 2). A filament is therefore made up of 8 tetramers (16 dimers or 32 single skeins) in cross-section. The length of a subunit is 50 nm and the length of an intermediate filament in wool and hair is 50 µm. 32 000 individual monomer keratin molecules, including 16 000 each of type I and type II form a nucleated filament. The details of how this occurs are not completely clear.

The intermediate filament associated proteins (IFAP) together with the filaments form the macrofibril. In hair, these proteins have long been known as a

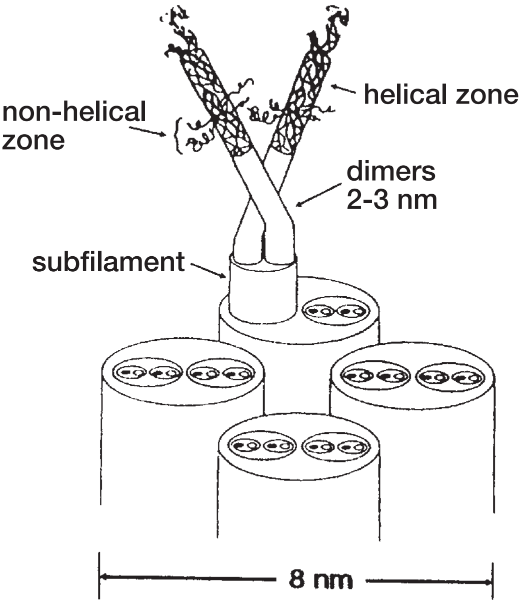

Fig. 2: Diagrammatic view of the intermediate filament from 8 protofilaments.

group of proteins containing on average 30 molar percent of cystine and have been isolated from the hair as soluble fractions by mercaptolysis, generally in the form of s-carboxymethyl derivatives or recently also as s-sulphates. There are however no generally recognised values either concerning the number of individual members of this family of sulphurous hair proteins nor the molecular masses. Even the ordered state is disputed. Some regard the entire "matrix" as amorphous, others as orientated at least in the fibre direction, and others even regard these proteins as paracrystalline, although by no means helical like the intermediate filament. One problem is the low yield of keratin and IFAP with reductive hair extraction of approx. 20% weight (source: Zahn).

Intermediate membrane in → Wool structure between the cortical layer and the scale-cell layer.

Intermediate reduction clear A reductive clear process to remove staining of the natural fibre component with disperse dyes in the dyeing of blends with synthetic fibres.

Intermediate solvent A solvent miscible in two different types of media such as methyl acetate (soluble in benzene and also miscible with 3 times its weight of water) and ethyl ether (soluble in benzene and also up to approx. 7% in water) etc. → Hydrotrope.

Intermediate support frame A frame containing fabric guiding elements installed between individual machines in a continuous production line to ensure trouble-free fabric feed from one machine to the next.

Intermicellar regions → Crystallites.

Intermingling (entanglement, interlacing). Intermingling involves the use of air jets to create turbulence in order to entangle the filaments of continuous filament yarns, without forming loops, after extrusion. Provides dimensional stability and cohesion for further processing without the need for a twisting process. If an intermingled yarn is produced from two varieties of differential-dyeing filaments, e.g. 50% deep-dyeing and 50% basic-dyeable types, effects from an intensive melange to a heather appearance are obtained after dyeing depending on the intermingling and mixing of the filaments, instead of the marl effects obtained with twisted yarns.

By comparison, intermingled yarns with four-sided cross-sections and hollow spaces are superior to all other forms by having an optimum combination of light-refracting and light-reflecting properties with minimal soil adhesion; the effect is most clearly observed in pile fabrics with a sideways-tilting pile.

Intermingling of filament yarns (→ Intermingling). Aerodynamic cohesion (produced by an air-jet) which, depending on the type and end-use of the particular synthetic filaments, may entirely or partially replace twisting and/or sizing. Excessive intermingling is undesirable since it can easily spoil the effect of the finished fabric. A high intermingling density is, however, desirable, i.e. a large number of interlacing points and their uniform distribution throughout the length of the filaments.

The intermingling process involves passing one or several filament yarns through the turbulent zone of an air-jet at right angles to the direction of the air stream. As a result, some or all the filament yarns are intermingled at localized points, i.e. they are intermingled with one another to achieve cohesion. A continuous jet of air produces a discontinuous quasi-periodic effect. Interlacing points (interlaces) alternating with open, non-interlaced areas of yarn are created by this means. Intermingling is often regarded as equivalent to air texturing. There are, however, considerable differences between the two processes (see Fig.). In air texturing,

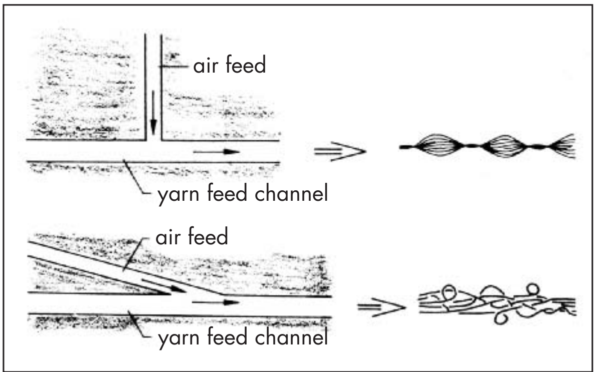

Fig.: Comparison of the principles of intermingling (top) and air texturing (below).

the filament yarn is over-fed at a rate of up to 30% through a turbulent air stream at an oblique angle so that the filaments are displaced relative to one another in a longitudinal direction thereby achieving a much higher level of entanglement by forming entangled loops in the filaments which imparts a hairy, staple yarn like character with the objective of producing texture or bulk. It is precisely this effect which should be avoided in the intermingling process (source: Weinsdörfer).

Intermittent (Lat.: *intermittere* = to leave off). To be suspended temporarily or at regular or irregular intervals; periodic.

Intermittent printing Printing on rotary screen printing machines whereby the printing operation of the screens is interrupted for a predetermined interval. By this means, larger repeats can be added to the normal rotary screen circumference during printing and design combinations are obtained which could not otherwise be realized on a printing machine.

Intermittent roller printing machine (“Jumper” printing machine). In this machine two sets of engraved printing rollers are employed, each set being brought in turn into contact with the fabric being printed on the pressure cylinder of the printing machine. As soon as the printing of one set, say that of the cross-border, is completed, its rollers are withdrawn or „jump away“ from contact with the pressure cylinder and the other set (“filling” rollers) simultaneously comes into action which is likewise withdrawn after printing a predetermined length of fabric. Intermittent machines are used for the printing of saris, sarongs, and certain types of Africa prints.

Intermolecular attraction forces → Secondary valency forces.

Internal A term which means within or centrally located. Used, for example, to indicate the position of typical groups in the long-chain thread molecules of textile auxiliaries. See also → External.

International Fabricare Institute (IFI). Founded in 1972 by the merger of two former leading American institutes of laundering (AIL) and drycleaning (NID). It is today the largest organization of its kind in the world concerned with the textile care sector (research, specialized courses, advisory service, information); → Technical and professional organizations.

International Federation of Associations of Textile Chemists and Colourists (IFATCC). Also known as the “Internationale Föderation der Vereine der Textilchemiker und Coloristen” (IFVTCC); → Technical and professional organizations.

International Grey Scale → Grey scales for fastness testing.

International Organization for Standardization → ISO.

International System of Units → SI System of Units.

International Textile Club (ITC). International professional organization of leading specialists from all branches of the textile industry; → Technical and professional organizations.

International Textile Service (ITS). A Swiss publishing house providing information on textile production. Publishes the quarterly technical journal “International Textile Bulletin” in several languages.

International Wool Secretariat (IWS). Independent organization for publicity and research service in the entire wool economy. Founded in 1937. Supported by the wool producers of Australia, New Zealand and South Africa with headquarters in London and branches in almost all textile countries. →: Woolmark; Technical and professional organizations.

International Wool Textile Organization (IWTO). Head organization of the world wool economy, resident in the U.K. → Technical and professional organizations.

Interpenetrating polymer networks → IPN.

Interweaving → Contraction.

Intimate blend A technique of mixing two or more dissimilar fibres in a very uniform mixture usually by mixing the fibres in loose stock form before or at the picker, in contrast to normal mixtures of warp and weft (e.g. polyester warp wool weft, and vice versa).

Intracellular A term describing processes within the cell (→ Crystallite), e.g. the further penetration of intracellular reactions from the intercellular spaces through the crystalline surface of the cell causing changes in the structure of the cellular building blocks. Of importance in severe fibre damage (acids: cellulose, caustic alkalis: wool).

Intramicellar Identical to → Intracellular.

Intramolecular salt A zwitterion molecule, e.g. betaine and the types of salt linkages in wool keratin. Attempts are also being made to describe intramolecular complexes as intramolecular salts.

Intrinsic error limit → Error limit.

Intrinsic viscosity → Viscosity index.

Intussusception dyeing (Lat.: *intus* = within, *susceptio* = deposition). A deposition dyeing in which new dye is progressively inserted into the thickness of an existing fibre wall. The cross-section of an intussusception dyeing is fully penetrated by dye, i.e. homogeneously dyed throughout, e.g. acetate acid wool and cationic dyeing. Compare → Apposition dyeing.

Inversion (Lat.: *invertere* = to invert),

I. A chemical reaction involving a change from one optically active configuration to the opposite configuration. The term inversion refers to the effect of a solution on the rotational direction of polarized light, e.g. the formation of a laevorotatory solution of glucose and fructose (→ Mutarotation) by the hydrolytic break down of a dextrorotatory solution of sucrose (cane-sugar). Glucose is dextrorotatory but fructose is more strongly laevorotatory which is the reason for the mixture formed (invert sugar) being laevorotatory.

II. Inversion is also used in the sense of an inversion of electrical charge, e.g. in so-called → Invert soaps, i.e. cationic textile auxiliaries in comparison with anionic ones.

Invert soaps Cationic textile auxiliaries including disinfectants and preservatives. The term invert soaps is used because their surface active effect is due to the large molecular cation, i.e. the opposite of common (anionic) soaps.

Invisible marking An example of invisible marking is the invisible labelling of finished fabric samples which are to be assessed by a third party against rival samples and where it appears justifiable to test the factual evidence experimentally where assessment was inconclusive. Principle: local print or lettering covered with a colourless solution which is later "developed" to reveal the colour after drying. "Developers" and corresponding dyeings are suitable for this purpose, e.g. sodium carbonate/phenolphthalein solution = red, lead acetate/sodium sulphide solution = black, salicylic acid solution/iron (III) chloride = bluish-violet, potassium tetroxalate/iron (III) chloride = bluish red, cobaltous (II) chloride solution when heated = deep blue. In all cases, samples can also be illuminated beneath the quartz lamp used for analysis for "rapid developing" (→ Fluorescence).

Invisible mending (Interweaving). The invisible mending of areas of fabric (clothing, home textiles, etc.) using a take-up needle. This is a needlework service provided by mending companies and dry cleaners. For small defects such as tears and holes, threads are pulled from the hem of the item and the needle is used to replace the damaged area thread by thread. The needle is woven through the fabric, the thread is drawn through and inserted (first the warp, and then the weft). For larger defects, a rectangular piece of the same material is taken (from a concealed area), this is frayed by 1–1.5 cm at all four ends and pinned to the damaged area to match the pattern. The frayed edges are then "woven into" the surrounding material using a latch needle.

Iodine (Gr.: *iodes* = violet-coloured: so named because of the colour of the vapour). Nonmetallic element of atomic number 53 and atomic weight 126.85. Valencies: mostly 1 and more seldom 3, 5, and 7. Iodine forms compounds which are mostly colourless. The element belongs to group VII of the periodic table under the → halogens. Pure iodine forms greyish-black graphite-like rhombic crystalline plates with a density of 4.93, m.p. 113.5°C and b.p. 184.4°C.

Iodine sublimes gradually even at room temperature (often causing a browning of the close surroundings). On heating to the boiling point, bluish-violet coloured toxic vapours are formed with a characteristic odour which cause severe catarrh-like reactions in the mucous membranes of the nose and eyes ("iodine cold"); TLV: ceiling 0.1 ppm in air. The violet colour of the vapours is caused by free I2 molecules whilst the brown colour of iodine solutions is, by contrast, caused by the formation of labile addition compounds between the iodine molecules and the solvent (charge transfer complexes).

Iodine azide reaction The reaction is used to distinguish between cupro and viscose fibres. It is based on the fact that slight traces of sulphur in viscose liberate nitrogen from iodine azide which rise to the surface of the fibre as bubbles (microscope). Procedure: 2 g sodium azide is dissolved in 100 ml of 0.1 n iodine solution. The fibres, previously degreased in petroleum ether, are placed in the reagent on a concave microscope slide with tweezers (without hand contact) and observed under low magnification. The formation of small bubbles only occurs with viscose. Iodine azide IN3 must be handled with care since it is easily detonated and is very explosive in the dry state.

Iodine number (iodine value). A measure of the amount of unsaturated acids present in fats and oils (i.e. the number of double bonds). It is obtained by finding the percentage of iodine by weight absorbed by the sample in a given time under standard conditions, i.e. the number of grams of iodine absorbed by 100 g of a fat or oil. To the cleaved double bonds of unsaturated fatty acids, elemental iodine is added according to the following equation:

$$\text{–CH=CH–} + I_2 \rightarrow \text{–CHI–CHI–}$$

forming a colourless iodine compound. The size of the iodine number thus indicates the proportion of unsaturated (free and esterified) fatty acids. Drying oils (linseed oil, poppy-seed oil, wood oil) have high iodine numbers (120–200); semi-drying oils (sesame oil, cottonseed oil, rapeseed oil, maize or corn oil, whale oil) have medium iodine numbers (95–120); whilst all non-drying oils and fats, on the other hand, have low iodine numbers (groundnut or peanut oil 86–98, castor oil 82–88, olive oil approx. 82, lard 60–68, palm oil 50–58, beef tallow 35–44, palm-kernel oil 10–18, wool grease 15–20, Japan wax 4–13, beeswax 8–11, sperm oil 4).

Iodine-potassium iodide solution (iodine test). 2 g iodine in 10 ml saturated potassium iodide solution (or 3 parts potassium iodide and 2 parts iodine in 45 parts water). Iodine is so loosely bound that it is liberated immediately in reactions. Uses:

I. For the detection of starch products: starch paste = dark blue; "soluble starch" = blue; dextrine = bluish-violet, reddish-violet or reddish-brown; maltose and glucose = colourless.

II. For the detection of mercerized cotton = bluish-black colour.

III. For the detection of polyvinyl alcohol in aqueous solution = blue colour.

Iodine solution → Iodine-potassium iodide solution.

Iodine sorption by cellulosic fibres The iodine sorption method is attributed to Schwertassek who attempted, amongst other things, to find a relationship between the iodine sorption number (ISN) and the proportion of crystalline regions in a cellulose sample. For this purpose, he measured absolutely crystalline and completely amorphous samples and produced a nomogram which indicated the relationship between the ISN and the degree of crystallinity. As a reference value he chose a partially hydrolyzed cotton for crystalline cellulose (ISN = 0) and starch or acetyl cellulose for the amorphous state. The influencing parameters for iodine sorption are: temperature, kinetics up to the point of equilibrium, concentration, thorough mixing, and the quantity of weighed cellulose (the smaller the weighing the more the iodine sorption). The bonding of iodine to cellulose generally takes place via adsorption forces and inclusion compounds. The sorption of iodine does not involve surface coverage. A uniform covering of the fibre has not been detected from investigations with the electron microscope. It must therefore be assumed that both molecular iodine as well as the tri-iodide are present. The tri-iodide is sorbed preferentially. Electrostatic interactions are formed between the partially positively-charged hydrogen atoms of the cellulose hydroxyl groups and the negative charge on the tri-iodide. The colour of the iodine-treated fibre sample can be taken as a further example for sorption of the tri-iodide. The brownish-black colour is indicative of tri-iodide uptake. This involves the formation of inclusion compounds in large voids of the fibre which do not exist in a chain form. Schwertassek explained the state of iodine in the fibre on the basis that amorphous cellulose is able to form blue iodine adducts (iodine chains with at least 14 iodine atoms) if the amorphous cellulose is capable of being transformed at a higher temperature and in the swollen state into the crystalline form. As a result, elongated channels can be formed between the crystallite units for the uptake of iodine chains.

Iodine-starch reaction → Iodine-potassium iodide solution.

Iodine-starch test The normal concentration of an enzyme in a desizing bath has an activity in the range from 50–300 Kilo-Novo-Units per litre (KNU/l) depending on the quantity of enzyme preparation used. The activity of a desizing liquor can be determined by the following method. The alpha-amylase in the desizing liquor degrades starch substrates. An iodine solution is used as an indicator so that the course of the reaction can be followed, and the time required to complete the degradation process is a measure of the enzyme activity. Two determinations are carried out in parallel, i.e. a standard of known activity and the sample of desizing liquor to be tested.

1. Solutions:

a) Water: approx. 1l distilled water is boiled for approx. 10 min and used to prepare the reagents and the substrates.

b) Buffer solution: 1 g sodium chloride + 7 g potassium dihydrogen phosphate + 0.5 g disodium hydrogen phosphate are dissolved in water and made up to 100 ml.

c) Iodine solution: stock solution (0.1 n) + 1.3 g iodine + 1.8 g potassium iodide are dissolved in water and made up to 100 ml. For the analysis, 5 ml of this solution are diluted with water to 1500 ml.

d) Standard alpha-amylase solution, e.g. 1 ml Dezyme 140 in 1 l of water.

2. Starch substrate: sufficient starch substrate for 5 analyses is prepared. 4.0 g of potato starch is sufficient. Soluble starch can also be used (provided it is always based on potato starch).

The starch is mixed with 50 ml water and the suspension poured into a tared 1 l beaker containing approx. 400 ml water which has been heated to approx. 55°C. The starch residue is swilled with 50 ml water and added to the contents of the beaker. The substrate is then heated to the boil under constant stirring and kept at the boil for 5 min. After cooling to approx. 50°C, 20 ml of buffer solution are added and the total weight is brought to 500 g with water. The substrate prepared in this way should have a pH of 5.8. In each case, 100 g of this substrate are transferred to 5 containers in a heated water bath at 40°C.

3. Analysis: 10 ml of enzyme solution (desizing liquor or standard) are added to 100 g of substrate which has been preheated in the water bath at 40°C and the stopwatch is started at the same time. In order to ensure complete mixing, air is conducted through the mixture or the contents are stirred vigorously with a glass rod. After 2 min a sample of 0.1 ml is withdrawn (corresponding to 2 drops from a Pasteur pipette with a flat-ground tip and an external diameter of 3 mm) and immediately mixed thoroughly with 60 ml iodine solution in a measuring cylinder. Samples of 0.1 ml are withdrawn at appropriate intervals of time until the iodine solution shows the same yellow colour as a blank test consisting solely of 60 ml iodine solution. The time taken to reach this point is noted. The coloration is best observed against a white background and is even more distinct when viewed vertically through the top of the measuring cylinder.

4. Calculation of activity: the amylase activity, expressed in KNU/l of desizing liquor, may be determined with the aid of the following equation:

$$A = A_S \cdot \frac{t_S}{t}$$

A = activity of desizing liquor [KNU/l],
A_s = activity of the standard [KNU/l],
t_s = reaction time of the standard,
t = reaction time of the liquor.

Iodine test → Iodine-potassium iodide solution.

Iodometry → Titration.

Ion-exchange chromatography → Chromatography.

Ion-exchange processes Modern ion exchange processes must fulfil the following requirements: total exhaustion of the bed capacity, high availability, low pollution of effluent , low space requirement, fully automated processes, constant water quality, even when the water flow varies, and the option of backwashing in order to enable substances, germs and fine grains of sand which can be filtered out to be rinsed away.

A distinction can be made between the ion exchange processes used predominantly by means of the regenerative techniques used and whether work takes place on a fixed bed or fluidised bed. In recent years, particular attention has been paid to reducing the regenerants used and consequently the salt fraction in the effluent. It was also necessary to investigate the behaviour of ion exchangers with respect to rinsing out pollutants and abraded resin, bacteria, particles etc. It was clearly demonstrated that the above mentioned substances cause difficulties in operation of such plants to a certain degree when ion exchange processes are being carried out, and that greater attention should be paid to these problems. Various regenerative techniques have been developed to optimise this type of plant.

I. Co-current regeneration: In the conventional co-current process, the exchangers are loaded and regenerated in the same direction. In particular where strong acid and strong alkali exchange resins are used, this requires a surplus of regenerant of up to 350% of the theoretical value in order to completely regenerate the resinous layer situated at the outflow. Despite this extremely high surplus, the very critical layers which cause the ion leakage into the pure water cannot be completely used to capacity. Univalent ions (labelled “C” in Fig. 1) break through, although the overall exchanger bed is still not fully loaded. When this break through occurs, the filtering activity must be discontinued. As a result, the entire ion exchange system is inefficient due to insufficient use of the regenerant and an insufficiently high percentage purity. If the problem of environmental protection is taken seriously, co-current regeneration exchangers should no longer be used and existing plants consequently dismantled.

II. The counterflow technique in the fixed bed process: It is possible to eliminate the disadvantages of the high regenerant surplus if regeneration occurs in the opposite direction to operation. This allows as yet unused regeneration chemicals to impinge on the critical ion exchanger layers, thus reducing the chemical surplus significantly to approx. 120–150% of the theoretical value. When the lowest exchanger layer has been completely regenerated, the ion leakage at the end of the exchanger bed is considerably lower, and consequently, the capacity utilised, with approx. half of the regenerant quantities used is considerably better than in the co-current process. Fig. 2 shows that the column is loaded from the top to the bottom in the fixed bed technique, with the exchange material settling as a compact bed on the nozzle plate of the exchanger. Regeneration takes place upwards. The regenerant is discharged from the upper end of the exchanger layer via a drainage system. The exchanger bed is fixed by a dynamic compressed air blanket located in the upper clearance zone of the exchanger during the regeneration process. It is possible to backwash and separate the exchanger bed when necessary via the upper clearance zone. This is predominantly required where rinsing is necessary. Although this process offers good operating conditions, the investment costs are relatively high.

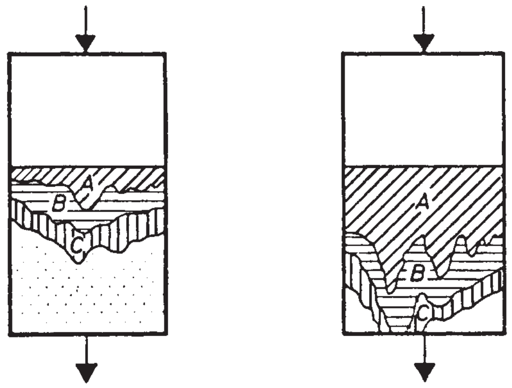

Fig. 1: Loading conditions of an ion exchange column in direct current regeneration (fixed bed).
Left = unloaded exchanger; right = loaded exchanger; A, B, C = variously highly adsorbed ions.

III. Counterflow technique using the fluidised bed process: This is a counterflow process where the sub-

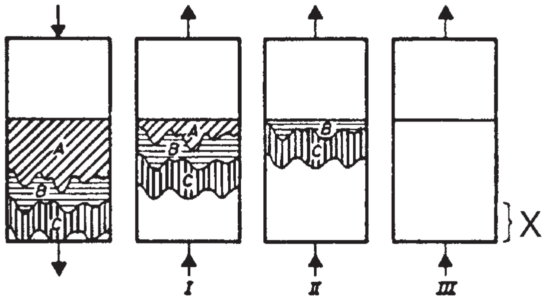

Fig. 2: Loading conditions of an ion exchanger column in alternating current regeneration with flow reversal possibility in the filter (fixed bed).
From left to right: loading; I.–III. regeneration phases; x = layer with best regeneration.

stance is loaded up-stream and a large proportion of the exchange bed is situated in the fluidised bed, whereas the smaller proportion settles as a fixed bed on the second upper nozzle plate. The fixed bed portion is essentially influenced by the rate of filtration. In order to maintain adequate water quality, a specific minimum fixed bed portion and an optimal exchanger rate is necessary. Regeneration occurs downwards, i.e. down-current. In the regeneration phase, the entire exchanger bed settles as the fixed bed on the nozzle plate. This prevents a rearrangement taking place during the regeneration phase with only negligible industrial or procedural outlay. This process is characterised by its simple construction and operating method. During recent years, this technique has extended into all areas of application. This has proved extremely worthwhile, although there are some disadvantages which can be seen repeatedly during operation. Essentially, the problem is backwashing where pollutants, abraded resin, germs etc. need to be rinsed out. It is not possible to avoid a rearrangement in the exchanger column where the process is more frequently interrupted, with the result that the water quality is affected by alternating loads or by turning off the water intake. Fig. 3 shows the various load situations of an ion exchange column using the fluidised bed process in countercurrent regeneration without internal backwashing. If the process has an external backwash tank, care must be taken that the resins are not mixed during backwashing (residual deposits in the backwash container) or that rinsing the resin is not linked to any extent with a particularly high outlay in terms of personnel and time.

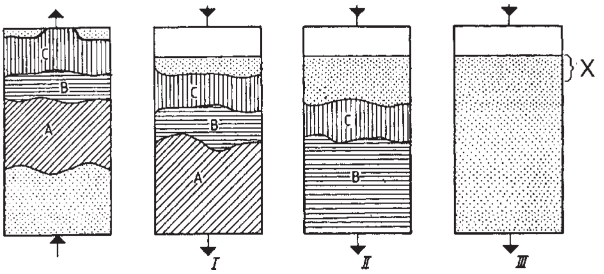

Fig. 3: Loading conditions of an ion exchanger column in alternating current regeneration (fluidised bed) with no internal flow reversal.
From left to right: loading; I.-III. regeneration phases; x = layer with best regeneration.

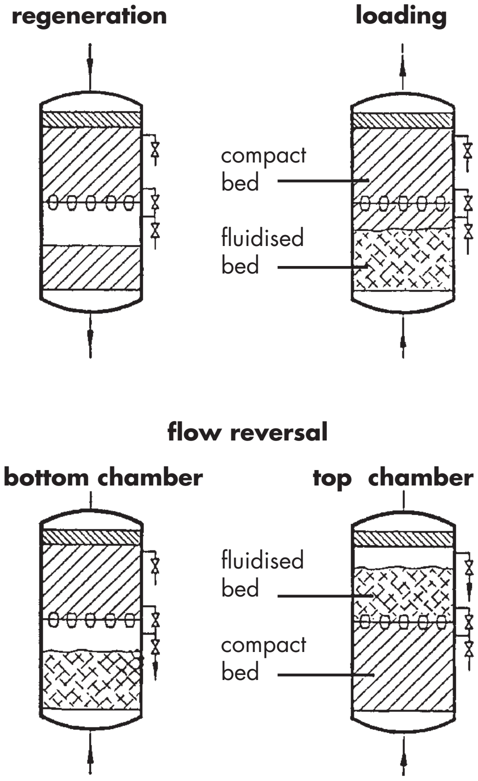

Fig. 4: Lift bed process stages.

IV. Liftbed countercurrent process: Optimisation and further development of the fluidised bed process results in the liftbed countercurrent process (Fig. 4). A third nozzle plate is fitted, thus separating the ion exchanger column into two chambers arranged above each other, both of which are filled with identical ion exchange material. The lower chamber of a liftbed exchanger is simply filled with up to 50% resin which is located in the middle nozzle plate during operation. This arrangement enables backwashing of the resin charge in the lower chamber. If necessary, resin in the upper chamber can be transported into the clearance space of the lower chamber enabling backwashing of the upper chamber. The resin is transported from the upper into the lower chamber and vice-versa by a simple pipe with fittings which is also referred to as a lift pipe. Another feature of the liftbed process is that it is possible to achieve a large exchanger layer height. This gives optimal exchanger capacities together with improved water quality. The fixed exchange bed in the upper chamber effectively prevents a rearrangement of the levels. This renders the system less sensitive in relation to load variations in the operating phase. This process can also be combined with the compound fluidised bed process, thus utilising the regenerant more efficiently. The higher installation costs and increased energy consumption due to the need for 3 nozzle plates to be installed should be taken into consideration.

V. Continuous ion exchange process: In this process, each exchange stage consists of an operating column, backwash column and regenerating and washing columns. The fully loaded exchange material is removed from the operating column, backwashed externally in the other columns, regenerated and washed before being transported back to the operating column. Only one exchange system is therefore required for continuous operation. The level of automation is higher than for other countercurrent and co-current plants. By controlling the resin transport from the load of the operating column, an optimal capacity utilisation is achieved (source: Marquardt).

Ion exchanger Granular, insoluble, inorganic or organic substances (e.g. crosslinked polystyrene) capable of interchanging accumulated → Ions (e.g. H^+, OH^- etc.) with other available ions in water, without affecting its structure and stability. A distinction is made between ion-exchangers according to the nature of the interchangeable ions:

I. Cationic exchangers (base exchangers). These are the most important ion-exchangers for water softening and are mainly high molecular weight polyvalent solid acids or their salts. They have acidic, positively charged exchange ions, i.e. acidic groups (SO_3H, COOH, OH) with mobile H^+ or Na^+, e.g. of the type $-SO_3Na^+$ or $-SO_3H^+$. The same compounds can function as

a) Sodium exchangers (Na exchangers, neutral exchangers): in this case the calcium and magnesium in water hardness salts are exchanged by sodium. Principle:
(A = exchanger)

$$Na_2\text{—}A + CaSO_4 \rightleftharpoons Ca\text{—}A + Na_2SO_4$$

The exhausted filter is regenerated with sodium chloride (5–10%) by the reverse reaction:

$$Ca\text{—}A + 2\,NaCl \rightleftharpoons Na_2\text{—}A + CaCl$$

b) Hydrogen exchangers (H exchangers); in this case hydrogen is exchanged by calcium, magnesium, sodium, etc. Principle:

$$H_2\text{—}A + CaSO_4 \rightleftharpoons Ca\text{—}A + H_2SO_4$$

This time, regeneration is carried out with hydrochloric acid:

$$Ca\text{—}A + HCl \rightleftharpoons H_2\text{—}A + CaCl_2$$

Cationic exchangers consist mainly of styrene and phenolic resins (water softening to 0°d is possible). The cation exchange is carried out either by co-current flow in which the water to be softened, and later the regenerating solution, flow downwards through the exchanger, or by counter-current flow in which the regenerating solution is passed through the resin in the opposite direction to the water being softened.

II. Anionic exchangers. These are high molecular weight, polyvalent bases or their salts which have basic, negatively-charged exchange ions, i.e. interchangeable OH groups against anions or end-groups suitable for the formation of acids. The principle of the exchange reaction is as follows:

$$A\text{—}OH + HCl \rightleftharpoons A\text{—}Cl + H_2O$$

Regeneration is carried out in this case with caustic soda solution (1–4%) or sodium carbonate (approx. 10%):

$$A\text{—}Cl + NaOH \rightleftharpoons A\text{—}OH + NaCl$$

By contrast, acid addition takes the following course:

$$A\text{—}NH_2 + HCl \rightleftharpoons A\text{—}NH_2\text{—}HCl$$

Regeneration is likewise effected with caustic soda solution:

$$A\text{—}NH_2\text{—}HCl + NaOH \rightleftharpoons A\text{—}NH_2 + NaCl + H_2O$$

Weak basic exchangers are suitable for the removal of high molecular weight organic compounds and amphoteric metal salts, and strong basic exchangers for weak acids, eg. carbonic acid, silicic acid, etc.

III. Mixed bed exchangers: i.e. a mixed bed or successive beds of anion and cation exchange resins results in complete water softening and the production of water qualities up to that of distilled water. In separate filters, the successive removal of bases with a hydrogen exchanger takes place in the first stage (as in I.b) and the removal of acids with an anion exchanger (or an anion accumulator) in the second stage (as in II.). Principle:

$$H_2\text{—}A + CaSO_4 \rightleftharpoons Ca\text{—}A + H_2SO_4$$

$$2\,A\text{—}OH + H_2SO_4 \rightleftharpoons A_2\text{—}SO_4 + 2\,H_2O$$

Ion-exchange resins Synthetic ion-exchange resins consist of various insoluble copolymers having a crosslinked three-dimensional structure to which ionic groups have been attached. An anionic resin has negative ions built into its structure and therefore exchanges positive ions. A cationic resin has positive ions built in and exchanges negative ions. Ion-exchange resins are synthetic organic polymers containing side-groups that can be ionized. → Organoliths.

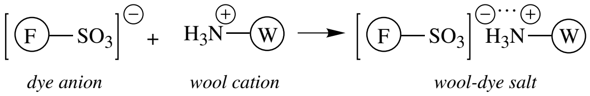
Ionic Relating to → Ions.

Ionic activity That property e.g. of textile auxiliaries to form → Ions in aqueous solution or dispersion by electrolytic dissociation. In this case the effectiveness of the textile auxiliary is due to its ability to carry an electric charge.

Ionic bond (electrostatic bond, polar bond, heteropolar bond, electrovalent bond). A → Chemical bonds which is based on the strong electrostatic attraction forces between cations and anions, and which owes its stability to the fact that certain atoms readily give up electrons and other atoms take up such electrons again. A typical example of this kind is the formation of sodium chloride (NaCl) from metallic sodium and gaseous chlorine. First of all each Na atom donates one electron which then becomes a Na ion: $Na \rightarrow Na^+$. For its part, the Cl atom accepts the donated electron and consequently becomes a Cl ion: $Cl \rightarrow Cl^-$. Due to the now actively charged state, the strongly electrostatic repulsion forces between ions with like charges and the attraction forces between oppositely charged ions, a regular arrangement of the ions takes place in the formation of the sodium chloride crystal:

$$2\,Na + Cl_2 \longrightarrow 2\,Na^+ + 2\,Cl^- \longrightarrow 2\,Na^+\,Cl^-$$

As the most well-known example in dyeing, mention can be made of the electrostatic dye bonding between the dye anion of an acid dye and the dissociated NH_3 groups of the wool fibre which then act as wool cations. The resultant reaction product represents a dyeing in the form of a wool-dye salt:



Ionic equation → Ionic reactions.

Ionic formula A type of formula which provides information on the composition of → Ions, their charge and charge sign, e.g. Na^+, Fe^{2+}, S^{2-}, SO_4^{2-}.

Ionic polarization → Polarization.

Ionic reactions Chemical reactions between → Electrolytes in solution always involve → Ions as reaction partners:

H^+ = acid reactions
OH^- = base reactions
SO_4^{2-} = sulphate reactions
Na^+ = sodium reactions

Such ionic reactions proceed (according to Pauling), almost without exception, in an extraordinarily short time because electrolytes of this kind are almost completely ionized or dissociated in solution. The neutralization reaction (see below) between acids and bases occurs instantly. In the ionic equation only the reaction which is actually proceeding is expressed, e.g. the combination of silver and chlorine ions to form silver chloride:

$$Ag^+ + Cl^- \rightarrow AgCl\downarrow$$

Neutralization is also a typical ionic reaction in which H ions of the acid and OH ions of the base combine to form undissociated H_2O releasing heat of neutralization. The neutralization of hydrochloric acid by caustic soda is written thus:

$$HCl + NaOH \rightarrow NaCl + HOH$$

and expressed as an ionic reaction:

$$H^+ + Cl^- + Na^+ + OH^- \rightarrow HOH + Na^+ + Cl^-$$

or, in the form of an ionic equation, simply as follows:

$$H^+ + OH^- \rightarrow HOH + 57{,}4\ kJ.$$

By contrast, the extremely numerous reactions between organic molecules mainly proceed as carrier functioning molecular reactions.

Ionization → Dissociation.

Ionizers Ionizers are devices which ionize the air by means of high voltage therefore removing the electrical charge on textiles. It is possible to use ionizers operating with high voltage where there is a risk of explosion. Explosion-proof peak-load ionizers do not have this disadvantage. They do not operate at high voltage. Ionization occurs via earthed peaks if the charge of the outgoing electrical field from the charged textile is sufficiently high. Ventilation can prevent explosive mixes accumulating on the peaks.

Ions (Gk.: *ienai* = to go, move). Atoms or groups of atoms carrying one or several positive or negative electrical charges. The ions present in an aqueous solution migrate to the oppositely charged electrodes when a direct current voltage is applied. Those ions which migrate to the cathode (positively charged ions) are cations and those which migrate to the anode (negatively charged ions) are anions. The transformation of an atom into an ion is called ionization. Cations are formed from neutral particles by losing, and anions by gaining, electrons. For these processes to occur, energy at least equal to the bonding energy of the electron (ionization energy, ionization potential) must be provided. This energy can be supplied in the form of chemical, thermal, light or electrical energy. The charge number of an ion is indicated at the top right of the atom symbol or the atom group in ionic formulae and the number of elementary charges precedes the sign. Examples: Cl^-, Li^+, Mg^{2+}, P^{3+}, S^{4+}, N^{3-}, OH^-, $HCOO^-$, $[CO(NO_2)_6]^{3-}$. In nature, the atoms of solid and liquid substances are mostly present as ions.

IONTEC Colombian standards organization; → Technical and professional organizations.

IOS, abbrev. for: Iraqi Organization for Standardization, Baghdad, Iraq; → Technical and professional organizations.

IPN, abbrev. for: interpenetrating polymer network. Mutually penetrating networks of polymers at the molecular level.

IR → Infrared.

Ir Chemical symbol for iridium (77).

IRAM (Sp.), abbrev. for: Instituto Argentino de Racionalización de Materiales, Buenos Aires, Argentina (Argentinian Standards Institute, including textile standards); → Technical and professional organizations.

IRCT (Fr.), abbrev. for: Institut de Recherches du Coton et des Textiles Exotiques, Paris, France (French Research Institute for Cotton and Exotic Fibres); → Technical and professional organizations.

Irish moss → Carragheen.

Iris print (rainbow, ombré and shadow hand block printing). This was once an important novelty print with multi-coloured effects blending into each other. This was achieved by a single print application using a device known as the iris block (approx. 30 small dye paste print compartments).

Iron (ferrum, Fe), I.1, atomic weight 56; soluble in diluted acids, hardly soluble in concentrated acids; moist air and water containing air cause the formation of hydroxide (rust). Chemically pure iron (grey iron) is a matt powder or (almost) silver-white and quite soft. Non-metallic compounds: iron is generally 2, 3 or 6-valent iron(II) hydroxide is quite a strong base, iron(III) hydroxide is a weak base (has the effect of an extremely weak acid against strong bases) iron(VI) hydroxide is a strong (ferric) acid (the same applies to sulphuric and chromic acid).

Iron(II), bivalent form of → Iron.

Iron(III), trivalent form of → Iron.

Iron bacteria The main iron bacteria are chlamydothrix, gallionella and crenothrix. They occur in untreated water containing iron and manganese, especially in pipes in the form of so-called iron-storing algae. They grow at a tremendous rate, causing pipe narrowing, silting-up, blockages, etc.

Iron buff (rust yellow, nankeen yellow). Rarely used mineral colour pigment for cotton discharge printing, military webbing, coloureds and washables, embroidery and knitting yarns. Especially in beige colouring for curtains and laces and associated yarns (to give an impression of ageing). This type of light shade does not fade, but tends to darken. Excellent fastness to light, air and atmospheric influences. Very good fastness to alkalis found in laundry soaps. Poor acid fastness. Low fastness to crocking (especially dark colours). Production: Impregnate with iron(II) sulphate, intermediate drying, reaction of weak alkali solution, pass through a calcium chloride solution (oxidation to form iron oxide). Organic acids give discharge effects (tartaric acid, citric acid).

Iron(III) chloride (ferric chloride), $FeCl_3 \cdot 6H_2O$. Molecular weight 270.41. Yellow-grey irregular crystals, deliquescent, easily soluble in water, alcohol and ether. Strong acid when dissolved (following hydrolysis). Use: only used very occasionally nowadays as a dye mordant in textile printing, used as an oxidising agent and for the detection of thioglycol.

Iron-contaminated process water This refers to process water containing iron (II) oxide (FeO). Encourages fibre damage by bleaching catalysts, rust stains, yellow muddy brown stains on white goods, change of shade where cationic and metal-sensitive dyestuffs are used.

Iron contamination of water This occurs e.g. when water is free from iron and is free from or has only low dissolved air content and the aggressive carbonic acid is present in iron pipes, especially after water has stagnated in them. The same occurs in water from which the iron has been removed. (Re-contamination with iron, often several mg/l iron content). Prevention: possibly by aerating the water.

Iron elimination If process water which is to be used for bleaching contains more than 0.1 mg/l of iron, this must be removed, i.e. the iron must be eliminated, in order to avoid the risk of yellowing the bleach goods. The iron is generally present as iron(II) hydrogencarbonate ($Fe[HCO_3]_2$) and is relatively easy to separate.

Ground water with a high iron content appears yellow to yellowish-brown and deposits a yellow, voluminous sediment consisting of ferrous hydrate on contact with air. This process can be accelerated by ventilating with atmospheric oxygen. Water containing iron is ventilated either in an open device while the water is allowed to flow across wooden racks or synthetic channels before being passed through a sand filter. In open devices, water containing iron can also be atomised, a process which also neutralises the water. In general, however, thorough aeration using a compressor in a sealed device is preferred. A piston compressor is required to ventilate large quantities of untreated water. The quantity of air should always be amply dimensioned; 1 g iron is required for approximately 5–10 l air. The iron flocculated during ventilation is removed from the layer of quartz chippings, stored in the device, by regular backwashing. According to experiments carried out in practice, the iron elimination process in open and sealed plants is simple to achieve with an average carbonate hardness and pH > 7, and is more difficult with low carbonate hardness. Where the iron content is above 4 mg/l, an open device must be added before the sealed device.

If the finishing company already has a waste water treatment plant which uses a precipitation process, or if the untreated water is industrially neutralised or decarbonised, the bivalent iron attached to the carbonic acid is also flocculated. If however, water containing iron is to be softened using a cation exchange process, a ventilation device must be added to avoid the exchange material being polluted or even totally obstructed by flocculated ferrous hydrate deposit. Manganese is a stable escort material for large quantities of iron and this is coprecipitated during ventilation if it is bound to carbonic acid. In other cases, a special treatment must be carried out in order to remove it (demanganization).

Ironing fastness Resistance of the shade to ironing. Test: duration 15 s, temperature 200°C (cotton), 150°C (wool, silk, viscose), 120°C (acetate, polyamide, polyester, acrylic);

I. Dry: The heated upper plate of the heating device is placed on the sample for 15 s.

II. Moist: Place a dry sample on dry cotton fabric, cover with cotton fabric which has been wetted to 100% moisture; 15 s as in I;

III. Wet: The sample and cotton fabric are saturated in water and squeezed off to 100% moisture. The wet sample is placed on a dry cotton fabric and covered with the wet cotton fabric; 15 s as in I.

Where methods II or III are used, bleeding is also assessed.

Ironing machines Ironing machines are used in making-up shops, laundries and dry-cleaning plants for rational shaping and finishing work in the press room. Ironing machines consist of an upper and lower plate. The article to be ironed is shaped between these two plates by means of pressure, heat and moisture (for underwear) or direct steam (for outerwear). It is then heat-set by a) contact drying in the case of underwear and b) drying and cooling extraction in the case of outerwear. The forms of the pressing surfaces (upper and lower plate) are adapted to the various spec. shaping requirements. The ironing covers which are elastic to a greater or lesser extent, must be totally permeable to air. Common combinations are as follows:

I. Upper and lower plate insulated; upper and under-steam; lower plate with extraction.

II. Upper plate uninsulated (metal), heated; lower plate insulated, with under-steam and extraction.

III. Upper plate uninsulated, heated; lower plate insulated, heated (contact drying). The high-performance pneumatic ironing machine which is activated via a hand switch and foot pedal with controllable pressure has replaced the manual model. In addition: automatic timing and function control of the individual operations by the programmer.

Ironing of garments Final treatment in drycleaning and the garment industry in the sense of shaping by smoothing using the combined effect of heat, moisture and pressure. A distinction is made between manual and machine ironing (→ Ironing machines). Manual ironing is preferred where machine ironing is not expected to give a satisfactory result. Manual ironing devices: ironing board, sleeve board, ironing pad, flat iron (if possible with electrically adjustable temperature control, with steam spray device), steam-heated piston shaping units. Manual ironing is generally carried out on the reverse of the fabric. Where this is not the case, a steam cloth is placed between the iron and the cloth face (this is not required for light fabrics which do not have a lustrous appearance after ironing). The ironing temperature must be adapted depending on the type of material being ironed, as certain damage caused by ironing is generally irreversible (e.g. on acetate, polyamide clothing).

Ironing presses → Ironing machines.

Ironing stains on acetate (fibre blends). Shiny areas, caused by ironing at too high a temperature or by contact with a heater during the dyeing process, i.e. temperatures of above 160°C. These are characterised by shrinkage and a harder handle or particularly lustrous areas, poss. a combination of the two. Removal: best results with liquor approx. 1 : 15, 15–20 min, 18–20°C (only 4–8% loss in tensile strength, higher temperatures give rise to greater losses) with 30% formic acid, stir and rinse. More pronounced ironing stains possible at 35–50°C. Dyed fabric is generally lightened and requires subsequent redyeing.

Ironing table Working surface for manual ironing in the garment industry and textile care available in various dimensions. Spec. ironing table with under-steam and suction, connected to electric steam flat iron with separate storage, available with spec. accessories such as water spray guns, pivotable narrow auxiliary ironing surfaces (sleeveboard), etc.

Ironing temperature The (highest) permissible temperature when ironing textiles before which damage occurs as a result of the fibres being softened or browned (see Tab.).

fibres	ironing temperature (°C)		beginning of softening or browning (°C)
	normal	max.	
cotton/ flax	180–200	200	215–220
wool/ silk	150–170	180	195–200
viskose/ cupro	150–170	180	195–200
acetate	150–170	180	210–220
polyamide	150–170	200	200–210
polyester	150–170	200	210–220
acrylic	150–170	220	230–240
polyvinyl-chloride	60– 70	80	90–100

Tab.: Ironing temperature of different fibres.

Ironing testers,

I. Ironing press, e.g. the Spuhrsche ironing press, is used for → Ironing test procedures in accordance with DIN 53 894 T1. It consists of a steam-permeable ironing table which is covered with a wool felt 15 mm thick of F2 hardness in accordance with DIN 61 200, and an ironing shoe of at least 600 x 200 mm which must exert a pressure of 0.4–0.5 N/cm^2 due to its weight onto the ironing table and be kept at temperatures of 120–200°C by electrical heating. Sections of a plain weave, absorbent cotton fabric (ironing cloth) with a fabric weight of 150–200 g/m^2 when air-dried are also required for the test.

II. Table ironing machine, e.g. the Hoffmann press is used for ironing samples in accordance with DIN 53 894 T2. It consists of a steam-heated ironing table and shoe with a working surface of 600 x 600 mm, 525 x 525 mm of which is perforated. Steam is only exhausted by the ironing shoe. This is in the form of saturated steam with a pressure of 5 bar. The suction air connection (0.10–0.12 bar) is located on the ironing table. The upholstering of the ironing shoe consists of one layer of tinned copper wire material in two-up-two-down weave and one layer of smooth, heat resistant textile fabric. The upholstering of the ironing table should consist of one layer of tinned copper wire material, 1 layer of wool felt and one layer of smooth, heat resistant textile fabric. Supporting surfaces can be found on all three sides of the ironing machine. These are used to support the areas of the goods to be tested which are not to be steamed when testing is to be carried out on the entire item.

Ironing test procedures In accordance with DIN 53 894:

I. Part 1: Determining the change in size (shrinkage or elongation) of textile fabrics when ironing with a moist ironing cloth on ironing presses. Method: Two (500 ± 5) mm long measuring ranges are marked 50 mm from the edges on a test sample of 200 x 600 mm, to enable the change of size both lengthwise and crosswise to be measured separately. A wool felt is placed on the ironing table of the ironing press, followed by a cotton cloth folded in two, then the test sample, which is covered by a moist ironing cloth. The residual moisture left in the fibre after ironing must not increase the weight of the sample by more than 8–10%: this can be achieved by varying the water content in the ironing cloth, the ironing temperature and the duration of ironing. After ironing, the sample is kept at standard atmosphere for 16 h and then the test results are calculated as a percentage from the change in length in comparison to the original length. From the two individual values, the arithmetical averages are calculated, together with the total average value for each direction tested from the various test samples. The relative surface change ΔF is calculated as a % using the formula:

$$\Delta F = \Delta K + \Delta S + \frac{\Delta K \cdot \Delta S}{100}$$

ΔK = relative change in length, lengthwise in %
ΔS = relative change in length, crosswise in %

II. Part 2: Determining the change in size (shrinkage or elongation) of textile fabrics (wovens and knitwear) following relaxation when steaming on ironing machines in a mobile state. Method: Testing can be carried out on test samples of 600 x 600 mm which have been cut out or on the item itself. Three (500 ± 5) mm long measuring ranges are marked both lengthwise and crosswise 250 mm apart on a test sample. Where the samples have been cut out, care should be taken that the outer measuring ranges are at least 50 mm from the edge of the sample. The test samples must be kept at standard atmosphere until immediately before steaming, as the change in size can depend to a large extent on the moisture of the fabric in steaming. The following treatment is carried out 5 times in succession (the 5th time only as far as step d):

a) lowering the ironing shoe to a distance of 10 mm;
b) 10 s steaming (only over-steam);
c) 10 s suction (through the ironing table);
d) lifting the ironing shoe;
e) gently shaking the test sample;
f) replacing centrally on the ironing table tension-free.

The samples are then left to dwell for 16 h in standard atmosphere and the arithmetical averages and the total average is calculated for each direction tested as described in part I. The values relating to change in length given when steaming on an ironing machine cannot generally be compared with the results of other shrink resistance tests; this applies e.g. to ironing under a moist cloth in accordance with DIN 53 894 T1 or immersing in warm water.

Ironing test reading → Formaldehyde release on ironing.

Iron mordant → Iron (III) sulphate.

Iron-on fabrics → Hot melt adhesives.

Iron oxidation Iron oxidation in plastic-lined iron pipes used for process water. Specific strains of bacteria, capable of corroding the protective plastic lining inside water pipelines, eat away the plastic layer so that the iron exposed in the water main can rust causing an irregular yellowish-brown discoloration of the water due to rust contamination.

Iron removal from water (A treatment frequently coupled with neutralization of acidic water). Hydrogen carbonates yield easily precipitated iron, whilst the sulphates yield iron in a form which is difficult to precipitate. Additions of caustic soda or caustic potash solution have an accelerating effect. Unwanted protective colloids are precipitated by aluminium sulphate or oxidative additives (permanganate, etc.). In general, 0.48 l of air is necessary for each 1 g of iron to be removed.

I. Open plants: by showering (through special nozzles) into a trickling installation (coke, broken lava, broken brick, concrete hurdles), especially useful for iron which is difficult to precipitate as well as in the presence of carbonic acid, followed by settling tanks (formation of insoluble hydroxides) and filtration or a second showering of the filter.

II. Closed plants: with compressed air (2–5% of the amount of water involved) and a filter backwashing system or, e.g. a manganese-permutite filter with simultaneous acid neutralization. Occupies less space, simple, contamination-proof. Small plants are also available for direct connection to boreholes or water mains with activated carbon filters. Principle of operation: oxidation of the bivalent to the trivalent form by atmospheric oxygen and formation of the colloidally dissolved hydroxide, slow flocculent precipitation followed by filtration.

III. Chemically: closed filtration (no contact with the outside air) over magnesite or dolomite for untreated water containing 3–5 mg/l of iron. Organically-bound iron (humate) can only be removed with aluminium sulphate, sodium aluminate or permanganate oxidation or, for small quantities of iron (0.1–0.3 mg/l of iron) with polyphosphate.

Iron(II)sulphate (ferrous sulphate, iron vitriol), $FeSO_4 \cdot 7\,H_2O$. Mol wt. 278; specific gravity 1.88. Greenish crystals, air exposure causes the formation of basic iron(III) sulphate, which is of low solubility. Use: to produce iron mordants, in vat dyeing (reducing agent) and as a precipitating agent in effluent treatment.

Iron(III)sulphate (ferric sulphate, sulphuric iron, iron mordant), $Fe_2(SO_4)_3$. Molecular weight 400. White/grey-white powder, deliquescent in air (brown solution), dissolves slowly in water. Basic iron(III) sulphate is only occasionally used today as an iron mordant for the weighting of silk.

Iron tests,

I. In dyeings: Incinerate goods to be tested, absorb using iron-free hydrochloric acid. Next oxidise with a few drops of hydrogen peroxide or concentrated nitric acid . Then either a) with ammonium or potassium thiocyanate solution = bluish red dyeing; or b) with potassium hexacyanoferrat II solution = blue precipitate (Prussian blue), in diluted solution = only bluish green dyeing. Limit concentration 1 : 500 000 in each instance.

II. In water: Generally present as iron (II) salts, then either a) with diluted hydrochloric acid + potassium hexacyanoferrat III solution = blue precipitate (Turbull blue); or b) first oxidise with hydrogen peroxide, then continue as in I a) or b).

Irradiation technology Since the capability of high-energy radiation to crosslink linear polymers and introduction of graft reactions has been known since a very early stage, it was a logical step to include textile fibres comprised of macromolecular materials in the radiochemical textile finishing processes, all the more so as the demand for diverse variation of properties in their articles is particularly pronounced in the textile industry. However, whereas in the plastics sector, processes such as the manufacturing of shrink film for packaging and heat-shrinkable sleeves for electrical insulation have been accepted in industrial production, irradiation technology has not as yet penetrated the textile industry. Of the various types of high-energy rays, only gamma or x-rays, consisting of high-energy photons, and electron beams, which are produced by acceleration in a high-voltage field, are used for technical and economic reasons. It is significant that the interaction between radiation and matter in the energy field in question is limited to the electrons, i.e. no radioactive decay occurs. A significant difference between the two forms of radiation is in their different adsorption behaviour. With electromagnetic gamma radiation, the adsorption is more or less proportional to the density of the material penetrated. This type of radiation displays good penetration capacity. With radiant energy of 1.2 MeV, as emitted from radioactive cobalt, the thickness of the half-value layer of a penetrated material of thickness 1 is approx. 10 cm, whereas the electron radiation is merely approx. 0.3 cm. Electron radiation is therefore well suited to thin layers such as textile webs, sheeting etc. In the case of gamma radiation, virtually all the energy is transferred to electrons, making the effects of both types of radiation at a comparable dose almost identical.

Irradiation technology can be seen in a simplified way as a method of producing free radicals. These can also be produced by peroxide or photochemically induced methods which generally give equivalent results in terms of quality. Given these circumstances, economic criteria are naturally particularly significant when choosing between the methods. As it is relatively expensive to produce irradiation energy per kWh, it is important that the best possible yield of irradiation energy is achieved. The quantity of product formed in a radiochemical process is directly proportional to the three values G, D and M, where G is the radiochemical energy yield, D is the dose of radiation and M the molecular weight of the product produced. The higher the value of G or the molecular weight of the quantum modified, the lower the energy costs. Chain processes are the most common systems with a high G-value, as found with graft-polymerisation or cross-linking using non-saturated bonds, whereas the high molecular weight of the polymers, as in the case e.g. in crosslinking polyethylene, also give a high yield. Another advantage of irradiation technology is that initiation and propagation phases are independent of one another, i.e. this type of process can e.g. be carried out at room temperature. Depending on whether disproportionation, recombination or propagation are to follow, the free radicals formed when irradiating textile fibres may cause 3 different reactions – decomposition or cross-linking of chain molecules, or, where monomers are present, graft polymerisation. The last reaction generally also results in larger quantities of homopolymers. As it is necessary to aim for as low a dose of radiation as possible both for economic reasons and as cross-linking is preferred to the decomposition reaction, suitable vinyl bonds which can carry out the appropriate chain reaction are generally added. There has been an increase in radiation-induced graft reactions, as the appropriate selection of various monomer systems can cause almost as many modifications to the properties of the substrate as desired. Two of the principal problems faced by the radiochemist who works with the fibres, are diffusion, which is becoming the determining factor concerning speed, especially with synthetic fibres, and the fact that due to the so-called "Trommsdorf" effect, only a few graft chains with very high molecular weights are formed, thus changing the properties of the fibre very little. On the other hand, there is an advantage in having graft reactions, in that they do not alter the basic properties of the substrate to any great extent and the properties of the graft polymers can be enhanced to a certain extent.

Irreversible Irreversible, as opposed to → Reversible. Term used to define the state of equilibrium of chemical reactions with equivalent properties, e.g. the formation of a precipitate which remains unchanged when a precipitate substance or a precipitable substance (or both) are exhausted. Example: Barium chloride and sodium sulphate = $BaCl_2 + Na_2SO_4 \rightarrow BaSO_4 + 2\ NaCl$.

Irrigated cotton Cotton which is cultivated under artificial irrigation (→ Rain-Grown-Cotton).

Irritant threshold concentration The weakest odour concentration of → Perfumes which can still be detected by the (human) olfactory system. Persons with a well developed sense of smell can achieve astonishing levels of agreement on these quantitative values which can be reproduced within narrow ranges as so-called → Odour threshold value. It has been authentically stated that the human nose is 100 times more sensitive than the best analytical apparatus currently available for the detection of threshold odour values.

IRS, abbrev. for: Irish Standard, ir. norm.

IRSFC (engl.), abbrev. for International Rayon and Synthetic Fibres Committee, analog. (french) → CIRFS, → Technical and professional organizations.

IS,

I. Indian Standard (ind. norm).

II. Irish Standard (→ IRS) (ir. norm).

Isfahan carpet Isfahan carpets are woven in the Iranian city of the same name as well as in the neighbouring villages. Isfahan, which is situated in the fertile plain of the Zaiandeh river in the centre of Iran, is the second largest city in the country. Isfahan carpets are woven on vertical looms. Backing in cotton; pile in very close cropped wool, some examples also having a silk pile. The Persian knot is used and the density is very high, i.e. approx. 400 000 knots per m^2. Isfahan carpets all have a floral design, usually with a central medallion on a field decorated by a motif of interlaced flowering branches. Some examples also have four corner decorations which have the same motifs and colours as those used for the central medallion. Carpets with scenes of flowers and animals are also quite common. Another decoration which is typical of this area is the one known as the "vase of flowers". A very wide colour range is used in Isfahan carpets to create a harmonious combination of ground and design with alternating light and dark colours.

ISI, abbrev. for ind. standard organization → Technical and professional organizations

ISIG, abbrev. for: ghan. standard organizations, → Technical and professional organizations.

Isinglass → Glue.

ISIRI, abbrev. for: Institute of Standards and Industrial Research of Iran, Teheran, Iran; →Technical and professional organizations.

"islands-in-the-sea" fibre A term used for a → Bicomponent fibres similar to the matrix/fibril type and described as a multiple interface or multicomponent fibre. The "islands" are fibrils of one or more polymers embedded in the "sea" (or matrix) consisting of a different polymer. The matrix is often dissolved away to leave ultra-fine filaments. The number and titre of these fine filaments is pre-programmed. Such fibres have been used in ion-exchange products as well as in imitation fur materials and in textile fabrics to achieve a different handle.

ISMIU Acronym for the "Institut por Standardizacia, Merki i Izmeritilni Uredi", i.e. the Bulgarian Institute for Standardization, Metrology and Measuring Instruments; → Technical and professional organizations.

ISO Acronym for the International Standards Organization, based in Geneva, Switzerland, founded in 1947. ISO is the international organization responsible for standardization and includes national standards bodies from numerous countries among its members. The working rules established by ISO committees are regarded as authoritative directives by member countries which helps to encourage the development of largely identical international and European standards, thereby promoting the international language of standardization and contributing to the improvement of international trade; → Technical and professional organizations.

iso- (Gk.: *isos* = equal). A prefix indicating:

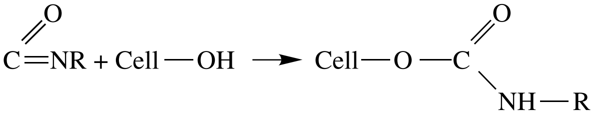
I. Equal or identical, e.g. isomagnetic.

II. An isomeric compound.

III. The presence of a branched carbon chain in the molecule.

Isobutanol (isobutyl alcohol), $(CH_3)_2CHCH_2OH$, → Alcohols.

Isocyanates Compounds containing the group –N=C=O. They are organic salts of isocyanuric acid. High molecular weight alkyl isocyanates or isothiocyanates form esters with cotton and regenerated cellulose resulting in cellulose alkyl urethanes with hydrophobic properties:



$$O{=}C{=}NR + \text{Cell}{-}OH \longrightarrow \text{Cell}{-}O{-}C({=}O){-}NH{-}R$$

Isocyanuric acids → Chloroisocyanuric acids.

Isocyclic compounds Compounds derived from → Cyclic hydrocarbons.

Isodiazotates → Antidiazotates.

Isoelectric point The pH of an aqueous solution at which dissolved amphoteric electrolytes appear to carry no charge. In the absence of other electrolytes, the isoelectric point at infinite dilution is identical with the point of zero charge where the sum of the actual charge on the particle (net charge) is zero. In amino acids, for example, both values are identical since they are not influenced by outside ions. For macromolecular ampholytes the isoelectric point and the point of zero charge do not necessarily coincide. In the case of proteins, for example, the characteristic location of the isoelectric point is influenced by the number of free acid and basic groups as well as their position in the molecule. The isoelectric point for wool lies at pH 4.9 and that for silk at pH 5.1, i.e. the neutral point for these fibres lies within the acidic range. At this neutral point the fibres exhibit their greatest internal strength, minimum swelling and reactivity as well as their lowest affinity for dyes.

Isoelectric wash → Acidic washing.

Isoionic point The pH of an aqueous solution, for example in which wool is immersed, which contains as many positive as negative ions. Also known as the ionic neutral point.

Isolines (isograms). Isolines are graphic representations in the form of lines along which the same value of a particular parameter prevails in the system represented (according to the designation of the abscissa and ordinate in a 2-dimensional graph or, in a 3-dimensional plot, the third axis), e.g. isobars: lines of identical pressure (p = a constant); isotherms: lines of identical temperature (T = a constant). One advantage of this statistical-mathematical modelling is the high degree of transparency provided by the opportunities for graphic representation.

Example of cold pad-batch reactive dyeing: both the depth of dyeing (Figs. 1 and 2) as well as the dye uptake (Figs. 3 and 4) exhibit the same fundamental behaviour. High dye uptakes and depths of dyeing are indeed achieved at pH 11 and a 12 h dwell time, but this set target cannot be fulfilled under these conditions. The reaction time, which should be completed after 4 h, must be emphasized in particular here since a constant rinsing-off time is not possible and the considerable change in target parameters is due to the high dependence of both target parameters on temperature over the entire temperature range investigated. Since both the temperature as well as the dwell time are now revealed as clear disturbance variables, the necessary reproduci-

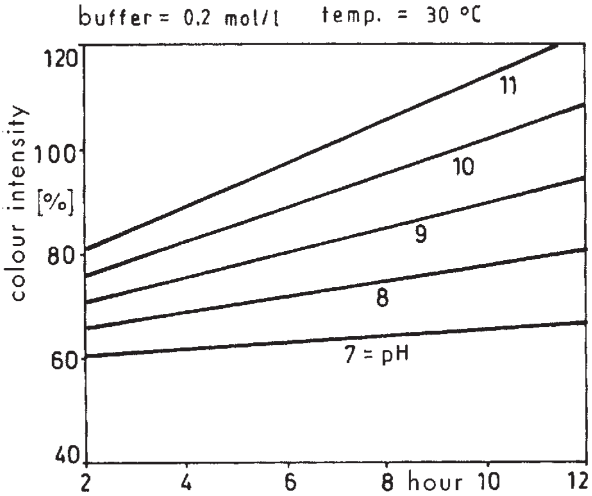


Fig. 1: Colour intensity as a function of storage time (C.I. Reactive Blue 19) in cold dwell reactive dyeing at various pH levels.

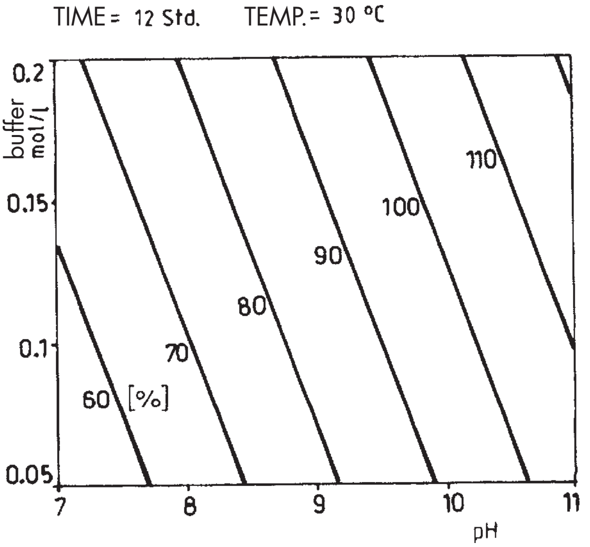

Fig. 2: Colour intensity isolines (C.I. Reactive Blue 19) in cold dwell reactive dyeing.

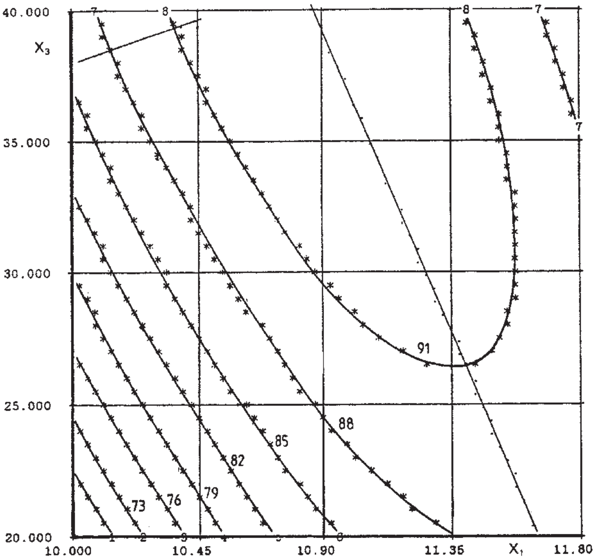

Fig. 3: Target dimension isolines: yield C.I. Reactive Orange 95 in warm dwell reactive dyeing.
time: 5h; X_1 = ph; X_3 = temperature

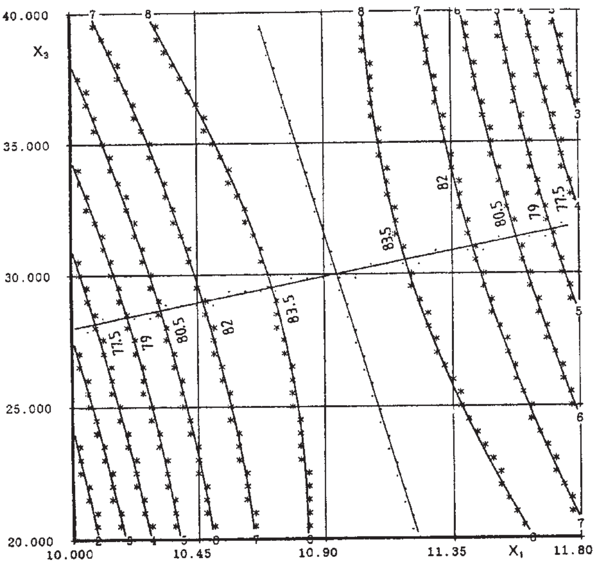

Fig. 4: Target dimension isolines: C.I. Reactive Orange 91 in warm dwell reactive dyeing.
time: 5h; X_1 = ph; X_3 = temperature

bility of the process is not possible and, consequently, any transfer of this process to production is out of the question. The creativity of the process developer is called upon once again here since he should now be in a position to deduce the causes of this result from the calculated model data in order (as in this case) to achieve the stated objectives by appropriate technical changes to the reaction technology.

The reaction behaviour of reactive dyes may therefore be clearly represented with the aid of isolines. C.I. Reactive Orange 95 (Fig. 3) exhibits high colour yields in the pH-range between 11 and 11.8 with stable process temperature conditions at the same time. In the case of C.I. Reactive Orange 91 (Fig. 4), a distinct colour yield maximum is apparent which is associated with narrow pH limits. At a pH > 11.3 and dwell conditions at temperatures > 25°C for dyeing, a fairly high degree of reverse hydrolysis occurs. An increase in the buffer concentration within the range investigated here only leads to a slight improvement in colour yield whilst the process reliability undergoes considerable improvement. This is especially noticeable when different amounts of residual alkali from fabric pretreatment are carried over into the dyebath. The influence of liquor storage time on colour yield is of no practical relevance under these particular test variations.

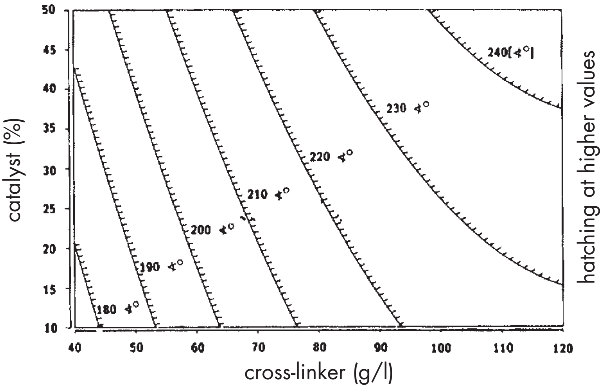

Fig. 5: Two-factor isoline diagram for dry crease recovery angle after washing in finishing with cross-linker C in combination with magnesium chloride hexahydrate.

An especially interesting relationship between the dry crease recovery angles and the ratios of crosslinking agent and quantities of catalyst in resin finishing may be represented with the aid of isolines. The isolines illustrated in Fig. 5 have been drawn up for various dry crease recovery angles dependent on the quantity of crosslinking agent and the ratio of catalyst for a curing temperature of 160°C and a curing time of 5 min. In order to obtain a dry crease recovery angle of 220°, for example, a 25% quantity of catalyst is required for the application of 100 g/l of a 45% solution of hydroxymethyl 4,5-dihydroxyethyleneurea, i.e. 25 g/l $MgCl_2 \cdot 6\,H_2O$. When 75 g/l of the crosslinker solution is used, the desired level is not reached with 25% of catalyst based on the crosslinker solution. With 75 g/l of crosslinker solution, 50% of catalyst already becomes necessary. In absolute terms, this is equivalent to 37.5 g/l of magnesium chloride hexahydrate.

In Fig. 6, dependence of the dry crease recovery angles after washing on the quantity of crosslinker and the ratio of catalyst for a curing temperature of 150°C and a curing time of 5 min is demonstrated by a 3-dimensional plot.

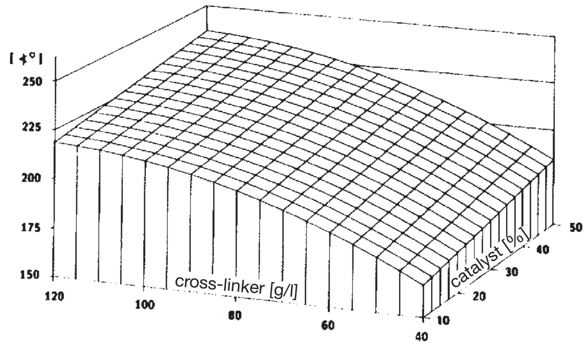

Fig. 6: 3D plot for dry crease recovery angle after washing for crosslinker C with magnesium chloride hexahydrate.

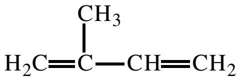
Isomeric (Gk.: *isos* = equal). As applied to compounds, a term which means of the same composition and the same molecular weight.

Isomeric compounds (isomers). Compounds possessing the same chemical composition (same molecuar weight, same empirical formula) but having different properties (e.g. with regard to their melting and boiling points, reactions and optical activity) which is usually due to different atomic arrangements within the molecule, i.e. they possess different structural formulae (→ cis-form; cis-trans isomerism). Some of the most well-known isomeric compounds are: ortho, meta and para compounds; monomers and polymers; mesomeric compounds; stereo isomers; tautomers; cis-trans isomers, etc.

Isomorphous (Gk.: isos = the same, and morphe = shape or form), to describe a substance with the same or similar crystal structure, e.g. the isomorphous (i) spherical form in contrast to the anisomorphous (a) fibrous form. The isomorphous property is based mainly on similar formulae and largely analogous arrangements of atoms, ions and molecules. Both states (a +i) are characteristic of, e.g. thermoplastic fibres: as a highly oriented, energy-rich form in the fibrous state (a), and in a low energy state as molten beads (i) = high temperature brings about a transformation into the molten state, i.e. by setting the molecules in motion through the introduction of heat energy, the a-state is destroyed and the a-fibre structure changes by shrinkage to the i-spherical structure (molten beads). By raising the order superimposed on the fibre molecules, the fibre becomes more receptive to dyes and a deeper dyeing results due to a reduction in the relative surface area of the shrunken fibre.

Isoprene (3-methyl-1,3-butadiene; 2-methyl-1,3-butadiene). The parent hydrocarbon of a homologous series which also includes → butadiene. It is a polymer unit in ethereal oils, terpenes, camphor, phytol and natural rubber. Due to reasons of cost, synthetic isoprene rubbers have had no technical importance hitherto.

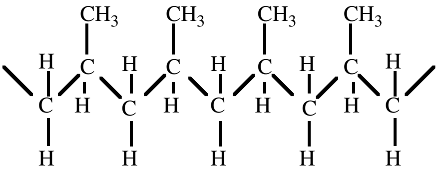


$$H_2C{=}\overset{CH_3}{\overset{|}{C}}{-}CH{=}CH_2$$

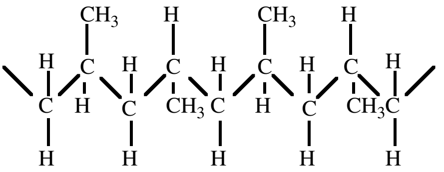
Isopropanol (2-propanol, isopropyl alcohol, dimethylcarbinol, IPA), $(CH_3)_2CHOH$. Colourless liquid with a pleasant alcoholic odour. Density 0.781; b.p. 82°C. Miscible with water in all proportions (solvent properties), soluble in alcohol, ether, etc. Chemically and physiologically similar to → Ethanol. Uses: extractions, spotting agent (tanning agent stains), component of soaps, polishes, etc.

Isotactic molecules Molecules having identical steric configurations of the groups on each asymmetric carbon atom on the chain. Catalysts with a stereotypical action are used to achieve this ordered molecular arrangement. → Syndiotactic molecules.

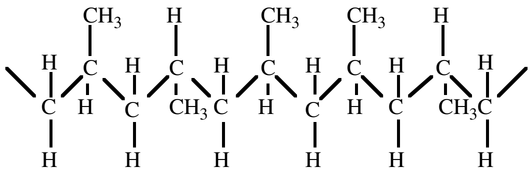
Isotactic polymers Synthetic macromolecules having a structure in which a regular spatial or stereo relationship exists between one repeat unit and the next and which have side chains ($-CH_3$, $-CH_2CH_3$, $-C_6H_5$, etc.) only on one side of the main chain, in contrast to polymers having side chains which alternate regularly on both sides (syndiotactic) or a random side chain configuration on all sides (atactic).



isotactic structure



syndiotactic structure



atactic structure

From the standpoint of fibre chemistry, isotactic polymers (e.g. polyolefin fibres) are of considerable importance because of the regularity of the chain structure by means of which, for example, favourable fibre-forming properties, high densities, high melting points, etc., can be specifically achieved. Isotactic polymers with the desired properties can be obtained in a controlled form by the addition polymerization of appropriate monomers with stereospecific catalysts.

Isothermal dyeing A rapid dyeing procedure carried out at constant temperature, e.g. for the HT-dyeing of disperse dyes on polyester.

Isotherms Lines (→ Isolines) connecting all points on a graph that correspond to the same temperature. For air and other gases, isotherms are used for heat, pressure, water vapour absorption (sorption isotherms), moisture vapour transmission (desorption isotherms) etc.

Isotopes All atomic nuclei are built up of protons and neutrons. An isotope is one of two or more atoms of the same element having the same number of protons (i.e. the same atomic number) in their nucleus but different numbers of neutrons. The presence of one or more extra neutrons in the nucleus means that different isotopes of the same element have different masses (atomic weights). Although isotopes have similar chemical properties, the slight difference in their masses is responsible for slight differences in their physical properties. All elements have several isotopes. Oxygen, for example exists principally as the isotope ^{16}O (i.e. with an atomic weight of 16) as well as very small amounts of ^{17}O and ^{18}O. There are relatively few naturally radioactive elements (e.g. radium) compared to the great number of radioactive elements produced synthetically (in nuclear reactors). Thus, one or more isotopes can be produced synthetically from any element in this way. These isotopes are, however, unstable and therefore emit radioactive radiation due to the fact that their composition differs from that of the natural number of protons and neutrons in the nucleus. This radiation can be detected easily and quickly with absolute certainty (even when localized). Such radioactive isotopes are important in textile research as well as in technological control systems of various kinds for the operation of control, indicating and regulating devices, etc. (an important isotope laboratory for textile research and teaching is located in Raleigh, NC, USA). For these applications, it is only necessary to have a substance (group) on which to carry out a series of measurements, linked to specific radioactive elements as indicators. Since even extremely small traces of radioactive substances can be readily detected, such isotopes may be used as radio indicators (RI) in practically minute quantities as they represent, in chemical terms, a chemically identical substance, selected at choice, which is chemically indistinguishable from the substance being monitored. Consequently, specific states of distribution and residues may be readily detected for control and investigation purposes by introducing such RI's as radioactive markers into textiles and application liquors of all types. Typical applications in the textile industry include, e.g.: the continuous control of dry or wet textiles in production processes, the monitoring of various finishing treatments, the distribution of synthetic resins on textile fabrics, the measurement and metering of dye concentrations in continuous dyeing processes, liquor circulation control, monitoring of dye migration in multicolour printing, determination of dye uptake capacity, quantities of finishes, coatings and print pastes applied to textiles, soil removal, detergent absorption, measurement and control of film thickness (fibres, yarns, slivers, foils, etc.), as well as to control the fill height in non-transparent containers, and control the extent of wear in bearings, etc. The most important RI in organic chemistry used up to now for textile applications is ^{14}C followed by ^{60}Co and ^{90}Sr, etc. Despite the well-known long-term damage to health caused by large doses of radiation, there is no direct danger to operatives using this type of equipment due to the very small amounts of radioactive isotope indicators employed, provided the substances are handled correctly. With the more penetrating gamma radiation, however, adequate precautions are essential.

Isotope radiation (isotope radiation emitters). The → Isotopes considered here include strontium 90, krypton 85 and promethium 147 which emit radiation of different intensities. When particles emitted by a radioactive isotope penetrate a material, the emission is attenuated in proportion to the mass of the substance. To determine the weight per unit area of textile webs by means of radioactive radiation, therefore, alternative isotopes are available to cover all ranges of weights encountered in the textile and allied industries. Krypton 85 is particularly suitable for all textile applications and is also the least problematic radioactive substance.

Isotropic (Gk.: *isos* = equal, *tropos* = direction). Having uniform physical properties in all directions in contrast to → anisotropic.

Isparta carpets Most of the carpets known by the name Isparta, or Sparta, have been woven at Smyrna (Izmir) in Turkey. The Persian knot is used. Sparta carpets are among the best from this particular area of Turkey. The decoration and techniques employed in Sparta carpets are very like those of the rough → Tabriz carpets, but they can be distinguished from the latter by the different feel of the fabric, i.e. they are more limp. The wool of the pile is somewhat lacking in lustre and the colours are usually pale, with ivory predominating in the ground and pink and light blue in the decoration.

ISTCL, abbrev. for: International Scientific and Technical Committee on Laundering. Secretariat: Krefeld, c/o wfk; → Technical and professional organizations.

Istle fibre → Ixtle fibre.

ITA (Sp.), abbrev. for: Instituto Textil Argentino, Buenos Aires, Argentina (Argentinian Textile Research Institute); → Technical and professional organizations.

Italian cloth Smooth, highly lustrous lining fabric (cotton, or cotton warp and worsted weft = half-wool Italian cloth) in satin weave.

ITC → International Textile Club.

ITCRA, abbrev. for: International Textile Care and Rental Association, U.K.; → Technical and professional organizations.

-ite A suffix used in chemistry to indicate an intermediate oxidation state of a metallic salt, analogous to -ous for the parent acid, e.g. sodium sulphite (Na_2SO_3), a salt of sulphurous acid, which contains one less oxygen atom than the sulphate (Na_2SO_4), i.e. a salt of sulphuric acid. → -ate.

ITF (Fr.), abbrev. for: Institut Textile de France (French Textile Research Institute); → Technical and professional organizations.

ItM (Ger.), abbrev. for: Institut für textile Meßtechnik, Mönchengladbach, Germany (German Institute for Textile Measuring Technology); → Technical and professional organizations.

ITMA (Ger.), abbrev. for: Internationale Textilmaschinen-Ausstellung (International Textile Machinery Exhibition). The largest and most important European exhibition of textile machinery held every 4 years at a different venue. Organized by: → CEMATEX.

ITMF, abbrev. for: International Textile Manufacturers' Federation, Headquarters: Zürich, Switzerland. Founded in 1978 as the successor to the IF-CATI. Umbrella organization of 32 textile associations in 38 countries on all continents; → Technical and professional organizations.

ITS → International Textile Service.

IUPAC, abbrev. for: International Union of Pure and Applied Chemistry. A voluntary non-profit association of national organizations representing chemists in 45 member countries. It was founded in 1919 for the standardization of nomenclature and coordination. Its headquarters are in Basle, Switzerland.

IUT (Fr.), abbrev. for: Institut Universitaire de Technologie de Lille (Technical Institute of the University of Lille), integrated with CREST; → Technical and professional organizations.

IVC (Ger.), abbrev. for: Industrie-Vereinigung Chemiefaser, Frankfurt, Germany (German Industrial Man-Made Fibres Association); → Technical and professional organizations.

IW dyeing method A method for dyeing those vat dyes (IW dyes) which have the maximum affinity for cotton at 40–50°C. → Vat dyeing.

IWS, abbrev. for: → International Wool Secretariat. → Technical and professional organizations.

IWS cold-dwell printing process for wool A printing process for the production of fast and brilliant shades on wool with reactive dyes of high reactivity which are stable to sodium bisulphite. The print pastes contain approx. 300 g/kg urea and 0–20 g/kg sodium bisulphite depending on the dye concentration. After printing, the fabric is allowed to stand in the wet state for approx. 24 h. Shorter dwell times are sufficient on chlorinated or Hercosett-treated wool. Finally, the goods are washed in dilute ammonia liquor.

IWS finish A process for the setting of wool fabrics. The fabric is moistened with Si-Ro-Set solution (MEAC/MEAS) by padding and squeezing. The fabric is permanently set by wet steam or gloss decatizing in the still moist state for 3–5 min. Finally the fabric is dried without tension.

IWS flame-retardant finish for wool Wool is treated with potassium hexafluorozirconate (K_2ZrF_6) or potassium hexafluorotitanate (K_2TiF_6) from a long liquor at 60°C or also from short liquors in various combinations with dyeing processes and/or antifelting crease-resist finishes.

IWS Superwash process → Superwash.

IWTO, abbrev. for: → International Wool Textile Organization; → Technical and professional organizations.

IWV (Ger.), abbrev. for: Internationale Wollvereinigung (analagous to → IWTO); → Technical and professional organizations.

Ixtle fibre (istle fibre, Tampico fibre). A fibre obtained from various tropical Central American agave and yucca trees (also palm fibres). Ixtle fibre belongs to the group of → Hard fibres and is similar to → Sisal although not a hemp variety. The fibres, of variable length, are stiffer and coarser than sisal. Uses: cords, ropes, brushes, flat carpets and coarse fabrics.

J

J symbol for → Joule.

J-acid (2-amino-5-naphthol-7-sulphonic acid). Organic intermediate used in the manufacture of azo dyes.

Jacquard fabric Collective term for a figured fabric woven with a design produced by lifting individual warp threads. Finely drawn, large repeat designs of great variety are obtained by this method which cannot be reproduced by dobby weaving. Typical jacquard fabrics include: damask, brocade, matelassé, and tapestries.

Jacquard mechanism A shedding mechanism on a weaving machine which controls the lifting of the warp threads via a harness with healds. Lifting of the ends is controlled by a data carrier, e.g. a chain of punched cards or by a loop of punched paper. The warp threads are lifted individually corresponding to the required design (analogous to jacquard mechanisms on knitting machines). Whilst shed formation with heald shafts (→ Dobby mechanism) involves the lifting of several warp threads in large groups, the number of groups of combined warp threads in the jacquard mechanism is small; in extreme cases each jacquard lifting hook can be supplied with a single thread so that separate control of every single warp thread is possible, e.g. as required in tapestries, figured gobelin and carpet weaving. As a consequence, the warp and weft repeats are theoretically unlimited.

Jacquard technology Knitting and weaving technology for the production of large repeat designs in which each warp thread can be lifted or each loop-forming operation can be individually controlled via a → jacquard mechanism. Named after the inventor, Joseph Marie Jacquard (1752–1834). Compared to fabric printing and dobby weaving, jacquard weaving represents the most expensive method of producing large repeat designs on textiles since, for each design, the individual lifting of a number of warp threads corresponding to the size of the design must be predetermined for each weft insertion. The design paper which controls the jacquard mechanism must then be punched out. Jacquard warp-knit and jacquard jersey can be reverse-plated on one side and, in this case, the back side of the fabric contains linked loops without floats. Float-plated jacquard designs are lighter but not as elastic as jacquard designs produced with double threads in which the backward thread floats of float-plated fabrics are avoided and those threads which do not participate in the jacquard design are knitted into the material.

Jacquard wire weaving machine A weaving machine with a jacquard control mechanism for the production of multicoloured → Wire carpets, e.g. Wilton and → Brussels carpets.

Japan silk (Japanese silk). A fine slub-free natural silk fabric with a satin weave produced from absolutely uniform yarns reeled from mulberry silk (warp and weft: raw silk). Also a collective term for fine natural silk fabrics without slubs for apparel use and lampshades. Specific constructions include pongé, Habutai, Helvetia silk, and Ningai. Japanese silk fabrics are sold in specific widths and lengths for export (22,8 x 3,8 m). The quality is indicated by an official quality stamp on the piece ends: red = first quality, blue = second quality and black = reject quality. The fabric weight is given in Japanese momme units per square yard (1 momme = 3,75 g). The lightest Japanese silks weigh 3–4 momme units, which corresponds to 13–18 g/m^2.

Japan wax (Japan tallow, sumac wax). A vegetable fat obtained from the fruits of a species of sumac (not a real wax). Available commercially in the form of small convex cakes or rectangular blocks, light grey in the raw state or yellowish-white (bleached). Water content up to 20%. At 10°C it is still a brittle solid but softens when held in the hand. Japan wax has a mp of 45–55°C. Soluble in benzene and naphtha, insoluble in water and cold alcohol. Readily saponified. Combustible. Uses: for textile sizes, finishes, etc.

Jaspé

I. A ply-like yarn produced from 2 differently coloured rovings lightly twisted together.

II. A filament yarn produced from two intermingled or air-jet textured strands of different chemical composition and cross-dyed to achieve 2 different colours.

III. Jaspé mouliné: a French term for a ply yarn produced from 2 jaspé threads (cotton and viscose) having a fine flammé appearance.

jato (Ger.) abbrev. for: Jahres-Tonne (tons/annum).

Java jute → Kenaf.

Java print A type of → Africa print with a particularly wide appeal among the indigenous populations of many African countries. The term “Java print” originates from the printed fabrics formerly produced in Indonesia with very characteristic designs although, nowadays, a modern “Java print” may be based on practically any multicoloured design having no connection with Java. A Java print generally consists of lemon yellow and gold resists on a green, blue (mostly phthalocyanine), dark red or brown ground. Procedure: cotton fabric, prepared with a naphthol, is printed with a resist agent (together with reactive dyes for coloured resists). The formation of diazo compounds in those parts of the design printed with the resists is inactivated in subsequent development more quickly than coupling with the naphtholate can take place.

Javelle water → Eau de Javelle.

J-box A large upright J-shaped vessel (which serves as a storage chamber) used in the continuous processing of textile fabrics mainly in rope form (seldom open-width) to provide the necessary reaction time for goods impregnated with chemical solutions, e.g. desizing, scouring or bleaching liquors (see Fig.). The impregnated fabric is plaited into the top of the long arm of the box from where it slides down and around the bottom before being withdrawn from the short arm. Duration of treatment depends on the process and may exceed 1 hour in some cases. Steam is used to heat up the fabric to the reaction temperature, either prior to entry in a steaming channel (Du Pont system) or in the J-box entry zone itself (Becco bleach system). Special J-boxes are also used for the treatment of tricot fabrics and as cold dwell units for cotton fabrics wetted with caustic soda liquor to induce stretch. J-boxes are usually constructed of stainless steel although, GRP (glass reinforced plastic) has been successfully employed for cold treatments, e.g. bleaching with sodium hypochlorite.

Jeans Originally an American term (now international) derived from Gênes (cloth from Genoa). The term was coined in the USA to describe tight-fitting trousers made of cotton twill, usually woven with a dark blue dyed warp and undyed weft (→ Denim), stitched on seams and pockets and having copper rivets here and there. As a rule, blue jeans are dyed with indigo and thus have limited colour fastness to rubbing and washing. At the beginning of the 1970’s, a casual and unconventional style of clothing based on blue jeans emerged which, from a wide variety of materials (brush denim, chambray, bullcord, cord velvet, brushed cord) and corduroy, spread to other garments and accessories such as skirts, jackets, shoes and bags that became the prototype of modern leisurewear.

The dyeing and finishing of ready-made jeans articles has gained increasing prominence in recent years. Originally used exclusively for workwear, jeans have gained a position of ever-increasing importance in the clothing market due to improvements in wearing comfort and their adoption by the fashion market. Designers soon learned how to make this original workwear material attractive to an ever increasing number of customers through innovative modifications and styling. As a result, it is impossible to imagine today’s clothing market without jeans in one form or another, e.g. “stone washed”, “moon washed” “used look” or “rodeo washed”.

The various processes used to obtain these different effects are not generally known in every detail. Consequently, the following example recipes can only serve as a general guide and are certainly subject to wide variations in practice. As a processing unit the drum washing machine is mainly used to achieve these effects.

I. Stone washed: a) the ready-made garment pieces are turned inside out and prewashed or desized; b) they

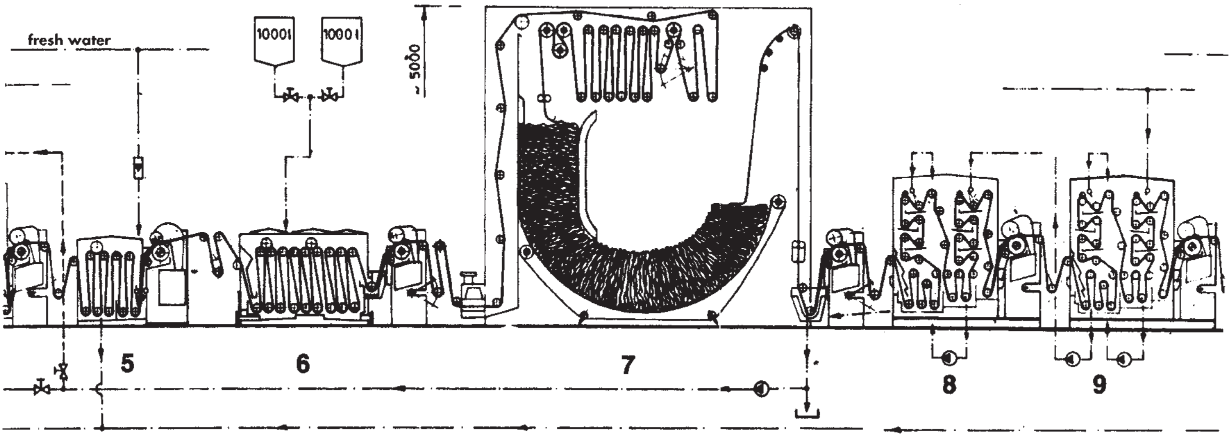


Fig.: Open-width bleaching stage with J-box (Küsters).
5 = roller vat with 10 m fabric content and high-efficiency squeezer with S-rolls for wet-on-wet pick-up; 6 = saturator compartment with 20 m fabric content for application of the bleaching agent; 7 = J-box with steaming zone in tight-strand passage, J-box storage section and pneumatic squeezer, nominal capacity: 600 kg/m fabric width; 8–9 = high-efficiency open-width washing machine meander type, fabric content 20 m per unit with pneumatic squeeze rolls.

are then taken out of the washing machine, turned face side out again and washed with chalky sandstone at a ratio of 1 : 3 (1 kg of garments: 3 kg stones; c) the garments are taken out of the machine, the stones removed, and bleaching is carried out with sodium hypochlorite (according to the desired shade). To minimise fibre damage, an alternative milder treatment can be given as follows:

1st bath: enzymatic desize followed by an intermediate rinse.
2nd bath: chemical stone wash treatment with enzymes followed by 2–3 rinses.
3rd bath: application of softener.

II. Snow washed: a) stones are soaked for 12 h in a solution of potassium permanganate; b) the wet stones are then hydro-extracted for 30–50 s in a centrifuge; c) the hydro extracted stones and garments are loaded into the washing machine for a cold treatment of 15–30 min; d) the stones are removed; e) the brown stains from the permanganate are washed off the garments with sulphurous acid followed by neutralization; f) a final application of softener is given. To minimise fibre damage, an alternative milder treatment can be given as follows:

1st bath: enzymatic desize followed by an intermediate rinse.
2nd bath: chemical stone wash followed by 2–3 rinses.
3rd bath: bleaching.
4th bath: application of softener.

Jelling machine → Gelling machine.

Jelly →: Gel; Colloid.

Jersey Originally the description for a milled wool fabric produced on the British island of Jersey, in the Channel Islands, and used for fishermen’s clothing. This fabric was produced on circular or supreme machines with a backing device. The elasticity of this knitted material was greatly reduced by the milling process so that it was also suitable for use in outerwear such as women’s jackets, dresses and quality goods. The single weft-knitted fabrics which alone qualify, on technical grounds, for the description “jersey” are nowadays often referred to as “single jersey” and the term is in no way limited to wool fabrics. Similar fabrics are thus produced on circular knitting machines (with and without a wevenit mechanism) in a variety of constructions. These knitted products, which have two face sides (double-knit) are described in the trade as “double jersey”. Textured crimp yarns produced from man-made fibres are mainly used for these fabrics. Today, even other materials produced on automatic circular knit, warp-knit and raschel machines in weave-knit constructions for women’s and mens’ outerwear garments are falsely described in the trade as jersey. Moreover, a “woven jersey” is produced from core-spun ply yarns as a matt, high quality, crêpe dress fabric with a surface similar to a knitted fabric. In summary, jersey is a collective term (generic name) for a range of outerwear fabrics (chiefly knitgoods) produced from a wide variety of yarns and production methods without any exact demarcation. Jersey articles are frequently encountered in the market with additional names such as, e.g. fine jersey, jean jersey, ripple jersey and silk jersey (produced from bright polyester yarns) having a completely different optical appearance.

Jersey finish on wool A milling treatment to reduce elasticity or stretch in order to make the fabric more suitable for e.g. outerwear.

JES abbrev. for: Japanese Export Standard.

Jet air circulation driers The most widely used driers of this type are stenter driers in which air flow is achieved by means of radial or axial fans via air ducts with round, oval or slit jets. The air is directed perpendicularly to both sides of the textile material (also tangentially in the case of swivelling jet nozzles) which is then deflected sideways and conducted back to the fans via heaters together with a controlled supply of fresh air. Since the textile material is supported on pins or clips along each edge, the width can be controlled within specific limits although this is not possible with the similarly constructed jet belt drier. In the latter type of drier, the material is transported on a conveyor belt (e.g. steel or textile fabric) through the drying chamber with separate air flows from above and below. In order to overcome the disadvantages of both systems in the finishing of sensitive knitgoods conveyor stenters, which represent a combination of stenter and belt drier, are now available. Further developments designed to eliminate damaging fabric tensions by a carrier effect with appropriately constructed jet nozzle systems and air flows include, e.g. swivelling jets, horizontal jets, carrier jets, air cushion stenters or driers, etc. which generally employ reduced rates of air flow.

Jet driers (steam jet driers). The principle on which these machines are based involves directing jets of a superheated steam/air mixture with a high steam content to both sides of the textile fabric without the introduction of fresh air. The high flow rate of the steam/air mixture generated in the jet nozzles by relaxation of pressure gives a high heat transfer and results in short drying times in the region of 10–20 s for normal fabrics of approx. 150 g/m^2. The high temperature of the drying medium (130–170°C) allows the application of a high proportion of superheated steam which is constantly drawn off with the water evaporated from the fabric. This steam/air mixture flows through suction channels over heating elements and is kept in circulation by fans via the heating elements, jets and the fabric. The steam atmosphere provides a high degree of protection against fabric damage since superheated steam largely displaces the air from the drier so that even low levels of residual atmospheric oxygen can no longer cause oxidative damage to the fabric. Provided they are used correctly, modern high-efficiency steam jet driers do not result in overdrying or other qualitative disadvantages in comparison to normal drying. Even with the heaviest wool materials no damaging influences are to be expected by rapid drying in superheated steam at 145°C – on the contrary improvements in handle are achieved. The use of jet driers in the finishing of fabrics with synthetic resins is generally superior to the older drying systems as far as uniformity of drying is concerned. In addition, they also offer the advantage of considerably shorter curing times and the risk of synthetic resin migration to the surface of the fabric is less.

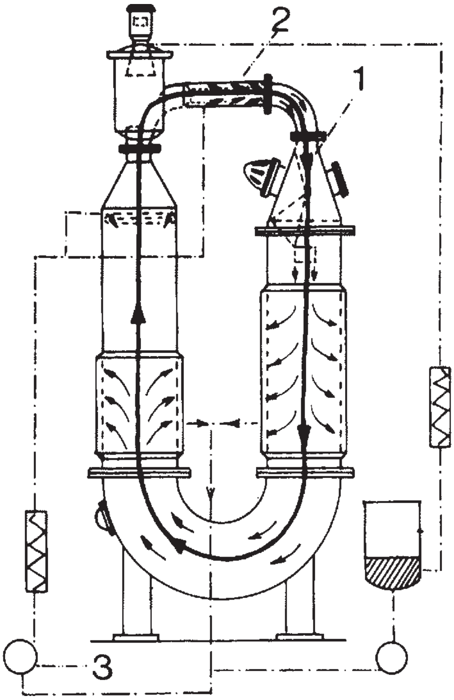

Fig. 2: Thies Jet Stream vertical fully-flooded machine (Jumbo Jet).
1 = fabric path; 2 = jet; 3 = pump.

Jet dyeing, development of The development of the jet dyeing machine closely parallels the introduction of synthetic fibre textiles to the fashion market. Although the so-called "Nyltest" shirting fabrics produced from polyamide warp-knits at the end of the 1950's were still being dyed in beam dyeing machines, the appearance of polyester circular-knits compelled machine makers to design a completely new type of dyeing machine. In dyeing this material, which first had to be slit into open-width and scoured, the loftiness (bulk) of the knitted fabric in particular had to be developed before the state of the material was heat set during the dyeing operation. The search for suitable dyeing methods culminated in the development of the → Jet dyeing machine. In these machines the fabric rope was not transported by a winch as in the HT winch dyeing machine, but by the dye liquor according to the jet principle via guiding and deflecting rollers or simply by a jet through a tube. Depending on the type of machine, the high fabric speeds of 120–160 m/min and the turbulence surrounding the fabric rope ensure a good shifting and opening of the rope so that the need for prior heat-setting is eliminated. Depending on requirements, fabric speed and lengthwise tension can be adjusted by regulating the liquor flow. Loading a jet dyeing machine with a relatively long run of fabric, depending on its weight per m^2 and construction, can be accomplished in a considerably shorter time than is possible in e.g. a HT-winch due to the higher fabric speed. For fabrics that do not require pre-setting, dyeing can be carried out by loading the fully-flooded horizontal (Fig. 1) or vertical (Fig. 2) jet dyeing machine with grey fabric and dyeing without a separate pre-scour. Occasionally, a short pre-scour is also given in the jet machine. The greatest problem with partially-flooded machines (Fig. 3) is foaming due mainly to the intense liquor movement. When foam development becomes excessive, constant fabric transport is no longer guaranteed and machine stoppages may even result. Although the addition of de-

foamers is indeed helpful in such cases these products only serve to create other problems (e.g. waste water pollution).

Defoamers are not stable throughout the entire dyeing process and may lead to the formation of stains which can only be removed with great difficulty. Fully-flooded machines, on the other hand, represent the optimum solution for dyeing textured polyester materials under HT conditions. However, if the material being dyed contains certain blend yarns, e.g. polyester combined with cellulosic or animal fibres, fibre abrasion due to high turbulence and high running speeds can cause problems. For such materials, machines which operate on the overflow principle (Fig. 4) are regarded as more ideal (→ Overflow dyeing machines). In these machines the material to be dyed receives a much more gentle treatment due to the lower fabric transport and liquor speeds so that fibre abrasion and associated weight losses are not as great a problem as when dyeing is carried out strictly according to the jet principle.

The drive and deflecting reel in the dome (or in later machines also in the chamber) is typical for overflow rope-dyeing machines as well as later examples of jet dyeing machines. Fig. 5 illustrates the small non-driven deflecting roll in a Hisaka jet for fabric transport from above to below.

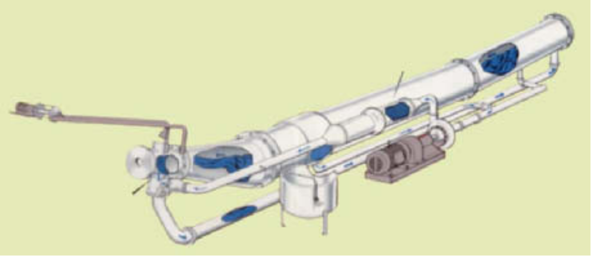

Fig. 5: Hisaka Circular Cut jet dyeing machine.

The "Fluido-Jet" was developed specifically for the rope dyeing of 100% silk fabrics (Fig. 6).

It is the result of a series of trials for dyeing all types of fabrics likely to suffer damage through contact with mechanical transport devices. The fabric rope moves horizontally in the open state without tangling. In the front part of the machine, the fabric rope is deflected by a guide bar immersed in the liquor thereby avoiding direct contact between fabric and metal bar. In the rear

section of the machine, the fabric is guided into the cylindrical dyeing tube via a specially shaped slide. The rinsing device and following channel have a special shape and location in order to prevent the extremely harmful twisting of the fabric rope.

The liquor ratio (10 : 1 to 15 : 1) and circulation speed (100–150 m/min) are particularly favourable for the type of fabric being treated. The average dyeing time and energy requirements (water and steam) have been reduced to about half that required in conventional machines. If required, a special parallel jet suitable for heavy fabrics can be supplied.

All models of jet dyeing machines can be used to dye two different batches of fabric or a single batch in double quantity when coupled one to another. All machines are fitted with a special safety device which automatically stops the circulation pump and triggers an alarm if fabric transport is brought to a standstill for any reason. The Jet-Stream machine is available in horizontal (Fig. 7) or vertical (Fig. 8) execution. Jet dyeing machines with non-driven winches (Fig. 9) are also available.

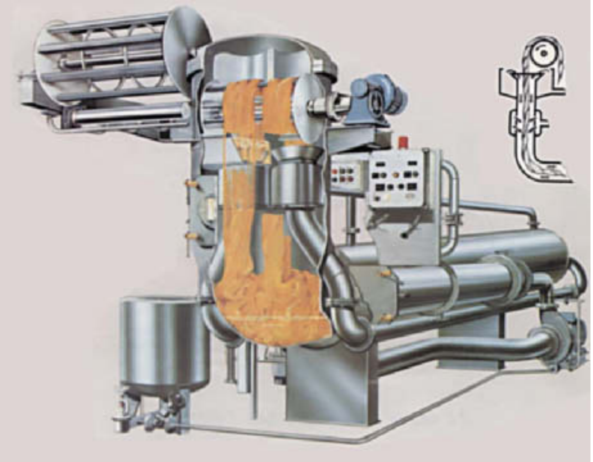

Fig. 8: Vertical Jet Stream unit with driven winch in the Rapidsuau jet (ATYC).

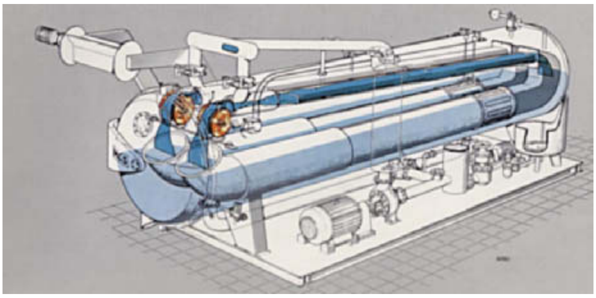

Fig. 9: Non-driven winch in the MCS Siluro jet.

The jet dyeing machine with a lower liquor level functions according to a two-phase principle, i.e. the jet is located in the gas phase above the liquor. When the liquor comes into contact with the rope of fabric in the jet, the air surrounding the rope is displaced without great loss of energy. Contact between liquor and rope is thus immediate and intense each time the rope passes through the jet. This is particularly important for the uniform distribution of dye, chemicals and temperature. There is no requirement to adapt the jet to suit different types of fabric. The same jet is used for lightweight as well as heavy materials, wovens, warp-knits or weft-knits. Rope speed is infinitely variable from 0 to more than 400 m/min. The choice of speed is determined by the dwell time; speed selection is thus dependent on the length of the fabric rope; a complete cycle should, as a rule, be less than 2 min or better still approx. 1 min.

Regulation of rope speed is achieved by means of the jet pressure and an infinitely variable driven reel. At these high speeds it is important for the rope to be well plaited after passing through the jet. For this purpose, the rope impinges on a baffle plate after leaving the jet so that the direction of movement is deflected and the rope opened out. The higher the speed the better the spread of the rope. Effective spreading of the rope has several advantages, e.g. lengthwise creases formed when the rope is drawn through the jet are smoothed out, and the fabric passes through the dwell chamber in an opened out state thereby preventing the formation of knots.

Rope transport:

a) Winch machine: the winch is driven in a clockwise direction (Fig. 10) and the rope has a much greater speed outside the dwell zone than within it. At the end of the dwell zone the rope, which is in a more or less uniform plaited condition, is then quite suddenly accelerated to the higher running speed. Inertial forces thus develop in this region which act on the fabric rope. In addition to these inertial forces, the static forces of the rope weight plus the weight of the liquor, before and after the winch, must also be added. These are designated as G_2 and G_1. According to Eytelwein, the following relationship exists between the forces acting on the rope at the winch:

$$P_2 \leq P_1 \cdot e^{\mu\alpha}$$

μ = coefficient of friction between rope and winch reel,
α = angle of wrap.

If,

$$P_2 = P_1 \cdot e^{\mu\alpha}$$

then P_2 is the max. rope force which, at given values of μ and α, can be transmitted without rope slippage on the winch reel.

However, if

$$P_2 < P_1 \cdot e^{\mu\alpha}$$

this means that the total angle of wrap available a is not necessary for the transfer of force but a smaller angle. This angle is called the transmission angle and may be assigned the symbol β; the following relationship is then obtained:

$$P_2 = P_1 \cdot e^{\mu\beta}$$

In the following considerations, it has been assumed that $\beta = \alpha$ and the max. rope force is

$$P_2 = P_1 \,.\, e^{\mu\alpha}$$

If the force

$$P_1 = G_1 = 0$$

then $P_2 = 0$, and rope slippage on the winch reel likewise occurs.

From equations (2) and (3) (Fig. 10a), it is apparent that undue stretching of the rope can be caused not only by a long length of free rope between the surface of the liquor and the winch reel, but also very probably by inertial forces acting on the rope at the end of the dwell zone.

b) Equation (1) under a) is also valid for the jet dyeing machine. The reel before the jet is not driven. Rope transport is effected by impulse exchange forces between the liquor and the rope. Equation (2b) expresses the same effect as (2a).

c) Softflow dyeing machine: as shown in Fig. 10 rope transport is achieved by a combination of the transport mechanisms described in a) and b). It is apparent from Fig. 10 that the risk of rope slippage on the winch reel is virtually eliminated by the force of the jet P_1 (equation 1). The action of the liquor impulse from the jet on the fabric rope is dependent on the nature of the fabric itself (open-structure fabric of low density or compact fabric of higher density). With denser fabrics, the liquor cannot penetrate the rope completely and runs off after a relatively short contact time. From the geometrical difference between the developing and dissipating impulse forces, a small force P results which moves the rope largely through surface forces acting on a relative small volume of the rope which can thus damage the material (the force per unit volume is great). In the case of fabrics with an open structure, the stream of liquor can penetrate the rope much more easily, the exit area of the liquor from the rope is greater, and the associated exit rate v2 is smaller which results in a greater impulse force P. However, this force acts on a larger rope volume and the force per unit volume is therefore lower which has the effect of transporting the fabric more gently. By installing a tube beneath the ring jet, the rope is penetrated more completely by the liquor, the exit rate v2 is even smaller as a consequence and the resulting impulse force is greater with a relatively small impulse force density giving a more "gentle" rope transport although a large transporting force is acting on the rope. The length of this tube installed beneath the jet is limited by the possibility of obstruction.

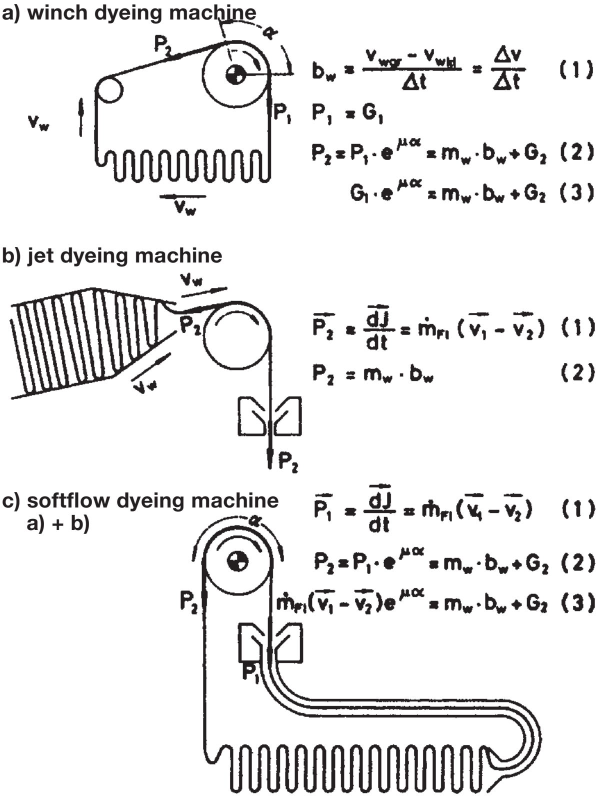

Fig. 10: Rope transport systems in the acceleration zone. m_w = mass of rope to be accelerated, b_w = rope acceleration, G_1 resp. G_2 = weight components of rope plus liquor, m_{Fl} = quantity of liquor entering/leaving the rope per unit time, v_1 resp. v_2 = flow rates of the liquor on entry/exit.

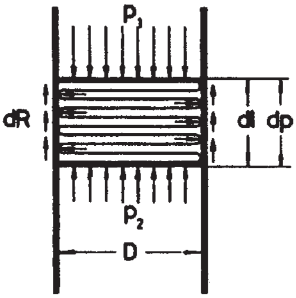
If a more “gentle” rope transport is required, which calls for a low impulse force density, then in order to avoid obstruction in the tube, the latter must have a greater diameter than the rope. The liquor is then able to penetrate the rope completely and also shift between the rope and the inner wall of the tube. The risk of obstructing this tube thus becomes much lower. The combination of a jet with an adjoining long tube is used in the soft-flow jet and is characterized by an extremely gentle rope transport. If, however, the ring jet is fed with a higher quantity of liquor the impulse force increases and less sensitive fabrics can be processed in a similar manner to a normal jet machine. The soft-flow machine described here can therefore be operated as a “soft-flow” or “less soft-flow” machine according to requirements. Because of this advantage, the machine is more universal in application than the other dyeing machines.



$$dp = p_1 - p_2$$

$$dP = dR$$

$$F = \frac{D^2}{4} \cdot \pi$$

$$dP = dp \cdot F = dp \cdot \frac{D^2}{4} \cdot \pi$$

$$dR = p \cdot D \cdot \pi \cdot k \cdot \mu \cdot dl$$

$$-dp \cdot \frac{D^2}{4} \cdot \pi = p \cdot D \cdot \pi \cdot k \cdot \mu \cdot dl$$

$$-\int_{p_1}^{p_2} \frac{dp}{p} = \frac{4 \cdot k \cdot \mu}{D} \int^{2} dl$$

$$\ln \frac{p_1}{p_2} = \frac{4 \cdot k \cdot \mu \cdot l}{D}$$

$$\frac{p_1}{p_2} = e^{\frac{4 \cdot k \cdot \mu \cdot l}{D}} \quad \text{resp.} \quad \frac{p_2}{p_1} = \frac{1}{e^{\frac{4 \cdot k \cdot \mu \cdot l}{D}}}$$

Fig. 11: Rope transport in the dwell zone and derivation of equation for rope movement.

The rope is moved forward in the dwell zone by differences in pressure forces. Even this process can be described mathematically by a model based on simplified assumptions. In Fig. 11 a schematic representation of the longitudinal section of a dwell zone assumed to be circular with a diameter D is given. In this tube the rope lies in a more or less ordered plaited state. This “rope packet” lies against the inner walls of the tube and a stream of liquor passes through it from above to below. From the section cut through the tube of length dl shown in Fig. 11, the pressure difference due to the liquor flow $dp = p_1 - p_2$ acts on the rope. The pressures p_1 and p_2 compress the rope so that it lies against the inner wall of the tube and during its liquor movement at this point a frictional force dR is produced which is dependent, among other things, on the friction factor m between rope/tube. The factor k is intended to take the transverse spread of the rope packet due to its longitudinal compression into account. This is dependent on, e.g. the amount of fabric in the tube, the character of the fabric, and the plaited condition of the rope (channeling), etc. $k < 1$ means that the transverse spread of the rope packet in the tube is less influenced by the longitudinal compression and vice versa. As can be seen from the equation, an exponential relationship exists between the pressure ratio of the pressures acting at the beginning and end of the tube length l and the other parameters (contributed by Vernazza).

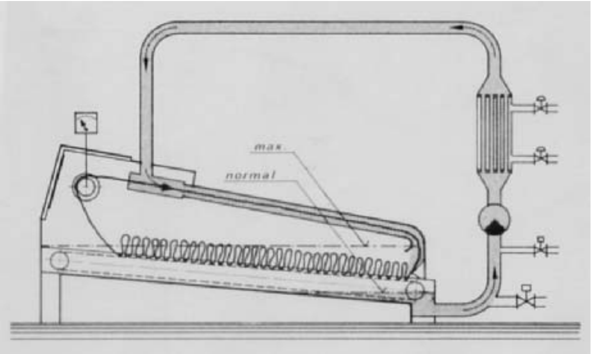


Fig. 12: Shorter liquor ratio by incorporation of a fabric support system in the form of a belt conveyor in the dwell chamber of the ESPA Miniflott-Jet (HT and atmospheric) of 100–2000 kg.

During the 1980’s, piece dyeing was given a new impetus by numerous new developments on the part of the machine maker. The liquor ratio, in particular, was considerably reduced by a variety of means (e.g. Fig. 12). Development led ultimately to the most modern derivatives of jet dyeing machines such as e.g. the Rotostream of Thies and the Then-Airflow machine.

The Rotostream dyeing machine is available in various executions with 1–6 storage chambers. Fabric transport is effected by means of a driven winch, a jet, and mechanically by rotation of the internal non-driven drum. Through modifications to the well-proven standard model, such as a lower position of the circulation pump, the heat exchanger and a shorter pipework system, a liquor ratio of 4 : 1 can be achieved. The fabric runs “dry” in a rotating storage chamber. Modification to the jet was also necessary in order to achieve adequate wetting of the fabric and secure fabric transport even with low volumes of liquor. A further advantage of this development is the elimination of time-consuming jet changes since, depending on the thickness of the rope, the jet nozzle itself adapts to the fabric. Speeds of up to 500 m/min are possible. Complete circulation of the liquor takes 2–6 min. In order to reduce mechanical stresses on the fabric surface, Thies have developed the Synchronized Dyeing System (SDS) in which the fabric flow, nozzle pressure and winch speed are synchronized. Cycle times during the individual phases of dyeing are variable. By this means, the times and dyeing phases critical for dyeing levelness are taken into account. The number of fabric cycles can be reduced by up to 60%. Programming of the control system is simple.

Compared to other jet dyeing machines, the most revolutionary development in fabric propulsion has been achieved in the Airflow. This system is based on an aerodynamic principle, i.e. fabric transport is not effected (as previously) by the dye or process liquor, but by a steam/air mixture. The product or dye preparations applied in this gas stream are finely distributed through several jet nozzles in a separate circulation and then sprayed or injected directly into the fabric. As a consequence, and depending on fabric quality, very low liquor ratios (2 : 1 to 4 : 1) with simultaneous high fabric speeds (up to 700 m/min) are achieved. In a 180 kg machine, complete turnover of the liquor takes approx. 8 min. The rate of turnover is 90 l/min. Programming is somewhat more complex since, for this machine system, the gas stream as well as the injection circuit must be programmed in relation to each other.

Savings in all liquor-dependent parameters such as steam, water and auxiliaries can be realized as a result of the liquor ratios achieved in short liquor jets, e.g. the quantities of salt can be reduced by more than 50 %. In conventional machines the costs of steam, water and electricity are approx. 0,40 DM/kg of fabric for a batch of polyester/viscose material. When the same batch is dyed in modern short liquor jets the costs lie between 0,075 and 0,10 DM/kg. Dyeings on synthetics result in small savings in dyes and a considerable reduction in dyeing times due to the quicker heating up and cooling down stages as well as the hot drop under HT conditions. On 100% cotton, a reduction of up to 10 % dye can be reckoned with although actual dyeing times cannot really be shortened.

Short-liquor jet dyeing systems have confronted the dyer with new problems: e.g. the distribution of dyes and auxiliaries on the fabric is only effected via the jet or the injection cycle since no dyebath, in the conventional sense, is available. The quantity of free liquor present in a single chamber machine (max. fabric capacity 180 kg) is approx. 200 l. Consequently, additions of dyes and fixation agents must be carefully metered. The distribution of dye and auxiliaries on the fabric is completed via a concentration migration process. This migration is dependent on a good capillary action which must be ensured by an optimum pretreatment. If the capillary effect is inadequate, i.e. the concentration gradient on the fibre cannot be balanced out, unlevel dyeings are inevitable.

Because of the waste water problems associated with dyeing, efforts have been made in the design of jet dyeing machines to achieve even shorter liquor ratios. Double rope systems are used for particularly lightweight knitgoods (see Figs. 13 and 14); special rope pilers for plaiting the fabric rope into the storage chamber are essential for running at low liquor ratios (see Figs. 15 and 16).

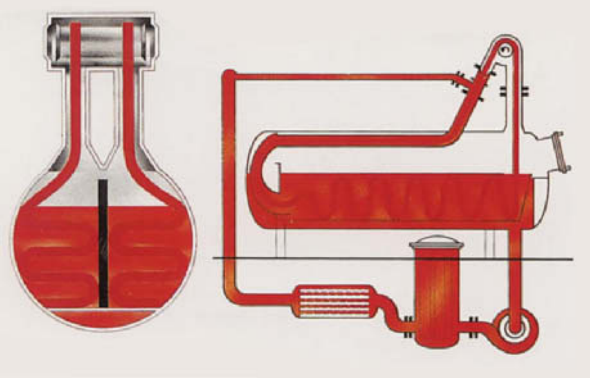

Fig. 13: Thies Soft-Stream with double rope.

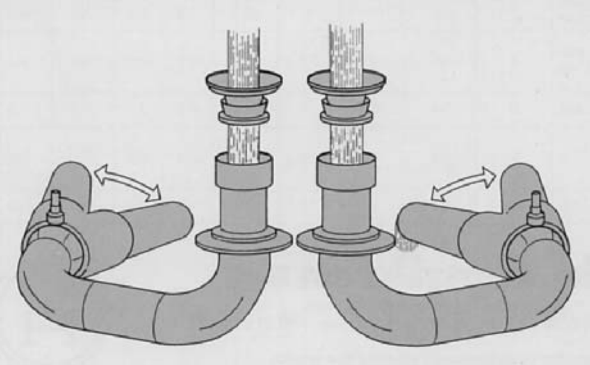

Fig. 14: Henriksen double rope system.

Taking the Colorstar jet dyeing system as an example, the great versatility of jet dyeing can be demonstrated (Fig. 17). The nominal capacity of the Colorstar machine is 180–200 kg per standard chamber. The capacity of approx. 180 kg is based on 100% cotton knit-

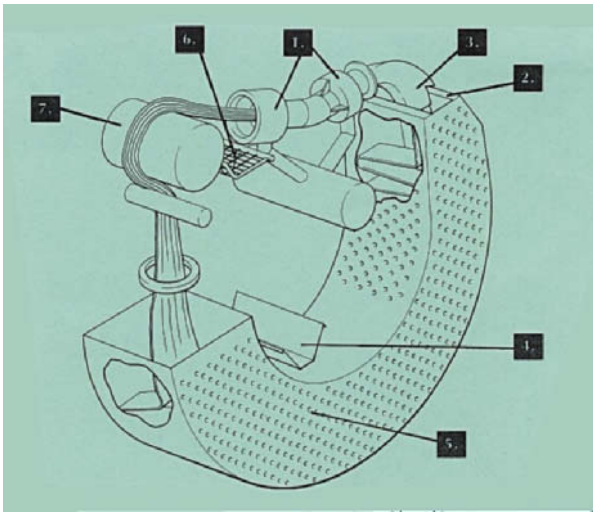

Fig. 15: Deposition tube in fabric container (Sclavos).
1 = jet system; 2 = bypass; 3 = deposition tube; 4 = rinsing trough; 5 = J-box; 6 = fabric speed regulation; 7 = winch.

goods and is approx. 200 kg for woven 100% cotton fabrics. On this basis, the smallest machine with only 2 chambers has a capacity to treat 360–400 kg of 100% cotton fabrics and the largest machine built up to now with 12 chambers can process 2160–2400 kg. For certain qualities, e.g. wool and wool blend woven fabrics or synthetic warp-knits, etc., the capacity is approx. 250 kg/standard chamber which thus corresponds to a capacity of 3000 kg for the largest machine with 12 storage chambers. For heavy, voluminous articles, larger storage chambers of even greater capacity may also be considered which have a positive influence on the price/performance ratio, liquor ratio and floor space requirements. For lightweight qualities, or articles for which shorter cycle times are desirable, even smaller

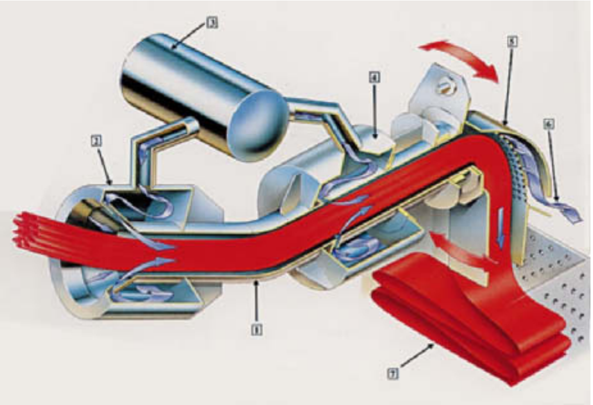

Fig. 16: Sclavos jet system.
1 = liquor/fabric guide tube as exchange zone;
3 = liquor distributor; 2 and 4 = jets; 5 = plaiter; 6 = bypass;
7 = plaited fabric.

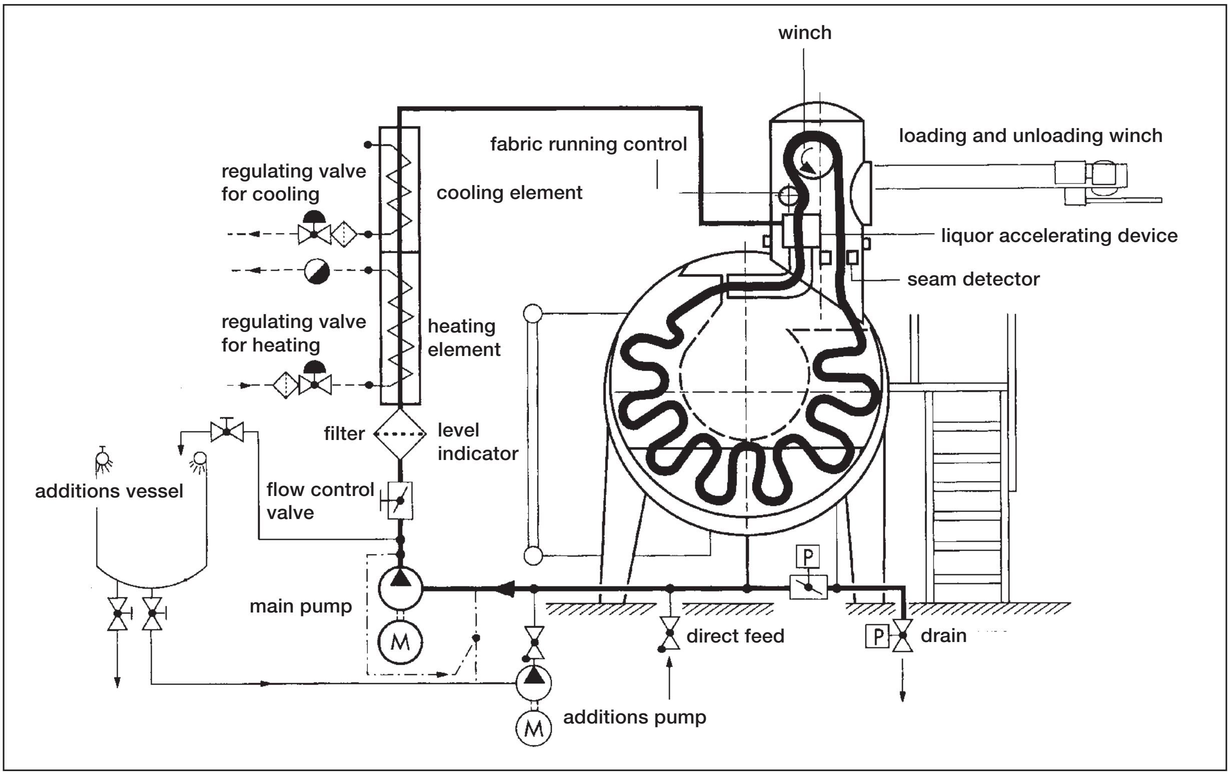

Fig. 17: Colorstar jet dyeing machine (Scholl).

chambers of lower capacity can also be used. Articles such as cotton interlock or single jersey are dyed at a liquor ratio of 5 : 1, woven fabrics containing a proportion of synthetic fibres at 4 : 1, and woven fabrics made entirely of synthetic fibres at 3 : 1. It is also possible to dye at higher liquor ratios on the Colorstar if necessary or desired.

Jet dyeing machines In a jet dyeing machine an endless rope of textile fabric, sewn end to end, is transported in a constant direction with the dye liquor in a narrow tube or chamber at temperatures up to approx. 142°C under pressure. Depending on machine design, the tube system is subdivided into a flow-through section and a dwell compartment (Fig. 1); several jet dyeing machines may be coupled together for high production. Liquor ratios from 5 : 1 to 10 : 1 are usual depending on fabric quality and type of machine. Considerable savings in time, dyes, textile auxiliaries and, above all, water, are achieved in jet dyeing machines. For crease-sensitive fabrics specially designed machines are also available.

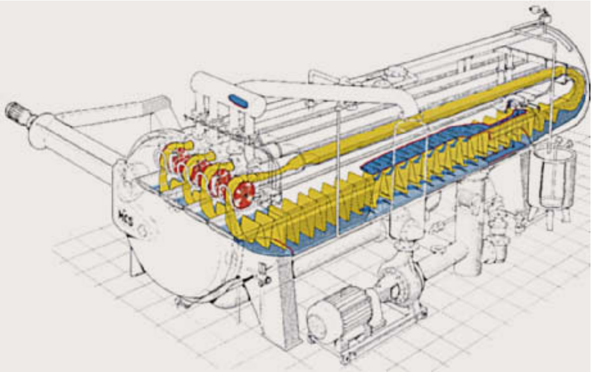

Fig. 1: MCS Siluro jet.

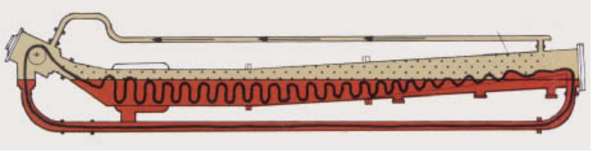

Fig. 2: Partially-flooded jet dyeing machine (Hisaka Jet) with separate circulation for air (above) and liquor (below).

Classification of jet dyeing machines according to functional principle:

1. Partially-flooded without transport jet.
2. With overflow principle.
3. With jet above the liquor surface.
4. With jet below the liquor surface (Fig. 2).
5. Fully-flooded with venturi jet.

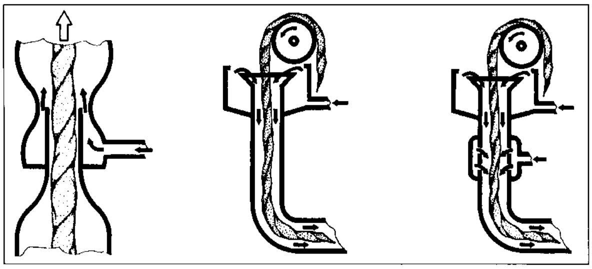

Fig. 3: Classic jet, overflow ATYC and Jet-Overflow "Rapidsuau" ATYC.

With the emergence of robust polyester knitgoods in the 1960's, fully-flooded jet dyeing machines were developed in which fabric transport was effected by means of a rapidly flowing liquor in the liquor exchange zone based on the venturi principle (Fig. 3). The trend in textile fabric development, however, has moved, and is moving, in the direction of lighter qualities which already contain "more air than fibres". Parallel to this development, greater consideration has been given to economic and ecological factors. Attempts have therefore been made to reduce the liquor-to-goods ratio so that savings could be realised not only in steam but water as well. Short liquor ratios also meant a reduction in the g/l of chemical and auxiliary additions which has been beneficial in terms of reduced waste water pollution.

From these considerations the first kier type machines with round storage chambers were developed. Due to the more stable flow of fabric, these machines offered advantages for very lightweight fabric qualities. Since the introduction of jet dyeing machines the advantages and disadvantages of jet or overflow systems have been the subject of continual discussion. The fundamental differences between the two systems are illustrated in Fig. 4.

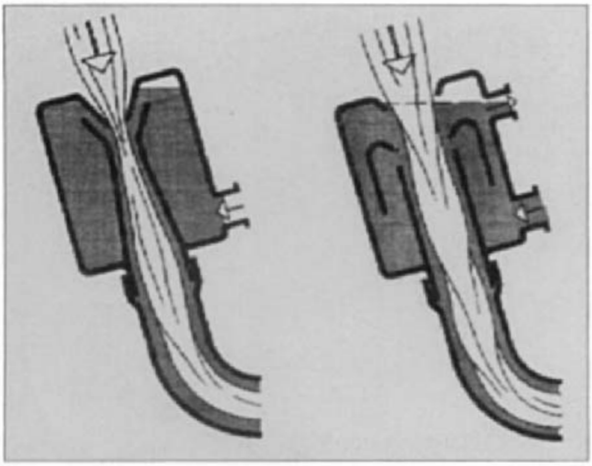

Fig. 4: Comparison between jet and overflow principle.

Jet dyeing machines

The initial development of jet dyeing machines began with pure jet systems derived from the so-called venturi jet. Here, the liquor passes through an orifice in the jet where it serves both to propel and shift the rope of fabric (Fig. 5).The effective force may be changed by the volume of liquor, the diameter of the jet and the jet orifice itself. This arrangement allows a relatively high fabric speed to be achieved. The German firm of Then has introduced a rectangular jet in the "Thenflow" machine (Fig. 6) which is claimed to offer the gentlest possible fabric treatment and allow a very wide range of fabric qualities to be dyed under gentle conditions without the need to change jet sizes.

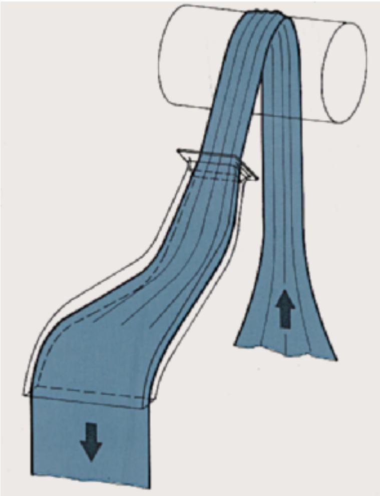

Fig. 5: Situation in the winch/jet region.

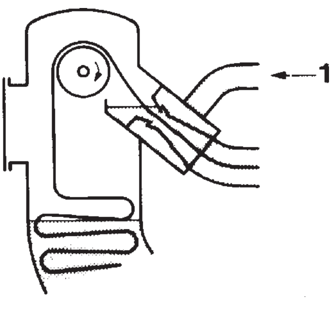

Fig. 6: Principle of the Thenflow.

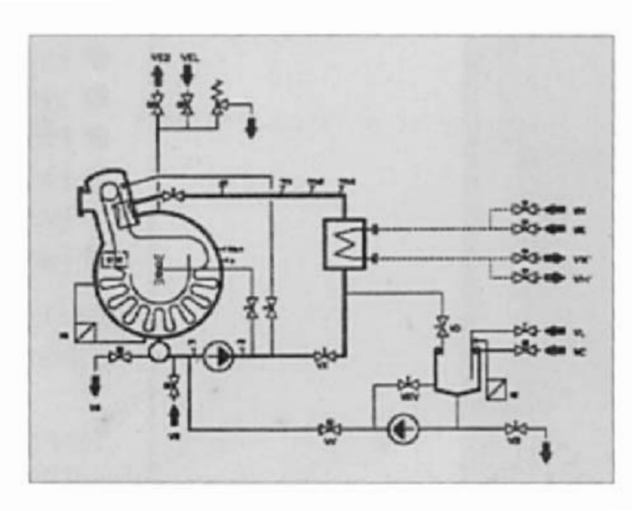

Fig. 7: Then Uniflow.

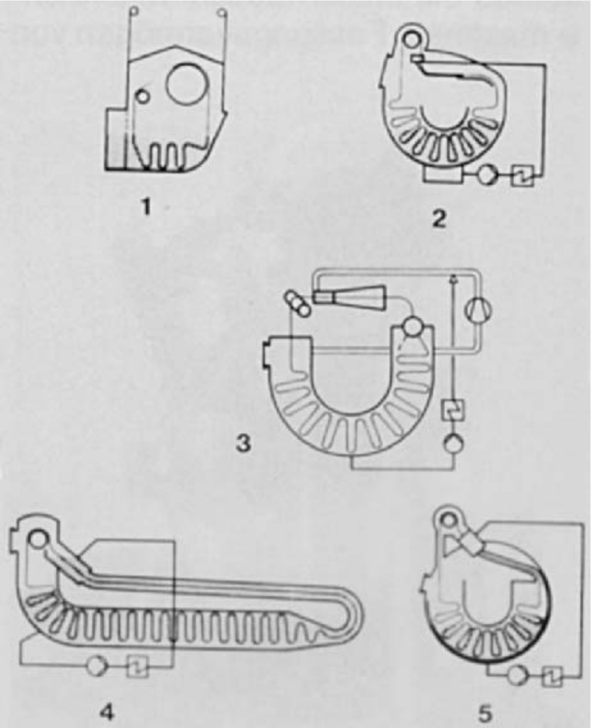

Fig. 8: Then piece dyeing machines.
1 = winch (liquor ratio 18 : 1); 2 = winch KFA (LR 10 : 1); 3 = Then Airflow HT (LR 2 : 1 to 4 : 1); 4 = Thenflow HT (LR 12 : 1); 5 = Economy Flow HT (LR 8 : 1).

The overflow system, in which the fabric rope is propelled by the liquor in an overflow condition, i.e. without dynamic pressure and dependent only on the height of fall, naturally provides the most gentle treatment as far as the fabric surface is concerned. High fabric speeds cannot be achieved because of the low dynamic force. However, the jet or overflow system is not solely responsible for the surface condition of the fabric. Other factors also play a part here such as the quality of the fabric itself. Moreover, factors such as fabric deposition in the storage chamber, fabric take up and friction on the reel, etc. all have a significant effect on the surface of the fabric.

The alternative to using either the jet or overflow system by means of a rapid change device has been realised in the "Uniflow" machine by Then (Fig. 7). Circulation of the fabric rope in the “Thenflow” is assisted by a driven reel. Fabric transport is effected by the liquor flow within the liquor exchange zone of the jet. The two jet dyeing machines “Thenflow” and “Economy Flow” differ in the form and arrangement of the fabric storage chamber, e.g. the “Thenflow” with a flooded horizontal storage chamber is more universal in application than the “Economy Flow” with a round storage chamber. In the latter, the fabric rope is transported above the liquor level to the side of the machine containing the reel and can therefore be used with a short liquor ratio at high fabric speeds as well.

The Then-Airflow (Fig. 8) has the shortest liquor ratio and requires no partial flooding of the storage chamber nor even a liquor sump due to the use of hot air as a fabric propulsion medium. Liquor ratios in this machine are determined by the nature of the fibre and the fabric construction and lie within the range of 2 : 1 to 4 : 1. The liquor ratio of 4 : 1 is only exceeded in the case of extremely heavy fabric qualities with high water retention (contributed by Quas).

Jet impingement Products and/or energy are applied via a carrier medium (water and/or air) to a textile fabric with the aid of jet nozzles. The action of thermal energy provides the necessary conditions for the activation of chemical reactions and/or the dynamic acceleration of physico-chemical processes in which the first part of the absorbed energy is mainly used to heat up the material. Since the reaction kinetics and diffusion processes are a function of the temperature, these processes only start to take place when the optimum temperature has been reached, i.e. the processes can only proceed to completion when the fibre and air or liquor have reached the treatment temperature. In practice, 2 important requirements must be observed in such processes:

1. The structure of the fabric must be uniformly penetrated.
2. Uniformity in the width and length must be constantly ensured.

In a jet application unit for liquors, products together with dynamic energy must be applied to a textile material simultaneously. Although the source of thermal energy can be selected at will, there are obvious advantages in choosing a suitable form of energy which is compatible with subsequent production processes. Steam is employed as a carrier of thermal energy in numerous textile finishing processes. The concept of an application unit with simultaneous action thus led to the idea of using mixing jet nozzles to spray a steam/chemical liquor mixture on to a textile fabric in a steam atmosphere (→ High wet pick-up). Although two-component mixing jet nozzles have been available for a long time, they were operated entirely with compressed air. An external mixture was selected as the mixing principle, which means that streams of steam and liquor exit the jet nozzle separately and mix in free space. Jet nozzles developed on this principle offer the following advantages (Raco Yet):

- liquor throughput can be adjusted over a wide range independently of the steam pressure to suit the fabric weight and running speed;
- the pressures in the liquor and steam on exiting the jet nozzle are of practice-relevant magnitudes;
- the most varied practical requirements are fulfilled by a simple exchange of jet nozzle components in a modular system;
- the essential jet nozzle characteristics required for uniform product application across the width of the fabric, e.g. optimum stream angle, are achieved.

Uniformity of application across the fabric width is achieved by overlapping the jet streams. For uniform application to the face and back sides of the fabric, a corresponding arrangement of jets is positioned on both sides of the fabric; here it is particularly advantageous if the two tapered air ducts containing the jet nozzles are staggered in relation to one another. The distance separating the jet nozzles from each other, the distance between the jet nozzles and the fabric and the angle of the air flow all interact in securing a uniform application across the width of the fabric. Process-dependent optimum distances thus need to be found which are compatible with the working limits of textile machines in a modular system.

In rope dyeing (jet dyeing machines), jet nozzles are required to perform a further task in addition to providing the means by which the fabric is impinged by a processing medium: i.e. the liquor stream from the jet nozzle is required to flow tangentially along the fabric rope and transport it along with it by taking advantage of the venturi principle. The flow characteristics of the jet nozzle must therefore be variable in order to provide suitable adjustment for fabrics and fabric surfaces of varying sensitivity (Fig. 1), i.e. the ratio between liquor

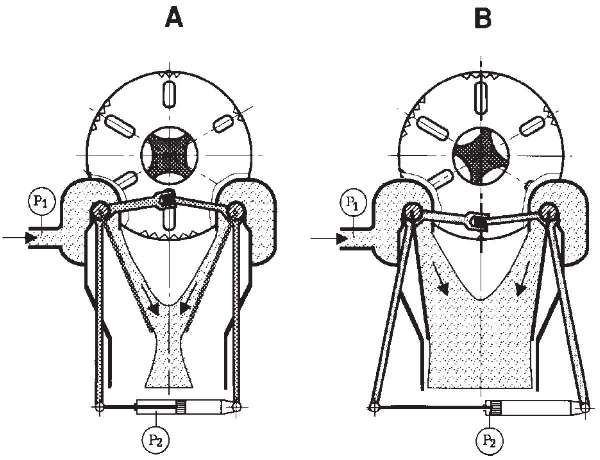

Fig. 1: Vario-nozzle (Thies) with approx. 5 jet sizes (A) from 50–120 mm and 1 overflow setting (B); no jet changing necessary.

flow rate and fabric speed must be variable (20 : 1 to 1 : 1).

For the treatment of open-width fabrics with hot air (e.g. drying, heat setting, thermosol process, curing, etc.), a high heat transfer in the region of air impact as well as a reduction in the impact stream during conversion into tangential flow is important. Formerly, only slit jets were used for this purpose.

In order to achieve a better packing density or concentration, round jets mounted in individual tapered air ducts were subsequently developed. The air flowing through round jets with a rotationally symmetrical heat transfer is able to find a way in the exhaust air spaces between the tapered air ducts without directly penetrating the jet streams. Despite this improvement, the 3 basic rules for an optimum geometry (by utilizing the total surface) are not fulfilled with this jet system either since, in the case of jet systems mounted in individual air ducts, there are always some zones with no air flow or zones which receive only a tangential stream with a low heat transfer (Figs. 2–4).

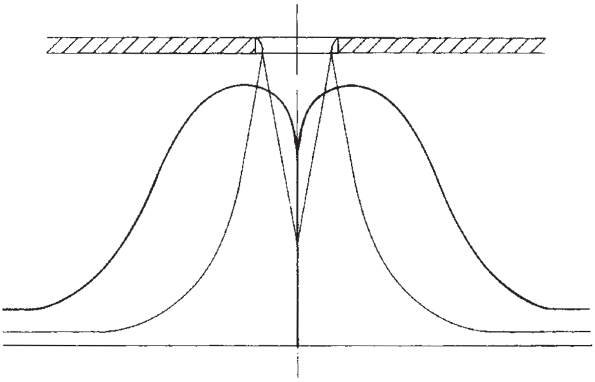

Fig. 2: Schematic representation of heat transfer from a single jet nozzle.

The optimum values for a favourable geometry with jet nozzle systems are as follows:

1. $$\frac{\text{distance nozzle/fabric (H)}}{\text{nozzle diameter (D)}} = 5$$

2. $$\frac{\text{area of nozzle}}{\text{area covered by air flow}} = 2\ \%$$

3. separation $= 1{,}4 \cdot H$

Optimum separation is not achieved in jet nozzle systems on individual air ducts. The Star-Jet system achieves an almost optimum utilization of the entire surface with large jet nozzles (Figs. 5 + 6). In this sys-

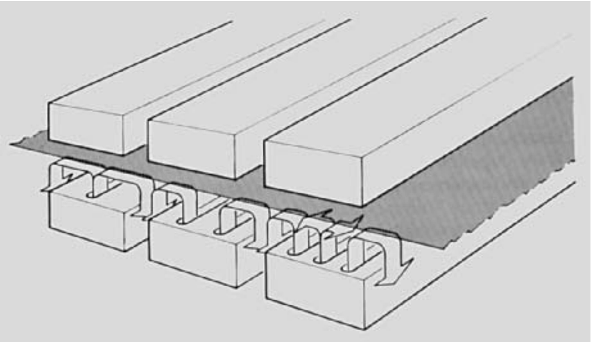

Fig. 3: Standard air ducts with different numbers of slit jets.

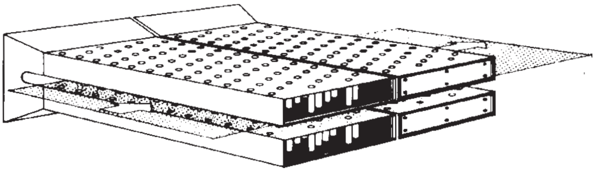

Fig. 5: Distribution of air ducts and nozzles in Star-Jet nozzle elements.

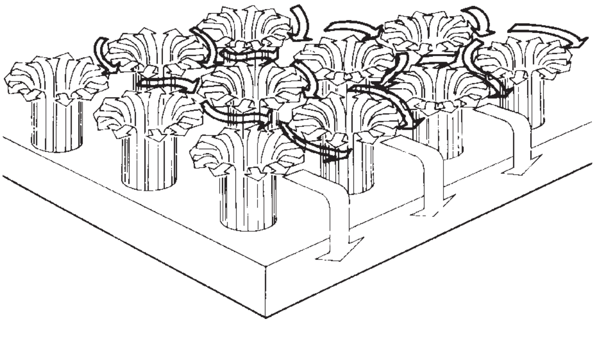

Fig. 4: Obstruction of impinging air by idealized representations of jet nozzle streams due solely to delayed air run-off in a standard round nozzle system (Babcock).

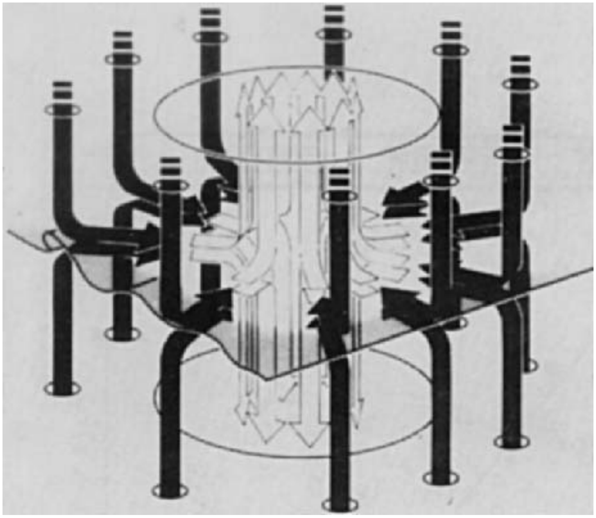

Fig. 6: Star-Jet nozzle (Babcock).

tem, several round jet streams have a discrete exhaust channel without disturbing the impinging air. As a consequence of these two measures, i.e. optimum distribution of air flow over the surface and no interruption of the individual round jet streams, heat transfer and therefore the evaporative capacity is increased by up to 12% (without any increase in fan capacity) in comparison to the usual round jets in individual air ducts. In the case of fabrics permeable to air, it is also recommended that the jets in the upper air ducts are staggered in relation to those in the lower air ducts. By this means, a certain degree of through-flow is also achieved in addition to the impinging air streams which further improves heat transfer (contributed by Carbonell, Farber and Gottschalk).

Jet nozzles Small nozzles used for the atomization of liquids into fine droplets or mist (mist projectors). In general, it can be said that a large bore produces coarse atomization and a small bore fine atomization. Increasing the pressure also results in finer atomization. Throughput is dependent on the bore of the jet and the pressure of the liquid, it changes roughly in proportion to the square root of the pressure.

Jet principle in textile driers In a jet drier, an impinging stream of hot air is directed through jet nozzles against both surfaces of the textile fabric being dried (at speeds up to 40 m/s). In this process the perpendicular component of the air flow is arrested on contact with the material and turned through 90° where it is present as a mixture of jet impingement air and deflected air thus forming a laminar boundary layer. As a consequence, not all surfaces of the individual capillaries in the interior of the fabric are reached by the impinging air flow (in contrast to through-flow drying). In principle, textile materials may be supported or unsupported for air jet drying (likewise in contrast to through-flow drying).

Jet printing → Ink jet printing.

Jet printing techniques In these methods of textile printing, liquid dye solutions are applied to a moving textile fabric with the aid of controlled jet nozzles (e.g. Chromotronic process, Electrocolor process, → Millitron process, → Ink jet printing, → Polychromatic dyeing, → TAK dyeing). → Jet impingement.

Jet rapid washer A washing machine for wool piece goods in rope form with an assembly of jet nozzles and perforated tunnel passages before the squeezer rolls. The fabric rope is sprayed with rinsing liquor from the jet nozzles which inflates the rope before the jet nozzle housing and between the jet nozzles and the squeezer rolls. This produces a very efficient washing and rinsing action at considerably higher running speeds than conventional washers. Manuf.: Hemmer.

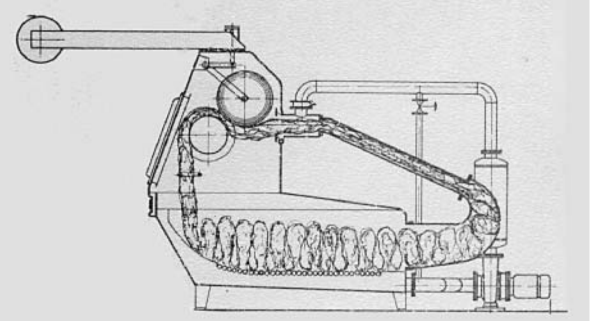

Fig. 1: MCS rope washing machine for continuous operation with jet liquor exchange system (side view).

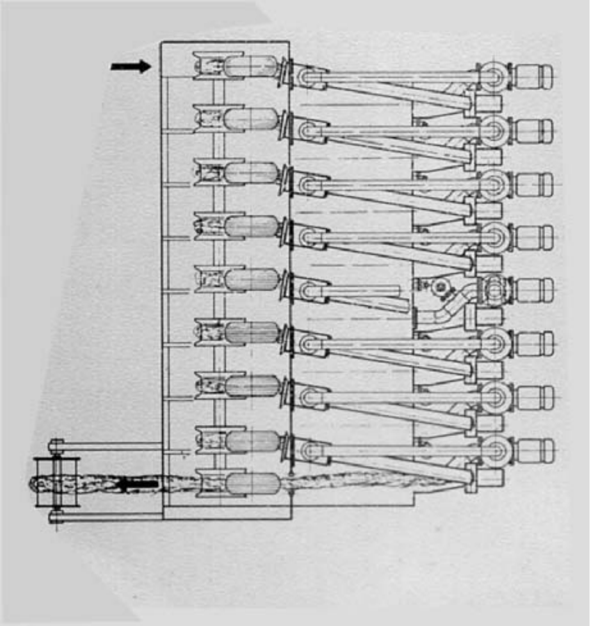

Fig. 2: MCS rope washing machine (top view).

Jet rope washing machines The continuous rope wash in jet rope washing machines takes advantage of the excellent liquor exchange of the jet system as well as the dwell time in the storage chambers (Fig. 1) so that both phases are incorporated into the washing process in an alternating rhythm:

- dissolution and detachment of soil by surfactant reaction with the impurities contained in the material (in the dwell zone)
- transport of detached soil (in the liquor exchange zone)

If necessary, different processes can be carried out successively in the individual compartments of a jet rope washing machine (Fig. 2).

Jet simulator A laboratory apparatus for pretesting the dispersion stability of disperse dye liquors, especially for use in rapid dyeing machines with large pump capacities and greatly increased rates of liquor circulation, e.g. 60 l/min/kg. From laboratory results obtained with a jet simulator system, the possibility exists to carry out preliminary evaluations of dispersion stability which are accurate to within approx. 90–95% of the behaviour under practical conditions. The test is carried out in a laboratory apparatus fitted with a flow recorder: instead of a yarn package with a perforated former, only a blank V4A tube (with 4–6 holes in the walls at the upper end, approx. 5 mm ∅) is placed in the material carrier and screwed tight. The filling height, quantity of liquor and working conditions correspond to the the jet or package dyeing machine being simulated. 250 ml of the cooled liquor on completion of the test is then filtered through a 7 cm ∅ special filter by suction and the filtration time measured by means of a stopwatch. Evaluation of the dried filter against a scale is then carried out (5 = very good, 1 = poor, 0 = thick filter cake or filtration time over 1 min).

Jet stenter The drying chamber in a typical jet stenter consists of a number of air ducts each of which has a type of closed air circulation and heating unit so that each drying chamber can be controlled to a specific temperature. The smallest unit of the counter type is the section with one fan. Each two constructively identical sections incorporate left and right handed ductings and fan and burner locations in alternate chambers so that any widthways variations in the velocity of one pair will be counterbalanced by the next. This two and two counter arrangement offers considerable advantages: 1) the completely symmetrical construction of the sections in relation to the centre of the machine and the fabric ensures uniform temperature and air distribution, 2) short air flows and minimum circulation losses ensure a high circulation efficiency as well as a high specific output and relatively low energy consumption. The paired arrangement of air ducts above and below the fabric are tapered towards the closed ends in order to achieve a more uniform distribution of air.

Jet washer

I. High efficiency open-width washing machine (Küsters) which works on the immersion-spray-suction principle, and is particularly suitable for long-staple carpet qualities. The machine employs slit washing jets with steplessly adjustable regulation of the minimum water quantity at speeds of 3–20 m/min (max. 100 l/min water for every 1 m working width) before the suction pipe. After deflection, the water flows downwards through the carpet pile into a sump (consisting of circulation becks, filter with automatic lint separator, pump and jet). The machine is suitable for working widths up to 500 cm and the quantity of water circulated is 2000 l/min for each 1 m working width (2 jets).

II. An element in continuous open-width treatment plants (Küsters) consisting of an immersion trough with liquor circulation pump and a cascade zone from the upper limit of which a coherent surge of water is released through slit jets and flows over the material.

Jig dyeing (jigger dyeing). The jigger is a short liquor dyeing machine for textile fabrics in open-width form. In jig dyeing, the fabric is transferred alternately from one batch roller to another through a bath of relatively low liquor capacity during each passage. The process, unlike many others, is economical and universally applicable if the actual running speeds can be individually adapted to the respective requirements of the dyeing process and the particular fabric quality, and the selected fabric speeds and fabric tensions remain constant throughout the entire fabric run from one batch roll to the other.

The trend to smaller dye lots has been incessant in recent years. This has been due to the adoption of more extended colour ranges and increased demands for flexibility as well as quicker response in dyeing. Although, in the meantime, dyeing in rope form has greatly increased in popularity due to current fashion trends, it is still true that no alternative exists to open-width processing for many woven fabrics during dyeing. The importance of jig dyeing has increased in recent years for this reason. Modern machines of improved efficiency are now supplied by various machine makers with the following features:

- bath circulation,
- several additions tanks and
- process automation by means of microprocessors (Fig. 1).

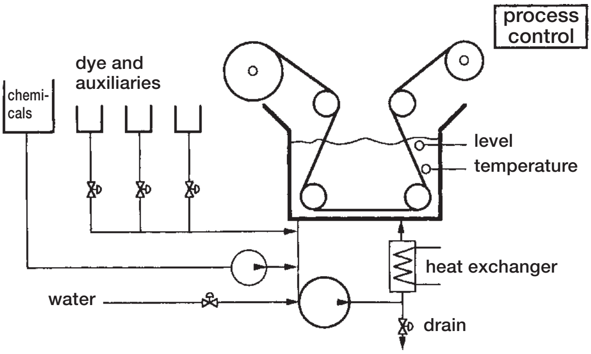

Fig. 1: Automation in jig dyeing.

In addition to their outstanding colour fastness, high dye yields are also a characteristic of Indanthren dyes which permits efficient dyeing with very low coloration of the dyehouse effluent. However, the high degree of fixation, plus the high rate of exhaustion, can result in unlevel dyeings. The addition of a levelling agent is therefore necessary if Indanthren dyes with a high rate of exhaustion are employed or pale to medium depth shades are to be dyed. During the application of vat dyes on the jigger very large quantities of sodium dithionite are required. This is due to the extremely large surface area of liquor that is exposed to the air and the turbulence caused by relatively high fabric speeds with consequent entrainment of air in the dye liquor.

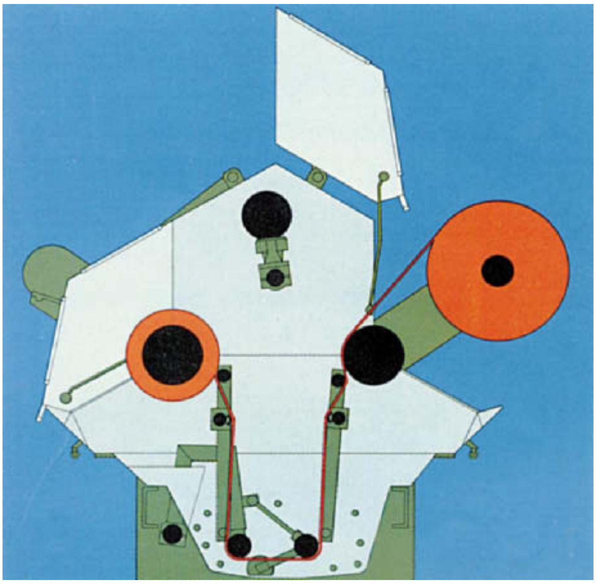

Fig. 2: Loading a Benninger jigger.

The jigger is less suitable for levelling out uneven dyeings since only a very small part of the entire batch is in contact with the dyebath at any one time. The probability that an unlevel dyeing will be obtained increases in the following order from top to bottom:

– pad-jig process with intermediate drying,
– pad-jig process without intermediate drying,
– jig pigmentation process,
– dyeing from the vat.

The pad-jig method with intermediate drying is certainly the most cost-intensive of the above methods but offers the advantage of better appearance in the dyeing of mercerized cotton besides providing greater flexibility in the dyehouse since the padded and dried fabrics can be stored for any length of time before development. In the case of polyester/cellulose fibre blends, intermediate drying is an absolute necessity for the subsequent thermosol process. The jig pigmentation method is employed when no dye padder is available. However, penetration and appearance (especially with tightly-woven fabrics) are not as good as in dyeings produced by the pad-jig process. Dyeing from the vat is hardly ever practised nowadays since it can be readily substituted by the more reliable jig pigmentation method without incurring additional costs.

In order to maintain the dye in a good vatted state in the dyebath and, above all, in the liquor retained within the fabric whilst on the roll, a certain minimum or base concentration of caustic soda and sodium dithionite must be available throughout the entire duration of dyeing. Moreover, at the beginning of each passage, the specific quantity of chemicals which will be consumed by atmospheric oxygen during that particular passage must already be present in the dyebath. In the jigger, the fabric wound on one roller is drawn by a second roller through the dyebath (Fig. 2). The machine stops when the end of the passage is reached, an operation carried out automatically on modern jiggers, the drive is then reversed and the fabric wound back on to the first roller again. In dyeing terminology each passage is referred to as an “end”. Depending on the particular process, dyeing is carried out over four to six ends and more. After two ends, all fabric qualities will have taken up approx. 85% of the max. possible amount of dye liquor. This is dependent on type of fabric, fabric speed and fabric tension. After four ends, an equilibrium is reached between dye on the cotton and dye in the bath. Various models of jiggers are designed to accomodate fabric widths up to 3,5 m and batch diameters up to 125 cm. Thus, batch sizes of up to 3000 m are possible. HT-jiggers are also available. In moder jiggers steplessly adjustable throughput speeds between 10–120 m/min can be preselected. Balanced drive systems ensure that the fabric speed remains constant despite the continually changing diameter of the batch during each end. Fabric speeds of 40–50 m/min are most commonly employed in jig dyeing. It is important that the fabric should run with minimum possible tension. Modern jiggers are equipped with tension control systems. Expanders of various types ensure crease-free running. The jigger is still an economically viable machine for dyeing batches up to 3000 m in particular, especially in automated dyehouses. The jigger is also compatible with the trend towards short liquor dyeing. However, the fact that level results in jig dyeing are dependent on many parameters and the risk of end-to-end and side-to-centre unlevelness increases with larger batch sizes must not be overlooked. Machine makers have made various attempts to reduce the likelihood of defective dyeings by offering additional features. In order to correct listing during dyeing some jiggers are provided with lateral traversing batch rollers. Attempts have also been made to heat the batch rollers to avoid end-to-end unlevelness caused by fabric cooling on the batch rollers and to overcome unlevelness at the edges of the batch due to inadequate liquor circulation by circulating the dye liquor. The fabric is batched off at the end of the dyeing process (Fig. 3).

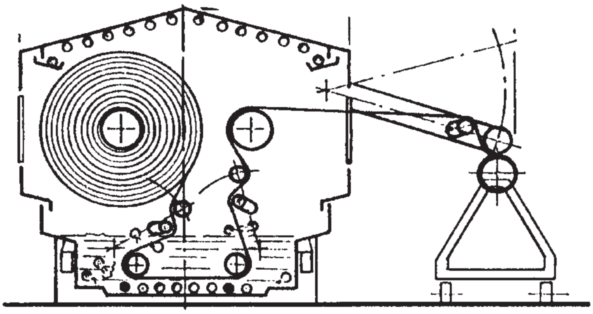

Fig. 3: Unloading a Caber jigger.

Jig dyeing

Most jiggers today are fitted with hoods. A combination jigger-beam washer is produced by Farmer Norton. In this machine the batch rollers are perforated and connected to a water supply so that the batch of fabric can be rinsed whilst still on the roll (to achieve savings in time). For good results in jig dyeing, the state of the fabric edges on the roll is particularly important, i.e. they should be neither too tight nor too slack and must not wander since otherwise creasing cannot be avoided. The problem can be minimized by batching the goods with perfectly straight edges before dyeing, preferably on a separate batching machine. Pile fabrics can also be dyed on the jigger provided the guide rollers have been suitably modified. Jiggers of this type are made by Mortensen. For woven and knitted fabrics which cannot tolerate lengthwise tension, tensionless open-width dyeing machines which operate on a “jigger” type principle (Jawatex) may also be employed.

If textile fabric is to be wound at an absolutely constant speed in the jigger, the rotational speed of both batch rollers must conform to the equation

$$\frac{1}{n_1^2} + \frac{1}{n_2^2} = \text{const.}$$

or, in other words, the sum of the squares of the effective diameters at any one time must remain constant. The manner in which this requirement is fulfilled in the unwinding drive of the CLA jigger is explained in Fig. 4. The diameter of the fabric batch changes continuously during the unwinding run. Therefore, both swivelling axes A–A of the spherical roller elements We, which are driven in parallel by connecting rods, must also be swung in such a way that their effective drive diameters correspond to the actual diameters of the fabric rolls. This task is performed by a hydraulic PI controller which receives its impulse from a pneumatically-loaded compensator roller. As a result, fabric tension is dependent entirely on the preselected pneumatic pressure. Even unbalanced batches cannot influence the fabric tension. The most important elements of this variable speed drive are the constantly excited DC motor and the control unit with silicon controlled rectifier. This drive system which is, in principle, very simple has a number of convincing advantages, e.g.:

- a wide infinitely variable speed range up to 1 : 10,
- simple speed adjustment by turning the knob of a potentiometer,
- good speed constancy and constant torque,
- smooth progression to the preselected running speed,
- smooth and, within certain limits, adjustable braking through braking resistance.

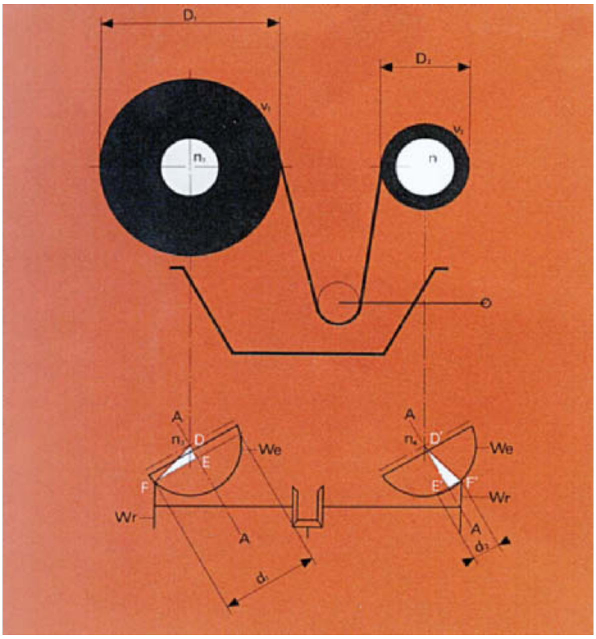

Fig. 4: Sketch illustrating the theoretical principle of the CLA unwinding drive.

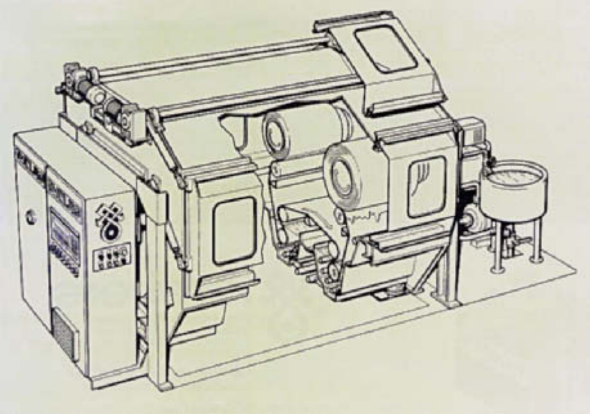

Fig. 5: Jigger based on short liquor technology (Küsters).

In jig dyeing, as already explained, the fabric runs back and forth between two rollers on which it is wound and unwound thereby passing through the dyebath (Fig. 5). The length of fabric actually immersed in the dyebath at any particular time is approx. 1 m. Since the running speed of the fabric can be 80–160 m/min, this means that any particular part of the running fabric has a dwell time of only approx. 0,5 s during its passage through the dyebath. As a consequence, only extremely small quantities of dye are absorbed substantively by the fibres during their short dwell time in the dyebath. Dye is transferred principally by the exchange of a specific volume of liquor from dyebath to fabric; the actual absorption of dye by the fibre takes place during the (much longer) period in which the fabric remains on the roll. If dye absorption does not occur rapidly, the fabric at both ends of the batch roll will be lighter in shade since, in these areas, dye is not absorbed before the next passage through the bath. This is in contrast to those areas lying deep within the batch roll where the "rest period" is considerably longer. If, on the other hand, the conditions for dye absorption are optimum, a risk of non-uniform dye distribution along the length of the fabric exists, since dye concentration in the dyebath varies exponentially from one end of the fabric roll to the other due to the dilution effect.

If jig dyeing is begun with the total quantity of dye in the bath, the dye concentration in the fabric K_v, may be calculated in relation to the initial concentration K_{bo} of the bath during the first passage as follows:

$$f = \frac{\text{total bath quantity}}{\text{dry weight of fabric}}$$

$$f_1 = \frac{\text{quantity of liquor in batched fabric}}{\text{dry weight of fabric}}$$

$$f - f_1 = \frac{\text{quantity of liquor in dye trough}}{\text{dry weight of fabric}}$$

$$F = \frac{f_1}{f - f_1}$$

$$= \frac{\text{quantity of liquor in batched fabric}}{\text{quantity of liquor in dye trough}}$$

M_v = weight of fabric
K_b = momentary dye concentration in dyebath
V_v = liquor in fabric = $f_1 \cdot M_v$
V_b = bath volume = $(f - f_1) \cdot M_v$

$$\frac{V_v}{V_b} = \frac{f_1}{f - f_1} = F$$

$$V_v = V_b \cdot F$$

p = degree of liquor exchange, i.e. that fraction of liquor contained in the fabric which is exchanged during the passage,
u = that part of the total fabric length which has just passed through the bath, so that at the beginning of the passage u = 0.

The exhaustion of dye from the bath is given by:

$$\begin{aligned} -V_b \cdot d\,K_b &= K_b \cdot p \cdot V_v \cdot du \\ &= K_b \cdot p \cdot F\,V_b \cdot du \end{aligned}$$

$$\frac{d\,K_b}{du} + p \cdot F \cdot K_b = 0$$

With the boundary condition $K_b = K_{b0}$ for $u = 0$, the solution to this differential equation is:

$$\frac{K_b}{K_{b0}} = e^{-p \cdot F \cdot u}$$

or, for the concentration on the fabric where $K_v = K_b \cdot p$

$$\frac{K_v}{K_{b0}} = p \cdot e^{-p \cdot F \cdot u}$$

In the following passage the uneven concentration distribution of the first passage is improved due to the opposing effect of the new exponential dye uptake. A complete balancing out is not possible, however. Thus, in order to prevent non-uniform dyeing, a practical procedure has been developed over the course of time whereby

- the total quantity of dye is divided into several portions (generally two) and each portion is added at the beginning of a new passage or "end";
- dyeing is begun at temperatures low enough to ensure that dye absorption in the fabric roll is only slight. During the course of a few ends, the dyebath is gradually heated up until the dyeing temperature is reached;
- the rate of dye absorption is controlled chemically, e.g. by progressively increasing the concentration of dyebath electrolyte (salt addition).

It is often common practice to combine the above three measures. From this example, however, it is clear that the procedure calls for much time and effort. The disadvantages of jig dyeing, as discussed in the foregoing text, are an inherent feature of the process itself and are equally applicable to atmospheric as well as HT-jiggers. The purchase of a HT-jigger, however, represents a considerably higher investment than a 100°C machine. For productivity in jig dyeing, therefore, it is essential that processing times are reduced to a minimum.

Jigger (jig dyeing machine) → Jig dyeing.

Jigger raising In order to achieve more efficient utilization of expensive raising machines with electronic fabric tension control systems and obviate the need to run textile fabrics over several raising machines in series, it is also possible to employ the jigger raising process (see Fig.) in which a batch of fabric is run back-

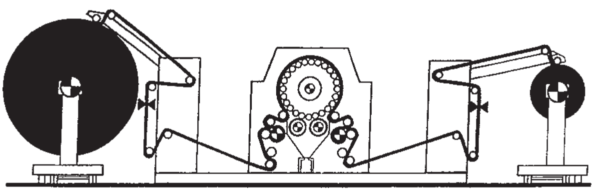

Fig.: Jigger raising principle of Menschner.

wards and forwards over the reversible raising cards. A particularly uniform raising effect can be achieved on knitted goods by this means.

Jigging stenter (jigging tenter). A type of stenter mainly used to "straighten" weft distortion in woven fabrics, e.g. bookbinder's calico. The two side chains are linked, one moving forward whilst the other moves back and vice versa which imparts an oscillating motion to the fabric. This diagonal or "to-and-fro" longitudinal movement helps to straighten the weft threads and reduce any inter yarn bonding between warp and weft thereby producing a softer fabric; → Mechanical breaking.

JIS abbrev. for: Japanese Industrial Standard, issued by the Japanese Industrial Standards Committee (JISC), Tokyo, Japan.

JIT abbrev. for: → Just in time.

Jobber An individual or firm that purchases large lots of textile fabric from producers or merchant converters for resale at wholesale prices in smaller quantities to other wholesale outlets.

Job dyeing A procedure formerly used for the redyeing of already worn garments or unattractive faded materials (for fashion studios, department stores, tailoring establishments). In contrast to conventional textile dyeing, this form of dyeing was nearly always concerned with defective goods or those having already suffered considerable wear and tear where no two pieces had the same background, composition or degree of wear. Despite these problems, the highest demands were often placed on dyed appearance, colour fastness, shape retention, quality, appearance, handle, strength, etc. The dyeing method (mainly carried out in dyeing kiers, winches, garment dyeing machines, paddle machines, etc.) was a correspondingly highly individualized operation. This form of garment dyeing was generally undertaken by departments affiliated to drycleaning and (less frequently) laundering establishments.

Joule (J). The derived SI unit of work for all forms of energy (mechanical, thermal and electrical) named after the English physicist James Prescott Joule (1818–1889). It is defined as the work done when the point of application of a force of 1 newton is displaced through a distance of 1 metre in the direction of the force. The joule is thus defined by the physical units energy x distance or work x time:

$$1\ \text{J} = 1\ \text{Nm (newton metre)}$$
$$= 1\ \text{Ws (watt second).}$$

The calorie, as the former unit of heat in use until 1977, has now been replaced by the joule.

Conversion: 1 J = 0,239 cal; 1 cal = 4,187 J.

Journal of the Society of Dyers and Colourists (JSDC). The leading British technical journal on textile coloration and finishing published by the → SDC, Bradford, U.K.

JPA abbrev. for: Japanese Standards Association; Japanese committee for technical standards; → Technical and professional organizations.

JR → Urena fibre, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

JS → Rosella fibre (roselle), → Textile fibre symbols, according to DIN 60 001 T4/08.91.

J-scray A J-shaped trough used for short duration intermediate storage of textile fabric (usually in the open-width state) between one process and another. The long arm of the J takes the form of an inclined plane on to which the fabric accumulates before being withdrawn from the short arm after a short dwell period.

JSDC abbrev. for: → Journal of the Society of Dyers and Colourists.

JTN abbrev. for: Japan Textile News, a leading Japanese textile journal published in English.

JU → Jute, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

Ju → Jute, → Textile fibre symbols, according to DIN 60 001 until 1988; from 1991 → JU.

Jumbo skin (jumbo hank) Hank of yarn of greatly increased weight, e.g. for wool = 2–5 kg per hank.

Jumper A knitted or crocheted garment similar to a pullover for covering the upper part of the body, usually made without fastenings at the front.

Just in time (JIT). A production management system of inventory keeping in which stocks are kept to a minimum and products delivered just before they are required. Likewise, finished goods are delivered to customers on demand. The system calls for a very high degree of cooperation between suppliers and customers throughout the entire chain of production. Advantages include a considerable release of "dead" capital which would otherwise be tied up in (often) slow-moving items of stock, improved cash-flow, reduced space requirements and reduced turnaround times between orders and delivery. A disadvantage is the greater vulnerability to production losses due to delays in delivery or defective components.

Jute A vegetable fibre belonging to the → Bast fibres. It is obtained from the stems of plants of the genus *Corchorus*, especially *Corchorus capsularis*. The jute plant is a herbaceous annual which grows to a height of 2–5 m and flourishes chiefly in tropical and sub-tropical countries (cultivated mainly in Bangladesh, India and China). The structure of the jute stem is similar to that of flax apart from the the position of the fibre bundles within the cortical layer. Jute fibre strands are polygonal in cross-section, usually with 5 or 6 sides. In a similar manner to hemp, primary fibres and, to strengthen the stem, secondary fibres develop between the primary fibres and the woody layer. In contrast to hemp, differentiation between the primary and secondary fibres in the mature state is no longer possible. From a chemical point of view, the jute fibre is similar to flax and is composed of: 63–75% cellulose, 9–10% water, 0,3–4% fats and waxes, 0,2–0,8% ash and 21–25% pectin and lignin. The lignin content of approx. 12% is the highest of all the vegetable fibres and explains the high lignification of this fibre. The structural build-up of the individual cell is similar to that of flax and hemp although, in the case of jute, lignin is present not only in the middle lamella but also in the cellulose layers of individual cells. Compared to other bast fibres, the individual jute cells have the shortest length (1–5 mm) and their thickness of only 15–25 µm is similar to flax and hemp. Commercial production of the fibre is carried out in a manner similar to that used for flax and hemp by freeing the fibres from the bast fibre bundles in retting and mechanical processes or by cottonizing. Properties: jute has relatively poor strength and durability. The fibres are soft and lustrous but lose strength when wet. Even the action of dilute acids causes a red coloration and destruction of the fibres; mineral acids have a more aggressive action on jute than on flax or hemp, and jute is readily dissolved by conc. acids. In contrast to other cellulosic fibres, the very high proportion of impurities in jute fibres, which cannot be removed without destroying the fibre itself, is responsible for its deviant affinity for dyes, i.e. the fibre also has an affinity for cationic, acid and disperse dyes besides the usual cellulosic dyes. Uses: tablecloths, curtains, wall-hangings, runners, carpet backings, sacks, ropes and cordage, etc.

Jute bagging (gunny) → Hessian.

Jute/hemp distinguishing test → Hemp/jute discrimination tests.

Jute line Fine yarn produced from long jute fibres after hackling.

Jute soiling Soiling which takes the form of brown stains on the polyamide pile in carpet dyeing due to the lignin and pectin impurities present in the jute ground fabric. Jute can severely reduce the light fastness of dyeings on polyamide carpets especially in light shades.

Jute stem structure → Flax stem structure.

Jute tow Coarse yarn produced from jute fibres.

JZS abbrev. for: Jugoslavenski Zavod za Standardizacija, Belgrade, Yugoslavia (Yugoslavian Standards Institute); → Technical and professional organizations.

K

K,

I. Element symbol for potassium (19).

II. → Twill weave DIN abbreviation.

III. → Kelvin (old unit symbol: °K).

k Unit symbol for → Kilo (one thousand times), factor 10^3.

KA → Casein fibres, → Textile fibre symbols, according to DIN 60 001.

Kagotsuko printing Typical Japanese resist printing process, comparable with paste resist printing (→ Resist printing).

Kalmuck (fries, swanboy). In general a 2-sided strongly raised soft cotton fabric, weight and roughened effect are even more marked than in → Melton; (cross) twill weave with back pick or as double cloth, striped or with a check pattern. Also long-haired, coarse, thick woollen fabrics. Application for heavy blankets, bed padding, table undercloths, backcloth materials, ironing board and mangle covers.

Kaloz process (lime and ozone), combined process for effluent cleaning, as a single stage or sequentially (= better results) by the precipitation of organic/inorganic impurities using calcium hydroxide. By the use of the correct techniques even fused and difficult to oxidise substances be made to oxidise more easily. Particularly suited for the cleaning of textile effluents due to its good decolorising effect. → Recalcination.

Kamdani Ancient Indian gold embroidery (silk thread wrapped in metal foil) of lighter style on fine fabric.

Kaolin (China clay, porcelain clay, terra alba), $Al_2O_3 \cdot 2\,SiO_2 \cdot 2\,H_2O$, density 2.1–2.6. White, loose powder, practically insoluble in water. Application: with starches and oils for filling and softening of finishes (bleached cotton goods, light coloured lining fabrics); pigment for viscose delustring (fixed in particular by sulphonated surfactants); also as spotting powder; as tailor's chalk, etc.

Kaolinite $[Al(OH)_2]_2[Si_2O_5]$. Predominant mineral in → Kaolin and clay, main component of bleaching earths and Fuller's earth.

Kapok → Vegetable hair fibres from the fruit pod of tropical cotton of the Bombaceen family (kapok, cotton or silk cotton; East and West Africa, India, Java, Sumatra, Mexico, Brazil). Single cell hollow fibres with large, air filled lumen. The cuticle is very thin and fatty. Length 10–40 mm, cross section round or oval. Width 20–30 µm. White or yellowy brown, soft, supply, lustrous. Microscopic: Smooth, pressed flat, typically many bends. Specifically extremely light, has a power to carry water of 20–30 times own weight, compressed 36 fold. Burns easily. Has 6–8 times the heat retention capacity of other fibres. Immune against moisture and all vermin (specific fat with toxin content). Consists primarily of cellulose, slightly lignified, therefore brittle and fragile. Difficult to wet, alkali sensitive (loss of lustre), less dye affinitive than cotton. Application: Preferred as cushion material (often faked); for swimming belts, bandages, hats; as kapok quilt lining. Less often spun: Pure after fat extraction; mixed with cotton, viscose, silk waste and wool.

Karabagh carpets Knotted carpets from the Southern Caucasus, patterning and colours similar to → Kazakh carpets, but shorter pile made of less lustrous wool. Approximately 150 000 Turkish knots per m^2.

Karl-Fischer method (KF process), simple, volumetric process for water determination, based upon the fact that iodine oxidizes sulphur dioxide to sulphuric acid in the presence of water. Particularly suitable in the presence of the smallest quantities of water in organic solvents, dyes, also in textiles. Available as stable, ready to use solution. When used carefully offers reliable, reproducible values.

Kashan carpets Knotted carpet from central Persia. Fine ornamentation on a matt red, violet or dark blue background. Around 350 000 Persian knots per m^2. Low, smooth pile made of fine wool.

Kasuri → Kasuri dyeing.

Kasuri dyeing (Kasuri-Resist), laborious, old Japanese dyeing technique of a white patterning on coloured ground by the partial resist of warp and weft threads and subsequent over-dyeing.

Katox-system An effluent treatment system that can be used together with other systems to create a complete effluent treatment plant for textile processes. It is based upon an activated carbon system that carries biologically active media in cyclone baths. The katox system for treating difficult effluents is based upon the use of high surface area substances (active carbon) as an exchange medium. The active carbon is used in a series of fluid beds in open baths (usually 3), through which the effluent is slowly passed (dwell time up to 9 h). The exchange media are fluidised over the cells located on the floor of the baths by aeration. The reaction baths are filled with different, but matched, media in a quantity up to 20 vol. % in relation to the bath volume. The downflow baffles keep the exchange media in the baths; only the finely dispersed carbon granules leave the system. These may be removed in a subsequent cleaning stage.

Active carbon, as a dispersion of fine particles, is characterised by a large specific surface area (external geometric factor); and a large internal surface area (internal geometric factor). Active carbon thus offers large surface area for exchange reactions. When specific active carbon grades are chosen, a synergistic effect is provided by the oxygen affinity of the surface.

The biological degradation of effluent constituents takes place on the expanded inner surface of the supporting medium, where chemical sorption ensures that activated oxygen is present in large quantities and is continuously supplemented by injected air. The supporting medium is not consumed, because it is not its adsorptive energy that is critical to the reaction, but rather the oxygen activated surfaces, which are continuously renewed. The bacteriological activity that occurs on the supporting medium, benefits from the high oxygen content, and high surface area of the supporting medium offers an artificially high concentrated form due to temporary adsorption. The fixation of the system onto the active carbon gives the chance for special biologically active systems to be included that multiply the effects as the microorganisms play an increasing role. The conditions are favourable to the microorganisms, and specific cultures develop that can assimilate the contents of the waste slurry as the generation cycle proceeds. There are differences between an hour (heterotropic bacteria) and days (autotropic nitrificants, specialists). Due to the retention of the microorganisms each type of bacteria is retained within the system regardless of the growth rate. Similarly, substances that are difficult to degrade are retained in the system longer due to temporary adsorption on the supporting material and are therefore subject to the effect of the colonised specialists for longer. The enzymes formed for the degradation of the organic effluent constituents of the microorganisms remain fixed on the supporting material as exoenzymes and when available they can accelerate the digestion of the pollutants. In addition it has been found that bound microorganisms and enzymes can bring about higher metabolic rates than those that are not fixed.

The linking of several fluid bed basins maximises the effectiveness of the plant as a whole by the exploitation of the plug flow. Plug flow means that there is a falling solids load gradient over the plant as a whole and a correspondingly varied digestion results. In the first bath the pollutants that can be easily biologically degraded are quickly degraded by a biological filter media. A “hard” effluent with altered composition flows into the second basin, whose BSB_5 content is lower, and therefore the $BSB_5 : CSB$ ratio is also lower. Corresponding to this situation, a changed, adapted biology forms on the supporting material of the second stage, with a high proportion of microbial specialists. The same applies for subsequent stages, which is why linking the stages together is so adaptable and efficient from the point of view of biological filter media.

The performance of the katox system can be increased still further by optimised reactor technology. Previously, the air intake was achieved by fans and porous aeration units located on the entire basin floor. Additional stirrers, together with the movement caused by the airflow, should ensure an intensive mixing of the effluent with atmospheric oxygen. The contact substances are fluidised in a rolling movement in the open basin, with the drive being provided by aeration cartridges on the basin floor. It is not necessary to keep the entire mass of base material suspended for a complete cleaning effect. So a solid forms at the bottom of the solution, which still allows material flow and which continuously participates in the circulating fluid bed / fixed bed (solid at the bottom of the solution), because aeration according to the rising air principle generates a partial draught. The contact substance is transported upwards to the surface by the air blown in from the deepest point, from where it sinks to the bottom of the basin in a wide arc. At the bottom of the basin the carrier speed is such that the contact substance is transported on to flow upwards again with the aerators. If this up-current made up of air bubbles, contact materials and waste water is passed over the aeration unit with the aid of a rising channel, there is a critical stabilisation of the flow and the contact mass transport and at the same time a consistent fluidisation over the entire volume of the basin.

Kawabata system System developed in Japan for handle evaluation (→ Kawabata system of handle evaluation). System developed to allow Japanese Technicians to use a single system of handle evaluation. Describes fabric handle in terms of 0 (slight) to 10 (very marked) with an overall rating scored as 0 (unacceptable) to 5 (excellent). The handle of a fabric is literally assessed by handling and recording the various sensations as e.g. hard, soft, full, thin, dry, greasy, granular, woolly, etc. These subjective assessments, common in the textile trade, are associated with problems. Any such assessment must be subjective and therefore directly dependent upon the assessor and will only have validity within their system of values. The lack of reproducible measurement results makes cooperation between different companies more difficult (weavers, finishers, dyers, clothing manufacturers); in addition the manufacture or finishing process is difficult to reproduce with regard to quality control. As the level of automation increases, objective, reproducible data is becoming more important. Therefore, attempts have been made in several countries to objectively describe cloth handle. The most successful work in this field is that conducted in Japan by Kawabata and his colleague which has yielded the KES-F system (Kawabata's Evaluation System for Fabrics). In this system various characteristics are used for handle evaluation:

Fukurami = fullness and softness
Hari = "non-drape" stiffness
Kishimi = scroopy handle
Koshimi = stiffness and elasticity
Numeri = flexible smoothness
Shinayakasa = suppleness with softness
Sofutosa = soft handle feel

These characteristics can be detected using four devices:

1. KES-F-1 for measuring fabric behaviour under tensile and shear loading.
2. KES-F-2 for measuring bending behaviour.
3. KES-F-3 for measuring fabric behaviour under compressive loading.
4. KES-F-4 for measuring surface characteristics of the fabric.

Method of deformation:	Measured and calculated (*) property:	Symbol:	Unit:
Traction	Ascending gradient (*)	LT	–
	Traction work	WT	J/m^2
	Recovery capacity	RT	%
	Extensibility	EM	%
Bending	Flexural strength	B	µNm
	Flexing hysteresis	2HB	mN
Shearing	Shear stability	G	N/m degrees
	Shear hysteresis at 0.5 degrees	2HG	N/m
	Shear hysteresis at 5 degrees	2HG5	N/m
Compression	Ascending gradient (*)	LC	–
	Compression work	WC	J/m^2
	Recovery capacity	RC	%
	Thickness at 0.5 g/cm^2	T	mm
Surface properties	Coefficient of friction	MIU	–
	Standard deviation of the coefficient of friction	MMD	–
	Surface roughness	SMD	µm
Deduced parameters	Shaping capability (*)	F	

Tab.: Kawabata measuring system for assessing textile fabric handle.

The Table lists the mechanical characteristics of the fabric, which can be measured using the KES-F system. If necessary these can be used to assess two characteristic properties of fabrics: The first is related to the handle and the other to the mouldability of the fabric, i.e. how this reacts to loading during shaping. The use and maintenance of the KES-F device requires a trained technical specialist, who is sufficiently competent to undertake the difficult, complex calibration. Another disadvantage is the time that is required for a test. A complete evaluation of a fabric can take 6–8 hours depending upon type. This disadvantage clearly represents a significant limitation to the application possibilities, in particular for the control of industrial process stages. In addition, the purchase price is very high.

The KES-F system has proved itself well as an instrument for research. Whether it can attain the same level of importance for routine handle determination in Europe as it already has in Japan depends not least upon whether quality requirements in the form of marks can be correlated with the European "handle culture".

Kawabata system of handle assessment The handle of a textile material is a very important quality feature because, together with the visual impression of the material, it often represents a decisive criterion for the sale or purchase of the textile item. In contrast to other fabric properties, which are evaluated in a consistent manner by the use of an objective test procedure, this significant quality criterion has up until now been assessed in a purely subjective manner, i.e. the finisher or manufacturer subjected the material to a tactile and visual evaluation, in which different experience and sensory values came into play depending upon the person performing the evaluation at the time. However, because handle is a complex phenomenon and is made up of numerous properties, it is clear that these subjective methods will bring indeterminable influences to bear during the evaluation. The associated lack of agreement and reproducibility of results is another reason why problems repeatedly cropped up in this connection between cloth manufacturers and clothing manufacturers. It is this lack of reproducible measuring results in particular which has made it necessary to develop a testing process which can yield an objective value for handle in relation to the human senses, and which thereby provides an optimal basis for comparison. The most successful work to date in the field of objective handle determination is that conducted in Japan by S. Kawabata and his colleagues. Their comprehensive investigations have led to a recognition of which mechanical-physical properties are critical for the handle of fabrics. On this basis they developed, in co-operation with the company Kato Tech. Co. LTD (Kyoto City), the so-called KES-F system (Kawabata's Evaluation System-Fabrics), which aims to facilitate the determination of the above-mentioned fabric properties. By means of the shear, tensile, bending, compression and surface property tests performed as part of the system, and taking into account the weight of the material, 16 characteristic parameters for the handle of a fabric are obtained. Kawabata and his colleague Niwa also correlated these properties with subjective handle expressions such as "stiffness" and "smoothness". However, this correlation is disputed outside Japan and it is very difficult to transfer to European conditions. Furthermore, the terms commonly used in Japan to describe handle can only be compared to Western measures by means of complicated paraphrasing, which means that it is impossible to make a precise and accurate translation. Nevertheless, the use of the KES-F system with regard to handle evaluation is of great importance, because even the consideration of the individual parameters can yield important insights into how handle is defined.

The principle of objective handle evaluation using the Kawabata system is based upon the determination of a number of mechanical-technological fabric properties, which have proved to be critical to the handle of a fabric. These are tensile and shear-elastic parameters, bending properties, compression, surface properties (friction and profile), weight and thickness of the textiles in question. The Kawabata procedure for the meaningful linking of the above-mentioned factors with regard to the objective evaluation of handle can be summarized as follows:

1. Cooperation with a range of Japanese textile experts first yielded the insight that there are two stages to the evaluation of handle in textiles, namely the so-called primary handle impression and a "total handle value" derived from this primary impression. A list of specific terminology is drawn up to describe the primary handle impressions (e.g. smoothness, stiffness).
2. Based upon this, the collection of 500 representative fabric samples was subjectively analysed by allocating marks between 0 (property not present) and 10 (property strongly marked).
3. Using pattern cards distributed within the industry showing samples marked between 0 and 10, it was now possible to make a numeric analysis (even though this was still only subjective).
4. The development of the KES-F system based upon 4 measuring devices then made it possible to determine 15 mechanical-technological fabric properties associated with handle. These 15 parameters were summarised in 6 "blocks", taking into account the fabric weight. The above-mentioned collection of 500 fabric samples was evaluated with the aid of this system.
5. Using a "progressive block regression" the standardized measured values were correlated with subjectively determined marks and a transformation equation was created for each handle impression. Using this transformation equation, the relevant mechanical-technological parameters for each new fabric sample could thus be expressed as a value between 0 and 10.
6. In a final stage the "total handle value" was determined from the primary handle impressions, which was itself correlated with a subjectively determined scale of 0 (= just acceptable) to 5 (= excellent). There are already transformation equations in existence for 5 different material classes, whereby these are characterized by the primary handle expressions currently in use (see Table).

MEN'S AND BOYS' WEAR winter	Koshi	-"stiffness and elasticity", flexural strength dominates, e.g. due to springiness, high woven fabric density, elastic resilient yarns;
	Numeri	-"pliable smoothness", smoothness, pliability, suppleness, softness, e.g. cashmere;
	Fukurami	-"fullness and softness", bulk, fullness, elastic, resilience, (warmth), e.g. rather thicker materials;
MEN'S AND BOYS' WEAR summer	Koshi	- as above;
	Fukurami	- as above;
	Shari	-"granularity", granular and rough surfaces (coolness), e.g. due to hard twist yarns;
	Hari	-"anti-drape (stiffness)", (≠ Koshi) independently of recovery capacity and elastic resilience;
WOMEN'S OUTERWEAR medium weight	Koshi	- as above;
	Numeri	- as above;
	Fukurami	- as above;
	Sofutosa	-"soft handle", softness, made up of Koshi, Numeri and Fukurami;
WOMEN'S OUTERWEAR thin	Koshi	- as above;
	Hari	- as above;
	Fukurami	- as above;
	Shari	- as above;
	Kishimi	-"scroopy handle", e.g. woven silk fabric
	Shinaya	-"suppleness with softness", made up of the other 5.

Tab.: Primary handle terms for different fabric classes according to Kawabata.

Kazakh carpets Tightly knotted, long pile carpets from the Caucasus. The large, bold, geometric patterning in bright dark red, blue, green, yellow and light ivory is typical. Dull silk sheen wool pile. 120 000–200 000 Turkish knots per m^2. The term Kazakh carpets is often wrongly used as a collective term for Caucasian carpets.

KD Ger. abbrev. for "Kräuseldehnung", → Crimp elongation.

KD-behaviour German expression for Load-Elongation behaviour (→ Stress-strain behaviour). Provides information about the interrelationship between tensile strength and extensibility behaviour of yarns.

KE → Kenaf, → Textile fibre symbols, according to DIN 60 001 T4/08.91 for certain jute fibres.

Kelvin (K), temperature scale of so-called absolute temperature values (→ Temperature), which begin at –273°C = 0 K. According to this scale, short wave radiation (light wavelength) has a high colour temperature and, conversely, blue light has a high colour temperature and red light a low colour temperature. In practice this means that direct sunlight is 5000–65 000 K, blue diffuse light is 5700–6600 K, white light with a completely overcast sky is 6400–6900 K and with a clear blue sky is 19 000–24 000 K. These differences naturally have an effect on colour matching. It should be noted that artificial light sources usually have a linear spectrum, whereas sunlight yields a band form spectrum.

Kemp,

I. Surface hairs, long, coarse animal hairs in the upper surface of the hair, usually medullated, strong, usually lustrous, rarely curled, low felting tendency. Problem as contaminant (soiling) in fine hairs, such as for example cashmere (as underside hairs).

II. Short, generally non-crimped hairs (e.g. rabbit hair), coarser filaments or slit (acetate, viscose) film yarn, white or coloured. Kemp is incorporated in spinning and produces a kempy fancy woven fabric with fibre tips and coarse fibres protruding from the face.

Kenaf (Bimli-jute, Gambo hemp, Ambari hemp, Bombay hemp, Mestha), similar to jute → Bast fibres (India, Soviet Union, China, Korea, Taiwan, Philippines, South Africa, Brazil, Cuba). The basic fibres have irregular wall thickness, an average length of 2 mm and a width of 20 µm. Kenaf has a lower lignin content (7.5–9.2%) than jute and is therefore less woody. It also differs from jute in its high sheen and increased strength. The stem fibres are separated in a similar way to jute. Application: As jute substitute and mixed with jute for the manufacture of packing material, rope goods and fabric. In addition to the fibre extraction the plant is also used for the production of oil.

Kendyr fibre (Turka fibre), of the → Bast fibres family. A winter resistant plant fibre from Turkestan. The stalk is cut annually; preparation takes place in a similar way to flax. The pure white, 80–120 cm long bast bundle with fibre strength up to 55 cN/tex can be processed by linen and tow spinning; by cottonising the kendyr fibre can also be used for fine spun yarn (mixing with cotton). The most important field of application is in the manufacture of highly rot-resistant fishing nets.

Keratin (Gk.: horn material), high molecular → Protein substance (scleroprotein) containing cystine. Basic substance of hair, nails, feathers and especially wool (wool keratin).

Keratin denaturing Keratin, which possesses a fibrous structure, is subject to a typical mechanism of reversible denaturing (the α-β-transition) when stretched. Discovered by Astbury. Fibre keratins such as wool and hair are multi-component fibres and fulfil the conditions of a compound structure. The three morphological main components are cuticle, cortex and cell membrane complex, which consist of further subcomponents. The cortex consists of individual cortex cells, which are themselves made up of macrofibrils (with intermacrofibrillated cement), microfibrils, protofibrils and α-helices. A particular importance is attributed to the microfibril matrix complex here, because it is one factor that determines the physical properties of the fibre keratin. This complex consists of part-helical, low sulphur microfibrils, which are stored in a non-helical, high sulphur matrix. The structure of the helices and the helix content are determined with the aid of the x-ray wide angle technique (Fig. 1).

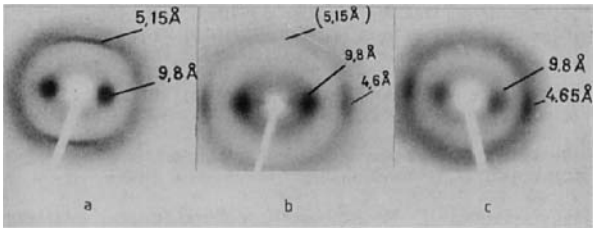

Fig. 1: X-ray panoramic diagrams of three different mohair test specimens (1 Å = 10^{-10} m) (Spei).
a = unstretched; b = 40% stretched; c = 60% stretched.

Under the assumption of a molecular mechanism of the α-β transition as postulated by Astbury, the α-content of the sample must decrease to the same degree that the β-content increases. However, this is not the case. After 40% extension of the fibre the 5.15-Å-meridian reflex (reflex intensity is a measure of the α-helix content of the sample) had entirely disappeared, but the 4.65 Å-equator reflex (reflex intensity is a measure for the β-content of the sample) is only relatively weakly marked and achieves a considerable gain in intensity at between 40–60%.

Combined thermoanalytic and X-ray examination (Figs. 2 and 3) of extended and tempered fibrous keratin have shown that the α-β transition follows a molecular mechanism up to expansion values of 60–80%: Structures that start out as crystalline α-helices are converted into extended β-pleated sheet structures. However, the possibility cannot be ruled out that the molecular α-β transition is overridden by a non-molecular transition, whereby previously extended amorphous keratin is converted into extended β structures by expansion crystallisation.

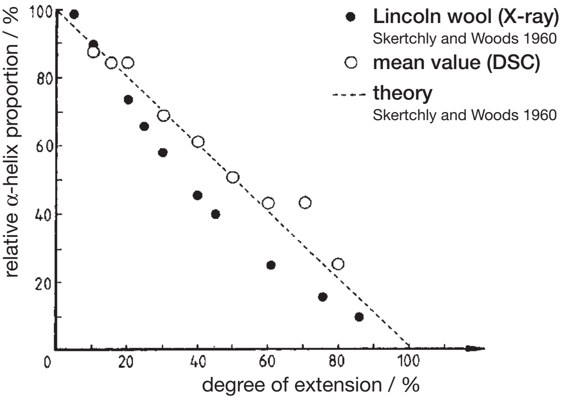

Fig. 2: Radiographically and thermoanalytically determined residual helix contents of stretched fibre keratins (Spei).

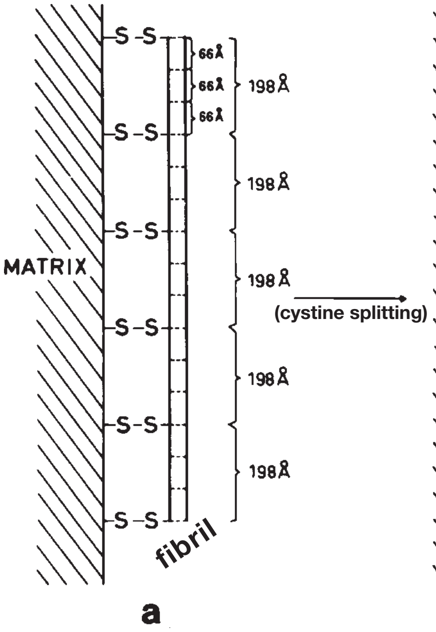

Fig. 3: Chemical grounds for a statistical bendig period of 198 Å ($1.98 \cdot 10^{-8}$ m) due to partial, uneven splitting of the cystine bridges between the microfibrils and the matrix (Spei).

Keratin parasites → Textile parasites.

Keratin sheet structure (polypeptide sheet structure, polypeptide lattice), consists of polypeptide main and side chains of wool keratin arranged in parallel in a plane. The stacking of keratin sheets, which are again cross connected by side chains, creates a multi-dimensionally elastically braced crystalline grid called →: Micelles or Crystallites.

Keratose High-molecular wool oxidation product, consisting of β-keratose (cuticula), α-keratose (microfibrils) and γ-keratose (matrix). Disulphide bonds are split by the oxidation of the wool keratin with peracetic acid and some of the side chains of the tryptophane (amino acids) are attacked. Such oxidized wool is easily soluble in diluted ammonia except for β-keratose; called α-keratose if precipitated by acidifying (the γ-keratose remains in the solution).

Kermes (scarlet), red → Natural dyes (a mordant dye). Is manufactured by the pulverisation of the female shield louse of the chestnut or kermes oak (Persia, Balkans, Spain). Active component: Carmine acid, related to → Cochineal. Mordant dyes for wool and silk. Light fastness and luminosity of equal value to the expensive → Purple.

KES-F-System (Kawabata's Evaluation System for Fabrics) → Kawabata system.

Keto-Enol tautomerism → Tautomerism.

Keto form → Ketones.

Keto group (carbonyl group), >C=O, characteristic group of → Ketones.

Ketohexamethylene → Cyclohexanone.

Ketone-aldehyde resins Condensation products of ketones and aldehydes, e.g. → Dimenthylolacetone. Application as reactant-type resin without chlorine retention.

Ketone resins Condensation products of → Ketones, such as → Methylcyclohexanone, also phenol modified.

Ketones Oxidation products of secondary alcohols with the typical keto group >C=O, e.g. in acetone $(CH_3)_2CO$. In chemical compounds we also talk of the keto form, which is typical of undissolved vat dyes, for example, unlike the (soluble) leuco compound, the so-called vat acids, which are called the enol form (enol leuco compound).

Ketoses → Sugars.

Key-lock principle In 1894 Emil Fischer developed the theory, to explain enzyme specificity, that the surface of an enzyme possesses a pocket (the "lock"), into which the substrate fits sterically like a "key", enabling the process of enzymatic catalysis to function. However, if certain neuronal distances are fulfilled in the sense of the key-lock principle, pseudo keys, i.e. similar substrates, can also lead to reactions of the enzyme. An example of this is provided by the recently developed silicon polyquats, which with increasing quat modification for the improvement of softness, bath extraction rates, water solubility, electrolyte stability etc. suddenly become highly toxic (Curare effect, see Fig.) if certain neuronal distances in the sense of the key-lock principle are fulfilled. There are equally good examples of modifications to a substrate, which is not converted by a certain enzyme, although the change in relation to the original substrate is only slight.

Although inhibitors fit in the lock as a key, they are not converted, but inhibit the enzyme. Thus the methyl group of acetic acids is linked to a certain enzyme. Mono fluoro acetic acid also fits sterically, but inhibits the enzyme. Mono chloro acetic acid, on the other hand, no longer fits sterically into the lock and there-

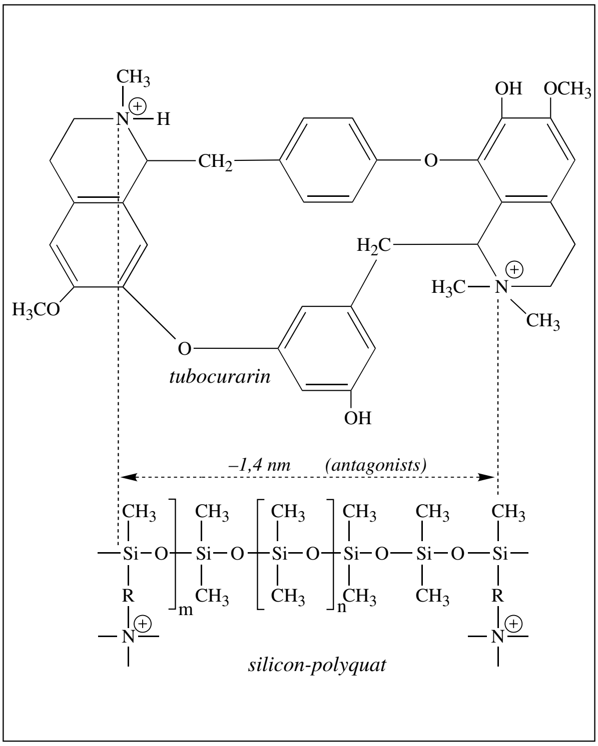

Fig.: Curare effect (from Stockhausen).

fore does not compete with acetic acid for the place in the enzyme pocket.

Kf → Kenaf, → Textile fibre symbols, according to DIN 60 001 till 1988, from 1991 → KE.

KF-dyeing process Short liquor ratio dyeing process on special dyeing equipment. In yarn equipment partial flooding with one-sided liquor circulation inner/outer and with minimum submerging of the yarn package and pressure pad (dyeing in liquor).

Kh, animal hair, → Textile fibre symbols, according to DIN 60 001 till 1988.

KH Standard abbrev. for temporary hardness; → Water hardness.

Kid leather → Leather.

Kidderminster carpets Double cloth carpets, in which two layers of cloth, manufactured from two warp and weft systems, lie on top of each other. The patterning is created by the threads of the cloth layers alternating, i.e. the wefts are inserted in tiers, which are sometimes formed by the warp threads of the upper cloth and sometimes by those of the lower cloth. This has the effect on the pattern that a red figure on a blue background on the front appears on the back as a blue figure on a red background (reversible carpet). It is woven without the use of heald shafts exclusively with Jacquard machines, with the depth of the harness being split according to the number of cloth layers. The Scottish or treeply carpet consists of three layers of cloth. These flat, but thick, carpets, usually made of wool yarn were first produced in the English town of Kidderminster.

Kier boil-chlorine bleach Combined process, consisting of → Kier-boiling with subsequent → Bleaching to achieve pure white, for cotton and cotton/viscose mixes with a fairly low viscose proportion. The disadvantage is that yellowing occurs over time and fibre loss occurs if viscose is present (approximately 8–10%, compared to approximately 5% for alkali scour-peroxide bleach and approximately 2% for oxidative bleaching). The kier boil-chlorine bleach has now been replaced by continuous bleaching processes.

Kier boil-chlorine-peroxide bleach Cotton bleach to achieve a non-yellowed white. If viscose is present 8–10% viscose losses occur, which can be reduced to approximately 3% by the transition to → Peroxide-hypochlorite-peroxide bleach. → Peroxide bleach.

Kier-boiling Alkaline scouring of cotton (in all processing stages) under pressure (1–4 bar) in the decatizing boiler to remove the natural impurities and increase the wetting out property.

Kier boiling aids (scouring aid), accelerate the cleaning process in the alkaline pretreatment of raw cotton, for example, by rapid wetting of the textile material. They promote the separation of wax and pectin substances, closed seed shells and prevent the re-extraction of dissolved impurities. Soaps have only limited use as kier boiling aids (water hardness); oil sulphonates act in a similar manner to soap, with highly sulphonated products being given preference. Fat solvent soaps aid the removal of wax to a certain degree, but are overrated. Soap-like synthetic products such as →: Fatty alcohol sulphates; Fatty acid condensation products etc. act as excellent emulsifiers and wetting promoters, depending upon their concentration.

Kier boiling assistant → Kier boiling aids.

Kier boiling fastness Resistance of the coloration of printing on textiles in all processing states during wet finishing with diluted NaOH under pressure. The test instructions apply primarily for natural cellulosic fibres. Two processes are used, one with and the other without the addition of an agent for the prevention of undesired reduction effects. Performance (DIN 54 032): Treat test piece wound in raw cotton fabric of 10 fold weight for 4 h at 120°C and 98 100 Pa in the kier boiling liquor with a liquor ratio of 1 : 50 in the pressure boiler. Solution I: 4 ml/l NaOH 35.5%; Solution II: 4 ml/l NaOH 35.5% + 4 g/l m-sodium m-nitrobenzene sulphonate. Evaluation with grey scale.

Kier boiling of coloured wovens Kier boiling of cotton fabrics with vat dyed effect threads. Because dissolved out fibre additives have a reduced effect, there is the danger that the vat dye will be dissolved, i.e. the dye will bleed out. In order to prevent this an alkaline liquor oxidation agent is added: Peroxide, persulphate, sodium m-nitrobenzene sulphonate.

Kier boil-peroxide bleach Full white bleach for easy to bleach cotton. Can be used in iron boiler (cement coating) without repacking.

Kier decatizing For achieving dimensional stability, voluminosity, handle and sheen in wool and wool mix fabrics. These are rolled up with backcloths (satin or molleton fabric) and treated in an evacuated boiler with saturated steam. Remaining shrinkage value below 1%.

→ Decatizing plays a particular role in the finishing of woollen fabrics, because it is generally the last stage in the finishing process and gives the product the most important properties that determine its quality. The most important of the classical decatizing processes, apart from kier decatizing, are finish decatizing and press lustre decatizing. Under normal finishing conditions, finish and press lustre decatizing, in which the fabric lengths are usually steamed for 3–5 min at 100–110°C (operating steam pressure 0.5–6 bar) and then cooled by aspirating for 2–5 min, generally do not provide permanent effects; in particular the desired dimensional stability is usually lost in garment manufacture, in which several intensive ironing processes are performed. As a result the shape of the fabric, which can be used to describe not only its dimensions in length and breadth, but also the smooth and level condition of the surface of the product or a crease or pleat, cannot be permanently fixed by these decatizing processes. The intensity of treatment is therefore only sufficient for cohesive and temporary fixing effects, which can be lost again by a subsequent steam treatment or by the treatment of the product in water. Kier decatizing employs much more intensive temperature, moisture and time conditions, however this can only be carried out discontinuously depending upon its design.

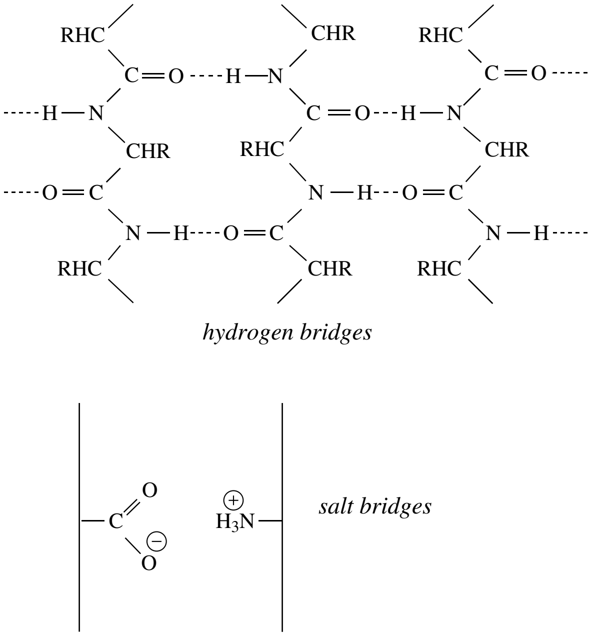

Fig. 1: Hydrogen and salt bridges re-oriented by steam decatizing.

Whereas only hydrogen bridges and salt bridges between the polypeptide chains of the wool are broken by the effect of the steam under the mild conditions of finish and press lustre decatizing (Fig. 1), it is assumed that in the harsher conditions of kier decatizing to a limited degree covalent cross bonds, the disulphide bonds of the cystine, will be hydrolytically split, thus achieving a permanent fixation.

$$\textcircled{W}-CH_2-S-S-CH_2-\textcircled{W} + H_2O$$

$$\longrightarrow \textcircled{W}-CH_2-SH + \textcircled{W}-CH_2-S-OH$$

According to the theory of the chemical mechanism of wool fixing, which is based upon the fundamental work of Speakman from 1936, it is precisely this breaking of the covalent disulphide bonds that represents the prerequisite for permanent fixing effects. Some subscribe to the opinion that the breaking of the covalent cross bond in the network of polypeptide chains merely makes it easier for deformation to occur, increases the mobility of the molecule chains and thus increases the number of hydrogen bridge bonds to be rearranged. An alternative theory is that the main contribution to dimensional stabilisation is the breaking and subsequent rearrangement of covalent cystine bonds (Fig. 2).

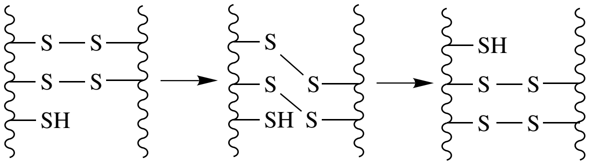

Fig. 2: Rearrangement of covalent cystine bridges by thiocatalysed disulphide exchange.

It is disadvantageous to the creation of a smooth production process that the kier decatizing stage must be inserted as a discontinuous intermediate stage in a series of continuous finishing processes. Commercial demands for higher production speeds, reduced personnel and energy costs and high quality products are resulting in efforts to invent new continuous decatizing machines that can be fully integrated into the production line, despite the favourable decatizing effects of discontinuous kier decatizing (Fig. 3).

The decatizing effects can be influenced by the following factors:

– pressure, which is generated by backcloth tension

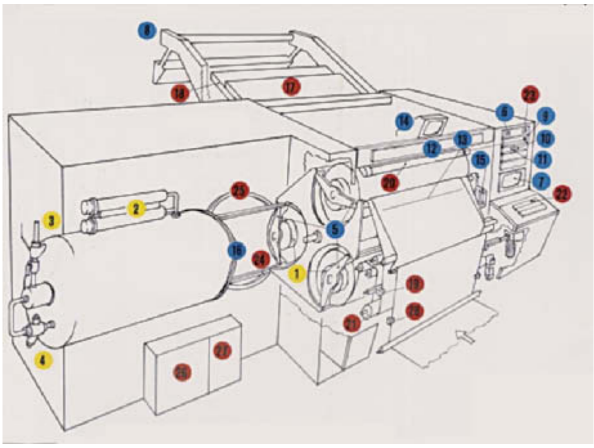

Fig. 3: Biela Shrunk "Suprema" kier decatizer.
1 = cylinder; 2 = steam control; 3 = cold cycle; 4 = starting cycle; 5 = truck; 6 + 7 + 9–14 = control and regulation functions; 8 = adjustable plaiting width; 15 + 16 = residual steam extraction; 17 = cold air blow-in; 18 = air extraction; 19 = automatic back grey guiding; 20 = presser roller; 21 = back grey drying calender; 22 = back grey tension control; 23 = presser roller control; 24 = automatic truck transport; 25 = door opening; 26 = electronic control panel; 27 = process control; 28 = automatic fabric guiding.

  and pressure from the pressure roller during the winding of the decatizing cylinder,
- steam pressure,
- treatment duration,
- fabric moisture during decatizing,
- cooling after decatizing,
- condition of the backcloth.

If these parameters act for an appropriate period they influence the surface pattern and the handle of the product according to the following rules:

a) Brilliant sheen (permanent) and solid handle: high steam pressure, medium steaming time, long cooling in tightly wound state, satin backcloth.
b) Brilliant sheen (permanent) and soft handle: high steam pressure, long steaming time, short cooling in less tightly wound state, satin backcloth.
c) Lower sheen (permanent) and solid handle: medium steam pressure, medium steaming time, long cooling in less tightly wound state, satin or molleton backcloth.
d) Low sheen (permanent) and soft handle: medium steam pressure, long steaming time, no cooling, winding with low tension, molleton backcloth.

Different manufacturers produce kier decatizing machines, the main differences being adjustable backcloth tension, diameter of the winding roller, winding system and boiler preparation, the possibility of changing the backcloth, capacity and steam flow direction. Structure and operation of a classical kier decatizing machine (Fig. 4): The undecatized material is passed via the high inlet, a material tensioner and several deflecting rollers via the run-in table and is wound on a tubular cylinder located in the decatizing boiler. After the boiler has been closed the programmed decatizing sequence begins. After treatment the boiler opens and the yarn package is aspirated. The material is fed to the delivery device via a conveyor belt. An additional cooling unit is installed under the conveyor belt.

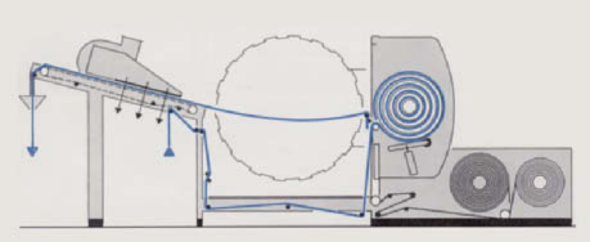

Fig. 4: Diagram of a Menschner/Kettling & Braun kier decatizing machine.

Lap formation (Fig. 5): Lap formation is critical for the quality of the decatized effect, because the fabric entering the lap is fixed in its existing state. The winding tension determines and alters the actual hardness of the lap, with pressure on the lower layers increasing as the number of layers increases; this creates a lap that is solid and hard at the bottom, whilst the outer layers are loose and soft. This gives rise to different decatizing effects at the start and end of the material. A variable pressure roller regulates the hardness of the batch, so that the pressure exerted rises as the diameter of the batch increases. This guarantees a constant winding hardness from the start to the end of the roll.

Decatizing boiler: The internal diameter of the boiler is in the range 900–1300 mm, as required. Automatic control of the decatizing programme promotes consistent material quality. Pressures of 1.5–3 bar are possible, the time can be set between 0–10 min. The steam flow direction can be set as outside to inside or inside to outside. The decatizing boiler can be filled via steam inlet valves. Saturated steam produces the best decatizing effect, superheated steam leads to the material drying out and yellowing and wet steam can lead to condensation marks. The deaeration of the boiler, i.e. filling with steam without the inclusion of air also takes place via steam inlet valves. After the decatizing process has finished the steam outlet valves open. The lid opens in two stages for pressure equalization. The decatizing boiler is surrounded by a pressure resistant wall, so that the intermediate area this creates acts as a steam storage container and heating jacket, and prevents steam from condensing on the inner walls of the boiler (condensation marks). At points where pipes or safety valves are welded on, draining of water is diverted via guiding plates to the lower part of the boiler. Steam should flow from outside to inside, because then the steam will already have expanded by the time it

Kier decatizing

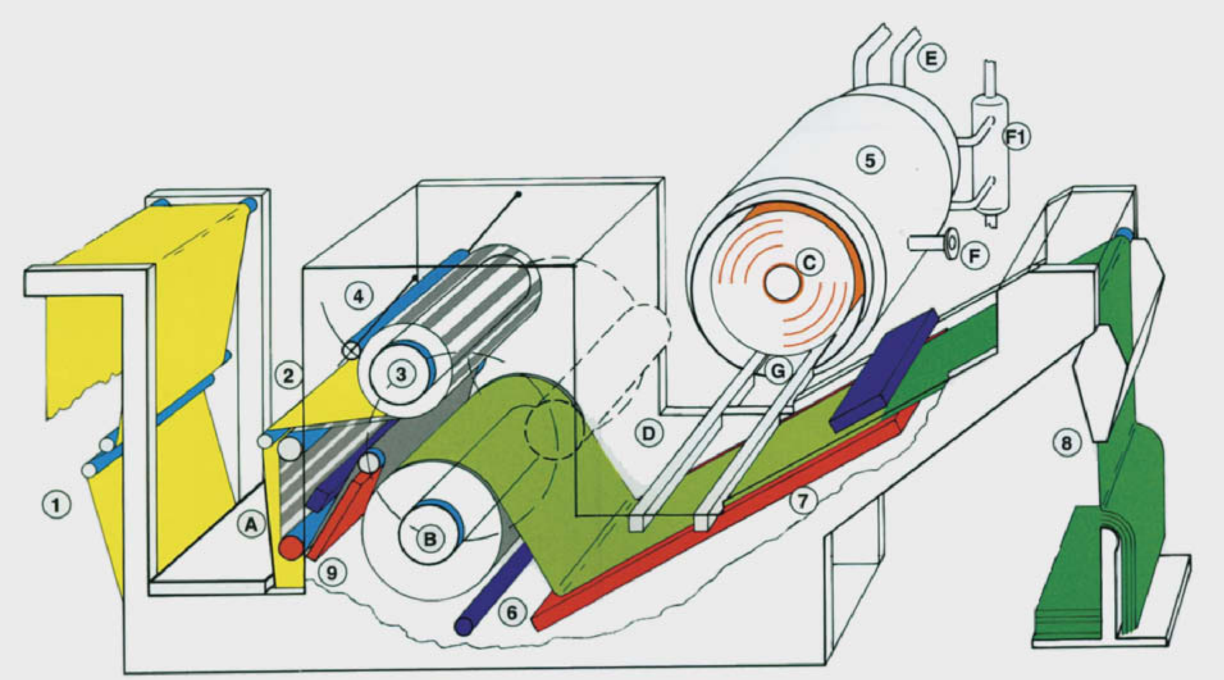

Fig. 5: TMT kier decatizer.
1 = automatic cloth centring device; 2 = perfect inspection of piece drawing-in; 3 = uniform winding of the cloth up to 100 m/min by means of d.c. motors with electronic speed and wrapper tension control; 4 = adjustable pressure roller; 5 = autoclave with innumerable vapour passages and types, Multiprogram System also with vacuum pump; 6 = automatic piece detaching and unloading at a synchronised velocity; 7 = thermal shock with a high stabilising power with multiple aspiration + blowing system; 8 = unloading of the batch on to a trestle or platform; 9 = satin moistening studied for high temperatures control of residual moist by means of a combined system aspirator + blower + calender roller; A = wrapper tension controlled by load cells (TMTSYS) and pressure of pressure roller are programmable and may be constant or variable during the winding-up phase. In the memory 100 different types of winding cycles may be stored; B = automatic wrapper centring by means of alternating axial movements (TMTSYS); C = special stainless anticondensate tube beams (TMTSYS) with min/max diameters studied for perfect quality and high production; D = only one trough carriage, less maintenance, no dripping from above, dirty and greasy parts are kept away from the cloth and the wrapper; E = autoclave, standard version, with 9 valves (inlet – relief – outlet – vacuum), all are configurable by means of Multiprogram system, adjustable vapour quantity, anticondensate labyrinth system (TMTSYS. In the memory 100 different vapour passages (xc), completely conceived by the user himself, may be stored; F = vapour treatment plant at the input with a series of containers, a reducing valve, collectors and by-passes (already fitted); F1 = vapour quality regulator; G = condensate aspiration from the beam by means of a vacuum pump; X = electric fittings centralised by PC and video terminal to supervise: – used programmes and parameters – illuminated diagram of autoclave cycle – a hundred messages for programmation and trouble locating Multiprogram System: basic and advanced software to use and programme (combining cycle xa and xc) over 100 programs to obtain permanent finish, PF 2000 effect; – data bank to record and certify every single treatment; – programmable meter counter, production counter, plaiter control monitor, winding levers and advanced feeding device are manufactured by TMT and can be fitted according to the requirements.

reaches the inner layers of the lap, which equalizes the differential pressure on the layers.

Extraction: The extraction of the steam trapped between the layers of the lap causes the steam to condense; the moisture produced is drawn into the material. Cooling the material once more on the conveyor belt prevents creases, breaks and folds during layering down. Extraction and cooling particularly influence the quality of material handle.

Backcloth: has several important functions:

- Separating the fabric layers to avoid imprinting,
- Transferring the surface pressure to decrease the thickness of the material,
- Leading the steam (heat and moisture) into and through the material,
- Gentle, fold free, low tension material transport during rolling and unrolling of the yarn package,
- Type and surface of the backcloth influence the handle and lustre (molleton for soft, voluminous handle and low lustre, satin for smooth handle and high lustre).

Problems: Faults may occur in the material during kier decatizing that are difficult or impossible to rectify. These include colour transition at the selvedge, caused by the backcloth being too narrow; thick areas of the material, foreign bodies or seams sewed with coarse thread, can press through the individual layers of the yarn package (regular imprints); differences in the decatizing effect may arise due to different yarn package pressure between inner and outer layers; decatizing folds caused by material entering the yarn package with folds. Excessive backcloth tension, excessive steam pressure and high residual acid content of carbonised material result in rapid wear to the backcloth (high operating costs). Other disadvantages are the discontinuous procedure and the use of direct steam, which can vary in quality.

History:

1960: Maschinenfabrik Gerhard Moers, Aachen, develops the first kier decatizing machine of the world (Fig. 6). This machine is delivered to Tuchfabrik Becker, Aachen-Soers.

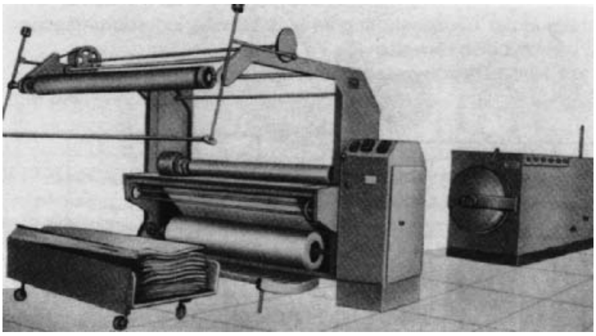

Fig. 6: First kier decatizer by Moers.

1961: A second similar machine is delivered to Textilingenieur-Schule, Aachen. In this machine with a diameter of 900 mm first experiments have been made with a cylinder diameter larger by 35% of the 100% vessel diameter (900 mm), i.e. cylinder diameter 315 mm.

From 1971 on: Vapermat 900 from Moers is successful (diameter 900 mm).

1973: Moers delivers the first machine with diameter 1000 mm and a cylinder diameter of 160 mm to Tuchfabrik Becker, where it is used for batches with 4 x 50 m wool fabric in molton wrapper. The machine is called Vapermat 1000 (Vapeur permanent automatique).

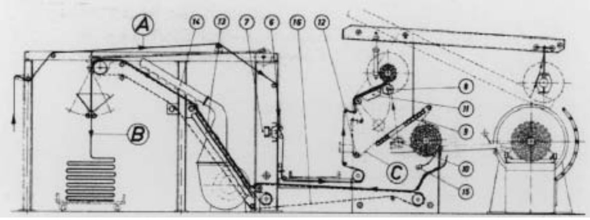

Fig. 7: Decoclav 1 from Kettling & Braun.

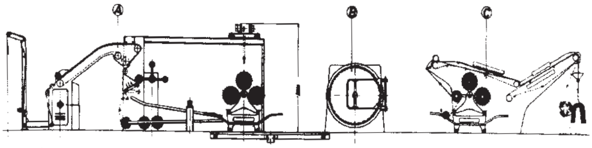

Fig. 8: Decoclav 3 from Kettling & Braun.

Mr Drabert develops on his way back from a visit to customers in South America in the plane back home the idea of Decoclav 1, built in the same year by Kettling & Braun (Fig. 7).

1975: Moers constructs a machine called Vapermat 1200 with a diameter of 1200 mm and a diameter of the cylinder of 160 mm. The machine is delivered to Tuchfabrik Becker, where it worked with batches of 6x50 m wool fabrics in molton wrapper.

At Kettling & Braun Mr Dieter Riedel constructs the Decoclav 3 (Fig. 8) which works with a star of three wound-up pieces being decatized at the same time in a vessel with a diameter of 1200 mm.

1979: At ITMA, Hannover, Moers shows the Vapermat 1200 with a cylinder of 450 mm diameter. At the same show Hemmer presents their first kier decatizer Permadec which works with a vessel diameter of 1000 mm and with vacuum inside the cylinder (diameter 300 mm) (Fig. 9).

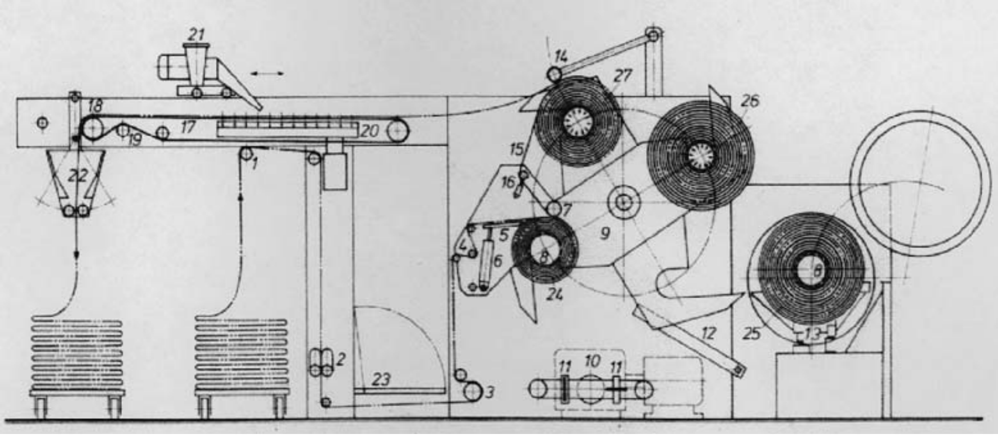

Fig. 9: Permadec (1979) from Hemmer.

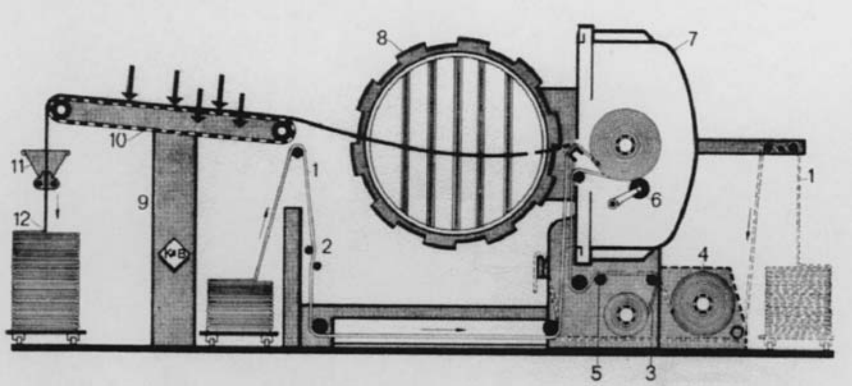

Fig. 10: Decoclav 2000 from Kettling & Braun.

1981: Mr Dieter Riedel at Drabert-Kettling & Braun, Minden, constructs the Decoclav 4 with a vessel diameter of 1300 mm. At the end of this year Draber, Kettling & Braun is sold to Menschner at Viersen-Dülken, where Decoclav 4 is built with a diameter of 1300 mm, but now called Decoclav - 8CL (from 1982 on).

Kettling & Braun presents the completely different system Decoclav 2000 (called "Bratpfanne") (Fig.10).

1982: Menschner built a very successful machine from 1982 on and sold it with 3 big versions to Tuchfabrik Becker as Decoclav 2200 (Fig. 11).

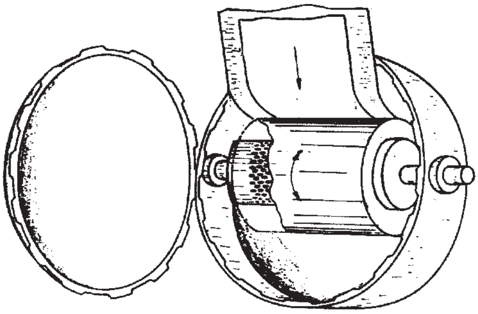

Fig. 11: Decoclav 2200 from Menschner.

Biella Shrunk presents the Cadet-System (Fig. 12) with

- autoclave diameter larger than 1000 mm,
- diameter of cylinder equal to 35% of vessel diameter,
- displacing element inside the cylinder.

Diameter of cylinder in Fig. 12:

type		diameter of cylinder (mm)	autoclav
I	(classic)	150	900
II		450	1040
III	(classic)	200	1040
IV		670	1300

Kier lining Treatment of pressure kiers and bleaching boilers with milk of lime, cement and water glass solution to prevent kier and bleach stains when the material touches unprotected boiler walls.

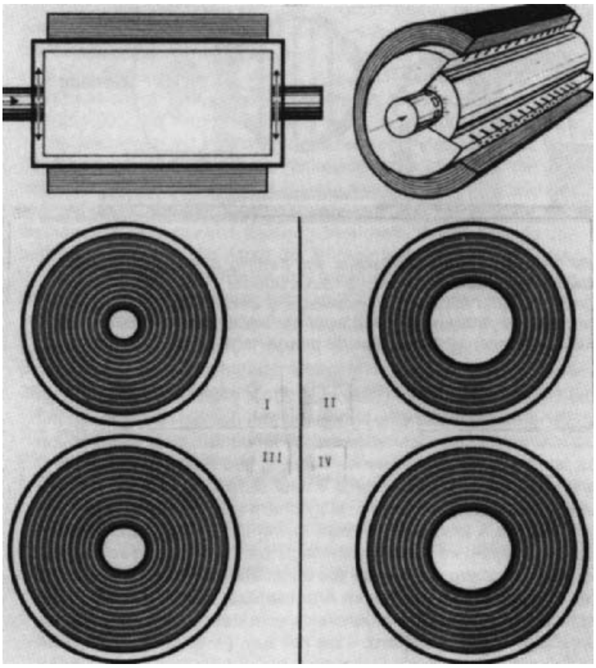

Fig. 12: Cadet-System from Biella Shrunk.

Kier stains arise due to unfavourable working conditions, such as hard, turbid water, poor, one-sided liquor circulation, inconsistent packing of the kier boiling material (channelling), wrong rinsing (cold instead of boiling hot), etc. This usually causes brownish deposits and uneven stains, which can only be removed by repeating the kier boiling or hot acid souring and boiling with sodium carbonate.

Kieselguhr (guhr, diatomaceous earth, infusorial earth, fossil meal, fossil dust), consists primarily of 70–90% amorphous silicic acid (SiO_2) and (raw kieselguhr) 3–12% water, is very fine grained, light (weight per litre 15–300 g) and usually light grey. Calcined kieselguhr is free from organic substances and water, a reddish (containing iron) or white powder; chemically very resistant, unburnable, heat and sound insulating, absorbent to fluids up to five times its weight. Consists of differently shaped, tiny silicic acid skeletons of prehistoric single cell algae (approx. 8000 types), extracted by open cast mining from large deposits (Lüneburg Heath; Lampoc/California, the largest deposit in the world). Individual frustules possess a huge number of very fine, normally air filled, grooves, hollows, capillaries etc., which explains their amazing lightness (1 cm^2 kieselguhr = over 1 billion diatomaceous shells). The unusually fine skeleton structure has an estimated diameter of just 0.1 μm. Such an extremely fine pored microstructure naturally favours the maximum possible filter activity in sewerage filters of contaminated organic solvents and in water filters. Even bacteria are retained (Berkefeld filter for water sterilization). To be suitable for use as a filter assistant, kieselguhr must possess a regular granulation and be fan sorted. Application: Heat (steam tubes, steam boilers) and sound insulation, packaging for irritating liquids (acid carboys, etc.); filter powder.

Kilim carpets Woven, bright, originally Turkish → Flat carpet with coarse wool weft. Sometimes with woven perforations, i.e. small open cracks on the border lines of the multi-coloured pattern. Used as floor carpet on thick felt underlay.

Kilo- (Gk.: chílioi = thousand), unit prefix for one thousand times = 10^3.

Kilogram (kg). 1 kg is the mass of the international kilogram prototype of a platinum-iridium body stored in the vicinity of Paris. → Mass.

K index,

I. Index in general use for characterizing a commercial grade of polyvinylchloride, calculated from its viscosity in solution and indicating its molecular weight. Polyvinylchloride with a K value of approximately 68–80 is usually used for coating.

II. Index used for the classification of basic (cationic) dyes with respect to their rate of strike (→ Association index K).

III. Index used in association with machines for measuring fabric length because of the effect on standardized length measurement due to the stretching of the material. The value is derived from the elastic characteristics of the fabric being measured (which are determined using prescribed apparatus) in combination with the effect of the tension applied during mechanical measurement (see also → K indices length measurement):

$$K = E \cdot G_A \left(1 + \frac{F'_M}{k\,G_A}\right)$$

E = extension of a sample of fabric subjected to a force of 10 N/m for every per metre width;
G_A = weight applied to the fabric per unit area expressed in N/m^2;
F'_M = force per metre width of fabric (N/m) exerted on the material by the machine during the measuring process;
k = proportional constant per unit length.

K indices length measurement For commercial purposes special machines are used to determine the length of textiles, cloth measuring machines which provide low-cost continuous measurement of material while the fabric remains in motion. In accordance with calibration regulation, such a machine must be calibrated so that the lengths it measures are accurate to within ± 0.3%. Up until the end of the fifties, during which time textiles were predominantly made from unyielding and thus low-stretch materials, this requirement could be met without difficulty by relatively simple machines. However, the development of elastic fibres and the increased prevalence of knitted goods has resulted in liability to error often exceeding the permitted calibration error range. The principle cause was the unintentional stretching of the textile fabric during measurement on account of the tension applied. In consequence, conventional measuring machines were no longer suitable for all types of material; new machines with tension compensating systems had to be developed appropriate to the → K index of stretch textiles. The K value was developed as an index for describing the elastic characteristics of material as displayed during the measuring process. By definition, the K index is an indicator of the dimensional error to be expected due to stretching during the measuring process, with K rising in proportion to the susceptibility to stretching of the material. As a result, the greater the K index of a material, the more extensive the technical requirement imposed on the machine with respect to tension compensating mechanisms which reduce the tension and thus the resulting extension at the point of measurement.

For this reason, machines for the measurement of textiles have, since 1978, been divided into four groups according to the K value of the materials which they may measure. The group code indicates which materials (K indices) may be measured using the machine. Machines of Group I, which are suitable for unyielding and low-stretch materials of low K value, possess limited tension compensating mechanisms, whereas Group IV machines must be equipped with a number of complex tension compensating mechanisms in order to accommodate high-stretch material with a high K value. The need for tension compensating mechanisms is independent of the method of measurement. However, it is of importance that the resistance to movement in the measuring device should not additionally stretch the material at the point of contact. Even in the case of newly developed techniques, the aim of which is to replace the inertia of the measuring wheel by a remote sensing device (e.g. laser Doppler effect, Correvit principle), the material being measured must at all times be transported past the point of measurement in a relaxed, i.e. in a minimally stretched state. In other words, remote measuring techniques cannot replace tension compensating mechanisms (source Mann and Zervos).

Kinetic equation in fibre loading Important process parameters regarding the mass transfer between textile and liquor can be determined by kinetic analyses. These parameters are the mass transfer constants and the adsorption isotherms in relation to process variables such as temperature, initial concentration, recipe and flow. For example, the diffusion of dispersion dyes in the fibre represents the slowest link in the reaction chain, and therefore determines the dyeing speed or the → Dyeing kinetics of the dyeing process. There is a formula based upon → Fick's equation which can be used to determine the → Diffusion coefficient during the initial phase of the dyeing process in the simplest manner:

$$\frac{c_t}{c_\infty} = 4\sqrt{\frac{D \cdot t}{\pi \cdot r^2}}$$

c_1 = dye on the fibre at time t,
c_∞ = dye on the fibre in the equilibrium state,
D = diffusion coefficient,
r = radius of the fibre.

The above formula simplifies to:

$$c_t = K \cdot \sqrt{t}$$

The mass transfer between the textile and the liquor can often be described in formal kinetic terms as a reaction of the first order, in which the transfer speed of the surface of the textile is proportional to the concentration of the mass to be transferred.

$$\frac{dc}{dt} = \beta\,(c_\infty - c)$$

$$\beta = \frac{D}{d}\,O$$

Solution within the boundaries t = 0, c = 0 and t, c:

$$\ln\left(1 - \frac{c}{c_\infty}\right) = -\beta\, t$$

c = momentary concentration on the fibre,
c_∞ = equilibrium concentration on the fibre,
β = mass transfer coefficient,
D = diffusion coefficient,
d = diffusion boundary layer thickness,
O = surface.

Kinetics Study of movement due to forces. Field of physical chemistry, which attempts to explain the macroscopically observed time variable properties and regularities of isolated or interacting substances based upon assumptions about the behaviour of free atoms and molecules. → Dyeing kinetics.

Kinetics in heterogeneous systems The kinetics of a process is related to the speed at which a process takes place, for example in solution, i.e. in a homogeneous system. A heterogeneous system is further complicated by phase limit problems and flow influences. Sizes, for example, demonstrate a characteristic, temperature dependent swelling behaviour, which can cause the thickness of the size film to multiply before the actual dissolution. This gives rise to the danger, particularly for starch sizes, of the fabric being loaded and thus the efficiency of the detergent being reduced. For a starch film to swell it is necessary for the intramolecular and intermolecular interactions of the amyloses and amylopectins to be dissolved until water absorption, and thus an increase in volume, is possible. If the swelling is a necessary step, which determines the speed of the dissolution process, then all structural units of the starch polymer must be solvated from the solvent, only then does solubility exist. Given a constant liquor flow rate a size film will be dissolved more quickly the thinner it is. The dissolution of the swollen size from the fabric can be described as a diffusion controlled process. In order to avoid long dissolution times for the polymers it is necessary to accelerate material transport in the diffusion boundary layer by turbulence. Intensively flowing past the fabric guarantees that the concentrated, highly viscose size solution is rapidly and completely mixed with the washing liquor on the fibre.

Desizing can be represented as a first order process, i.e. the reaction speed is not only dependent upon temperature, but also upon the concentration of the initial material. Because in this case, the speed v has a different magnitude at every point in time, this is a differential change. The differential quotient in general form is:

$$v = -\frac{d[A]}{d[t]} = k[A]$$

The quotient sign is positive if the concentration is decreasing and negative if it is increasing. The reaction speed is proportional to the concentration of the educt, the proportionality factor is termed speed constant k. For desizing kinetics the speed constant, the so-called mass transfer coefficient β, is determined from the change of the size mass m on the material over time:

$$-\frac{dm}{dt} = \beta \cdot O \cdot m \qquad \frac{dm}{dt} = -\beta^* \cdot m$$

Rearranging gives:

$$\frac{dm}{m} = -\beta^* \cdot dt$$

Solving the differential equation within the boundaries $t = 0$, $m = m_O$ and t, m:

$$\int_{m_O}^{m} \frac{dm}{m} = -\beta^* \int_{0}^{t} dt$$

$$\ln \frac{m}{m_O} = -\beta^* \cdot t$$

Where $m = m_O - m_B$ we get:

$$\ln \left(\frac{m_O - m_B}{m_O} \right) = -\beta^* \cdot t$$

$$\ln \left(1 - \frac{m_B}{m_O} \right) = -\beta^* \cdot t$$

t = time
β = mass transfer coefficient
O = surface of the fabric
β^* = the sum of β and O,
m = momentary size mass,
m_O = size mass on raw fabric,
m_B = size mass in the liquor.

On the assumption that the size mass in the bath reaches the initial size mass m_O at the time $t \rightarrow \infty$, we can also write the expression $m_{B\infty}$ for m_O. If we relate the size mass to a certain volume then we can replace m in the last equation with c.

$$\ln \left(1 - \frac{c_B}{c_O} \right) = -\beta^* \cdot t$$

If we plot the natural logarithm in the bracketed expression as a function of time then, under the condition of a first order reaction, this yields a straight line, the gradient of which is the mass transfer coefficient β^* (according to Heidemann).

Kinetics in homogeneous systems In order to find the speed constant of a reaction spectrophotometrically tracked in the UV or visible wavelength range, the extinction/time value pairs must be matched to a suitable function. The form of the function depends upon the order of the reaction being considered. The curve is based upon the "method of the least error squares". Extinction/time curves have a linear path,

a) if it is a reaction of zero order or
b) if a reaction of a higher order is being investigated using the "initial speed method".

The relationship between → Extinction and time can be described using an equation (Fig., a).

$$E = (E_A^0 - E_B^0)\frac{1 - kt}{c_A^0} + E_B^0$$

$$y = a \cdot x + b$$

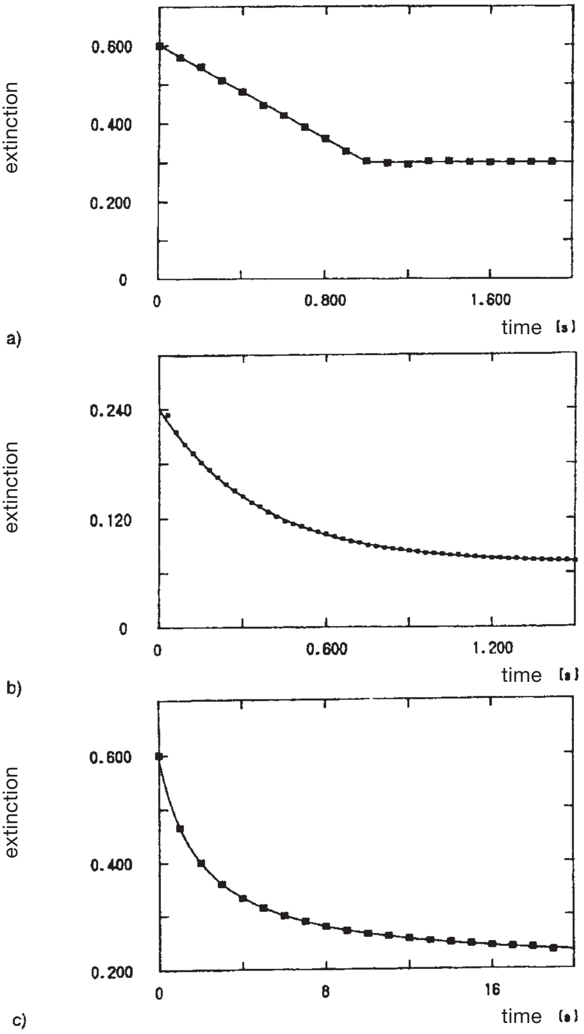

Fig.: Typical curve for a reaction a) zero order; b) 1st order; c) 2nd order, measured by extinction of the colour imparting component.

An exponential curve is obtained for a reaction of the 1st order or for a reaction that is being investigated under pseudo 1st order conditions (Fig., b).

$$E = (E_A^0 - E_B^0)\exp(-k_{obs}t) + E_B^0$$

$$y = a \cdot \exp(-cx) + b$$

A hyperbolic curve is obtained for a reaction of the 2nd order or for a reaction that is being investigated under stochiometric conditions (Fig., c).

$$E = \frac{(E_A^0 - E_B^0)}{1 + c_A^0\, kt} + E_B^0$$

$$y = \frac{a}{1 + cx} + b$$

The concept of keeping the reaction speed as low as possible, i.e. also obtaining as simple a measuring signal as possible (extinction/time curve) leads to the use of the "excess method". In this there is a deficit of the colour imparting reaction partner in comparison to all other reactands. This reduces the order of the reaction to that in the speed law with the deficit partners. In most cases this yields a reaction path of the 1st order. This is also known as a pseudo 1st order reaction. Getting a pseudo 0 order or a pseudo 2nd order is a major exception. If this method is not applicable, then the "initial reaction speed method" or the stochiometric conversion must be used. In the first case this yields a linear path of the extinction/time curve, in the second case a hyperbolic path generally results.

King bobbin One-sided → Conical packages with precision cross winding.

Kinking effect with textured yarns Tendency of a yarn textured using the torsion procedure to regain its original twist.

Kiss dyeing process Dyeing liquor application onto the fibre tips or on the back, often for carpet material.

Kiss print Special printing technique used in the rotary screen printing of carpets. Carpet transport on a needled backcloth which can be adjusted by electric push-button control. By controlling the height between back cloth and template a tunnel is formed, the height and thickness of which correspond with those of the carpet. Because this does not alter the position of the pile, a sharp printing edge is obtained. – Manuf.: P. Zimmer.

Kiss roll (lick roller) → Cover roller.

Km → Camel hair, → Textile fibre symbols, according to DIN 60 001 till 1988, from 1991 → WK.

Knife-coating principle The knife application unit (spreader) consists of the doctor blade holder, the doctor blade with lateral limit blocks and possibly a doctor blade liner. The coating substance is applied to the doctor blade, which is set at a defined distance between knife and fabric using the doctor blade holder. In continuous coating the base material moves under the fixed doctor blade. This movement exerts a shear force on the paste, forcing it to flow. The shear force applied can be varied by varying the working speed, the doctor blade profile and the tilt angle of the blade, which can also be varied by adjusting the doctor blade holder. Furthermore, the viscosity of the coating substance also has an effect. The paste is spread by the movement of the base material, and it should be noted that, when applied correctly, the paste rolls in front of the knife. The coating thickness is primarily determined by the distance from the knife to the fabric. Furthermore it is also determined by the tilt angle and the heel, which is the part of the coating knife, which is applied to the textile substrate. The higher the desired application quantity, the broader the knife heel selected and the lower the doctor blade, i.e. the greater the doctor blade angle, the lower the paste application.

Application is further varied by altering the working speed and tension of the base material. It is clear that numerous parameters interact during doctoring, so it is necessary to harmonize these parameters to achieve a satisfactory coating.

The coating thickness depends upon:

- doctoring speed,
- doctor blade tilt angle,
- doctor blade profile (heel),
- doctor blade distance,
- base material tension,
- paste viscosity.

For the application of the paste the spreader can be equipped with various doctor blade systems, depending upon the item. These differ in the shape of the coating knife and the type of support. In addition to the guiding of the textile during the coating process, i.e. the type of support, we differentiate between:

- air blade,
- knife on blanket coater,
- knife over roll coater.

The coaters of modern coating plants are generally variably equipped.

I. Air blade: In an air blade system the doctor blade acts directly onto the material without an underlay (Fig. 1). The carrier belt is drawn via two small tables or movable rollers. A supporting blade directly in front of the doctor blade aids even application in an air blade with roller guides.

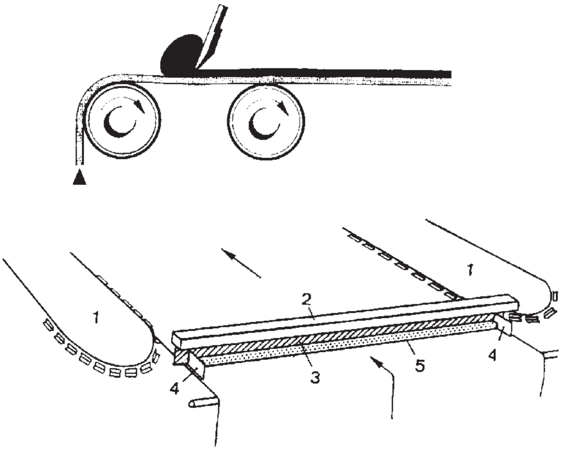

Fig. 1: Air knife principle.
Top: Air knife. Below: Air knife located at take-up on stenter frame (1 = stenter chains; 2 = knife mounting; 3 = air knife; 4 = cheek blades; 5 = coating paste).

The air blade makes it possible to achieve a low application quantity and is particularly suitable for dense, tightly stretched fabrics. It is often used for the preparation of light fabrics, when the coating substance should not penetrate too far into the fabric. These thin coatings are particularly favoured by the use of doctor blades without a marked heel. These are usually narrow, rounded off pointed knives with a width of 1–3 mm. The application weight is dependent upon the tension and speed of the carrier belt. It is 10–20 g/m^2. The air blade achieves satisfactory results in relatively low cost plants on stable, thin textile materials, but also has disadvantages. These are:

- limitation of the substrate used due to high material tension;
- shaving effect, which means that soiling is possible due to loose threads and fibres;
- tension in the substrate and flow characteristics of the paste cause inconsistent material quality, which is difficult to control by corrective machine settings.

II. Knife on blanket coater: The doctor blade works against a doctor blade underlay, which is an endless rubber belt that runs over driven rollers and is fitted with a support roller just in front of, behind or below the blade (Fig. 2).

The knife on blanket coater is suitable for thin or open carriers, which are to be coated without bleeding through and are unsuited for coating using the air blade system due to low stability. It is particularly commonly used for the coating of uneven substrates, e.g. roughened cotton fabric. Thin coats with a uniform thickness can be applied, particularly if the support roller is located under the blade, whilst the other positions permit a more elastic guidance.

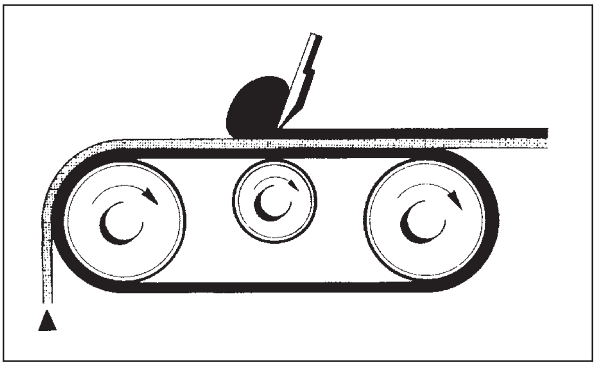

Fig. 2: Rubber sheet knife.

The paste application can also be varied by the pressure of the rubber blanket against the material and by the tilt angle of the doctor blade. For precoatings, narrow, rounded coating blades with a width of 1–3 mm are preferred. Otherwise for higher coats doctor blades with a wider, flatter heel of 3–20 mm are used. These shoe blades have a sharply angled undercut on the back, which is designed to prevent drops of coating material which have gathered on the back from being pushed off and spoiling the coating.

The drawback of this process lies in the rubber blanket condition. Firstly, intensive maintenance is necessary to control swelling or rubbing of the blanket. Secondly, the application method is difficult to control due to the varying forces on the rubber blanket, which result from unevenness of the substrate and the paste. Certain irregularities can be attributed to the varying hardness of the rubber blanket in places.

III. Knife over roll coater: A roller, over which the carrier is fed from below, serves as the doctor blade underlay in this method (Fig. 3). The knife over roll

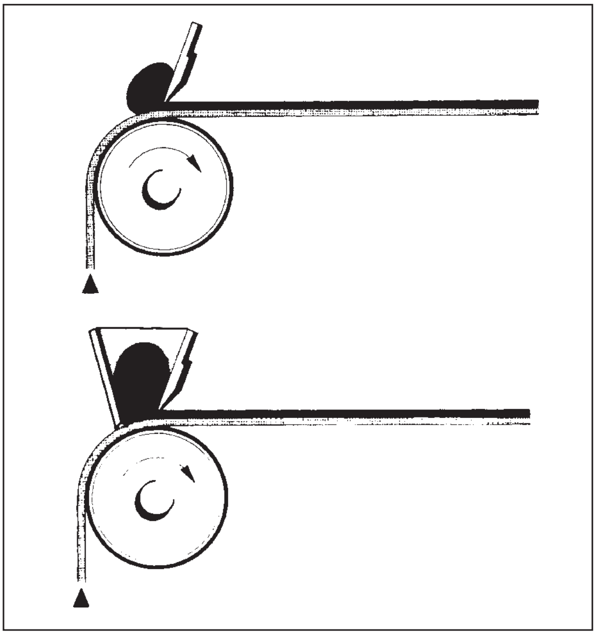

Fig. 3: Roller knife compared to trough knife.

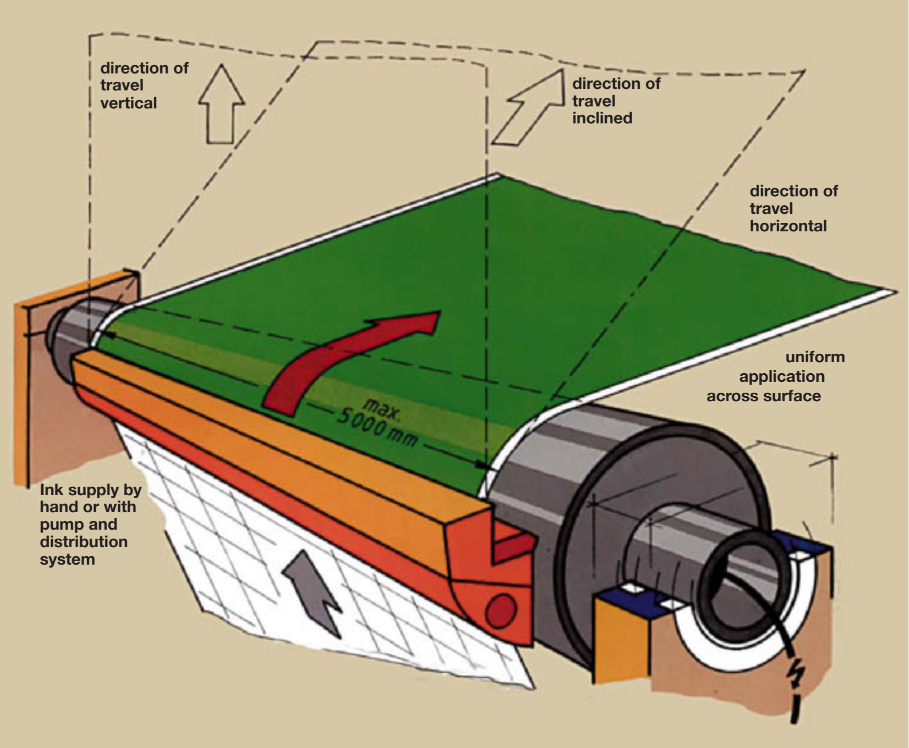

Fig. 4: Magnetic roller knife by Zimmer (Magnoroll '92).

coater is particularly suitable for high coating weights, as low coating quantities and less dense carriers lead to the paste bleeding through. High precision coatings can be achieved, as the material tension and paste viscosity have only a slight influence. The coating thickness is determined by the distance between roller and doctor blade. If necessary the penetration can be controlled by this doctor blade position. Furthermore, the application quantity is also dependent upon the width of the heel. Thick layers can be achieved with a wide heel.

Rubber or steel rollers are used with the knife over roll coater. Both achieve good results with low investment. The rubber roller is suited for uneven fabrics, but can also be used for smooth material. Depending upon the coating knife used and the hardness of the rubber roller, the coating effect is similar to that of the knife on blanket coater. In order to guarantee a uniform distance between substrate and heel, the knife is matched to the roller surface. If the doctor blade is precisely ground on the roller, great coating precision can be achieved with smooth, even surfaces. However, the roller encourages an undesired penetration of the coating substance, so preparation must take place. Thin coatings are difficult to control. Uneven points in the carrier lead to uncoated points or damage to the textile. The evenness of the coating can also be impaired by the doctor blade deflecting if high thrust forces are exerted by highly viscose pastes in front of the doctor blade. Therefore, magnet-roll doctor blades are recommended for full surface coatings over large working widths (Fig. 4).

Knife-coat machine → Coating machine.

Knife-on-blanket coating → Doctor blade for coating and laminating, which is supported on an endless rubber blanket.

Knifing Carpets with polyacrylonitrile or polyamide cut pile are drawn under a doctor blade to align the pile in warmed state.

Knit-deknit method (Whitaker process), a knit-pressure-fixation-rewinding process for the texturizing of yarns (similar crinkle). → Space dyeing.

Knitgoods finishing The trend towards continuous treatment is becoming more pronounced. Finishing lines for tubular knitgoods are made up of a squeezing device, horizontal dryer and high performance calender. The Fig. 1 shows typical wet finishing lines for knitgoods and Fig. 2 typical dry finishing.

Knitgoods, pretreatment A specialized technology has been created for the finishing of knitgoods, which takes into account the high two dimensional elasticity of knitgoods by appropriate modifications to existing machines. Knitgoods are finished in tubular (Figs. 1 and 2) or open-width (Fig. 3) form (piece goods) and as manufactured items of clothing. Pretreatments: Washing, bleaching, optical brightening, fixing, mercerizing, shrinking.

I. Cotton: Treatment of large batches discontinuously in hank form (pack system bleaching) or continuously in open-width form either using immersion aggregates or the impregnation steam method.

II. Synthetics: Most synthetic materials are sensitive

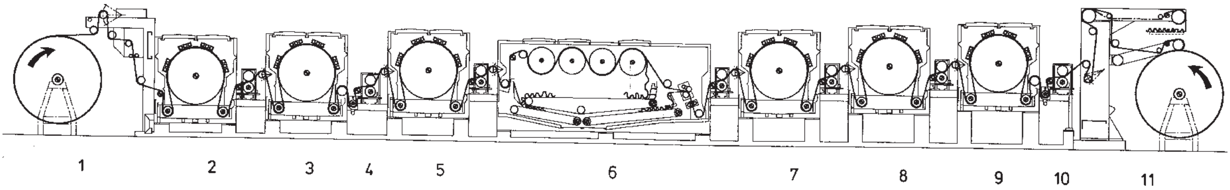

Fig. 1: Product line and functions schematic of the pre and post treatment Trikoflex 2000 facility (Kleinewefers KTM). 1, 11 = unrolling and rolling; 2, 3 = rinsing; 4, 10 = cooling; 5 = impregnating; 6 = immersion; 7, 8, 9 = rinsing.

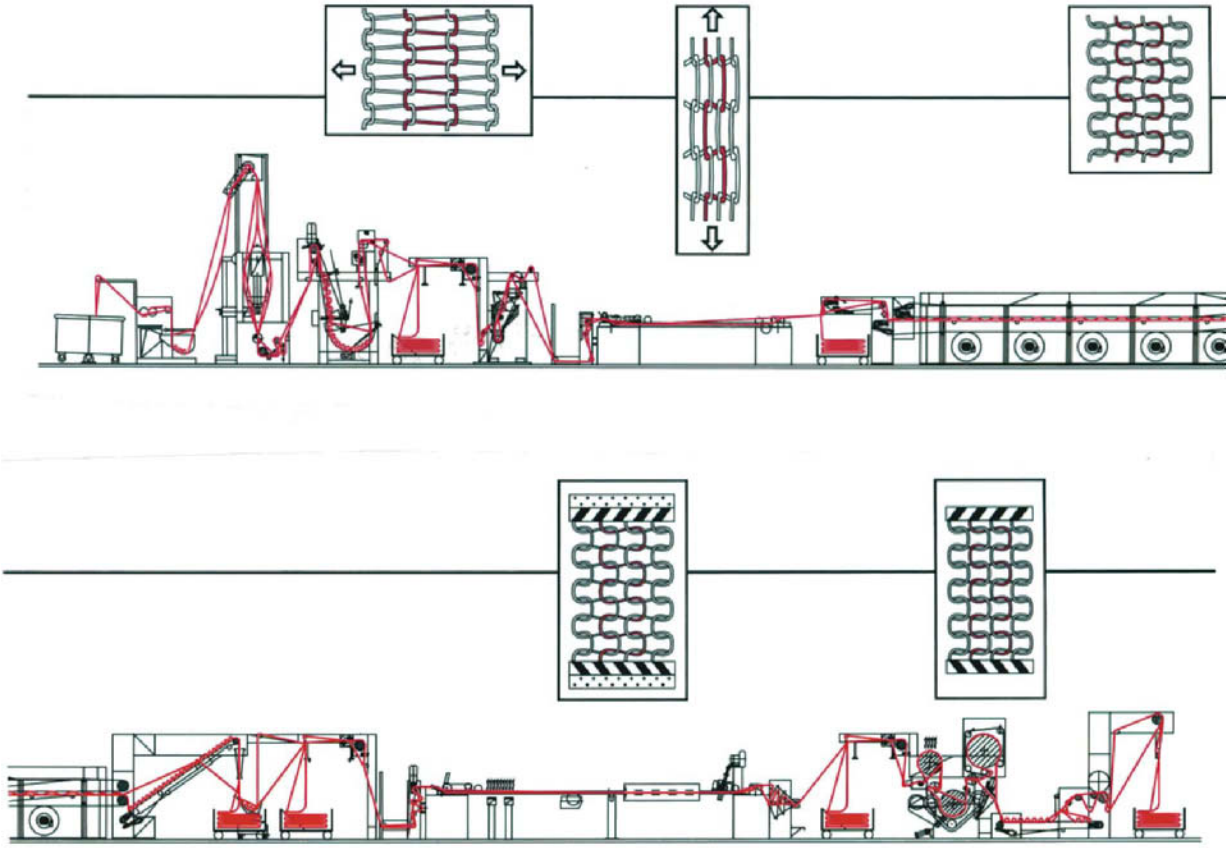

Fig. 2: Knitwear finishing line by Monforts.

to deformation. Raw material should therefore be stored rolled, and impact on the material must not be too high during finishing. Tubular knitgood qualities must be cut and rolled. Even less sensitive synthetics can only be cut after washing. Solvent washing is also used for the prewashing of knitgoods made of synthetic fibres.

a) Polyamide: Depending upon preparation, material can be fixed raw. However, if there is a danger of sticking, then washing takes place first. Some qualities can be cleaned in the dyebath; in this case thermofixation takes place after dyeing.

b) Polyacrylonitrile: Thermofixation not necessary. Washing at max. 60°C. For subsequent rinsing the temperature is reduced slowly, otherwise rope creases are fixed.

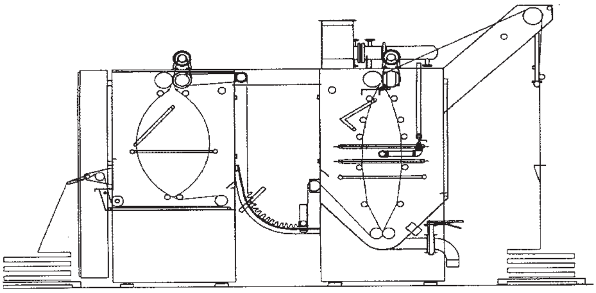

Fig. 1: Hydrosetting of Lycra-containing tubular cotton knitwear on an “Aquarius WEE 1.4” using Miltopan GB as abrasioning Zeolith-silicate.

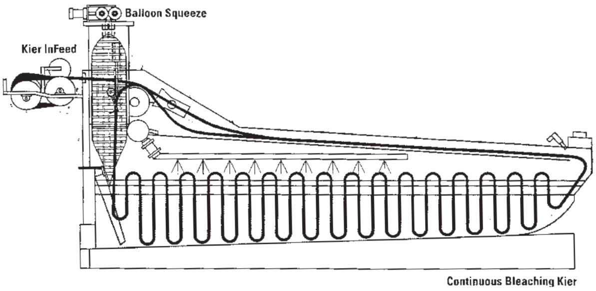

Fig. 2: Continuous bleaching kier from Jemco for tubular knit.

c) Polyester: These qualities are mainly produced from texturized yarns. Tubular knitgoods are cut, washed open-width, relaxed, dried and thermset.

d) Elastane: These qualities should not be stored for long periods (uneven shrinkage). Tubular knitgoods should be cut. First, complete deshrinking is necessary, which takes place on steaming tables or in hot water depending upon the material. Shrinking can also take place on carrying strap-stenter with max. advance. Then it is washed, dried and fixed on the stenter.

Knitgoods, problems in finishing Due to their constructive elements, knitgoods are characterized by high elasticity and always try to return to the most energetically favourable form. However, intermediate stages can also be temporarily fixed (Fig. 1), and thus the main problem of knitgood finishing is working without tension.

The concept of the relaxed structure can be described mathematically by rearranging the Munden's equations. Equations for the classical structure theory of knitgoods:

row density (rows/cm) $RD = u_{rd}/lz$

wale density (wales/cm) $SD = u_{sd}/lz$

stitch density (stitches/cm) $MD = RD \cdot SD$

fabric weight (g/m²) $Ag = (0.1 \cdot u_{md} \cdot T)\, lz$

knit width $$B = \frac{(N \cdot lz)}{(N_{ZB} \cdot u_{sd})} = \frac{N}{SD}$$

stitch form factor $$FF = \frac{RD}{SD} = \frac{u_{rd}}{u_{sd}}$$

density factor (tex $^{1}/2$/cm) $$K = N_Z \sqrt{\frac{T}{lz}}$$

u = weave independent correction factor, e.g. for a right-left material: $u_{rd} = 5.7$; $u_{sd} = 4.1$; $u_{md} = 23.5$;
N = total number of needles,
N_Z = number of needles of a structure cell,
N_{ZB} = number of needles of a structure cell width,
T = yarn fineness in tex,
lz = stitch length, thread length of the structure cell in cm.

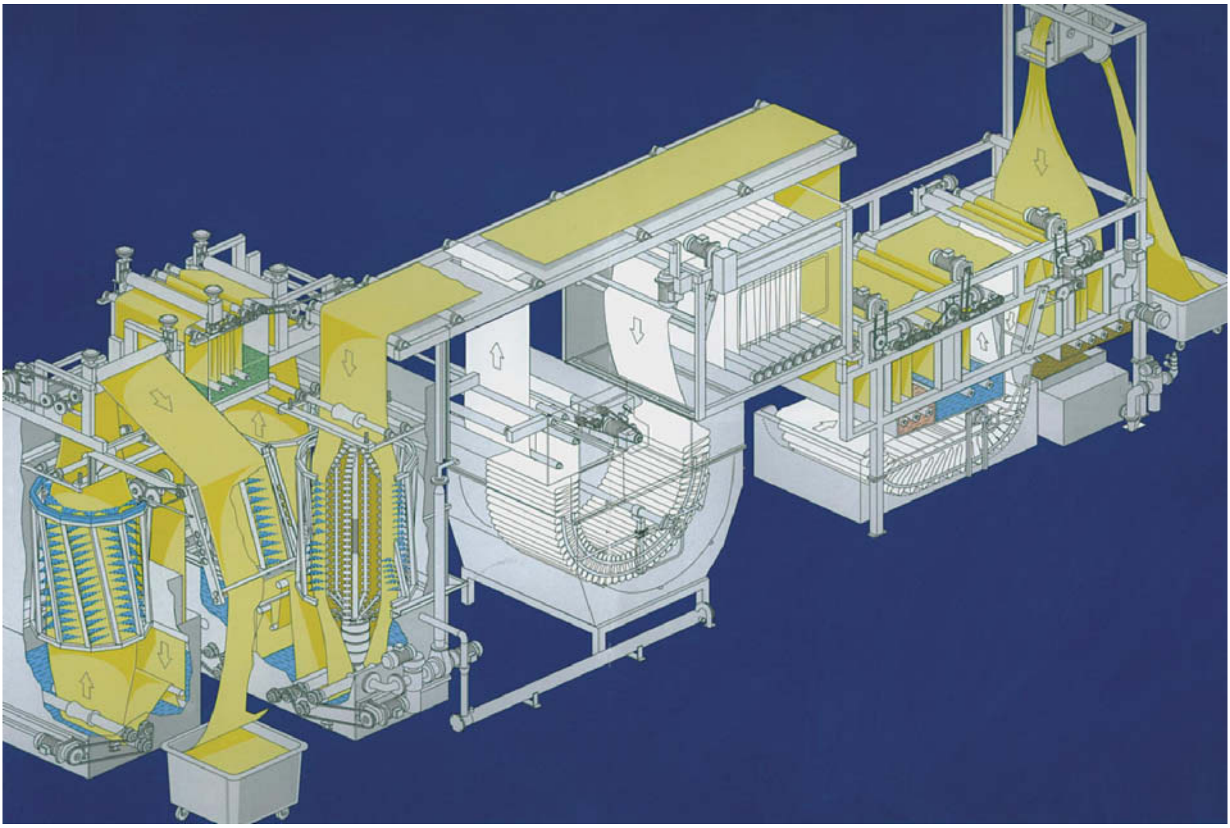

Fig. 3: Eco combine-pretreatment unit form Dornier for tubular cotton knitwear.

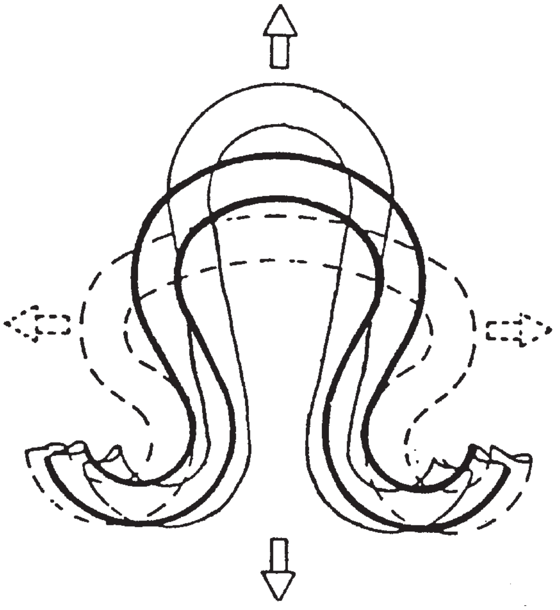

Fig. 1: *The configuration of a loop under differing conditions of tension.*

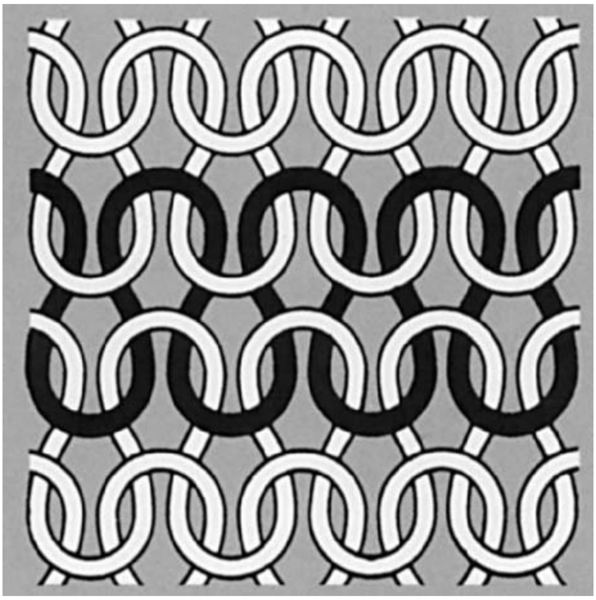

Fig. 2: *Knitgoods in a relaxed state.*

These equations include the following conclusions:

1. In the manufacture of knitgoods the relaxed stitch density MD is determined by the set stitch length.
2. The relaxed knitgood width B is determined by the distance of the stitch wale and then by the stitch length and the number of needles of the machine.
3. The relaxed fabric weight Ag is proportional to the ratio of yarn fineness and the stitch length.
4. The stitch form factor FF reflects the relationship between wale density and row density. The most stable RL material has a stitch form factor of 1.3.

$$FF = \frac{RD}{SD} = \frac{u_{rd}}{u_{sd}} = 1{,}3$$

It is clear that the basic dimensions of knitters are set.

Cotton has a small elastic range in comparison with other fibres. If a hosiery or knitted fabric made of cotton is loaded beyond its elastic range, then the knitgood is no longer able, despite constructively determined elasticity, to return to the stable state: it takes on a permanent expansion. If repeatedly stretched with incrementally increasing power, the value of permanent expansion increases. The more stretchable the knitting links, the more sensitive the material is to deformation (Fig. 2–4). Cotton knitgoods are not able to reverse a deformation by their own power. Knit dimensions are determined by the selected knit conditions, primarily the stitch length. It should always be ensured that the stitch length remains constant. This should be ensured:

a) by the use of row length measuring instruments;
b) with the aid of a suitable thread regulating wheel.

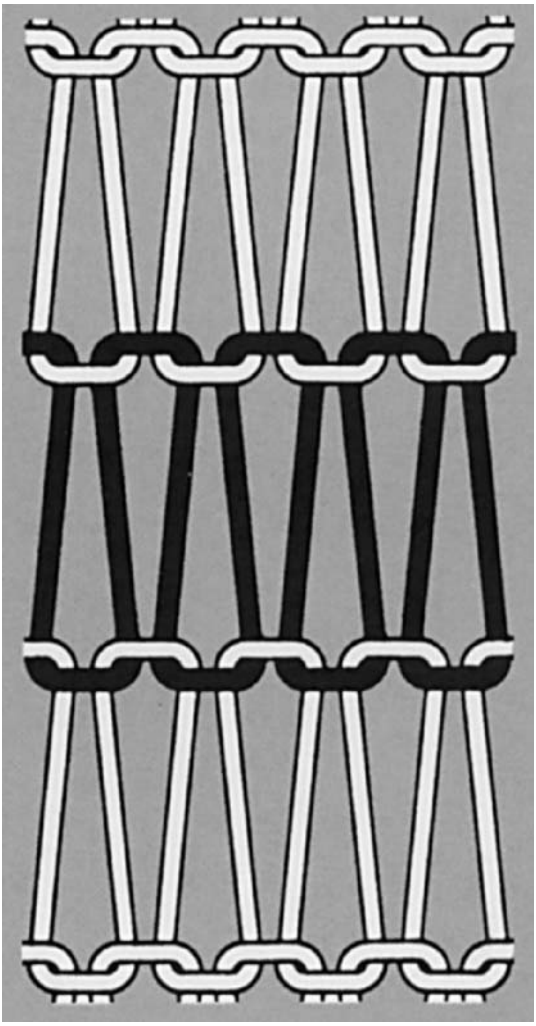

Fig. 3: *Knitgoods subjected to longitudinal tension.*

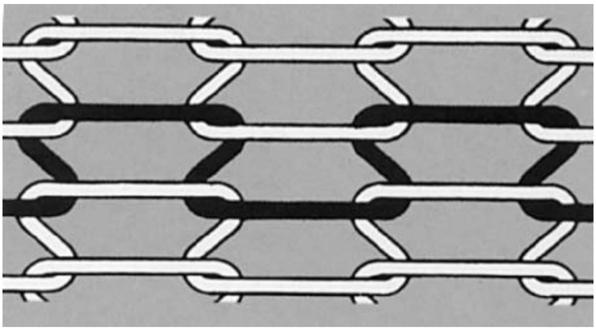

Fig. 4: Knitgoods subjected to lateral tension.

These thread applicators have the task of feeding the yarn to the needle, at an adjustable, constant speed, so that no irregularities occur in the knit pattern. The stitch length thus remains constant;

c) by consistent, constant setting of the feed section.

In order to facilitate a strike-off of the stitch, a certain draw off strength must be maintained. It is not possible to give the stitch its most energetically favourable form at this stage. However, the draw off strength must be increased

- the more systems are located around a knitting machine. Rows of stitches are produced in rapid succession and must be rapidly and safely transported downwards;
- by increasing production speeds, in association with increased centrifugal force,
- due to the processing of raw, poorly waxed yarn.

If hosiery that has been deformed by high draw off tension wound on a roll, then the material has no possibility of decreasing this shrinkage potential. To permit dry relaxation to take place, where possible the knitgoods should be taken off or left in an unwound state. If the knitgoods are subject to a tension free wet treatment in deformed state, then the stitches try to achieve their most energetically favourable state, i.e. the circular stitch. It tends towards the state of lowest bending energy; this means that the internal forces of the stitch do not bring about any change to the stitch shape. After the shrinking, the released volume around the fibre means that fibre movements are only possible if the frictional forces caused by mechanical effects, in particular tumbling or the addition of a lubricant can be reduced. If there is full swelling, the knitgood construction and thus the tension present is blocked, preventing full relaxation. Repeated swelling and shrinking or mechanical reversed loadings during wet treatment cause the latent tensions in dense yarn and hosiery areas continues to break down until all fibres have the opportunity to relax.

Fibre migration occurs due to the relaxed fibres interlocking and sliding into one another, which also increases the cross section of the yarn. The material shrinkage continues until the adjoining thread compounds are resting on each other. In theory the swelling shrinkage is fully reversible, however friction forces and the fibre migration that has already taken place impede the return of the material into the original dimension. The latter process is called progressive shrinkage and is evident after the release of the residual shrinkage. The material specific characteristic value of shrinkage must be carefully recorded and checked in the individual production stages. In the final finishing of cotton knitgoods the determination of the shrinkage potential is essential, because the finisher must know the values of dimensional change for the necessary shrinkage stabilisation and for machine settings.

The final check must incorporate a verification of whether the shrinkage present at the start has been compensated by the shrinking process. Basically, cotton knitgoods possess insufficient wet stability. During bleaching, dyeing and washing the following basic deformation problems occur:

- Due to its high water absorption capacity a cotton material is capable of increasing its own weight by several times. As a result it is clear that the material suffers stretching just by loose hanging.
- When the warp knitted fabric is in the dyeing or bleaching liquor then movement of the material and possibly also liquor circulation is necessary; the forces that occur have a negative effect on the dimensional stability of the knitgoods.

The dimensional changes that occur due to loading are dependent upon the method, but the order of magnitude of the stretching is not. There are various machines and methods, which can be termed low or high drawing. It is up to the finisher to decide which quality requirements he wants to meet and which techniques are to be used (discontinuous process in comparison to continuous systems, such as for example hydro-extraction by centrifuge instead of squeezing). Wet finishing is thus responsible for the increasing and decreasing of the shrinkage potential. In order to keep this to an acceptable level, the lowest possible tension and drawing should be used during bleaching and dyeing and in particular during work processes such as wet folding and expanding.

The drying process can contribute towards compensating for a proportion of the shrinkage potential. For this to occur the material must be given the opportunity of relaxing freely by tensionless material feed or dwelling. The factors of heat, moisture and mechanics are necessary for the shrinking of cotton knitgoods. If a swollen cotton material, which has an excess moisture of at least 30 %, has the moisture extracted by heat, as occurs during drying, then the deswelling gives rise to hollows in the knit structure. Friction at the binding points can be overcome by mechanical effects, e.g. by shaking devices or fans; the material is able to compact its stitch structure and thus to shrink. However, the principle still holds that a greater proportion of the shrinkage potential can be reduced, when this is also high. In principle it is important that the material has a uniform moisture content, because varying moisture contents cause the properties of the cotton fibre to vary.

The selected drier

- determines material quality,
- can cause structure development,
- can realise the reduction of a certain shrinkage potential,
- determines the machine output and thus the production speed (this aspect is of commercial importance to the finisher).

Stable stitch geometry for knitgoods made of non fixable fibre yarns is defined as follows. The fully relaxed state is characterized by the ideally shaped stitch, which is achieved if the forces from the bending of the yarn into stitch loops and the friction forces at the linkage points, which must have reached a minimum value, are in equilibrium. The stitch has achieved the status of the lowest bending energy, i.e. in the fully relaxed state the internal forces of the thread loop cannot bring about any change in the stitch shape. This stitch shape is largely independent of the yarn diameter and the fibre; it is primarily determined by the length of the stitch.

Knitgoods resin-finishing → Resin finishing of knitgoods.

Knitted carpet (knitted velvet pile carpet), created from knitted fabric bonded to a stabilising fabric. A backing is then attached to this composite material. The pile layer is usually roughened, creating the knitted velvet pile carpet. → Stitch bonding, Raschel and Raschel batt-on-base carpet.

Knitted composites → Bonded fabrics, bonded in the interweaving or cross stitch methods, similar to → Stitch bonded fabrics.

Knitted curtains The manufacture of knitted curtains (→ Warp-knitted fabrics) has developed into an important branch of knitting. There have been several reasons for this. One significant point is the development of the raschel machine into a highly versatile unit which can provide high production output and almost unlimited possibilities for the construction and patterning of the fabric. Secondly, the man-made fibre industry has been able to provide an ideally suited material in the form of filament yarns. Finally, the attractive pricing of knitted curtains has allowed a large group of consumers to improve the look of their home. Before the last war the construction of raschel machines was concentrated in the Apolda area of Thüringen. Curtain material was manufactured from cotton on these machines on a small scale. There were also crochetting machines. At the time, high quality curtains were woven, whether with gauze weave as marquisette or as voile. In comparison to the current situation, the market for curtains was significantly smaller then.

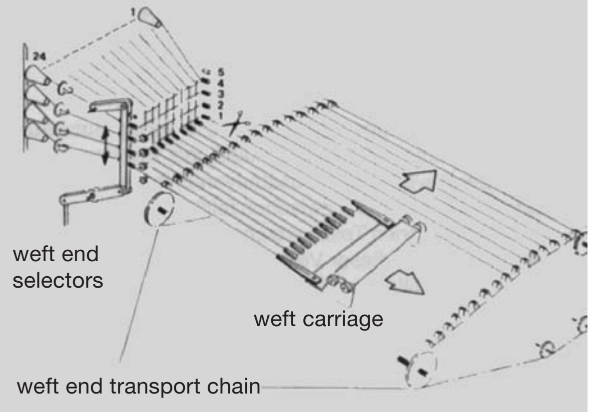

Fig.: Knitted curtain production.

A critical factor in the rapid rise of knitted curtains was the non-slip quality of the grid structure that forms the basis of the knitted curtain. An asymmetric weft layout, created by two parallel rows laid against each other, means that movement is no longer possible. Filament yarns made a significant contribution to the acceleration of production and increasing utility. Before polyester yarn was available, viscose filament yarn was often used. Large knitters perform warping themselves and draw the yarn on large cylindrical reels, whose diameter is matched to the reel distances in the frame. The reels, which are on the bobbin frame behind the jacquard raschel machines, must be particularly precise with regard to winding on and the unimpeded passage of thread. Stimulated by a trend towards greater structuring of curtains in the 1970s, the insertion of weft threads began to be used, initially on course yarns. These were the so-called single thread weft. In this reverse weft principle there was the option of using up to 6 threads alternately. When the market demanded finer curtain structures, the magazine weft entry system was developed. The principle of weft insertion over the whole working width is depicted in Fig. Nowadays weft thread selection takes place electronically. For this different and differently coloured, yarn attachments are available at the frame (according to Furkert).

Knitted fabrics Collective term for warp-knitted and knitted fabrics: Textile materials made of →: Stitches; Loop and Floating using single or multi-thread systems with a horizontal or vertical thread path. Unlike woven fabric, which consists of two thread systems crossing each other at right angles (Fig. 1), warp-knitted and knitted fabrics are textile materials, whose smallest unit is the stitch. The stitch consists of a thread loop, which is held by other stitches or stitch loops. The points of contact of two stitches above or below each other are termed linkage points (Fig. 2). Therefore, the

Knitted fabrics

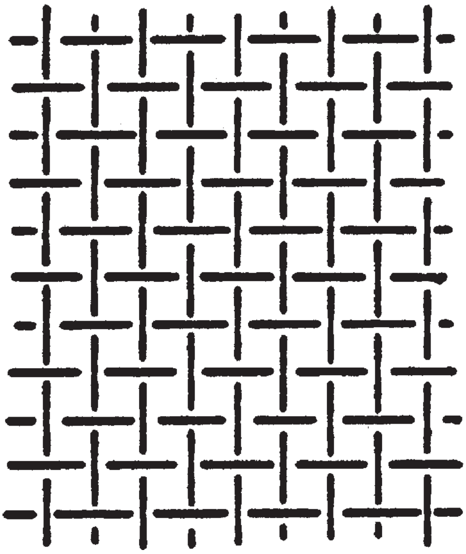

Fig. 1: Woven fabric.

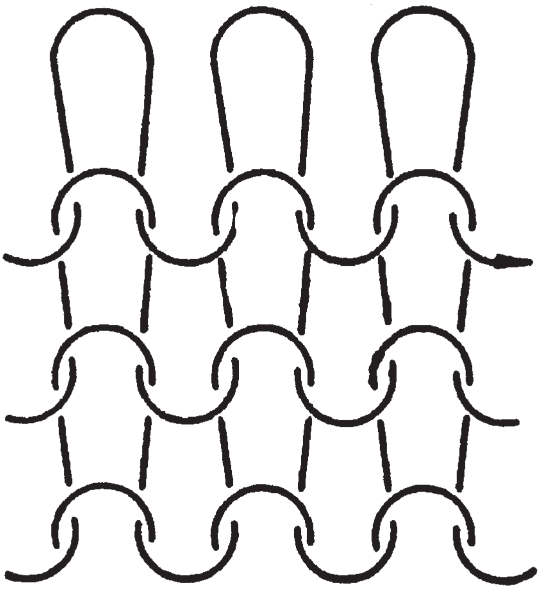

Fig. 2: Knitted fabric.

stitch has four linkage points. Due to their constructive elements, knitted fabrics are characterized by high elasticity, i.e. they always attempt to return to a state near the stable state, the round form of the stitch.

The euphoria of the 1960s, when attempts were made to replace the woven fabric of outer clothing with knitted fabric, which can be produced more quickly, has passed, giving way to a more rational way of thinking. Men's outer clothing is produced as knitgoods in the leisure sector, whereas in ladies' outer clothing the proportion of knitted articles is more widely dispersed.

Knitgoods have fully established themselves in the traditional underwear sector and in the sport and leisure clothing sector. In recent years there has been a move away from the simple T-shirt to high quality articles in this sector. However, increasing quality in this field has brought problems with it due to the use of ever finer and denser structures. The increase in sewing faults is directly related to this, plus the increase in manufacturing speed brought about by quicker sewing machines. For this reason, improving manufacturing ability is one of the primary goals of every item of knitgood manufacturing equipment.

Classification:

I. Weft-knitted goods (knitted fabrics): The threads run crosswise through the fabric. Produced on flat or round knitting machines or weft knitting machines. The threads can be separated out of knitgoods or weft-knitted goods (they form → Ladder/run).

II. Warp knit fabrics (→ Warp-knitted fabrics): Vertical warp-knitted fabrics made of as many threads as the number of stitches per unit width; the threads run lengthways through the fabric. The threads cannot be separated out.

During knitting, individual moving needles form the threads into stitch wales. In weaving, needles moving together (needle bars) form the row of stitches.

→ Knitgoods manufactured on knitting machines. Unlike → Warp-knitted fabrics the stitch formation takes place sequentially (Fig. 3), i.e., each stitch is formed and completed individually, whereas in knitting several stitches are always formed at the same time (according to Hofer).

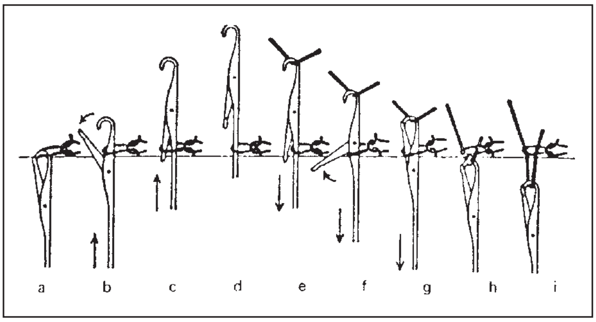

Fig. 3: Stages in the creation of a stitch during knitting.

The individual phases of stitch formation in knitting are illustrated in Fig. 3:

a) The old stitch is formed, the latch type needle begins to rise.
b) The old stitch opens the tongue until it
c) slides over it and
d) comes to lie behind the tongue on the shaft.
e) The new thread is positioned,
f) the needle slides downwards, the old stitch closes the tongue,
g) the old stitch slides over the tongue and closes the positioned thread,

h) the new stitch is pulled through the old.
i) The needle has reached the lowest point, the material is pulled away and when next raised the needle reaches position a).

Knitted plush → Plush cloth, (e.g. for imitation fur) manufactured knitgoods with cut plush loops that are firmly bonded to the knitted base. Manufactured on circular knitting machines and tubular hosing machines.

Knops (knots),

I. Symptom of a fault: Caused by knots or knot-like thickenings due to inextricably entwined fibres.

II. Yarn effect: In the form of dot-like or knot-like thickenings, fluffy places etc. in slub yarns.

III. Weaving effect: As the V- or W-weave loop formation in pile fabrics (pile loops); also similar in pile carpets.

IV. Denepping: Removal of unevenness in fabrics (knots, spun-in wool flock, curls, trapped pieces of thread etc.) using tweezers and fabric relaxation. The dyeing of undyed or off-shade dyed weaving points using so-called retouching pencils, this occurs after weaving or before or after wool scour.

Knops resistance (pile fixation), important durability property of pile fabrics. The force necessary to pull out individual loops/cut loops is measured with a tensile strength testing machine with a special holding device. Typical knop resistance in carpets is 2–6 (max. 10) N.

Knot density (slub or knot density), number of knots, or slubs in relation to 1 m^2 of an Oriental carpet. Top quality pieces contain up to 1 million, normal material 50 000–500 000, cheap pieces only approx. 15 000 knots or slubs.

Knot strength Used to evaluate the flexibility or (opposite) brittleness and bending strength, generally the transverse strength of yarns and ply-yarns. The knot breaking strength test is performed in accordance with DIN 53 842 in the same way as the simple → Tensile strength test. In the area of the free clamping length a knot is created with a defined preliminary tensile force. A knotted and an unknotted thread are tested alternately. The knot (maximum) tensile force is quoted in relation to the original (maximum) tensile force.

Knots Loops of threads, string, ropes etc. We differentiate between different types of knots, which either serve for the connection of two ends (e.g. in weaving) or for the creation of pile on carpets (see Fig.) (knotted carpets).

I. Knots in weaving: Single weaver's knots, double weaver's knots, tension knots (for the connection of threads coming from opposite directions, e.g. broken ends), cats head knots (connection of parallel threads).

II. Knots on knotted carpets: Persian knots, Smyrna knots (Ghiordes or Turkish knots).

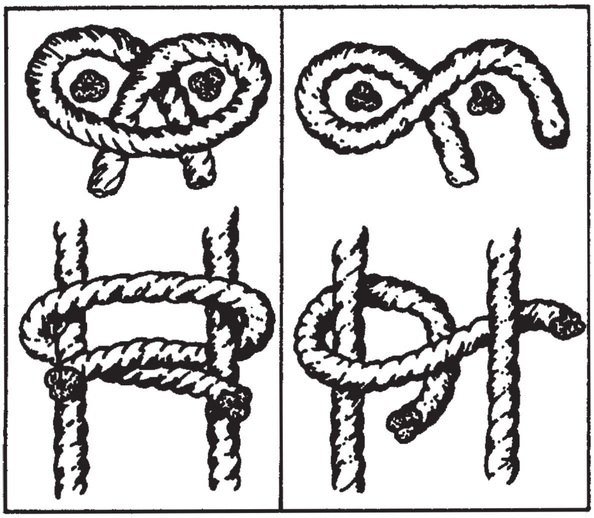

Fig.: Knots on knotted carpets.
Left: Smyrna knot, right: Persian knot.

Knotted carpets Pile carpets, created by the knotting of brightly coloured threads in a warp system. With the exception of weaving technology, the oldest and most common process for the manual production of carpets. We differentiate between Persian and Turkish → Knots. → Oriental carpets.

Ko → Coir fibres, → Textile fibre symbols, according to DIN 60 001 till 1988, from 1991 → CC.

KOB Abbrev. for children's outerwear.

Koch's contraction reaction → Contraction reaction.

Kogasin Aliphatic hydrocarbon, according to the Fischer-Tropsch method for the production of wash-active substances: Kogasin I boiling range 160–230°C (C_{10}–C_{13}); Kogasin II boiling range 230–320°C (C_{14}–C_{18}).

Kolloxan → Collodion cotton.

Konticrab machine This continuous boiling and fixing machine replaces the old, labour intensive and uneconomical boiling machine (crabbing jack) for the crabbing of wool and wool mix fabrics. It consists of an

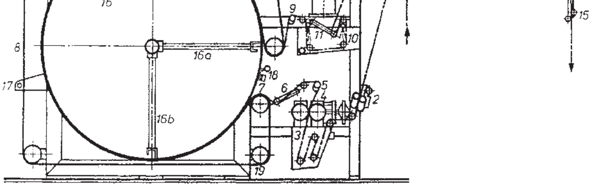

Fig. 1: Kontricrab (Hemmer).
1–7 = inlet trough with tension regulation and squeezing unit; 8 = rubber band; 9–15 = outlet with cooling trough and squeezing unit; 16 = heating drum.

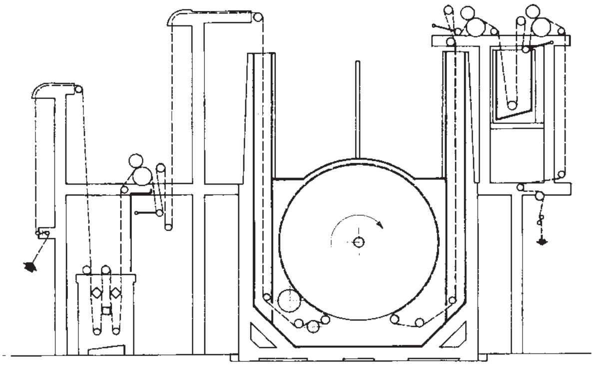

Fig. 2: Konticrab (MAT).

inlet for dry or wet material and a hot water trough with an adjoining pair of squeeze rollers. The material passes via a spreader roller between an endless rubber blanket above a heated drum and finally through a cooling trough (Figs. 1 and 2).

Kordofan gum→ Gum arabic.

Kotonin → Cottonized flax.

KP → Kapok, → Textile fibre symbols, according to DIN 60 001 T4/ 08.91.

Kp → Kapok, → Textile fibre symbols, according to DIN 60 001 till 1988, from 1991 → KP.

Kr Element symbol for Krypton (36).

Kracher Thick and knotty points in yarn.

Krafft point (t_K or T_K), of an ionic surfactant is the temperature of the triple point in the surfactant's phase diagram, at which equilibrium exists between the solid phase (crystal or gel), real saturated solution and saturated solution with micelles. Behaviour of the surfactant at high concentration: below the Krafft point = solid phase, above the Krafft point = solution with micelles. At low concentration the surfactant always forms real solutions. In the soap industry the temperature at which a transparent soap solution goes cloudy during the cooling process is called the Krafft point.

Krätzen More or less sharply limited points in hosiery after dyeing, at which hosiery stitches are more dense and irregular, presumably points which, due to bagginess during the fixing of the raw material, did not lie close to the hosiery form and therefore had inadequate tension. Removable by → Postboarding.

Kronos titanium white → Titanium dioxide (from Norwegian ilmenite) in different types with varying TiO_2 content (up to 98%). Chemically barely corrodible, unchanging white with maximum covering effect. Used for printing dyes, delustring, paints.

Kubelka Munk value (K/S). Describes the optical properties of a coloured sample as a double constant made up of K = light absorption (absorption constant of dyes) and S = light dispersal (determined by textile material). If K/S values for the maximum absorption wavelengths are displayed logarithmically as a function of the dyestuff concentration C, then in the ideal case this produces a straight line with a gradient of 45°, with dyeing or printing errors, for example, showing up as measuring points that deviate from the straight line. Calculated using

$$K/S = \frac{(1 - \beta)^2}{2\,\beta}$$

β = luminosity coefficient

Deviations also arise due to the concentration dependent absorptive capacity and different extraction, etc.

Kula rugs Prayer rugs from the Turkish city of Kula. Velvety smooth pile, approximately 150 000 knots per m^2. The large red or blue prayer niche is framed by a border with stylised, often tiny flowers. The masarli kula (cemetery kula carpet) is a special type.

Kurkuma → Natural dyes.

Kyanol Substance discovered by F.F. Runge in coaltar in 1833, which A.W. Hofmann recognized to be identical to → Aniline in 1843.

Kz → Cashmere, → Textile fibre symbols, according to DIN 60 001 until 1988, from 1991 → WS.

L

L DIN abbrev. for linen weave (→ Weave).

l Abbrev. for (→ Litre (volumetric measure).

LA → Rubber fibres (latex), and → Textile fibre symbols, according to DIN 60 001 T4/08.91.

La Symbol for the element Lanthanum (57).

Label printer Different types are used in a thermal print process, either single-coloured textile labels or multicolour, wash fast, printed on one or both sides.

Label printer machine A small flat-film printing machine for textile tapes or fabric patterns to be subsequently cut.

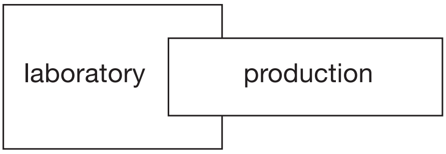
Laboratory In order to understand and assess the dyeing laboratory and its tasks and functions, it must not be regarded as a department on its own but in terms of its relationship to and interaction with the other areas in the textile finishing factory. The interaction between the laboratory and production is largely dependent on the distribution of tasks. These can be classified as follows:

- preparation of production,
- monitoring and correction during production,
- end-product control.

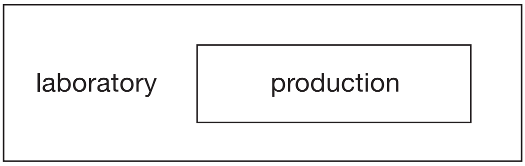
At the same time, it is possible to set up three models to illustrate the relationship between the laboratory and production.

1. The laboratory has a pure preparation function (control of raw materials, dyes, chemicals, textile goods and formulation).

2. In addition to the preparation function, the laboratory also has a correction function, i.e. due to its control tasks, the laboratory also carries some of the responsibility which would otherwise be solely the domain of production. Production is relieved but this presupposes a significant amount of collaboration.



3. The laboratory is also entrusted with quality control and therefore has the functions of preparation, correction and end control. In this case, the majority of the responsibility is held by the laboratory which leads to improved communication and a better assessment of laboratory-to-production reproducibility. A prerequisite for this is close collaboration between those responsible in the laboratory with those in charge of production.



Every textile factory decides differently in regard to the distribution of tasks depending on the production organization and company objectives. However, no factory can do without the services of a production laboratory. The following tasks must be taken care of:

- receiving inspection of textile goods, dyes, ancillary aids etc.,
- control of production water,
- laying down of quality criteria and development of appropriate test methods,
- selection of reasonable finishing methods and finishing products,
- making up of formulations for new articles and shades,
- production control,
- correction of off-standard dyeings and prints,
- testing of colour fastness and technological properties,
- determination of the cause of problems.

Depending on the size of the company, one laboratory takes over all the tasks or the tasks are shared between the test laboratory and dyeing laboratory. The question as to how much the importance of a dyeing laboratory is recognised by the company's management arises again and again, and this is reflected by the degree of investment made in this area. Investment is certainly adversely affected by the fact that the effectiveness of a laboratory cannot be described in terms of a clear relationship between costs and efficiency. The more accurate the work of a laboratory is, the better the results are which are achieved in production; in other words, a reduction in the number of dyeing defects and colour deviations produce savings in costs, in time, machine utilisation, energy and chemicals and dyes. Savings in cost can also be made by selecting more economic methods and optimising the process. There are numerous tests which can be used to define the viability of laboratory trials:

a) the cost of the dyed batch is equated to 100%,
b) in relation to the actual dyeing, additional costs arise from
  - samples 4–8%,
  - shading and patterns 12–49%,
  - redyeing 98–169%
  - pilot plant dyeing 19–31%,
c) the corresponding cost of the laboratory, on the other hand, amounts to a mere 2–4%.

It is easy to see that it is possible to carry out many adjustments in the laboratory before the costs reach those incurred by adding additional amounts of dye during production. Also to be taken into account is the number of batches: the more batches there are, the more the laboratory costs are spread out until their final impact on production becomes relatively minute.

The most important requirements in a laboratory context are laboratory reproducibility and laboratory-to-production reproducibility. A high level of laboratory reproducibility means that the laboratory values compare well with each other; the same results are only achieved by using the same conditions. This is essential for collaboration between production and the laboratory, for example, when converting laboratory formulations into production formulations. Laboratory reproducibility is crucially dependent on the accuracy of the work carried out in the laboratory. The following factors have an effect an the result and can impair the accuracy:

1. the starting materials, such as textile goods (homogeneity, preparation and conditioning), dyes and auxiliaries;
2. working procedure, such as weighing the starting materials and volumetric preparation of stock solutions;
3. laboratory equipment, such as the accuracy of the scales, pipettes and measuring cylinders and dyeing machines (the greater the number of parameters which can be programmed, the more accurate the result) or colour-measurement system;
4. dyeing conditions, such as liquor ratio, dyeing method, water quality, after-treatment and drying methods.

Reproducibility within the laboratory is also a prerequisite for a high level of laboratory-to-production reproducibility and, in addition to this, chemical and technological parameters are also important for the laboratory-to-production reproducibility. Not all parameters can be measured in the laboratory because, on the one hand, the technical facilities are limited and on the other hand, the production parameters themselves could be recorded better and more completely.

Chemical parameters:
- properties of the individual products,
- composition of the treatment liquor,
- temperature,
- pH,
- homogeneity and reactivity of the goods.

Technological parameters:
- period of treatment,
- type of agitation used for the goods and liquor,
- temperature distribution in the liquor,
- homogeneity of the liquor composition,
- distribution of liquor on the material,
- stress factors,
- pressure on the material,
- physical properties of the substrate.

In general, it can be stated that chemical parameters are easier to convey from the laboratory to production than technological parameters. These can be used to determine the demand according to production-oriented laboratory dyeing machines or pilot plants. In most cases, 100% laboratory-to-production is not achievable. For this reason, every factory operates with specific laboratory-to-production reproducibility factors based on years of experience in each case.

It is important to bear in mind that defects produced in the laboratory are amplified many times in production. A significant proportion of production defects have their origin in the laboratory. This is even more serious in the case of multi-step processes where defects which are within the range of tolerance for the individual steps become unacceptable due to the additive effect of the steps. A fundamental distinction can be made between systematic and coincidental defects. In the first case, for example, the inaccuracy of a temperature probe does not effect laboratory reproducibility but may affect the laboratory-to-production reproducibility. On the other hand, defects which are random also impair laboratory reproducibility. However, precise defect analysis and assignment is not always available. Examples of a few possible defects which can arise in the laboratory are listed below:

- different forms of pre-treatment and conditioning of goods,
- weighing errors in the case of goods, dye and ancillary aids,
- errors which may occur while preparing the stock solutions,
- volumetric errors during pipetting,
- fluctuations in the moisture content of the dyes.

The following steps must be taken to increase the accuracy:

- standardise the working methods,
- exclude human error,
- draw up exact specifications for transferring the laboratory results to production.

A critical factor in this connection is extensive automation of the working procedures. Even if the absolute accuracy is insignificantly greater than that of manual methods, reproducibility will be considerably improved by:

- automating the preparation of the formulation by means of colorimetry and colorimetric evaluation of the results;
- automating sample preparation and dye-liquor addition; errors which occur while adding the stock solutions, weighing the sample and pipetting can be avoided by using an automatic dispenser (Fig. 1);
- automating the dyeing process by using a large number of programmable parameters and controlling parameters such as the course of temperature w.r.t. time;
- automating the organisation of the working procedures via computer networking the individual operating areas to facilitate problem-free communication and data transmission.

Fig. 1: Dispenser (by datacolor) for dispensing standard solutions in the laboratory.

Automation mainly serves to improve quality and avoid errors. Savings in staff and direct profitability calculations are not of primary importance. However, by automating time-consuming routine work, more time is made available for development work, problem solving and process optimisation. The importance of the other equipment in the laboratory, such as analytical balances, colour measurement equipment, moisture meters, instruments for determining colour fastness, pH meters, pipettes, temperature measurement equipment, titration equipment and drying cabinets etc., must not be overlooked. The quality of the laboratory results is dependent on the interaction and additive effects of all steps in the working procedure. Visual contact with the dye liquors in the laboratory dyeing machine increases the accuracy of the dyeing results (Fig. 2).

Fig. 2: Ahiba Turbocolor with transparent walled dye containers.

Automatic equipment for dosing dyes and auxiliaries has been improved in the past in a number of respects but does not deviate in principle from automatic dosing equipment which is already well known. The same applied to the stock-solution dosing equipment where the emphasis was on improving the precision, accuracy of weighing and automation. In the meantime, vat dyes and disperse dyes are handled well by dosing units (Fig. 3). However, the equipment requires regular, careful maintenance so the impact on efficiency can only be calculated as being rather small.

Work hygiene is of particular importance, both in the laboratory and in production. The laboratory bench in Fig. 4 is equipped with a vertical pressure and exhaust stream and retains the dust at source, thus minimising the contamination of equipment and clothing. Preliminary filters with large retention capacities and absolute filters are fitted under the bench for safe and hygienic maintenance. Because the air stream is circulated, the laboratory bench stands on its own and can easily be switched between departments.

In the meantime, colorimetry has become an essential component in the textile finishing factory. However, opinion on the proficiency of colour-measurement

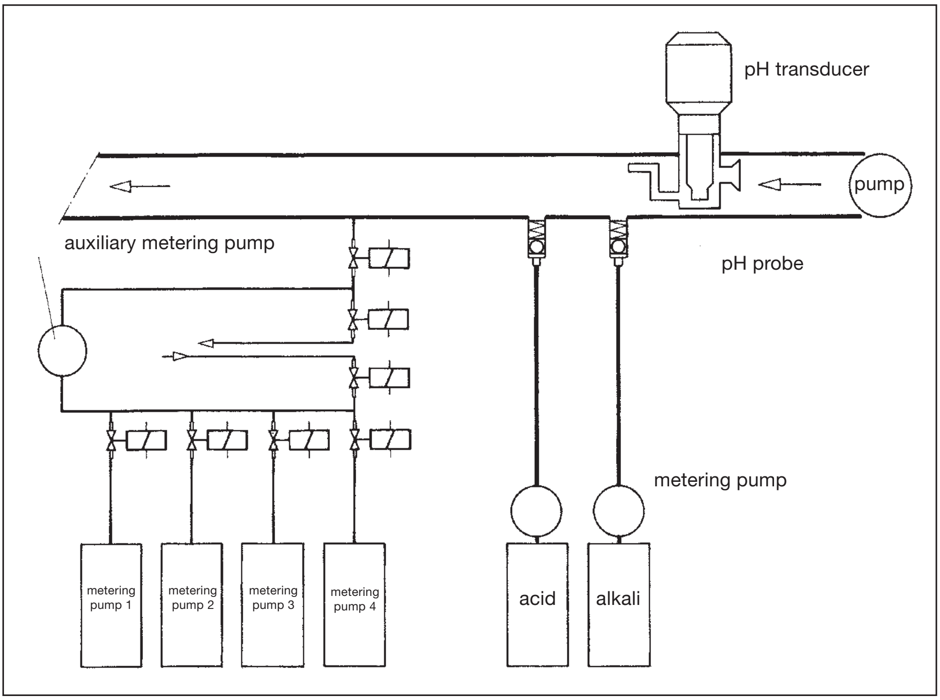


Fig. 3: Laboratory dye dose metering system (Benz).

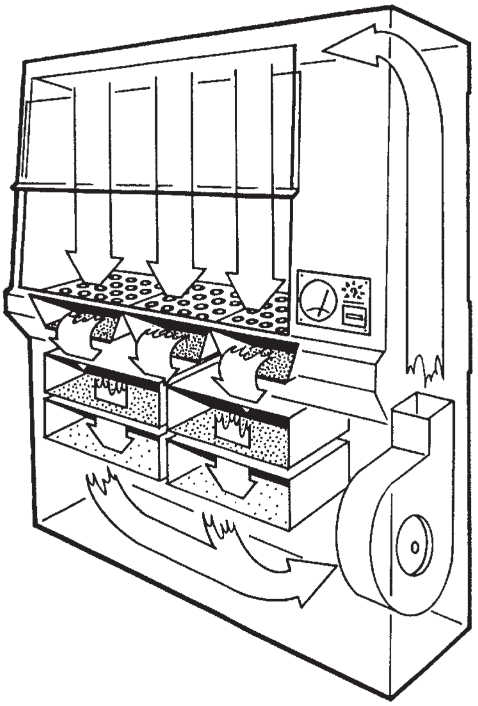

Fig. 4: Dust control bench for laboratory use (formerly ICS-Texikon, now datacolor international).

systems in regard to colour matching and the preparation of formulations is divided. Colorimetry can only be regarded as an aid, and the final decision has to be made on a visual basis or visual means alone have to be used as the only valid criteria. To start with, colorimetry was mainly used for establishing or calculating the formulation alone. The CAC (Computer-Aided Colouring) system opens new perspectives for creating new colours on the screen or colour print on paper or materials which are mainly used in the printing industry.

Colorimetry retains a central position in the area of automated design in particular. Thus, it is no longer a question of instruments but colour and formulation systems. Apart from the stand point of colorimetry, formulation print outs, networking with dye kitchens/weighing stations and process-control computers are required for production (Fig. 5). The colorimeter PC station is often the starting point for the computer networking of individual production areas. The original idea of automation designs is to network all departments and work stations taking part in production in order to increase the availability of the necessary information while, at the same time, pursuing the following goals:

- to reduce the sources of error, as data is no longer transferred manually,
- to increase quality in order to meet the ever higher requirements,
- to achieve “just in time” production in order to maintain short deadlines,
- to increase productivity,
- to avoid complaints,
- to reduce costs,
- to reduce the consumption of energy, water, air, dyes and chemicals.

The aim, therefore, is to optimise the process by linking the laboratory, production and administration via PC

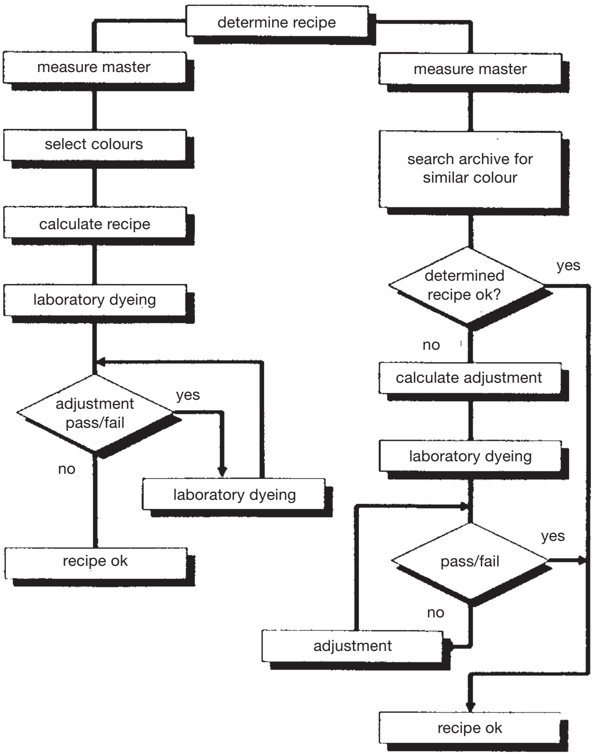

Fig. 5: Determining dye recipes using laboratory dyeing.

networking. Several companies are offering ready-made system solutions:

1. Datacolor produces the integrated Colour Network (ICN) (Fig. 6). This is an integrated network-based solution in industrial colorimetry. The core of the system is a database server, upon which are stored the company's own database. The data which is stored and managed centrally is available to all users at the ICN work stations. In addition to this, special software packages, such as Osiris for colour data processing, are provided for each application area. Apart from the PC-based work stations, various different units such as weighing systems, dispensers and dyeing machines can also be integrated into the ICN. It is also possible to set up links to the central PPS computer, host computers or machine controllers via file transfer.

2. Another supplier in the Total Colour Management area is ICS Texicon. In this case, the emphasis is on the colorimetric unit being used as the central control member as the "real-time multi-user". This is networked with other production systems and units. Software programs are available which are specifically used for the data recording and control and evaluation of, for example:

– colour strength,
– substrate routines,
– correlation,
– laboratory-to-production reproducibility
– formulation and top-up calculation for continuous and batch dyeing,
– batch preparation,
– storage and formulation archiving,
– machine programs,
– management programmes,
– dye kitchen software.

These layouts are available from suppliers but it may not necessarily be possible to use them in a textile finishing factory exactly in this form. Every factory has different specifications with regard to organisation and existing computer systems or satellite solutions. A decision to integrate individual departments into a high-level system involves a high level of investment and is mostly carried out in stages. Computer systems are basically classified into technical and business systems. Essential components of the business systems are order processing, disposition, establishing and pursuing deadlines and production planning. All important data relating to the batches to be processed are recorded and can be accessed as required. Batch data is also echoed during formulation preparation or after the finishing process is over. The industrial computer system deals with the laboratory and production areas. First of all, laboratory formulation is prepared either using colorimetric measurement or by accessing formulations saved beforehand. Dyeing is then carried out in the laboratory with the dosing stations and dyeing machine integrated into the network.

When assessing the future course of development for the laboratory, it is important to consider the general automation problems of the whole finishing factory and the economic position of textile finishing or the textile industry for the future as well as the specific technical conditions. Generally, the trend towards automation is

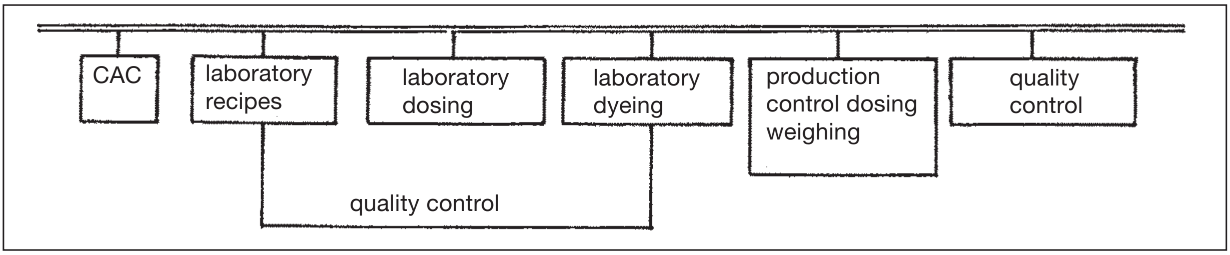

Fig. 6: Integrated Colour Network (datacolor).

clear to see. The important position occupied by the laboratory in this connection arises from the need for costs savings in production and a quality assurance system. The finishing laboratory is given further weight as part of increased efforts in the area of environmental protection: on the one hand, it can assist in reducing additions during production and on the other, the laboratory method can be optimised in regard to energy consumption and environmental loading.

As far as laboratory equipment is concerned, it can be assumed that it is the multi-position dyeing machine which will be of the greatest significance in the future. At the same time, the capacity for imitating air flow with liquor ratios down to 1 : 3 is also important. A further requirement for laboratory machines is a capacity for exact production-simulated dosing during the dyeing process. A trend for the future is, for example, heating the liquor directly by electrical means, heating the liquor using IR radiation or by using alternative heating media such as Bellatoni or aluminium blocks as a replacement for glycol heating medium.

High precision adjustable dyeing machines which simulate production conditions will be more widely used but will be restricted to high-quality, high-turnover finishing factories as the equipment demands high investment without offering high capacities in return. Modern SPC controllers also contribute to simulating the production process as much as possible. However, 100% laboratory-to-production reproducibility will not be a reality in the future either but it will, nevertheless, continue to improve. As a means of scaling up, pilot plants are one possibility in this direction but they are too expensive to procure and too costly to run. All the small components such as pipettes, small dispensers and balances etc. will contribute to optimising the laboratory results as much as possible. The question is, how the dyeing laboratory of the future will appear as a whole. It is still unknown whether European laboratories will follow what has already become reality in Japan, such as the one-man laboratory using robots, or whether it will be possible to create a laboratory without laboratory dyeing, i.e. by using Computer-Aided Colouring alone.

In quality control in the dye industry, approximately 50–80 parameters have to be checked for each dye and several thousand dye samples are tested every year (Fig. 8). This yields a flood of data which can only be overcome with the help of computer-supported data logging and evaluation. Here, laboratory robots can help during weighing out and dosing procedures and during sample taking (Fig. 7).

Examples of special pieces of equipment for the dyeing laboratory which are useful are listed below.

1. The dyeing laboratory is frequently given the task of investigating foaming during the dyeing processes and the effect of defoamers. Until now, the absence of suitable laboratory test methods has thrown into question the meaningfulness of the results; fre-

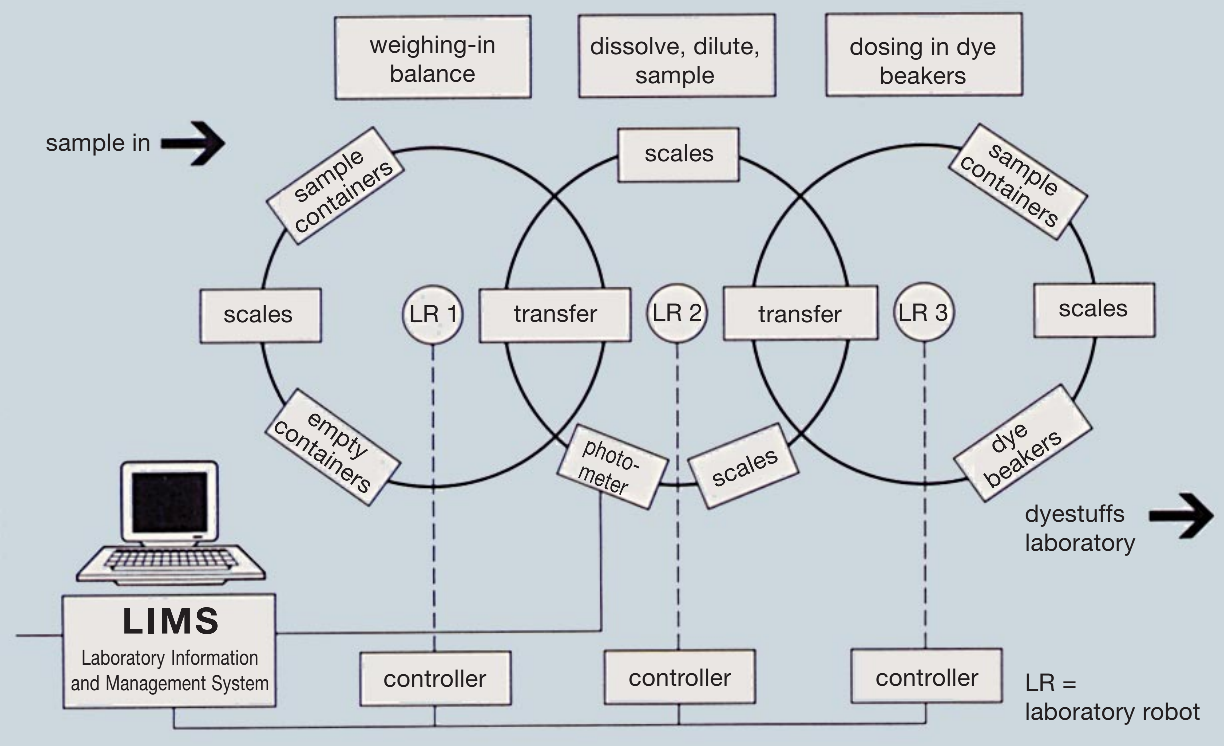

Fig. 7: Automated system.

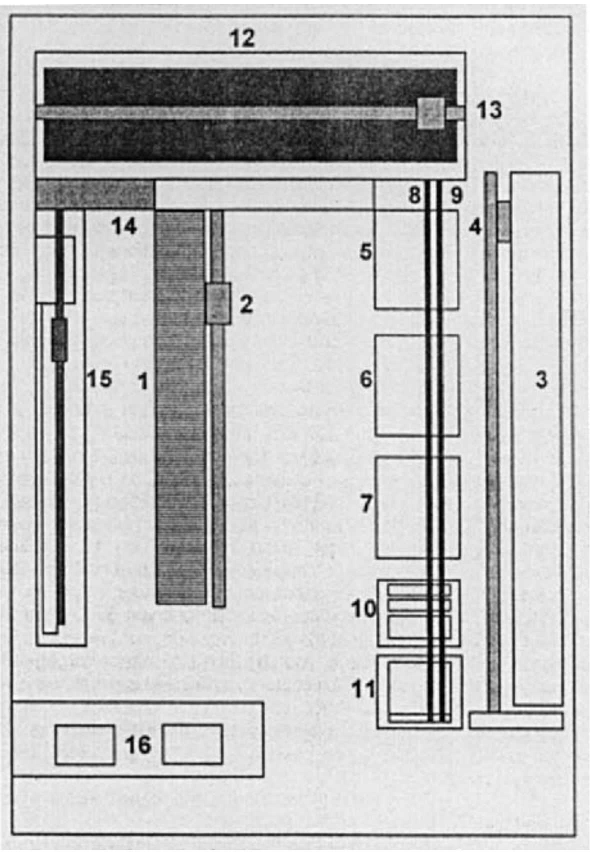

Fig. 8: Aladys (Ciba-Geigy); layout of the laboratory dye robot.
1 = store of various textiles; 2 = winding robot; 3 = dyestuffs and chemical products store with robot (4) serving the 6 dosing stations (5, 6, and 7); 8 and 9 = linear transfer lines; 10 = output device; 11 = waste water collection; 12 = dyeing station with 84 dyers; 13 = robot; 14 = drier; 15 = delivery belt for dyed samples; 16 = 2 computers.

quently, the result in production is not confirmed. Zeltex supplies a test instrument, the "Foamy", which can be connected to circulation dyeing machines with an external circulation system – the foam is generated via a nozzle. It includes a dosing unit for chemicals such as defoamers. The test area is heated or cooled as desired in order to provide constant temperature conditions for the test solution. Control is achieved via the dyeing machine. The height of the foam must be determined visually, although an automatic foam-height detector with PC interface is planned.

2. Officine Bisio s.a.s. manufactures a laboratory instrument for examining the change in colour and gloss in relation to pressure, vapour and temperature. A reproducible prediction about the dyed goods is given for finishing steps which follow within a short time (10 s).
3. The air-permeability test allows a prediction to be made on the beam dyeing of less permeable fabrics. Goodbrand-Jeffreys Ltd has developed a portable electrical acoustic air-permeability tester for quick on-site testing. The value for the air permeability is indicated directly on a digital display. It would be desirable to check whether there is a correlation between this method and the ISO/DIN method so that this instrument could also be used in the quality control of technical textiles outside the test laboratory.
4. Heraeus Instruments produce the Xenotest 1200 CPS (Fig. 9), a program-controlled rapid light-radiation device with radiation control which has been shown to be suitable for various different applications. In order to improve reproducibility, set-point

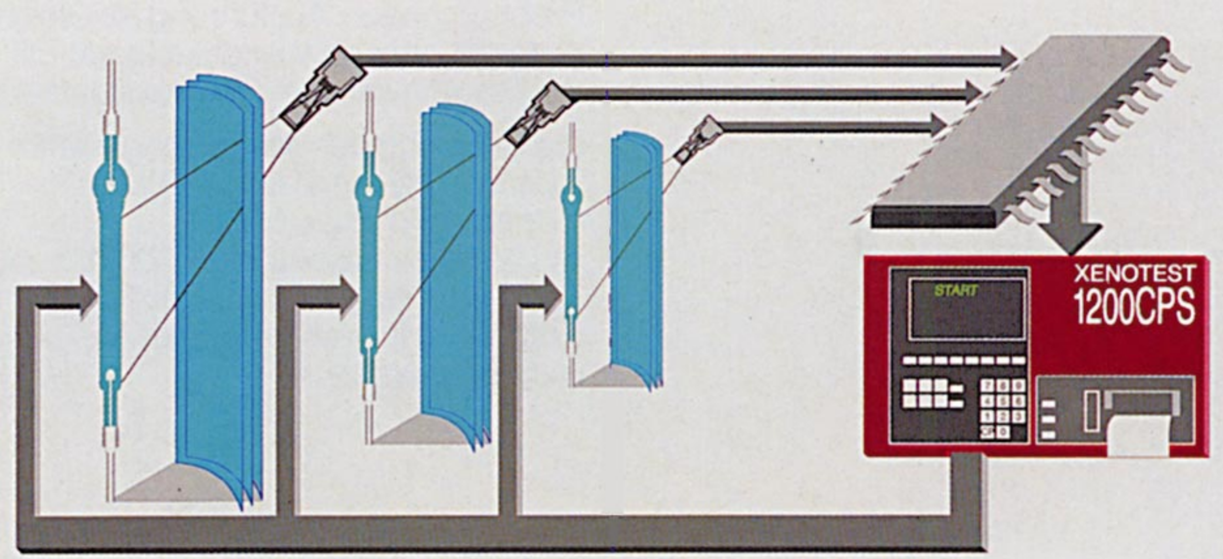

Fig. 9: Controlled irradiation intensity with the Xenotest 1200 CPS (Heraeus).

and actual values are constantly compared with all specified weather exposure parameters and corrected and documented where necessary. The values can be accessed at any time. After a period of weathering, the operating data are printed out as a log. The Xenotest was developed as a smaller but just as versatile and flexible unit for light-radiation and weathering testing. Heraeus Instruments recommend setting up all light-radiation instruments in air-conditioned rooms in order to avoid temperature fluctuations in the sample area. Xenoserv is a service package provided by Heraeus which is intended for the user who wants to procure monitoring equipment complying with DIN 9000.

5. Atlas SFTS has developed the Ci radiation unit series further. In addition to the Ci 35 A, which has made a name for itself in hot light-radiation testing, there is the smaller Ci 3000 model. The results and performance of this unit are comparable to those of the larger instruments, the Ci 35 A and Ci 65 A. For example, the sample temperature, black standard temperature and the radiation dose can be measured as well.

Laboratory coating unit This consists of a coating table and coating head, infrared field (optional) and drying box with a 20–250°C temperature controller. The sample size (coating area) is 45 x 100 cm max. This is also used as a laminator for polyurethane and a printing, calendering and schreinering device – Manuf.: Mathis.

Laboratory continuous dyeing machines The basic design is based on the requirement for setting up laboratory machines which simulate the plants and processes used in production as far as possible. The reproducibility of laboratory results in the production process must be ensured by maintaining certain established parameters. On the other hand, there is also the desire for flexibility which can be realised by assembling individual units according to a modular principle rather than, under certain circumstances, neglecting specific characteristics of the production plant such as the Shore hardness of the padder rollers and dwell times, etc.

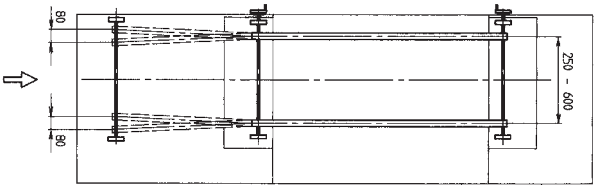

Fig. 2: Working width (in mm) of a continuous laboratory drier.

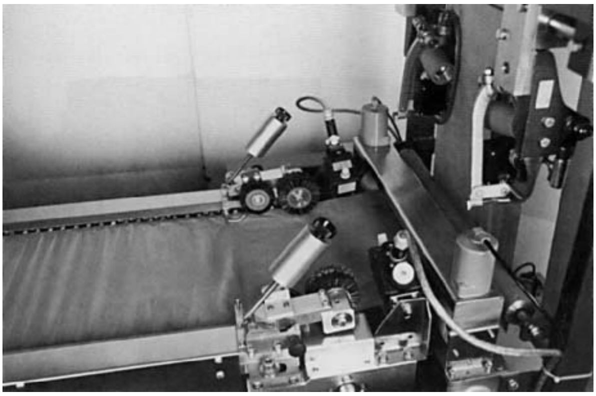

Fig. 3: Fabric feed on a laboratory drier (Mathis) with optical scanner.

The normal working widths are 250 or 600 mm (Fig. 2). The basic set-up for a laboratory continuous drying machine consists of a padder and drier (Fig. 1). Laboratory stenters can be of elaborate construction at the goods feed and may also have expanders and optical edge scanners for automatic pinning-down and adjustment facilities for under- and overfeed (10%) as well as 2 continuous needle chains (Fig. 3). Laboratory pad-steam plant may certainly be regarded as a more convenient set-up. This may be equipped, for example, with a vertical IR drier on the front end and a supplementary chemical trough as well as an air circulation system for the steam chamber and washers on the other end so the unit can be used both for the pad-steam process and the thermosol process.

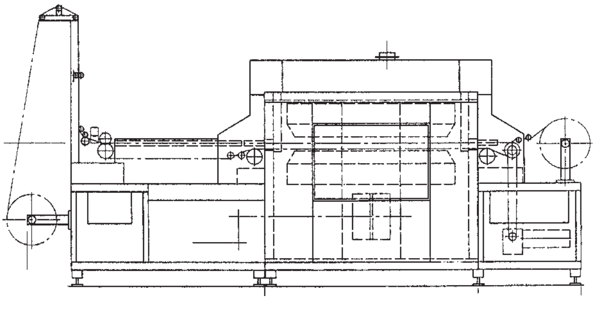

Fig. 1: Section of a continuous drier (Benz) for laboratory use.

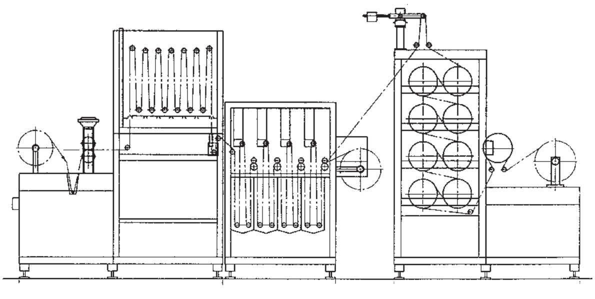

Fig. 4: Continuous laboratory system with pad, drier/steamer, wide washing roller vat and cylinder drier.

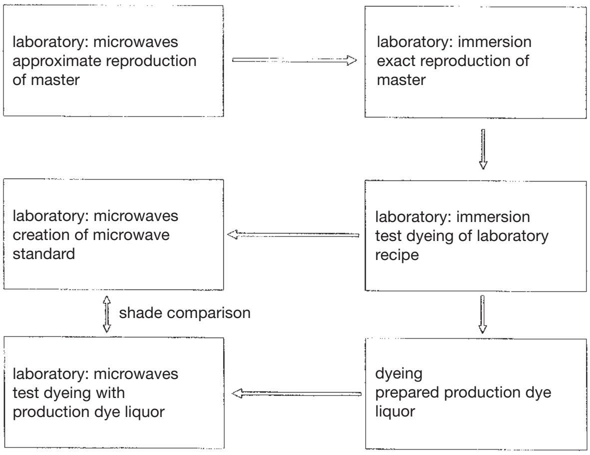

Fig. 5: Creation of laboratory recipes and testing production dye liquors using microwaves.

More complicated speciality plants can simulate whole production lines (for example, padding, steaming or drying, after washing and cylinder drying as in Fig. 4. With a little experience, a continuous dyeing process complete with padder and microwave drier can be reconstructed (Fig. 5). In this system, drying and steaming take place fairly rapidly in the microwave unit and merge seamlessly with each other. For example, the combined laboratory dyeing machine depicted in Fig. 6 is a very specific simulation of production plants for the continuous dyeing of tufted carpet goods - the coating and fixing of the dye liquor makes it possible to transfer a considerable amount of the process data determined in the laboratory to the production plant.

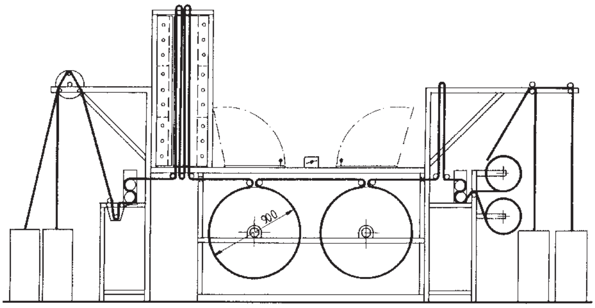

Fig. 6: Application of the sieve drum technique in a laboratory dyeing facility (Fleissner).

Laboratory dispensers for stock solutions These are suitable for large textile-finishing plants that have a high demand for dissolved dyes in different concentrations or require many different dyes. The dispensers relieve the laboratory technician in his daily routine work. A single or several concentrations of a dye must be prepared depending on the process and desired depth of shade. A dispenser operates with more precision so human errors are excluded and their consequences avoided. A lab dispenser (Fig.) is made up of single modules, i.e. a balance and a cabinet with water and chemical tank or a connection to the water supply. A hot plate and a rotating magnetic stirrer may be integrated to make up the dye solution with hot water. Multi-station dispensers are equipped with a conveyor system. The operating principle of the dispensers consists of accurately weighing out an approximate amount of the dye in accordance with the standardised concentration and, based on this value, determining and adding the amount of water required to make the solution up to the desired concentration.

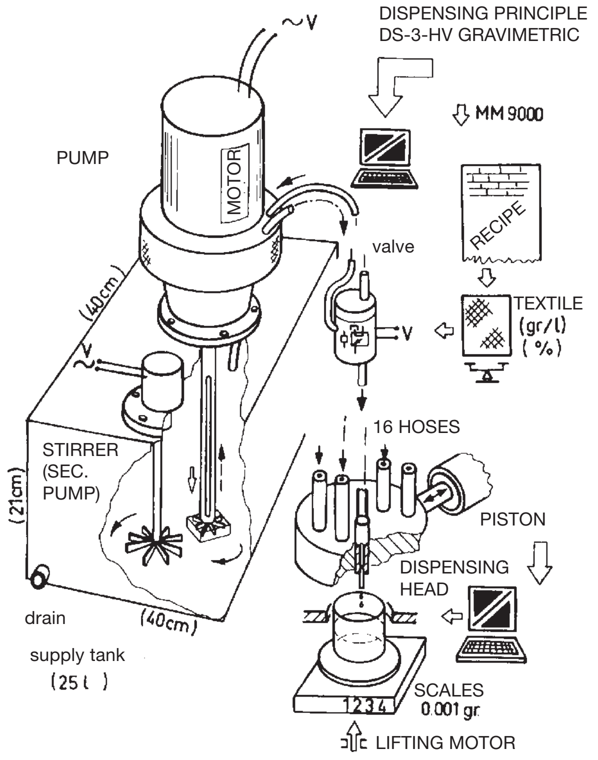

Fig.: DS-3 laboratory dispenser for textile printing ink by Gain.

The simplest system consists of a balance and a water and chemical tank. This can also be equipped with mixer plate and magnetic stirrer system for beakers. The weighing accuracy for the unit lies between 0.01 and 0.02 g. Designs with an accuracy of 0.001 g are supplied by various makers as an optional extra. Data may be stored by connecting the equipment to a computer; this is important, for example, for checking the age and quality of the stock solution. Thus, data can be recorded. All dispensers can be connected to a PC or computer and can operate in combination with metering units via a data connection.

Essentially, a separate stock system is advisable as this makes it possible for the dyer to automate the system in the laboratory in stages. The laboratory technicians can be introduced to a progressively automated technology in stages. Among other things, metering units may be integrated at a later date. Integrated dispensers, on the other hand, are sensible in a small laboratory as the number of liquors per day is smaller and the dispenser is not fully utilised. The advantage of separate units is that solutions can be made up independently while utilising the dispenser fully and when there is a technical fault with the dispenser.

Laboratory dye dispensing systems The first dosing systems for the dyehouse laboratory were presented at the ITMA ’87. Systems were developed in Japan and European producers followed suit later on. Many companies market equipment manufactured in Asia. Italian manufacturers build their own. The first units were run without software and were controlled via simple controllers. They were still relatively imprecise and involved a small number of containers – a maximum of 50–60 flasks.

Laboratory dosing systems (Fig. 1) have a role in:

1. Minimising errors by excluding the sources of human error during formulation and while dosing the dye by:
   - weighing the liquor and the sample with a precision of 0.01–0.001 g,
   - making an exact solution,
   - reducing the sources of error during pipetting.
2. Standardising the working procedures in order to guarantee reproducibility during the manufacturing process used for dye solutions and therefore the dyeing processes themselves.
3. Data management by:
   - storing all data associated with the dye liquors and
   - storing the formulations.
4. Cost saving, (which has an impact on production) by reducing the level of defective dyeing and 2nd quality dyeing, in terms of:
   - personnel and dyeing time during production,
   - dyes and ancillary aids for the production equipment,
   - reduction in effluent and effluent loading,
   - by improved quality,
   - optimum utilisation of the dye plant,
   - minimising the shut-down time and the running in of additional dye,
   - reducing the operating costs.

Fig. 1: Gain DS-3 dispenser (formerly ICS-Texikon).

Laboratory dye dosing systems operate according to the following principles:

- dosing automatically from stock solutions,
- storing all dyeing and dyestuff data,
- adopting the stored laboratory recipes and dyeing auxiliaries,
- weighing the dye and making batch calculations for all parameters,
- sending the formulations to the dosing unit,
- starting automatic dosing,
- pumping the stock solutions to the dyeing flasks through hoses and dosing them gravimetrically by means of high-precision balances,
- the technician removes the prepared flask from the equipment,
- special devices prevent stock solutions from sedimenting in pipes and containers.

Dye dosing systems are controlled via a PC in the laboratory from which all formulations are activated and passed on to the plant. In comparison to other systems, this type has a greater role than any other SPC controller. Integration into complete design solutions is important but it is still unknown whether Total Colour Management or INC Integrated Network Management will win through. Other factors contribute in this respect, such as capital available for investment, number of departments to be added and the company structure. Essentially, automation by means of laboratory dye dosing systems means more exact reproduction of dye liquors. The individual steps in the process, such as weighing, filling the containers and stirring the solutions etc., should be automated as much a possible in order to assist the laboratory. At the same time, it is not the time factor or saving in personnel which is of greater importance but improvement in reproducibility through higher precision and, above all, the avoidance of possible sources of error. The laboratory dye dosing equipment relieves the laboratory technicians but does not take over their work altogether.

When using the laboratory dye dosing systems, the following points must be taken into account.

Although dosing systems operate faster than a laboratory technician, there is a need for careful maintenance and a certain amount of time must be devoted to setting up and preparation and, for this reason, using equipment such as this does not always result in saving time. One advantage is that the operation of the dispenser is programmed automatically so that it can even work during the night and dye liquors are already available ready for use at the beginning of the early shift in

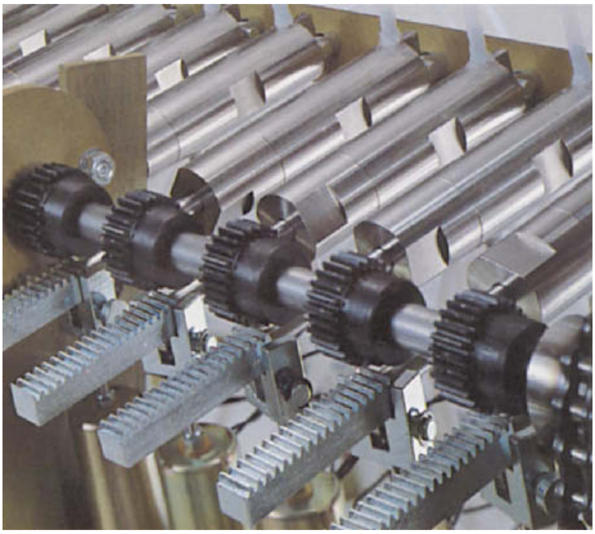

Fig. 2: Rack-and-pinion drive in a dispenser (Ishizaka).

the morning. Two or three concentrations of the dye being used are required to make optimum dosing possible across a wide range of formulations. This is catered for by using a large number of bottles of stock solution. Precipitation or dispersion of the dyes can be prevented using electrical stirrers or certain ancillary aids. A dosing system does not operate absolutely precisely but the results are significantly more reproducible than those produced by a laboratory technician carrying out routine manual laboratory operations. The automatic addition of stock solutions is around ten times more accurate than manual production. If errors or malfunctions do occur, these are indicated. Precision can be achieved, for example, by constant-flow pumping systems (Fig. 2) for liquid brands, the liquid dye solutions remaining in the hose connections being pumped back after weighing.

Laboratory dye dosing systems can also be used in the print-shop laboratory. Many units are equipped for the combined use of high- and low-viscosity dyes. There does not appear to be any great difference in the preparation of viscous dyes.

Laboratory dyeing machines These are classified according to the different dyeing principles upon which they are based as follows.

1. Liquor and goods circulate.
2. Liquor static but goods circulate.
3. Liquor circulates but goods static (flow processes).

Before the beginning of the twentieth century, textile finishing was a manual process. Process development was restricted to the dyes themselves and, in some cases, was a trade secret. However, this picture changed with the emergence of synthetic dyes and textile finishing increasingly developed into an industrial sector. Dye manufacturers invested in large research laboratories so the greater part of the development took place there. Another important change-around took place in the fifties with the production of synthetic fibres. As well as this, there came a plethora of new finishing processes, dyes and auxiliaries. The industrial range of application increased significantly and was supported partially by fibre manufacturers and machine builders. The results of this development work was for the main part legally protected by patents. There was no great need for the textile finishing factories themselves to invest much in production laboratories. Under external pressure from the customers, the laboratory was in many ways only directed towards matching the growing quality requirements of the customers by improving the quality control facilities. Since then, however, the laboratory has developed into an economic factor which cannot be ignored. Test and control functions as well as optimising the products and processes used were, for the most part, carried out in the textile laboratory, the development tasks predominantly falling into the domain of the chemical industry. The importance of the laboratory in the finishing process will grow, particularly where there is increased automation. The laboratory no longer plays a subordinate role to production but now occupies a position of equal importance where collaboration between the individual task areas is essential. The historical development took place as follows:

ca. 1870	Since the beginning of industrial dyeing, colour adjustment was carried out using simple laboratory equipment: – open beakers, heated using a heating surface and manual stirring, – heating surface replaced by a heating bath for even temperature distribution.
since 1950	Development of miniaturised production dyeing machines: pilot plants.
1960	Principle of closed, agitated dyeing beakers.
1963	Use of other methods to replace the manual movement of liquor, for example, moving the goods.
1967	Striving for greater production accuracy using flow systems.
1987	Since ITMA 1987: replacing glycol, the standard heating medium, with other heating media such as Bellatoni or infrared.

Under conventional laboratory conditions, working with beakers in motion in a glycol bath is still widespread. The development of “alternative” technologies for heating dye liquors has lead to the following procedures (Fig.).

- The IR method heats the dye liquor using long-wave radiation energy. The heating medium is no longer needed and work with the laboratory equipment is essentially cleaner and easier.
- Electrically heated systems heat the dye liquor directly and the need for a heating medium is fully

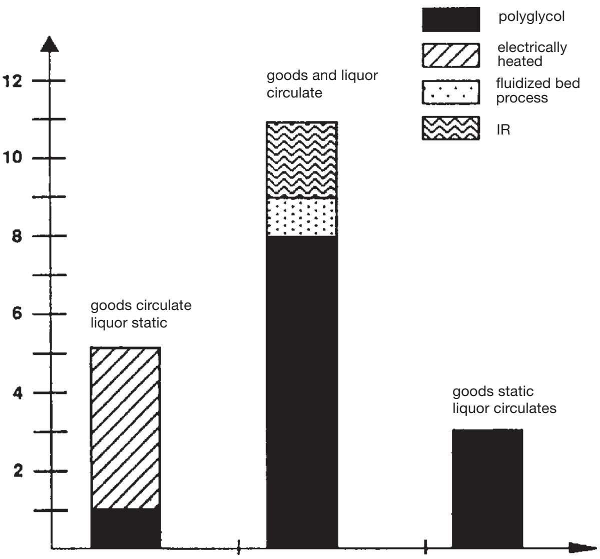

Fig.: Quantitative distribution of the different heating methods in laboratory dyeing machines.

redundant. However, the construction of the equipment is expensive.

- The fluidised bed or quartz-sand method involves the electrical heating of glass beads as fine as sand. This dry heating medium is easier to handle than liquid glycol.

The laboratory-to-production reproducibility is similar to that of glycol method. All alternative technologies are essentially simpler to handle.

For the most part, flow systems are fitted with electrical heaters. However, for dyeing principle with both goods and liquor in motion in beakers, electrical heating is not an option. Here, the tendency is to use radiation energy and dry heating media. In the case of the dyeing principle involving static liquor and goods in motion, no alternative technologies to glycol are available. There is a clear trend towards excluding sources of error through automation and greater accuracy. Using modern control systems, parameters can be recorded and controlled with a greater level of reproducibility and this leads to improved laboratory-to-production reproducibility. The exact simulation and recording of parameters crucial for production plants on a laboratory dyeing machine is problematic anyway. For this reason, it is more important to improve the technical capabilities of a laboratory dyeing machine by increasing the potential for logging, recording and controlling dyeing kinetics and process parameters. This means that increasing importance will continually be placed on the controllers on laboratory dyeing machines. Regulator controllers are being replaced by SPC or microprocessor controllers.

Control units, so-called multi-process controllers, are available through which all laboratory dyeing machines can be controlled. These can also be integrated into a factory-wide automation system such as the LACOS software supplied by Integrated Color Network.

On the one hand, it is possible to upgrade conventional laboratory dyeing machines with microprocessor controllers. On the other hand, a further alternative in regard to optimising the laboratory dyeing process is presented by installing HT circulation dyeing machines, supplied by Ahiba and Zeltex, which make it possible to control and regulate the process exactly. Dyeing parameters are not only set but regulated, i.e. controlled and readjusted during the whole dyeing process. These laboratory dyeing machines offer optimum laboratory-to-production reproducibility, particularly in regard to production dyeing machines used in cross-wound yarn package or beam dyeing as, in this case, the nature of liquor flow through the goods is directly comparable. Also to take into consideration in this connection is the type of makeup of the fibres during the dyeing process. The fabric appearance changes due to the different dyeing machines depending on whether the goods are dyed in a pressed or loose state. This influences the colour effect of the fibres. Whether the use of pilot plants for laboratory dyeing will win through is questionable. Because the principle of construction for these machines simulates that of full-scale plants (pilot plant suppliers also supply production plants) the dyeing parameters and control are in relative good agreement, thus ensuring good laboratory-to-production reproducibility. On the other hand, the high investment costs speak against it, i.e. high purchase price and high costs in terms of time, goods to be dyed, chemicals and dyes.

Laboratory dyeing principle – circulating liquid, static goods This dyeing principle is based on the flow system and is therefore directly comparable to the production machines of cross-wound yarn packages and beam dyehouses where the goods are subjected to a stream of liquor. The goods are made up on material carriers and are static during the dyeing process, whereas the liquor moves, flowing through the goods. In this method, many parameters may be controlled, defining the dyeing process and, therefore, increasing the laboratory-to-production reproducibility.

Praxitest and Multicolor (Fig. 1) are well known older systems. Where the highest demands in terms of levelness, dye penetration and reproducibility are required in a dyeing laboratory, it is necessary to resort to more expensive systems. Of course, demand and availability are lower in this sector than in the area where cheap machines are used for routine trials. Flow systems are by far the most gentle on the material to be dyed. The sample make-up is time consuming in the case of yarn or fabric where it is necessary to re-package or batch on to a perforated beam. Units with several

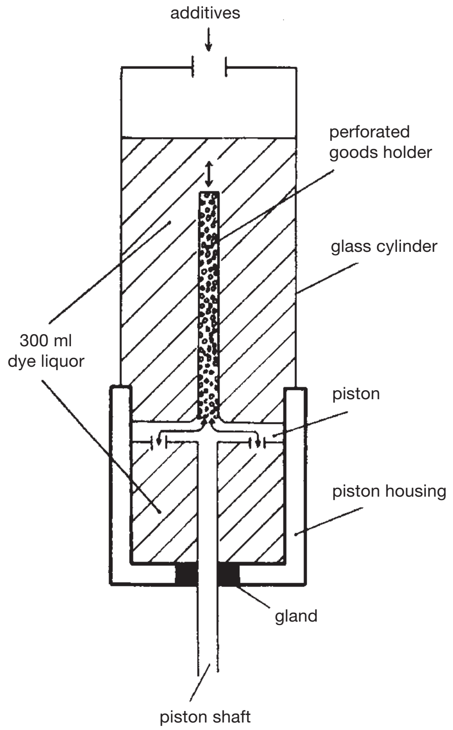

Fig. 1: Liquor circulation in the Pretema-Multicolor-System.

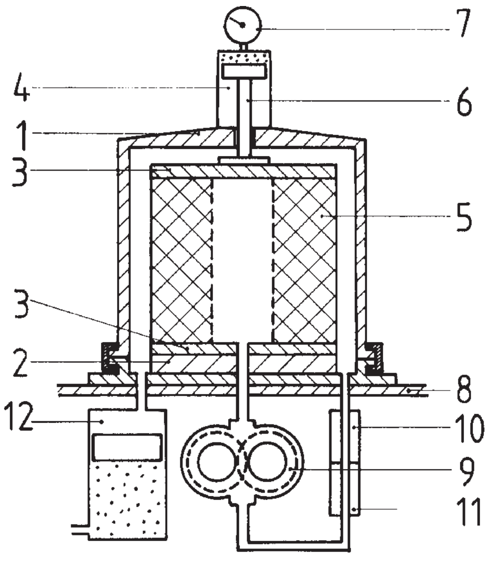

Fig. 2: Diagram of the Colorstar laboratory dyeing machine (Zeltex) with gear pump and computer.
1 = dyeing bell; 2 = impeller plates; 3 = cover plate;
4 = hydraulic press; 5 = package; 6 = piston shaft;
7 = manometer; 8 = work disk; 9 = gear pump; 10 = heater;
11 = water cooling; 12 = liquor reservoir.

dyeing positions offer the advantage that each dyeing position can be driven independently. In the case of Praxitest and Multicolor, both the liquor and the substrate can be observed during dyeing. Further additions to the dye liquor are possible at any time. When dyeing loose stock, a liquor ratio of 1 : 5 can be achieved.

While the Praxitest with a single dyeing position is exclusively used in research, machines such as the Pretema-Multicolor are use in the following areas: stability tests on dispersions, absorption behaviour of dyes, levelling tests for dark shades (end-to-end non-uniformity) and targeted adjustments. In terms of efficiency, the Praxitest pump system compares unfavourably to the Multicolor flow system which is based on a piston lift. The pump produces heat which is fed to the dyeing process in uncontrollable amounts. The uneven temperature distribution across the liquor causes problems. The streaming principle of the Praxitest and Multicolor systems is realised in an elaborate form in order to dye yarn packages or flanged bobbins. In this regard, the most elaborate is the Colorstar system which uses a gear pump (Fig. 2). Other units use a peripheral-wheel pump.

Fig. 3 shows that the delivery pressure of a gear pump is practically independent of the quantity of liquor delivered. The change in the speed of a gear pump results in a change in the flow of liquor which is proportional to the speed. In the case of a peripheral wheel pump, the quantity of liquor delivered decreases for the same pump speed with increasing pressure. On production machines, however, rotary pumps such as centrifugal or axial-flow pumps predominate. Each type of dyeing machine has different pump characteristics. These technological parameters have a great influence on the result. In the case of Colorstar, the delivery characteristics of the gear pump have now been incorporated in a computer program. At the same time, the performance characteristics of the pump on the production machines have been recorded, programmed and assigned to the parameters of the laboratory machine. With the help of a program such as this, it is possible to adjust the pump characteristics of the production machine and increase reproducibility from laboratory to production.

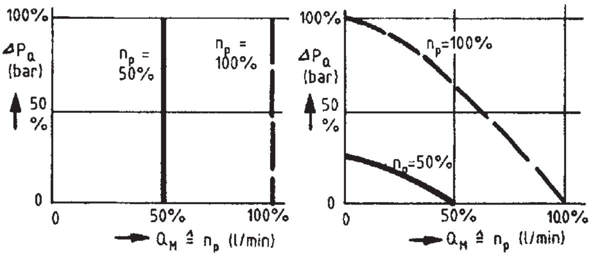

Fig. 3: Characteristic curves for a gear pump (left) and a centrifugal pump (right) at 100% and 50% of standard revolutions.

Laboratory dyeing principle – circulating liquor and goods The dye liquor and the goods are placed in

Laboratory dyeing principle – circulating liquor and goods

Fig. 1: Roller dye bath by Jagri.

a beaker and subjected to movement, e.g., via axial motion (Fig. 1), end-over-end tumbling (Fig. 2) or shaking movements. In this way, both liquor and goods are subjected to motion during the dyeing process and, technologically, this is the most simple and oldest method used and has relatively few controllable parameters. It is the most widely used in the world because it is uncomplicated, caters for large dyeing capacities and can be used under high-temperature conditions.

This dyeing principle is suitable for all types of samples. As a rule, no material carriers are required, but they are sometimes available as a special feature, for example, in the case of delicate yarns. The unit specifications differ in regard to the number of dyeing positions, capacity and temperature ranges. An important criterion is the possibility of dosing during the dyeing process. Sealing problems may occur depending on the type of closure used for the beaker. As a rule, these seals are made from Teflon which seal but, after a certain time, mould themselves to the beaker on which they are used. This means that, wherever possible, each beaker should only be sealed using the cover that belongs to it. The parameters relating to reproducibility reveal factors which can be regulated by controlling the unit in question.

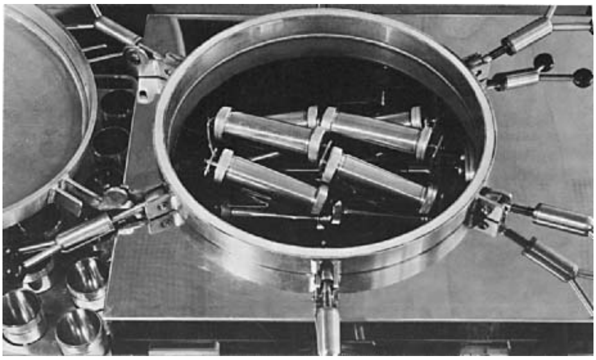

Fig. 2: Callebaut-De Blicquy (formerly distributed by Isal) with water bath in high temperature boiler.

Most units which are available are supplied with glycol as a heating medium. Roaches offers the IR and fluidised bed process and Mathis (Fig. 3) an IR unit for heating up the liquor as alternatives. The advantage of dyeing by agitating both the goods and liquor is that it is generally not necessary to make up samples on material carriers. High-temperature dyeing is possible with the exception of Osci-Color (Fig. 5) because the system is open. Dyeing and handling is simplest in the case of the beaker dyeing method (Fig. 4). It is the most wide spread method possible where a large number of colour adjustments can be rapidly carried out. The disadvantage is that the relative motion of liquor to goods is never monitored and this can have a detrimental effect on levelness and reproducibility. The goods are subject to relatively high levels of stress. Because the bath is heated indirectly, temperature control is inexact; only the temperature of the hot bath is measured. Aluminium

blocks or silicate fluids are presented as alternatives to the environmentally problematic glycol heating medium, but these are still too complicated to implement. The old high-temperature dyeing vessel using water as the heating medium and tumbling dye beakers (Callebaut de Blicquy, Fig. 2) is no longer available, although this is the best solution from an ecological point of view.

Laboratory dyeing principle - static liquor, circulating goods In a static beaker the liquor is moved more or less. (Figs. 1 and 2). The relative movement required between the substrate and the liquor is achieved by moving the goods (made up on material carriers). This is mainly a lifting movement which may sometimes be combined with rotational movement. The method is used in many dyehouses where all kinds of goods are dyed at temperatures below 100°C.

The Texomat (Fig. 3) can be converted for high-temperature conditions. However, this has not proved successful in practice: The arrangement produces mechanical difficulties, operates partly via solenoid systems and the seals are bad. As is the case for other machines, with this machine, the liquor is visible so the process can be monitored.

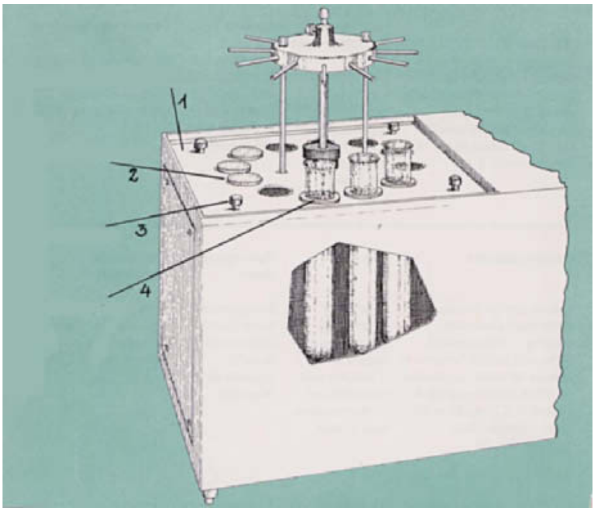

Fig. 2: Beaker dyeing apparatus (Roaches) with centrally located lifting mechanism.
1 = exchangeable cover plate; 2 = lids to avoid steaming; 3 = securing screw; 4 = dyeing beaker in mounting.

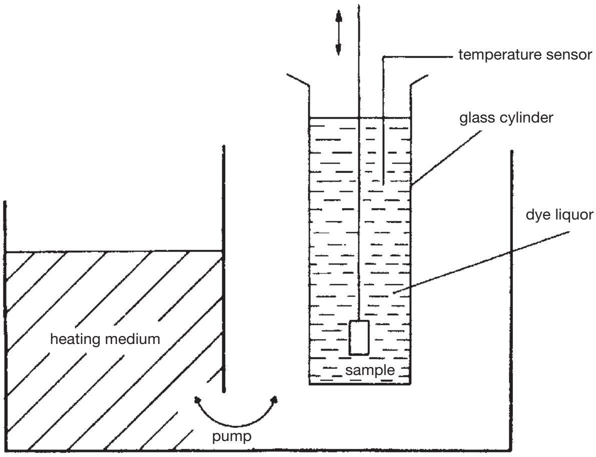

Fig. 1: Schematic of a beaker dyeing apparatus (static beaker, Multimat-Renigal system).

The advantage of laboratory dyeing with the goods in motion and static liquor is that dyeing on delicate goods can be carried out fast and reliably. If the liquor is visible, the exhaustion process in the bath can be observed and this can sometimes be informative. The disadvantage is that these machines can generally only be used for dyeing at temperature below 100°C and, because the system is open and the liquor is static, the temperature distribution and heat transfer are not optimised. This has a detrimental effect on the quality of the result. Glycol, which is used as the heating medium,

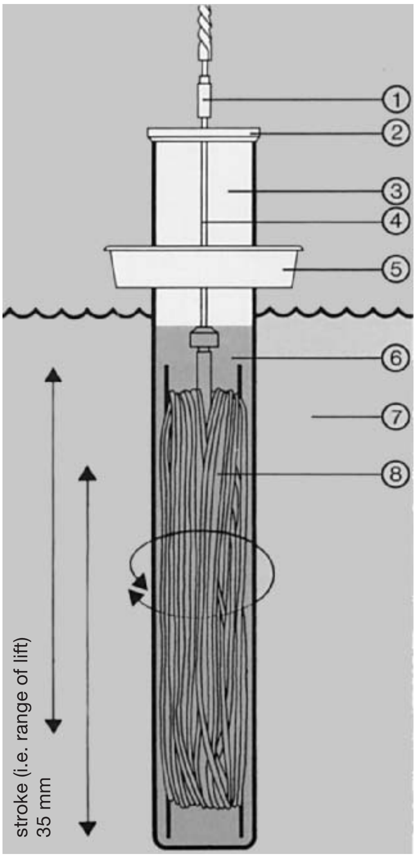

Fig. 3: Texomat GVII BT 412 by Ahiba with 4 beakers each holding 4 l.

manufacturer	type	capacity	minimum liquor ratio
Mathis	JFL	40 – 120 g	1 : 8
Benz	HT 140	1 – 3 kg	1 : 8
Then	OFHT 5	up to 5 kg	not given
Thies	micro soft	up to 10 kg	1 : 4
Thies	mini soft	up to 30 kg	1 : 4
Thies	midi soft	up to 60 kg	1 : 4

Tab.: Technical comparison of various laboratory pilot scale dyeing machines.

does not decrease in viscosity until high temperatures are reached and this can lead to a stagnation in heat transfer. It is therefore necessary to equip the bath with a mixing device. Dyeing can only be carried out at high liquor ratios (greater than 1 : 15) and it is also necessary to make up samples on material carriers and this takes time.

Laboratory pilot scale dyeing machines Reproducibility of formulations prepared in the laboratory using the available (→ Laboratory dyeing machines) is limited. On the one hand, they are based on experience in selecting the methods and the other, on the process-control capability via appropriate control systems for the laboratory dyeing machines. Frequently, when scaling up from laboratory to production, dyeing is still carried out on medium scale. This is used to prepare the patterns, optimise the process under practice conditions and investigate problems which could arise while dyeing on production scale but do not appear during the small scale laboratory dyeing of, e.g., 20 g material.

Laboratory pilot plants are modelled on full-scale production machines and represent a sort of "production in miniature". In contrast to the laboratory machines, not only can parameters which are determined by the dye formulation be readjusted, but features of the machine which have a decisive influence on result can also be simulated. For this reason, the trial-to-bulk reproducibility is usually significantly higher than is the case for laboratory dyeing machines. Pilot plants can be subdivided into smaller scale (1–3 kg) and larger scale units (10–50 kg), the demarcation being somewhat fluid (Tab.). Circulating liquor dyeing machines for dyeing packages are most frequently used for colour adjustments. (Fig. 1). For other processes, the advantage of the best possible way of scaling up must be weighed up against the high price which approaches that of a production machine. Because of the high costs, many finishers cannot afford to run this form of laboratory dyeing. The larger pilot plants are widely used in sampling dyehouses or used for dyeing special, small batches. They are only used for colour adjustment in the case of difficult shades or expensive raw materials.

1. Winches: these are used for economic dyeing and washing light to moderately heavy material which is

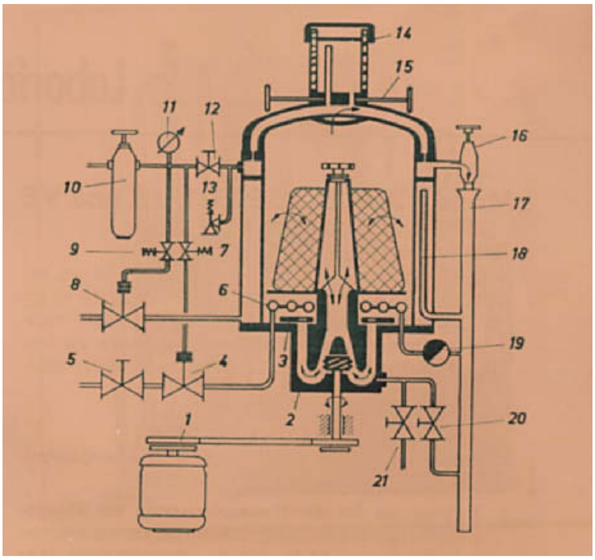

Fig. 1: MTM Obermaier circulation dyeing machine.

not sensitive to creasing. Process: the fabrics are sewn together in rope form, guided over a rotating winch, and plaited down in the dye liquor in the winch beck where they dwell for a short time. Dye exhaustion occurs during the repetition of this cycle. Dyeing is carried out in long liquor ratios. Winches for laboratory use are available from Roaches (50–100 l) and Mathis (10 l). They differ only in the liquor capacity. Both can only be used for the atmospheric range and have a dyeing drum as an optional extra. The winch vat supplied by Mathis also contains a paddle and a retainer for dyeing flasks.

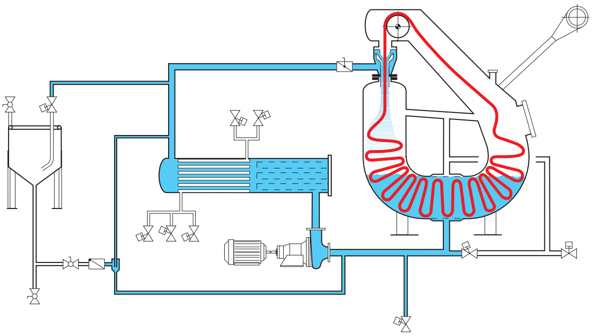

Fig. 2: Thies "mini-soft" piece dyeing machine.

2. Jet dyeing machines are used for goods which are not sensitive to creasing and are often used for polyester. Process: the aim is to reduce the liquor ratio. Dyeing can be carried out under high-temperature conditions. The fabric is circulated by the force of the jet and, in some cases, with a winch as well. The high rate of fabric and liquor interaction improves dye levelness at low liquor ratios. Jet dyeing machines are available from Mathis, Roaches, Benz and Thies (Fig. 2). Thies supply dyeing machines with capacities of up to 60 kg goods. The Mathis machines (Fig. 3) are designed for atmospheric use with goods of 100–1500 g and are suitable for high-temperature conditions for goods of 40–120 g and various different applications: jet dyeing using different jet diameters, dyeing drums, centrifuge, paddle, and high-temperature flasks (100,150 and 200 ml).

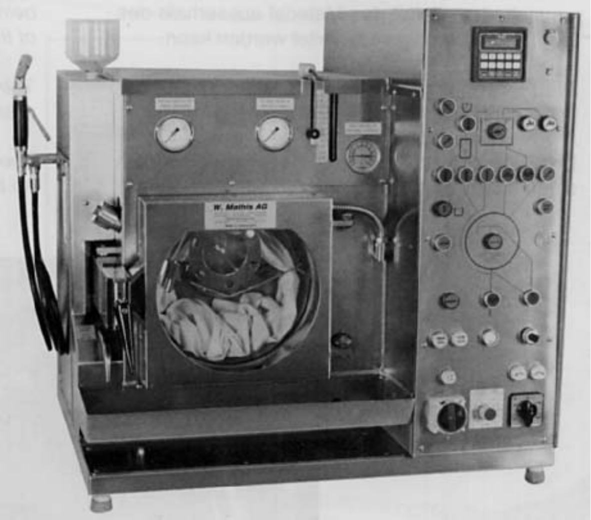

Fig. 3: IFL jet dyeing machine (Mathis).

3. Circulating liquor dyeing machines: for dyeing yarn and cones or tubes. Method: packages are placed in the machine on posts; dyes and auxiliaries are added using dosing tanks. The liquor is pumped through the packages while, in most cases, alternating the direction of flow (in-out and out-in). Circulating liquor dyeing machines are available from Jasper, Roaches, Isal, Then and Thies. MTM Obermaier supplied a high-temperature laboratory dyeing machine for 1–3 packages or with a dyeing bath for 7 packages which sits on top. It is also suitable for dyeing other material make-ups through different applications. The high-temperature pilot unit in Fig. 4 was developed from the high-temperature laboratory unit (mini-compact). With this, a unit is available by which all the following physical data of a treatment process can be measured and therefore reproduced:
- temperature,
- differential pressure,
- flow,
- pH,
- redox potential,
- conductivity,
- total water,
- rinsing water,
- exhaustion curve.

The dye bathe on the unit usually takes 3 packages with 6" lift. The bath has a glass mantle so that the behaviour of the yarn packages can also be monitored during the

Fig. 4: Laboratory dyeing machine for 3 packages in a dyeing column (Jasper).

treatment process (e.g., to see whether the system leaks and check the behaviour during the change in circulation etc.). The circulation pump is fitted with a variable-speed motor (frequency converter).

Jasper has also developed the 1-Plus-2 system to better utilise the capacity of the laboratory dyeing machine for the actual dyeing. Time-consuming pre- and after treatments, which are carried out under conditions of atmospheric pressure, are carried out in two treatment units next to the dyeing machine. An ancillary device is designed to draw the required chemicals from storage containers and another ancillary device is provided for pressing and unravelling press-cakes. The integrated chemical dosing unit is part of the standard design as much as the process controller (filling, time and temperature control, drain and rinse, etc.) is. In the case of Bellini and Bene Madinox, the yarn-dyeing machines are linked to a PC for controlling the process and recording the data so that important parameters such as pH control and flow rate can be worked out and established for production-scale process.

4. Jigger: for dyeing materials which are sensitive to creasing such as silk. Method: dyeing, bleaching, degumming and desizing piece goods in full width. The fabric is unwound from a roll, run through the liquor and wound on to a second roll. The fabric is run several times or “ends” through the liquor in this way. Laboratory jiggers for atmospheric dyeing are available from Mathis, Benz, Mezzera and Roaches.

5. Drum dyeing machines: for fully-fashioned goods dyehouses. Method: dyeing stockings, pullovers or sample pieces in a drum. The principle is similar to that of the household washing machine. Sufficient liquor exchange is achieved by the motion of the drum. Roaches supplies the Rotohose laboratory dyeing machine which has a perforated drum with partitions or blades.

Laboratory steamer Non-continuous saturated and high temperature steamer. Also used for adjusting formulations in carpet dyeing and fixing carpet prints. Used for a maximum pattern size of 70 x 150 cm, at temperatures up to 200°C and moisture control between 10 and 98%. Dwell times range from 10 s to 60 min – Manuf.: Mathis.

Laboratory to bulk reproducibility The dyeing laboratory plays an important part in optimising the costs of exhaust or continuous dyeing. In the laboratory, the colour shades are determined as recipes for particular dyeing methods. If the appearance in production is identical, i.e. without making further additions at the first attempt, and agrees reproducibly with the laboratory during all repeat dyeings, the reproducibility of the laboratory results in practice is good. Among the factors which affect the laboratory-to-bulk reproducibility are, for example, liquor ratio, temperature, flow mechanism in dyeing and liquor pick-up in the padder. (→ Laboratory).

Laboratory washing machines Laboratory washing machines are mainly used for testing wash-fastness and other fastness tests carried out in the laboratory.

Lace Lace is a more or less fine textile product with translucent base and dense pattern. Can be made by hand or machine. Genuine lace (hand made) is classified as follows: filet lace, crochet lace, bobbin lace, knotted lace. Knitted lace, (machine made): braided lace, weaver’s lace, bonded lace and embroidered lace. In the case of embroidered laces (for example Plauener laces) the base fabric is embroidered with a design and then removed as a piece process according to a pattern (→ Burn out style) or cut.

Lace effects → Burn out styles.

Lace galloon This is a fine, delicate copy of the genuine Valencienne lace on the weaver’s lace machine. Knitted ribbons of this type are called galloons. Chiefly made of cotton but also containing a small proportion of polyamide for strength.

Lace making Simultaneous braiding (interlacing) and twisting of threads (yarn, twist) in a diagonal direction for the manufacture of laces, small covers and similar items. These are classified into handmade lace (lace pillow), which in terms of quantity no longer has any significance, and machine-made on lace making machines. In the last case, the bobbins travel around each other in the warp sheet.

Lace Tweed Very light-weight Raschel-knitted fabrics made of natural silk, crêpe or polyamide warp. The bulky, roving or even wadding-type weft material is predominant and covers the warp (spun thread fine support structure). No qualitative requirements have developed.

Lacquer bases Film-forming component (such as natural or synthetic resin) in → Lacquers.

Lacquer-only screens Production of film-printing screens by the pre-lacquering or dissolving-out process using photochemical techniques. This method involves applying the lacquer to the screen, where the lacquer acquires better anchorage in the gauze than with post lacquering. Next, the photosensitive coating is applied and the copy made by laying a transparency on top and exposing it to light. The screens are developed as usual by dissolving out the non-illuminated areas. The lacquer is dissolved from the areas where no hardened copy coating remains and then special lacquers are used which, as a rule, are not suitable for post lacquering methods. → Photosensitive lacquer.

Lacquer printing Local gloss print chiefly produced in film printing using film(hole) screens, on thin fabrics and in Rouleaux printing (→ Chintz prints). Matt to high gloss effects are achieved with a certain degree of relief effect (depending on the thickness of the metal screen which ranges from approx. 0.3–1 mm).

Lacquers In most cases substances soluble in volatile solvents which form a thin, adherent, continuous film on the substrate by evaporation or physico-chemical processes. They are also important for the textile finisher, e.g., as different types of protective coatings, → Screen lacquers for film printing and for use in modern → Lacquer printing . Composition: in principle, lacquers consist of solvents and thinners (oil of turpentine, spirits, butyl or amyl acetate and toluene etc.) and so-called lacquer solids made from binders (substances such as natural and/or synthetic resin, cellulose products, chlorinated rubber and linseed oil), plasticisers and coloured pigments. Lacquers are classified according to their composition as follows:

I. Oil- (resin) lacquers: These are the oldest type of so-called “long-oil” varnishes with resin (e.g. copal + linseed oil + oil of turpentine) or without resin (e.g. so-called enamel lacquers for white internal and external coatings consisting of oil of turpentine + zinc white + boiled linseed oil + wood oil additive). Increasing the oil content prolongs the drying period but improves resistance to weathering. The use of oil-based lacquers is decreasing in favour of alkyd resin lacquers.

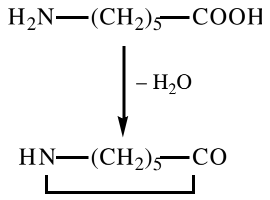
II. Cellulose lacquers: First among these are the different high-gloss collodium lacquers corresponding to the oldest type of so-called zapon varnishes (made from dissolved collodium wool or cheap film-formers or celluloid in amyl acetate) and pure nitro lacquers (nitro-cellulose dissolved in ethyl or butyl acetate etc. diluted with toluene etc.) used in lacquer printing and in pigment and bronze printing etc. Plasticisers are used as softeners. Pigmented lacquers of different types, such as fast lacquer dyes, are also used in the textile printing mentioned above and in leather dyeing. The nitro combination lacquers of complex composition contain either natural or synthetic resins as well, among these being combinations with alkyd resins which are customary in textile printing, and, to some extent, in rust-protection coatings. The acetate lacquers, made from cellulose acetate in solvents, such as acetone, ethyl acetate, butyl acetate, cyclohexanone and butyrolactone, are used in textile printing as fixers instead of these.

III. Synthetic resin lacquers: among these are, for example, phenolic resin lacquers made from phenolic plastic, spirits and another solvent, either as a so-called stove enamel (where infrared drying at 90–150°C follows curing) or “cold cure” lacquers with the later addition of very dilute acid (used as wood lacquers in particular). Pure phenolic resin lacquers are very hard, are of low elasticity, have excellent resistance to water, solvents and dilute acids, susceptible to alkalis and limited light fastness. Modified phenolic resins contain an integrated fatty acids, polyester or resin acids for improving elasticity. In the last case, significant amounts of linseed oil or similar substance can be solublised to produce oil-resinous lacquers (so-called synthetic copals) with high light fastness and high corrosion-protection properties for internal and external coatings. Although pure urea resin lacquers have high hardnesses, and a higher resistance to yellowing due to light or heat and are resistant to petrol, hydrocarbons and mineral oils, they are too brittle. For this reason, they are mostly only used in combination with nitro-cellulose for air-drying lacquers or with alkyd resins for stove enamels. Unlike the latter, urea lacquers modified with polyesters are characterised by significantly improved elasticity; they are suitable for acid-cured alkyd combinations and stove enamels which, in comparison to urea resin alkyd combinations, have the advantage of not yellowing even at very high temperatures. The different types of alkyd-resin lacquers have gained in significance in lacquer printing. In this case, the modified alkyd resins with condensed fatty acids (which can also be combined with nitro-cellulose) are of particular importance. They are soluble in hydrocarbons and tolerant to oils, harden in air during oxidation and polymerise in the final stage, which is insoluble. Chlorinated rubber lacquers (dissolved in solvents such as methyl acetate, butyl acetate, toluene and oil of turpentine) are also of interest and used in bronze, pigment and matt white printing.

Lacquer screen → Rotary screen printing machine.

Lacquer solids Solid components in → Lacquers.

Lactams Lactams are so-called internal amides made from amino acids or hydroxycarboxylic amides, produced from amino acids with the displacement of water (e.g., from 2-aminohexanoic acid (adipinic acid) → Caprolactam.



ε-aminocaprolactam

Lactates Salts of → Lactic acid $C_2H_4(OH)COOH$ (e.g., aluminium, chromium, titanic acid and tin lactate) which are used as dye mordants in dyeing and printing.

Lactic acid $CH_3CH(OH)COOH$; MW 90. The salts are called lactates. It is a viscous, pale yellow-to-brown hygroscopic liquid (miscible with alcohol or ether) or colourless crystals; high reducing power (gradual effect). Impurities (liquid): under certain circumstances, traces of heavy metals and calcium sulphate. Used as a wool mordant, in the manufacture of numerous dye mordants, as a substitute for tartaric acid and citric acid (leads to the softening of textiles to produce soft, silk handle without weakening the fibre or lustre), as a dye solvent (diphenyl and aniline-black pad dyes) and in aniline-black dyeing (aniline lactate), leather dyeing and finishing and for spotting agents, etc.

Lactones So-called internal ester of hydroxycarboxylic acids. These are classified into α, β, γ and δ higher lactones. The higher members of this group with 15–17 ring-links have a strong and, in most cases, pleasant smell.

Lactophenol cotton blue Substance used for revealing microscopic evidence of wool damage. Prepare a mixture from 50 ml chemically pure lactic acid, 20 g phenol, 40 ml glycerine and 20 ml water. Mix 50 ml of this with 10 ml aqueous blue solution, i.e. a 2% solution of soluble blue B (Hoechst), place a single drop on to a microscope slide with the test specimen, arrange and cover with a coverslip. Findings:

a) Mould fungus: after 30 min, the mould structure will turn blue and the spores blue or yellow to brown.
b) Fibre damage on the wool: after a few hours, the damaged fibres will be blue and undamaged fibres colourless.
c) Mould fungus on cotton: procedure and behaviour as for wool.

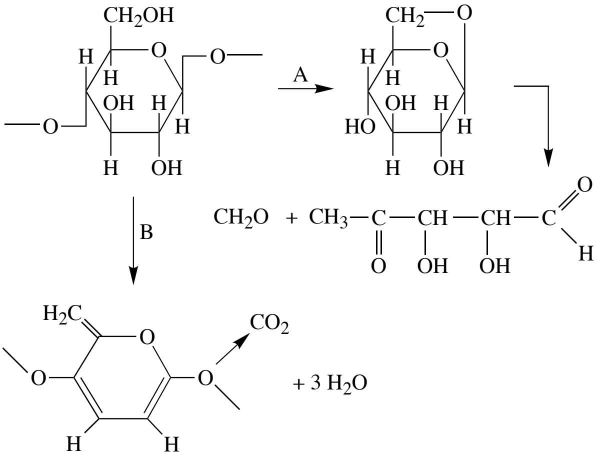
Ladder and snag-proof tester Instrument used for the testing of → Snag and laddering resistance, including the snagging of knitted goods.

Ladderproof finishes (snag and ladderproof and antisnag finishes). Treatment of knitted fabrics, usually made from fine yarns, and stockings against laddering and snags. Antisnag agents are used for this purpose. They are applied during exhaustion or spraying processes.

Ladder/run Appearance of a flaw in weft knit fabrics, especially women's hosiery. Arises as a result of a wale or wales having been mechanically undone or opened following thread breakage, where in addition to the stitch originally affected, those stitches connected to it also become undone in succession.

Ladik rugs Knotted prayer rugs from the Anatolian area of the same name. The separation of the pattern into middle, lower and upper sections is characteristic. Predominant colours are red, blue and yellow. Ornamentation is in the form of stylised flowers (tulips and carnations), short pile with around 200 000 Turkish knots per m^2.

Laevoglucosan Chemical compound produced during the initial pyrolysis of cellulose as the primary depolymerisation product by the breaking of the cellulosic glucoside bonds and in the next step with the formaldehyde cleaving forms a hydroxyketoaldehyde which then decomposes via various routes. In the case of flame-retardant finishing, it is assumed that the formation of laevoglucosan is suppressed, while H_2O cleavage becomes more significant during decomposition.



Laevo-rotary → Optical activity.

Lambert-Beer's Law The attenuation of electromagnetic radiation in a medium is termed → Extinction. In the case of solutions of dissolved molecules, the attenuation is essentially caused by absorption while that for dispersed particles also contains a scattering component.

extinction = adsorption + scattering

Where I_0 is the intensity of parallel electromagnetic radiation impinging on a layer of solution or dispersion of thickness b [cm] and concentration c [mol/l], under certain conditions, the following relationship applies to the intensity of radiation which emerges from the sample:

$$I = I_0 \cdot 10^{-\varepsilon(\lambda)\,c\,b}$$

where ε(λ) [l/mol/cm] is the decadic molar extinction coefficient which is concentration dependent within a defined range and is specific to the substance. ε(λ) is dependent on the wavelength λ, the polarisation of the incident rays and the solvent as well as the prevailing conditions in the solution or dispersion, such as pressure and temperature. In the case of dispersions, ε(λ) consists of the two components $\varepsilon_A(\lambda)$ for absorption and $\varepsilon_S(\lambda)$ for scattering. Thus,

$$\varepsilon(\lambda) = \varepsilon_A(\lambda) + \varepsilon_S(\lambda)$$

Among other things, $\varepsilon_S(\lambda)$ is dependent on the size, shape and orientation of the particles. Providing

$$\varepsilon_S(\lambda)\,c\,b << 1$$

multiple scattering plays a subordinate role and $\varepsilon_S(\lambda)$ may be regarded as being independent of concentration. Under these circumstances, dispersions can be measured by introducing the decadic extinction

$$A = \log (I_0/I)$$

to give the Lambert-Beer's law expressed by the following relationship:

$$A = \varepsilon(\lambda)\ c\ b$$

Its validity, i.e. the linear relationship between the extinction coefficient A and the concentration c within the range of the dye concentrations to be measured, is prerequisite for the quantitative photometric determination of dissolved and dispersed dyes where the effort to be put into calibration measurements must be small. Even for multi-component analysis, the applicability of the Lambert-Beer's law is crucial as, where this is not so, time consuming formulation-specific multi-point calibration curves will be necessary.

One of the most important effects in the case of dyes dissolved at molecular level is the concentration-dependent formation of associate structures. In the case of dispersed dyes, it is the scattered light which has the greatest influence on the extinction spectra. In practice, the conditions under which these effects have the least influence must be assessed. A proportion of dye may exist in its associated form in the solution (e.g., dimers and polyassociates) depending on the concentration. The extinction spectra of dissolved monomolecular dyes and their associate structures are different in most cases. Thus, for a certain dye concentration, the extinction spectrum for the solution represents the sum of the spectrum for the monomolecular dissolved dye and the spectrum of the different associate forms in the prevailing ratio. For this reason, it is advisable to carry out measurements on soluble dyes at the lowest possible concentrations. In order for the measurement error not to be too large, it must be ensured that the extinction values lie within the measurement range appropriate for the photometer. Measurements carried out at low concentrations are made considerably easier by relatively high specific absorptions, such as those for reactive dyes (source: Locher and Firmann).

Lambswool → Wool from the first shearing of young sheep.

Lamé,

I. A patterned fabric with → Metallized yarns woven in.

II. A generic name for → Metallized yarns.

Lamella,

I. A thin leaf or disc.

II. The term membrane lamella is used in fibre histology, for example, in the case of cellulose fibres and synthetic polymers. The two-dimensional system consisting of cellulose chains arranged in parallel and bonded to each other via hydrogen bonds represents the building block for the three-dimensional → Micelle (Fig. 1).

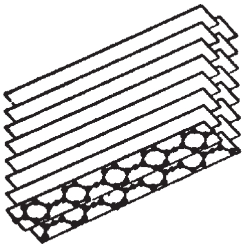


Fig. 1: Three-dimensional lamellae structure in cellulose.

Fig. 2 shows the macrostructure of a slow-cooled linear polyethylene. The (centro-symmetric) spherolites are produced by the radial growth of lamella packages. The crystalline and amorphous regions are clearly defined. If the polyethylene melt is cooled down rapidly, the spherolites are considerably smaller and poorly arranged.

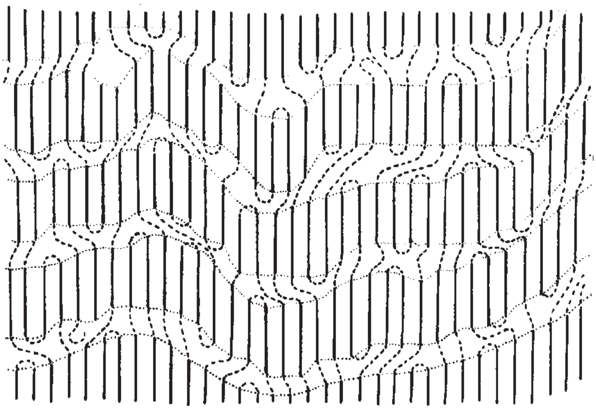

Fig. 2: Structure of lamellae packets (schematic).

III. The skin of blisters/bubbles such as those found in → Foam.

Lamellar macromolecule In crystalline areas (in the plane of the paper), the structure of two-dimensional or lamella macromolecules in the sense of so-called chain grids (→ Pleated sheet structure), for example, in the case of cellulose (lamella), wool (keratin grates), synthetics (crystallite) and silk.

Laminar Regular, sheet form, low friction.

Laminar boundary layer A layer consisting of gas or liquid that is carried along with the interface of a sold body in the direction of its motion as it moves in relation to the gas or liquid. If, for example, the surface of a textile fibre is regarded as the "river bank" and the surrounding liquor as the "river" then the flow profile may appear as illustrated in Fig. 1.

Zone 2 represents the fibre as the solid substrate. Zone I represents the bath, which is circulated by pumps, (dyebath with high initial dye concentration or washing liquor with initial soiling level at almost zero)

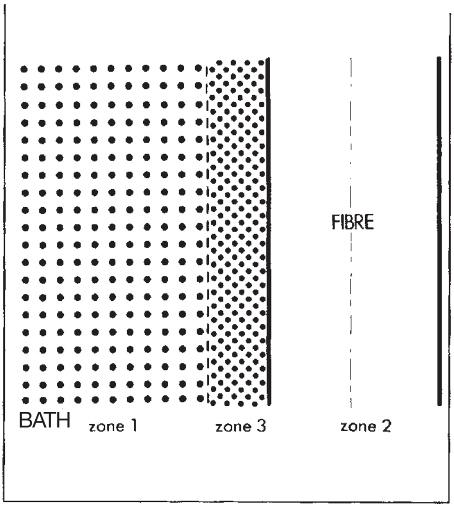

Fig. 1: Flow profile with three zones: turbulent (1), laminar (3), fibre body (static, 2).

where turbulent flow predominates. Zone 3 is the laminar boundary layer with a characteristic flow profile. If during dyeing the boundary layer is left undisturbed, the even distribution of dye found at the start of the dyeing process will gradually become uneven as the dye molecules are absorbed on the fibre surface and, because the liquor is “stationary”, the rate of replenishment within the layer is not as fast as the rate of depletion due to the adsorbtion process.

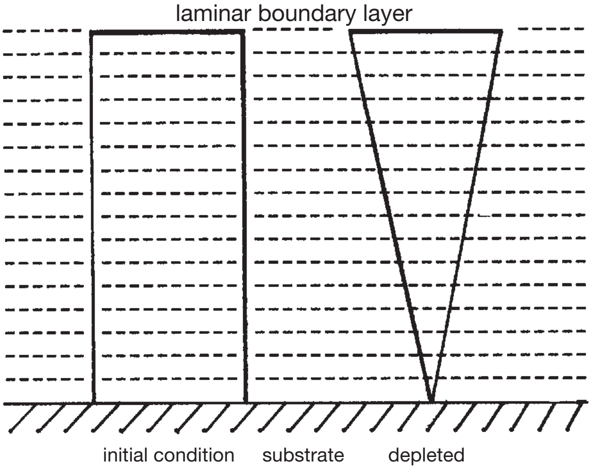

Fig. 2: Situation within a laminar boundary layer during dyeing of a substrate.

In Fig. 2, the even distribution of dye is shown on the left, and the depletion of dye at the substrate surface, caused by the diffusion of absorbed dye molecules on to the fibre while the concentration of dye is insufficiently replenished in the laminar boundary layer due to the lack of turbulence, is shown on the right.

Laminar flow Form of stationary liquids or gasses where their layers move past each other without turbulence, contrasts with → Turbulent flow.

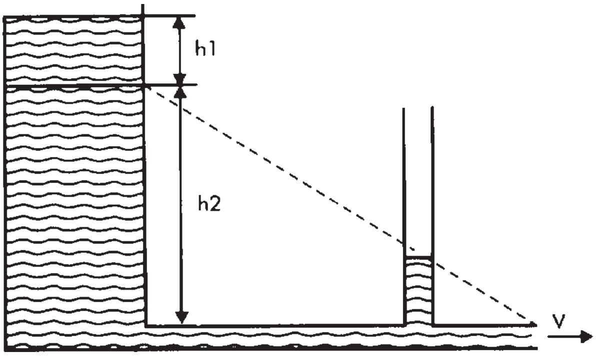

Fig.: Diagram explaining laminar flow.

If water is allowed to enter a vertical round tank with a horizontal drain at the bottom at the same speed at which it is allowed to escape through the outlet (Fig.), the velocity of flow at the outlet is given by:

$$v = \sqrt{2 g h_1}$$

From this, it can be seen that the proportion of flow corresponding to h_2 is reduced by losses due to friction. The losses due to friction are shown by a gradient of flow from the wall towards the centre (or in the case of flowing river water, from the banks towards the centre of the river) in the flow medium of the vertical tank. At the wall, the flow rate is almost zero whereas in the centre, the flow is at its maximum. This produces a flow profile with lamina flow at the boundary and turbulent flow in the centre of the pipe.

Laminated fabrics → Bonded fabrics made from at least two sheet materials of which at least one has textile character.

Laminated plastics Sheet form from paper, textile or wood, impregnated with synthetic resin (mostly phenoplasts) and then hot pressed. Hard semi-manufactured goods such as rods, pipes, profiles and slabs used for containers, apparatus or machine construction further machined for gear wheels and housings.

Laminates These are produced by bonding textiles and non-textile sheet materials using surface adhesives (→ Laminating). They fall into the following classifications:

1. Textile/foam laminates: two-layered sheet materials, produced by bonding a fabric (textile sheet material) or knitted fabric to a sheet of foam.
2. Sandwich laminates: three-layered flat materials, the two outer fabrics or knitted textile layers being

glued to either side of a sheet of foam as the middle layer.

Lamina thickness swelling This method, which has long been used in the paper industry, has been modified for textiles and developed further into a quick method for measuring the → Swelling of textiles, measurement of.

Laminating Bonding together of two or more layers of similar or differing flat textile materials (Figs. 1–4) such as wovens, knit goods, films, felt, paper, nonwovens, fleeces and foam films. If a foam or another non-textile flat material is bonded to a textile surface, this is termed laminating (e.g., by thermal bonding between the textile surface and the foam). If a textile surface (as the face fabric) is bonded to a lining fabric by a binder (foam), the term used is → Bonding.

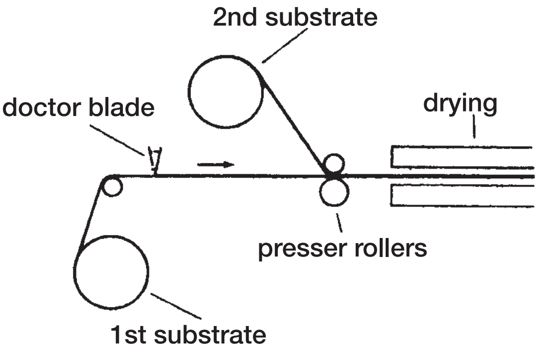

Fig. 1: Laminating principle.

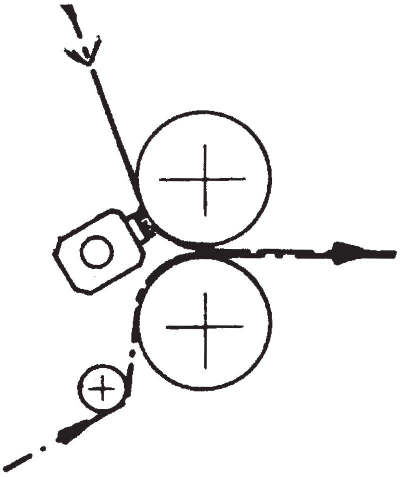

Fig. 2: Flame-lamination by the single-system.

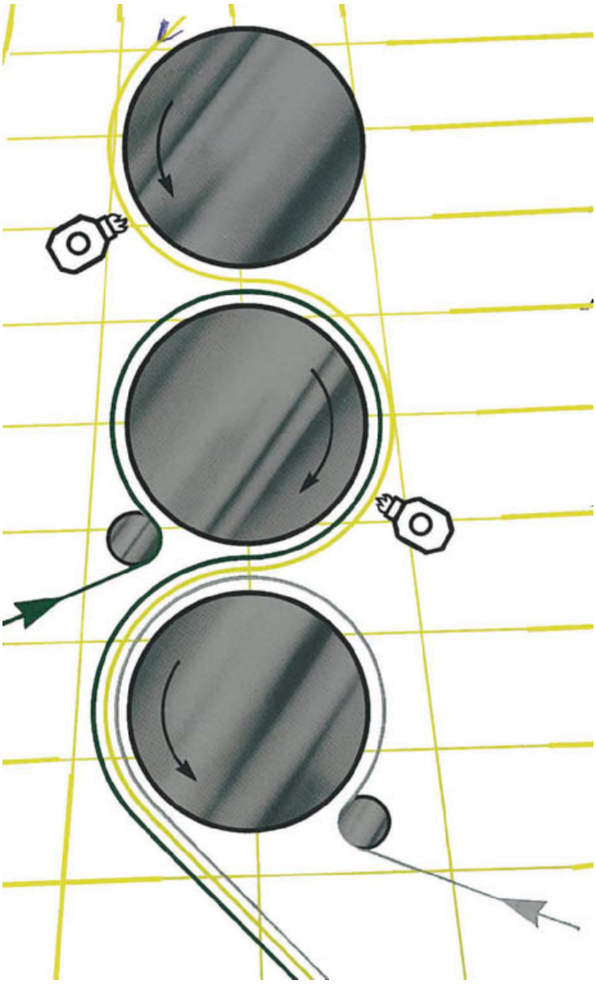

Fig. 3: Flame-lamination by the Sandwich-system

With the inventation of the Swimming Roll in 1956, the first deflection controlled roll in the world, Küsters made today‘s production widths for the calendering process possible (Fig. 6). This experience in roll systems has been used for the development of the new ultrasonic calender (Figs. 7 + 8). Küsters have the know how to manufacture precision rolls. Together with the equipment of Hermann-Ultraschall, those precision rolls make an excellent combination. The high precision of the roll, the stable mounting of the welding heads combined with the accurate gap control system, guarantee a consistent, uniform bonding process across the complete roller width and throughout the complete time of operation. The optimized design of the vibration system enables the machine to achieve production speeds previously considered to be impossible.

In general, laminating is also used to bond preformed hard plastic films to another material using bonding agents or adhesives (Figs. 5 + 9 and 10 + 11). In this way e.g. bonded sheet materials from cellulosic and polyethylene are produced where the cellulose confers aroma sealing and the polyethylene is waterproof. Bonded films made from polyisobutylene (bond to steel) and polyethylene (corrosion protection) are used

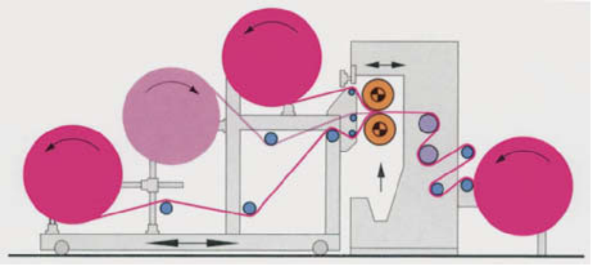

Fig. 6: Normal lamination.

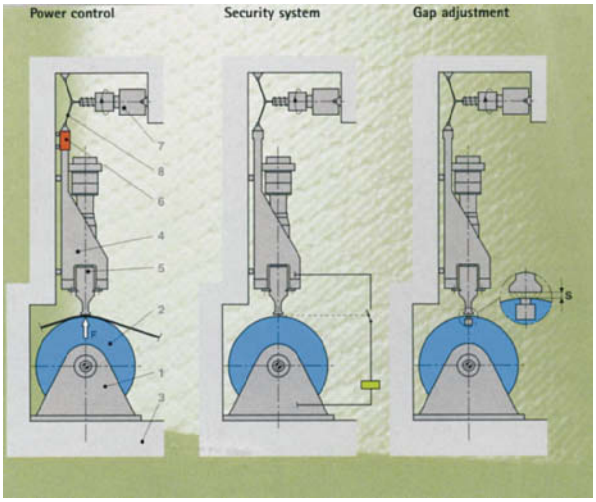

Fig. 7: Power control, security system and gap adjustment in an ultrasonic unit (Küsters).
1 = bearing; 2 = roll; 3 = frame; 4 = actuator; 5 = welding head; 6 = load cell; 7 = stepper motor; 8 = toggle lever.

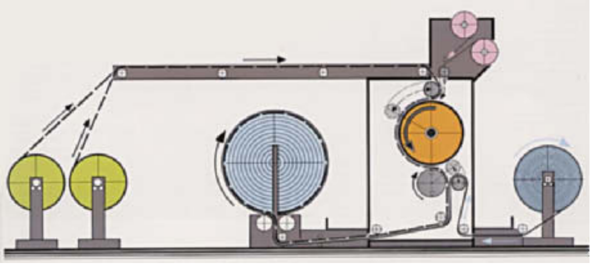

Fig. 10: Lemaire laminating calender.

in the construction of chemical apparatus. Sheet steel laminated with polyvinyl chloride can be worked like ordinary steel but is resistant to corrosion without further treatment. Polytetrafluoroethylene films are sometimes applied to aircraft so that it is difficult to wet and thus helps to reduce icing problems.

Bonded materials are often made using a process similar to laminating. In the case of synthetic leathers, layers of different synthetic materials are put together. For example, a product is manufactured consisting of an upper layer of polyurethane, a middle layer of mixed

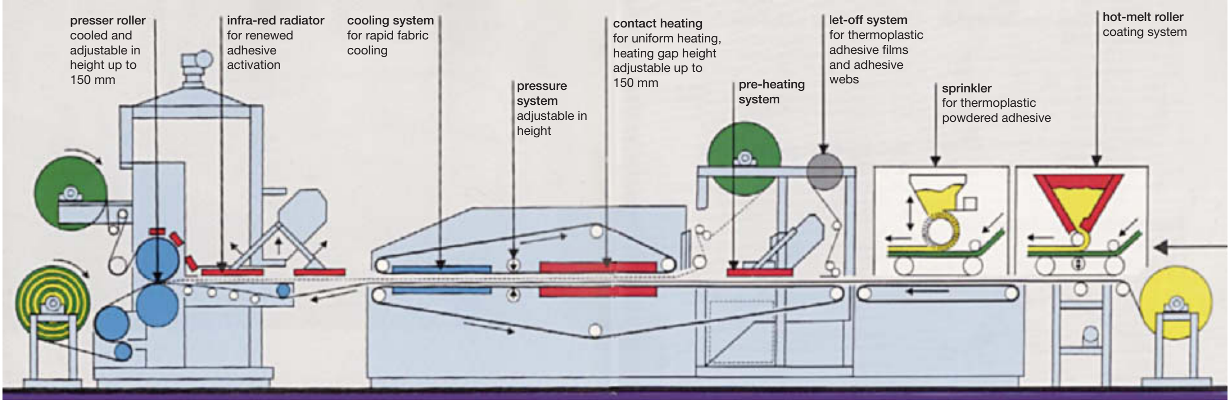

Fig. 11: Meyer flat bed laminating system.

textile made from 95% polyethyleneterephthalate and 5% cotton and a bottom layer made from polyethyleneterephthalate fleece. Bonded materials are mainly used as structural materials. → Coating.

Laminating calender This is used to bond textile or paper webs by hot-melt spray coating or with thermoplastic films (Figs. 1 and 2).

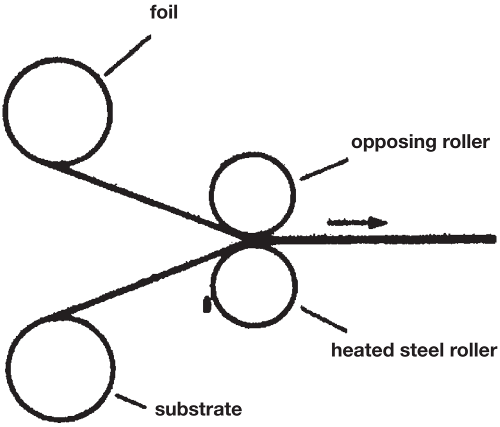

Fig. 1: Diagram showing principle of the laminating calender.

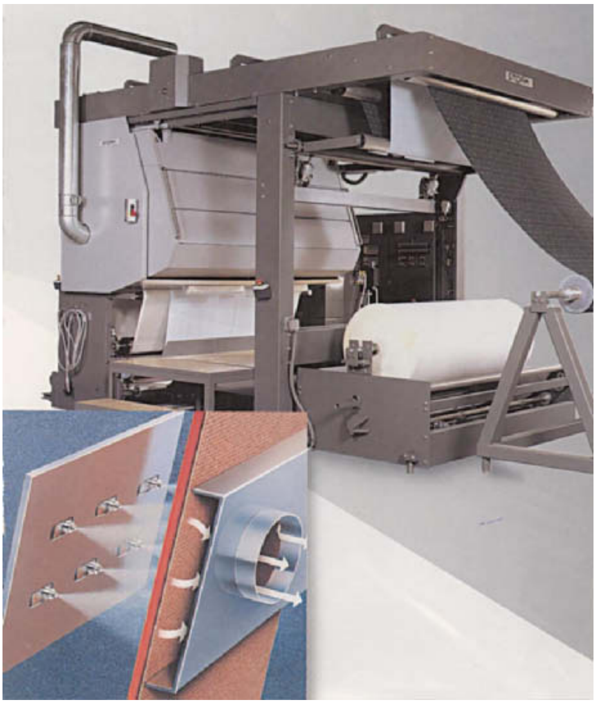

Fig. 2: Laminating calender with hot-melt spray coating (Stork).

Laminating carpet Term formerly used for → Bonded-pile carpets.

Laminating machines This section presents the technology on the use of the Primal acrylic emulsions as adhesives for bonding fabric to fabric, to foam, to nonwovens, to film and to fibrefill. These acrylic emulsions from Rohm and Haas Company are the backbone of a good laminate. Being water-based, they are easily formulated, applied and cleaned up, without objectionable odour or danger of fire hazard or air pollution. Fabric-to-fabric laminates based on the reactive Primal emulsions are durable to post-dyeings as well as to multiple washings and drycleanings. Their lack of discolouration on ageing and on exposure to light, allowing them to be used on light coloured fabrics, is yet a further advantage.

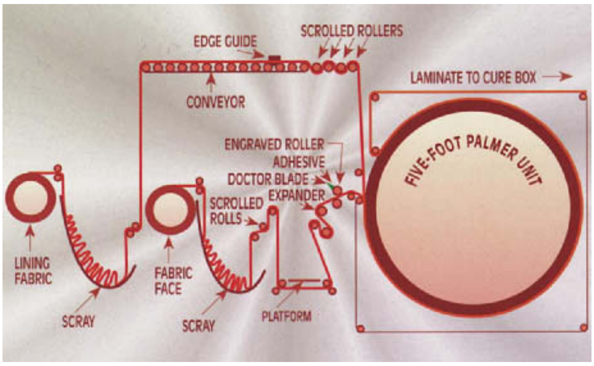

Fig. 1: Diagram of a typical textile laminating machine.

A diagram of a typical laminating machine is shown in Fig.1. Operating speeds on these machines are usually about 20 to 40 metres per minute. The maximum speed at which the machine can run is dependent not only on the time needed for properly curing the acrylic adhesive but also on the limits of fabric handling equipment such as straighteners. Adhesive is usually applied to the shell fabric or the film with one or more metal or metal and rubber rolls. Three of the most commonly used combinations are illustrated in Fig. 2. The kiss roll method (Fig. 2A) is preferred for applying adhesive to lace fabric which requires a continuous adhesive film because of its small surface area. The applicator roll is smooth and the amount of adhesive applied is regulated by the doctor blade.

Fig. 2B shows the “doctor blade reservoir” method, which is probably the most commonly used. In this method, the applicator roll is engraved. Fig. 2C depicts the use of a transfer roll which turns in the adhesive mix and contacts an engraved roll. A reverse transfer roll, where the engraved roll runs in the opposite direction to the fabric, can also be used.

The amount of adhesive applied is dependent on the fabric to be laminated. Fabric construction, its absorbency, hydrophobicity and surface characteristics will

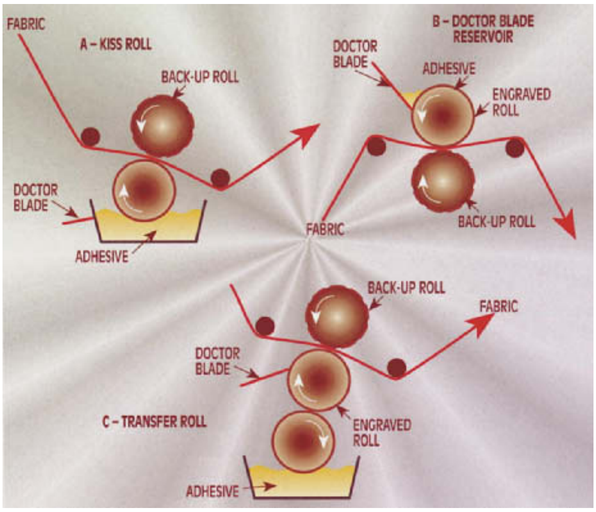

Fig. 2: Methods of adhesive application.

all influence the amount of adhesive needed as well as its penetration into the fabric. The adhesive should remain on the surface of the fabric to be available for contact with the backing fabric in order to form a good bond. Usually from 80 to 180 adhesive/m^2 fabric are applied. Probably the most important variable that affects the amount of adhesive applied is the engraved roll used. These rolls are available in a wide variety of types, including dot, quadrangular and lined patterns. Other factors which influence the amount of adhesive applied are: speed and direction of the engraved roll; coating viscosity; rheology; pressure from the backup roll; and where a backup roll is not employed, the amount of wrap-around.

Most of the factors mentioned that affect the applied solids also affect the penetration of the adhesive. Undue penetration can cause unsightly strike-through as well as stiffening of the hand of the fabric. The fabric should be married promptly after the application of the adhesive and dried immediately. Proper control of pressure is essential when a nip or pressure rolls are used to ensure that good contact is made but that there is not excessive penetration of the adhesive. Another method of marrying the fabrics is to use a large steam or oil-heated cylinder, a Palmer unit, which has an endless blanket wrapped around it. This method is the one illustrated in Fig. 1. The blanket presses the laminate lightly against the heated cylinder and prevents slippage of fabric during the early drying period. Laminates can also be dried over a series of heated small diameter cans. Heat is not applied uniformly, in this process, since the sides of the fabric receive heat alternately as the laminate travels from one drying can to the next. An endless blanket will reduce the tendency for the fabric layers to shift during the initial drying period. If strike-through is apparent, cutting the temperature of the initial drying cans can be effective in eliminating this problem, but it is not feasible if curing conditions are marginal.

The next processing step, curing, is one of the most important in laminating with acrylic adhesives. The bonded structure must be cured to make the adhesive durable to washing and drycleaning. The time and temperature necessary are dependent on the particular fabrics and adhesive formulation as well as whether curing is done on heated rolls or in a hor air range.

The ingredients in these typical formulations should be added slowly and in the order listed. Because of the final high viscosities of laminating adhesives, a power mixer is essential. The power requirements of the mixer will depend upon batch size and final viscosity, but a three to five horse power unit should be sufficient for drum-size batches at laminating viscosities of 40 000 to 80 000 cps. Mixers with a marine-type propeller are preferred, because paddle- and disc-type impellers will not provide adequate agitation. The blade should be about one-half the diameter of the mixing tank. When formulating in drums or larger containers, two blades, both directing the mix downward, should be used. The shaft should be off-centre and canted slightly for optimum liquid movement. Gear reducers are suggested to lower the speed of mixers to 300 to 500 rmp. without reducing power. These speeds ensure uniform mixing without whipping excess air into the adhesive. Lightning mixers and similar equipment are available in a variety of models and sizes. Drums are often used as mixing tanks. Larger tanks can be constructed of stainless steel, glass fibre-reinforced polyester or moulded polyethylene. The size of the tank should allow for adhesive depth to be about twice the tank diameter. The mixer should be mounted externally, not on the sides of the drum or tank. All mixer tanks should be covered to prevent adhesive contamination and skinning.

Laminating of dry bonding (principle of dry bonding). A thermofusible film placed between two materials is brought on a continuous basis to its melting temperature and permanently bonds the two materials (→ Bonding of textiles). The elements to be bonded can

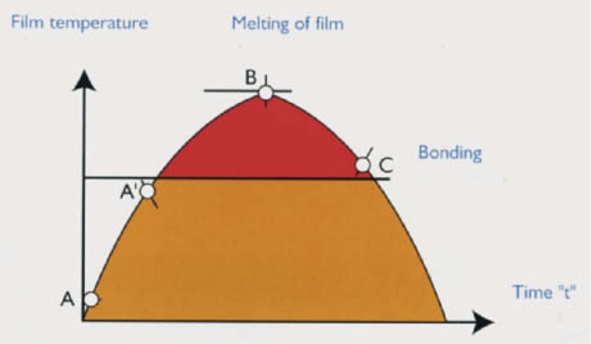

Fig. 1: Requirements of the dry bonding.

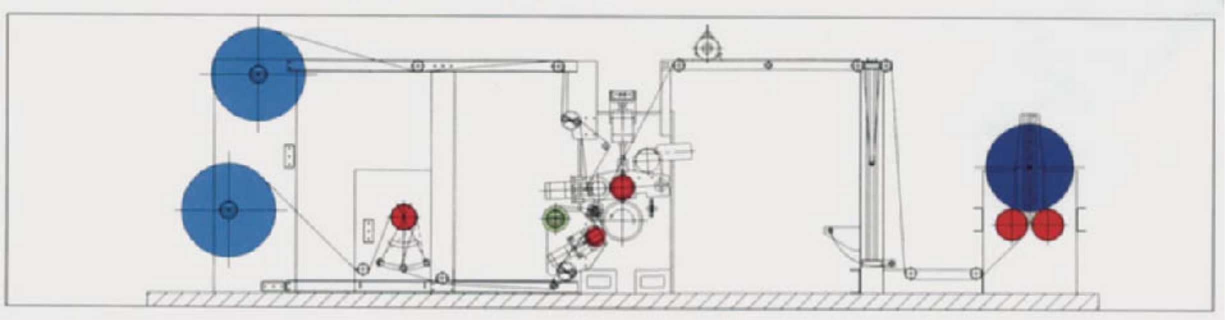

Fig. 2: Lemaire calender for dry laminating.

be either in roll form or in sheets. E.g., to perfectly bond foam to fabric, the film should first be in contact with the foam surface. This thermofusible film is heated to a temperature higher than its melting point, and immediately prior to its cooling, the fabric is compressed onto the foam to which the film is already adhered. The time needed do bond depends on the time of exposure to heat and the dimensions of the heating systems.

Fig. 1 illustrates the requirements on a practical basis: upon exiting from the heated surface where the film has been brought to its melting point, it is necessary to maintain this condition of the film for a given amount of time “t” after which time the second surface to be bonded will be pressed into the bonded assembly (B–C curve). A corresponding equipment is shwon in Fig. 2.

Laminating on rotary screen printing machines Rotary screen printing machines can be used for laminating all web-type materials. This may be a machine especially designed for dry laminating with extended facilities for wet laminating. Alternatively, a printing machine may be used before pressing (wet-in-wet) as a form of wet laminating or, particularly in the case of stretch-sensitive and low- or non-absorbent materials such as plastic and metal films, a printing machine may be used which facilitates laminating before or after the printing process, with intermediate drying after each print position.

Laminating technology Bonding textile materials with other non-textile flat materials such as paper and plastics. Techniques:

1. Adhesive is applied to one laminate component in the form of a paste (coating process), powder (powder point coating process) or melt (roller melt process) and this is pressed with a second or third component.
2. The surface of a foam is melted using a flame and pressed onto a textile material (→ Flame laminating, Fig. 1).
3. A (foamable) thermoplastic is first applied to a carrier such as paper (release paper) or continuous metal band and released at the moment of bonding (transfer or reverse process). This process can be used to produce very thin coatings.

The flame laminating process, using thermoplastic foams, is widely used, for example, in the manufacture of car upholstery. The surface of the foam is melted by heating it on one side. In the finished product, the foam layer has a clearly recognisable thickness of 0.5 mm which can be felt. In the case of the sandwich method, the laminate consists of two textile surfaces of different type which are bonded on both sides with foam sheet.

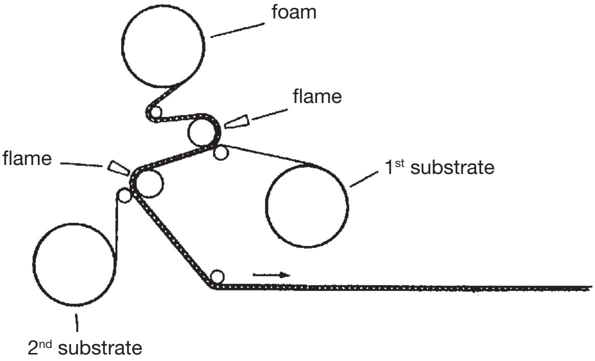

Fig. 1: Flame laminating machine.

The flame method is also used for double-sided laminating. The foam is melted on both sides from the heat of the flame. The procedure is to melt first one side by passing it near gas flames and pressing it with the first component material and then to melt the other side

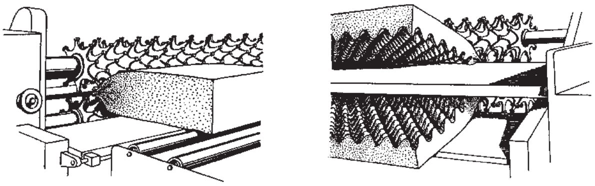

Fig. 2: Cutting a polyurethane foam in elastically deformed state to structure its surface.

with the gas flames and press the laminate with the second component material. With single side flame laminating, the foam can be structured on the side that is not laminated to the textile (Fig. 2).

Dot coating with powder or paste: Here we present a comparative report on two related techniques, namely dot coating with powder and with paste (Figs. 3 and 4). Both methods employ copolyester or copolyamide adhesives which, in the form of powder, are applied to the substrate by appropriately shaped rolls or wheels. The adhesive is then fused under an infrared radiation source.

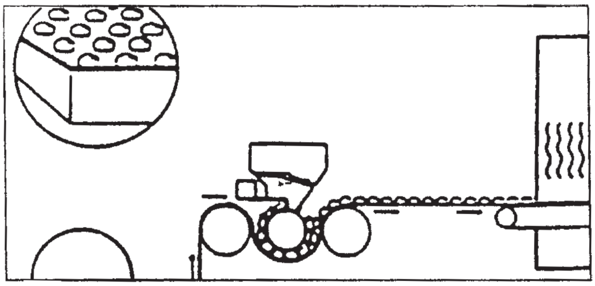

Fig. 3: Powder dot coating method.

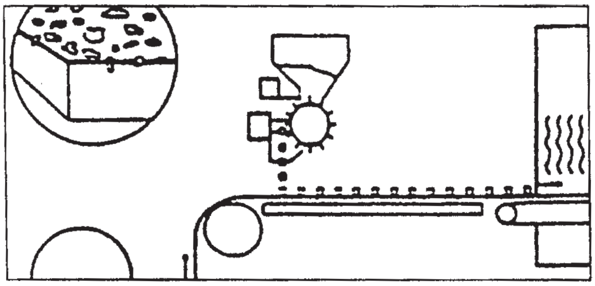

Fig. 4: Paste dot coating method.

A fundamentally different technique is to employ an adhesive that has already been melted or activated. Examples of this technique are:

- screen printing,
- roller printing,
- spray application,
- a new technology “Porous Coat”.

With both screen printing (Fig. 5) and roller printing, a squeegee roller produces discrete dot coating of adhesive on the substrate. In the spray method there is no direct contact and it is also possible to use reactive adhesives, for example polyurethane hot-melts. Customer requirements reveal a growing demand in end-uses involving long-term temperatures of around 120°C, for example in the car industry. It is difficult for these requirements to be met by conventional methods such as dot coating with powder or paste, screen printing or roller printing. Rather than copolyester or copolyamide, these methods employ reactive polyurethane adhesives which dissipate into the environmental atmosphere under the effects of heat.

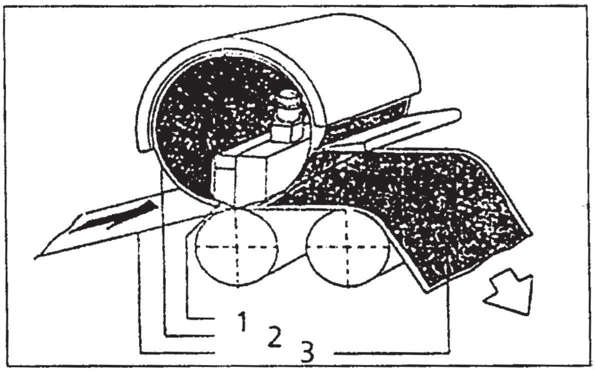

Fig. 5: Screen print method.
1 = snap-on nozzle; 2 = cylindrical screen; 3 = nonwoven.

Spray technology: This method combines the advantages of application without direct contact and uniform application using conventional polyamide/polyester or ethylene vinyl acetate adhesives and also reactive adhesives such as reactive polyurethane hot-melts. One of the principal distinctions between these two methods is that no contact is made with the substrate being coated with the adhesive. This non-contact application has its advantages for very thin or delicate materials as there is little or no influence of temperature on the laminate. Maximum precision of application is achieved in the spray method by using a gear pump in the spray head. Adhesive is applied by two independently controlled air jets which produce an elliptical ap-

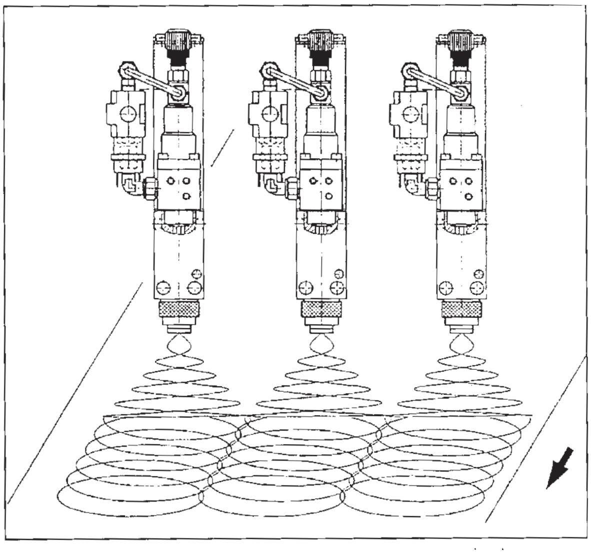

Fig. 6: Spray method. Adhesive application with two independently controlled heated air jets which produce an elliptical application of the string of adhesive.

plication of the string of adhesive (Fig. 6). These attributes make spray technology interesting for a large number of end-uses. The limitations of the process are evident when penetration of adhesive into the substrate is required, since the adhesive remains predominantly on the surface.

The “Porous Coat” method: A “Porous Coat” system consists of a variety of components (Fig. 7). The example illustrated is the configuration when using adhesives supplied in drums, for example reactive polyurethane hot-melts, or when using adhesives in granulate form, e.g. polyester or polyamides.

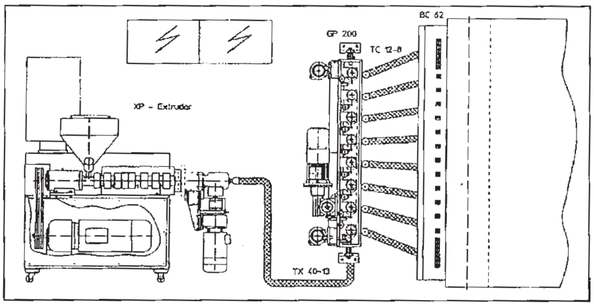

Fig. 7: Diagram of the “Porous Coat” system using polyester or polyamide in granulate form.

1. Adhesive supplied in drums: The adhesive is transferred into a reservoir by heated drum plunger fitted with a gear pump. From here it is pumped at controlled pressure into a central pressure pump unit by a gear pump, from where every feed hose and consequently every pressure zone of the “Porous Coat” applicator head is supplied with metered volumetric amounts of adhesive.

2. Adhesive supplied in granulate form: The adhesive is melted down in an extruder and, with a gear pump bolted on to the extruder, is metered volumetrically into the central pressure pump unit which then supplies the applicator head. This new technology permits positive application of unvarying amounts of adhesive from a special slit extrusion die. This type of dot application enables the amount of adhesive used to be reduced by as much as 30% compared with conventional methods of application. This prevents undesirable wastage due to adhesive penetrating too deeply into the substrate with consequent loss of pliability in the laminate. Thanks to its various automatic control systems the process is versatile and productive, for example its automatic width selection. This automatic system enables width changes to be implemented even whilst production is continuing, in adjustment increments of 3 cm. For instance, a slit extrusion die 1.70 m wide can be changed down to a coating width of 1.40 m or even narrower, with an electronic circuit automatically compensating the motor and/or pump speed and ensuring that the precise amount of adhesive applied is kept constant. Another option is to vary the position of the extrusion die in relation to the substrate. This enables the adhesive to be applied on the surface of the laminate or deep in the laminate as required. Using adhesive that is already in melted form also increases the production rate as there is no need to use an infrared heat source to heat the coating following application. Speeds as high as 100 m/min can be realistically attained.

Lanameter An instrument used for measuring fibre fineness including that of chemical fibres. It consists of a desk-shaped housing which has a diagonally arranged measuring matt disc upon which the fibres magnified 500 times are projected. The thickness measurement is accurate to within 0.001 mm.

Lancé Fabrics with an associated group patterning (figuring) which is formed by a second warp and/or weft system. The patterning only appears in stripes even if the pattern itself shows no stripe arrangement. The threads not required for patterning on the face float or are woven in at points on the reverse (in contrast to → Broché).

Lanolin → Wool fat.

Lanometer (Rapid Lanometer) – instrument for testing the thickness of fibres, particularly wool. The total cross-section of 100 parallel bundled fibres is measured using a special calliper. Dividing the measurement by 100 gives the average fibre thickness (→ Lanameter).

Lanthionine Sulphur-containing → Amino acids as a thioester of cystine where the cystine sulphur has been replaced by a simple sulphur atom.

$$\mathrm{HOOC{-}\underset{\displaystyle NH_2}{\underset{|}{CH}}{-}CH_2{-}S{-}CH_2{-}\underset{\displaystyle NH_2}{\underset{|}{CH}}{-}COOH}$$

Lanthionine is non-reactive which explains the alkali resistance of the lanthionine sulphur. The lanthionine complex R–CH_2–S–CH_2–R plays a role as an intermediate in the alkaline treatment of wool. The mechanism of damage to the cystine in the wool caused by alkali has been thoroughly investigated. According to this work after the splitting of a proton from the α carbon atom, a β-elimination leads to the formation of a thiocysteine- and a dihydroalanine-residue (β-aminoacrylic acid):

$$\mathrm{{>}CH{-}CH_2{-}S{-}S{-}CH_2{<}} \xrightarrow{OH^-} \mathrm{\ominus{>}C{-}CH_2{-}S{-}S{-}CH_2{-}CH{<}}$$

$$\mathrm{\ominus{>}C{-}CH_2{-}S{-}S{-}CH_2{-}CH{<}} \rightarrow \mathrm{{>}C{=}CH_2 + {}^{\ominus}S{-}S{-}CH_2{-}CH{<}}$$

$$\mathrm{{}^{\ominus}S{-}S{-}CH_2{-}CH{<}} \rightarrow \mathrm{{>}CH{-}CH_2{-}S^{\ominus} + S}$$

$$\mathrm{{>}CH{-}CH_2{-}S^{\ominus}} \xrightarrow{OH^-} \mathrm{{>}CH{=}CH_2 + S^{2\ominus} + H_2O}$$

Next Page

The thiocysteine residues formed decompose into a cysteine residue and sulphur, the cysteine continuing to react due to the hydroxyl ions to form the dehydroalanine residue.

A second mechanism which has been postulated describes the formation of dehydroalanine directly from cysteine by cleavage of the H_2S group. The hydroxyamino acid, serine, reacts in a similar way.

$$>CH{-}CH_2{-}OH \rightarrow >C{=}CH_2$$

The reactive dehydroalanine residues thus generated can form the following products with the corresponding amino acids or other nucleophilic reactants present in the wool:

$$>C{=}CH_2 + >CH{-}CH_2{-}SH \rightarrow >CH{-}CH_2{-}S{-}CH_2{-}CH<$$

lanthionine

$$>C{=}CH_2 + >CH{-}(CH_2)_4{-}NH_2 \rightarrow >CH{-}CH_2{-}NH{-}(CH_2)_4{-}CH<$$

lysinoalanine

$$>C{=}CH_2 + >CH{-}(CH_2)_3{-}NH_3 \rightarrow >CH{-}CH_2{-}NH{-}(CH_2)_3{-}CH<$$

ornithinoalanine

$$>C{=}CH_2 + NH_3 \rightarrow >CH{-}CH_2{-}NH_2$$

β-aminoalanine

$$>C{=}CH_2 + H_2O \rightarrow >CH{-}CH_2{-}OH$$

serine

$$>C{=}CH_2 + H_2S \rightarrow >CH{-}CH_2{-}SH$$

cysteine

During the reaction with the nucleophilic amino acid side chains, new lanthionine, ornithinoalanine and lysinoalanine cross-links are produced in the wool fibre from the original disulphide links. It is generally accepted that the formation of lanthionine leads to a deterioration in the mechanical properties. This can be explained by the unzipping-like thiodisulphide exchange which takes place as the wool is stretched. With the formation of lanthionine and extension of the other links produced while damage caused by the alkali is taking place, this exchange is prevented, leading to a stiffening of the wool and worsening of the mechanical properties. Both in the case of alkali damage with the formation of lanthionine and in the case of the thiodisulphide exchange, Mechelbeck established in 1963 that the free H_2S formed from the cysteine acts as a catalyst. Thus, the following reactions may be considered conceivable:

$$>CH{-}CH_2{-}SH \rightarrow >C{=}CH_2 + H_2S$$

$$>CH{-}CH_2{-}OH \rightarrow >C{=}CH_2 + H_2O$$

$$>CH{-}CH_2{-}S{-}S{-}CH_2{-}HC< + H_2S \rightarrow >CH{-}CH_2{-}S{-}S{-}H + HS{-}CH_2{-}HC<$$

$$>CH{-}CH_2{-}S{-}SH + HC{=}C< \rightarrow >CH{-}CH_2{-}S{-}S{-}CH_2{-}HC<$$

This mechanism would explain the significant deterioration in mechanical properties seen to accompany alkali damage – the chain-segment mobility of the wool proteins is increased by cleavage and reforming of the cysteine links. This can produce a more pronounced change in the conformation than a change in pH alone. The newly formed cystine links may be formed at completely different sites to those before the bonds were broken and hold the wool protein chains in their new conformation. This would be possible, e.g., if the thiocysteine residue reacts with one of the dehydroalanine residues arising from the serine (source: Werkes).

Lapping,

I. Covering immersion rollers of a padder or impression cylinder (in the case of Rouleaux printing presses) with a fabric for the purpose of improving the liquor pickup or providing an even, elastic pressure pad. → Lappings; Tubular felt.

II. Difference in diameter between the centre and end of the roller in the case of the elastic rollers of calenders.

III. Lowest layers of the cover on decatising cylinders.

Lappings Used for iron printing cylinders in roller printing. These can be made from ramie or viscose in the warp and wool in the weft.

Large batch rolls Used to transport large quantities of goods and for storage for continuous processing machinery. Special winding machines are used to make large batch rolls (for example, Hyperbola-, surface and other winding devices). → Giant batch rolls.

Large repeat print styles Large repeat printed articles are on the one hand the → Sari and sarong of traditional Far-Eastern ladies' clothing and traditional clothing of the black African population and on the other, table cloths, bed linen, curtains, terry towels, ready-to-wear patterned ladies' outer clothing, flags and printed carpets.

Large repeat printing Printing on rotary printing machines with large circumference screens. These increase the design possibilities but at an extremely high cost. Screens are significantly more expensive and sometimes the components of the printing machinery have to be changed bring the circumference of the screen to 2 m. A further development is electronic controlled → Intermittent printing by two partially engraved complementary screens which lift and print in a reciprocating manner. Their use is of interest for large repeats for black-out curtains and shower curtains.

Large repeat rotary screens These combine the advantage of a high print speed offered by the rotary screen with that of a large format offered by the flat screen. For reasons of stability, the perimeter of the screen can only be increased to 2 m. They are used for printing table cloths, carpets, deco fabric and clothing materials with special patterns.

Previous Page

LAS Linear → Alkyl benzene sulphonates.

Laser Abbreviation for “Light Amplification by Stimulated Emission of Radiation”, i.e. light amplification by excited emission of radiation. The laser is an instrument for producing very small, concentrated spots of high-intensity light. The possible areas of application in the textile industry are measurement and testing methods, photochemical processes and material processing:

a) heating threads,
b) patterning effects on textiles to change their dyeability,
c) producing surface roughness,
d) welding,
e) cutting textile webs whilst simultaneously sealing the raw edges,
f) cutting,
g) monitoring for surface defects.

On account of its high radiation density and controllable power, the laser has found a place in many areas of material processing where the advantages of laser radiation with its characteristic monochromatic and parallel nature, extreme power of convergence and power density are exploited. Infrared lasers such as CO_2 lasers, neodymium YAG lasers, neodymium-gas lasers and ultraviolet lasers such as excimer-lasers are used for material processing involving direct interaction between the laser and the material. Argon- and krypton-ion lasers and dye lasers on the other hand have a catalytic role in surface treatments (chemical processes). Used in industry for years, the IR lasers, predominantly CO_2 lasers with $\lambda = 10.6\ \mu m$, are utilised in metal processing. These generate continuous radiation of the highest energy with effective efficiencies of up to 20%. By exciting the rotational or oscillating states of the molecules, the radiation energy is made available almost completely in the form of thermal energy. Because of the high power of the lasers used today, enough energy is deposited in a given material volume to be used for industrial purposes, such as welding, in spite of the low absorption coefficient for IR radiation in the case of most materials. For textiles, the CO_2 laser can be used industrially as an intense, directional heat source which can be applied locally.

Radiation using IR lasers appears to be problematic for all surface treatments of polymers. The treatment is critical in regard to the experimental conditions and if the choice of laser intensity is unsuitable, the materials will be heated beyond their melting points. Controlled treatment of the surface alone is not possible in the case of the classical interaction because the absorption coefficients are low and plasma coupling analogous to metal processing has so far not been achieved. The use of excimer-lasers which operate within the ultraviolet range offer more possibilities. The advantages of using UV light are mainly to be found in the high extinction coefficients which range from about 10^3–10^4 for most organic polymers within the 400 nm wavelength range. The high absorption coefficients and the energy situation of the UV radiation offered by these lasers make possible the high-precision processing of sensitive polymer materials. Excimer-lasers are therefore used in the processing of polymer films made from polyester, polyamide and polymethylmethacrylate etc. where the controlled removal of material is of paramount importance. These are pulsed gas lasers containing noble-gas halogenide molecules which are stable in their excited state (excimer = excited dimer). The lasers can be operated at different wavelengths in the UV spectrum depending on the choice of excimer.

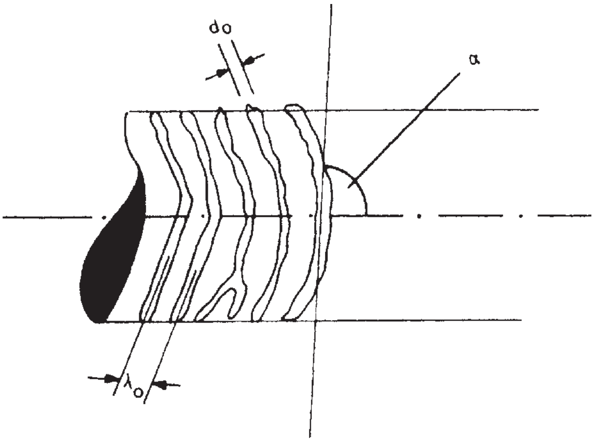

Fig.: Characteristics of the surface structure of polymers following irradiation by UV laser (according to Schollmeyer).

Examination of the irradiated surface yielded an interesting aspect of the UV laser radiation of polymers. On the one hand, the knowledge gained from experiments on polymer films relates to the chemical composition of the immediate surface. On the other, physical changes to the structure of the irradiated surfaces are described as well. Unlike the surface of plastic films which is smooth, the surface exposed by ablation shows a structure which can be described as a uniform arrangement of hills and valleys typically 1–2 µm apart (Fig.). A conclusive explanation for the appearance of such structures has so far not been forthcoming (source: Bahners and Schollmeyer).

Laser Doppler Effect Describes the frequency shift of monochromatic laser light when reflected from materials in motion. This effect can be used, for example, for contact-free length measurement on textile webs. The measurement set-up differs according to whether it is a difference or reference Doppler method. The reference method is also used in the textile industry for velocity measurement in association with large helium/neon lasers. For the purpose of miniaturisation

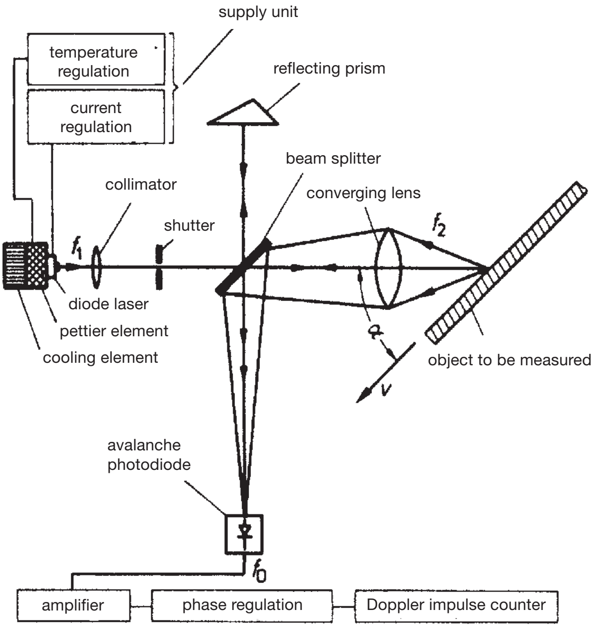

Fig.: Optical construction and electronic signal processing in the contact-free measurement of length using the reference Doppler process.

coupled with high radiation power, a compact laser diode is used as the light source with a stabilised wavelength of 784.580 nm.

An optical arrangement which is similar to a Michelson interferometer (see Fig.) is used for length measurement according to the reference Doppler method. The transmitted laser diode beam with frequency f_1 is split into a measurement and reference beam by means of a beam splitter. The measurement beam which passes straight through and forms the velocity vector v with an angle α, impinges on the moving goods to be measured and is reflected diffusely from the rough surface. Because of the Doppler effect, the frequency of the scattered light changes to f_2 and can be collected via a lens system and, via the beam splitter, is superimposed with the reference beam on its return path from the mirror prism. Superimposing the two light beams of neighbouring frequencies produces a frequency difference f_D, i.e. a beat frequency which represents a parameter related to the advance velocity v of the goods being measured. The intensity fluctuations of the laser light produced by the beat are converted into an electrical signal via an Avalanche Photodiode. The following equation applies to the beat of Doppler frequency f_D picked up from the output of the photodiode:

$$f_D = \frac{2\,v \cdot \cos\alpha}{\lambda}$$

where λ is the wavelength of the measurement beam emitted and the high order components can be neglected. The Doppler signal oscillations are continually counted for the length measurement. The number of Doppler oscillations counted within a measurement period t is n. The following relationship then applies to the distance l advanced by the goods being measured during the same period t:

$$l = v \cdot t = \frac{n \cdot \lambda}{2 \cdot \cos\alpha}$$

This equation shows that, providing λ and α are constant, the number of the recordable Doppler oscillations n is dependent on the distance advanced by the goods being measured alone and not on the speed. By counting the oscillations, it is possible to decide on the length of the measured goods sought for. However, a prerequisite for this is that the large fluctuations in the amplitude of the Doppler signal caused by the surface structure are compensated for electronically. The macrostructure of the surface, on the other hand, does not affect the Doppler frequency or the length measurement.

The Doppler signal at the avalanche diode output is processed by means of a special electronic circuit to give a continuous pulse count. The heart of the electronic unit is a phase-locking loop (PLL) covering several frequency ranges with automatic forward and back switching which is used to compensate for large fluctuations in the amplitude of the Doppler signal. At the same time, an internal oscillator is controlled so that its phase agrees with that of the Doppler signal or shows a constant phase difference, i.e. it in a synchronised state. In this synchronised state, the oscillator signal is used for the oscillation count instead of the original Doppler signal. If the synchronised state is momentarily interrupted due to extreme fluctuations in amplitude, then the oscillator frequency aims, in accordance with an exponential function, for the middle frequency of the prevailing PLL range where the fluctuations in measurement arise. These fluctuations are greater, the further the frequency just left lies below (positive sign) or above (negative sign) the middle frequency. Synchronisation starts again when a certain signal level has been reached. Due to the low advance speeds of the textile machines (approx. 1.65 m/s max.), the Doppler frequency range in question is relatively small, stretching from approx. 110 kHz to approx. 2.5 MHz and is divided up into 8 sub-domains (according to Zervos).

Laser light If a single wave of light is observed (Fig. 1), then this will appear as an electromagnetic transverse wave. The directions of oscillation of the electrical and magnetic vectors are at right angles to the direction of radiation and perpendicular to each other. The wavelength λ is found from two neighbouring maxima of the sine-wave oscillation. Visible light lies within the wavelength range of 400–700 nm which, in a

Laser positioning unit

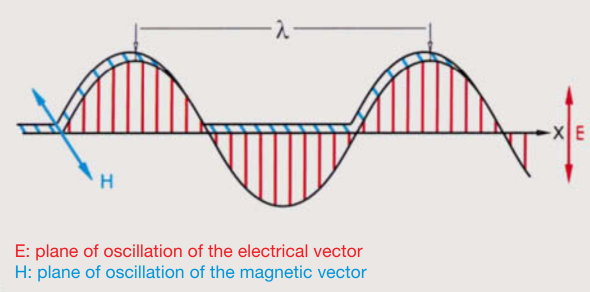

Fig. 1: Linear polarized light wave.

vacuum, corresponds to a frequency of 10^{14}–0^{15} Hz. Consequently, white light is composed of a spectrum of wavelengths and completely randomly emitted, i.e. out-of-phase wave chains.

In contrast to this, a laser can emit monochromatic light of one or several wavelengths which may be regarded as coherent. Waves which are emitted from a single source simultaneously are described as being coherent. The length of coherence is found from the line width of the laser light used and corresponds to the length of a wave chain oscillating in phase.

The resulting waves may be amplified, extinguished or shifted depending on the phase of the original wave chains. This phenomenon is called interference and is only found for coherent and, therefore, monochromatic light (Figs. 2 + 3).

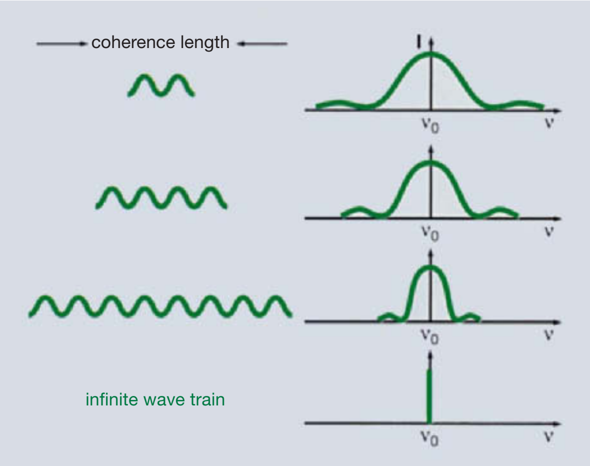

Fig. 2: Coherence length and frequency width of monochromatic laser light.

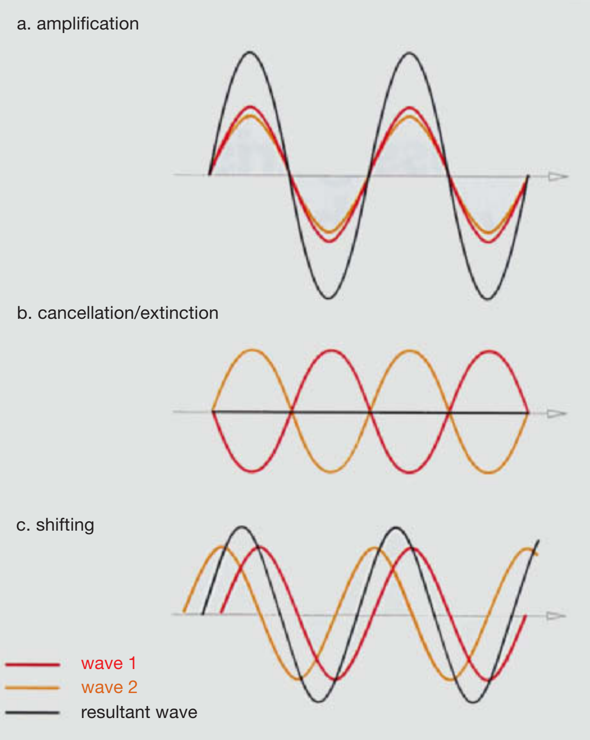

Fig. 3: Interference between two wave trains.

Laser positioning unit This device is used in rotary screen printing to position rotary screens during a pattern change. It enables precise adjustment to be made to the longitudinal, lateral and diagonal registers. Laser beams search for start marks on the screens to obtain the register (Figs. 1–3).

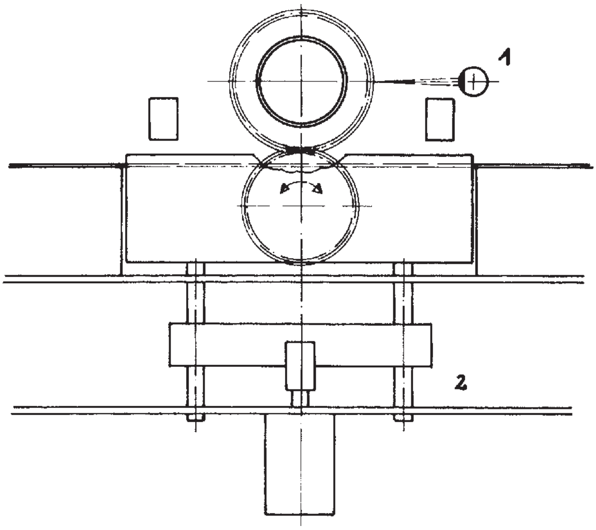

Fig. 1: Laser positioning unit for precise location of screen rollers.
1 = laser interrogation; 2 = step motor drive.

Laser Scanning Analyzer (LSA). These are used as a rapid high-resolution monitoring system for laser

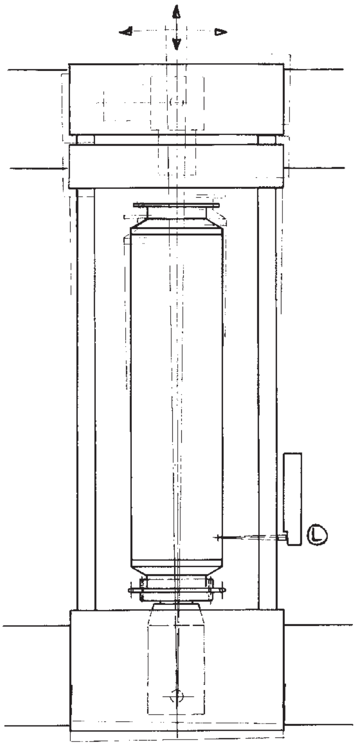

Fig. 2: Laser interrogation (L) of a screen roller in plan view.

control of optically detectable surface defects on material webs such as textiles, paper, rubber, plastic and non-wovens etc. whilst in motion. The LSA detects and analyses the surface defects. An integrated processor determines the size and number of defects, triggers the alarm signal and controls the marking and recording devices as well as other external monitoring equipment. Manuf.: Ferranti.

Laser screen engraving Various recording methods find use in the different colour separation processes and, on occasion, in direct engraving processes such as variable block mapping (non-continuous line location with offset) or continuous spiral recording and decoding (e.g., the Chromatograph CTX 330 from Hell).

In this case, an electronically controlled diamond-tipped engraving tool is used to engrave the copper cylinder directly. However, mechanical systems hit the upper limits of stability under load relatively quickly. In the case of classical systems, the speed of plot is limited by the speed of the controller and the necessity of the signal duration to achieve the desired effect (e.g., mechanical removal of copper by the diamond tip). It was for this reason that the use of lasers was considered but, what was being considered, was a “loosening” of a filled body e.g., a screen). However, from the amount of energy calculated to supply a laser of sufficient power it became apparent that a method such as this would not be economically viable. The following method has recently been developed: a laser beam that can be modulated is made to travel in a spiral across a classical nickel screen which had been completely blocked-off with lacquer. The CO_2 laser would be sufficiently powerful to burn the lacquer off in microseconds leaving the specified voids in the screen open. Theoretically, a laser flash such a this would last from 5–7 μs. Up to 27 000 spots could be picked off per second. A device has therefore been produced for this purpose and can apply the design to the screen directly at high speed and with high precision. The edges of the burnt out holes are sharply contoured and are sealed by the singeing and melting process. The lacquer used for this purpose is not related in any way to the original photosensitive lacquers and can be selected from an existing range of the most durable lacquers (even self cross-linking) thus offering the following advantages:

- lacquered nickel screens can be prepared and kept in stock,
- in the case of self cross-linking lacquers, drying alone and not stoving is required,
- the screen is ready after the laser treatment; no after-treatment is required,
- defects have so far hardly ever been observed because the data supplied by the computer merely controls a laser beam and nothing mechanical,
- the tracing speed depends on the mesh of the screen

as this determines the line density of the advance movement,

- the time used is shortened by the fact that the film no longer needs to be exposed, nor does the exposed screen need to be developed (washed out), dried, hardened or indeed re-lacquered with extraction or subjected to heat treatment a second time.

The screen is pushed on to a nickel/wood cylinder. The bearings are open on one side and the screen can be changed so that different repeat sizes from 640–1017 mm can be used. An elastic pneumatic support is used in fixing the screen to the cylinder, i.e. the nickel cylinder is pneumatically set under excess pressure which gives rise to the slight stretching which is enough to hold the precisely fitting screen in the exact position. The cylinder is now allowed to run in the two precision bearings which are centred exactly. From a mark on the screen, its exact circumference is calculated by a computer and, using this, the number of pulses from the laser impingeing on the surface during a single revolution is established. In regard to adjustment, avoidance of “seams” or having to work with adhesive stripes, this is better and simpler than the copying or exposure process using a film. Apart from this, the difficulties encountered in mounting the films on the circumferences which are not quite exact, in spite of high precision adopted in making the screens using electrodeposition, are excluded (according to Eibl).

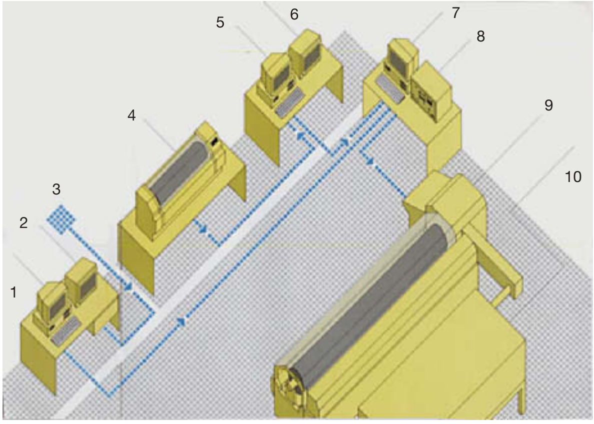

Fig. 1: Laser screen engraving department (Stork).
1 = computer: CAD input; 2 = control colour computer screen; 3 = design development system; 4 = drum scanner; 5 = computer: drum scanner; 6 = control colour computer screen; 7 = computer: laser engraver; 8 = control unit; 9 = laser engraver; 10 = laser unit.

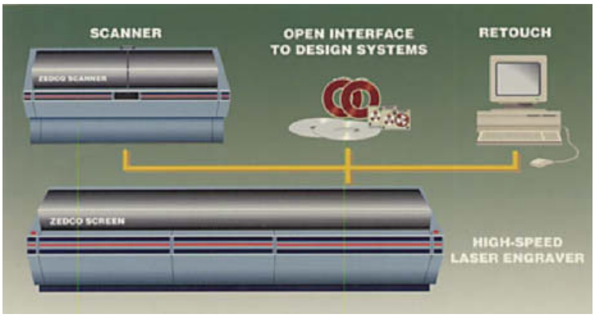

Fig. 2: Laser screen engraving (Zedco Screen System) with scanner, interface, retouch station and laser engraving machine.

Fig. 1 shows a laser screen-engraving department in which the design can be stored digitally during the operation and then transferred to the screen. The time-consuming and costly preparation of the films is thus made more economic and, in some cases, completely superfluous. The development and polymerization stages after engraving the screen are no longer necessary. The screens are immediately ready for use. The laser can be focused to a resolution of 50 µm; previously the resolution was limited to 100 µm. With this higher resolution, screens can be made, for example, for printing silk ties with cashmere patterns involving the highest detail. In addition to this, using laser engraving it is possible to engrave typical Rouleaux designs on the screens directly. All engraving methods in common use can be carried out both with and without tension roller and, in the last case, it is also possible to choose between screens with or without end rings. If engraving is to be carried out with end rings, these can be bonded in beforehand so that the screen can then be used immediately after engraving. If the design is selected without end rings or tension roller, the repeat can be changed immediately, quickly and without any intermediate steps.

Other components for a plant such as this could be:

a) MCD system (Manual Computer Design) for correcting or retouching designs or for preparing colour separations with overlappings based on a contour drawing. The MCD system can be used to mirror the design and prepare diagonal geometric patterns such as those of Zedco (Fig. 2).
b) An 800 W generator can be added to the plant for wide machines.
c) Automatic focus and repeat adjustment, for example, from Zedco (Fig. 3).
d) Through fine adjustment, suitable for engraving half-tone designs on screens with mesh sizes of 125 and 155.
e) TS 90 scanner (black and white) with high processing speeds and high resolution.
f) CS scanner for colour scanning, is capable of scanning half-tones and colours just as well as the usual black-and-white designs, with electronic point generator, speeds of 1000 r.p.m. and resolutions down to 12.5 µm (Fig. 4).
g) FP 89 film plotter with a maximum width of 1850 mm and maximum circumference of 1018 mm.

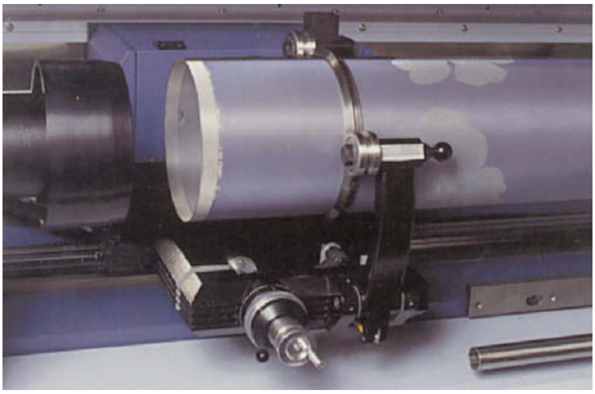

Fig. 3: Feeding the screen roller into the laser engraver (Zedco).

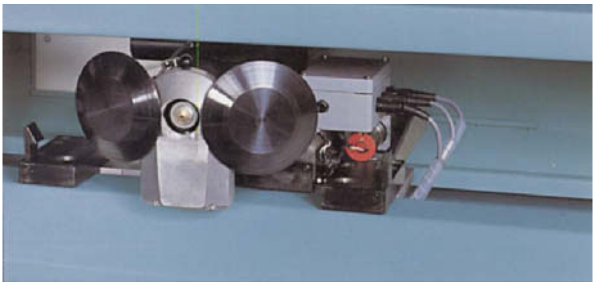

Fig. 4: Laser engraving machine (Stork LE-3000) with high-speed laser (max. speed 1000 rpm).

Fig. 5: Flat screen laser engraving (M. S.).

Since ITMA 1991, laser engraving tools have also been available for flat screens (from M.S.). (Fig. 5).

Latent crimp Crimp in a texturised yarn, produced by thermal treatment or by stretching and subsequent relaxation, can be released.

Lateral register in roller printing By shifting the bearing shells horizontally, it is possible to move the printing roller into the correct position so that the engraved figuring matches the whole pattern exactly in the repeat. However, the bearing shells can also be shifted sideways via threaded spindles so that the spindles and the printing cylinder are moved together to a different position. The bearing shells are then screwed back on one side. This device is referred to as the lateral register in Rouleaux printing.

Latex Basically, the liquid extract from the rubber tree (Hevea brasiliensis) and other plants including lianas (a.k.a. → Caoutchouc) that supply a liquid form of latex. Latex is used as the starting material for the manufacture of materials such as latex yarns. However, these days the natural product is only rarely used on its own and is more frequently used mixed with → Synthetic rubber. For this reason, latex now usually refers to mixed emulsions of natural rubber and vulcanisable synthetic rubber.

Emulsions of water-insoluble polymers are produced by emulsion polymerisation. They are used as latexes during the following process stages (in the manufacture of carpet backing, for example).

Typical parameters in an emulsion polymerisation process are (see Fig.):

1. Start:

a) One micelle consists of 50-100 surfactant molecules, each monomer micelle having a diameter of 4–5 nm. There are approx. 10^{18} empty emulsifier micelles at the beginning of the polymerisation and 10^{10} monomer droplets per ml (∅ 1000 nm).

2. Reaction (started by initiation):

b) At 50°C, approx. 10^{13} radicals per ml of emulsion are formed per second. 10–20% of the conversion soon takes place, there being approx. 10^{15} particles per ml present.

c) Next, all unused (empty) emulsifier micelles are consumed, achieving a conversion rate of 50–60%.

d) All monomer droplets are consumed by the end of the process.

e) The final diameter of the latex particles is from 50–300 nm.

Latex yarns Yarns extruded from latex, elastic rubber yarns (→ Rubber fibres) that are subsequently vulcanised.

Lattice-feed table A continuous roller-operated lattice conveyer made from wood, metal or plastic laths used to convey any type of goods. They often form the connection between two non-continuous processes.

Laundered articles → Laundry articles finished in a “cupboard dry” condition.

Laundering, clearing → Fabric clean washing agent.

Laundering, hydrodynamic process → Fabric clean flow wash process.

Laundering performance (washing perform-

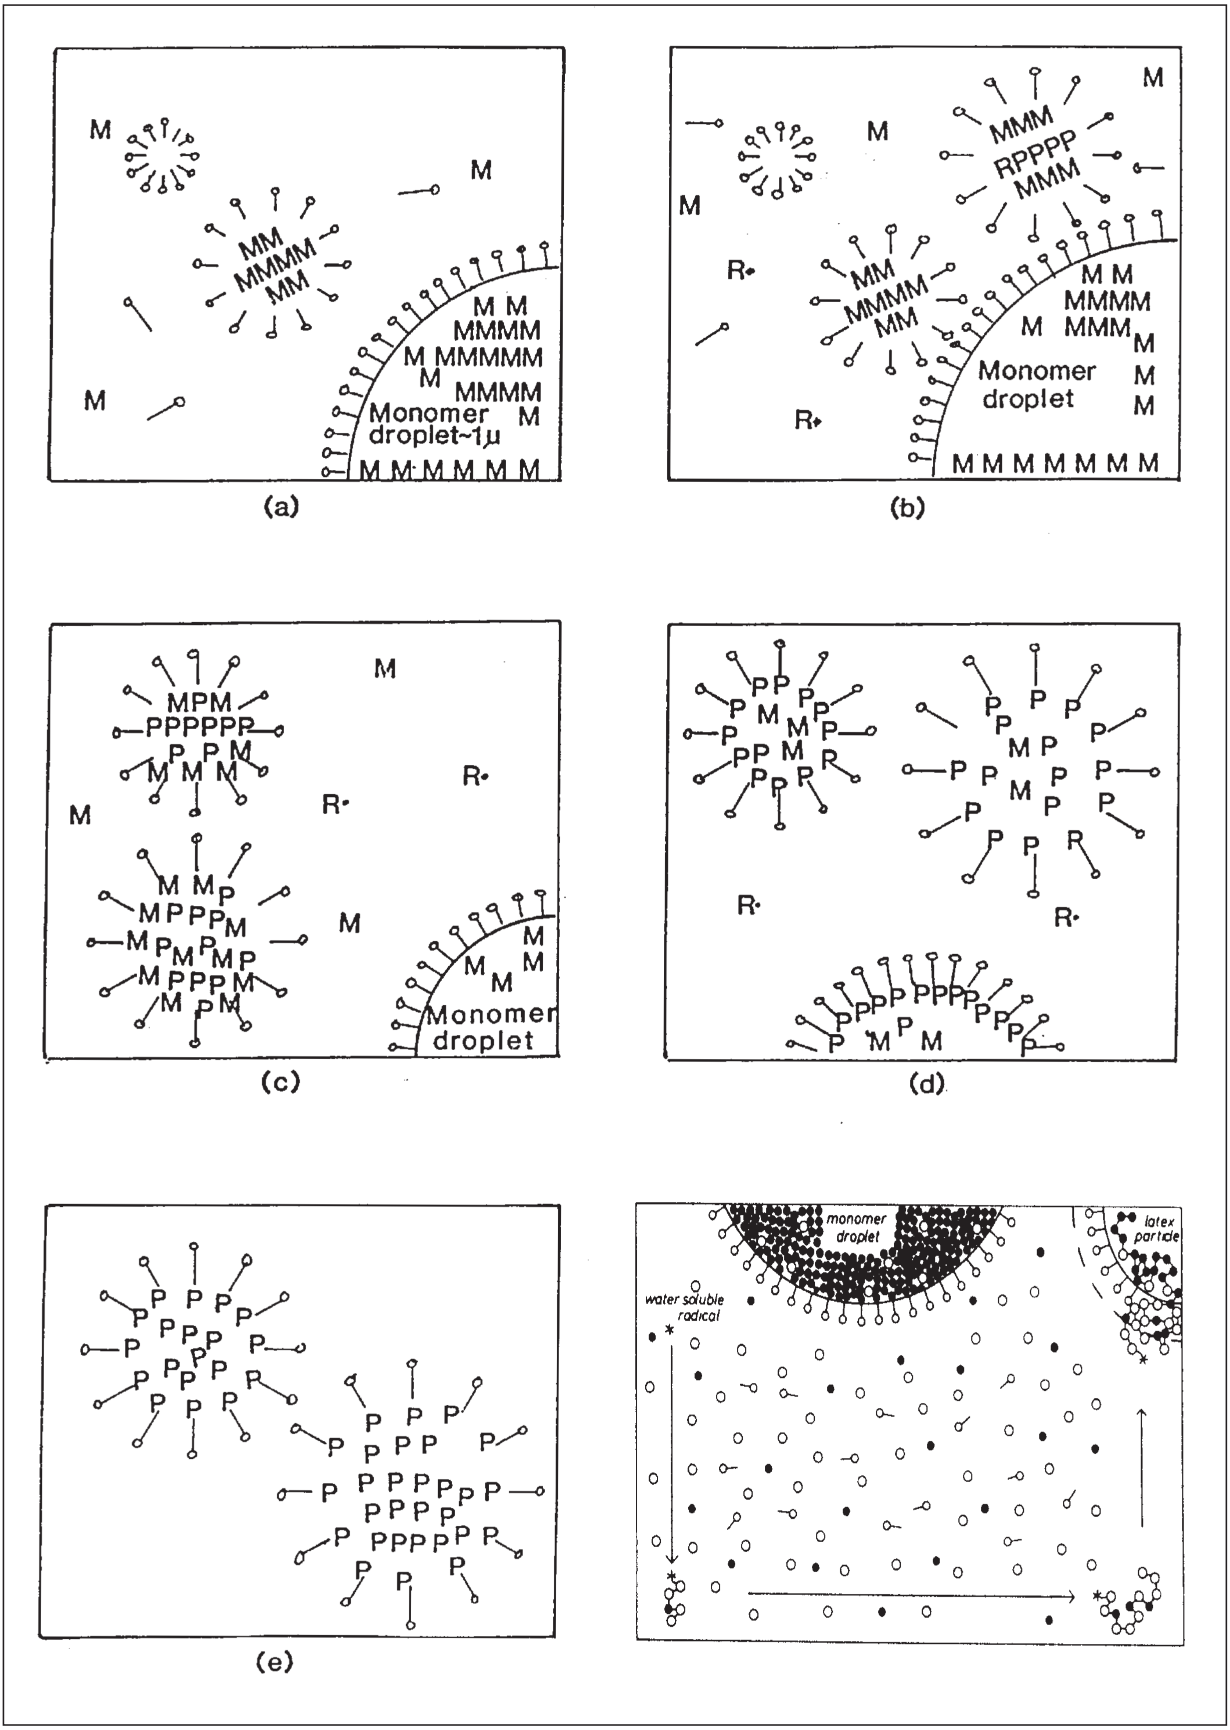

Fig.: The latex polymerisation process. M = monomer; P = polymer; R· = initiating radical.

ance). Laundry efficiency in terms of kg/hour processed. High laundering performance requires economy in processing. It is directly proportional to the loading ratio and inversely proportional to the required laundry time, i.e. the higher the loading ratio (in kg/l) and the shorter the time, the higher the performance, though only in relation to the laundry throughput.

Launder-O-meter (wash-O-meter) This is an American standard washing machine consisting of a heated boiler with motorised drive for using 10–20 screw-on bottles (500 ml capacity and 42 rpm) that contain 15 steels balls (∅ 6 mm) to mechanically manipulate the test samples during testing. This apparatus is especially recommended for laundering and milling durability testing but is also used as a wet fastness testing and HT dyeing machine. Manuf.: Atlas Electric.

Laundrinform Swiss information service based in Zurich for the laundry industry → Technical and professional organizations.

Laundry Industrial plant (large-scale plants are usually of industrial form) normally engaged in the → Washing of → Laundry.

Laundry articles Textile contract goods that are cleansed to remove soiling in → Washing machines.

Laundry for 100°C wash describes textiles that can withstand being laundered at the boil. Classified according to the Krefelder Wäschereiforschung (Krefeld Laundry Research Institute) as follows:

- underwear and bed linen etc.,
- intensive wash,
- pocket handkerchieves,
- kitchen laundry,
- workwear.

Laundry goods Classified as follows:

I. White goods: a) Raw calico and b) light resination finish (such as chiffon, cretonne and renforcé), glazed finish (such as lawn), heavy finish (such as shirting).

II. Clothing: a) underwear in smooth (such as batiste, chiffon, cretonne and renforcé) or brushed (such as beaver and flannel), b) outer clothing such as blouses and shirts, white (e.g. batiste, linen, poplin, and renforcé), yarn-dyed (e.g. bast silk, batiste, poplin and zephyr) printed (e.g. percale), brushed (flannel) and collars.

III. Batiste for blouses, lining, dresses, aprons and laundry etc.

IV. Bath-, hand-, kitchen-towels and pocket handkerchieves in grey/bleached, rope-dyed, linen-union and linen grey/bleached.

V. Bed linen and bedding: a) pillows slips and bed covers, white (plain smooth weave and patterned, either striped or figured) and coloured (yarn-dyed checks or floral prints), b) non-removable covers for feather filling, mattresses, quilts, in smooth weave (linen and twill), atlas weave, striped or figured.

VI. Table cloths and serviettes.

Laundry machines Machines for → Washing in the laundry including those for pre- and post-treatments. Differentiated as follows:

I. According to internal drum construction (→ Inner drum): a) single-sided: →: Front loading washing machine; Tub washing machine, b) double-sided: → Horizontal washing machines and long-drum washing machines, c) suspended without bearings.

II. According to the wash system: a) static liquor: multi-bath washing machines, b) flowing liquor: clear flow-, counter flow- and through flow- washing machines, c) according to batch separation: through flow-washing machines).

Laundry machines also include the →: Driers for textile materials; Centifruges; Mangle; Pressing in the laundry.

Laundry marker → Textile markers (inks, pencils, ball-point pens and marker pens) especially designed for the laundry and dry cleaning, with appropriate practical durability but easily removed in case of spotting.

Laundry quality control In laundries, for process and quality control, regular tests are carried out on fabric washed with the laundry, after 25 and 50 washes, to monitor →: Tensile strength loss; Damage factor; Ash content; Whiteness, degree of.

Laundry softeners → Fabric softeners.

Laundry wash,

I. → Raw wool scouring (as opposed to → Backwash).

II. Washing of soiled linen in the → Laundry (as opposed to → Domestic washing).

Lauric acid $C_{11}H_{25}COOH$. Component of coconut oil, laurel oil and sperm oil. Among other things, used for the manufacture of textile auxiliaries such as detergents.

Lawn Bleached linen, cotton or half linen fabrics with a linen finish. Mainly used for regularly washed articles.

Lay → Plaiting down.

Layered silicates From natural and synthetic sources, layered silicates have special structures that have shown interesting technical application properties. Used together with surfactants they have found many and varied applications so that an understanding of the interactions between layered silicates and surfactants has now become essential.

The different types of soils and their possible interactions with substances relevant to the environment are manifold. In order to provide a physico-chemical explanation for the contamination of soils due to environmentally problematic substances, the important components of the soil must be examined. Clay materials are laminated silicates of high reactivity. As can be seen in the case of kaolinite and montmorillonite in Fig. 1, for example, layered silicates consist of two or three

Layered silicates

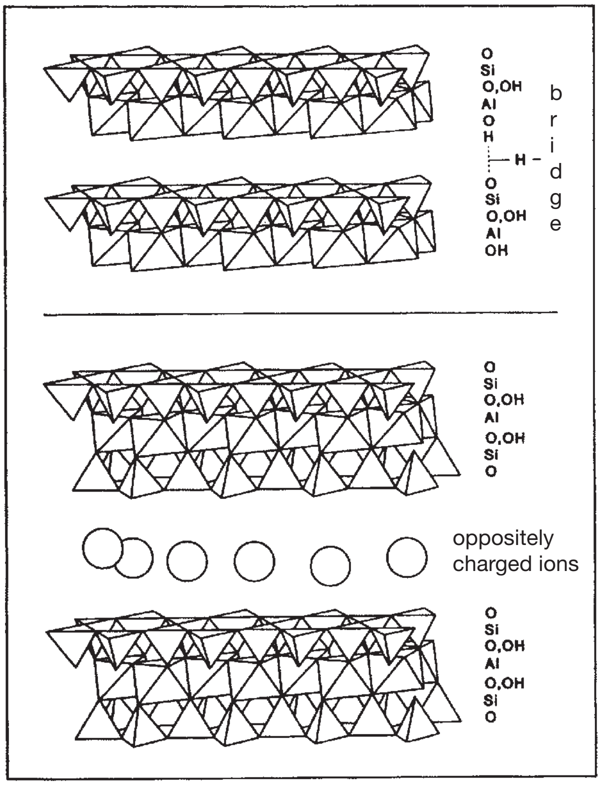

Fig. 1: Schematic representation of the structure of layered silicates as found in kaolinites (top) and montmorillonites (below).

layers with tetrahedral and octahedral structures. The co-ordinate silicon ions in the tetrahedral layers are surrounded by oxygen atoms and the co-ordinate aluminium ions in the octahedral layers are surrounded both by oxygen ions and hydroxyl groups. The charge in the layers occurs because co-ordinate metal ions have been substituted with atoms of lower valency (e.g., magnesium ions instead of aluminium ions). This fault in the lattice produces a negative excess charge in the layers which is compensated for by the positive charge of cations, such as calcium or sodium, located between the layers. The edges can carry positive charges of different magnitude depending on the pH.

Montmorillonite is a three-layered silicate with swelling properties, i.e. water can be absorbed between the layers and the cations there can be exchanged for others. The situation is different for kaolinite which does not have swelling properties because the hydrogen bonds between the two layers prevent swelling. As montmorillonite makes up the major proportion of naturally occurring bentonite, the natural occurrence of this clay is widespread. Kaolinite is correspondingly the main component of kaolin.

Within the layered lattice of this group of substances, the four oxygen atoms which surround the silicon atoms form a tetrahedral structure. However, three of these also represent the corners of neighbouring tetrahedra. The two tetrahedral layers are joined via the cor-

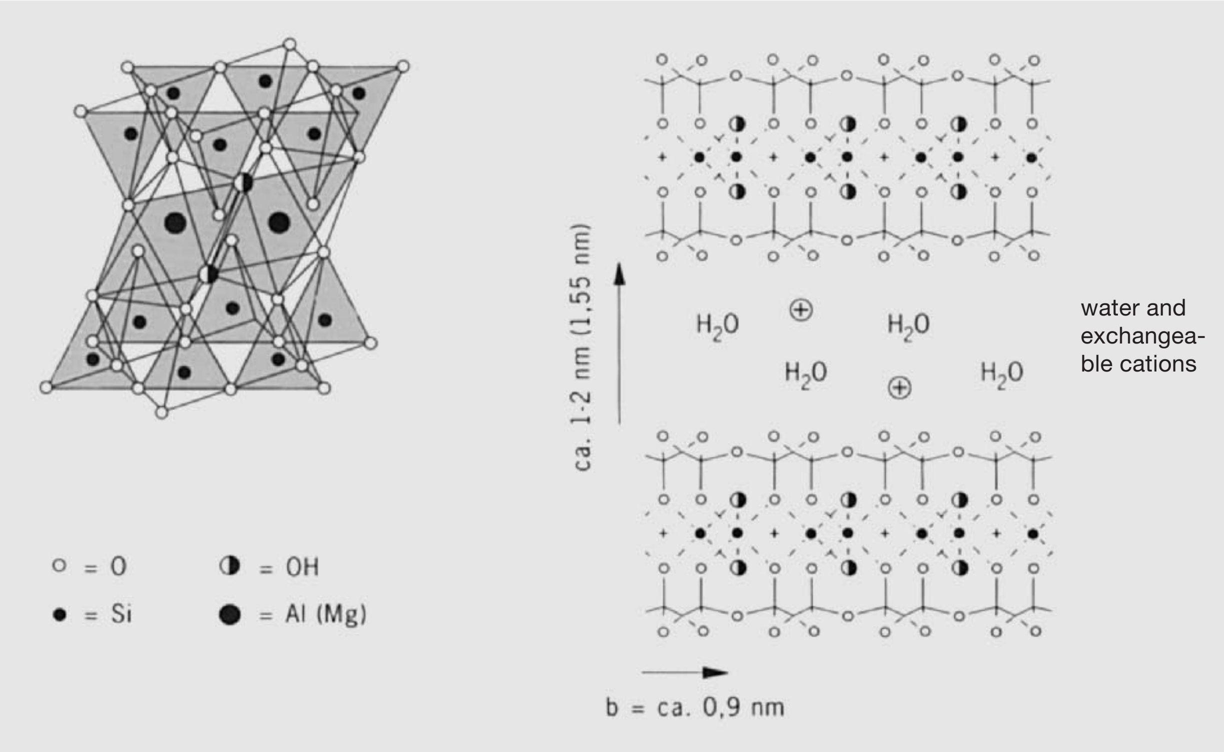

Fig. 2: Structure of layered silicates.

ners of the tetrahedra through metal ions such as Al^{3+}, Mg^{2+} or Li^{+}. At the same time, the cations which form the co-ordinate bonds are arrange octahedrally, the free valencies being satisfied by hydroxyl groups. Depending on the valency of the co-ordinating cations, the silicates are described as di-octahedral or tri-octahedral (Fig. 2). Cationic surfactants are absorbed on layered silicates of low charge in single, double or pseudo-triple layers. The amount of surfactant absorbed is determined by the swelling properties of the layered silicate and the structure of the cationic surfactant. The main points of possible interaction between cationic surfactants and layered silicates in the individual layers of soil, the soil levels, vary and depend on the physical properties of the soil.

Soil is a mineral, porous medium the pores of which contain air, water and organic and inorganic substances dissolved in water. The upper layer (the so-called top soil) is saturated with vegetation, humus, animal life (such as worms and lava, etc.) and micro-organisms. The oxygen content decreases with increasing depth, i.e. a transition exists from aerobic to increasingly anaerobic conditions. The proportion of biological material and humus also decreases as the percentage mineral content increases. The different layers of soil are identified as top soil, subsoil and bedrock, the subsoil and bedrock containing predominantly mineral components such as layered silicates (source: Schwurger).

Lay-on-air stenter An air control system for the fabric running in parallel to the fabric pathway and using a combination of slit and jets. Two fans in a vertical shaft with changeable direction of flow. These ventilators, in each field, allow an over and under-flow of air to be split through regulating flaps to control the air flow. The fabric is carried by the stream of hot air emerging from the jets without the aid of any additional guiding mechanisms.

L-calender To achieve the optimum calendering effect the parameters speed, temperature and pressure must be matched to the quality of fabric. Three- and multi-roller calenders define the pressure via a central pressure unit (Fig. 1). The changes in pressure act equally on all nips. In the three-roller Nipco L-calender according to the Kleinwefers KTM pattern, the working pressures are individually controlled at each nip, i.e. two effects, such as lustre and handle, can be achieved for the goods during a single run in one calender (Fig. 2).

Design characteristics:

- two calender nips where the working pressures can be adjusted individually,
- special rotating, wear-resistant, high elasticity cover,
- electrical motor-driven pressure-width control with angle measurement.
- steel roller with maintenance-free electrical hot water system.

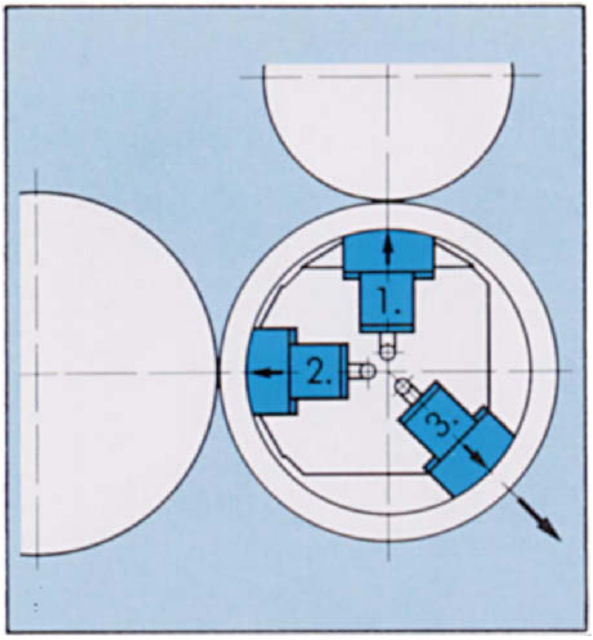

Fig. 1: Arrangement of the supports and of the three calender rollers in L-form.
1 = to steel roller; 2 = to cotton roller; 3 = as drawback element.

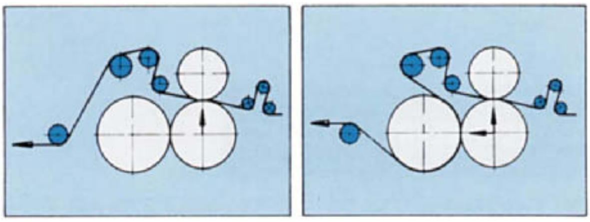

Fig. 2: Passage of fabric over Nipco roller.
Left: through one gap only for glazed and sheen effect; right: with the special cotton roller for a glazed and matt effect with a soft handle.

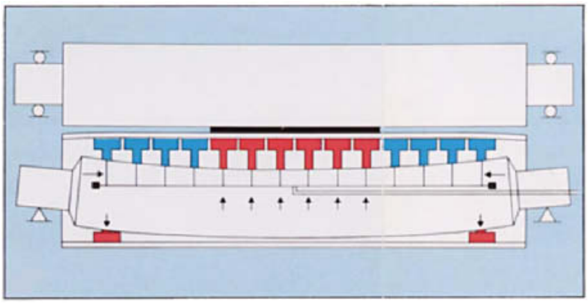

Fig. 3: Paired Nipco and steel rollers carrying a narrow fabric sheet.

The high-elasticity polyamide-based special cover rotates around a static yolk fitted with pressure elements arranged at 90° to each other. The cover is guided on a defined hydraulic fluid film and is not integrated with bearing forces in its dynamic components. Hydrostatic back-pressure stabilises the cover and guarantees a defined load contour in the individually controllable calender nips (Fig. 3). The contact surface of the cover for heating the steel roller is controlled simultaneously via the back-pressure in association with the motor-driven width adjustment.

LC-50 and LD-50 values These parameters are used to describe the lethal concentration (→ Lethal limit) of toxic substances. The acute toxicity is given as the average lethal dose (50% of tests) in mg/kg live body weight for oral toxicity (LD-50) and as the lethal concentration in mg/l for inhalation toxicity (LC-50).

LDPE Low-density polyethylene; → Polyethylene.

Lé French carpet-width measurement unit. 1 lé = approx. 70 cm.

Lea Non-metric unit in the English measurement system.

I. Lea yarn number for linen yarn (1 lea = 1 hank at 300 yards/lb; corresponds to the American Cut-system for carded yarns) and synthetic fibre yarns (1 lea = 1 hank at 120 yards/lb on 1.5 yards reels).

II. Lea strength: tensile strength giving the no. of lbs tensile load required to break 1 lea of a particular yarn.

III. Lea Test: Skein strength test (fibre-bundle tensile strength).

Lead (Pb). Atomic weight 206.9. Very soft, blue-grey metal (softest heavy metal) highly ductile, low strength and easily worked; surface oxidises on contact with moist air, strongly attacked by carbon-dioxide-free water (lead pipework), soluble in nitric, acetic and lactic acids but barely soluble in hydrochloric and sulphuric acids. Compounds: Lead is mainly bivalent, most of its salts are colourless and highly poisonous, its oxides are yellow to reddish. The dioxide hydrate $PbO_2 \cdot H_2O$ is a weak acid (lead acid, salts = plumbates). Lead nitrite and acetate are very soluble (lead sugar); lead chloride is easily soluble in hot water and low solubility in cold water; lead chromate (yellow) sulphate and sulphite (charcoal grey) are almost insoluble in neutral solutions, precipitation is caused by hydroxides and phosphorous and carbonic acids. Use: metal for metal sheeting, linings, pipes, lead-acid accumulators, alloys (+ Sb/Sn = cheaper bearing material), for colours and coatings, salts etching and waterproof impregnations, etc.

Leader cloth Cheap fabric which is used as the first layer on the jigger and also in drying and steaming and other continuous processes to lead the piece goods. Often made from polypropylene (low dyeability and economic). → Back grey.

Lead soap Lead soap is produced similarly to lime soaps by → Water hardening salts.

Lead, test for dyeings The sample is ashed and the ash dissolved in dilute nitric acid. The filtrate is mixed with some sodium acetate and potassium dichromate and gently heated. A yellow precipitate of lead chromate is produced which (unlike barium and mercury chromate) dissolves in caustic soda and ammoniacal tartaric acid.

Leaf fibres Sub-group of → Hard fibres in the form of woody fibres and vascular bundle components from the leaves or leaf sheaths of numerous sub-tropical plant species (such as sisal and manila). Fibre extraction by manual or mechanical methods; fibre preparation by rotting often produces poorer qualities.

Leasing The renting of capital commodities and long service items or industrial plant by lease financing or lease-purchase agreements. Used increasingly as an alternative means of finance in the textile and finishing industries.

Leather Skins or pelts prepared by → Tanning. Depending on the tanning process, a flexible (as in the case of chrome leather) to soft (e.g., chamois leather) material, resistant to humidity and hot water (except in the case of white leather). Lacquered leather is made by coating with (coloured) desiccant-containing linseed oil. Split leather is produced by splitting thicker bark-tanned leather which has been patterned using heated rollers to make grained leather. Depending on its surface texture, leather differs according to whether it is smooth (glazed from lamb or kid pelts) or rough, for example, in the case of soft glove leather with the flesh side of the gazelle hide or sheep pelt on the outside and with the grain removed (chair, Danish, suede leather) or (wild) leather from deer, fawn or antelope hides which are matt and velvety (Fig.).

Animal skin consists of collagen fibres in different layers as follows:

1. outer skin (epidermis),
2. corium (cutis),
3. adipose tissue (subcutis).

The outerskin is removed by the tanner using chemicals or by using enzymes and mechanical means. Only the corium is used for making leather and the adipose tissue is stripped off mechanically. Collagen has the following physical characteristics: it is water-insoluble, has pronounced swelling properties, a characteristic shrinking temperature and gluing ability via heat and aqueous alkalis. The skin can be preserved and stabilized.

The corium consists of a lattice structure of collagen and fibres of connective-tissue which branch and cross over each other without beginning or end and are linked in all directions. They are divided into papilla and reticular layers. The papilla layer has a particularly fine and dense fibre network on its surface and produces the so-called grain. This determines the appearance of the finished leather. The reticular layer, which is the most critical of the two in leather production, is thicker than the papilla layer and determines the mechanical properties. When the hide is removed from the carcass, it is con-

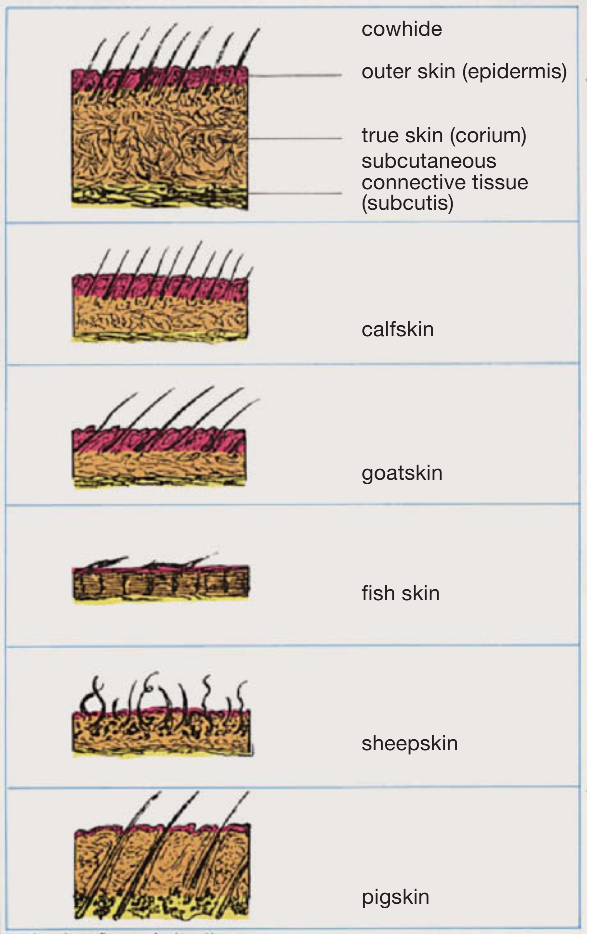

Fig.: Histological structure of different animal skins.

verted into leather by means of several chemical or chemi-mechanical treatments to prepare it for use as a starting material in the production of leather goods.

Leather after-treatment in dry cleaning Re-fatting with suitable → Re-oiling agents to compensate for the stiff handle of leather clothing after cleansing by coating or immersing in a fat liquoring bath to produce a natural soft handle. In the case of suede, it is sometimes necessary to re-dye the articles using a spray gun or dye dusting powders. The leather is restored to shape by careful steaming and evaporation and brushing with brass-wire brushes in the case of suede leather.

Leather cloth A coated, light calico cloth, elastic and waterproof for table cloths and the lining of hats, etc.

Leather dyeing,

I. Dyeing in drums: With drum dyeing the temperature must not exceed 48°C to avoid shrinkage of the leather. The drum is run at approx. 10 rpm in order to avoid abrasion and damage to the grain. The liquor volume is calculated on the dry weight of leather at ca. 500–700% or approx. 200–300% of the folded weight. Large amounts of similar types of leather can be dyed in the vat at the same time. The advantages of this method are its precision and gentle treatment of the leather.

II. Dyeing in dye winches: thin and sensitive leathers and split grain leather in particular are dyed on winches. Drum dyeing is less suitable for these sensitive leathers as the very thin skins tend to roll up, become knotted and even tear. The mechanical loading in the drum is too great. A longer liquor ratio is used on the winch. The advantages are a high degree of levelness, less handling and the gentle treatment of the leather. The disadvantages are low dyestuff exhaustion and the rapid cooling of the liquor.

III. Dyeing with brushes: brush dyeing is always used when the leather must be dyed on the grain side only, when the leather has already been partially dressed before dyeing or to avoid high dyestuff consumption. Dyeing is started with the grain side being moistened with warm water at 35°C. Small amounts of wetting agent are added when necessary. After this, acid dye solution at 35–40°C is applied to the surface with a brush three or four times. This process is repeated to obtain even coloration. A dye liquor containing 1–3 g/l acetic or formic acid is added while brush coating for the last time. This acidifies and fixes the dye. The brush liquor is thickened with alginate thickener to reduce penetration of the dye into the leather.

IV. Spray dyeing: spray dyeing is suitable for dry leather where a high level of uniformity and good penetration of the dye solution is achieved using solvents and penetration aids, especially in the case of vegetable-tanned leathers. Dyes with particularly high solubility are suitable for spray dyeing. Dyes with low solubility are not suitable as they partially crystallise out on the leather surface. The dye solution should be sprayed on to the leather using a spray gun at a temperature of 40°C and a pressure of 4–6 bar at a distance of 0.5–1 m from the surface. The concentration of the spray liquor in the case of acid dyes is 5–10 g/l and the concentration for cationic dyes is 2–5 g/l.

Leather dyes Term used by numerous companies for dyes (such as cationic, acid and direct etc.) used for dyeing leather. Unlike textiles, leather has a number of individual components resulting from structural differences which cannot be dyed uniformly. Another difference between leather and textile dyeing is that leather is not a flat material of uniform thickness but a three-dimensional structure up to 3 mm thick in which the dyes penetrate to different depths and at different strengths. A third characteristic is that while dyeing the leather, two different surfaces are dyed at the same time: the less reactive grain side and the strongly reactive flesh side. For a few dyes, the colour intensity on the flesh side can be seven times stronger than it is on the grain side. The same difficulties also limit the use of optical methods for measuring the dye strength and adjusting and re-adjusting the colour tone. When dyeing leather, different parameters must be taken into account. The theoretical consideration must include the chemical processes taking place during ionic bonding to the leather fibre as well as the diffusion processes within the leather, the equilibrium in the dye liquor and its influence via the parameters of the dyeing method, the effect of the ancillary aids and finally, the physico-chemical changes taking place in the leather which are caused by the conditions of the dyeing process.

The collagen is chiefly dyed in a tanned state, i.e. as leather. This can be done using any of the dyes also used for wool, silk, polyamide and cotton in the textile industry. These dyes must be carefully selected according to the tanning method used and type of leather. Typical leather dyes are metal-complex, acid and substantive dyes which develop “secondary valency forces” as they bond ionically with the collagen. Depending on the type of leather, the dyeing temperature used for leather dyeing lies between 40°C and 60°C and the pH used ranges from 3 to 8. Since the beginning of the seventies, the requirements in regard to the quantity and quality of leather dyeing has continuously increased. The quality of the leather dyeing depends on the raw hide, the chemi-mechanical treatment, the type or method of tanning, the dye, the dyeing method, the chemicals or auxiliary aids and the dressing. The dye and the dyeing method have a large influence on the quality of dyeing in the leather dyeing process.

There are numerous ranges of dye to select from. Some dyes have good light fastnesses but insufficient wet fastness. Other dyes have high fastnesses but the colour shades do not satisfy the requirements. These properties are determined by the chemical structure of the dye itself.

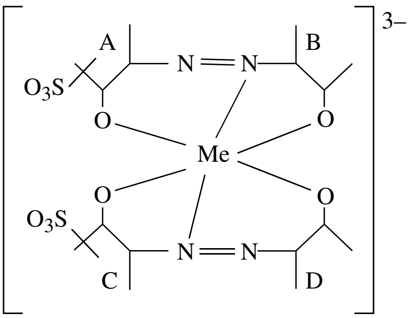

Fig.: Typical structure of a leather dye with 2 sulpho groups and 3 anionic charges. A, B, C, D are aromatic systems of the chromophore.

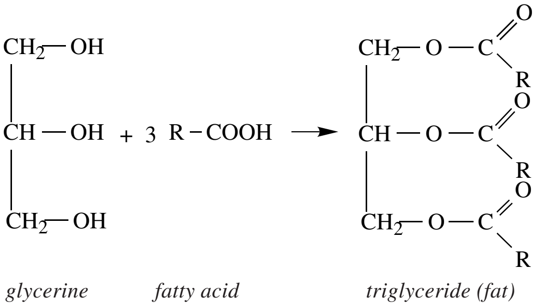
Although the typical metal-complex dye (Fig.) can be regarded as an anionic entity, basically it has amphoteric character because both cationic groups and anionic groups are actively present. The complex-forming ions can be those of iron, chrome, copper or cobalt. These metal ions bond with the hydroxyl, amino and carboxyl groups of the azo-dye molecule to form water-soluble metal complexes. Either one or two dye molecules bond to each metal ion to give 1 : 1 or 1 : 2 metal-complex dyes respectively.

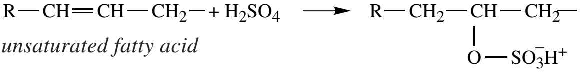
Leather fat-liquoring Water retention influences the softness of leather but the dehydrating effect of the tanning process can cause a drastic change. Leather becomes brittle, stiff and inflexible if it is over-dried. The purpose of fat-liquoring, by forming a fat film around the leather fibres, creates and increases the insulation effect. Maximum softness is achieved by the additional mechanical effects of staking. The breaking strength of leather is increased by the orientation of the fat-liquored fibres that takes place. The aim of every fat-liquoring process is to achieve the greatest possible penetration of fat into the leather.

Fat liquors are typically esters of the tri-functional alcohol glycerine and higher fatty acids.



The fats or oils which are mainly used in the leather industry may be from animal origin, such as tallow, fish oil and neatsfoot oil, or vegetable sources, such as olive oil, linseed oil, coconut oil and castor oil etc. The end characteristics of animal and vegetable fats and oils are developed during the formulation processes. When using emulsions of animal or vegetable fats and oils, in most cases, it is partially unsulphonated fats which are used, the sulphonated triglycerides acting as emulsifiers for the remaining non-sulphonated hydrophobic fats. By using formulated fats and oils, the so-called oil and fat liquors, it is possible to obtain an even distribution of the oil droplets on the surface and in the pores of the tanned leather, thus making the leather soft and semi-water resistant. The fat, oil and paraffin modification procedures most widely used are sulphonation (sulphiting), sulphation and chlorosulphonation.

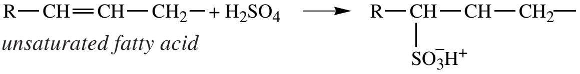
sulphation:



$$R-CH=CH-CH_2- + H_2SO_4 \longrightarrow R-CH_2-\underset{|}{CH}(O-SO_3^-H^+)-CH_2-$$

unsaturated fatty acid

sulphonation:



$$R-CH=CH-CH_2- + H_2SO_4 \longrightarrow R-CH(SO_3^-H^+)-CH-CH_2-$$

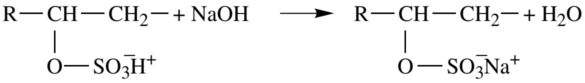
unsaturated fatty acid

sulphation:

$$R-\underset{\displaystyle OH}{\underset{|}{CH}}-CH_2- + H_2SO_4 \longrightarrow R-\underset{\displaystyle O-SO_3^-H^+}{\underset{|}{CH}}-CH_2- + H_2O$$

hydroxy fatty acid

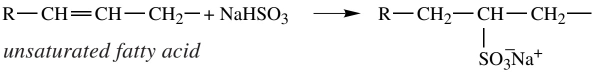
The water-soluble ester salts are produced by neutraliszing the ($-SO_3^-H^+$) groups with caustic soda, ammonia or organic bases.



$$R-\underset{\displaystyle O-SO_3^-H^+}{\underset{|}{CH}}-CH_2- + NaOH \longrightarrow R-\underset{\displaystyle O-SO_3^-Na^+}{\underset{|}{CH}}-CH_2- + H_2O$$

fatty acid sulphate

The water-soluble ester salts are produced directly via sodium hydrogen sulphite ($NaHSO_3$).

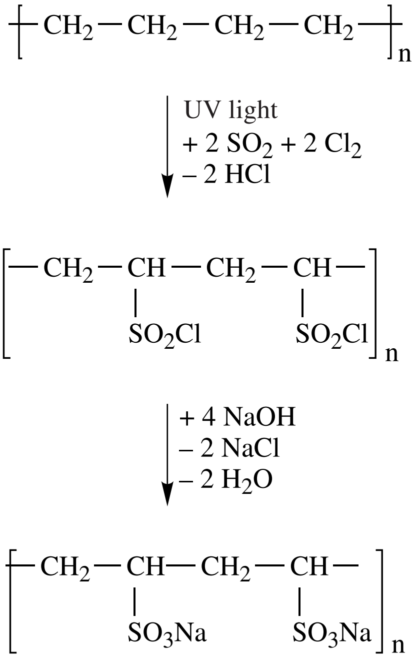


$$R-CH=CH-CH_2- + NaHSO_3 \longrightarrow R-CH_2-\underset{\displaystyle SO_3^-Na^+}{\underset{|}{CH}}-CH_2-$$

unsaturated fatty acid

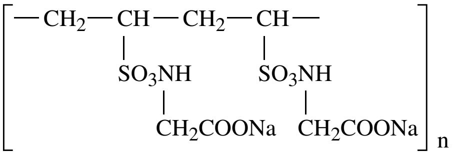
fatty acid sulphonate

Unsaturated fatty acids must be present for sulphonation to take place. The purpose of sulphonation is to make the fat or oil water-soluble. Good emulsions are obtained with 3% SO_3^- and transparent solutions are obtained on reaching 4%. In the case of synthetic fat-liquoring agents containing high-molecular, straight-chain hydrocarbons, the water-soluble sodium salt of the hydrocarbon sulphonic acid is produced via chlorosulphonation.



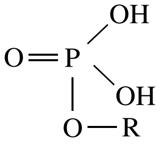
$$\left[-CH_2-CH_2-CH_2-CH_2-\right]_n \xrightarrow[\displaystyle -2\,HCl]{\displaystyle UV\ light,\ +2\,SO_2+2\,Cl_2} \left[-CH_2-\underset{\displaystyle SO_2Cl}{\underset{|}{CH}}-CH_2-\underset{\displaystyle SO_2Cl}{\underset{|}{CH}}-\right]_n \xrightarrow[\displaystyle -2\,NaCl,\ -2\,H_2O]{\displaystyle +4\,NaOH} \left[-CH_2-\underset{\displaystyle SO_3Na}{\underset{|}{CH}}-CH_2-\underset{\displaystyle SO_3Na}{\underset{|}{CH}}-\right]_n$$

Neutralization can also be achieved with ammonia followed by the sodium salt of chloroacetic acid which results in a better fat-liquoring effect and stronger bond to the substances in the hide.



$$\left[-CH_2-\underset{\displaystyle \underset{\displaystyle CH_2COONa}{\underset{|}{SO_3NH}}}{\underset{|}{CH}}-CH_2-\underset{\displaystyle \underset{\displaystyle CH_2COONa}{\underset{|}{SO_3NH}}}{\underset{|}{CH}}-\right]_n$$

In addition to the fat or oil components, there may be other emulsifiers with lipophilic and acido groups present in the fat mixture. Emulsifiers such as these may in general have the following constituents, as in the case of phosphoric acid esters.



R = lipophilic group

$= -C_nH_{2n-1}$

$= -C_nH_{2n-1}$

$= C_nH_{2n+1}(O-[CH_2]_2)_mOH$

In acid range, fat-liquoring agents in which the active group is an anion bond to the NH_3^- groups but in the alkaline range, cationic fat-liquoring agents bond to the COO^- groups of collagen. Bonding can also take place via secondary valence forces arising from groups containing oxygen or chlorine. Coordinate inclusion of acidic groups in the complex domain of chrome tanning agents is also possible. The non-extraction of fat from leather can be promoted by increasing the degree of sulphonation, using multi-bonded metal tanning agents and by using more emulsifier and unsaturated fatty acids in the fat-liquoring agent.

Leather glue → Glue.

Leather production The term leather applies to all products which are made from the different animal hides using one or more chemical or mechanical treatments to change their properties so that they no longer show the negative characteristics of raw hide. The treatments required are classified according to the nature of the raw hide, the method or type of tanning and the purpose for which the leather is to be used (e.g. Figs. 1 and 2).

Mechanical leather processing: Collected under this heading are all processes taking place at different stages during leather treatment and in most cases used to produce certain effects. They represent a supplementary function to the chemical processes.

1. Depilation and scraping: The hair is removed mechanically or manually and the epidermis destroyed.
2. Fleshing: The flesh and fat residues such as muscle and subcutaneous connective tissue are removed using a cutter block (knife roller) (Fig. 3).

Leather production

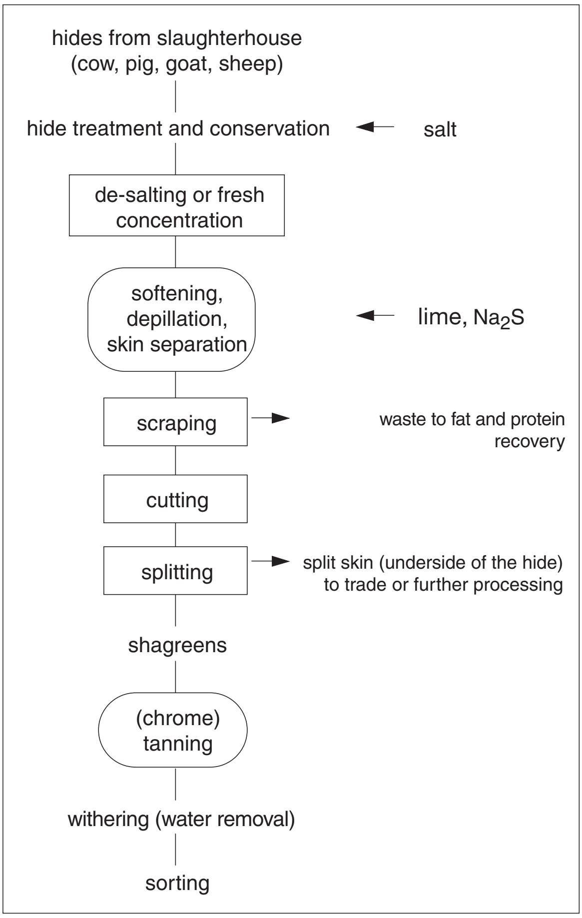


Fig. 1: Production cycle in leather manufacture (Wetblue).

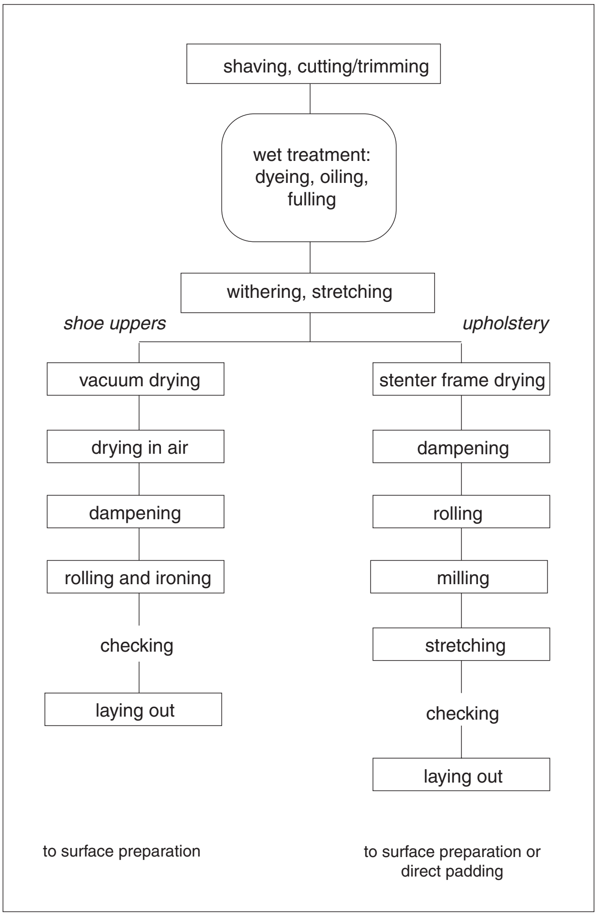

Fig. 2: Treatment processes for crust leather used as shoe or upholstery leather.

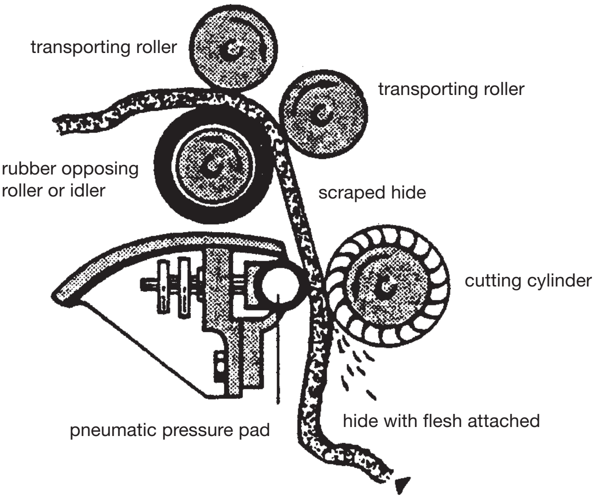

Fig. 3: Leather processing: fleshing on the scraping machine.

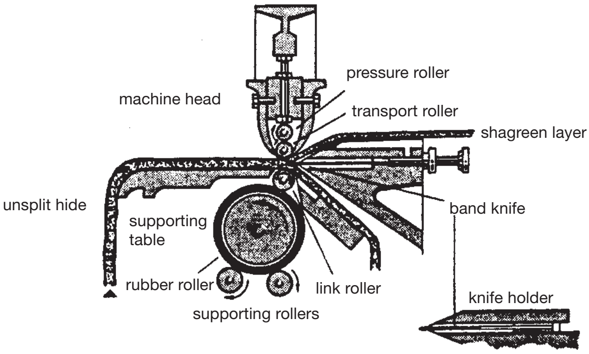

Fig. 4: Leather processing: splitting on a splitting machine.

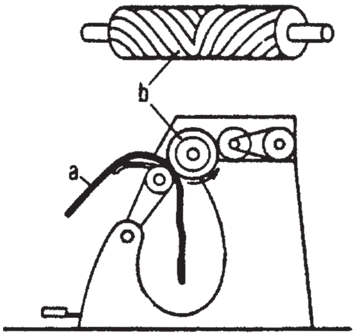

Fig. 5: Leather processing: shaving on a shaving machine.
a = leather; b = shaving roller.

3. Splitting: The lime-soaked hide is split into two or several layers: grain split, middle split and flesh split (Fig. 4).
4. Shaving: reducing the thick parts of a hide and producing a final thickness (Fig. 5).
5. Grinding: The grain and flesh splits are ground during dressing to produce the different effects.
6. Dewatering: Excess water is removed using blunt knife rollers before drying (Fig. 6).
7. Staking: The leather is softened by means of a vibrating metal-spiked plate (Fig. 7).
8. Drying: heat is used to evaporate off the water.
9. Grain stamping: The grain effect is embossed on to the leather using a grain-embossing machine.
10. Ironing and glazing: The surface is stabilized and glazed using heat and pressure.

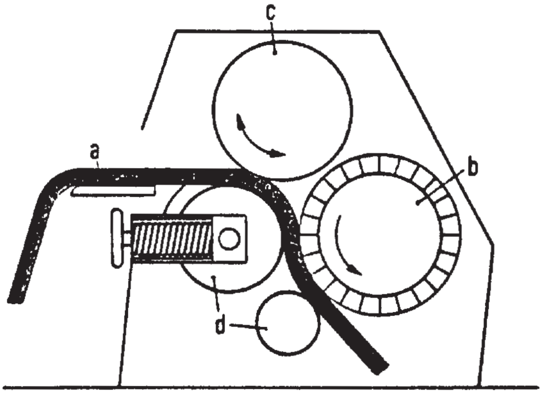

Fig. 6: Leather processing: withering press.
a = leather; b = stretching roller; c = transport roller;
d = pressure rollers.

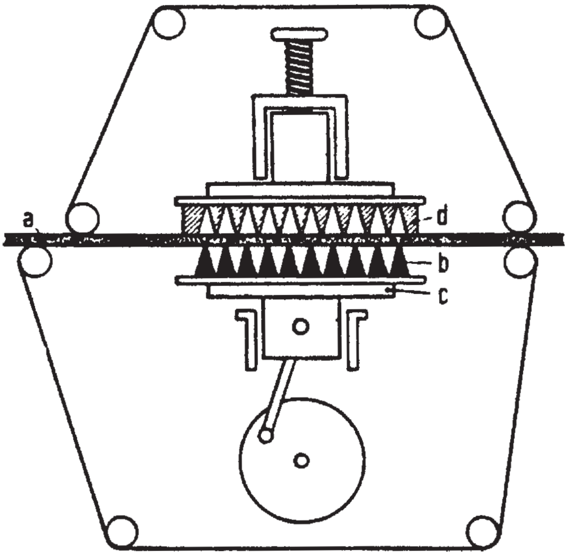

Fig. 7: Leather processing: vibration rolling machine.
a = leather; b = metal points; c = vibration plate; d = foam rubber plate.

Leather production, wet processing This collective term describes all the work and processes used to convert the preserved hide into a hide stripped of hair, i.e. hide prepared for the tanning process. The purpose of the softening process is to swell the hide and impart suppleness and flexibility to the individual fibres and to provide a cleaning effect. An exchange takes place between the salt solution stored in the collagen fibre structure and the soft water, ensuring diffusion of salt out of the hide and the absorption of water into the hide. The softening effect can by the addition of sharpener, acid and alkali be increased (attributed to the swelling of the collagen caused by acids and alkalis). Wetting agents can be used to reduce the interfacial surface tension between the water and the hide. A very important process carried out before tanning is liming. The purpose of lime-soaking is to loosen and remove the hair and relax the hide at the same time. The quick lime-sodium sulphide lime, a mixture of $Ca(OH)_2$ and Na_2S, loosens the structure by swelling the collagen, the sodium sulphide promotes the decomposition of the keratin, thus thoroughly loosening the hair as well as swelling the hide.

$$2\,Na_2S + 2\,H_2O \rightarrow 2\,NaOH + 2\,NaSH$$
$$2\,NaSH + Ca(OH)_2 \rightarrow 2\,NaOH + Ca(SH)_2$$

$$2\,Na_2S + 2\,H_2O + Ca(OH)_2 \rightarrow 4\,NaOH + Ca(SH)_2$$

In the presence of OH^- ions, the sulphur hydride has a powerful loosening effect on the hair and the caustic soda has a powerful swelling effect on the hide fibres while saponifying the hide fat as the same time. A lime soak can be used on its own as alkalis also break the disulphide links of the amino acid cystine in water.

$$>CH{-}CH_2{-}S{-}S{-}CH_2{-}CH< \xrightarrow{OH^-} >CH{-}CH_2{-}SOH + HS{-}CH_2{-}CH<$$

The mercapto (cystine-) sulphenic acid formed during the hydrolytic cleavage is very reactive and decomposes as follows:

$$>CH{-}CH_2{-}SOH \rightarrow >CH{-}CHO + H_2S$$

The aldehyde thus formed can bring about re-cross-linking with the cysteine which is produced:

$$>CH{-}CHO + HS{-}CH_2{-}CH< \rightarrow$$
$$>CH{-}CH_2{-}S{-}CHOH{-}CH<$$

Lanthionine-complex type cross-linkages may also be formed:

$$R{-}CH_2{-}S{-}CH_2{-}R$$

Re-cross-linking takes place during alkali treatment by incorporating calcium ions after the disulphide bonds have been broken, primarily through alkaline hydrolysis:

$$>CH{-}CH_2{-}SOH + HS{-}CH_2{-}CH< + Ca^{2+} \rightarrow$$
$$>CH{-}CH_2{-}SOCa{-}S{-}CH_2CH< + 2\,H^+$$

The lime-sodium sulphide lime soak combines the advantages of a hydroxyl lime soak, where the hairs are loosened due to hydrolysis of the protoplasmic proteins in the epidermis, with those of a sulphide lime soak, which accelerates keratin hydrolysis and loosens the hair while attacking it at the same time.

The de-liming acids have to compete with the "collagen acids" in removing and neutralising the lime bound to the collagen and only those with an acid dissociation constant greater than $2 \cdot 10^{-1}$ are used. The lime salts formed during the process are removed by rinsing. The hide is relaxed further during the pickling process due to a loosening up of the collagen structure by a tryptic pancrease proteolytic enzyme such as trypsin. Carbohydrate components, particularly neutral sugars and amino sugars "leucopolysaccharides" are broken down. The prepared, de-haired hides are treated with a solution of acids and salts before tanning. The purpose of the pickling solution is to retard the chrome tanning process by chemically converting the hide using acids. The free amino groups are ionised (charged) by saturating the hide with acid. The basicity of the chrome salt is reduced at the same time, leading to a reduction in hide shrinkage. The risk of the grain shrinking (surface tanning) is removed. The salt in the pickling solution reduces the undesirable swelling effect of the pickling acids on the surface by suppressing acid dissociation.

$$\text{collagen-}NH_3X \rightarrow \text{collagen-}NH_3^+ + X^- \ (X^- \text{ anion})$$

Sodium chloride ($NaCl \rightarrow Na^+ + Cl^-$) supplies excess anions to drive the reaction to the left. The charge on the acid groups can be suppressed again by adding more salt. However, this effect only occurs within certain limitations for the reasons mentioned above. Both inorganic and organic acids can be used.

Leather tanning A high degree of stabilisation of the leather structure is achieved through the bonding of chrome to carboxylic acid groups, thus forming so-called binuclear chrome complexes between two carboxylic acid groups of the amino acids in the collagen structure. The stability is so high that the collagen fibres are resistant to boiling (Fig.). The process is termed collagen tanning and it is this which turns hide into leather.

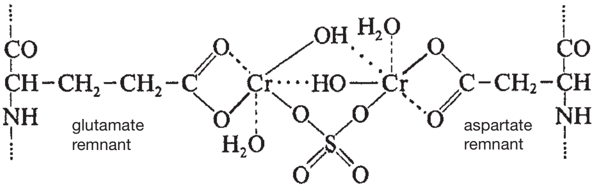

Fig.: Bi-nuclear chromium complex in a collagen fibre.

The chrome is integrated intramolecularly, i.e. from one part of a collagen molecule in the fibrils to another part of the same molecule. Where there are 0.8–0.92 milliequivealents of "chromable" carboxyl groups per gram collagen, between 3.63% and 6.22% chrome or between 5.30% and 6.22% chrome(III) oxide Cr_2O_3 may be bound to the leather, depending on the composition of the cross-links (Tab.) and assuming binuclear complexes are formed.

carboxyl groups m-equivalents	composition of cross-link	Cr	Cr_2O_3 % in leather
0,8	$Cr_2(OH)_2(H_2O)_2SO_4$	3,75	5,49
0,8	$Cr_2(OH)_2(H_2O)_2(SO_4)_2$	3,63	5,30
0,8	$Cr(OH)_4$	3,89	5,69
0,92	$Cr_2(OH)_2(H_2O)_2SO_4$	4,26	6,22

Tab.: Composition of cross-links in chromium leather.

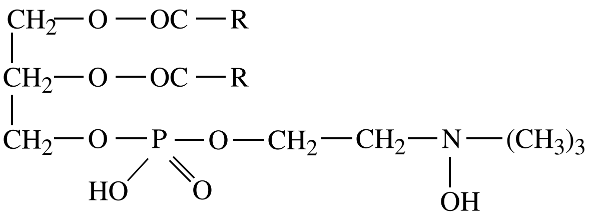
In leather manufacture, the pickled de-haired hide, in which the main substance is positively charged, is tanned using, for example, a 33% basic chrome(III) liquor. During the chrome-tanning process, multinuclear hydroxy compounds (so-called basic chrome salts) of chrome(III) sulphate are formed by the gradual addition of caustic soda, while the pH of the so-called liquor (containing the chrome) is raised from 3 to 4. At higher pH (between 5 and 6, depending on the chrome concentration) non-active insoluble chrome(III) hydroxide would precipitate out.

Chrome tanning produces a firm, flexible leather which is stable in both hot and cold water and is resistant to heat and bacteria. It is pale bluish green in its undried state, (termed “wetblue” as semi-manufactured goods). A mixture of potassium aluminium sulphate, sodium chloride, egg yolk and wheat flour is used as a mineral tanning agent in the production of kid leather (fine glossy goat or lamb leather). → Tanning; Vegetable tanning.

Leblanc soda Term from the oldest method of manufacture for → Sodium carbonate.

LECARIM French textile research organization in Mazamet; → Technical and professional organizations.

Lecithin The phosphoric acid ester of natural fats with a choline group. It is included among the lipoids.



Lecithin is obtained from soybean oil which contains up to 4%. It is a brownish yellow, hygroscopic, wax-like mass which is freely soluble in alcohol and ether, etc. In water, lecithin first swells, and later,forms a translucent colloidal solution. It is used as a lubricanting agent and softener for sizes and finishes, especially in polyamide hose finishing; also contained in softeners with accompanying stabilizing effect for oxidative bleaches.

Legal protection of designs Legal protection of tools and equipment or their components in so far as they are used to work with or used in a new form, arrangement or device. In the case of designs changes must be significant. Usually valid for 3 years but this can be extended by 3 years. → Registered design.

Legislation on environmental protection The concept of “integrated environmental protection”, i.e. production and finishing processes are applied that use the highest possible quantitative proportion of products and energy, is the correct basis for all parties with a commitment to environmental protection. In an age of strong global integration, the textile finisher must have a clear concept for controlling his environmental impact and that this will help to protect the future of his own working environment. This dependency is better understood as a shared environment rather than a surrounding environment. The sharpened public awareness of ecological matters has put much pressure on the legislators so that the textile finisher, as a significant consumer of water, air and energy as production media, is now confronted with a flood of environmental legislation, whose impact on the industrial sector is still not yet fully understood. The German Water Resources Law of 23.9.86 (Fig. 1), requires the textile processor to meet the following controls:

- the conditions of the Regulation on the limitation on emissions and their impact, e.g. Effluent Regulations (textile manufacture) of 5.9.84;
- environmental audit as an information- and early warning-system;
- application of “the polluter pays” principle.

Reetz has defined the environmental law in terms of three levels of legislation:

- Federal Law: BImSchG (Bundes-Immissionsschutzgesetz – Federal Immission Protection Law) with 4th BImSchV (Bundes-Immissionsschutzverordnung – Federal Immission Protection Regulation) and with TA Luft (Technische Anleitung zur Reinhaltung der Luft – Technical Instructions for Air Purity: → TI-air); WHG (Wasserhaushaltsgesetz – Wa-

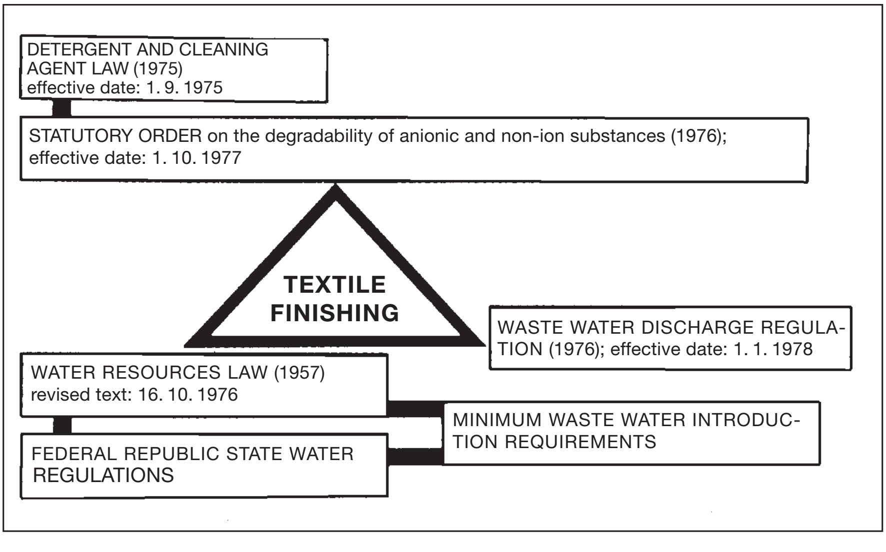


Fig. 1: Most important Federal German Republic water protection laws and regulations.

ter Resources Law); AbwAG (Abwasserabgabengesetz – Waste Water Discharge Regulation); AbfG (Gesetz über die Beiseitigung von Abfällen – Waste Disposal Law); GefStoffV (Gefahrstoffverordnung – Dangerous Substances Regulations); VwVfG (Verwaltungsverfassungsgesetz – Administration Constitution Law);
- State Law: LWG (Landeswassergesetz – State Water Law); IndEV (Industrielle Emissionsverordnung – Industrial Emmissions Regulations); EKVO (Eigenkontrollverordnung – Self-checking Act); VAwS (Verordnung über Anlagen zum Lagern, Abfüllen und Umschlagen wassergefährdender Stoffe – Regulation for the Handling of Substances Hazardous to Water); SmogV (Smog Verordnung – Smog Regulation); VLwF (Verordnung über das Lagern wassergefährdeter Flüssigkeiten – Regulations for the Storage of Liquids Harmful to Water); LBO (Landbewirtschaftungsordnung – Land Management Regulations);
- Local Government Law, bylaws such as AbwS (Abwasser-Satzung – Waste Water Statutes).

According to Reetz, the following areas are pertinent to environmental protection within the area of textile finishing:

1. Dangerous substances which are toxic, non-degrading, accumulate in the environment, carcinogenic, ovary damaging or mutagenic (WHG § 7a).
2. Substances which are harmful to water according to a constantly up-dated reference list (in accordance with § 19g WHG) regulates the storage, filling, manufacture, handling and application.
3. Dangerous substances (according to the GefStoffV – Dangerous Substances Regulations), which are toxic (T), slightly poisonous (Xn), corrosive (Z), irritating (Xi), highly flammable (F+) or combustible (O). Handling dangerous substances is regulated under § 17 (Common duty of protection); § 18 (Duty to monitor, MAK [Maximale Arbeitsplatzkonzentration – Threshold Limit Value]; TRK [Technische Richtkonzentration – Technical guideline concentration]; BAT [Biologischer Arbeitsstoff Toleranzwert - Tolerance Limit of Biological Substances]); § 20 (Operating Guidelines); § 21 (Duty of Care).

These areas are in the domain of environmental quality control so the textile finisher must determine which of his by-products fall within these controls and then further measure their impact. The Water Resources Law requires improvement in the aquatic environment and it is a stipulation that water must not contain any dangerous substances after use. The Origin of Waste Water Law states that textile finishing is a possible source of effluent containing dangerous substances so the textile finisher must remove any by-product before he can discharge effluent directly into open water systems (drainage water) or, if he discharges indirectly into the sewers, to treat the effluent to a condition that is acceptable to the local effluent treatment works.

Thus it can be seen that the textile finisher must pay for the cost of the volume and content of his effluent discharge, whether direct or indirect to the sewers, so he has a very strong incentive to reduce his effluent volumes and control any hazardous substances that it may contain (Effluent Cost Law). In the discussion between the authorities and those affected about interpreting the broad and blurred definition of § 7a of the Water Resources Law in regard to "dangerous substances", a distinction must be made between the desired standards (guidelines for effluent cleaning according to Code of Practice A 115 of January 1983) and the reality of the limits in the statutes governing regional sewage treatment plant operators. The practical guidelines of the national standard, which may vary from state to state, lie somewhere between the Federal Law and its regional interpretations. In the future, of course, increasing attention must be paid to developments in the European context. Basically, a distinction must be made between legislation controlling the handling of a certain environmental medium (media legislation in relation to water and air) and legislation controlling the handling of products such as detergents, tetrachloroethylene (perchloroethylene) or formaldehyde (product legislation controlling the storage and use of dangerous substances). At the same time, legal arguments frequently flare up between textile finishers and authorities as to what is to become the "the industrial standard" for restricting or monitoring exhaust gases and effluent from production or cleaning them.

Environmental legislation covering textile finishing:

1. Handling chemicals:
   a) Law on chemicals:
      - Dangerous Substances Regulations with Appendices I–VI,
      - Classification and identification of dangerous substances and preparations,
      - Dangerous substances which are carcinogenic, ovary damaging or mutagenic,
      - Dangerous substances which are poisonous, corrosive, irritating and chronically harmful,
      - Certain dangerous substances which are combustible, explosive and flammable,
      - Supply investigations,
      - Dangerous substances and preparations which are classified.

   b) List of TLVs (Threshold Limit Values).
   c) List of BATs (Tolerance Limit of Biological Substances).
   d) List of TRKs (Technical guideline concentration).
   e) Regulation on flammable liquids.
   f) Storage of chemicals and textile auxiliary aids.

2. Waste water hazard: Water Resources Management Law, Local Regulations, Register of Substances Harmful to Water, Detergent and Cleansing agent Law, Surfactant Regulation and Effluent Emission Law.
3. Exhaust loading and environmental pollution: Federal Immission Protection Law (Fig. 2) and associated legal regulations:
   – TI-air (Technical Instructions for Air),
   – TI-noise (Technical Instructions for Noise).
4. Disposal of waste liquors, waste products and effluent sludge: Waste Law, Procedure Regulation and Effluent Sludge Regulation.
5. Physiological effects of textile goods: Dangerous Substance Regulations including Appendices I–VI, allergic effects, smell, skin tolerance and prevention of poisons in the home (home furnishings).
6. Law relating to environmental issues (contamination liability): law on liability for environmental damage and amendment to the Water Resources Law and the Federal Immission Protection Law (1.1.1991).
7. Environmental Penalty Law: 2nd Law on controlling environmental criminality (1992 in process of legislation).

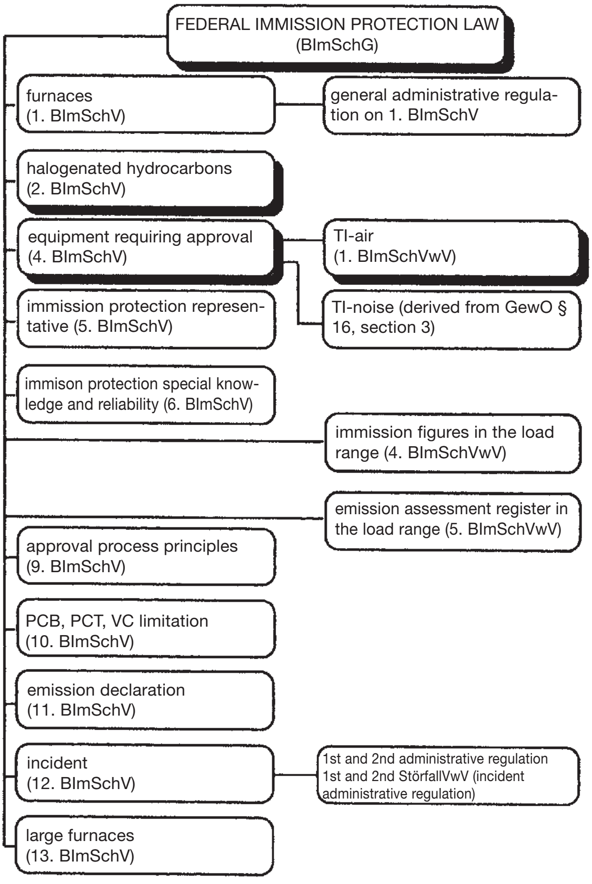

Fig. 2: Organigram of German Federal Immission Protection Law (Bundes-Immissionsschutzgesetz).

In regard to the disposal of effluent, in most case, textile finishing factories discharge "indirectly to the public sewage system". They must acquire official approval for discharging effluent into the public sewage treatment plant and this contains threshold values in regard to loading and concentration. Substances registered include seven heavy metals, four volatile chlorohydrocarbons, AOX (organic halogen X) and free chlorine. AOX is a sum parameter, i.e. the corresponding test methods express the total without differentiating between the different species. This is significantly cheaper than a qualitative and quantitative analysis of the individual substances. The sum parameters which are very often used in effluent analysis are TOC, COD, BOD and AOX.

If the textile finisher discharges his effluent into the sewer system after intensive cleaning in the factory's own treatment plant, then he is confronted with the Waste Water Discharge Regulation which, in this case, regulates more according to the quantity discharged to sewer than the harmful substances it contains. On the other hand, the effluent released into the sewer system must comply with a particular water-quality classification after the discharge point which takes into consideration the biological quality of the open water, i.e. the survival capacity of certain organisms in the mixture of flowing water and discharged water.

If the effluent is discharged into the public drains, then it must be ensured, for example, that the effluent will not attack concrete due to its sulphate content. The maximum sulphate concentration of, for example, 400 mg/l SO_4^{2-} seems reasonable as the corresponding requirements of the legislator protects the textile finisher from serious consequences which he may have to suffer according to the principle of causation if the effluent causes extensive damage to the drain system due to sulphate or damage to the effluent treatment plant (such as a collapse of the biological equilibrium) due to other substances harmful to water.

It is known that, in relation to eutrofication problems, there is intense activity in the search for substitutes for phosphates in detergents. Citric acid and nitrilotriacetic acid (NTA) have been introduced as substitutes for sodium polyphosphate or sodium aluminium sulphate as a detergent builder in detergents. However, as phosphates also come from agricultural sources, the construction of sewage treatment plants with a third purification stage was discussed some time ago. Such discussions in regard to phosphate affect the textile finisher if he softens hard water in the textile finishing process using water softeners or consciously uses phosphates as builders in the washing processes. The list of substances harmful to water is constantly growing and also affects both their storage in the factory and their handling. Surfactants are affected in particular but so are all substances which may release heavy metals.

According to the Dangerous Substances Regulation, the responsibility rests with the employer to provide operating guidelines for handling dangerous substances. The safety data sheets of all chemicals used in the chemical industry are, therefore, an important source of information in the matter of avoiding hazards. From these, the textile finisher can find out how the by-products of his work will affect the environment and what measures must be taken for assuring the quality of the environment. A typical example of conscientious behaviour is found in the way the manufacturers and users of the alkyphenolethoxylate (APEO)-based surfactants responded after recognising their damaging effect on the environment. The remaining test methods for determining the bio-degradability of APEO show that the products meet the requirements of these tests. The metabolites of APEO are, in fact, toxic to fish (Fig. 3).

Voluntary restriction in regard to these products has given rise to a successful search for APEO substitutes, of which the ones predominantly on the market are the fatty alcoholethoxylates which have a similar application range. Of course, the surfactant manufacturers are affected by the Chemical Law most of all. However, the example shows that the user, who also has some responsibility, can take action as well.

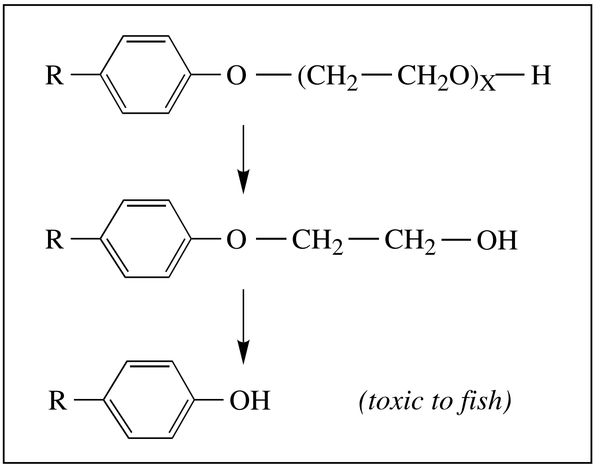

Fig. 3: Biological degradation of APEO to metabolites toxic to fish.

Apart from the solvent, water, and the solid or dissolved particles, the textile finisher must also direct his attention towards air pollution, which has been subject to regulation since 1985 under the 4th Federal Immission Protection Law. Indeed, this law also has something to say about the protection of certain areas from noise. However, textile finishing normally produces relatively little in the way of noise emission. Air pollution is defined in the TA-Luft (Federal Government Technical Instructions for Air, 1986). Of course, the threshold of interference is a point of contention between the authorities and textile finishing industry when existing plant is being evaluated. At a regional level, there is no opportunity for discussion when new plant is applied for. Of course, textile driers and furnaces (steam boilers) are particularly affected by the Federal Government Technical Instructions for Air. However, processes during which unknown by-products are produced also represent potential sources of exhaust-gas emission under certain circumstances during chemical or thermal conversion (resin finishing and heat setting). Finally, the textile finisher must come to terms with product-related environmental protection. Formaldehyde can be released from crease-free finished fabrics during storage and use due to partial hydrolysis of unconverted N methylol and N alkyloxymethyl compounds and, under certain circumstances, cross-linked cellulose. Of interest for the toxicological evaluation of formaldehyde in this application, is the amount released under the conditions of use and reabsorbed by the skin or reabsorbed from the respiratory air.

Leisure wear Style of clothing which, in comparison to the so-called conventional-classical clothing, is designed more to meet the user's requirements and place more emphasis on comfort with light fabrics and a casual style with the trend of fabric compositions towards synthetic mixtures and ease of care; used for shirts, ladies' suits, dresses, men's jackets, trousers, suits and trouser suits. Further developments in → Casual wear.

Length measurement Usually made on the running fabric by means of measuring wheels, i.e. a wheel with known circumference is pressed against the fabric under a defined pressure. The number of rotations is recorded via a mechanical or electronic counter (turning impulse generator) from which the corresponding length or speed is determined. One variant of this method is the determination of rotations at a guide roller and back calculating this to the running lengths. All these methods have the following disadvantages:

- the measurement wheel is subject to wear, i.e. changes in diameter;
- material specific slip between the measurement wheel and the goods;
- measurements frequently take place at a drive point, i.e. the fibre is not relaxed;
- pressure sensitive goods may be damaged;
- goods may be deformed if wet, moist or hot or fibres may be disturbed.

These problems demonstrate that sufficient measurement accuracy in production can only be achieved under favourable conditions.

With pile fabrics a more marked variation can occur due to the reaction between the wheel and the fabric pile. Mechanically driven goods move the measurement wheel by means of friction. The elastic fibres are moved out of their original position by the force exerted by the wheel which means that the speed of the goods base weave being measured V_{Mg} no longer agrees with the speed of the measurement wheel V_{Mr}. Fig. 1 is a schematic presentation of length measurement on knitted-type piled textiles. In the first case a), measurement is carried out with the nap, i.e. the pile is leaning in against the direction of the fabric movement. As a result of the force between the pile and the measurement wheel, the inclination of the pile increases and the outer casing of the measurement wheel lags behind the forward moving ground weave of the goods. Thus, $V_{Mr} < V_{Mg}$ and the measurement has a negative bias (under-reads). In the second case b), measurement is carried out against the nap, i.e. the pile is leaning in the same direction as the direction of advance. The relationship between the measurement wheel and the goods is reversed so giving rise to positive deviations in the length measurements (over reading). In both cases, the calibrated tolerance of ±0.3% allowed for textile measurement machines is exceeded many times over. Typical pile dependent deviations are of the order ± 2–4%.

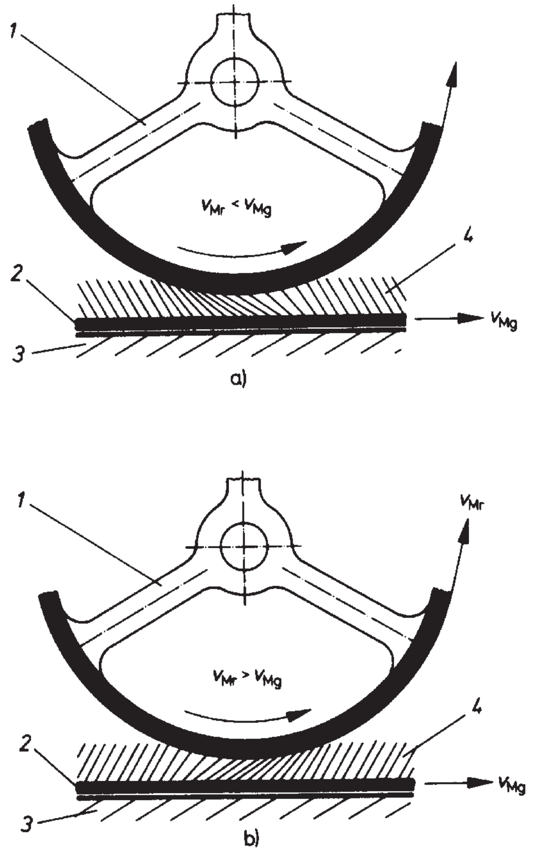

Fig. 1: Diagram of scanning textiles with pile: a) with the pile, b) against the pile.
1 = measuring wheel; 2 = sample material backing; 3 = straight feed; 4 = elastic pile fibres; v_{Mg} = velocity of sample backing material; v_{Mr} = circumferential velocity of measuring wheel.

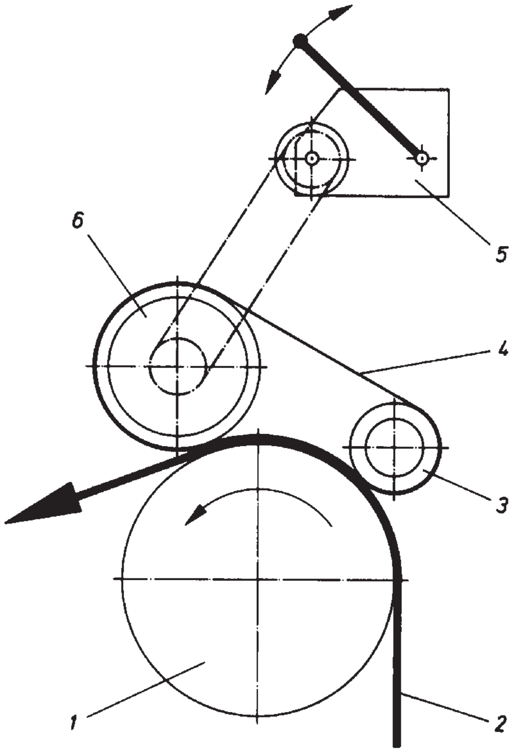

Fig. 2: Diagram of indirect mechanical length scanning.
1 = drive roller; 2 = sample; 3 = tail wheel; 4 = belt; 5 = counter; 6 = measuring wheel.

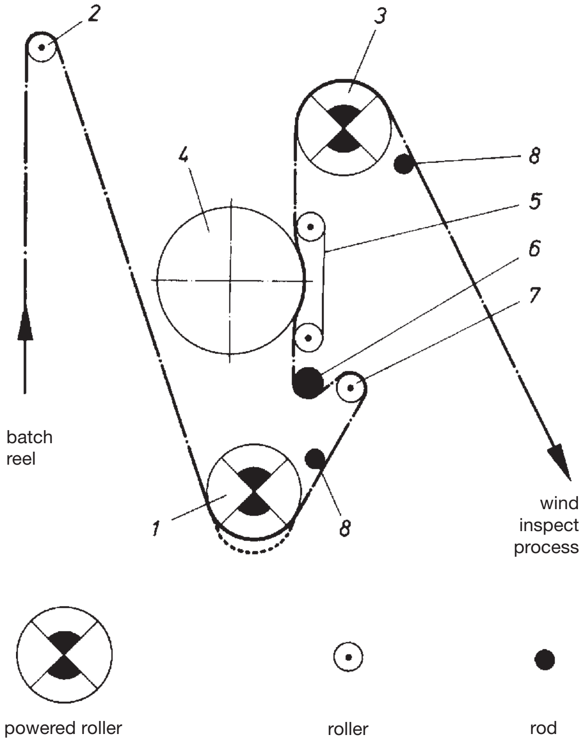

Fig. 3: Traction regulation using pressure belt (as proposed by the Physical-Technical Laboratory, Braunschweig).
1 + 3 = pull roller; 2 + 7 = roller; 4 = measuring wheel; 5 = pressure belt; 6 + 8 = rod.

The deviations just described can be reduced to the calibrated tolerances if, instead of the measurement wheel impinging on a straight run of material, the fabric to be measured is guided round the circumference of measurement wheel. The friction between the wheel in this arrangement is much higher so that, in the case of piled fabrics, deviations in the movement of the fibres has little effect on the circumferential velocity of the wheel. An even better arrangement is via indirect contact with the goods being measured using a belt, as shown in Figs. 2 and 3. The belt is used as a link between the goods being measured and the wheel and caters for a high transmission of surface-frictional force. Using this principle of length measurement, the deviations due to slip and similar problems can be reduced by a justifiable amount, but it is not suitable for goods which are sensitive to touch. Laser technology, for example, using the reference Doppler method can be used for contact-free measurement with these materials instead (→ Laser Doppler Effect) (source: Zervos).

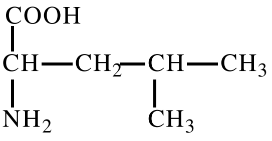
Leno fabrics (àjour fabrics, filigree work, gauzes), in most cases, transparent fabrics with → Gauze weave, leno weave such as ajour fabrics, etamine, net-curtain fabrics, gauzes, marquisette and similar weaves; also used for fashion effects in dress and blouse fabrics.

Lethal index Concentration of a → Poison in mg/m^3/min. required to lead to the death of an adult → ct Product.

Lethal limit Lethal limit for poisons: → LC-50 and LD-50 values; Death rate for fish in effluent.

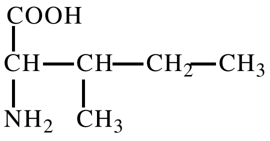
Letterpress printing (book printing). The ink is transferred from the raised printing areas of a roller or similar device.

Leucine, iso-leucine → Amino acids monoamino-monocarboxylic acids):



$$\begin{array}{llll} \mathrm{COOH} & & & \\ | & & & \\ \mathrm{CH} - & \mathrm{CH_2} - & \mathrm{CH} - & \mathrm{CH_3} \\ | & & | & \\ \mathrm{NH_2} & & \mathrm{CH_3} & \end{array}$$

leucine



$$\begin{array}{llll} \mathrm{COOH} & & & \\ | & & & \\ \mathrm{CH} - & \mathrm{CH} - & \mathrm{CH_2} - & \mathrm{CH_3} \\ | & | & & \\ \mathrm{NH_2} & \mathrm{CH_3} & & \end{array}$$

iso-leucine

found in wool (11.3%) and silk (0.8%).

Leuco- (Gk.), white, colourless.

Leuco compounds Water-soluble colourless reduction compounds, for example, vat and sulphur dyes, in aqueous and alkaline liquors (→ Vat) that are fibre substantive and are rendered insoluble through oxidation to become fixed in the fibre. In most cases, leuco compounds are a different colour to the final oxidized dyestuff. Originally, the term leuco compounds was only used for colourless reduced-dye compounds such as the reduced form of indigo which is completely colourless in acid solutions. Nowadays, the term is also used for the coloured reduction compounds of vat dyes and similar. An example of more or less colourless leuco compounds are the natural dyes which are "dissolved down" to this state during reduction bleaching.

Leuco-sulphur dyes Powder-form of (→ Sulphur dyes) which already contain the reducing chemicals necessary for solution and dyeing. Applied without the addition of sodium sulphide. No longer commercially available.

Levantine squeegee oil stone A natural stone of particular grain size (Levantine), soaked with oil; also known simply as an "oilstone". Used for sharpening or grinding the cutting blade to make it sharp and smooth.

Level controller An automatic measuring device for controlling the level of liquids and printing pastes etc., operates according to various principles. The level of aqueous liquids can be determined by closure of a d.c. circuit or by a pressure switch on the floor of the tank. Mechanical sensors based on a float detection principle are used. Level controllers are a series of measuring systems that use the sensing device to compare should/is values (microprocessor) and subsequently control an on/off device to adjust the actual level of the liquor. The level controller shown in Fig. is suitable for use on a dye padder. This is particularly suitable for strongly foaming, sticky and aggressive liquids. All components coming into contact with the liquid are made from acid-resistant steel so the controller can be used for dilute acids and alkalis.

The PRA 30 level controller monitors and controls liquid levels with an accuracy of ± 1 mm. It consists of a sensor (1), an electronic amplifier (2), solenoid valve (3), push button (4), indicator lamp (5) and an end

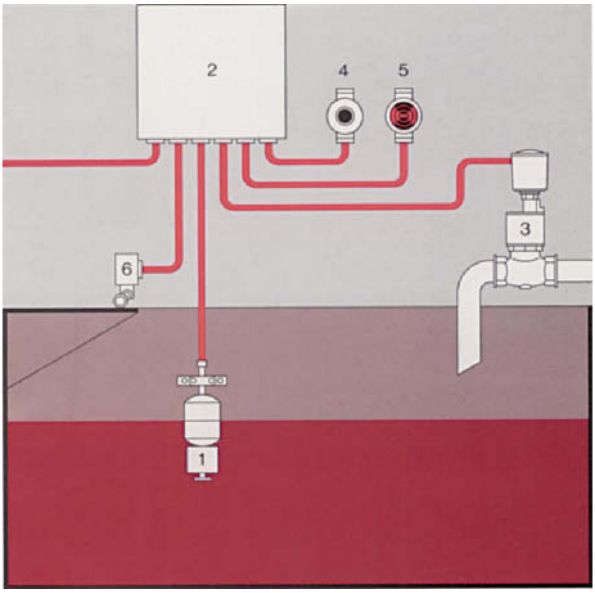


Fig.: Level controller PRA 30 (Erhardt and Leimer).

switch (6) which is only used for lowering and tipping troughs. Optical and acoustic alarms can also be linked into the system. A delivery pump for controlling the supply and discharge of liquid can be used instead of the solenoid valve.

Level dyeing test for package dyed polyester yarn → Shock dyeing test.

Levelling →: Levelling properties; Levelness.

Levelling agent Agents which are added to the dyebath or pad liquor. There is a difference between a) fibre-affinity levelling agents which absorb more quickly on to the fibre than the dye, temporarily block the fibre absorption sites and are then slowly replaced by the dye; and b) dye-affinity levelling agents which, due an interaction with the dye in the bath, increase the size of the dye molecule so that the complex takes longer to diffuse into the fibre. Under dyeing conditions they produce an even distribution of the dye within the textile material and on its surface. The product is based on surface active agents and preparations such as sulphonated oils, fatty acid esters and fatty acid amides, fatty acid condensation products, alkyl sulphates, alkylaryl sulphonates, alkyl and alkylaryl polyglycolethers and fatty acid polyglycolesters as well as amine derivatives. Also used as protective colloids, e.g., for fatty acid-protein condensation products.

The effectiveness of different levelling agents can compared using the Time-Step Levelling Test. On reaching boiling point (time 0), fabric samples of identical size (or 2.5 g wool felt samples) are placed in a dyebath after time intervals of 4, 16 and 32 minutes receptively. Dyeing continues for a further 30 minutes after the last piece has been placed in the bath. After removing the dyed material (4 samples), a 2.5 g fabric sample (or wool sample) is immersed in the bath until the remaining liquor is completely exhausted. Dyeing is continued for a further 30 minutes at boiling point. When the fabric samples are removed from the bath they are squeezed out while still hot and thoroughly rinsed in 250 ml cold water and then removed. In order to establish the drainage properties, a fabric sample is dyed in the same rinse liquor at boiling point.

The liquor ratio, for example during dyeing, is 1 : 50 in comparison to 10 g material. The dyebath contains 1% dye + 10% sodium sulphate calc. + 3% acetic acid (60%) at approx. pH 4.5, + x% levelling agent. The assessment is made by comparing the difference in depth of colour between the individual samples in comparison to the result using the comparison product.

Levelling capacity of dyes → Levelling properties; also the ability of a dyestuff to cover differences in exhaustion onto a substrate. The property of the dye, on the fibre, to migrate from a site of higher concentration to a site of lower concentration. The levelling capacity is dependent on time, temperature and additions of electrolyte and auxiliaries.

Levelling dyes General term for acid dyes with outstanding levelling properties for dyeing wool.

Levelling in finishing A distinction is made between levelling as a treatment on so-called → Fabric straightening machines and the masking of irregularities such as streaks and bands. These are treated with press-fast or ironing-fast stitch-colour corrections or colour pencils (also called retouching or tinting), particularly common for finished wool goods with deep dyed warp and white weft, and for carded-yarn goods before finishing.

Levelling index The five-step → Grey scale for fastness testing of the German Fastness Commission (DEK) corresponding steps for the evaluation of levelness/unlevelness produced according to the so-called Fransen method of dyeing. 5 on the scale represents uniform and 1 significantly non-uniform coloration.

Levelling phase in dyeing During normal dyeing cycles, the rate of exhaustion gives no dimension to a levelling phase. It is accepted that surface adsorbtion of dyestuff onto the fibre surface ocurrs more or less unevenly and experience has shown that this initial unlevelness will disappear after sufficient time during the levelling phase. Levelling (migration) rather than even exhaustion is regarded as the crucial characteristic of levelling dyestuffs (in this context, levelness refers to the uniform distribution of dye on the textile fibre).

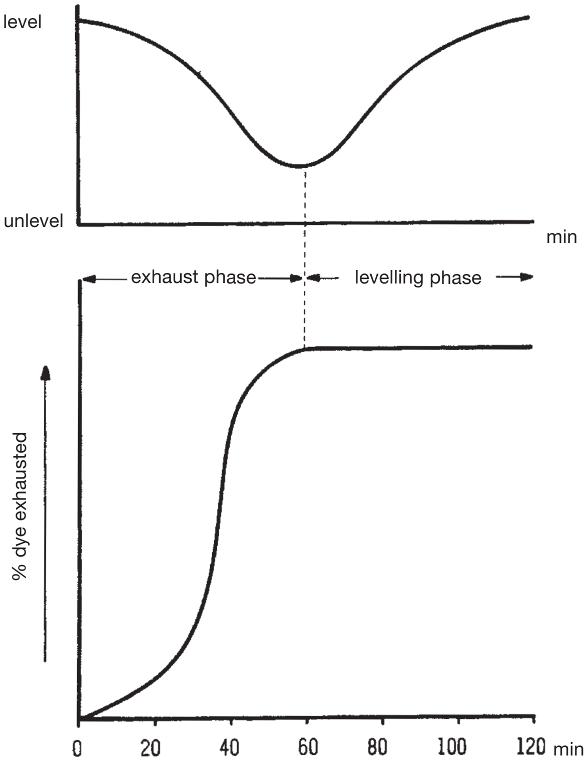

Fig. 1: Exhaust curve and levelness in the standard HT process.

Levelling properties

The lower part of Fig. 1 shows a typical absorption curve for a dispersion dye on polyester fibre during the course of a conventional HT process. The dyeing process consists of an adsorption phase and a levelling phase. A schematic presentation of the levelness of dyeing during the dyeing process is shown in the upper section. The initial state is the undyed textile which may be regarded as uniform. The dyeing increasingly becomes non-uniform during the adsorption phase; during the levelling phase, uniformity increases again. However, during this process, a considerable amount of the dyeing time is devoted to levelling the distribution of adsorbed dye which can be very uneven. The often relatively long levelling phase can be significantly reduced if the adsorption of dye at the start is as uniform as possible. The viability of this route has been proven in the case of cationic dyes and polyacrylonitryl fibres. This knowledge has contributed to process control in the case of polyester fibres, as taking suitable measures to increase the efficiency of the dyeing process has allowed the introduction of so-called rapid dyeing methods.

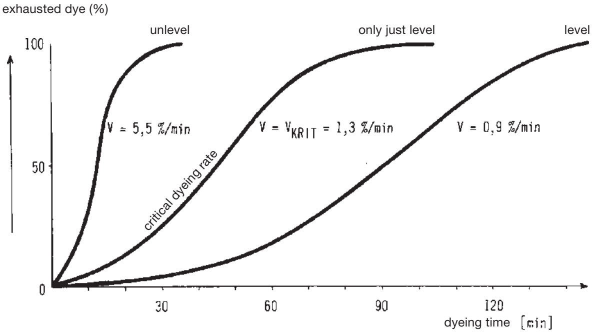

Fig. 2: Critical dyeing rate with a given system.

The critical rate of dyeing (Fig. 2) gives the limits for the production of level dyeings. If the curve is altogether too flat, then time is being wasted. If the curve is too steep, then the critical dyeing speed has been exceeded and dyeing during the adsorption phase is more or less non-uniform. Of course, a certain amount of non-uniformity at the start is acceptable when sufficient time is available for the levelling phase to give a uniform result by the end of the process. This corresponds to the term "acceptable adsorption non-uniformity".

The task of dyeing rapidly and uniformly, therefore, requires that the dye adsorption speed is matched to the critical or just allowable dyeing speed as determined by the machine and other conditions. This is most easily achieved by using a method involving temperature control. Within the temperature ranges in which the dye adsorbs slowly, or if the dyebath is already significantly exhausted, absorption is accelerated by rapid heating. For those cases where the dye has a particularly high adsorption rate, adsorption can be slowed down by heating slowly.

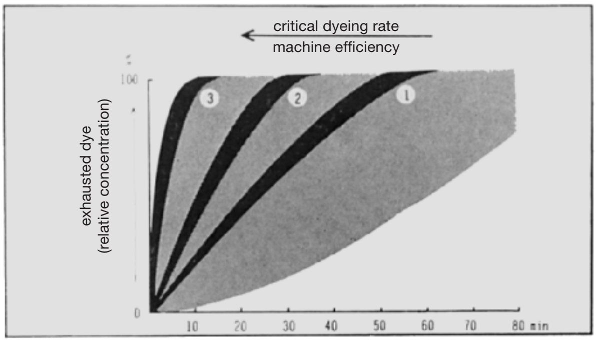

Fig. 3: Exhaust curve bunching due to process control in adjusting to the critical dyeing rate.

The starting position represents a great variety of possible adsorption curves which can lie within a wide range; this range is shown by the areas highlighted in grey in Fig. 3. Process control is used to bundle these adsorption curves into a narrow group. This process must be oriented to the critical dyeing speed if dyeing is to be uniform from the start. For any given substrate, the more efficient the machine is the higher is the critical dyeing speed. How much the rate of adsorption can be increased, therefore, depends greatly on whether an appropriately efficient machine is available. This relationship is represented by curve groups 1, 2 and 3 where 3 corresponds to the highest requirements.

Levelling properties Term used for the ability of a dye to exhaust evenly onto goods, i.e. the levelling out of different dye concentrations or amounts per unit area. Critical in achieving a level dyeing are → Exhaustion rate and migration properties of the dyestuff.

Levelling property test,

I. Roll test: Fabric is rolled on part of a glass rod and the half not on the rod is immersed in the dyebath. Dye according to the method usually used for the dye in question and then immerse the undyed portion and continue to dye. The levelness between the two halves of the fabric are assessed.

II. Migration test: Part of the sample is removed before the start of dyeing and immersed in the dyebath as mentioned under item I; in this also, an assessment of the colour difference is made between the sample and migration sample.

III. SDC migration test: a sample of fabric is dyed in a dyebath, while a second comparison sample is dyed in a "blind" dyebath, i.e. a bath without dye but containing auxiliary aids. After the treatment is over, the half of the "blind" sample is swapped for half of the "normal" sample and this is dyed in the "blind" bath for a further thirty minutes. The contrast between the two samples is assessed with the aid of a grey colour scale.

IV. → Strike migration test.

V. Felt chromatogram: The liquor is allowed to circulate through columns of felted fibre under certain conditions for a long period of time and the uniformity of the dyeing on the felt assessed.

Levelling risks The sum of all dyestuff and dye-process specific parameters which affect levelness in a dyeing process. Such parameters are, for example:

- constitution and finish of the dye,
- temperature-dependent exhaustion properties,
- reactivity,
- diffusion,
- migration properties,
- fabric preparation,
- temperature control,
- auxiliaries and electrolyte additions,
- dyeing time,
- machine-dependency of the dyeing process.

Levelness This term is used to describe the uniformity of distribution of a finishing substance on and within goods after treatment. It is frequently used as a parameter for the certainty and economy of a dyeing process. A dyeing is judged as level when the dyed goods have the same depth of colour and colour tone all over (optimum levelness). The levelness tolerance largely depends on the use to which the goods are later put. Basically, levelness can be controlled according to two strategies:

I. The principle of controlled adsorption, i.e., mainly uniform adsorption and relatively short migration phase for full penetration dyeing.

II. Migration method, i.e. rapid absorption and extended migration phase for levelling non-uniformity.

The choice of method depends on the dyeing machine system, the type and make up of the textile and the economic considerations. The process control is also dependent on the dye and dye auxiliary aids which are used.

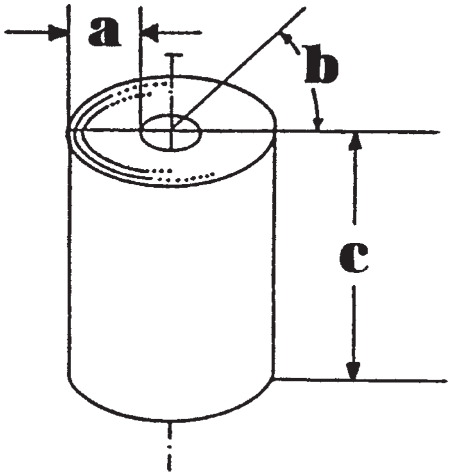

Fig. 1: Dye gradients in yarn packages.
a = radial; 2 = azimuthal; c = axial.

Package dyeing can be analysed for levelness, for example, by describing a package in three-dimensional terms, i.e. by a radial, axial and azimuthal dye distribution (Fig. 1). However, initially it is sufficient to illustrate the situation in terms of radial dye distribution.

Example: the levelness of dyeing is tested by taking a sample from the middle package on the press column in the dyeing system. Samples are taken from the inner and outer layers of the package at predetermined intervals. The distribution of sites from which the samples

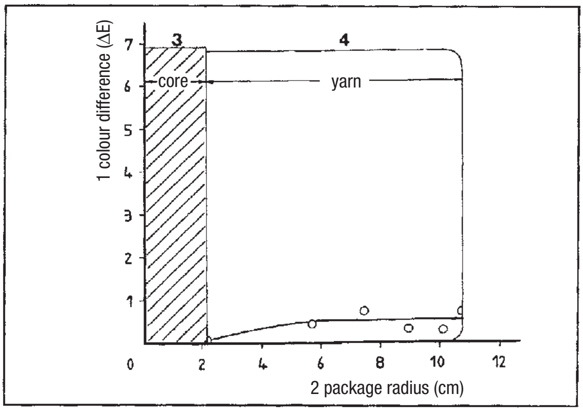

Fig. 2: Levelness testing: level dyeing, as ΔE < 0.5.

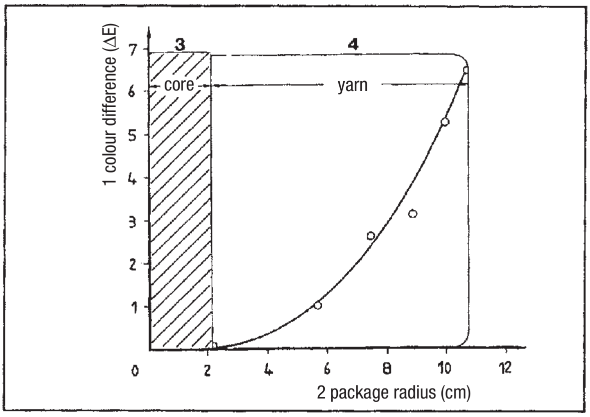

Fig. 3: Levelness testing: unlevel dyeing, as ΔE > 1.

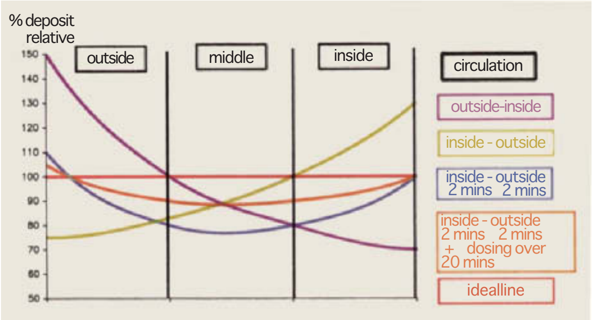

Fig. 4: Relation between levelness and liquor circulation.

are taken is selected to correspond to the package diameters; thus ensuring even distribution throughout the package in terms of its volume, i.e. the liquor must penetrate the same amount of yarn from one sample site to another. Knitted pieces are prepared from the samples of yarn (n = 5–6) and these are subjected to colorimetric measurement (Figs. 2 and 3). Fig. 4 shows the relationship between levelness and liquor circulation.

Leviathan (hebr. liwjathan = giant), continuously operating plant for washing loose wool which is sluiced through 5–7 wash vats (2500–4400 l capacity) by means of (fork, drag and shake) rakes in accordance with the pass-on principle. Mangle rollers are located between each vat and the liquor is controlled by the counter-flow principle. The liquor flows at approx. 40-50 l/min. The capacity is ca. 300–400 kg/h. Washing agent consumption for 1000 kg raw wool is approx. 20 kg soap, 1–2 kg hard water stable detergent and 12 kg sodium carbonate.

L-form → Optical activity.

L/H Abbrev. denoting an aqueous → Emulsion, for example an oil (Gk.: lipos) in water (Gk.: hydro) system.

LI → Flax (linen), → Textile fibre symbol, according to DIN 60 001 T4/08.91.

Li Symbol for the element lithium (3).

Liebemann's indophenol reaction Test for nitrosoamines or easily nitrosatable imidazolidones and pyrimidones in synthetic resin finishes (→ Nitrite reaction). Procedure: fuse 1 ml nitrosoamine containing solution with 0.5 g phenol, mix with 3 ml concentrated sulphuric acid and after 2 minutes pour over ice. Then add excess sodium hydroxide. In the presence of phenol, nitrosoamines yield violet to deep-blue indophenols.

Ligands (Lat: ligamen = band, bond), term used for inside a complexing molecule (→ Complex compounds) for atoms or atomic groups which surround a so-called central ion; for example, in potassium hexacyanoferrate (III) $K_3[Fe(CN)_6]$ the complex is $[Fe(CN)_6]$, the central ion is (Fe^{3+}) and the ligands are $(CN^-)_6$, i.e. the six cyanide groups are arranged around the Fe^{3+} ion.

Light → Light wavelengths.

Light barrier Opto-electronic safety or monitoring device used for machines; also used for the automated opening or closing of doors etc. Operates according to the → Photocell principle.

Light cabinet Colour-matching cabinet; → Colour matching of dyed/printed samples.

Light (colour),

I. → Lightness.

II. Term used for classification according to "white and pastel shades".

Light damage → Photochemical fibre degradation, yellowing of textiles.

Light edges → Edge-to-edge unevenness.

Light exposure damage The strength of textile fibres decreases with the time of exposure to sunlight (Fig.). The complex photochemical reactions vary dependent on the type of fibre. Polyamide 6, where the decrease can be 50% and more, is at particular risk, whereas natural fibres are affected less. (→ Photochemical fibre degradation).

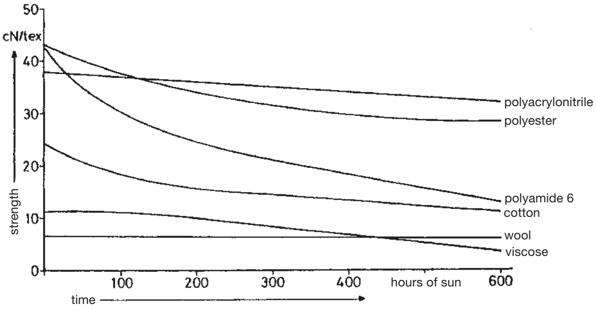

Fig.: Light exposure damage in the form of strength losses of various fibres.

Light fading Exposure to light, through photochemical reactions, causes damage to dyeings; recognisable as changes in the colour tone.

Light fastness When textiles are in use, typical quality characteristics such as colour fastness or strength parameters may change due to external factors. In this connection, the effect of long-term exposure to light in particular can give rise to changes. When wool is exposed to radiation from sunlight, for example, protein and possibly nuclein components absorb energy. This gives rise to photochemical reactions, such as the oxidation of amino acids, cleavage of peptide chains and cross-links, cross-link reactions and double bond formation. The mechanical strength of the irradiated goods is reduced. The effects can be clearly seen, e.g., in the case of car upholstery. Sunlight can cause a considerable rise in temperature in some cases, such as the inside of a car. Measurements have shown that, on the parcel shelf in particular, the temperature can reach 122°C. A light fastness test in accordance with DIN 54 004 is of little help. To some extent, car manufacturers require a different type of light fastness such as → High-temperature light fastness.

In the case of car upholstery, light-fastness testing at elevated temperatures is required to simulate the combined effect of long-term exposure to light and high fabric temperature. The type of long term solar radiation can alter the strength of the coated fabrics in different ways depending on the thickness of the coating (Fig.). At the same time, environmental effects on the different irradiated sites accelerate the decrease in tear strength by different amounts. This type of complex long-term behaviour (irradiation, temperature and rain etc.) in the

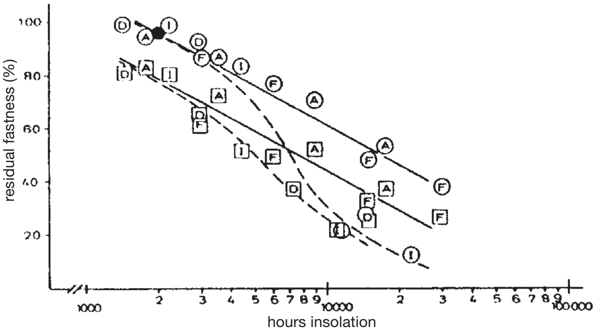

Fig.: Residual fastness in relation to insolation hours (practical weathering at 2000 hour Xeno test).
Coating thickness 20 µm (❑) or 50 µm (0).
D = Wuppertal; A = Ebnit; I = Dormeletto; F = Miami.

case of coated fabrics can in no way be predicted from artificial weathering, so it is necessary to use real weathering in various different climates for periods of 2–5 years in order to give a quality prognosis (Fig.).

The resistance of textiles to the effects of UV radiation is an important factor in the area of net-curtain fabrics, ready-made curtains, belts, carpets or geotextiles. On the one hand, the fibre producer is endeavouring to stabilize his products to UV radiation and on the other, test institutes are looking for a short duration test method to provide information on fabric behaviour in the presence of sunlight which is to some extent accurate. A short duration test to simulate the real conditions is always fraught with problems: while the processes in practice take place slowly and are caused by relatively weak effects, the short-duration test has to highlight these same effects quickly (in most cases without intermediate periods of recovery) and under the increased influence of a particular effect. In addition to this, several effects are always at work simultaneously in practice and these interact with each other. In the laboratory test, however, only one or at most two or three effects can be examined at the same time.

During outside weathering, the following factors are important in the case of textiles:

1. Due to radiation, the textile can be at a higher temperature than the surrounding air. This temperature may not be high enough to induce thermal decomposition processes. However, the reactions which are taking place are probably hydrolytic, oxidative and secondary photochemical processes which proceed faster the higher the temperature.
2. Moisture and rain in particular can cause physical damage (freezing) and swelling. Hydrolysis and catalysis can be initiated by rain and air and are aided by dirt.
3. Wind stresses textiles mechanically, especially by the impact of tiny particles.
4. The attack of air pollution can be extremely aggressive for textile fibres. Worth mentioning in particular are SO_2, SO_3, H_2S, $(NO)_x$ and O_3. Organic compounds (unsaturated alkyls and aromatic compounds) are catalysts for photo-oxidation.

The chemical bonds in textile fibres are mainly broken by the short UV wavelengths of the solar radiation. The UV component varies strongly with geographical location and altitude. Seasonal changes and changes throughout the day are significant and vary from year to year. These fluctuations are greater the shorter the wavelength. To some extent, all these effects have interactions, i.e. their effects on the textile may show some synergy. Outside weathering at different locations or different times cannot therefore be compared. If this is not possible, it will be hardly possible to develop artificial radiation or weathering which can be used to predict the general behaviour of textiles on exposure to the sun.

Light fastness testing The most significant factor in weathering is the effect of solar radiation. The sun radiates a continuous spectrum ranging from UV radiation (Wavelengths < 380 nm), through visible (wavelengths 380–780 nm) to infrared heat radiation (wavelengths > 780 nm). Radiation meeting the earth includes wavelengths ranging from approx. 300–3000 nm which corresponds to part direct solar radiation and part diffuse celestial radiation = solar and sky radiation. The last mentioned is not constant but varies according to position, time of day and time of year.

Artificial radiation sources, for colour measurement and testing, were developed by the Commission International de l'Eclairage (CIE) and standardised as a global radiation distribution in the standard illuminant D65 according to CIE Publications Nos. 15 and 20. When considering the effects of solar radiation, it must be remembered that it is the short wave UV radiation which is crucial in triggering photochemical decomposition reactions in fibres and dyes even though this represents only approx. 5% of global radiation. The UV radiation range is therefore very important when carrying out light-fastness tests; well simulated solar radiation is an essential requirement for radiation sources used in accelerated weathering devices. The combination of the type of radiation source and the optical filter system used is decisive for accelerated weathering equipment and the results it produces. The radiation emitted by xenon gas-discharge lamps represents the best possible technically realisable simulation of solar radiation. Since their initial use in the Xenotest 150 in the fifties (W.C. Heraeus GmbH Original Hanau product range) these radiation sources have been adopted across the world and have largely superseded the carbon-arc radiation sources introduced at the beginning of the twentieth century. The ISO standards and many national standards for the determination of light fastness in textiles exclusively require that filtered xenon-arc radiation sources be used in accelerated weathering equipment.

Light fastness testing

1. Illumination in Xenotest 450 in accordance with or in line with ISO 105-B02: the samples are arranged in a circle and rotated at a distance of approx. 25 cm around the xenon-arc lamp. UV and IR filters are placed between the sample carriers and the xenon-arc lamp. Illumination is carried out at air temperature of 35°C and air humidity of 65% rh.
2. Illumination by UV lamp: the samples are arranged in a circle around a high-pressure mercury-vapour lamp at a distance of approx. 28 cm. The samples are stationary. The temperature and humidity of the test room are not controlled.
3. Illumination in the Fadeometer - AATCC Test Method 16A – 1977: the samples are rotated in a circle around a carbon-arc lamp at a distance of approx. 25 cm.
4. Weathering in the Xenotest in accordance with ISO 105-B04: the samples are sprayed for 1 minute during illumination (demineralised water) and dried for 29 minutes (without additional heat or moisture).

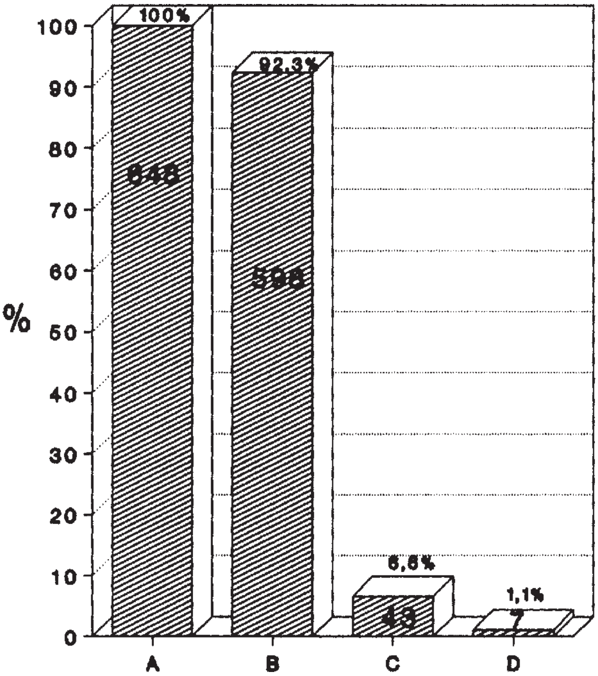

Fig.: Comparison of light fastness values obtained by colorimetry and by visual assessment.
A = overall evaluation; B = no deviation from visual assesment; C = deviation ± 0.5 points from visual assessment; D = deviation ± 1.0 points from visual assessment.

The measurement of intensity of radiation (radiation flux per unit area, expressed in W/m^2) or the radiation (radiation intensity integrated over time, expressed in Ws/m^2 or J/m^2) in accelerated weathering equipment places high demands on the long-term stability of the measurement equipment due to the conditions prevailing in the test room (high temperature and humidity). One radiation measurement instrument, for example, the Radialux (W.C.Heraeus GmbH Origin Hanau product range), is available for use in the Xenotest tester and in natural weathering tests. The Radialux consists of the processing units with LCD display for reading off the values and a UV and global sensor for measurement within the 300–400 nm and 300–800 nm wavelength ranges. The sensors are made of stainless steel and are cylindrical in shape in order to receive the optical and electronic units used for recording the measured values. They are inserted into the Xenotest tester instead of a sample carrier and are therefore subjected to the same conditions as the sample. The power is supplied via two special 7V lithium batteries. The incident ray passes through a scattering lens made of Teflon to a cosine recorder, through optical filters to establish the current measurement range and then strikes a photo diode. In order to read a sample value, the sensor is removed from the Xenotest tester and connected to a processor unit by means of a cable. After pressing the function keys, the radiation sample appears on the digital display in Wh/m^2. The average radiation intensity is calculated from the sample value divided by the time of exposure. Where the arrangement of the sensor is stationary, as is the case for the Suntest apparatus (also Heraeus) or a natural weathering test stand, the current radiation intensity can be read off in W/m^2 directly.

For illuminations in accordance with ISO 105/B01 and B02, the ISO light fastness scale (Blue scale) is used. This scale consists of a series of standard-depth dyeings using blue dyes on woollen fabric which are arranged in order of increasing light fastness labelled from 1 (very low) to 8 (very high). These standard-depth dyeings are known as blue types 1–8 or BT 1–8.

In the case of illumination in accordance with the AATCC method 16 the American light-fastness scale is used. In this case, graduation is achieved by an internal mixture of a worsted wool with very poor light fastness and a worsted wool with very good light fastness. The American scale is labelled L2–L9. In the case of both scales, each step should require double the illumination time to achieve the same colour as the step below.

Visual evaluation of the colour change is encumbered by a large amount of scatter. For this reason, efforts have been made to carry out the evaluation using colorimetric methods. When comparing a shade change in the sample against a grey scale (for example, in the case of wash fastness) the colorimetric method is clearly more reliable than the visual assessment. On average, the standard deviation to be expected when using colorimetry is around 0.3 against the 0.55 expected in the case of visual assessment. For light fastness, on the other hand, both the colour change in the illuminated sample and the illuminated different coloured wool-blue depths of the light fastness scale must be assessed. In the case of the visual assessment, this comparison is direct. When the colorimetric method is used, the points on the grey scale for the sample and wool-blue depth are determined independently. The light-fastness points determined using colorimetry compare well with values obtained visually (multi assessment) (Fig.). During the time of the colour change, nearly all of the seven cases with a deviation of ± 1.0 points resulted from the xenon-arc illumination (ISO 105/B02) and could be attributed to the Blue depths 4 and 5, between which there is relatively little difference, (source: Weber, Kübler and Ushöfer).

Light hardening of phosensitive coatings Found in coatings which rely on the use of → Light-sensitive films in which chemical reactions are triggered by light energy. These reactions lead to changes in the properties which can be used to produce patterns (→ Screen making). Normally, gelatine is used which, when mixed with chrome salts, forms an insoluble compound (→ Chrome gelatine) when exposed to light radiation for long periods. In most cases, the reaction of gelatine with certain chrome (III) compounds brought about by the photochemical reduction of chrome (VI) compounds (chiefly potassium and ammonium dichromate) are utilised to harden the carrier coats. Chrome salts do not show this effect until they are incorporated into colloidal organic substances. The sources of illumination used for light-hardening are mainly carbon-arc lamps, high-pressure mercury-vapour lamps or appropriate incandescent lamps. The threshold value is the degree of hardening during light hardening. For chrome-silver paper, this value is 0.5 and for compounds produced from gelatine and chrome salts this is $8 \cdot 10^6$.

Light-induced ageing, resistance to Fastness characteristic of pigment prints which appears as a change in wet fastness properties after the printed pattern has been exposed to light.

Light intensity Basic parameter of the SI system (→ SI units) with the candela as the fundamental unit (unit symbol: cd).

Light microscope Simple → Microscopes, consisting of two lens systems inside a tube: a) the objective consisting of several individual lenses which is placed directly over the object to be viewed (objective) and b) the eyepiece containing two lens systems (condensing and eyepiece lens) 2–4 cm apart which enlarges again the reversed image enlarged by (a), as through a magnifying glass. Corresponding enlargements and resolutions (ability to recognise the finest details) of the object are created by moving (a) in relation to (b) (Fig.). The resolution, of course, decreases with increasing magnification and is dependent on the wavelength of the light, i.e. if the fine structure is of the same magnitude as the wavelength, then this will produce diffraction effects (blurred, contourless microscopic image). Consequently, using a light microscope for magnifications above 2000 x is to no avail, so an → Electron microscope must be used instead.

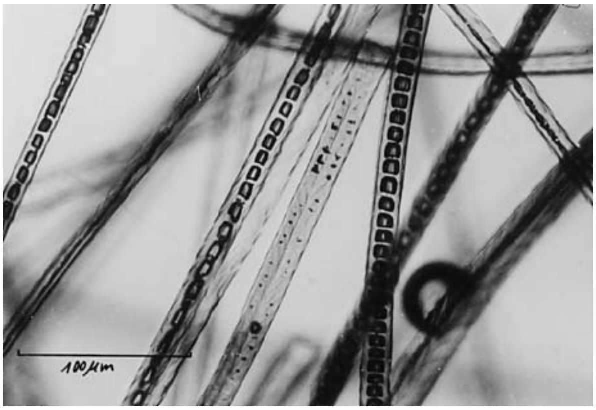

Fig.: Longitudinal view of angora fibres under the light microscope.

Lightness Used as a so-called blackness value integrated component of coloured and non-coloured light sensitivities (dependent on illumination). During → Colour measurement of coloured bodies it is identical to the luminosity coefficient β and can be clearly seen from the spectral remission curve. As measurement value (→ Colorimetric measure) this lightness is used in the so-called Standard Colour Value (Relative lightness, lightness value or lightness index) Y = 100%.

Light protective finishes for wool Treatments for wool textiles to protect fibres and dyes from the effects of light and in particular UV radiation, for example, so-called UV absorbers (Fig. 1). After exposure to light, wool in particular is subject to numerous changes. Initially, the wool is bleached (photo-bleaching or first break). As exposure continues, especially if there are other damaging influences such as temperature and a high proportion of UV in the light radiation (perhaps during the summer months in southern countries), the wool appears to yellow (→ Yellowing of wool). Apart from changes in colour, the wool is subject to changes in its chemical composition when exposed to light. These are in the form of amino acid decomposition, photo-oxidation of cystine and methionine and the aromatic amino acids, chiefly tryptophan and tyrosine. Photodegradation of histidine, lysine and other amino acids may also take place as a result of exposure to light. Photo-oxidation of wool also produces changes to its solubility properties, which can be in the form of increased alkali or

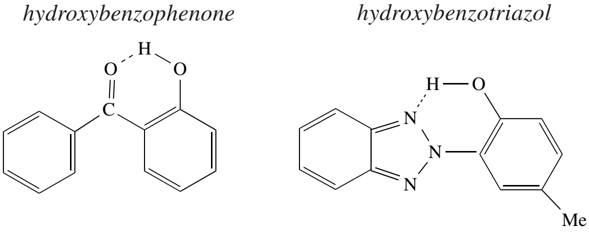

Fig. 1: Structures of UV absorbers.

pronase solubility. After short periods of exposure to light, new cross-links may also be formed which can, for example, lead to decreased urea-bisulphite solubility. Apart from the change in chemical composition of wool, light damage may cause a loss in mechanical stability.

Before now, sulphonated hydroxybenzophenones, hydroxybenzotriazols and hydroxyphenyltriazines have been used as UV absorbers on wool. Sulphonated UV absorbers have been found to be quite effective in reducing photo-yellowing.

Apart from UV absorbers which deactivate incident light and render it harmless, UV screeners used for stabilising polymers and cosmetics can also be exploited. These are able to reflect UV light, scatter it or absorb it on the surface of a polymer material and prevent it from reaching the interior of the material. Pigments such as titanium dioxide, barium sulphate, zinc oxide and iron oxide are used as UV screeners. Apart from UV absorbers, other light screening agents can be used as light-protective finishes for polymers. These are able to deactivate any photo-products which have formed (sec. stabilisation). They function as radical catchers, antioxidants or singlet oxygen quenchers (Fig. 2).

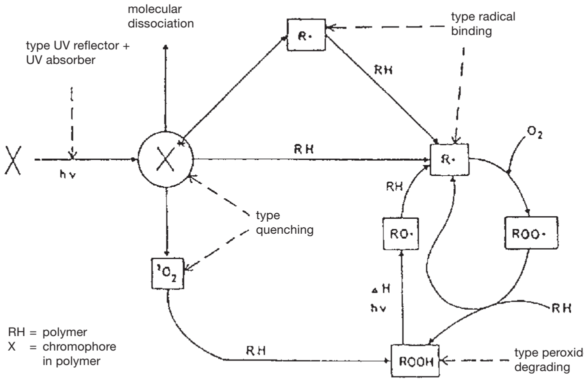

Fig. 2: Photodegradation and stabilisation mechanisms of polymers.

Sulphonated UV absorbers of the hydrobenzophenone and hydroxybenzotriazol type are able to protect wool from photo-yellowing and other light damage as the substituents in these substances have a significant influence on the effectiveness. Straight sulphonate hydroxybenzophenones have a characteristic yellow colour which on application to wool turns it yellow. Sulphonated hydroxybenzotriazoles do not have this effect. UV absorbers operate in many different ways. In general, they not only function as UV absorbers but also act as radical catchers or decompose hydroperoxides. It is assumed that UV absorbers based on the above-mentioned substances operate by de-activating radiation energy via intramolecular hydrogen bonds between hydroxyl groups and keto or triazol residues.

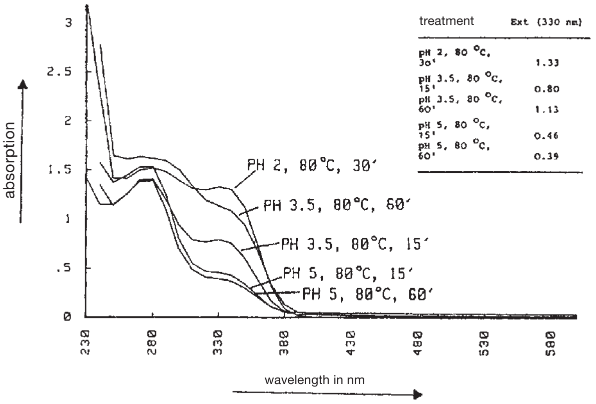

Fig. 3: UV absorption spectra of wool samples treated with Cibafest W under varying conditions.

In the case of sulphonated hydroxybenzophenones under strongly acidic conditions, the intramolecular hydrogen bonds are fully developed in wool (Fig. 3). Until now, application has been recommended under strongly acidic conditions (pH 2). The photo-stabilising effect of hydrobenzotriazole is not due to an energy transfer via the intramolecular hydrogen bonds. Stabilisation of these bonds is therefore not as important as it is for hydroxybenzophenones. However, in the case of the sulphonated hydroxybenzotriazol, Cibafast W (Ciba Geigy), effective stabilisation was found for wool after application under weaker acid conditions (up to pH 5), i.e. conditions which are normal for dyeing wool.

After application of Cibafast W at higher pH's, a light-protection finish can be obtained for the treated wool which is comparable to that produced by applications under strongly acid conditions. The effect of sulphonated hydroxybenzotriazol is seen in the delay in yellowing and improved chemical and mechanical stability. After application of Cibafast W at pH 5, good rates of bath exhaustion were found for the fibre but with low UV absorptions at 330 nm.

The radical catchers used were sterically hindered phenols or amines. Esters of the octadecyltertbutylhydroxyphenyl propionate type are characterised by poor water solubility. Their use as light-protection agents for wool is therefore limited. Although absorption of the light-protection agent is achieved for wool via application using hydrophobic solvent systems, this does not lead to photo-stabilisation. Sterically hindered phenol applied to wool together with sulphonated UV absorbers shows, at most, a synergistic effect. → Yellowing on storage is known and has been attributed to the migration of phenol-based antioxidants from the packaging materials. This means that problems could arise during the storage of wool which has been treated with antioxidants containing phenols. Sterically hindered amines of the piperidine type (Fig. 4) act as radical catchers. Radicals produced by photo-reactions (in *bis(1,2,2,6,6-pentamethyl-4-piperidyl)sebacate*

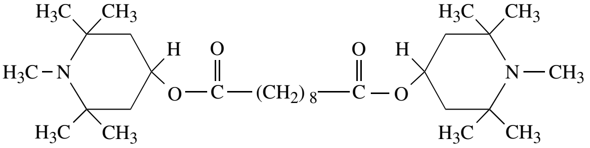

Fig. 4: Structure of the sterically inhibited amine tinuvine 292 (Ciba Geigy).

most cases, peroxides, hydroperoxides and CH radicals) are de-activated via circulation systems in which radicals are caught by the amine residues of the piperidine. Increased radical concentrations have been found for exposed wool. Sulphur radicals are formed in particular, but also those which are produced by the cleavage of NH or CH bonds. Thus, using radical catchers as light stabilisers for wool appears to be a reasonable route to take. The most well-known sterically hindered amines are of high-molecular type and, on solubility grounds, are therefore not suitable for use as stabilisers for wool via application from a dyebath.

The photo-degradation of wool is oxidative. Apart from the formation of cysteic acid from cystine, oxidation products of tryptophan are formed in particular. Antioxidants should therefore be appropriate for use in light-protection finishes for wool. As antioxidants, sterically hindered phenols and phosphite esters are used for stabilising polymers. Phosphite esters act as hydroperoxide decomposers. The calcium salt of sterically hindered phenol (Fig. 5) absorbs well on to wool (source: Schäfer and Gröger).

[calcium-bis-(3,5-di-ter.butyl-4-hydroxyl-benzyl-monoethyl-phosphanate]

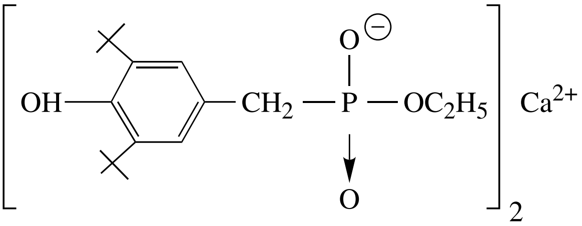

Fig. 5: Structure of the antioxidant Irganox 1425 (Ciba Geigy).

Light resistance testing of fibres and yarns Used to assess damage resulting from xenon arc light using a co-illuminated → Blue scale as a numerical value. Samples of similar thread- and fibre-titres and similar twist, in the case of yarns, are advisable for comparison exposures. Where necessary, agents which have been used for post-treatment must be removed. The samples are mounted stress-free in the case of fibres or under slight tension in the case of threads, and isolated from the effects of air from all sides. The start of discolouring from Step VI on the blue scale serves as the exposure unit. At least three exposure units are required to assess the course of damage. During exposure, the air temperature and the air humidity in the apparatus must be monitored. The light damage is assessed before and after each exposure by determining a) the wet strength and wet expansion and, if desired, b) the average degree of polymerization or damage factors.

Light sensitive coatings Used in the manufacture of print screens according to the photochemical method. The typical coatings are based on → Chrome gelatine and polyvinyl acetate. → Light hardening of photosensitive coatings.

Light sensitivity → Photochemical reactions.

Light sources → Standard illuminants.

Light table A glass plate which is illuminated from underneath and used for checking the opacity and register of diapositives. → Screen making.

Light tenderer → Vat-dyes and fibre damage.

Light transmission measuring instrument Instrument for determining the degree of openness of printing screens. This facilitates precise photometric recording of the open printing areas and shows it directly on a digital display as a percentage of the total surface area. The value obtained, together with the mesh size and theoretical ink volume, gives the quantity of printing paste required per pattern and colour. Procedure: the negative film of each pattern or each printing ink paste is entered and the percentage printing area can be read off the display within a few seconds.

Light wavelengths Changes in the energy state of electrons within an atomic shell from a higher to a lower state are shown by the emission of energy in the form of an electromagnetic wave. Light is identified as a certain range of wavelengths of which the range of visible light waves represents only a part. Visible light contains wavelengths that give rise to reactions within the eye, i.e. trigger the process of seeing. Beyond this so-called visible spectrum, which is necessarily restricted by the sensitivity of the eye (→ Eye sensitivity to hue, chroma and brightness), are wavelengths of higher and lower energy that are of importance to the textile industry.

Optics is the science of light. It deals with phenomena perceived by a sense organ, the eye. The structure of its different branches developed through history has come about as follows:

Opinion about the nature of light has changed several times over the centuries. Newton had developed a particle theory by 1672. According to this, a light source sends out small particles which move in straight lines at enormous speed until they enter the eye where they trigger the sense stimulus either directly or after reflection from other objects. Using this theory, Newton was in a position to explain reflection and refraction of light. The phenomena of refraction and interfer-

Optics is the science of light. It deals with phenomena perceived by a sense organ, the eye. The structure of its different branches developed through history has come about as follows:

Opinion about the nature of light has changed several times over the centuries. Newton had developed a particle theory by 1672. According to this, a light source sends out small particles which move in straight lines at enormous speed until they enter the eye where they trigger the sense stimulus either directly or after reflection from other objects. Using this theory, Newton was in a position to explain reflection and refraction of light. The phenomena of refraction and interference of light could initially only be explained by the wave theory of light developed by Huygens (1678) which was later substantiated by the work of Young (1802). If at first the opinion was that these waves were elastic longitudinal waves in a universe filled with “ether”, then the conclusion drawn after the discovery of polarisation of light by Malus (1808) and Fresnel (1815) was that light was a transverse wave. The nature of light waves as electromagnetic transverse waves was finally recognised by Maxwell in 1865. The Maxwell equations have as their solution electromagnetic waves which spread out in a vacuum at the speed of light. As it was possible to derive all the laws of optics from the basic equations of electrodynamics, optics became a branch of electrodynamics.

Classification of visible light within the total spectrum of electromagnetic waves: the visible spectrum lies within the range of wavelengths $\lambda = 380–780$ nm. The wavelength is related to the frequency f and speed of light c via the equation $c = \lambda \cdot f$. With the speed of light in a vacuum at $c_0 = 299\,792.458$ km/s, the frequencies of visible light range from $f = 3.84 \cdot 10^{14}$ to $7.89 \cdot 10^{14}$ Hz. Accordingly, the human eye is sensitive to a frequency of one octave.

The wave theory of light had been established by the end of the nineteenth century but at the turn of the twentieth century, experiments were known that could not be interpreted by wave theory. Difficulties always arise when light interacts with materials, for example, in the case of absorption and emission of light. One way out was discovered by Einstein (1905) with the introduction of his quantum theory of light. According to this, light consists of individual light quanta which exchange energy with material in self-contained packets, i.e. in discrete quantities. Depending on the experiment, therefore, light was interpreted either in terms of streams of particles or as an electromagnetic wave. This twin function in the description was termed wave-particle dualism. A theoretical description which united both aspects was not available until the arrival of quantum optics or quantum electrodynamics.

Geometrical optics was based on the premise that, in a homogeneous medium, light rays radiate in straight lines. The term “rays” originated from particle theory, where the path of a particle was describes as a straight ray. Even in wave theory, the light ray has a meaningful place: it corresponds to the normal on the wavefront. In the case of point-shaped light source with concentric spherical-shaped wavefronts, the rays emitted by the light source are perpendicular to wavefronts. The sum of all rays which are restricted by the aperture is termed a ray beam or ray bundle. If the rays are emitted from a point source, or intersect at a point, the bundle is homocentric. In the case of plane waves, such as those transmitted by lasers or are found at large distances from the light source, the rays are parallel. Light rays which intersect have no effect on each other. Each ray continues to behave as if no others were present (source: Hering, Martin and Strohrer).

Lightweight coating Lightweight coating can be achieved using a blade in the run-in zone of a stenter. Coatings are usually very thin and are often applied as several coats (Fig.).

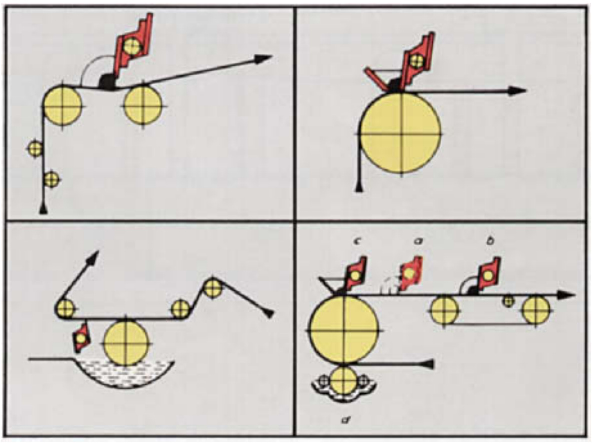

Fig.: Lightweight coating upstream of stenter frame (according to Brückner): from aqueous solution or from dissolvent (in microporous coating).

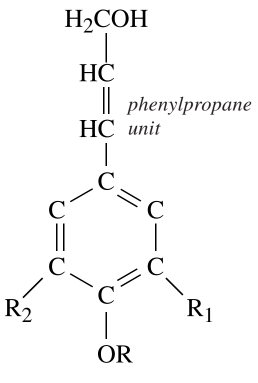
Lignin Found in the “woody” parts of → Cellulose that occur with the progressive maturing of a plant and as the cellulose cells thicken. A component, for example, of sulphite cellulose waste liquor. The name lignin was first coined by F. Schultz to describe that part of wood which dissolves when oxidized with potassium chlorate $KClO_3$ and nitric acid HNO_3 and then treated with dilute ammonia. It was later further defined by P. Klason to the calculated difference between wood and cellulose plus hemicelluloses. In general, lignin is defined as those polymeric, amorphous, encrusted substances in wood made up of methoxyl containing phenylpropane units which are not hydrolysed by acids. In terms of quantity, lignin is the most important component after cellulose of the woody cells of any plants. In herbaceous plants, there is less lignin and the content fluctuates greatly; grass contains 15–20% depending on the age, coniferous woods contain 26–30% and deciduous woods contain approx. 20–22% lignin. In wood it is associated with cellulose in the intercellular regions where it is found as a secondary substance in the interfibril capillary areas of the cellulose fibres forming the cellulose wall. This process of lignification produces a composite material, somewhat resembling steel-reinforced concrete, which is composed of lignin, which provides high compressive strength, and cellulose which provides high tensile strength. Within this close association with cellulose, a significant part or all of the lignin is bound to other polysaccharides but not to the cellulose. Characteristically, the lignin is unevenly distributed within the cell structure of the wood. Between the cell walls, i.e, the area of the middle lamella, the lignin content is high. The primary cell wall is also lignified while the secondary cell wall, especially in the case of deciduous trees, contains much less lignin. In general, the concentration of lignin in the fibre is at a maximum on the outside and decreases towards the lumen in the centre.

Various different types of vegetable matter also containing lignin are found in raw wool. Australian scoured wool is recognisable by the snail clovers (Lat. genus Medicago) which it typically contains. These may contain up to 30% lignin. The diameter lies between 3 and 8 mm depending on the species and their weight varies from 14 to 15 mg. The seed husk is covered with protective hairs which tangle with the coat of the animal. A second group is composed of the sandbur (lat. genus Cenchrus). Although they appear only occasionally, they are very difficult to remove from the wool due to their sharp thorns. They are 7–11 mm long and weigh 17 mg. The burweed (Xanthium spinosum) has a thick woody kernel. Because of their compact structure, they often fall out when the bales are opened. Straw and leaf remnants weigh less. However, they can impair the appearance of the fabric considerably. Due to their elastic properties, they move out of the way of all machinery. Some of the barley grasses (Hordeum leoprinum) also get into the raw material.

I. Monomers: there is always a degree of uncertainty when analysing the chemical structure of lignin. However, it has been shown that lignin has aromatic character and is a derivative of phenylpropane. The central unit of the molecule is a benzene ring carrying methoxyl and hydroxyl groups as active groups and a propane chain.



As well as the methoxyl group, each benzene nucleus has one aromatic oxygen to which can be assigned either a free or an alkoxylated phenolic hydroxyl group. The hydroxyl groups may appear on the benzene nucleus (phenol-) and on the propane chain. The phenylpropanes contain one or two methoxyl groups, depending on the type of wood. Only an extremely small number of free carboxyl groups occur in lignin. Carboxyl groups appear more frequently in the form of esters, particularly in the lignins of deciduous woods, bamboos and grasses. In coniferous woods, coniferols are found almost alone, whereas deciduous woods contain the sinapyl alcohols as well. The lower plants contain mixtures of both types or precursors. A third type appears in the case of grasses, cumaryl alcohol, which is formed together with the other two. Grasses are probably able to convert one form of the monomer into another.

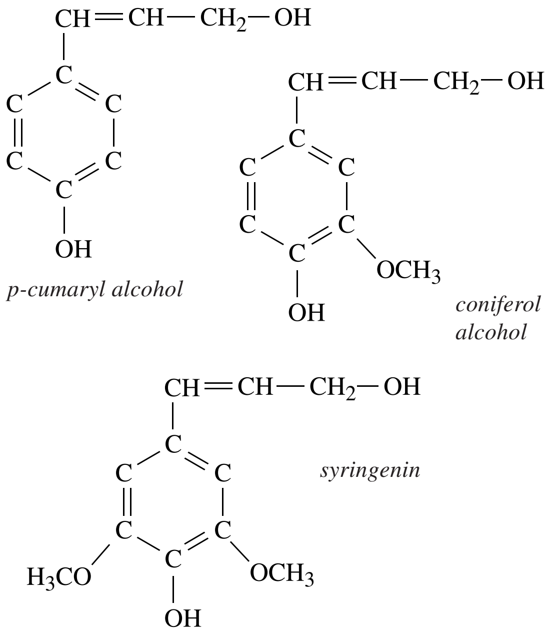


Fig. 1: Various monomers of lignin.

Indeed, different lignin monomers have been found in the same plant cell (Fig. 1). The elementary composition of milled wood lignin, a pale cream powder, corresponds to the coniferol minus 2 H; as well as this, each phenylpropane unit contains approximately 0.4 mol bound H_2O. As lignin consists completely or almost completely of phenylpropane units, the composition is frequently expressed in C_9 units. Spruce lignin, for example, corresponds to the empirical formula $C_9H_7O_2 \cdot H_2O_{0.4} \cdot OCH_{3\,0.94}$. As an auxiliary agent for analysis, the methoxyl content produces different values for the different types of lignin: deciduous lignins contain 20–22%, coniferous lignins contain 14–16% and the lignins of the grasses, among other monocotyledonous plants, also contain approx. 14–16% or less in terms of methoxyl groups. Lignins vary so much that the question arises as to how far this concept can be extended. A general boundary is provided by the fact that lignin is defined as an aromatic substance different from carbohydrates; lignins strengthen the polysaccharides in plants and convert the cell tissue into wood. However, this is not sufficient as a definition of lignin. In some areas, it is conceivable for these tasks to be fulfilled by silicic acid, tannic acids and other phenols and their polymerisation products. Indeed, they may even support lignin in this role in many trees.

II. Macromolecule: Based on the investigation into the structure of lignin, Freundenberg was able to define the structure of coniferous lignin more correctly and comprehensively than ever before. He was able to achieve this by examining the structural unit of a model lignin and carrying out biochemical experiments on lignin synthesis by dehydrogenation polymerisation of the p-cinnamyl alcohols. The structural units of the lignin are linked together via C–C or C–O bonds.

The C–C bonds are formed

- between two nuclei,
- between two side chains,
- between a nucleus and side chains.

Bonds such as these contain lignin at 25–35%, and are not broken during the delignification process. Approximately 65–75% of acrylopropane units are linked to neighbouring units via ether linkages. These break during delignification to varying degrees. The lignin model appears to be very complicated, as the starting radical has different mesomeric possibilities. This gives the molecule a variable and irregular structure which cannot be described by a general formula but only by a general structural principle. The molecular weight of lignins are found on average to be 10 000.

III. Biosynthesis: The process of lignification is irreversible; once the lignin has been produced by the living plasma and incorporated in the cell membrane, it is never metabolised by the plant again. The cell dies and with that, the lignin takes over the function of providing the plant with mechanical strength and protecting it from swelling. At room temperature, lignin is similar to a brittle thermoplastic and on heating, it becomes soft and malleable. Lignin sulphonates, as produced during the pulping of wood, have colloidal properties and are used as dispersants (Fig. 2).

IV. Chemical properties: Lignin is closely associated with the polysaccharides in the cell wall via various different linkages. For this reason, the time taken for and degree of completion of delignification is also significantly influenced by the chemical structure of the individual layers in the cell wall. Finally, a combination of chemical and morphological working methods is necessary for its elucidation. In the case of the chemical properties, it is necessary to include the history of the lignin while looking at it from the different points of view. Lignin can be established qualitatively using phloroglucine and hydrochloric acid, the so-called Wiesner reaction. This colorimetric reaction is attributed to the coniferal group. A dye is produced which has the structure presented in Fig. 3.

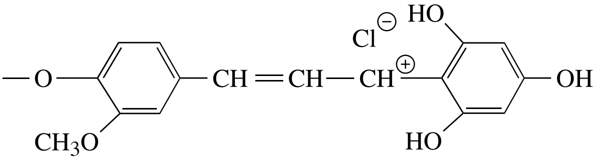

Fig. 3: Lignin pigment produced by phloroglucin-hydrochloric.

Liloc-Overflow HT piece-dye machine with goods conveyed through the liquor without jets. Jagri introduced the first type of overflow soft-dyeing machine from Japan in West Germany in 1971 under the name “Liloc”. With the Liloc- Overflow, the machine is divided into a reaction zone and liquor-exchange zone for the first time (Figs. 1 and 2). In this type of machine i.e, with a system in which the liquor was not moved much faster than the goods in the enclosed liquor-exchange zone, there was so little mechanical manipula-

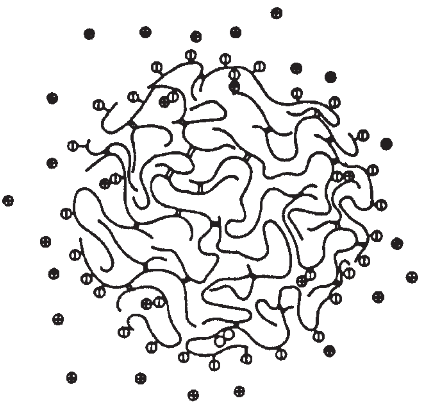

Fig. 2: Model of lignin sulphonate microgel dissolved in water and surrounded by oppositely charged positive ions.

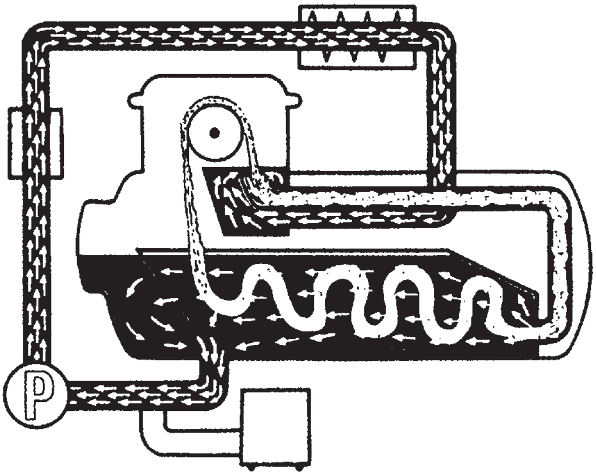

Fig. 1: Diagram of Liloc-Overflow process (Jagri).

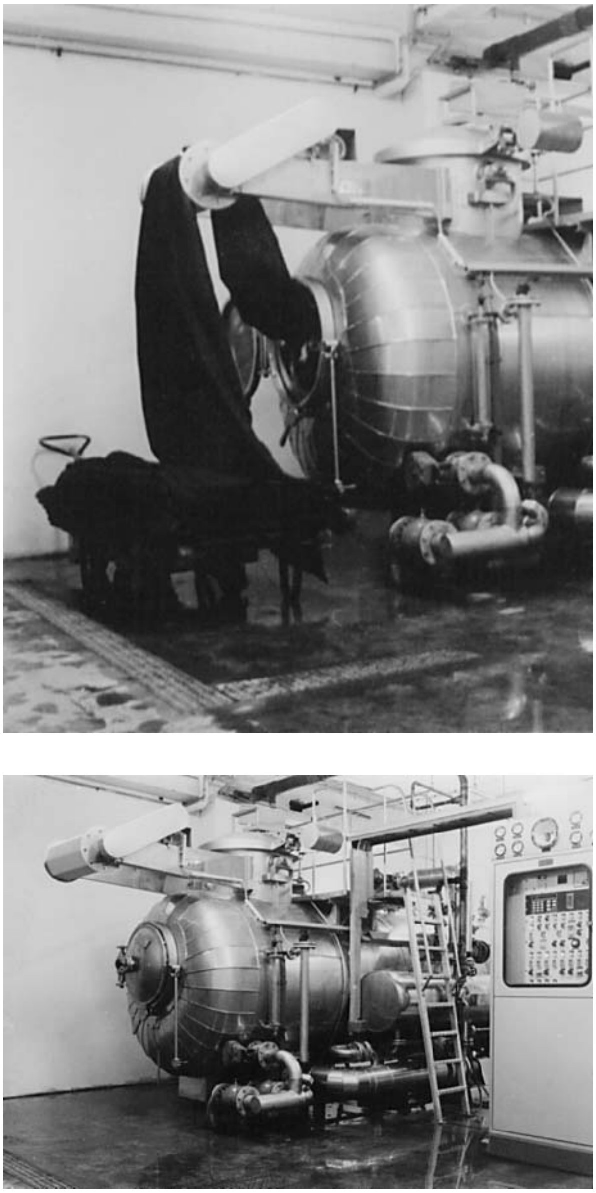

Fig. 2: Liloc-Overflow dyeing machine by Jagri.

tion of the goods that dye penetration into smooth worsted cloth was sufficient without having to sew it into tubes. For the Liloc-Overflow dome, which the winch operated in the air space above the liquor, was typical. The simple jet machines achieve the free movement of the conveyor winch by increasing the size of the vessel or by positioning the dye vessel at an angle. Former manuf.: Jagri.

Limbacher Artikel (simplex knit), suede-type finished knitted fabric made from cotton, used for gloves in particular. Strong alkali treatment is used to achieve a more compact structure.

Lime → Calcium carbonate.

Lime-baryta process Water softening process used where there is a high level of sulphate hardness and high permanent hardness. Degree of softening up to approx. 1–2°d.

Lime boil → Kier boiling.

Lime hardness → Water-hardness salts.

Lime soaking Initial treatment of hides or pelts before → Tanning, during which the scarfskin and adipose tissue are split from the corium before it is further processed.

Lime soap Lime soap is produced by the displacement principle converting soluble Na stearate soap into insoluble Ca stearate soap (lime soap) according to the following equation:

$$2\,C_{17}H_{35}COONa + Ca(OH)_2 \rightarrow \\ (C_{17}H_{35}COO)_2Ca + 2\,NaOH$$

109.3 g sodium stearate soap is converted into lime soap by 10 g CaO which corresponds to 1 m^3 water at 1°d. In Tab. 1 are shown the amounts of worthless lime soap precipitated by 1 m^3 water at 1–25°d.

degree of hardness °d	g of soap destroyed by 1 m³ of water	
	textile laundry soap cakes 60% fatty acid = approx. 56% pure soap	highly concentrated needle soap 82% fatty acid = approx. 88.5% pure soap

25	0,80	16,0	84,0
29	0,12	2,4	97,6

Tab. 2: Soap losses relative to degree of hardness of water.

Lime soap dispersant The name given to this group of substances is derived from the predominance of carbonate hardness (lime hardness). Unlike deactivating additives, lime soap dispersants prevent precipitation forming colloidal dispersions so that no precipitation of lime soaps or other similar substances can take place. The dispersant should be added before or with the soap because lime soap which has already been formed cannot in most cases be removed (Tab.). These dispersants also have wetting, washing and protective colloid properties.

Laundry soap dispersing capacity of surfactants

Quaternary ammonium salt	70
Secondary alkyl sulphate	70
Sodium laurate	70

Tab.: Laundry soap dispersing capacity of surfactants.

Lime soap stains In most cases, these are white deposits that can impair the colour of dyed textiles. The appearance varies, for example, appearing on both sides or as crusty whitish matting effect. Removal: fatty-alcohol sulphate solution (warm) then formic or citric acid 1 : 8–10 (warm).

Lime-soda water softening process This process is used for water with a high carbonate and non-carbonate hardness. Calcium carbonate (lime) and sodium carbonate (soda) are used concurrently, achieving water hardness of 1–2°d. The precipitation time can be reduced by preheating.

Lime water → Calcium oxide.

Lime water softening process Oldest method used for precipitating out hardness salts with calcium hydroxide; also used for de-acidifying water (stoichiometric amounts). Softening is possible up to around 2–4°d depending on the non-carbonate hardness. Not very suitable for water with a high chloride content as this increases the solubility of calcium carbonate.

Lime wool → Skin wool, (slipe wool) obtained by de-hairing, i.e. by separating the wool from the skin by hydrolysis using calcium carbonate, sodium sulphide. Results in wool which is generally damaged.

Limit concentration The concentration of a substance in solution at which a proof reaction can still be found. The limit concentration is stated in g/ml dilution; → Detection limit.

Limit controller A limit controller is a controller which prevents a set limit concentration of a specific variable being exceeded.

Limit strength → Tensile strength.

Limp handle value → Kawabata system.

Linear density of fibres and yarns The linear density of fibres, yarns etc. is a measure of the density of textile materials. Under the standardised system of units of measurement (→: Tex-system; SI units) the mass per unit length (Tex) is the only measure now permitted to express density. The length per unit mass which was formerly the standard (Nm = metric count) is still used in many areas, although the term is no longer permitted. Neither are any English or French designations and information in denier (den.) allowed. The Tex system has been internationally standardised and introduced in most countries (see Tab.). This system expresses: fibres in decitex (dtex), cable, tapes and roving yarn in kilotex (ktex), and yarns in tex.

$$1\ \text{tex} = \frac{1\ \text{g}}{1\,000\ \text{m}}$$

$$1\ \text{dtex} = \frac{0{,}1\ \text{g}}{1\,000\ \text{m}} = 10^{-1}\ \text{tex}$$

$$1\ \text{ktex} = \frac{1\ \text{kg}}{1\,000\ \text{m}} = 10^{3}\ \text{tex}$$

	dtex	den	Nm	Ne_B	Ne_L	Ne_K	Ne_W	Nf
dtex	x 1,0	x 0,9	$\frac{10000}{dtex}$	$\frac{5900}{dtex}$	$\frac{16500}{dtex}$	$\frac{8860}{dtex}$	$\frac{19400}{dtex}$	$\frac{5000}{dtex}$
den	x 1,1	x 1,0	$\frac{9000}{den}$	$\frac{5320}{den}$	$\frac{14880}{den}$	$\frac{7970}{den}$	$\frac{17440}{den}$	$\frac{4500}{den}$

Tab.: Count conversion table.

Linear pressure This refers to the pressure per cm of roller length in the nip of two press-rollers.

Line deposit (finishing),

I. Insoluble lime and magnesium soaps precipitated on textiles.

II. Term used for → Sodium hydroxide for soap boiling.

Linen This is a generic term for laundry, clothing, furnishing fabrics etc. made from → Flax. Various commercial terms based on a) the composition (pure linen, union linen); b) the origin (e.g. Bielefeld linen); c) the appearance (unbleached or bleached linen, blue linen); d) the weave (smooth fabrics in plain weave, drill linen in twill weave, linen damask with figuring); e) the quality (coarse linen, fine linen, linen batiste) and f) the use (e.g. linen sheeting, tailor's linen, linen interlining). Linen and linen union fabrics are important because of the sustainable raw material. About half of the content of linen union fabrics comes from linen. A min. linen content of 38% is prescribed for this designation, and one thread system, i.e. the warp or the weft, must consist of linen. The overwhelming majority consist of a cotton warp and a linen weft (predominantly tow yarn). The best known exception are the so-called Gminder linen union fabrics, which have a fibre blend of cotton and (cottonised) flax in both the warp and the weft and have an appearance similar to linen (these materials are no longer classed as linen unions under current RAL regulations). In order to reduce the crease sensitivity (very low elongation), linen is occasionally mixed with wool for the ladies' outerwear sector (so-called woollen linen). Pure and union linen are used for underwear fabric, batiste, table damask, hand-towel damask, face cloths, huckaback hand-towels, terry materials, kitchen towels, mattress materials and (high-quality) outerwear. → Flax processing.

Whereas pure linen is generally resin finished to a particular finish, in the case of blends, the aim is to achieve the linen look with the surface typical for the flax fibre, although a light final handle is preferred. An easy-care finish with a soft, smooth handle is therefore used. During resin finishing with low formaldehyde content, wash-and-wear behaviour and wrinkle recovery are of prime concern for cotton blends. With viscose blends, the emphasis is on the necessary dimensional stability.

Linen bleaching process cycle This is a classic process cycle in the → Bleaching of linen. Consists of boiling with sodium carbonate, hypochlorite bleach and anti-chlor. This takes approx. 8 h. The process is repeated until the desired whiteness is achieved. Two stages are used to achieve full-white on linen union fabric: the linen yarn is bleached and then further bleached as fabric using the standard process for bleaching cellulose.

Linen fibre → Flax.

Linen interlining (Tailor's canvas). Stiffening and interlining. A type of fine → Buckram, but more elastic, with a less stiff finish. Natural coloured linen tow yarn or linen union.

Linen pretreatment This is a complex and cost-intensive procedure. After the flax has been processed (retting and mechanical processing) and following a gentle alkali extraction treatment, oxidative bleaching generally takes place in several stages. A combination of peroxide and chlorite bleach is generally used for this. A pure peroxide bleach under standard conditions for cotton does not provide the required results with linen. As linen still contains approx. 20% hemicellulose, which is partially soluble in alkali, there is a high weight loss of material when strong alkali peroxide bleach is used. To obtain the characteristic linen handle, it is not generally recommended that the substance used on the fibre is completely removed. The chlorite bleach serves to oxidise the dark coloured lignins. From an ecological point of view, however, chlorite bleach should be avoided.

Linen, resin finishing This must be carried out extremely carefully. Processes which affect the abrasion resistance as little as possible are preferred. Wet cross-linking with DMDHEU (dimethyloldihydroxyethyleneurea) (furnishing fabrics, tablecloths) are particularly suitable. In classic dry cross-linking processes, highly reactive resin finishing agents such as urea-formaldehyde compounds and DMEU (dimethylolethyleneurea) are used. The shock-cure process with shock catalysts is also gaining in importance. Wet cross-linking systems are little used. Additives to increase strength should also be applied regardless of which method is used.

Linen union Linen union is smooth or figured fabrics (tablewear) made from flax (tow) and cotton yarn, in either warp or weft.

Line recorder This is the generic term for recording devices which reproduce the time history of measured variables in the form of a continuous curve. In contrast to: point recorders.

Line(yarn) Fine linen made from dressed flax or long-fibre flax.

Lining fabrics Lining fabrics are used for the lining of outerwear. Depending on the intended use (ladies' or men's suits, trousers, pockets, sleeves, coats, etc.), they are made from viscose, acetate, synthetic fibres, and also of cotton or wool. The quality of the lining fabric plays a crucial factor in determining the serviceability of the finished garment.

1. Inside linings for men's and ladies' suits and coats: these are partly visible and therefore must display a certain elegance in addition to their actual intended purpose. They should have good abrasion resistance and fastness to perspiration and be smooth to achieve a high non-cling effect.
   a) Serge: smooth, coloured fabric in twill weave: trade name depending on the appearance or use, e.g. artificial silk serge, cotton serge, serge-rayé, serge façonné, clothing or lining serge.
   b) Taffeta: smooth, coloured fabric in taffeta weave made from viscose or acetate; stiffer than a); predominantly single-coloured or taffeta warp/weft colouring.

   c) Rhadamé: heavy viscose coat lining in twill weave.
   d) Atlas: heavy men's winter-coat lining in atlas weave.
   e) Duchesse: very lustrous, light viscose or acetate lining material in atlas weave (satin duchesse); used for ladies' outerwear.
   f) Moroccan: sandy handle, supple drape; crimped viscose fabric with normal yarns in the warp and crepe (2 Z, 2 S) yarns in the weft; used for ladies' outerwear.
2. Sleeve linings: Printed with small figured effects or woven in stripes, yarn dyed; viscose or acetate in taffeta or warp satin weave; the smoothness is particularly important.
3. Waistcoat linings are divided into:
   a) Back linings: generally cotton or viscose serge.
   b) Inside linings: generally consisting of cotton printed with small figured effects or single colour viscose material.
4. Pocket linings: Cotton fabrics are used predominantly here; some have a filled finish to reduce soiling and increase wear resistance. A distinction is made between:
   a) Lining for sports jackets and waistcoats: generally in twill, dark-based, twilled cotton fabric.
   b) Lining for trouser pockets: tend to be light in colour (beige, grey); generally only particularly firm cotton fabrics such as pocketing, moleskin, nankeen, unfinished twill, and pocket drill.
   c) Lining for coat pockets: generally twill; for heavy coats mainly pocket velvet or pocket flannel .
5. Other:
   a) Glacé thread lining: warp satin weave, dark sleeve lining, often used for uniform coats; warp consists of shiny, lustrous cotton yarns (glacé thread).
   b) Jaconnet: plain weave, fine, smoothly finished cotton lining; generally grey or black. Used as knee lining and to line leather goods (handbags).
6. Knitted lining fabric: single-face, generally circular knitted cotton knitwear which also has an additional lining thread. A distinction is made between conventional in-laid fabric and fleece with building thread, where the binding thread is hidden by a face thread. Finished goods have plain stitches on one face and may be raised on the reverse.

Linitest Washfastness tester which can also be used as a laboratory dyeing machine; can also be used for HT-dyeing. – Manuf.: Heraeus/Original Hanau.

Linizing Permanent finish to make cotton fabrics look like linen e.g. with strong caustic and cuprammonium solutions whereby the fabric surface is partially dissolved and subsequently coagulated.

Links-links fabric, purl fabric → Knitted fabrics which only have purl stitches visible on both fabric faces. The purl stitch courses conceal the adjacent plain stitches, as can be seen in the crosswise extension of the fabric.

Linoxyn → Linseed oil is (air) oxidised and polymerised to form a thin, transparent, skin, e.g. by the oxidation of (linseed-) oil size.

Linseed oil A typical drying oil obtained from linseed or flax seed. Hot pressing gives a dark, strong smelling oil, cold pressing gives a lighter, milder oil, and extraction produces a non-sticking oil. When fresh, linseed oil is a sticky gold-yellow/brown with a typical mild odour. Poss. contamination by cotton, soya, rapeseed, hemp, corn, mineral, resin oil or hardened train oil. Used as oil-based size.

Linseed oil size → Oil size.

Linsey-wolsey (Linsey-woolsey). Hard-wearing material (cotton, viscose filament yarn, spun viscose, linen, wool, mostly multi- fibres) in plain weave and other constructions (incl. imitation knits), single- or multi-coloured, striped, checked, etc.; for garment fabrics, dirndl fabrics and decorative materials.

Lint Small hairs, fibrils, thread waste (twisted) etc. projecting from the surface of threads, yarns, fabrics, knitwear. Generally caused by material used and method of processing (error phenomena). Examples: dead cotton (→ Motes), fluffy silk (→ Floss), residue of broken retracted capillary threads (lint portion drawn above location of break, undrawn below) can be removed from yarns and fabrics, e.g. by singeing.

Lint doctor In roller printing, the → Doctor blade removes excess print paste, the lint doctor is located on the opposite side of the printing roller, behind the printing surface formed by the roller and printing cylinder, to remove excess print paste left on the roller after printing. This prevents the print paste from contaminating the following fabric.

Lint filter for textile effluents A common form of lint filter is a sieving device with no moving parts which has a self-cleaning curved mesh bottom plate and does not clog due to the particular form of the sieve bars, is corrosion-proof and free from parts subject to wear. Suitable for removing fibres from all types of liquids, even in difficult circumstances, e.g. waste water containing oil, solids loading and aggressivity.

Linters Linters are short fibres which remain on the seed husks after ginning the cotton, also short-staple waste from cotton fibres. Unsuitable for spinning due to their short length. Used in the production of regenerated synthetic fibres (acetate, cupro, viscose).

Lipases → Enzymes of the principal hydrolase group which act on fats and oils by water displacement to form fatty acids and glycerine. More rapid splitting of fats with a low melting point (larger proportion of unsaturated acids). In comparison to esterases, lipases act on water insoluble emulsified fats, and are therefore used in enzyme mixes (pectinases, proteases or amylases) for the gentle removal of grease spots or fatty substances as so-called soaking materials for particularly soiled laundry; also used for starch desizing agents with optimal action at 35–40°C. By adding lipases, the detergency efficiency of prewashing agents which do not contain anionic surfactants is improved. The effect is dependent on temperature, lipase concentration and the intensity of the fat contamination. Under practical conditions, however, the improvements achieved with lipases were low and were exceeded by adding a nonionic surfactant. The stability of commonly used commercial lipases under washing conditions is sufficient, but not ideal. Under a test arrangement, the grease removal by detergents containing lipases at 20°C is almost exclusively due to the lipase effect, at 30°C this is due to the additive effect of lipases and surfactant, at 40°C due more to the surfactant effect. The lipase effect at 30°C increases as the concentration is increased but decreases as the grease soiling increases.

Lipoids Lipoids are similar to fats (neutral fats, wax, fatty alcohol, etc.).

Lipophile (Gk.: lipo(id) = fatty; phil = loving, friendly). Lipophilic substances are “associated with grease”, “fond of grease”, i.e. they are easily soluble in fats, oils, hydrocarbons and organic solvents. The lilophilic molecular portion (nonpolar residue) corresponds in textile auxiliary structure to the hydrophobic hydrocarbon residue. The same applies to synthetic fibres with corresponding molecular structure. Involves metal abrasion with fats or oils which have a longer reaction time, graphite etc. adheres particularly well within the fibre and is difficult to remove. Contrast: → Lipophobe.

Lipophilic groups Lipophilic groups are molecular groups which have an → Endophilic reaction in an organic, non gaseous phase.

Lipophobe Exophile properties for an organic, non-gaseous phase, → Exophilic. Contrast: → Lipophile.

Lipophobic groups Lipophobic groups are molecular groups which have an → Exophilic reaction in an organic, non gaseous phase.

Lip seals These are heated slits at the fabric entry and exit zones (e.g. on a Krostewitz steamer) which are used for sealing during the passage of the cloth.

Liquefied gas Gas that is a liquid under pressure and reverts back to its gaseous phase when the pressure is released, e.g. the hydrocarbons propane, butane and (for petrochemistry) the associated gasolefines propene, butene and compounds. Propane is most commonly found as a bottled gas for domestic use, commercial purposes, welding non-ferrous metals and plastics. Butane is mainly found in commercial and industrial sectors; generally after premixing with air. Small quantities of liquefied gas are transported in compressed air cylinders (steel cylinders), and larger quantities in compressed air tankers (in the liquid phase). Storage of liquid gas: small quantities are stored in pressure flasks, medium-sized quantities in pressure cylinders and large quantities are stored in fixed pressure vessels. These type of storage facilities are subject to relevant safety regulations (pressurised gas regulations) and official monitoring (TÜV).

Liquid ammonia process Treatment of cotton textiles in a specially developed piece of equipment with liquid ammonia (–33°C). Finishing effects on textiles finished using liquid ammonia: good shrinkage stability, high smoothing capacity, good crease recovery, almost comparable mercerizing effects to those achieved with caustic soda mercerisation. Lustre is a secondary consideration. This finishing process dates back to the developmental work of the “Norwegian Textile Institute”, the Norwegian consortium, “TEDECO” and the “Sanforized Company” in the 1960s. The process was then introduced in the 1970s, originally in the USA, as a finishing treatment for denim fabric and other heavy cotton fabrics, as the treatment causes interesting effects on these articles, in particular an excellent dimensional stability to washing and tumble-drying, a pleasant soft handle and improved smooth-drying properties. The liquid ammonia process is increasingly being used as a pre-treatment for shirt, blouse and dress materials made from 100% cotton which are subsequently given an easy-care finish. It is also possible to use this process for fabrics made from other cellulose fibres, e.g. linen and regenerated fibres. The treatment takes place in such a way that the fabric is impregnated with liquid ammonia at its boiling temperature (–33°C), thus causing the cellulose fibres to swell rapidly. The ammonia is then volatilised by guiding the fabric over a heated drying cylinder and any residual traces are removed from the material in a subsequent steaming zone. The expelled ammonia is liquefied once again and reused. The fabric is treated in various finishing stages, e.g. boiling off (bleaching is carried out after the ammonia treatment), mercerising, solid-shade dyeing, or colour-woven.

The cellulose polymer chains can be regarded as stretched semi-rigid chains, whose conformation is stabilised by intramolecular hydrogen bridges. By forming intermolecular interactions (Van der Waals forces, hydrogen bridges), the chains arrange themselves into supramolecular ordered sectors, whereby the crystalline areas alternate with somewhat less distinct ordered areas in the fibre axis. The ordered states are arranged in fibrils which are separated from one another by long-chain interference zones (microvoids) along the fibre axis. When water is used on cellulose fibres, the water molecules are only able to split the hydrogen bridges in areas where the hydrogen bridges have a low density between the fibrils (interfibrillar swelling), whereas swelling in liquid ammonia also affects the ordered states in the fibrils themselves, including the crystal-

Liquid ammonia process

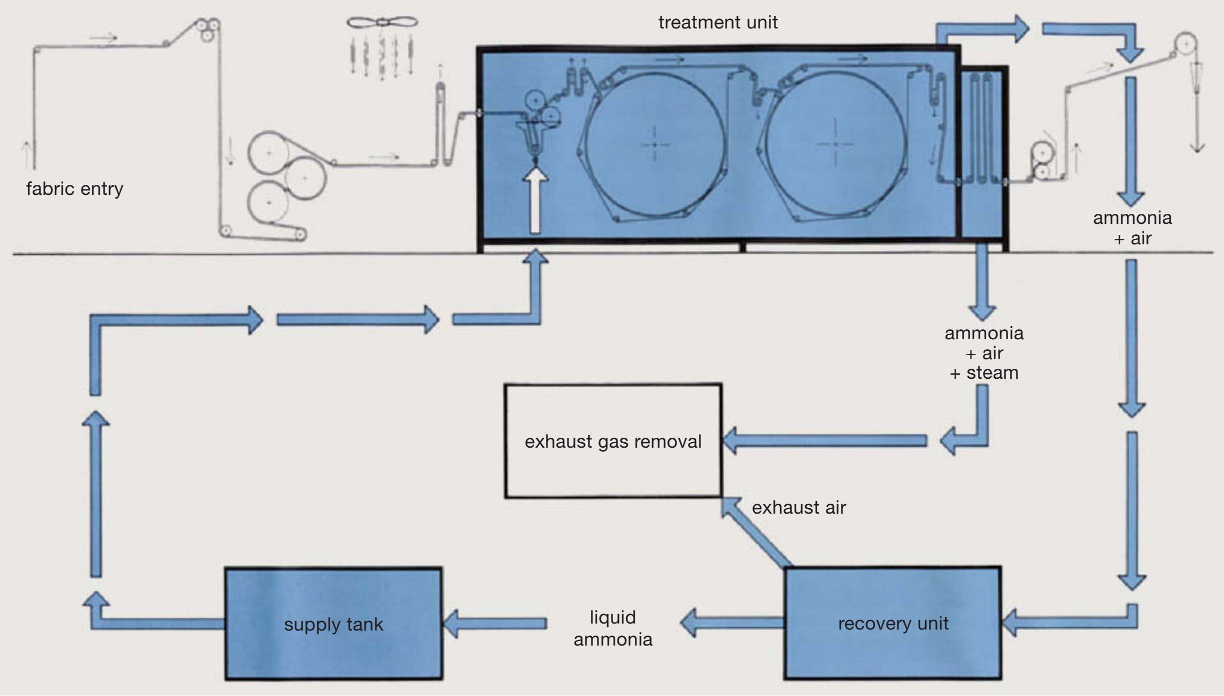

Fig. 1: Treatment of cotton piecegoods with liquid ammonia in accordance with the "duralized" process (Monforts).

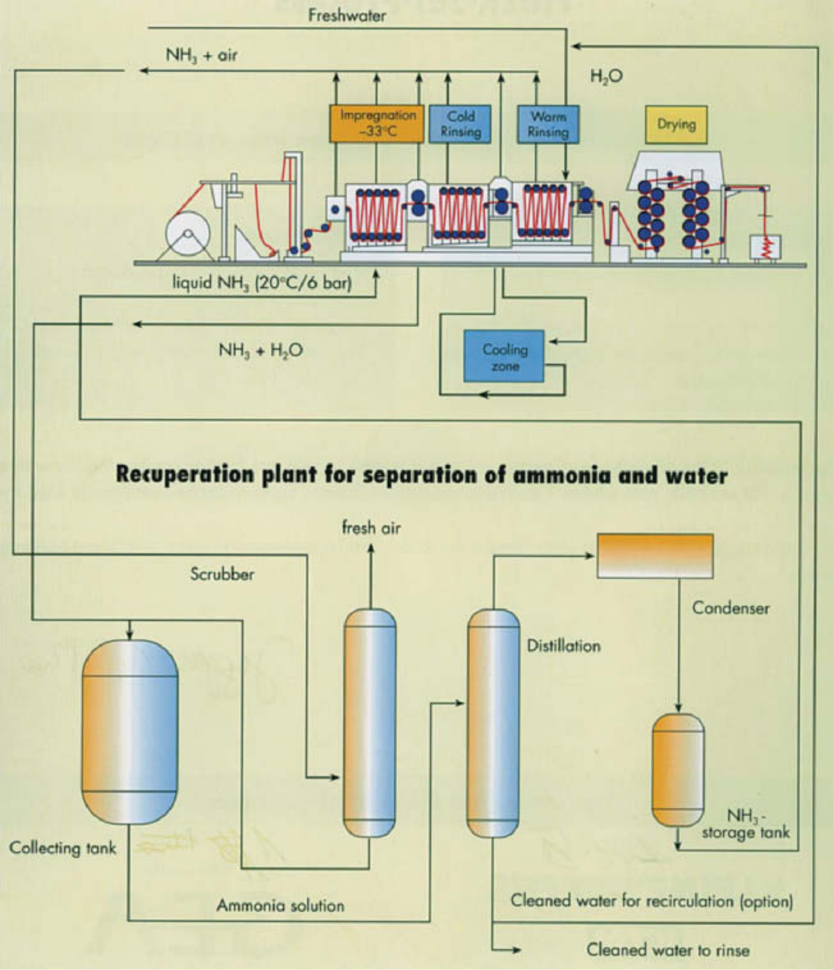

Fig. 2: HPA-system for finishing with liquid ammonia (Kleinewefers KTM).

lites (intrafibrillar and intracrystalline swelling). This is principally due to the higher basicity of the ammonia molecules in comparison to water, which makes it possible to split the dense hydrogen bridge network into crystalline zones. If inter- and intramolecular interactions are split in oriented cellulose fibres due to the effect of a swelling agent, the fibre can be shrunk to a greater or lesser degree. The main cause of this is the disorientation of fibrils and molecular chains during the swelling process. If the fibre is kept at a constant length during this process, a shrinking force develops. The extent of shrinkage and the shrinking force is dependent on both the orientation of the fibre structure and the fibrillar and crystal structure, as well as on the swelling conditions (swelling agent, temperature, tension). (Source: Bredereck).

It should be noted that it is just as expensive to purchase the treatment section as the recovery plant for liquid ammonia. Monforts produces a suitable plant (see Fig. 1) as well as Kleinewefers KTM (Fig. 2).

Liquid crystal display (LCD). This is a digital display which uses the optical behaviour of specific crystals in the electric field, rather than glow wires for the display (→ Liquid crystals).

Liquid crystals These are organic substances which are between plastic and liquid, possess indistinct boundary forms through to drop shapes and display double refraction or optical rotation.

If a molecule, such as a polymer chain, is sufficiently firm, the phenomenon of liquid crystallinity can arise beyond a specific concentration. This phenomenon is also referred to as mesomorphous or liquid anisotropy. This was predicted by Flory in as early as 1956 for polymers, and was confirmed experimentally by Herman in 1962. By increasing the concentration of rigid and semi-rigid macromolecules, a saturated solution with undissolved polymers can be formed, or alternatively, by placing more dissolved polymers in a specific area, the system is forced to form groupings with parallel polymer chains. By adding further polymers, the area of the ordered state is increased still further (Fig. 1).

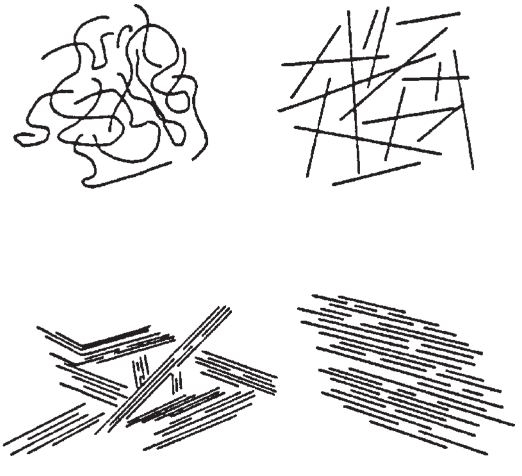

Fig. 1: Schematic diagram of polymer conditions in solutions.

The formation of a liquid crystal phase is accompanied by several specific phenomena, e.g. an opalescence when stirring and erratic changes to the viscosity of the solution. When the polymer concentration is increased in the isotropic area, the viscosity initially displays a normal increase up until a critical point at which the anisotropic liquid crystalline phase forms (Fig. 2); next the viscosity of the solution decreases as the polymer concentration increases. Above a specific concentration the viscosity then continues to rise. This behaviour is described for poly-γ-benzyl-L-glutamate in m-cresol and for an aromatic copolyamide in a mix of hexamethyl phosphorous triamide and N-methylpyrrolidone. The general progression of the viscosity curve is described in Fig. 2. This rheological behaviour is significant for practical application as it enables highly concentrated solutions to be spun.

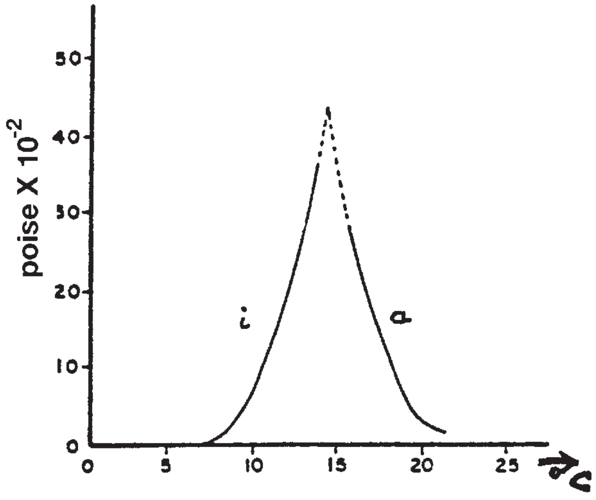

Fig. 2: Example of the development of the viscosity of a polymer solution with anisotropic (a) phase relative to concentration. i = isotrope phase.

Liquid dyes Liquid paste. Easy to handle, simple to measure, therefore well-suited for automated yarn dyeing and continuous plant. Formulation of → Dyestuff.

Liquid fast colour bases Fast colour bases for naphthols in liquid form. Advantages: Easily diazotisable with no residues, with virtually no pollution caused by nitrous fumes. Partly true solutions, partly dispersions.

Liquid fats These contain mainly → Oleic acids: e.g. olive oil, sesame oil, soya bean oil. Use: As a base for soaps with solutions of particularly low viscosity, for washing, soaping, degumming etc.

Liquid heating medium Polyglycol ether compound → Heat transfer medium. Density 1.12; Boiling range 260–310°C. M.p. 160°C. Waterwhite, odourless, not easily volatilized, non-corrosive, hygroscopic.

Liquid photometry by means of fibre optics The dyer requires the current visual depth of shade of the textile during the exhaustion stage of dyeing in order to project the final appearance of the shade (Fig. 1) or if the batch displays unlevelness. No suitable sensor is currently known for such measurements. It is conceivable that glass fibre sensors could be inserted into the dyeing packages and could then be used to track the spectral reflection and consequently the build up of colour on the fabric. In dyeing machines with fabric circulation, it would also be conceivable to convey the fabric past a window where a reflectance measurement could be taken. Next, the problem of evaluating reflectance measurements on wet goods in a liquor which partially absorbs the light, as opposed to clear water, would need to be solved. A further difficulty is that the reflectance measurement records the surface dyestuff addition to a much greater extent than the dyestuff portion in the fibres.

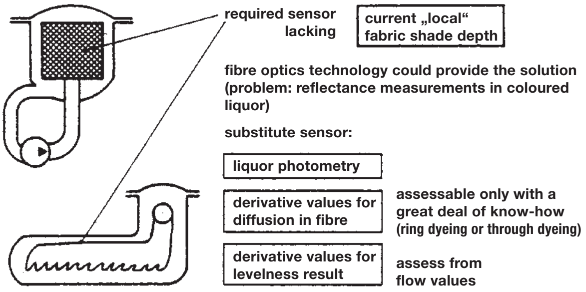

Fig. 1: Sensor for determining current fabric shade depth in the dyeing machine.

Liquid photometry is a possible solution to the problem of monitoring shade. In many cases, it should be possible to give information on the concentration of the individual non-exhausted dye residues, on whether the correct depth of shade can be expected, and if one dyestuff has been selectively blocked. The visual impression of a dye is determined by the dye penetration as well as the quantity of dyestuff absorbed. This correction would then have to be projected using experimental values and liquid photometry should be superimposed. The partial aspect of depth of colour and shade is insufficient however. The levelness of the batch must also be guaranteed. The measurement of the dyestuff concentration in the liquor does not give any direct useful information for this. Due to the natural connections between the absorption rate (significant rate of dyeing) and the risk of unlevel dyeings, it is possible to form an exhaust curve using liquid photometry. This can be used to calculate the significant rate of dyeing and introduce measures to prevent unlevel dyeing in good time. An essential prerequisite for this is that the “operating system” (i.e. the dyeing machine with its liquor circulation controller and the textile fabric in its standard form) remain constant. Whereas the liquor circulation can still be relatively well recorded using flow metering or alternatively using the pump speed, differential pressure, bypass and ring adjustment, there is still no real information concerning possible deformation of the fabric package during dyeing.

There are two basic methods of obtaining source data. Commercial systems such as “Colorex” (Barco) arrange the control equipment in the bypass. In the “Colorex” device, the elementary sensor is in the form of a movable cuvette. This enables adaptation to the Lambert-Beer’s law.

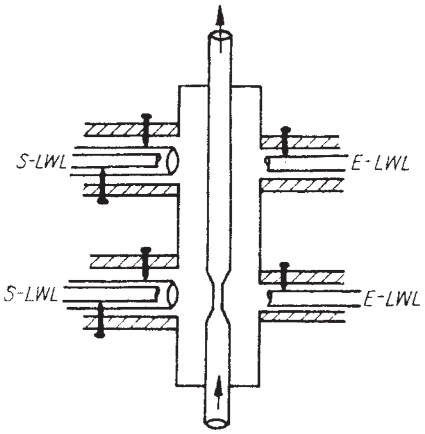

Fig. 2: Principle of a variable flow sensor for liquor photometry.
S-LWL = transmitter beam waveguide; E-LWL = receiver beam waveguide.

Glass tubes with irregular inner profile are adequate under simplified conditions (Fig. 2). When controlling waste water treatment plants, monitoring rinsing processes for dyes etc. it is not always possible to use a bypass. Spec. probes which are immersed into the medium are advantageous here (e.g. the dip sensor). A fibre optic receiver which is vertically displaceable enables variable gap widths to be adjusted. The reflex sensor also fulfils the same purpose (Fig. 3). In this case, a variable sensor length provides different intensities. The openings must be carefully sealed as the foreign ions that penetrate the optical fibre increase condensation, cause hydrolysis of the gas, and alter the colour and density of the optical resin used as an embedding medium, etc.

The obvious advantage provided by the possibilities of the fibre optic device is in the easy accessibility of

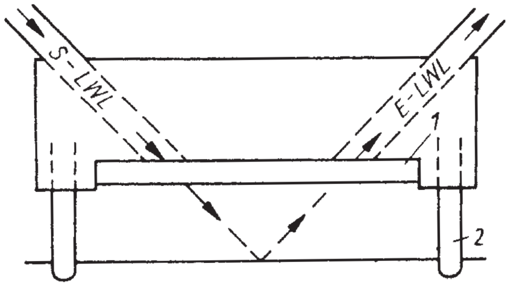

Fig. 3: Principle of a reflex sensor for liquor photometry.
1 = optical window; 2 = mirror.

the structural parts. The advantage of the continuous signal sequence (e.g. if the response time for photo-diodes is 10^{-7} s) can only be utilised if the information is adequately processed, however. It is not possible to manage the dyestuff and fibre characteristics which are required to control dyeing processes without the aid of a computer. Calculations relating to additions to the machines used to control the dyestuff extract are made using a computer from the very outset. The necessary software is not always generally accessible and system-compatible. However, there are also disadvantages: the cost of coupling and branching is increased; sources of error arise due to mechanical strain and curvatures occur when laying the fibre optic device. Lint and micro-bubbles cause the signal intensity to be altered. The material exchange is seen to lag behind in the gap when there is little liquor circulation. Soiling on the surface also results in further errors at the inlets and outlets in the medium.

Liquid ring vacuum pump A so-called displacement pump to transport extracted gases and vapours with the aid of a rotating liquid, the liquid ring. An eccentrically positioned impeller rotates within a cylindrical housing (see Fig.); a rotating fluid forms working areas with the impeller which vary periodically. Use: at large capacity ranges to evacuate equipment, pipes etc.; often as a water-ring vacuum pump (water is used as the operating liquid), e.g. when yarn steaming.

Liquor Liquid treatment medium (water, organic solvents) for textile finishing, laundry and dry-cleaning.

Liquor application This refers to the application of the treatment liquor on textile fabrics.

Liquor application systems A distinction is made between the following when applying dissolved products:

1. Low wet pick-up.
2. Standard wet pick-up.
3. High wet pick-up.

Low wet pick-up is suitable for
- spray application,
- foam application (Fig. 1),
- kiss roll padding.

Standard wet pick-up takes place in the padder (Fig. 2).

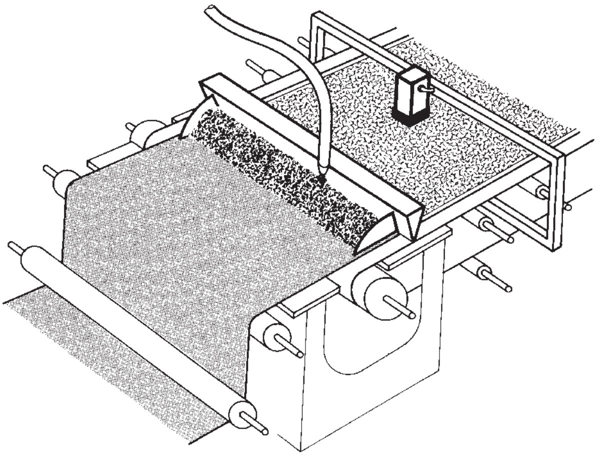

Fig. 1: Foam application.

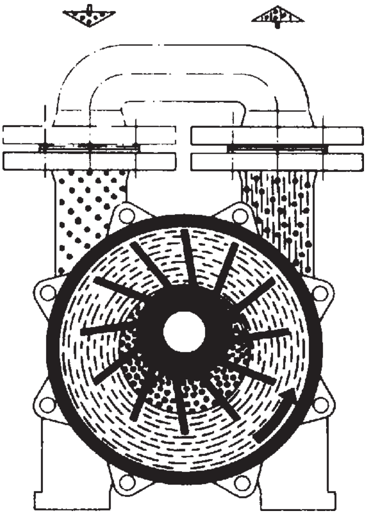

Fig.: Section through a 2-stage liquid vacuum pump (SIHI).

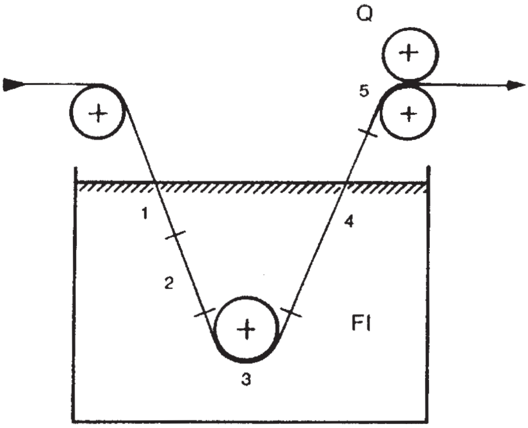

Fig. 2: Schematic padding diagram .
1 = wetting with liquor Fl; 2 = 1st immersion phase;
3 = deflection roller passage; 4 = 2nd immersion phase;
5 = water extraction by squeeze unit Q.

Liquor application systems

Fig. 3: Padder roller flexure.
L = bearing counterpressure; P = pressure.

In a standard padder, the liquor application is greater in the centre than at the edge as all the rollers deflect (Fig. 3).

There are therefore various systems to ensure an even distribution of pressure across the width of the rollers, e.g.

- Nipco roller with a pressure ram battery (Fig. 4). In extreme circumstances, it is (theoretically) possible to control each ram individually,
- Swimming roller (Küsters (Fig. 5)),
- Variflex (Babcock),
- CVC roller (Monforts),
- Bicoflex (Kleinewefers KTM).

The wetting process can be intensified by:

- immersed squeeze units (Fig. 6),
- steaming chambers arranged in front of the trough (Fig. 7),
- vacuum impregnation.

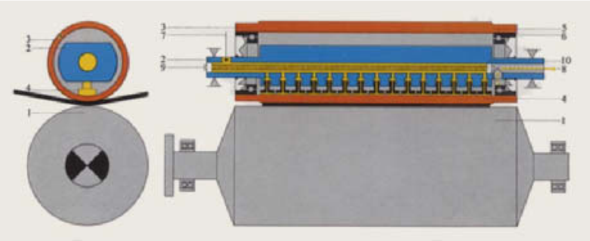

Fig. 4: Nipco roller pressure regulation (Kleinewefers KTM).

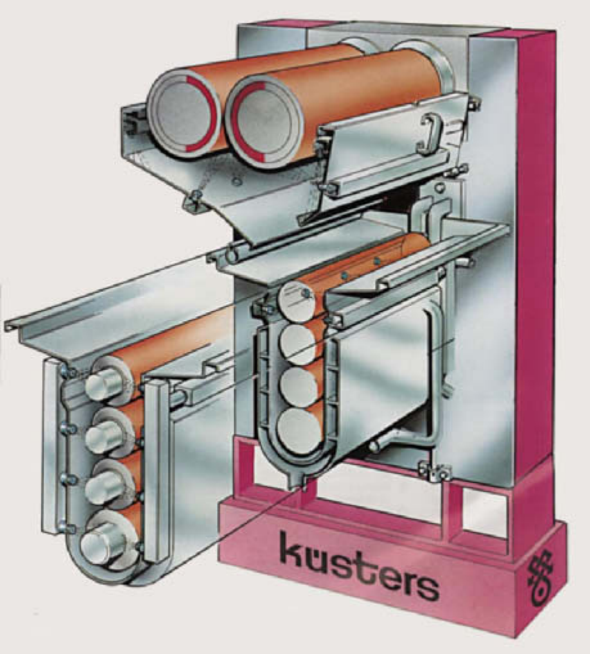

Fig. 5: Küsters "swimming roller".

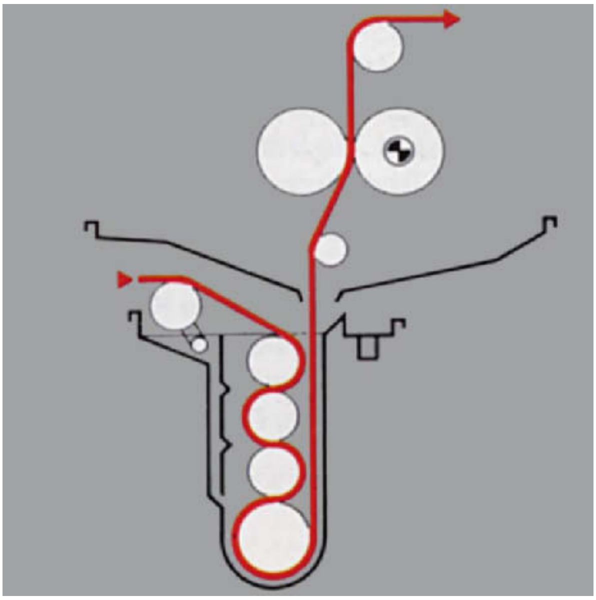

Fig. 6: Nip padder with submerged squeeze unit.

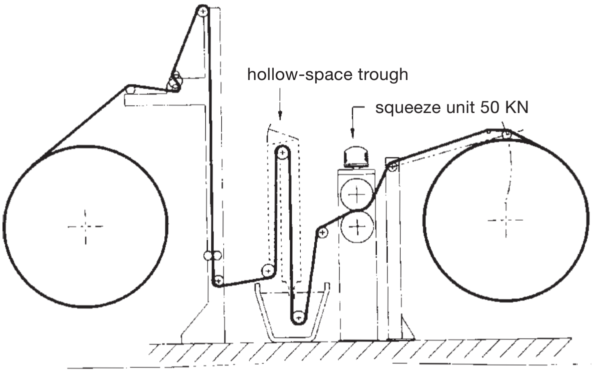

Fig. 7: Vertical padder with steam lock.

Different solutions that do not have long term stability are mixed shortly before the impregnation process. It is possible to control their use (Fig. 8).

High wet pick-up, e.g. more than 100% liquor application can be of interest:

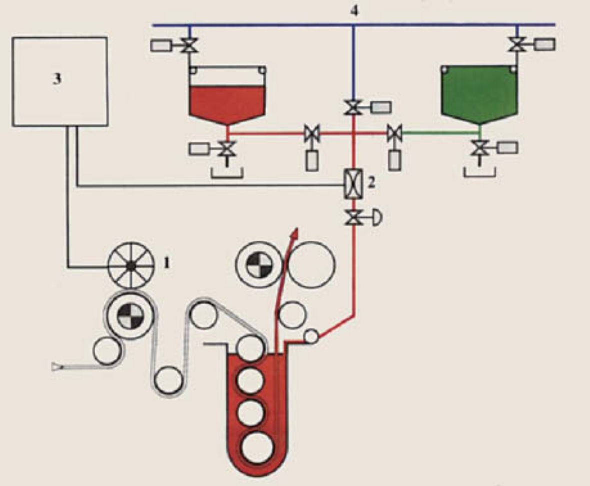

Fig. 8: Construction principle of dye liquor consumption analysis on a dye padder and software (Küsters processing technology).
1 = metre counter; 2 = flow measurement; 3 = processor; 4 = water connection for automatic rinsing.

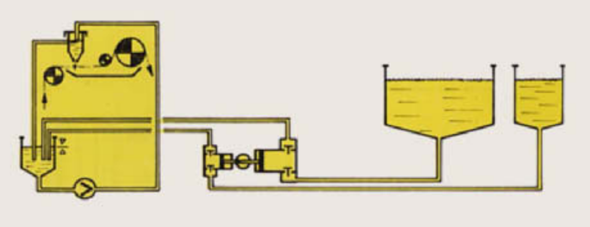

Fig. 9: Texo-Roll by Brückner.

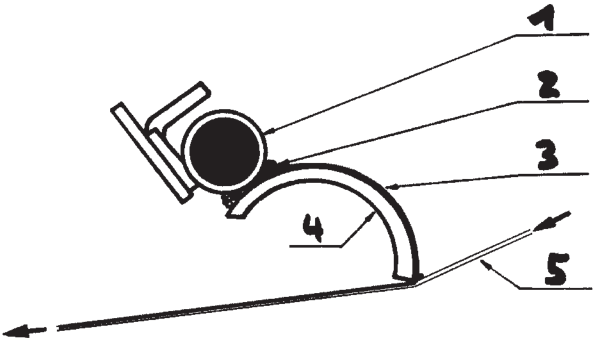

Fig. 10: Westpoint "Curved Blade".
1 = feed collector; 2 = plastic seal; 3 = finishing liquor film; 4 = curved feed plate; 5 = fabric.

- with Flexnip, a type of aquaplaning effect is used (Küsters).
- with Menzel's Optimax, the fabric passes upwards through an initial nip and then passes a second horizontal padder slightly removed from the first.

Flow coating processes also aim for high liquor applications (Figs. 9 and 10).

Liquor by-pass flow Designation for volume of liquor which e.g. flows past the cuff in a beam dyeing machine and which causes tailing or unlevelness.

Liquor calculations Correctly measured bath additives require knowledge of the liquor volume of dyeing machines. Unfortunately, in many companies, these are still often unknown, particularly as regards different bath heights for small batches. So-called constants are always calculated for each machine. It is only necessary to measure this once, as the bath height is found by multiplying the constants with the desired volume of the bath. All measurements are given in decimetres for breadth (B), diameter (D), height of bath (H), depth (T), maximum depth (T_1), minimum depth (T_2), volume (V).

I. Rectangular vats:

$$V = B \cdot T \cdot H$$

$$H = \frac{1}{B \cdot T} \cdot V$$

II. Cylindrical vats:

$$V = 3{,}14 \cdot \frac{D}{2} \cdot \frac{D}{2} \cdot H$$

$$H = \frac{1}{3{,}14 \cdot \frac{D}{2} \cdot \frac{D}{2}} \cdot V$$

III. Curved winch vats:

$$V = \frac{B \cdot H\,(T_1 + T_2)}{2}$$

$$H = \frac{2}{B\,(T_1 + T_2)}$$

IV. Complex dyeing machines: With respect to pipes, pumps and any divider inserts, not easy to define. Best to use titration. An accurately weighed quantity of pure sodium carbonate is added to the machine, mixed well and the concentration of the solution is defined with 1 n hydrochloric acid.

Liquor circulation This is the liquor throughput in l or kg/minute. The number of liquor rotations is inversely proportional to the heating-up time and to the liquor ratio. The heating-up time in the critical temperature range can therefore be reduced proportionally to the reduction in the liquor-to-goods ratio (→ Liquor flow reversal) where the conditions are unchanged (pumping capacity, substrate, hue, dyestuff, chemicals).

Liquor concentration Concentration of additives, taking into consideration the → Liquor-to-goods ratio.

Liquor cycle → Liquor circulation as a movement of the treatment bath through the material to be dyed with the aid of the circulation pump. The liquor cycle per unit of time is dependent on the pump capacity and the flow resistance of the dyeing machine. A high liquor cycle per unit of time is desired in order to avoid excessive differences in concentration arising on the substrate between the dye liquor entering and exiting. The dyestuff feed must therefore be larger than the absorptive capacity of the fibre.

Liquor exchange coefficient From a finishing liquor which contains 100 g/l of a substantive product, a squeezing effect of 80% gives a product application of 80 g/kg or 8%. If the squeezing effect deteriorates to 85% or 90%, the product application increases by 0.5% or 1%. Such deviations cannot be detected by differences in the finishing effects (e.g. handle, creasing behaviour). In pad-dyeing, the liquor exchange in the padding trough is influenced by several factors. In the past, the concentration of the feeding liquor was taken to be governed by the squeezing difference with the liquor exchange coefficient tacitly assumed to be $\alpha = 1$. As the liquor exchange coefficient is in practice actually 0.3–0.6 in the padding troughs, the bath concentration changes constantly and significantly where the concentration of the feeding liquor is the same.

Example: Based on the assumption that $\alpha = 1$ and a squeezing difference of 20%, the bath concentration of 100 g/l of a product with a feeding liquor concentration of 500 g/l can in theory be kept constant. If the fact that $\alpha < 1$ is taken into consideration, however, the bath concentration alters in line with the complex formula which makes the difficulty in recording the liquor exchange clear due to its differential nature:

$$C_B = C_0 \cdot e^{-\frac{m_F \cdot b \cdot v \cdot t}{V_0}} + \frac{X_2 - X_1}{X_2 - (1-\alpha) \cdot X_1} \cdot C_N \cdot \left(1 - e^{-\frac{m_F \cdot b \cdot v \cdot t}{V_0}}\right)$$

C_B = bath concentration in time t,
C_0 = bath concentration in the beginning,
m_f = mass of texiles,
b = fabric width,
v = throughput rate,
t = running time,
V_0 = liquor volume of trough
X_2 = squeezing effect after impregnation,
X_1 = moisture of fabrics at the beginning,
C_N = concentration of the feeding liquor.

Where the concentration of the feeding liquor is the same and the value of α varies, the bath concentration in the padder should have reached the following values after 1 h in each instance:

exchange coefficient	1.0	0.6	0.5	0.3
bath concentration g/l	100	147	166	227

This example demonstrates that it is not possible to guarantee any constant product application in the wet-on-wet process on the padder due to the fact that the exchange coefficients cannot be controlled in practice. In the case of slop-pad minimal application, there is no liquor exchange, i.e. $\alpha = 0$ and

$$\frac{X_2 - X_1}{X_2 - (1-\alpha) \cdot X_1} = 1$$

The concentration of the finishing liquor can be kept constant under these circumstances (Manuf.: Stenker).

Liquor flow The most important function of a dyeing machine is to achieve uniform dyeing in a defined and above all homogenous flow of liquor throughout the fibre mass from the volume elements of the yarn interstices through to the macroscopic dimensions of the textile fabric. The connection between the impinging flow and dyestuff absorption of a substrate is described in a considerably simplified form by the convective diffusion model. This model combines the flow profile of the liquor with the concentration gradient of the dyestuff across the substrate surface.

A distinction is made between:

a) m_s = dyestuff transmission via absorption from the liquor onto the substrate surface and
b) m_k = dyestuff transmission by convection in the flowing liquor.

The system can be characterised by approximation via the quotient q of these rates:

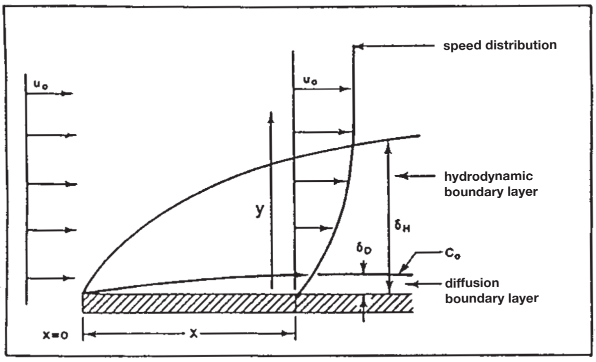

Fig. 1: Flow profile at substrate surfaces.
u_0 = liquor flow rate; c_0 = dye concentration in the liquor; The dimensions of the boundary layers s_H and s_D are defined for the 95% value of u_0 or c_0. The start section x_0 up to the formation of a constant profile is not taken into account.

$$q = \frac{m_k}{m_s}$$

In a stationary liquor, i.e. $q << 1$, the dyestuff is bound to the substrate surface by sorption. This process continues until the sorption equilibrium of the dyestuff on the surface of the substrate in question is reached (the sorption equilibrium should not be affected by diffusion of the dyestuff within the fibre). At the same time the liquor layer close to the surface is rapidly depleted of dyestuff, i.e. the dyestuff transmission takes place predominantly by means of controlled diffusion and $\sigma_D > \sigma_H$ applies. If the substrate is impinged with liquor, however, i.e. for $q >> 1$, when the dyeing rate is increased at the same time, the layer close to the surface which has been depleted in dyestuff can be cleared and replaced by fresh liquor high in dyestuff. Now $\sigma_H > \sigma_D$ applies. The model (Fig. 1) demonstrates how the liquor flow affects the dyeing rate by means of a simplified model. It also demonstrates that flows which differ locally on the substrate must result in unlevel dyeing. Level dyeing is therefore only possible in an homogenous liquor flow profile for $m_k >> m_s$. However, these conditions are not always possible for technical reasons. A practical solution is to adjust a quasi-stationary equilibrium between m_k and m_s. Level dyeing is only possible in a uniform flow profile which is constant over time.

The liquor flow therefore effects the dyestuff transmission (but also conversely the removal of soil e.g. when washing) as follows (Fig. 2):

1. Transmission of the dyestuff to the outer surface of the textile (e.g. surface of a package of a moving fabric). Takes place by convection (liquor flow and/or fabric movement) and free diffusion in the laminary boundary layer.
2. Transmission of the dyestuff through the textile (i.e. the interstices between the yarns and between the filaments or fibres in the yarn) to the fibre surface. This occurs by convection (with generally significantly lower liquor flow than outside the textile) and diffusion, whereby the liquor dyes the textile as it passes through it and consequently decreases in dyestuff content.

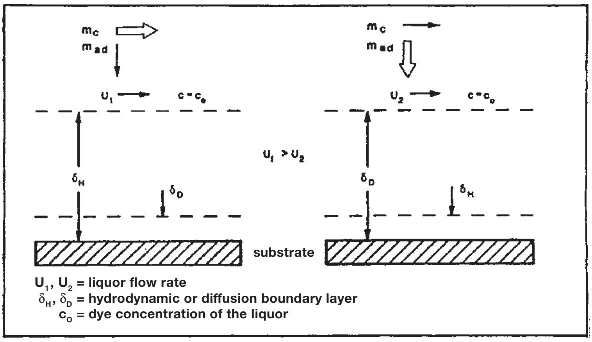

Fig. 2: Fabric transport at the substrate surface. The dilation of the boundary layers in the system is determined by the sorption and convection ratio.

Fick's law of diffusion for dyestuff in the fibre is based on diffusion of the dyestuff by a diffusion boundary layer in the liquor. The exhaust curves calculated for constant conditions shows a delayed exhaustion in comparison to the curves of the models without boundary layers. The effect on the flow by the parameters

$$l = \frac{D_L \cdot r_F}{k \cdot D_F \cdot \delta_D}$$

can be described using a Nernst adsorption equation. It characterises the ratio of the rates of diffusion to the fibre surface (diffusion coefficient D_L in the liquor, depth of the diffusion boundary layer δ_D) and the diffusion in the fibre (radius r_F, diffusion coefficient D_F and distribution coefficient k). The lower the value of l, the greater the effect of the flow.

The liquor flow is not uniform within the textile mass, however. In package dyeing (beam dyeing, crosswound yarn package dyeing) the situation is as follows:

1. The laminary boundary layer with decreasing liquor flow on the surface of the textile results in a somewhat slower exhaustion due to the effect of the diffusion boundary layer. This does not have a significant effect on the uniformity of the dyeing and only contributes to the lack of uniformity in less impinged areas to a small extent.
2. The low flow though the inside of the yarn or points of intersection: the denser a yarn in relation to the package density or the permeability of a surrounding textile fabric, the less it is impinged at the same average liquor throughput Q. This has an effect locally in yarn which is poorly penetrated or globally in packages with a significant difference between inside, centre and outside of the packages.
3. The uneven flow in the package: edges which have been poorly impinged or channelling in packages or insufficient liquor flow of a fabric accumulator in machines are the most common causes of unlevel dyeing. When assessing lack of uniformity, the local minimum Q_{min} is used in the place of the overall flow Q. Unfortunately, Q_{min} is not known more accurately under practical conditions.
4. The change of direction of the liquor flow in pack-dyeing machines: alternating the flow on packages reduces unlevelness. Frequent alternations, e.g. after each revolution, are not recommended. Changing the direction after every 2–4 revolutions is most favourable when the flow is approximately equal in

both directions and provides almost the same levelness as double flow with flow only from one direction. Where the flow occurs from outside to the inside, the yarn packages may become compressed with significant increase of the differential pressure, reduced flow or even deformation of the yarn package or the tube and channelling (according to Schollmeyer, Heidemann and Hoffmann).

Liquor flow direction The direction of the current within either a dye liquor or fastening liquor.

Liquor flow in packages The characteristics of flow within a yarn package (see Fig.) are an important parameter governing the even dyeing of yarn. As the temperature rises the viscosity of the liquor, and thus also the differential pressure, reduces. It follows so that the flow rate at the dyeing temperature can be controlled by means of the differential pressure (e.g. direct current motor, frequency converter, bypass). The differential pressure is a measure of fluid friction within the yarn winding and therefore of shear stress. Flow related characteristics, information concerning dyestuff transport or dyeing conditions, differences in winding density and methods for measuring and testing the distribution of winding density within yarn packages are all of great importance; due to the greater winding density in compressed packages and the greater surface area of yarn they contain, rapid wetting and venting is significant. Penetration enhancers and anti-foaming agents added in advance to the dyeing liquor have proved themselves in this application (according to Mosimann).

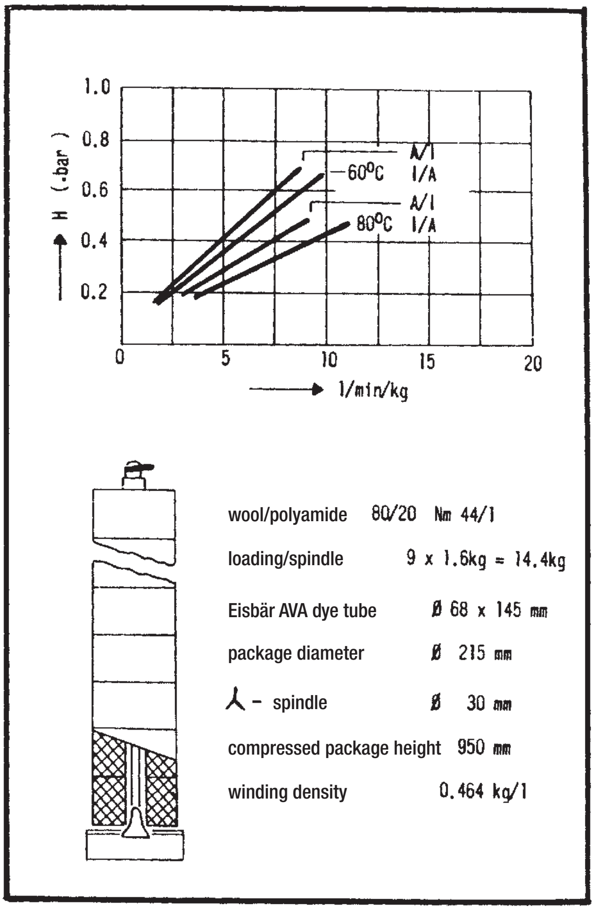

Fig.: Liquor flow and permeability relative to temperature and flow direction (wool/polyamide, Nm 44/1) (Mosimann).

Liquor flow reversal It has proved best to change the direction of liquor flow with every completed circulation of the bath volume (→ Liquor circulation) during through flow processes (see Fig.). However, in practice the liquor flow direction is changed after every two to three full circulations. For optimum results the liquor flow direction should be changed every 20–30 seconds, or at the least every 80–120 seconds, whereby the time allowed for outside-to-inside circulation should always be longer than that for the reverse direction in keeping with the reduced flow through rate of the liquor.

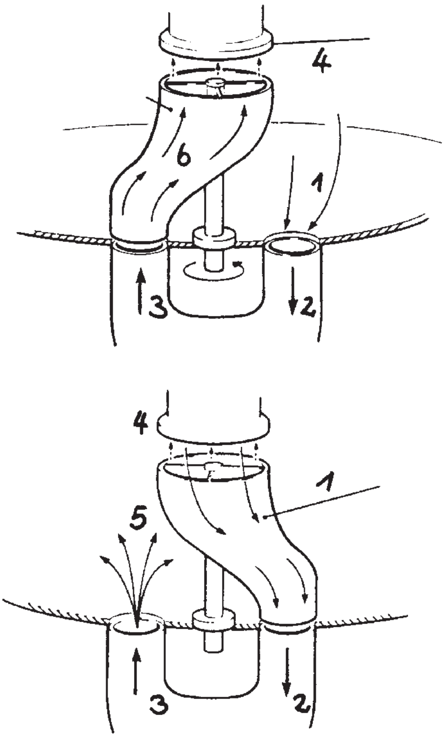

Fig.: Liquor direction change via a sort of "switch system" (Longclose) with the use of a unilaterally operating centrifugal pump.
1 = liquor return flow from material; 2 = suction side of pump; 3 = pressure side of pump; 4 = material carrier connecting piece; 5 = liquor flow out to in; 6 = liquor flow in to out.

Liquor heating by hot water This allows for good heat utilization. The process is possible for hot water temperatures up to 190°C; every steam boiler system can be used for hot water generation. The hot water generated, circulated by a pump, can be used immediately for heating purposes in indirect heating systems (loop: boiler – application – boiler). Advantages: best utilization of heat (unused residual heat is returned to the boiler, whereas steam operation leads to heat loss through water condensation), no change in liquor level or pH due to accumulation of condensate, only limited top-up feeding of the boiler required, no corrosion. Disadvantages: high cost of facility, direct heating not possible. Modern steam heating systems are able to compete with hot water heating systems.

Liquor level Either the level or the quantity of liquor contained within a dye bath, etc.

Liquor pick-up Also → Pick-up. The pick-up of liquor in the pad mangle is dependent upon:

- the squeezing pressure of the squeezer,
- the textile material,
- composition of the pad dyeing liquor,
- temperature of the dyeing liquor,
- throughput speed of the goods.

Liquor quantity → Liquor-to-goods ratio.

Liquor stability The physical and chemical resistance of dyeing and other treatment liquors.

Liquor throughput The relationship liquor to quantity of goods to time, e.g. 1 l of liquor flowing through 1 kg of goods per hour. → Liquor circulation.

Liquor volume calculation Fill the dyeing machinery with water and add 1000 g of dry, pure sodium carbonate then stir until dissolved. Extract 500 ml and titrate with hydrochloric acid until neutralized.

Liquor wedge arises in both horizontal and vertical broadloom washing machines between the guide roller serving as principal washing element (1) and the travelling sheet of fabric (2), i.e. shortly after the installed spray pipe (3) which constantly applies a film of liquor to the fabric (see Fig.). As a consequence hydrostatic pressure builds within the liquor wedge and forces liquor through the fabric.

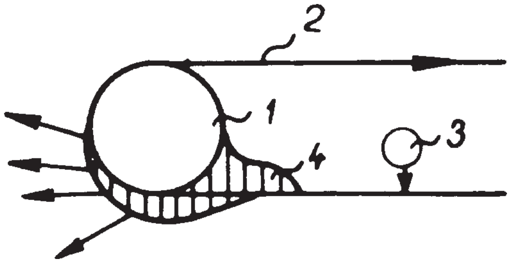

Fig.: Liquor wedge formation.
1 = deflection roller; 2 = fabric; 3 = liquor feed; 4 = liquor wedge.

Liquor-to-goods ratio The ratio of goods (kilograms) to liquor (litres), defined more precisely as: the ratio of the dry weight in kg of the goods, including all associated materials, measured immediately prior to the finishing process, to the volume in litres of the entire treatment liquor in the system at a temperature of 20°C at the time of the measurement. An essential factor when drawing up recipes (for dyeing, bleaching, etc.) is the establishment of freely reproducible values, and these play a deciding role when calculating the requirements for the heating steam. Every reduction in the liquor-to-goods ratio creates savings in time, water, waste water, energy and additional resources – within, of course, the bounds of technical and technological limitations (→ Liquor circulation). The following categorization is made according to liquor-to-goods ratio:

short liquor	1 : 10
standard liquor	1 : 20–30
long liquor	1 : 50–100

The liquor-to-goods ratio suitable for each type of dyeing apparatus is a decisive criterion in the selection of apparatus to be used:

jigger	1 : 1–8
apparatus	1 : 5–10
vat	1 : 20–30
paddle winch dyer	1 : 20–25
paddle machine	1 : 150
star wheel dyer	1 : 100–300

A reduction in the liquor-to-goods ratio may be aided by: a) making possible the maximum utilization of the space within an apparatus by suitable construction (Fig. 1) and b) exploiting this space by using optimum textile make-up and item size. Presupposing that the apparatus itself is ideally set up, it then rests largely in the hands of the finisher to achieve a lower liquor-to-goods ratio by ensuring a high packing density of the goods (Fig. 2). It is on account of this that presses are used in practice, also because of the increase in production which results. With the exception of special cases (sewing thread, filaments etc.), the following packing or winding densities may be attained:

loose material	300–500 kg/m³
strands in suspension system	80–130 kg/m³

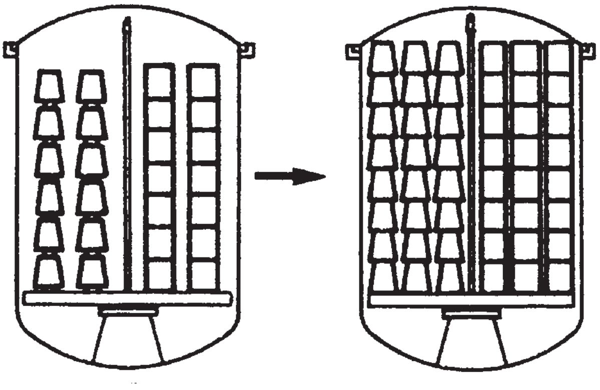

Fig. 1: Shortening liquor ratio by max. machine utilization.

soft winding	140–220 kg/m^3
crosswound yarn packages on rigid cores	300–450 kg/m^3
piece goods on beams	250–00 kg/m^3
piece goods in paddle winch vat	80–150 kg/m^3
piece goods in dyeing machine	150–200 kg/m^3

It is also possible to reduce the liquor-to-goods ratio by inserting displacement devices into locations which cannot be filled with material (Fig. 3). Their effectiveness should, however, not be exaggerated as it is less than generally assumed. Displacement devices for single packages or columns of packages do not achieve the desired effect, so that use is restricted to special cases in two-level apparatus when, for reasons of item size only, one material holder is used.

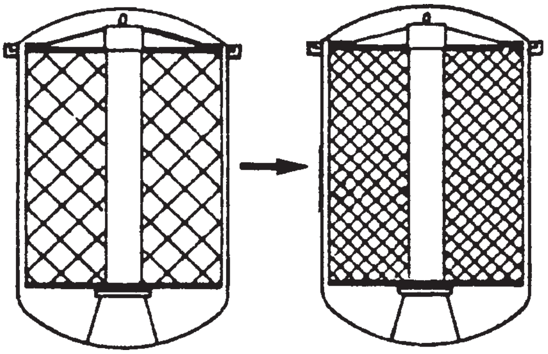

Fig. 2: Increasing packing density in order to achieve a shorter liquor ratio.

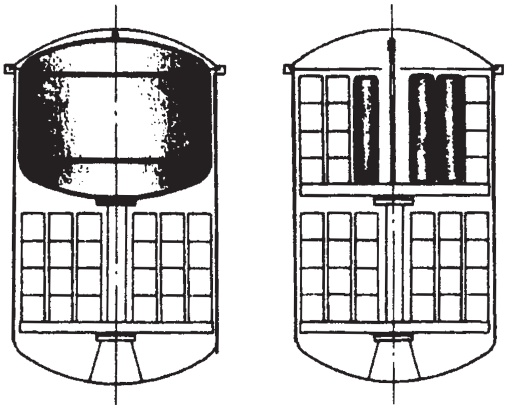

Fig. 3: Use of displacing elements with less than fully loaded machines.

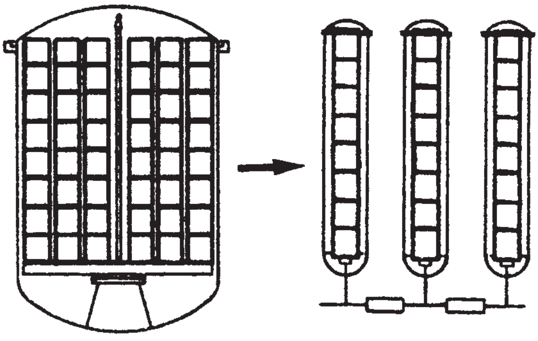

Fig. 4: Splitting up a large dyeing machine into small dyeing zones related to dye columns.

A further possibility is to adapt the form of the apparatus to match the make-up of the goods to be dyed (Fig. 4), in other words a purely machine technological measure which is particularly suited to dyeing apparatus for packages. A variety of such devices is on the market; they are more difficult to use and the facility takes up more space. A further disadvantage is the relatively narrow limitation imposed on package diameter since any reduction in diameter increases the liquor-to-goods ratio.

The liquor circulation pump and the heating and cooling systems may be built directly into the curved base of the autoclave, which cannot anyway be filled with material (Fig. 5). This does away with the piping otherwise needed for liquor circulation and as well as reducing the liquor-to-goods ratio, it also eliminates losses due to flow resistance. The measure has a favourable effect on drive efficiency and therefore on the consumption of electrical energy.

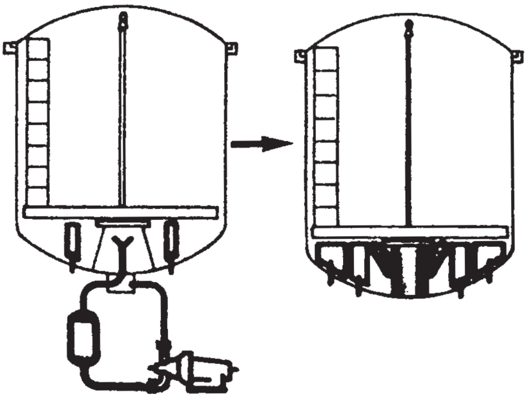

Fig. 5: Integrating the circulation pump into the dye vat.

Items with a make-up such as flocks, cross-wound packages, rocket spindles, muffs, warped beams and so on, which may be dyed from the inside to the outside, allow for processing in only partially flooded apparatus, which provides a simple and relatively effective way of reducing the liquor-to-goods ratio. In order to allow processing with as low a level of liquor as possible, the dyeing apparatus must be constructed so as to permit unhindered return of the liquor to the circulation pump while working at an adequate specific liquor flow rate. Compact systems, in which a multi-stage axial pump is integrated into the dye vat along with a heating coil, dispense with a secondary loop to an additional tank whose contents may be fed into the main loop by a an auxiliary pump. When used for well assembled compact columns composed of cylindrical packages with axially flexible cores, such a system can even dye "in sump", whereby the liquor is pumped from inside to outside and a small amount of liquor cascades down the package columns to the drain. Antifoaming agents are required to prevent frothing of the liquor. Maintaining pressure in the air space (air or inert gas), known as pressurized operation, assists maximum performance by the circulation pump even at the lowest of liquor levels.

In order to reduce the liquor-to-goods ratio in hank dyeing machines by taking account of the pipe and pump volumes, the heat exchanger can be placed within the reaction chamber (as in yarn dyeing machines), which allows for the shortest possible pipes connecting from the sump (which contains the heat exchanger pipe) via the pump to the overflow tank. In gentle dyeing machines the liquor film should be calculated at the minimum required to penetrate the goods. The liquor, which flows gently from the spray nozzles, not only aids the draining of the goods but also aids penetration on account of constant changes from laminar to turbulent flow.

The minimum application system for aqueous dye liquor requires only as much liquor as is taken up by the fabric sheet through capillary action and adhesion. Excess liquor must drain immediately from the lowest point of the treatment chamber and then flow into a collecting tank. Accordingly, there is no liquor surface level within the treatment chamber. The collecting tank is able to hold sufficient liquor reserve to enable problem free operation of the circulation pump. If one assumes that this system requires a significantly lower pump capacity, the collecting tank need only hold approximately 150 litres of free liquor in order to feed the pump. Goods of some qualities can take up liquor to a maximum of 300%; if the quantity of free liquor is added to this, then in the least favourable case a liquor-to-goods ratio of 1 : 5 is attained with a machine possessing only a single storage rack. Examples are:

– 1 rack, 80 kg goods, 300% liquor take-up

$$FV = \frac{(3 \cdot 80) + 150}{80} = 4{,}87 \cong 1:5$$

– 3 racks, 240 kg goods, 300% liquor take-up

$$FV = \frac{(3 \cdot 240) + 150}{240} = 3{,}62 \cong 1:4$$

– 3 racks, 240 kg goods, 250% liquor take-up

$$FV = \frac{(2{,}5 \cdot 240) + 150}{240} = 3{,}12 \cong 1:3$$

– 4 racks, 320 kg goods, 200% liquor take-up

$$FV = \frac{(2 \cdot 320) + 150}{320} = 2{,}46 \cong 1:2{,}5$$

Every liquor-to-goods ratio achievable on the basis of the characteristics of any specific fabric takes account of the total liquor volume required in order to dissolve the quantity of dyestuff and chemicals needed even for deep dyeing.

Listing → Tailing.

Lithium (Li) → Alkali metals atomic weight 6.94. Burns with a colourless flame, chemically related to → Sodium.

Lithium chloride (LiCl), density 2.968. Forms colourless crystals or a white powder (deliquescent). Strongly hygroscopic; poisonous. Uses: in air-conditioning systems as a water-retaining regeneratable substance; as conductivity measuring sensors for hygrometers.

Lithium chloride hygrometer In keeping with the principle of humidity detection, a suitable sensor comprises a wick soaked in → Lithium chloride and wrapped in a heating coil whose electrical heating effect depends precisely on the moisture content of the surrounding air. Operating on the definition of conductivity, so-called sensor platelets which are composed of a thin layer of lithium chloride embedded in a film of hygroscopic plastic are used to register humidity. Such platelets change electrical resistance logarithmically with increasing relative humidity, a characteristic which can be amplified to operate a regulator, pen recorder or similar device.

Lithography A flat printing (planography) process used in paper printing in which a polished and engraved stone was originally used as a printing plate (Gk.: lithos = stone).

Litmus A blue pigment obtained from lichen used as an indicator in solution or by colouration of paper. A distinction is made between red litmus paper, which reacts to an alkali by turning blue, and blue litmus paper, which reacts to an acid by turning red. Its neutral colour is violet. Its transition range (pH 5–8) is easily influenced by the presence of weak acids (e.g. carbon dioxide in air, therefore store litmus in a well-sealed brown bottle). Its sensitivity is approximately 1 : 20 000 for potassium hydroxide, 1 : 50 000 for hydrochloric acid (i.e. 1 g dissolved in 50 litres). Litmus is only used as a test for acidity and alkalinity; it is not used to measure pH value.

Litre Fluid measure, i.e. spatial or volumetric measurement equal to 1000 cm^3 of water at 4°C, which equals 1 l or 1000 ml.

Litre weight (L). The weight of a → Litre of gas expressed in grams, calculated by dividing the weight G by the volume V. Analogous to the varying weight of liquids (specific gravity, → Density), the litre weight varies between different gases occupying the same volume; e.g. litre weight in grams: acetylene 1.1708; ammonia 0.7713; chlorine 3.220; hydrogen chloride 1.6391; carbon dioxide 1.9768; air 1.2928; sulphur dioxide 2.9256; hydrogen 0.08987.

LL fabrics → Links-links fabric, purl fabric.

Llama hair South American ruminant, member of the camelidae (camel family); its wool is of various colours, having coarse guard hairs with a diameter up to 150 µm and fine underhair with a diameter of 20–35 µm; it has around 100 almost invisible scales per millimetre. → Animal hair fibres.

Lm → Llama hair, → Textile fibre symbols, according to DIN 60 001 until 1988; from 1991 changed to → WL.

lm Lumen, SI unit of luminous flux. → Lux.

Load ratio The ratio of the filling weight of goods in kg to the volume in litres of, e.g., the washing or dry cleaning drum. Frequently used ratios are:

a) Washing machines: drum washing machines 1 : 12–14; flow wash systems 1 : 16

b) Dry cleaning machines: long drum type 1 : 16–17; high-level drum type 1 : 18–22.

The guide value is the filling factor, calculated as the ratio between the volume of the drum in litres to the filling weight in kilograms of the goods. Example: for a high level drum type dry cleaning machine the filling factor is usually 18–22.

Locust bean flour (fine flour), the ground seeds of the fruit of the locust bean, or carob tree, a leguminous plant native to the Mediterranean, giving a very light, almost dusty whitish or light brown flour (the mechanically shelled beans are better than the chemically shelled; there are shell-rich and shell-free varieties, also bleached and unbleached). Active substance → Carob. To dissolve: disperse in glycerine, dilute with water. Thickened solutions are not considered smooth and have the disadvantage that they tend to liquefy and decay after being left to stand for several days: this may be prevented by adding proteins and preserving agents. A locust bean flour solution may be coagulated using alkaline lye, alkaline carbonate or perborate.

Loden,

I. Woven woollen goods in an unfinished state (unsized).

II. Predominantly woollen, coloured blended coarse material made from spun virgin wool and fleece (heavily milled and carded, not cropped), also with admixtures of camelhair, alpaca or mohair for higher quality. The name is derived from Old High German lodo = coarse cloth. It was originally a coarse hand made cloth among the upland peoples of Southern Germany. Loden now represents a general term for a relatively thick, usually olive green, red brown or dark grey material of tough character, often impregnated to make it waterproof. The most usual form of weave is twill. According to the finish or application a distinction is made between: a) melton-loden with a melton finish, primarily used for skirts, dresses, trousers and suits for hunters, farmers and foresters, and impregnated when used for coats: b) brushed loden with a long brushed finish is used solely for coats and cloaks, whereby the direction of combing serves to promote the water repellent effect.

Logarithm (log, Gk.: logos + arithmos), a ratio for the purpose of simplifying the calculation of mathematical equations, whereby natural multiplication is converted into addition and division is converted into subtraction. Negative logarithms play a role in textile finishing with respect to → pH. For example, pH 7 may be expressed as negative log "10^{-7}" which implies that 1 litre of water contains 10^{-7} grams of hydrogen ions.

Logistics The textile business is classically divided up in an organizational diagram into divisions, areas, responsibilities, departments etc. Conceptual thinking, or compartmentalized thought, lies behind this segmentation. These concepts are precisely segregated one from another; losses in effectiveness can arise at any interface due to an inadequate flow of information or because of unclear areas of competence. Integrated network thinking always considers a business as a logical system which exists to supply the market. Logistics encompasses the following technical and commercial specialities and may be divided into:

- disposition
- production planning, production control
- central purchasing
- despatching.

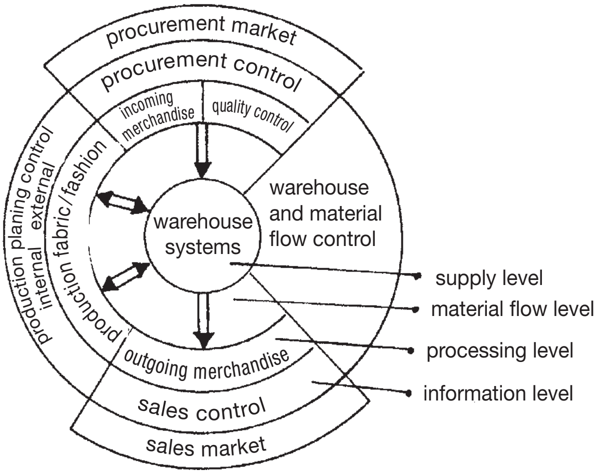

Fig.: Cybernetic logistics relationship diagram.

developmental stages of organisation	organisation by speciality, functional organisation	organisation by system, cybernetic organisation
applicability	when qualified specialists required in a slowly changing world	when coordination with no time lag required in a rapidly changing complicated world
models, focal point	the scientifically orientated speciality	the process orientated system
basic principle	unity of knowledge	unity of the control loop
key phrase	all substantive matters are to be dealt with by a suitably trained specialist	all control processes in the system are to be integrated
starting point	division of tasks and traditional disciplines, types of training and career path	system analysis, process interrelations, needs for agreement, types of mentality
prestige	number of subordinates	importance of the assigned subsystem to the success of the entire system
responsibility	responsible for fulfilling ones own tasks	jointly responsible for the working of the entire system
coordination	by agreement between managers of specialist areas	constant direct agreement among operatives
criteria (control)	observation of methodical rules, achieving isolated sub-optimums	realisation of models as desired effects upon the entire system. Maximum performance in isolation does not find approval.

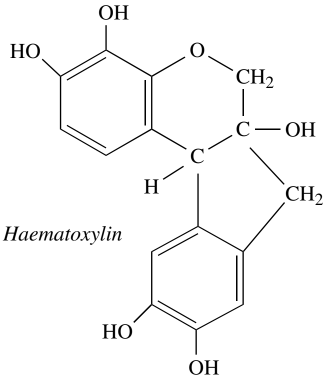
Tab.: Comparing "functional organization" with "cybernetic organization".

These different levels are seen as interacting intensively within a cybernetic logistics model (see Fig.).

Functional thinking (see Tab.) in traditional organizations is too rigid to be able to react quickly and flexibly to market requirements ("quick response") such as fashion changes, or to be able to deliver "just in time" (i.e. exactly at the moment when a customer is ready to further process goods) while tying up the minimum amount of capital in holding warehouses.

In order to realise the main goal of logistics (the supply of the market to be exploited by the marketing department) it is necessary that reliable data for prognoses are kept up to date and that real-time information concerning capacity, the state of production (at home and abroad) and warehouse stocks is available. This in turn requires that an integrated EDP system covering prognosis to delivery is available or at least in development. Only in a few instances will an EDP system actually be available to a newly installed logistics area. Instead, more or less group-constrained solutions will be in operation. It will initially be possible to make do with the available group-constrained solutions while still achieving success provided that the employees can substitute for the missing integration through high quality cooperation using communication and whole-system concepts.

Logwood The heartwood of the tropical logwood tree (heamatoxylon campechianum). Its active substance is colourless haematoxylin, which is extracted by oxidative fermentation, and from which the red derivative haematin is obtained through oxidation.



Haematoxylin

Fixing is done using metal mordant: tin = reddish violet; alum (potassium aluminium sulphate) = greyish violet; chrome = dark blue-black; iron = grey-black; copper = dull green-blue. Formerly an important mordant dye for silk (with simultaneous aggrevating action), logwood substances are nowadays used only as additives with certain synthetic dyes. Characteristics: excellently wear fastness with good wash fastness and satisfactory light fastness. Disadvantages are its fading to green in light and its colour change towards red when affected by strong acid.

Logwood black test → Hydrochloric acid test.

Logwood extract (noir reduit), extract of → Logwood, used in printing.

LOI (Limited Oxygen Index). LOI is the standard value for characterising combustion properties. The LOI test is a method devised by General Electric for testing the combustion behaviour of polymers and also textiles, and represents the minimum concentration of oxygen mixed with nitrogen at which a textile material no longer burns. The original term Limited Oxygen Index has in the meantime been shortened to Oxygen Index, i.e. to OI, and may also be described as limiting oxygen level (Fig. 1).

The test sample is stretched within a frame and suspended in an oxygen-nitrogen mixture, then ignited so that it burns from the top downwards. The minimum amount of oxygen which supports burning over a period of 3 minutes, or the burning of a 50 mm length of the sample, is determined. The test frame with the sample (40 x 100 mm) is placed in the testing column and the oxygen concentration is then set. The gas mixture is blown through the column for 30 seconds at a velocity of 4 ± 1 cm/s (at 760 bar and 273.15 K) and the sample is ignited using a special burner. The fabric must then either burn for at least 3 minutes or it must burn completely along a length of 50 mm. The LOI is read off from a scale (Fig. 2). Measurements are conducted ac-

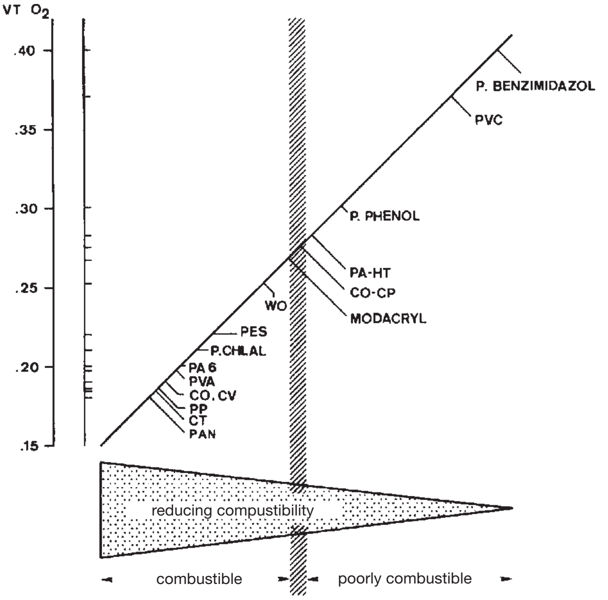


Fig. 1: The limited oxygen index of various fibres.
P = poly-; CO-CP = flame retardant treated cotton.

cording to ASTM D2863-76. The ignition source is a 25 mm propane/butane flame. The contact time between flame and fabric, i.e. the ignition time, is not specified under the standard. However, since the ignition time is important, the time for contact between flame and the environmentally conditioned fabric sample (standard conditions) is set at 5 seconds.

The LOI is determined primarily by the type of fibre in the sample and only to a small degree by the apparent fabric density or pore volume (see Tab.). The pore volume is determined by the density of both the fibre itself and the fabric weave. As the number of pores increases, the flame resistance of the fabric decreases.

The fact that almost the same LOI is measured for the same substrate when ignition from above is carried out at different ignition temperatures is a contributory reason for choosing ignition from above. Furthermore, the vertical test with ignition from above causes no additional warming of the substrate front, as would be the case with ignition from below. When testing woollen fabrics using ignition from below, the measured oxygen index is strongly influenced by the ignition temperature. Only small variations in ignition temperature may lead to false results. This finding also confirms the risk associated with the vertical test when igniting from below. At the same time, however, it must be made clear that the measurement of the oxygen requirement should be regarded neither as sole criterion nor sole method for assessing the combustion behaviour of various substrates, but is rather to be seen in a supporting capacity.

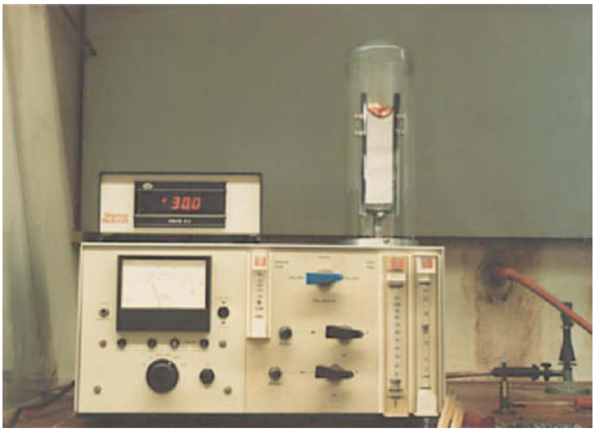

Fig. 2: LOI measuring apparatus.

material	apparent density (g/cm³)		index	LOI value	
	min.	max.		min.	max.
cotton	0,19	0,30	158	18,1	18,5
viscose	0,46	0,53	123	18,4	18,9
wool	0,31	0,34	109	25,1	27,0
PES	0,10	0,23	230	22,6	24,2
PA	0,22	0,67	305	27,0	31,0
PAN	0,18	0,27	150	19,8	20,9
PES/cotton	0,18	0,47	281	16,9	19,5
PES/wool	0,13	0,43	358	21,6	24,0

Tab.: The relationship between LOI and fibre density (according to Jeler).

When measuring the oxygen requirement, either a length of 50 mm of the sample must be burnt or else the burning process must persist for approximately 3 minutes at the minimum available oxygen concentration. At the same time any additional observation of melting, dripping, shrinking or blackening and so on is to be recorded. Care must be taken that the surrounding temperature remains low and that the pyrolysis gas can escape unhindered. Switching on an extractor fan above the glass bell is an advantage.

Experience to date shows that fibres with an LOI < 27–28 will not burn in air. Acrylic (polyacrylnitrile), triacetate, polypropylene and acetate still burn at the lowest concentration of oxygen in the oxygen-nitrogen mixture. Polyester and wool require a relatively high oxygen concentration. Fibres such as aramides, which are not combustible in air under normal conditions, have an extremely high LOI. In other words, combustibility may be deduced from the LOI.
The LOI values of various fibres are:

acrylic	18.0
triacetate	18.4
polypropylene	18.6
viscose	18.9

cotton	19.0
polyamide	20.0
polyester	22.0
wool	25.2
aramide	28.2
carbon fibre	35.0
polyvinylchloride	37.1
cotton/polyester 50/50	18.4

A very useful indication of the effectiveness of flame retardants on fibres is also given. For this test the sample is suspended vertically in an oxygen-nitrogen mixture and ignited, and the oxygen concentration adjusted until the sample burns for at least 5 minutes. The concentration of oxygen required for this is again an indication of combustibility, in other words the higher the LOI the less combustible is the substrate.

London forces Dispersion forces (→ Secondary valency forces) named in Anglo-Saxon literature after the physicist of the same name.

London shrinking process The purposeful restoration of the temporary stretching or tension arising in wool or wool-mix fabrics as a result of the production process by applying the principle of → Shrinkage. The fabric is laid in a tension-free state in damp decatizing wrappers for approximately 12 hours with subsequent slow and tension-free drying. In the process a cloth shrinks by approximately 5–10%.

London shrunk → Shrinking machine for wool and wool-mix fabrics. The fabric travels tension-free from the feed roller in a loose loop to the steam cylinder and then over a sloping, polished heating plate where weft and warp are allowed to relax entirely. The speed of the fabric and the steam intensity may be regulated to achieve any desired shrinkage effect suitable to any fabric. Uses: mainly following decatizing, or following pressing and before final decatizing. – Manuf.: Kettling & Braun.

Long-chain dye process Continuous indigo dyeing process for cotton warp yarns. The threads gathered together into strings (warps) are passed through several pre-wetting and dye baths. After each immersion in a dye bath the material is squeezed out and the indigo oxidized in air. There follows a final rinse or post-treatment, the continuous drying on a drum or cylinder drier, after which the dried strings are opened and wound onto warp beams.

Long cylinder The → Inner drum of a double drum machine, being mounted at both ends and with a ratio of drum height to drum depth (or length) > 1. The filling factor is 23–25.

Longitudinal (Lat.: longus = long) running or laid out lengthwise.

Long liquor Used for a liquor containing a large quantity of fluid, e.g. 1 : 40. Opposite: → Short liquor.

Long-steaming method Original steaming method in the two-stage printing process. The dried print is padded with reducing agent and, according to the thickening agent, with caustic soda, potassium carbonate, calcified sodium carbonate, sodium tetraborate or aluminium sulphate together with a wetting agent, and then steamed for 10–15 min. The process had the advantage that older types of steamer could also be used.

Look Term used to describe a fashion trend or style, e.g. the used look, safari look, etc.

Loomstate fabrics (loomstate plain weave, loomstate cloth), woven fabric coming from the weaving machine into the trade. The goods as such are not finished but usually merely brushed on a cleaning machine and if necessary steamed. Such loomstate fabrics may be raw fabric (e.g. untreated cotton, homespun etc. = loomstate cloth; hand woven linens = loomstate plain weave) or dyed fabrics (yarn dyed, printed, bleached) or patterned, etc.

Loop,

I. Any loop or swag of material, e.g. a loop of yarn, a loop of fabric (in a long loop drier or similar device). Loop fabrics are similar to Bouclé fabrics, except that while the latter's decorative threads possess only knot-like thickenings or small loops, loop fabrics have larger round loops which, in the case of strong patterns, may have a diameter equivalent to that of a pencil.

II. (pole stitch, plush stitch) a basic element of knitted fabric in combination with → Stitches appearing on the reverse side as regular long loops of thread (plush stitches) which are connected with plain stitches.

Loop-bonded composites → Fused bounded nonwoven.

Loop drier Piece goods are moved through the drier in long loops (long loop drier, suspended loop drier) or short loops (→ Short loop drier) with the reverse side suspended on the rail so that the right side of the goods may dry without contact or tension.→ Drying systems.

Loop-Dye 1 for 6 Warp dyeing facility for indigo; → Indigo dyeing.

Loop pile carpets Carpets made with closed → Pile loops. In the case of → Tufted carpets the loops of thread are stitched fast into the backing material. The loops, which are anchored in the backing material by a backing layer, provide the loop pile of the carpet.

Loop strength A means of assessing the suppleness or (the opposite) roughness and stiffness of yarns and twists, i.e. in general their transverse firmness. The loop pull test is carried out according to DIN 53843 analogous to the simple → Tensile strength test. Two threads are looped through each other so that they are held in the space between two clamps. The maximum loop tractive force is given as a ratio of the original maximum tractive force.

Loop transfer technique A minimal application process using indirect transfer of the treatment liquid. The liquid is first applied to an absorbent transfer medium by means of soaking, and the goods to be treated are then brought together with the transfer medium in a pair of squeezer rollers.

Loose stock A fine, light and loose structure composed of either smooth or tangled individual fibres (naturally washed, cut or torn). For example, loose viscose stock (or viscose flock) refers to piles of viscose fibres, usually cut to 30–150 mm, delivered for the purpose of yarn manufacture. Similarly, loose cotton is also referred to as loose cotton stock.

Loose stock dyeing Loose fibres, pressed into a cake in a suitable casing, may be dyed with through-flow liquor (Fig. 1). The case has both a perforated inner wall and a perforated outer wall. Reversal of the direction of rotation of the axial pump allows the flow direction of the liquor to be switched between inside-to-outside and outside-to-inside.

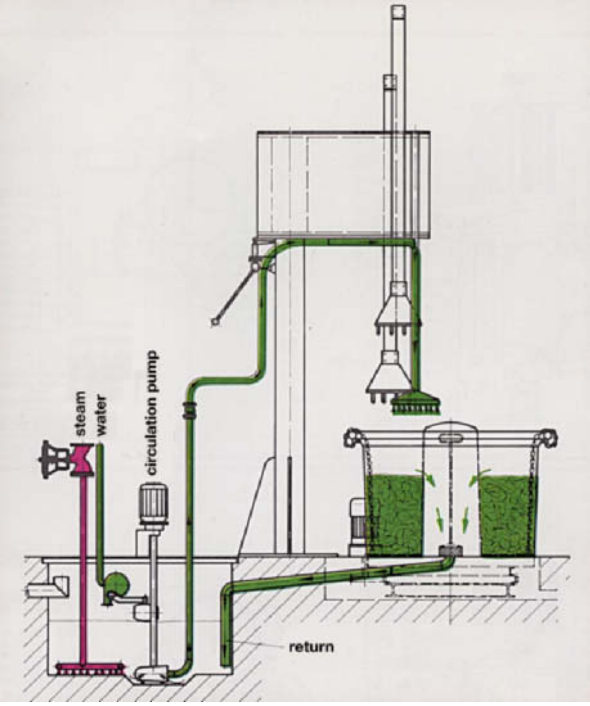

Fig. 1: Loose stock stamping machine.

The Krantz dyeing machine “OF/C1” is used primarily for the dyeing of loose material at temperatures up to 100°C (Fig. 2). The machine includes a built-in reversible axial pump capable of a change rotation and driven by a V-belt.

Loose stock packing device Used for the mechanical packing of loose material in apparatus pack cylinders.

Lot, batch (test batch) the number of items to be presented at a time for product testing. Also used in the sense of consignment in combination with other terms, e.g. production batch, delivery batch.

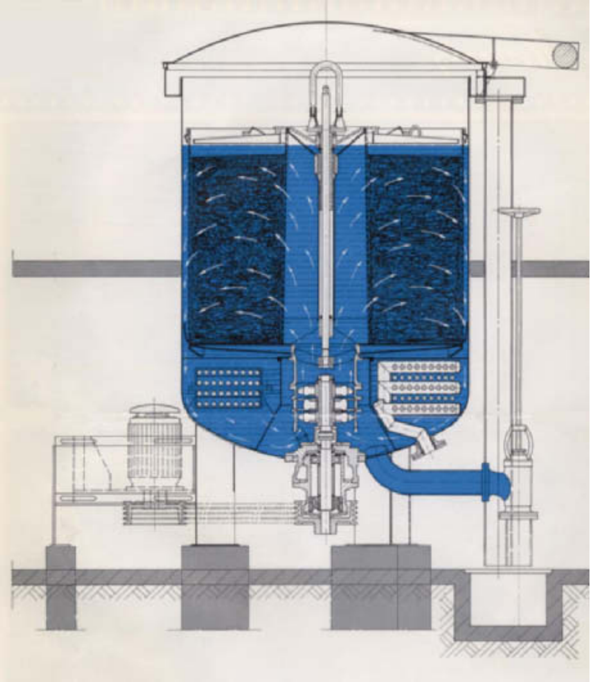

Fig. 2: Krantz loose stock dyeing machine.

Lot size The number of units in a → Lot, batch.

Lot system Dependent upon the organizational combining of all customer orders falling within a period of time so as to make a single large manufacturing order, which may then proceed as a unit through all manufacturing stages up to despatching (one-way throughput has time advantages, avoids leaving single items behind and improves production control).

Low add-on → Low wet pick-up

Low-density polyethylene (LDPE) → Polyethylene.

Low-Dyeing Polyamide → Differential dyeing polyamide fibres.

Low foaming The weak foaming characteristic of general purpose washing powders intended for use in a drum washing machine.

Low-formaldehyde finishing agents Finishing products with a low proportion of formaldehyde in the product (→ Low-formaldehyde resin finishing). From the range of N-methylol- and N-alkoxymethyl compounds, with which one can specifically keep below formaldehyde limit values without impairment of the known technological data. In resin finishing, it is predominantly compounds based on 4,5-di-hydroxyethene urea which are used, which demonstrably do not split off any formaldehyde in the finishing process, and which in the product itself are set to be low-formaldehyde.

Low-formaldehyde resin finishing Resin finishing of textiles with proportions of free formaldehyde on the finished goods being as low as possible. Measures for reduction:

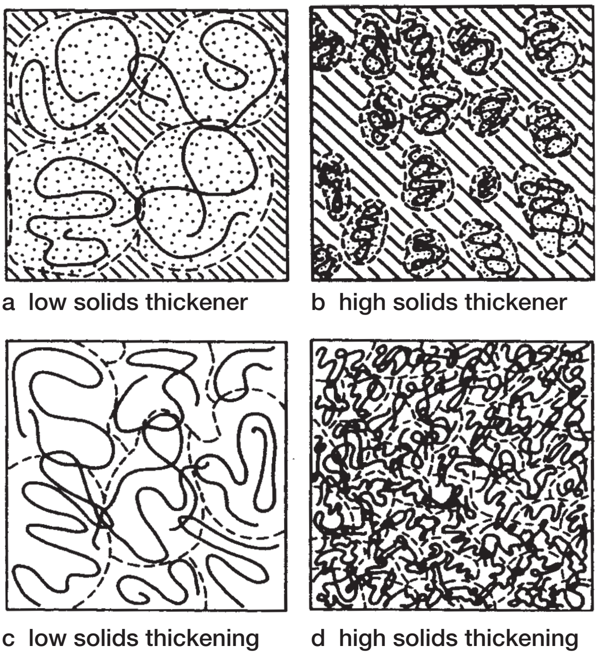
1. Choice of resin finishing products: products with a high resistance to hydrolysis, e.g. based on dimethoxymethyl-4,5-dimethoxyimidazolidone, are usual.
2. Process engineering: e.g. after-scouring of the finished textiles. Addition of formaldehyde acceptors to the finishing liquor, after-treatment with formaldehyde acceptors. When suitable resin finishing products are used, usually no process engineering measures are needed. Formaldehyde limit values on cotton 150 ppm, on polyester/cotton (65/35) 75 ppm.

Low/high solids thickeners Thickening with a small or large amount of → Solids content. Low solids thickeners = slow drying, soft elastic film. High solids thickeners = rapid drying, film more or less brittle/hard, contours standing sharply, but danger of splitting off.

Due to their high molecular weight, low solids thickeners form large gel bundles with a low bundle density. Even with low polymer concentrations, individual snags occur in the edge areas of these gel bundles, so that their freedom of movement is restricted. The viscosity curve shows the sharp rise in viscosity which is typical for the network solution after the critical concentration has been exceeded. The resistance which these polymer solutions demonstrate against a deformation is determined by the resistance which the linkage points of the network demonstrate in relation to mechanical stressing.

The situation with high solids thickeners is different. Initially, with a rise in thickening concentration one observes only a slight rise in the viscosity of the solution. The smaller, denser bundle packages of thickening agent can still move freely at these concentrations, and there is still sufficient free solvent available.

In this concentration range, the viscosity-raising effect of the high solids polymers is based not on the formation of a network, but on the fact that the gel bundles increase the frictional resistance of the flow layers, in that they act, so to speak, as flow breakers. If one increases the proportion of polymers, then with this thickening system too one finally reaches the critical concentration, and a steeper rise in viscosity is observed. The smaller gel molecules now likewise form a network. The figure shows a comparison of the two networks. Although they have a completely different appearance, nevertheless no differences can be established through viscosity measurement. (Manuf.: Schultz).



a low solids thickener b high solids thickener

c low solids thickening d high solids thickening

Fig.: Low and high solids thickener in diluted solution and in concentrated thickening (German Textile and Fibre Research Institute – Deutsche Institute für Textil- und Faserforschung, Denkendorf).

Low-liquor dyeing Dyeing process for yarn packages in circulating liquor machines (stacking system) with liquor reduced approx. 50%. Liquor direction exclusively from the inside to the outside (see Fig.).

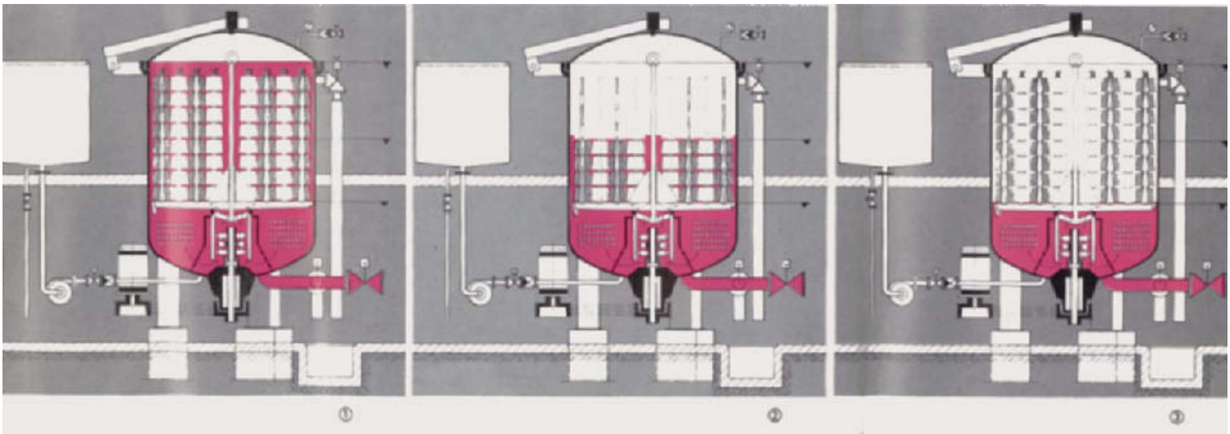


Fig.: Krantz yarn dyeing apparatus using the low-liquor dyeing technique.
1 = pressurized operation; 2 = partially flooded; 3 = low-liquor dyeing method.

Low pressure A low pressure (→ Air pressure). Not to be confused with negative pressure (→ Vacuum).

Low pressure dye winches Pressure winches for use at 103–105°C.

Low-pressure hank dyeing machine Vertical dyer for temperatures up to 110°C.

Low sulphurized oils → Sulphonated surfactants.

Low temperature dyeing Method of dyeing with direct dyes on cellulose fibres by exhaust method, at the lowest possible temperature (40–60°C). Whilst on the one hand there are savings to be made, on the other hand there are significant defects, e.g. lower dye penetration. Among reactive dyes, on the other hand, there is a range of dyes which can be dyed normally “cold”, i.e. at 40/50°C. When dyeing wool, temperatures of less than 80°C (also termed cold dyers) as possible only when larger amounts of solvent agents are used (e.g. formic acid). Actual advantages are yielded by the → Cold pad-batch process, above all when dyeing with reactive dyes on cellulose goods. Direct dyes can also be used when hydrotropic agents are used.

Low-temperature plasma LTP is used for modifying fibres and textiles, as an environmentally friendly and energy-saving alternative to some existing additive finishing processes. A suitable plasma for this is deemed to be a highly active mixture of ions, electrons and excited gas molecules, which can most easily be created through glow discharge at a pressure of ≤ 1330 Pa. For the modification of thermoplastic polymers, the use of LTP with relatively high electron energy together with low gas temperature is of particular interest. The depth of action of the LTP is limited to the surface of the fibre. The changes brought about in the polyester fibres by the action of plasma depend on the type of gas and gas pressure, the specific energy density and the treatment time, as well as on the type of energy supply. The treatment of fabrics of textured polyester fibres with air plasma over a period of 5–30 seconds, at a current density of 0.5-2.0 mA per cm^2 and a gas pressure of 133 Pa brings about considerable changes in the fabric characteristics: reduces the drop penetration time from ≥ 300 seconds to ≤ 1 second, raises the suction height from ≤ 20 mm to ≥ 200 mm; at the same time, the soil-release effect is comparable with the effects which can be achieved with additive soil-release finishing. These effects are wash-resistant. Quite different effects, e.g. hydrophobic, oleophobic or adhesion improvement, can be achieved by mixing inert gases with selected gases, e.g. halogens.

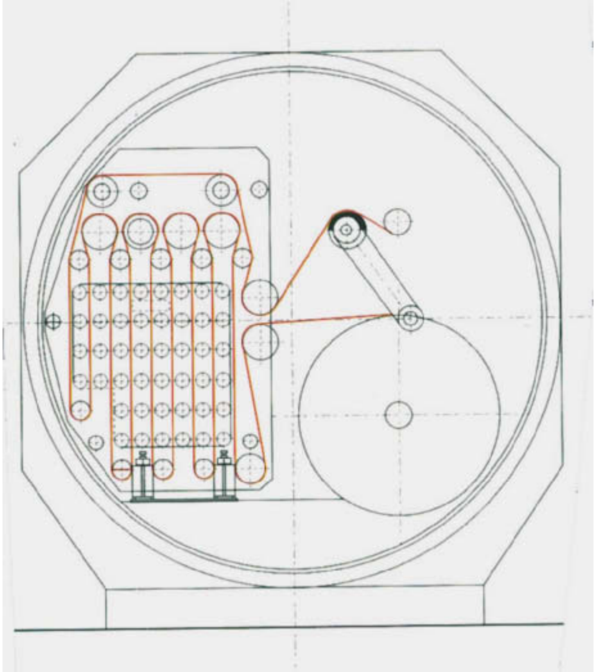

Fig.: Discontiuous plasma application.

Low-temperature plasma process in the textile sector For the modification of textile surfaces. In contrast to the → Corona treatment, in the plasma process the glow discharge takes place in a vacuum of approx. 1 mbar (see Fig). With this process, polymer films can be grafted on; where the wettability can be increased or reduced to hydrophobic effects, as desired. The dyeing affinity can also be altered. → Plasma treatment.

Low wet pick-up Minimum-liquor application; application of finishing liquors to textiles without excess liquor which would subsequently need to be removed. The principal aim is the capillary saturation of the material, e.g. cotton approx. 35% liquor loading, in general < 40% (Fig. 1). If, in the case of low wet pick-up, so little liquor is applied that complete distribution over the width of the goods is no longer possible, this is termed “deficit application”. In the field of textile finishing, low wet pick-up has gained in importance due to the increase in energy costs. However, the qualitative advantages of articles produced using low wet pick-up have also won this technology its place in the range of application methods. Thus the minimum application of

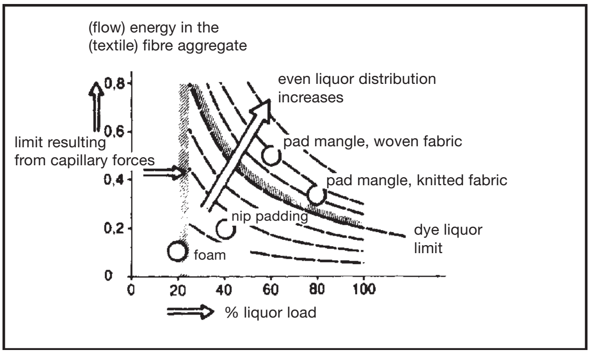

Fig. 1: Relationship of even liquor distribution to the liquor loading and the (flow) energy in low wet pick-up (after Kretschmer).

resin finishing chemicals, e.g. in the case of cotton fabrics, avoids the migration of the cross-linking agents in the water to the fabric surface, and the associated uneven cross-linking over the fabric cross section, since less water needs to be evaporated during drying. In this way, better strength values are achieved for the cross-linked cotton fabric. Besides qualitative aspects, in the case of one low wet pick-up variant, namely foam application, interest is focused on energy-saving efforts.

Low wet pick-up of alkalis for fixing reactive dyes of particularly high reactivity in the two-phase printing process takes place e.g. through spraying the fixing solution in the electrical field through which the printed goods pass.

The purpose of an applicator is to apply products with a carrier medium (usually water) to the goods. A check on the application amount carried out after the application requires that the residues of the mixture which are eliminated in the process can be fed back to the applicator. Ensuring that a precisely controlled amount is applied over the length of the goods is made more difficult by the left-over liquor being fed back and being mixed with the starting liquor, through so-called substantivity effects of individual products present in the liquor. This means that the recirculated liquor has a lower concentration of these products than the original liquor, through which – even if the amount of liquor applied is strictly monitored – the amount of the product received by the goods is progressively reduced. This problem is well known in continuous dyeing processes, but is of great importance in other finishing processes too, such as e.g. in the pre-treatment of cotton goods. The applicators can be divided up according to the criteria shown in the Tab.

1. Application of the liquor in excess amounts, with down-stream removal of the excess.
2. Application of a predetermined amount of liquor (with simultaneous monitoring of the amount of liquor applied).

	pick-up quantity		
	minimal	*normal*	*maximal*
with downstream removal of excess	F + C	F I	F I
with simultaneous control of pick-up	S C P	S	S M **A**

Tab.: Types of pick-up mechanism.
F = pad mangle; F+ = pad mangle with special quetsch system; I = impregnation vat; S = spray system; C = foam; P = pad; M = special pick-up mechanisms; A = addition pick-up.

To remove the excess, as a rule elements are used which simultaneously ensure a subsequent penetration of the liquor into the goods (pressure rollers, and suction extraction devices). In order to achieve the minimum application, attempts were made, using precision pressure rollers and suction extraction devices, to reduce the remaining liquor. The substantivity effects in the recirculated liquor could not, however, be eliminated. In the field of textile finishing, those applicators were considered which permit a one-sided application of the products (usually in the form of high-viscosity pastes). These applicators are among those which apply a controlled amount of the product/medium mixture to the goods, in practice at any rate amounts of less than 1 litre per kilogram.

I. Foam: The starting liquor is mixed with air, through which a slight foam is created. This foam is then applied to the goods, and usually passes through a down-stream doctor blade device or a suction device, in order to remove the excess foam. Main use: resin finishing/finishing.

II. Spraying devices: Jets or fast-rotating disks (WEKO) (onto which the liquor falls in droplet form) are used. Main use: resin finishing/finishing. With this application device, products have to be applied to the textile goods simultaneously with dynamic and thermal energy. The use of jets appears to be the most suitable element for fulfilling these requirements. Although the source of the thermal energy can be freely chosen, it is sensible to match the choice of energy form to the subsequent production processes. In a large number of textile finishing processes (an example of which would be continuous pre-treatment), steam is the medium for the thermal energy. The concept of a simultaneously acting application device therefore led to the idea of using steam/chemical liquor mixing jets for spraying the chemical liquor onto a run of textile goods in the steam box (Raco-Yet). Dual-substance mixing jets are well known in engineering, but they are operated exclusively with compressed air.

III. Slop-pad systems: A thin film of the liquor which is to be applied is created on a cylinder with a highly polished surface; this film is then transferred to the goods either via contact, or through an intermedi-

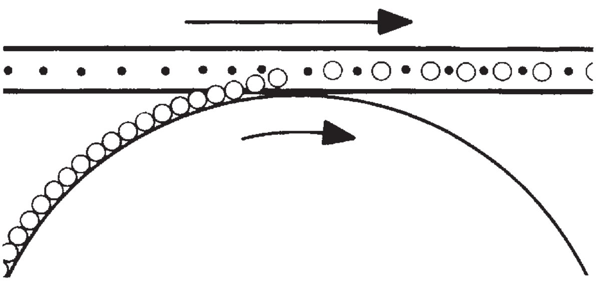

Fig. 2: Low wet pick-up concept.

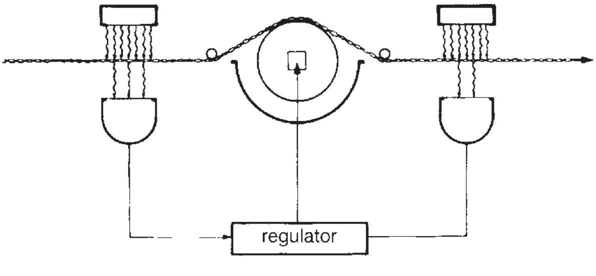

Fig. 3: Closed control loop in the Triatex-MA system.

ate carrier cylinder. Main use: resin finishing/finishing.

The speed ratio of fabric and application roller determines the application amount precisely and reproducibly. This low wet pick-up technology is made possible by a specially developed low wet pick-up plant with measurement and control technology (Fig. 2). The result is a continuously monitored minimum application, which can be set (Fig. 3). The low wet pick-up technique yields the minimum application necessary for capillary saturation without excess liquor. The treatment processes for applying finishing products are concluded by drying.

LP Abbrev. for Low Pressure (steam); → Steam.

LR Abbrev. for → Liquor-to-goods-ratio, in job specifications.

Lr Symbol for the element Lawrencium (103).

Lu Symbol for the element Lutetium (71).

Lubricants These serve to improve the ability of fibres to slide over one another in material processing, e.g. →: Scrooping agents; Sewing thread lubricants; Textile lubricants.

Lubricating felt Felt or leather soaked in oil, for cooling the top blade spirals on → Shearing machines.

Lubrication → Yarn lubrication.

Ludigol treatment Name given to the impregnation of printed goods with Ludigol (BASF), a weak oxidant (m-Nitrobenzol sulphonic acid sodium), which is used in order to render harmless any unwanted coatings on the goods left by printing pastes containing reducing agents. In coloured discharge printing (with vat dyes) on well-dischargeable ground coats, Ludigol can be dispensed with. Working method: usually on printing machines with a finely engraved roller, or by slop-padding of the background (see Fig.). Can take place before or after printing and drying. In flat screen printing, serves to intercept any splashing discharge agent by means of oxidation, and thus avoids unwanted discharge stains.

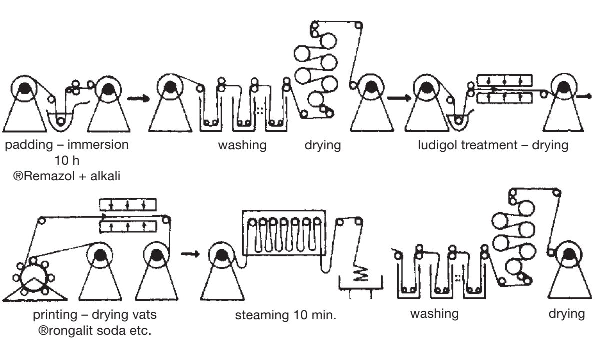

Fig.: Classic discharge-dye articles with impregnation based on ludigol.

Lukewarm, tepid Temperature of 30–35°C; in care instructions, 32–43°C.

Lumen,

I. Unit of → Luminous flux.

II. Cavity in the single-celled cotton fibre, which encloses the dead protoplasms. In turn, it is enclosed by the so-called tertiary, secondary and primary walls in the cotton structure.

Luminescence (Latin): Luminous light emitted by bodies below the normal incandescent temperature, in filtered UV light, with the colour and intensity depending on the chemical composition of the respective substance. Unfiltered, the invisible short-wave rays (→ Light wavelength) are absorbed; filtered, they are converted into visible, longer-wave light (complementary colour). Important use of luminescence in textile finishing through optical brighteners, i.e. products which themselves are non-coloured, but which when activated by the UV also present in daylight are stimulated to blue fluorescence, and thus increase the apparent whiteness. In a stricter sense, we talk of → Fluorescence and → Phosphorescence. The wavelength of the luminescent light is usually the same as or greater than that of the exciting light, but never smaller (Stokes' rule). In concrete terms, a distinction is made according to the origin of different types of luminescence:

I. Photo-luminescence: the luminous effect through absorbed light which is emitted immediately in another wavelength (fluorescence), which yields more or less after-glow after the light source has been switched off (phosphorescence).

II. Chemo-luminescence: the luminous effect caused by chemical reactions, where energy which is released does not convert into heat as it usually does, but directly into light (typical luminescence of phosphorous through air oxidation of the phosphorous vapours). Occurs as bio-luminescence in certain organisms (e.g. glow-worms).

III. Electro-luminescence: where luminous gases are electrically discharged (fluorescent lights).

Luminescence analysis Practical application for the filtered UV light which is produced by UV lamps, qualitative evaluation of any → Luminescence which occurs, whose appearance can vary depending on the chemical composition, through which numerous characteristics are revealed which would escape detection when observed in daylight. Influences which are to be taken into account here: light source, filter, object form (solid, powder, liquid), possible solvent, temperature, reaction, level of purity (constitution), particle size etc. Used for detection or differentiation in numerous textile-chemical investigations, e.g. of fibres, maturity of cotton, fibre damage (over-bleaching or oxycellulose, acid- or alkali damage etc.), dyeing (identity, differences in evenness), impurities or residues of warp glazes, sizing agents, textile lubricants, scrooping agents, numerous oils and greases, stains (mould, fungus, metal soap, oil stains, etc.; detection of blood), etc. The results can be assessed photographically.

Luminescent pigments, radioactive (→ Luminophores). Pigments which are made luminous by added radioactive elements. They are classified into 13 stages of brightness. When processed with binding agents, they form so-called radioactive luminous colours.

Luminophores A group of inorganic and organic substances which yield either → Luminescence (radioactive preparations), → Fluorescence (mostly organic, so-called fluorescent dyes), or → Phosphorescence (mostly inorganic, so-called phosphors).

Luminous colours → Phosphors.

Luminous control panel Orientation image in the control and regulation of automated technological processes. Individual symbols contain signal lamps which signal the operational status of the plant, e.g. with flashing and steady lights, or which with the aid of different colours enable faults to be spotted, together with their causes.

Luminous dyes → Fluorescent dyes.

Luminous flux The derived → SI unit is the lumen (unit symbol: lm).

Lunar caustic → Silver, silver nitrate.

Lustra fabrics (from "lustre"). For these goods, highly lustrous wools or hair are used; besides coarse wools, these include mohair and alpaca. In some cases the warp is of viscose and the weft of more lustrous material.

Lustre in textile finishing When a ray of light falls on a surface, it can be reflected or absorbed, or can pass through the material (Fig. 1). In many cases, these three phenomena occur alongside one another. Since lustre is mainly a surface phenomenon, in general the reflected light is accorded the greatest significance. However, the impression of lustre is often decisively influenced or modified accordingly by the light absorption (colour) and the transparency of the body. Two types of light reflection are distinguished: mirror reflection (complete mirror) and diffuse reflection (Fig. 2).

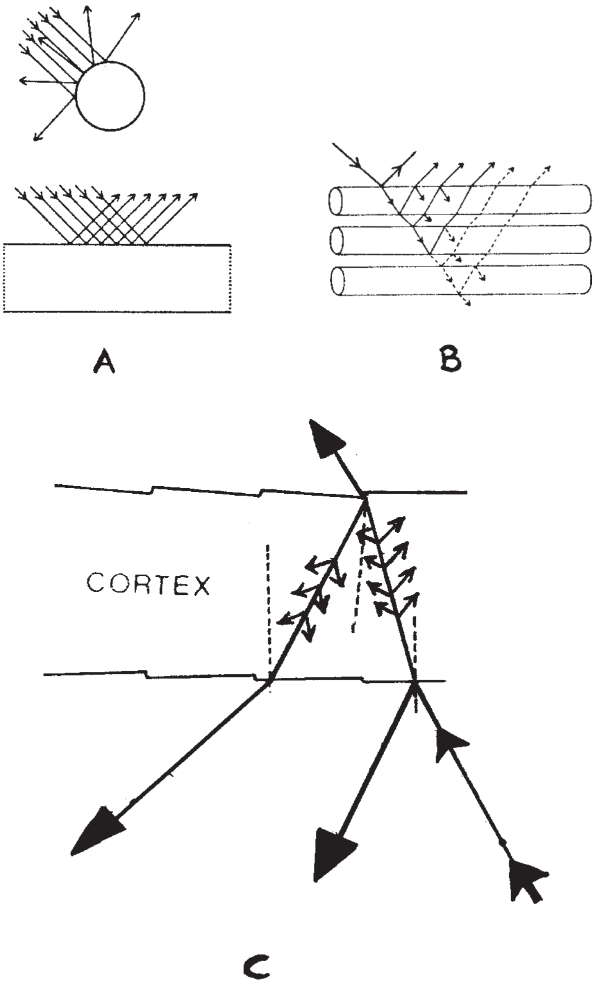

Fig. 1: Reflection (A), refraction (B) and absorption (C) of the impinging light.

The term "lustre" describes a subjectively perceptible optical impression of a surface. Lustre is defined as a "physiological-optical impression of contrast"; a surface is lustrous if its brightness appears to differ at different directions of observation or incident light. On the other hand, a surface is perceived to be matt if it conveys the same impression of brightness from all angles of observation and regardless of the direction of incident light. These optical impressions are based on the fact that in matt surfaces, the individual surface elements which reflect the incident light in a regular manner (which must be small enough not to be detected as an individual surface by the resolution capabilities of the eye) are oriented in such an irregular manner that on the statistical average no direction is preferred. In the case of lustrous surfaces, on the other hand, these surface elements are present in an orderly state. The nature of this order depends on the structure of the surface. In an item of fabric, the degree of order in the surface elements of the fibre material – which reflect the light in a regular manner – is determined by the following features of the fibre or elementary filaments:

- surface condition,
- cross-sectional shape,
- fineness (diameter),
- axial spatial curvature in the yarn and weave relationship.

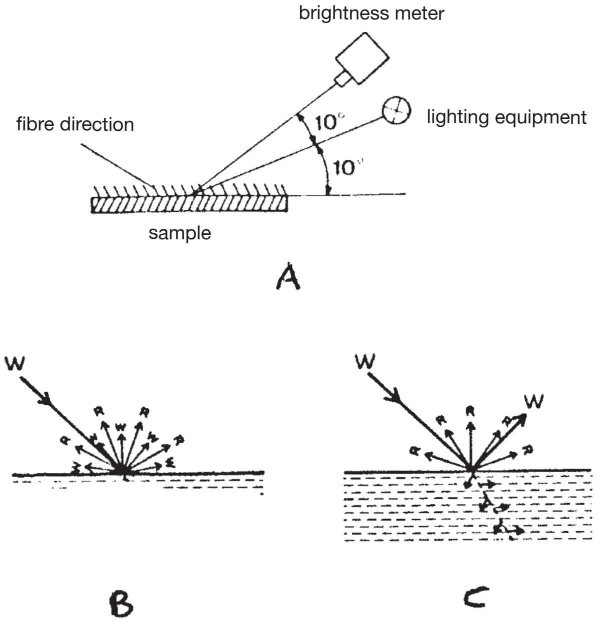

Fig. 2: Mirror reflection (A), diffuse reflection (B) and C: mixture of A and B.

Fibre materials whose surface elements are already of irregular orientation due to the first two features lead to matt fabric (regardless of their fineness and their axial spatial curvature). Fabrics made of fibre materials whose surface elements are present in an ordered state, due to their surface condition or their cross-sectional shape, have less lustre, the higher the fineness (the smaller the diameter) and the stronger the axial spatial curvature of the fibres or elementary filaments; in both cases the degree of ordering of the surface elements is reduced. The first three features are specific to the fibre substance. In the case of chemical fibre substances, these are determined by the spinning process. The axial spatial curvature can be influenced

- by crimping of the fibres, or through texturing of the filament yarns,
- by the yarn twist,
- by the thread- and fabric construction,
- through the formation or reinforcement of fibre ends or loops projecting from the fabric construction, e.g. through brushing or emerising.

These measures reach their limits where, for other reasons e.g. certain fabric constructions are required, smooth filament yarns with low twist have to be used, or the thread- and fabric construction excludes a roughening or emerising process. For fabrics of polyester and polyamide fibre substances, another possibility for reducing lustre, which is due to features specific to fibre substance, consists in equipping the surfaces of the fibres or elementary filaments with a micro-structure. This includes the alkalisation of polyester fabrics and the UV laser radiation of polyester fabrics and polyamide fabrics. In both cases, fibre substance is worn off, and the new surfaces are scarred or have a “hill and valley structure”. Through these methods, a surface condition of the fibre substance is created which is similar to that which natural fibres have, or to that which special polyester fibre substances acquire from the spinning process. Whilst the reinforcement of the axial spatial curvature of the fibres or elementary filaments in the yarn and the weave only indirectly leads to a reduced lustre, with micro-structuring of the fibre surface the actual cause of the lustre is eliminated.

In textile finishing, lustre (also termed sparkling effect) is created with pearlescent pigments as well as with spangles and sequins. Pearlescent pigment diameter 1–100 µm (in textile printing, predominantly 60 µm), spangle and sequin diameter 100–1000 µm. Pearlescent pigments are transparent, thin, plate-like pigments with high refractive indices, smooth surfaces and without any natural colour where possible. As the name suggests, pearlescent pigments are pigments which lend the objects on or in which they are located an appearance which is similar to mother of pearl. Furthermore, pearlescent pigments can be used to achieve effects which lend many objects a more pleasing or attractive and value-adding appearance. The most important pearlescent pigments are natural fish scale, basic lead carbonate, bismuth oxychloride and titanium dioxide mica. Of these, due to their mechanical, chemical and physiological characteristics, only titanium dioxide mica is considered for textile applications. Titanium dioxide mica pearlescent pigments (Fig. 3) are produced by applying a thin layer of titanium dioxide onto mica. The mica particles, with thicknesses of 200–500 nm and diameters of between 3–1500 µm serve as carriers for the titanium dioxide layers, which are around 50–150 nm thick.

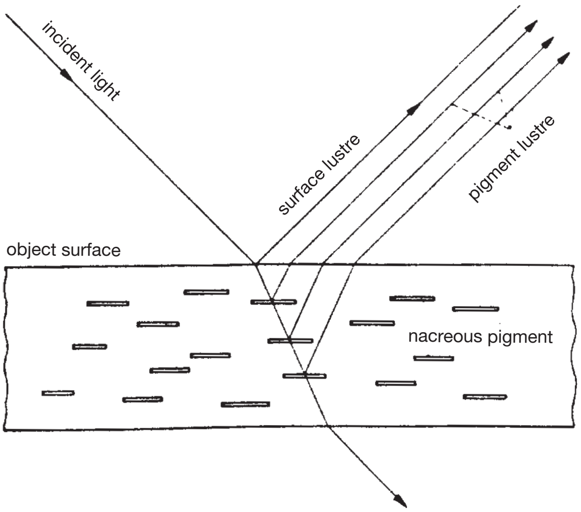

Fig. 3: Schematic diagram of the inter-reflection characteristic of nacreous pigment.

Pearlescent pigments owe their lustre, like the metal-effect pigments, to their lamellar form. However, unlike the latter, they consist of translucent, strongly refractive substances. In the case of parallel orientation, only a proportion of the incident light – which depends on the refractive index – is reflected, whilst the rest is let through and is divided up on further pigment lamellae in the same way. The lustre is said to come from deep down. Titanium dioxide micas are divided up by the manufacturers into areas of differing granulation. This classification runs from silk matt to glitter effects. Titanium dioxide mica pearlescent effects must be resistant to acids and alkalis, as well as to high temperatures and the solvents used in dry cleaning.

For the sake of completeness, bronze print should also be mentioned. Besides the silver-white pearlescent effects which dominate in textile printing, in the efforts to preserve lustre wherever it can be achieved, the so-called interference pearlescent pigments have become established in some print collections. In physical terms, an interference colour is defined as a colour which depends on the thickness and double refraction of a crystal, which arises when light passes through this crystal. Interference phenomena, also known as colours of thin lamellae, occur in the reflection of light on thin, permeable layers such as mica, soap bubbles or oil films. Interference pigments are produced in the same way and from the same raw materials as the corresponding colourless pearlescent pigments, from which they differ only in terms of dimension. The difficulty with their manufacture lies in the fact that all the lamellae must be exactly the same thickness as far as possible; deviations of the mean lamella thickness of just a few nm can be perceived by the naked eye as a colour displacement. Due to their unique physical nature, special effects are possible with interference pigments. In the case of parallel orientation in colourless media, they show complementary colours in the top view and through view, which vary with the angle of observation and lead to changing colour effects. This is particularly effective on goods which have previously been dyed dark. The application of pearlescent pigments in textile printing takes place largely in accordance with the same rules as are known for printing with bronze powder brands.

Glitter printing has been established for some years, particularly in motif printing. Through simple modification, lurex-like effects can be achieved via a whole-surface application; the diversity of the shape and colour of the glitter available opens up a wide colour range. A paste which contains 2–5 grams of polyester glitter and other additives is applied to the whole surface of the textile material, either similarly to a one-sided doctor finish, or by printing. The screen mesh size depends on the fineness of the mica. Work is carried out with a 60 mesh screen on a rotary printing machine. Afterwards, it is dried and fixed for 5 minutes at 150°C dry heat.

Lustre, measurement of Lustre, defined as the reflection of directional or specular rereflection, can be recorded subjectively by means of comparison measurements against normal white, or objectively with a photoelement. The measurement results which are found must not be confused with those of diffuse reflectivity, which is recorded e.g. in the case of coloured surfaces as the degree of remission via colour measurement with devices in the manner of the photoelectric universal colorimeter with reflector insert, or with devices for special technical purposes with simpler reflection measuring devices on a similar principle. In measuring lustre, the illumination should always be precisely at a certain angle (usually 45° in this case, non-standardised) to the surface of the goods to be measured. Colour measurement devices can also be used for measuring lustre. Usual lustre measuring devices are e.g. goniophotometers for static goods, whilst reflection spectrometers or laser scanners are used for measurements on moving goods. For all devices, the method is based on the recording of light energy by a detector. The difference is that in the latter, the goods move in the goods direction, and are thus scanned by the light beam. Through this, the detector detects differing energy values, which are dependent on the reflection; with the graphic or computational evaluation of these, one can draw conclusions about the thread density, surface structure and lustre. The fewer fluctuations the established light energy has, and the higher its intensity, the higher the lustre of the goods. The formula for calculating the lustre L in % is:

$$L = \frac{(Y_H - Y_L) \cdot 100}{Y_L}$$

where

Y_H = reflection maximum,

Y_L = reflection minimum.

The values depend on the device.

Lustring,

I. Constituent part of yarn finishing for the production of yarn with a high lustre and high level of smoothness. Takes place by means of solubilised bleach and waxes, paraffin, etc., as well as mechanical processing, which brings about adhesion of projecting fibre tips to the fibre core; e.g. through dry smoothing under stretching, rubbing, pressing and brushing treatment, between heated pairs of rollers etc. (lustring, glazing, polishing machines).

II. In the lustring of fabrics (pile fabrics), a combination of beating, brushing and waxing serves to achieve a standing, glossy pile.

Lux Unit of → Illumination.

Lyobipolarity If one compares this with the term tenside or surface-active agent, then in the latter the inter-granular activity and the surface tension-lowering characteristics which it can bring about are quite specifically highlighted, whereas the term lyobipolarity expresses the polar dimorphism of the molecule and the associated orientation tendency in the interface. Thus lyobipolarity is the characteristic, generally of higher-molecular chemical compounds, of simultaneously having affinity for two solvent media which cannot be dissolved in one another (e.g. water and inorganic solvents) (hydrophilic and lyophilic), due to their bipolar structure. One consequence is enrichment at interfaces, of which the case of emulsification of both solvent media with one another is an example. Typical examples include dry cleaning detergents, soluble in both organic solvents and water (fibre moisture, dirt/moisture) and enabled - through bipolarity - to form a clear solution with water (→ Solubilising power), which enables the cleaning-promoting activity in the first place. Lyobipolar compounds include e.g. sodium oleate $C_{17}H_{33}COONa$ (soluble to 10 parts in water, to 20 parts in alcohol), sodium dodecyl-benzol-sulphonate etc. On the other hand, we know of lyounipolar compounds which have affinity either only to water (hydrophilic) or only to oil (lyophilic). Lyobipolarity can be weakened or strengthened by the addition of adsorbable molecules.

Lyocell fibre finishing Cellulose is a natural polymer, a resource that can be regenerated at will, with reserves all over the world. The gross annual production of plant cellulose is 26 x 10^6 t, the potential is hundreds of millions of tons. Like natural cellulose fibre, regenerated cellulose fibre has many advantages: good moisture absorption, anti-static properties, good dyeing properties, easily made flame-retardant and produces comfortable clothing. On the other hand, regenerated cellulose fibre such as viscose, which can cause pollution problems in the spinning process, has many disadvantages: it has a lower wet tenacity, the production cycle is longer, etc. Lyocell fibre is a new solvent-spinning cellulose fibre with many advantages: higher tenacity, shorter production cycle and it causes no pollution.

By upgrading the plant capacities for lyocell fibres, which are spun from the solvent NMMO, the prerequisites have been created for the propagation of this novel fibre type. With its characteristic features, such as tendency to fibrillation, high wet tear resistance and environmentally friendly manufacturing process, this fibre is bound to conquer new territory. In particular in the field of highly fashionable garments, high-grade denim articles, underwear and technical textiles, this new fibre type is expected to partly edge out viscose, modal, polynosic and cupro fibres, but also cotton and synthetics. Economical and ecological aspects as well as the limited availability of cotton speak for this innovative fibre type.

If one compares the various regenerated cellulose fibres, one will notice that lyocell fibres differ from other fibres in two essential points (Figs. 1 + 2). Their distinct tendency to fibrillation and their high tear strength make it possible to create new fashionable articles using special process technologies. Due to their high wet tear strength lyocell yarns can, for instance, be used on special rope, slasher and loop dyeing ranges for warp dyeing with indigo.

The active group of amine oxides, which dissolve cellulose, was discovered sixty years ago. Since substances of this kind decompose easily, particularly at raised temperatures, in contact with reducing groups - i.e. with end groups of cellulose for example - or under the influence of metal ions, the former were only able to assert themselves roughly 30 years later when N-Methyl-morpholine-N-oxide, which is considerably more stable, was discovered. Now known as NMMO, the product haunts scientific journals (Fig. 3). Up until a few years ago, it was not possible to obtain NMMO in the quantities required for industry since no alternatve industrial application was known until then. The high costs of the solvent, for the reason just named, demanded the development of an almost closed circuit process. This can, however, only be accomplished when the manufacture of the solvent in particular is designed so as to prevent thermal decomposition of the NMMO apart from stabilising and recovery technologies.

Amine oxides are not new substances. They are practically ubiquitous, which means that they, for example, make up a considerable washing-active part of personal hygiene products which normally undergo intensive dermatological and toxicological examinations. It should, therefore, be possible to deduce toxicological

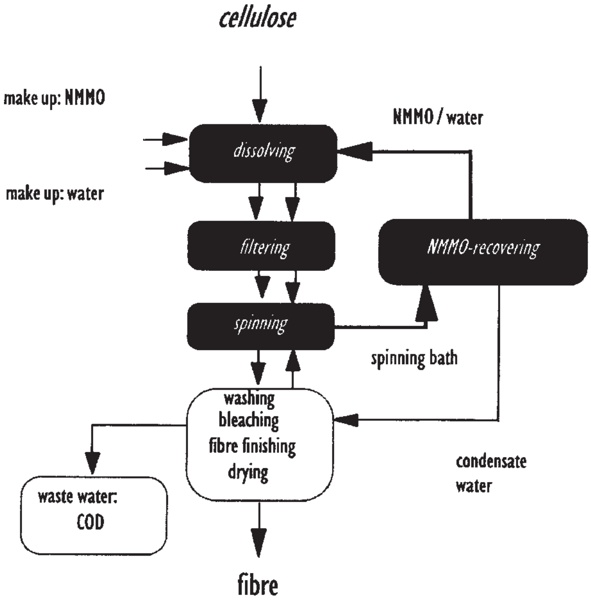

Fig. 3: NMMO.

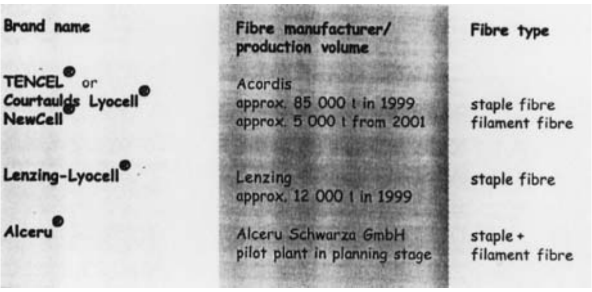
safeness for industrial applications. Toxicological examinations were of course also carried out on NMMO itself. In the five examinations on hand carried out on various living organisms in the food chain, i.e. on rats - representing mammals - fish, small crayfish (Daphnia), algae and bacteria, it was apparent that NMMO is less toxic than ethanol. The discovery that the mutagenesis test according to AMES was negative was also of great significance since NMMO is considered toxicologically and clinically harmless.

The extremely high amount of water required for cotton immediately catches the eye. Compared to cotton, lyocell reveals lower consumption factors, and requires only half the amount of chemicals, which are not nearly as environmentally harmful, since cotton, for example, requires a share of those chemicals to protect it from pests - environmentally harmful and health-hazardous chemicals such as pesticides, insecticides and fertilisers are still necessary - which makes it necessary to test cotton prior to its use. Lyocell easily complies with the Eco-Tex 100 Standard.

During the preparation of the spinning solution and the spinning process, although lyocell fibre may come into contact with amine oxide, the crystal type of lyocell fibre still belongs to cellulose II, like viscose staple and viscose filament. The molecular weight distribution of lyocell fibre is narrower and the average molecular weight of lyocell fibre is larger than that of viscose fibre. Moreover, the microcosmic stucture of lyocell fibre is more compact and the degree of orientation is also larger than that of the common viscose fibre.

According to BISFA the generic name for these fibres is lyocell (symbol: CLY). This term comprises all cellulosic fibres spun from an organic solvent. Fig. 4 gives a survey of the various brands and manufacturers. In the clothing sector, the fibre is mainly available at a fineness of 1.3 or 1.7 decitex and as wool type at 3.3 decitex. Lyocell microfibres of around 0.9 decitex are in the trial stage. The worldwide production capacity of approx. 110 000 tons per year is expected to be achieved in 1999. In the group of regenerated cellulosic fibres, lyocell already ranks second after viscose and before cupro, modal and polynosic fibres.



Brand name	Fibre manufacturer/ production volume	Fibre type
TENCEL® or Courtaulds Lyocell® NewCell®	Acordis approx. 85 000 t in 1999 approx. 5 000 t from 2001	staple fibre filament fibre
Lenzing-Lyocell®	Lenzing approx. 12 000 t in 1999	staple fibre
Alceru®	Alceru Schwarza GmbH pilot plant in planning stage	staple + filament fibre

Fig. 4: Market survey.

Lyocell fibre finishing

There are two ways of processing lyocell that have asserted themselves in the market: About 40% of the fibre is processed conventionally in piece or hank form; the majority is, however, processed as made-up garments. Scarcely any other fibre imposes comparable requirements on process technology and textile chemical/finishing know-how on the way from the fibre to the ready-for-sale textile. With this fibre in particular, it is essential to realise that not only the finisher is responsible for a successful finish, but all those that are involved in the production of the textile. For this reason (Fig. 5), all members of the textile chain, from the fibre producer, spinner, weaver or knitter, finisher, machine constructor, dyestuff and auxiliary supplier, right through to the maker-up and garment washer, are dependent on close cooperation. Since the characteristics of a lyocell product are decisively determined by the yarn and fabric construction, standard processing routes or recipes can only be a guideline for the optimum process in each case.

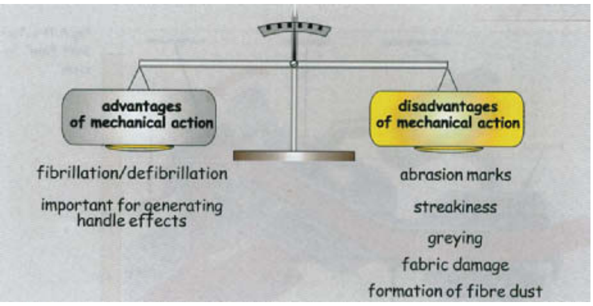


Fig. 5: Lyocell fibre advantages and disadvantages of mechanical action.

The two decisive machine-related factors that determine the possibilities and limits of a lyocell finish are mechanical energy input and a smooth running of the goods. Free movement of the goods is essential for a uniform fibrillation and largely depends on the machinery used. Due to the high swelling of the fibres (Fig. 7) the spaces between the fibres, especially when woven, are reduced and the textile becomes less flexible. Smooth running of the textile becomes more difficult. With rising square metre weight, the risk of abrasion marks and running creases grows. This undesired side effect can be controlled by blending lyocell with synthetic fibres, such as polyester or polyamide, that do not or only slightly swell. For 100% lyocell fabrics an open-width alkaline treatment is recommended.

Lyocell fibres differ in structure and several textile properties from conventional viscose fibres. The high fibrillation tendency, which is shown in wet state in mechanical stress, is characteristic of lyocell. This phenomenon is used to give textiles interesting surface effects. The fibrillation reduction can be realised by cross-linking the cellulose chains. In textile finishing mainly reactant cross-linking agents with low formaldehyde are used. The improved wet abrasion behaviour and the reduced wash greying of the lyocell textiles

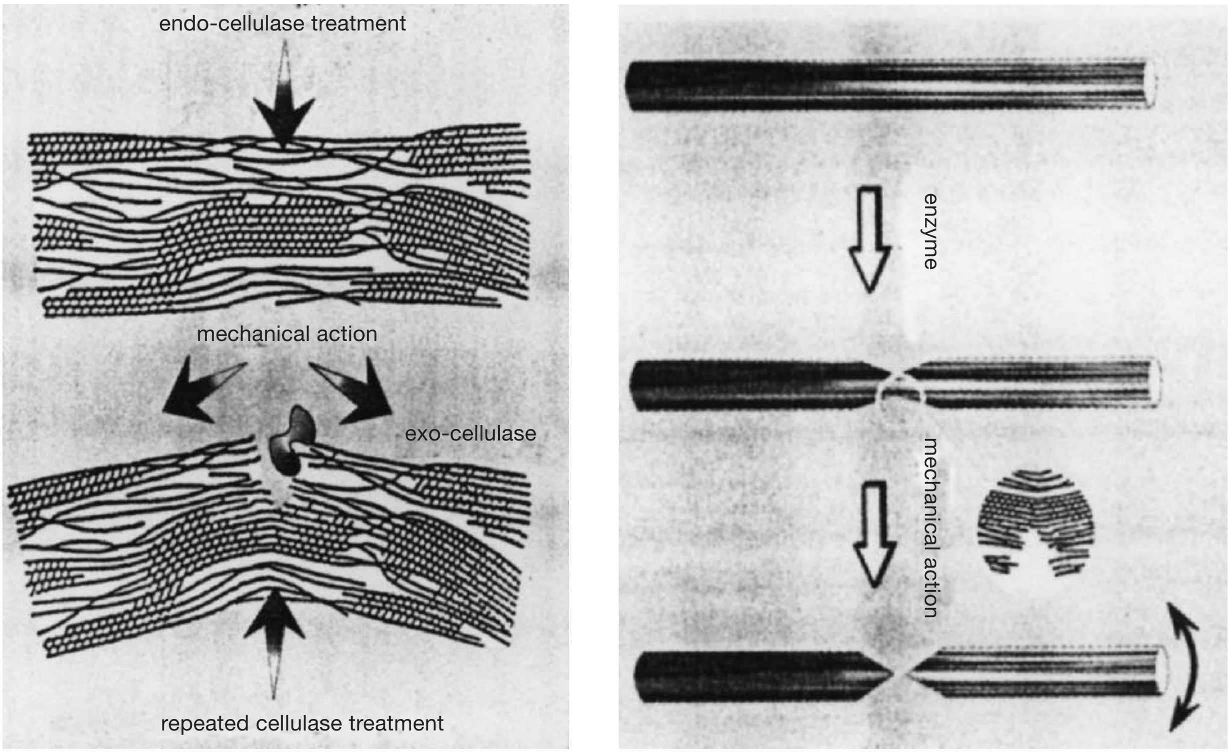

Fig. 6: Fibrillation mechanism.

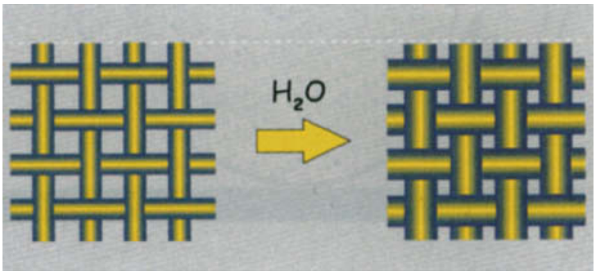

Fig. 7: Fibre swelling.

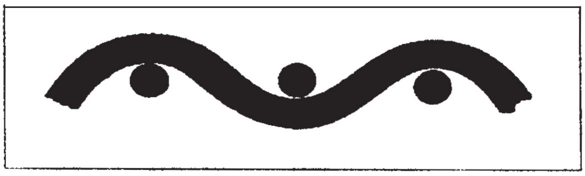
prove the positive influence of cross-linkers on the fibrillation behaviour. As resin finishing is not always desired, alternative cross-linker systems had to be investigated. One possibilty are the multifunctional reactive dyestuffs. High fixation yields and excellent colour fastness are reached by using these modern dyestuffs. The existence of more than one reactive group in the dyestuff molecule is a prerequisite to make cross-linkages between cellulosic hydroxyl groups possible.

To get an objective assessment of the fibrillation of lyocell fabrics a modified wet abrasion test, according to Martindale, is suitable. This method includes the chafing of the wet fabric until holes are visible. The fibrillation tendency of lyocell fibres can be influenced by dyeing with multifunctional reactive dyestuffs, but not all bi- and polyfunctional reactive dyestuffs cause the same effect. The constitution of the dyestuff molecule and the application conditions also influence the wet abrasion resistance. Different reactive dyestuffs applied in the same initial concentration do not give the same results concerning wet fibrillation. Surprisingly there are even differences between two monofunctional dyestuffs. The higher wet fibrillation resistance using Reactive Red 158 is explainable by the bireactivity of the difluorodichloropyrimidine group. This group not only makes it possible to create covalent bindings, it possibly causes the creation of hydrogen bridges, which again might be the reason to make cross-linking feasible. Similar effects have been found by resin finishing with so-called self cross-linking agents. Just a minimum increase of the wet fibrillation resistance is reached using Reactive Blue 211. The reason is probably the relatively rigid arrangement of the two MCT-groups in the centre of the dyestuff molecules, which in the first place just leads to a one-sided fixation of the dyestuff. Compared to Reactive Blue 211 the symmetric and the lateral arrangement of the two VS-groups on the chromophore of Reactive Black 5 improves considerably the wet fibrillation behaviour. This is also valid for the bifunctional Reactive Blue 225 and the trifunctional Reactive Red 228. The hetero-bifunctional dyestuffs Reactive Red 198 and Blue 235 fit into a medium wet abrasion level.

Until now nothing was known about the changes of the wrinkle behaviour of lyocell fabrics by applying multifunctional reactive dyestuffs. The cross-linking reactivity of several dyestuffs gives reason to expect results even here. Even though the dry wrinkle recovery angle does not change much, the wet recovery angle depending on the dyestuff has increases between 24° and 52°. An exception is the dyestuff Reactive Blue 19. Having just one-functional binding, it causes only small changes of the wet wrinkle recovery behaviour of the lyocell fabric. The difference between the dry and wet wrinkle behaviour of reactive dyed fabrics is connected with the swelling state of the fibre during the cross-linking reaction. The fibres are swollen during dyeing. The incorporation of dyestuff cross-linking bridges in the wet state causes the self-flattening of the lyocell fabric only if the fabric itself is wet. The dry state of the fabric has hardly any effects because the cross-linking bridges are not tightly tensed any more. In

a) raw fabric – without fibrillation/hairiness



b) raw fabric – with yarn fibrillation

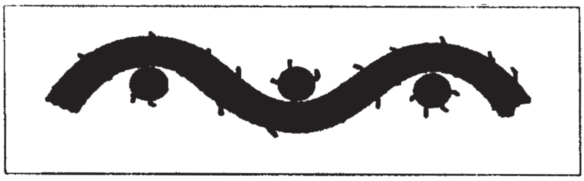
d) fabric after cellulase treatment



e) secondary fibrillation (“Peach Skin” effect)

Fig. 8: Fibrillation mechanism.

cross-linking lyocell fabrics with reactive dyestuffs, a connection is found between wet abrasion resistance and wrinkle recovery behaviour.

Today's society expects both a good wash-and-wear behaviour and good wet and dry wrinkle recovery. Therefore the effects of the combination between reactive dyeing and resin finishing are important. Dyeing was carried out with a monofunctional and a bifunctional dyestuff. During the following dry cross-linking process the reactant cross-linking agent Fixapret ECO (BASF), containing low formaldehyde, was used. Wet fibrillation tests of the treated fabrics should give answers to the fibrillation behaviour. The fabrics which were only dyed confirmed experiences that the monofunctional dyestuff does not increase the wet fibrillation tendency. Only the following reactant resin finishing process causes a higher wet fibrillation level, depending on the amount of cross-linking agent used. The bifunctional dyeing process shows a definite dependence of the wet fibrillation resistance on the dyestuff concentration. These wet abrasion values are altogether on a higher level than with the monofunctional dyestuff. Using 40 g/l Fixapret ECO in a 2%-dyeing, wet abrasion values of more than 1000 are reached, which is at the same level as non-finished viscose fabrics and thus should not show any fibrillation problems. Similar to the wet abrasion behaviour the monofunctional reactive dyestuff influences wet wrinkle recovery angles to a smaller extent than the bifunctional dyestuff. Neither the monofunctional nor the bifunctional dyestuff improves the dry wrinkle recovery angle. By additional cross-linking with Fixapret ECO, 40 g/l cross-linker causes an average increase of the wet wrinkle recovery angles by 50° and the dry wrinkle recovery angles by 30°, compared to the raw fabric.

Besides the reactive dyestuffs, colourless textile auxiliaries exist, which possess reactive groups and are able to react with hydroxyl groups of cellulose. Examples of these are Sandospace R paste, which is a reserving agent of Clariant, and the test product AE 4425 (Ciba Spezialitätenchemie), which was developed for a controlled fibrillation of lyocell. Out of many tested Clariant products Sandospace R paste is a favourable product in the exhaust procedure concerning the increase of the wet abrasion resistance of the lyocell fabrics. Both with Sandospace R and with AE 4425 the results of the wet abrasion resistance of the lyocell fabrics are increased by using comparable amounts of pure substances depending on the concentration. With parallel tests with lyocell fibres treated the same way deficiencies in the textile features occurred, which is why the initial concentration should be under 6% related to a 100% pure cross-linking agent. The wrinkle behaviour of lyocell fabrics finished with the two products shows similarities with the bireactive dyed fabrics. This also seems to indicate that there is a cross-linking reaction.

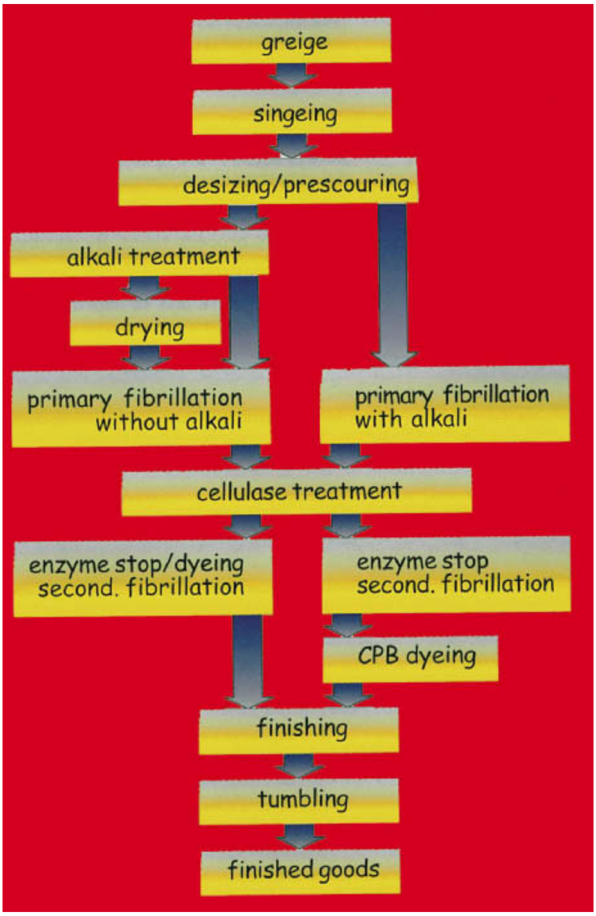


Fig. 9: Example: Combined open-width/rope treatment.

The swollen state of the fibre in the cross-linking reaction step is the reason for the large increase of the wet wrinkle recovery and for the fact that the dry wrinkle recovery angle does not change much.

A typical example for production of a peach skin effect on woven fabric contains the following finishing route (Fig. 9). After singeing and desizing in open-width, the fabric is treated open-width with alkali. The fibre swells substantially at this stage. Even when the alkali has been washed off, the fibre remains slightly swollen. This has a positive effect on subsequent wet finishing processes because it makes the goods more flexible and thus improves running properties. The risk of permanent crease marks is lower than if initial swelling occurs during treatment in rope form. During subsequent primary fibrillation, any fibrils that are not fully bonded are brought to the surface of the fabric. Primary fibrillation should preferably take place in an aerodynamic jet (Fig. 10), as this ensures uniform fibrillation. Since lyocell fabrics are prone to wet rigidity, temperatures < 60°C should generally be avoided and a suitable crease inhibitor should be added to all baths. This also minimises the risk of crease marks. If fibrillation is not uniform, there is a risk of streaks that cannot be levelled

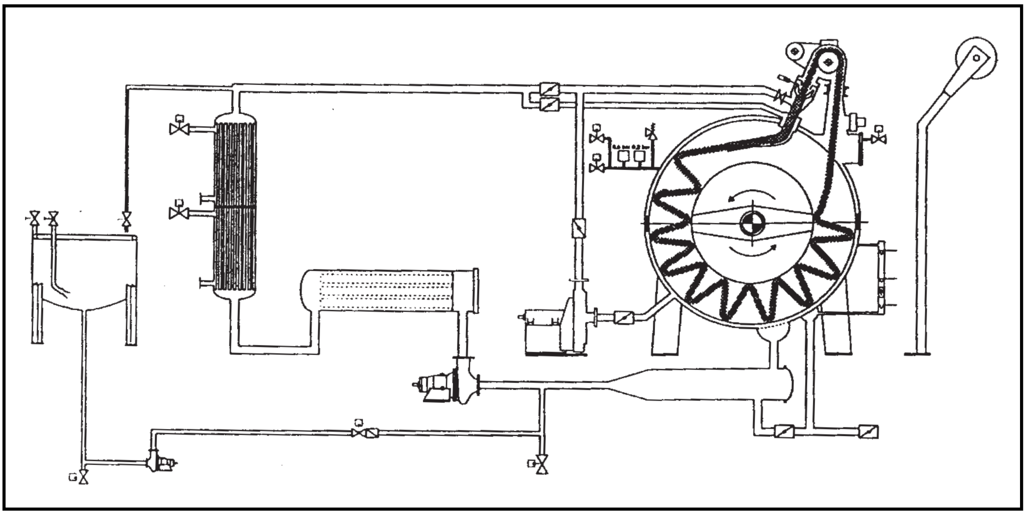

Fig. 10: Air-roto.

out at subsequent treatment stages. The linty fibrils loosened during primary fibrillation (Fig. 8) are then decomposed by cellulase during subsequent enzymatic defibrillation. The enzyme activity (Fig. 6) is stopped by raising the temperature and/or adding alkali.

Exhaust dyeings should preferably be carried out on aerodynamic jets. Secondary fibrillation occurs at this stage, creating a pile comprising short, extremely fine fibrils. Migration processes (80 (–90)°C → 60°C) improve levelness and trigger secondary fibrillation because elevated temperatures are used. Alternatively, the fabric can be dyed open-width using the cold pad-batch process. In this case, secondary fibrillation cannot take place during dyeing because the fabric is not exposed to any mechanical forces. To create peach-skin effects, secondary fibrillation can be carried out either before or after cold pad-batch dyeing.

High concentrations of some dyestuff chromophores with bi- or multifunctional reactive groups (e.g. Reactive Black 5) may impair fibrillation or cause cross-linking. In such cases, it is advisable to carry out secondary fibrillation before dyeing (e.g. during the enzyme stop process). Tumble-drying raises the fibrils and thus creates the desired peach-skin effect. To prevent continued fibrillation, frosting and formation of crease marks in domestic laundering, a resin finish should be applied. This is the only way to ensure that the handle and appearance of the goods is retained after repeated domestic laundering cycles.

Lyogel Fluid-rich → Gel of the jelly type. Opposite: → Xerogel.

Lyophilic Prevailing tendency, in a substance which is distributed in a liquid medium, towards endophilia. Solvent-affinity, solvent-attracting characteristic (similar to → Hydrophilic property). One also speaks of “lyophilic groups” in connection with textile auxiliaries. Opposite: → Lyophobic.

Lyophilic groups Molecular group which behaves in an → Endophilic manner in relation to a liquid phase.

Lyophobic Prevailing tendency, in a substance which is distributed in a liquid medium, towards exophilia. Solvent-fleeing, anti-solvent, solvent-repelling characteristic (similar to → Hydrophobic). Opposite: → Lyophilic.

Lyophobic groups Molecular group which behaves in an → Exophilic manner in relation to a liquid phase.

Lyopolarity → Lyobipolarity.

Lyotropic (Gk.) Phenomenon in which the solubility of a substance which is hard to dissolve in a solvent is increased by the addition of a third substance. This third substance is termed a “lyotropic agent”. Relates to characteristics of the coagulation of lyophilic colloids. Here, the flocculation power of salts depends on their attraction to solvents.

Lyounipolarity → Lyobipolarity.

Lysalbinic acid/protalbinic acid → Polypeptides with 6–10 peptide groups (molecules of lower → Amino acids) which have arisen through the alkaline decomposition (hydrolysis) of protein substances (leather waste, albumin, fish meal, etc.), and with an estimated molecular weight of around 450–800. Conventionally used term, but not strictly defined compounds of water-soluble protein decomposition products. They are of an amphoteric nature, belong to the group of surface-active protective colloids, and often serve to protect the fibre, as a levelling agent etc., especially for wool. Such products represent alkaline salts (lysalbinates, protalbinates) and contain further additives, e.g. oil sulphonates, fatty alcohol sulphates, etc.

-lysis (Gk.: lysis) Relates to the structural loosening, decomposition, splitting of a bond through e.g. → Hydrolysis, → Sulphitolysis.

M

M, symbol for → Mega (times a million); factor 10^6.

m,

I. Symbol for → Milli- (thousandth); factor 10^{-3}.

II. Symbol for → Metre, 1 m = 100 cm = 1000 mm.

μ, symbol for → Micro- (millionth); factor 10^{-6}.

m- → Meta-.

MA,

I. → Modacrylic fibres, symbol according to the → EDP key system → MAC.

II. → Low wet pick-up.

Ma → Manila fibre, → Textile fibre symbols, according to DIN 60 001 until 1988, from 1991 → AB.

ma, symbol for → Myria (ten thousand times), factor 10^4.

MAC → Modacrylic fibres, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

MacAdam unit → Colour difference formulae.

Mace Snag Tester Testing device for checking the formation of snags in chain hosiery. Four rotating (60 rpm) aluminium cylinders are assigned to the samples. A sphere supplied with mandrels hangs loosely above each cylinder, whereby several mandrels are supported by the sample. The snags are pulled by rotating the cylinders. After 10 minutes of rotating the samples are compared under stipulated conditions using standard photos. Marking: 5 = no snags, 1 = considerable formation of snags. Samples are tested in longitudinal and transverse directions. For knitwear → Snagging Box (ICI).

Mach nozzle, Narrow slotted nozzle (0.025 mm), from which steam (5–7 bar) is blown right across the fabric width at a great flow velocity (ca. 450 m/s) to drain up to 25% of the residual moisture content. The steam thereby carries along a large part of the adhering water and is deposited in a special-purpose condenser (re-use of condensation). Substantial energy cost reduction. → Water extraction throughflow method.

Machine elements Machines alleviate and/or replace human labour. They increase the operating productivity and improve the quality of products. All machines consist of the same machine elements, which can be assembled into units depending on the function of the machine. Subdivisions are made between:

- unit for power production,
- unit for transmission of forces and movements,
- unit for the processing of a tool.

Machine elements include the machine parts which reappear in the building of all machines and so form the basic components of machines or driving gears. Three main focuses are purposely selected according to the areas of application:

- machine elements to connect machine parts,
- machine elements to transmit rotary motions,
- machine elements to convert movements.

Machine parts can be connected in a detachable or permanent way using machine elements.

a) Detachable connections: screws, pins, splines, featherkeys and bolts.

b) Permanent connections:
  - rivets: solid, dense and fixed connections, e.g. made of two steel plates through a compressed riveted shaft with riveted tops;
  - soldering: bonding of two metals using a molten, light, metallic solder, which flows into the “solder gap” and ingresses into the basic materials and so creates a connection;
  - welding: the combining of metal materials using the application of heat or pressure or both with and without adding materials of the same type is called welding according to DIN 1910. Similar or different types of thermoplastic materials can also be welded to these bonds;
  - adhesives: using adhesives different or similar materials are firmly bonded together with adhesive resins or double component adhesives (adhesive and hardening agent);
  - shrinking: materials are expanded using heat; they contract when cold. Shrinkage bonds are produced from these properties. Materials are intensely heated, pushed onto other materials and sit tightly after cooling down.

Machine-hour costs The costs relating to the normal annual number of hours, during which the one relevant machine (system) is in operation. Purpose: economic composition calculation for possible replacements as well as basis for prime cost calculation. Machine-hour costs consist of business loans for machine operation; the operating materials required for machines (power, light, etc.); repairs, insurance premiums, contribution of taxes, interest, write-offs, salaries, heating, public levies and costs of company's welfare facilities.

Machine-made carpets Machine produced carpets, in the narrower sense, term for machine woven or knotted carpets.

Machine time Component of → Useful life of working.

Machine utilisation planning The optimum sequences for given quality assessment (minimum throughput time as well) are determined from the technically possible sequences using the means of → Operational planning of individual finishing processes. → Processing sequence in textile finishing.

Machine-washable wool Woollen items, mostly knitted fabric, which are washable in domestic washing machines with a care cycle (ca. 40°C) according to particular → Antifelting finish without damaging the appearance of the fabric, handle or wearing characteristics. Antifelt finishing is generally carried out in the combed top. IWS standards for machine washable items (→ Superwash).

The washability of wool is increasingly important; the more easy-care wear properties are disappearing and chemical cleaning is problematic for ecological reasons. The antifelting finish of wool using chlorine or chlorine compounds will still only be feasible in a limited way using the legal AOX limit. This situation encouraged the development of new replacement products and for available ones to be revised, which produces improved effects and safer processes. Nevertheless →Antifelting finish remains technically superior and demands particular know-how, adaptation to customers' wishes, to wool material and available machines. New finishings for machine-washable wool items are (besides plasma) based on:

- peroxy-monosulphates,
- polymers such as polyethers, polysiloxanes, amongst others,
- and poly-quaternary compounds.

Machine-woven carpets Machine woven textile floor coverings. →: Pile wire; Double plush; Reversible; Axminster carpets.

Mackey test is used to test grease, which is based on heat accumulation from autoxidation (→ Oxidation of oils), for self-combustion. A previously scoured piece of cotton wool is impregnated with the oil or grease to be tested and exposed (in the Mackey device) to a temperature of 100°C (short test – test period up to 3 h) or 75°C (long test up to 48 h), in which the cotton wool temperature is checked. The latter rises very quickly for an oil with multiple unsaturated fatty acids through spontaneous oxidation. A non-combustible grease product withstands the Mackey test at 100°C (tolerance ±5°C).

Maco cotton (Maco), reddish/brownish/yellow, first-rate Egyptian cotton; very fine, longitudinally stapled fibres, uniform spun yarns.

Maco cotton test As a result of higher prices for genuine maco cotton there is interest in test methods for cheaper imitations. Such methods can be created using simple steaming or direct sulphur or iron buff coloration. Tests:

I. Staple length.

II. Boil sample with thinned nitric acid: real maco turns yellow; reddish tone disappears. If the colour shade becomes considerably, deeper however, simple steaming was carried out.

III. Effect of concentrated sulphuric acid: chromatic shades of colour are produced with direct dyeing.

IV. Boiling with tin salt and hydrochloric acid: decolorizing with sulphur dyeing. If you hold lead acetate paper over the reagent glass opening when boiling, dark brown/black dyeing appears with sulphur dyeing.

V. With potassium hexacyanoferrat(II) and hydrochloric acid: blue coloration with iron buff dyeing.

Macramé Precursor of pillow lace. Threads are elaborately knotted by hand from the warp threads which stick out of carpets. Can be used as a needlework technique with typical varied knottings, e.g. for flower garlands. The name has degenerated into coarse etched points worked on as a curtain base.

Macro- (Gk.: makrós = large), prefix with the meaning "long", "large".

Macroemulsions → Coalescence.

Macrofibrils Designation for cell units of the fibrillar type in → Wool structure, e.g. firstly in the sense of spindle cells and secondly where there is no direct connection with the actual fibrils (bundles). Integrated process of sulphur-rich keratin proteins, which show a variable affinity for heavy metals after reduction. Macrofibrils in intermacrofibrillar material are a biological unit in keratin fibrils.

Macromolecular bundle → Micelles.

Macromolecules Expression for polymers (coined by Staudinger), high molecular so-called "gigantic molecules" made of at least several hundred atoms with molecular weight > 10 000. Structure made of → Monomers, either thickly knotted or cross-linked (starch, aminoplasts, phenolic plastics) or more or less longitudinally stretched → Chain molecules (→ Polymers) as in cellulose, polypeptides, etc. Classification into a) natural macromolecules (e.g. starch; cellulose; pectins; caoutchouc; proteins; enzymes); b) converted (regenerated) natural macromolecules (e.g. viscose; vulcanized caoutchouc; leather) and c) synthetic macromolecules (e.g. polymerization-, polycondensation-, polyaddition products). Special natural macromolecules are mostly mixtures of macromolecules similar in construction, but different in size.

Macropolymers → High polymers.

Macroporous films The creation of these structures is possible by removing water-soluble fillers from a polymer matrix. Aqueous polyurethane dispersions have proven suitable. Films, which have a macroporous structure after substrates have been removed, can be produced through the deposit of salts amongst other substances, such as starch. As the polymer does not have any specific interactions with substances, which are deposited in the pores, it should be possible for water not only to be deposited in place of other substances, but also emitted again.

A microporous finishing of textiles is used to improve wearing comfort, as air and water vapour get through such textiles. Comparable effects, such as water vapour transmission, should not be expected from a macroporous finishing. There are also principle differences in polymers, which are in a position to absorb large quantites of water. Hydrogels or super absorbers do enable a multiple of their own weight to bind to water, but this does not become free again with mechanical stresses. Corresponding products are used in hygienic items and in the technology sector (according to Schollmeyer).

Macroscopic Visible with naked (so-called unarmed) eye; e.g. small individual fibres of a yarn, whose surface structure is however → Microscopic.

Madder (Turkey red), fiery red → Natural dyes (a mordant dye). Origin: ground root of the shrub-type madder plant (Orient, Mediterranean area, America). Effective component: alizarin (dioxyanthrachinon) from the Middle East. Lizari (alizari) and purpurin. Mordant dye for wool and cotton. Total fastness even surpasses indigo. Was already mentioned in the Bible (Egypt, Persia and India). Had its heyday during the 17th century.

Made-to-measure polymers It is possible to construct polymer molecules chemically using their chemical structure so that they are either extremely flexible and form irregular balls in melting or else are even in liquid crystal form even before solidifying into stiff rods in a strictly parallel packing. Two routes can be taken in order to approach these parallel molecular packings. In the first case one starts with existing polymers and develops specialised processing techniques, which force a parallelisation of the molecular chains. With polyester sheets, for example, a tear resistance is achieved increased by more than double using a threefold drawing (longitudinal/transverse/longitudinal). By gel spinning, manufactured polyethylene threads have a resistance close to the theoretical maximum value through parallelisation of the macromolecules. It is a multiple higher than for polyethylene threads produced in the normal way. In the second case, polymers have been sought, in which the chemical structure already produces a high stiffness in the macromolecules. This is the prerequisite for the individual macromolecules already being found voluntarily in a parallel arrangement in the molten state in microscopic dimensions, i.e. subjecting itself to self-organisation. This state of preferential orientation is expanded to macroscopic dimensions by the following processing step. The liquid crystal polyester Vectra from Hoechst Celanese (Fig. 1) displays such behaviour, for example.

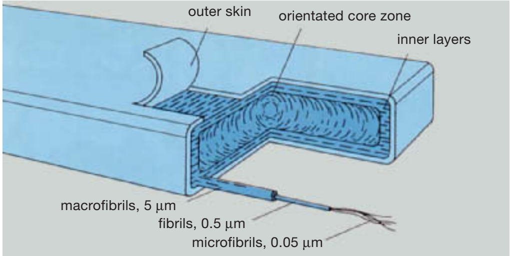

Fig. 1: Injection moulding from the liquid polymer Vectra.

The material spectrum of made-to-measure polymers ranges from polyethylene with flexible tangled molecules to polymers with noticeably restricted flexibility (polyester on polyethylene terephthalate base) and also the stiff-chained liquid crystal polyesters (LCP) or even to the extremely rigid structures of carbon polymers, which include, for example, carbon fibres, carbon glass and carbon-fibre-reinforced compos-

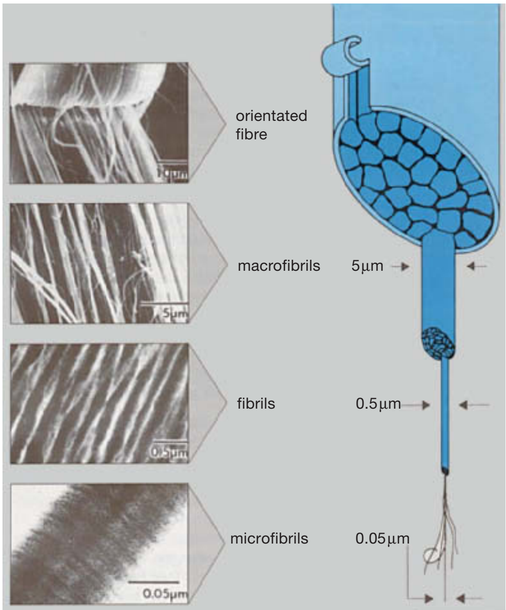

Fig. 2: Structure model of the liquid crystalline polymer Vectra (Hoechst).

ites (CFC). The resistance of the polymers to heat increases in parallel to the stiffness of the molecules.

The liquid crystal polymer Vectra from Hoechst Celanese (Fig. 2) is an example of one of the polymers, which are stable at high temperatures and fulfil high mechanical requirements. Liquid crystal polymers are a class of self-boosting high performance materials. They spontaneously assume an extremely complicated morphology when die-casting. The high resistance to heat of more than 240°C, chemical resistance as well as being flame retardant and electric strength allow the use of Vectra in electronics and space travel or even as a benzine supply lead in a car engine (according to Hoechst).

MAE → MacAdam unit.

Magazine screen printing machine Magazine screen printing machines were the first step towards full mechanization of screen printing. The development started from the fact that a machine with the smallest space required was requested for reasons of space. The printing table is only large enough to enable printing of a report and is equipped with moveable back grey printing in the form of an endless ribbon. The printing screens in question are accommodated in magazines of different design. A distinction is made between staple magazines and magazine screens. So-called “Carousel suspension” and “Serial magazines” are recognized in magazine screen design.

Magnesium Mg; atomic weight 24.36. Shiny, silvery white metal of low density. In air, an outer layer of almost transparent carbonate forms; with boiling water there is formation of magnesium oxide and hydrogen. When lit magnesium oxide is produced (formation of a very intensive white light). The magnesium cation (such as alkali and earth alkali ions) forms colourless salts with colourless anions. Magnesium chloride is water-soluble (even easily soluble in waterless alcohol); magnesium bromide, iodide, nitrate and sulphate are also water-soluble. Magnesium hydroxide is insoluble. Magnesium carbonate and phosphate are not easily dissoluble. Ammonium salts increase the water solubility of salts which are not easily dissoluble or are non-soluble. Application: powder or strip for the purposes of illumination; “lightning powder” (mixture of 1 part magnesium and 2 parts potassium chlorate), drying of alcohols.

Magnesium chloride (chlorinated magnesium), $MgCl_2 \cdot 6\,H_2O$; molecular weight 203. Melted and in crystals, very hygroscopic, water-soluble. Application: finishing additions (hygroscopes, binders and hardening agents), etc.

Magnesium hardness (MgH), unit per °d of magnesium oxide (MgO) 7.15 mg/l water. → Water hardness salts.

Magnesium silicate Agent for stabilising and controlling the oxygen output in bleaching agents; slightly alkaline to neutral, resistant to temperature and alkalines.

Magnesium soap Formation of similar → Lime soap, caused by water hardening salts.

Magnesium sulphate (epsom salt, sulphuric acid magnesium), $MgSO_4 \cdot 7\,H_2O$; molecular weight 246; density 1.68. Colourless crystals, often impure, resistant to damp air, weathered in dry air, water-soluble. Application: finishing addition (hardening and sealing agent in particular for cotton goods) in flame-retardant impregnation.

Magnetic-particle coupling or brake is in principle structured as an electromagnetic friction coupling or brake (Fig. 1). For torque transmission and/or braking, a friction-ended compound is produced between the radially arranged primary and secondary assembly. A special magnetic particle, which is in the system-dependant low radial air gap between the primary and secondary assembly, is used for this. These two assemblies are stored independently from each other. The outer assembly is also a field spool (magnetic part) and can be electrically switched using direct current via sliprings or fixed connections. Tapped holes fitted laterally on the magnetic part and the hole executed with the keyway on the secondary assembly facilitate a simple adaptation (magnetic flux in Fig. 2). The power is supplied to the couplings via axially contacting sliprings.

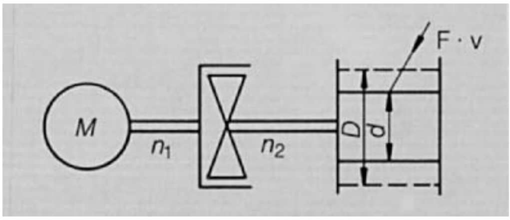

Fig. 1: Winding, unwinding, acceleration and braking of centrifugal masses.
v = discharge speed; D = max. diameter; d = minimum diameter; F = discharge force; M = motor torque; n_1 and n_2 = speeds, which the magnetic particle coupling matches to one another, i.e. equalizes.

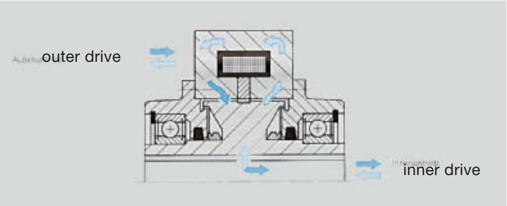

Fig. 2: Flow of forces in the magnetic particle coupling by Lenze.

The brakes are electrically connected to a flat reed connector installed on the end of the primary part. In cases where a magnetic-particle coupling is to be used as a safety or dry-fluid coupling, layout in accordance with the required torque is generally sufficient. A check of the performable quantity of heat must be carried out if there are frequent successive switching operations and in continuous operation. The safe slack time until a temperature limit is reached can be determined.

Magnet-roll systems Functional units of permanent or electromagnets as well as rollers of magnetizable material. Application as blade systems for flat and rotational film machines or as squeezing devices for magnetic drum foulard and for coating systems (Figs. 1 and 2). The permanent or electromagnet is shaped as a relocatable magnetic beam in screen printing and as a drum for foulard. The roller may consist of cylindrical iron bars, which are also covered with plastic if necessary, or a tube.

The magnetic pressure of rod squeegees has proved particularly suitable for precision coatings with great consistency of sheet thickness across the width of the cloth. Adhesive bonded coating, junction coating, lacquering or PVC coating in 2 strokes (Fig. 3) can be carried out as fully flat coatings or partial and/or sample coating shapes (e.g. powder point coating). Indirect glue coating can be achieved by dosing onto the magnetic roller and transmitting to the fabric guide (Fig. 4).

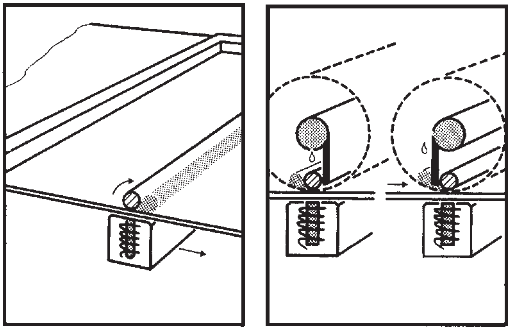

Fig. 1: Magnet squeegee by Zimmer for flat and rotation screen printing.

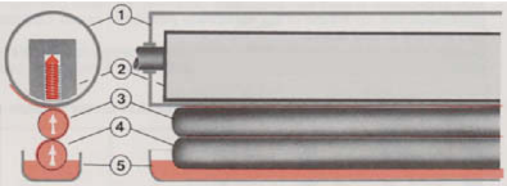

Fig. 2: Magnetic pressure system for product application (Roto-Stabil magnet roller by Zimmer).
1 = magnetic roller; 2 = magnet; 3 = application roller; 4 = immersion and metering roller; 5 = trough.

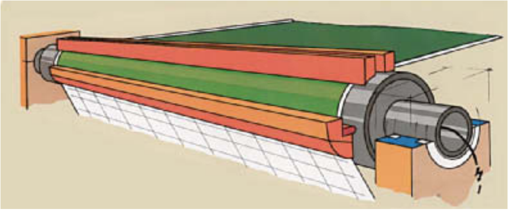

Fig. 3: Magnetic pressure used in the coating of canvas fabrics: 70 g/m^2 base coat (light green) plus 80 g/m^2 finishing coat (dark green); Magnoroll '92, Type s9+12 by Zimmer.

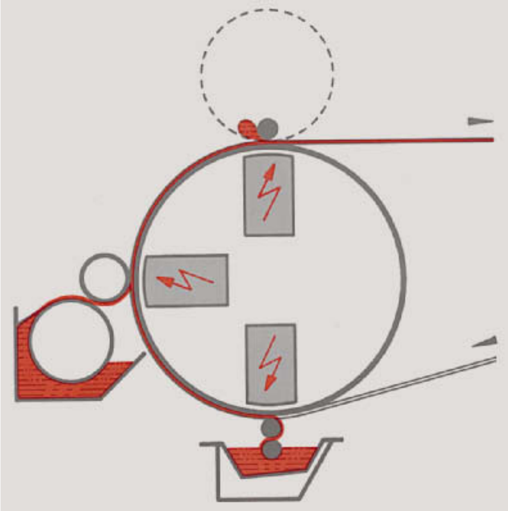

Fig. 4: Magnetic roller application in full-surface or partially-patterned rotary screen coating (Magnetic system "Plus" by Zimmer).

Cylindrical iron bars are inserted into clamped flat or round screens in automated flat screen printing. Their movement and printing pressure is a result of electromagnets running back and forth (controllable) under the back grey, whereby the fabric glued on the back grey in chain direction is contacted each time and pushed further by repeat length. Application also in rotary screen printing (Fig. 5).

Magnifying glasses chiefly consist of a composite lens (ocular), which should always be held directly in front of the eye. Allow linear magnifications up to 60 times. Very varied designs. Usually monocular (for one eye) as → Counting glass and similar, as well as binocular (for both eyes; bifocal magnifying glasses) for materials testing, etc.

Maguey fibre → Manila fibre.

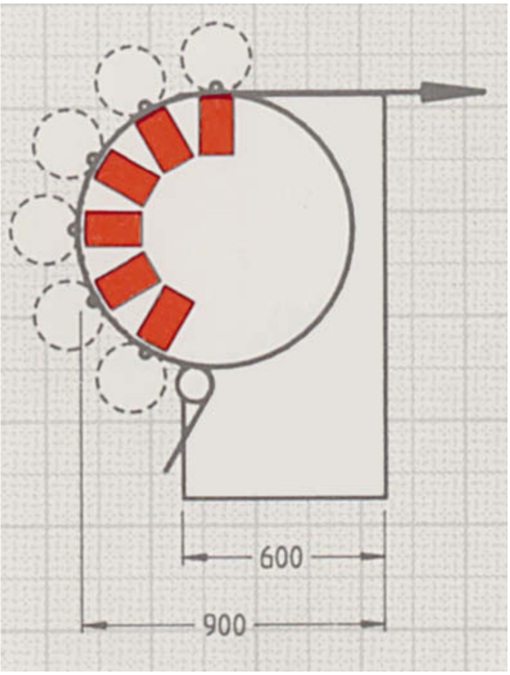

Fig. 5: Application of magnetic pressure as compact pressure zone in Magnoroll rotation screen printing (Zimmer).

Mahagony or Anacardia gum → Vegetable gums from Brazil, Martinique and Guadeloupe, which are very similar to gum arabic. Reddish colour. Besides mainly arabinose also contain bassorin and dextrin. They are not completely water-soluble.

Mahogany sulphonates In petroleum refining, besides the water-soluble “green acids”, the oil-soluble “petroleum sulphonates” which are produced. Application: esp. in USA as mineral oil emulsifiers for cheap lubricating and batch oils.

Maifoss process Dyeing to achieve “2 shades” on the same wool fibre or on different wool fibres in one dye bath. Particularly sought out dyestuffs are used for this; besides these you can use dyeing auxiliaries, which also increase the colour contrast. Colour blend imitations achieved in this way produce interesting effects, but have only found limited distribution, as effects largely depend on the wool quality used and are therefore hardly reproduceable from one batch to another. → Multi-colour process facilitates multi-colour effects in single-bath dyeing process.

Mains water (of towns), containing cloud matter from time to time, usually (to a greater or lesser extent) containing air from water return. Oxygen absorption seasonally temperature-dependent (tendency at 0°C = 14.56 mg/l, at 20°C = 9.09 mg/l); frequently nitrates as well (usually low, 0.01–1 mg/l), often chloride (frequently 30 mg/l; also in 1 mg/l for sterilizing), hardening salts, free chlorine (amongst others frequently iron and manganese, lead as well). For the textile finisher, mains water as industrial useful water is the most expensive and is therefore merely (if at all) used for sensitive products/processes. → Process water.

Maize starch Crystals, pieces, powder. White/ yellowish/red, a little more gloss than wheat starch. Handle as wheat starch (not so crunchy). Seldom distorted. Water content 12–14%. Heated bloating: swelling at 50°C, start at 55°C, end of glueing at 62.5°C. Paste: Greater adhesive and stiffening strength than wheat and potato starch, less than rice starch; acidic production thinner; alkaline thicker. Reaction against chemicals such as potato starch. Chemical finishing handle: very hard, but very pithy. Application → Starch.

Making up of finished textiles Textile form of making up, set to internal company purposes of finishing or packaging, distribution, marketing; e.g. the form, in which goods sold by the metre are presented on the counter ready for sale, i.e. folded, rolled or wound, the packaging of all kinds of products ready for trade, e.g. yarn make-up: to itself, wound up on cardboard, on paper board rolls, made up in a set, made up in an assortment, etc.; for piece goods: in a particular length, on rolls, layers (in the pile), fitted pieces, each simple or twisted (twice as wide), on drum or winding boards, slides, frames, in boxes, etc. Fabric inspection, making up and packaging are automated in large productions (see Fig.).

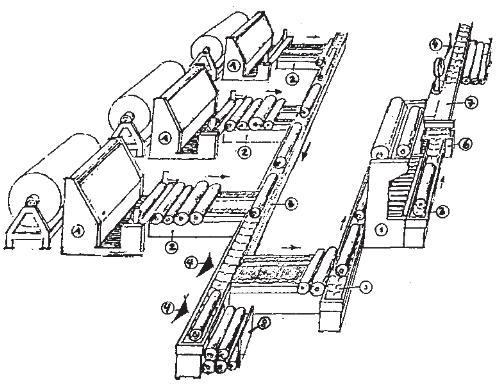

Fig.: Fully automatic packaging of rolled pieces after fabric inspection.
1 = fabric inspection with length measurement;
2 = transverse conveyance to making up; 3 = lengthwise conveyance; 4 = entry to film packaging (= 5) or sorted out as returns (= 9); 6 = labelling; 7 = scales; 8 = collection point for whole colour batches.

Maleate Salt and/or ester of → Maleic acid.

Maleic acid (cis-form), large white prisms, easily water-soluble. Application: for the production of synthetic resins (→ Maleic resin).

Maleic resin (colophony-) maleic acid resins, condensation resins, similar to → Alkyd resins.

Mostly in a modified form, e.g. esterified from colophony and/or abietic acid/maleic acid adduct with polyalcohols. These maleic resins have a high softening point, good resistance to water, lightness and good light fastness. Soluble in almost all organic solvents; partially soluble in alcohol. Application: for paint varnish, coatings (e.g. oilcloth production); addition for cellulose varnished bonds, etc.

Malifil process → Stitched-bonded composites from bonded threads, e.g. from an untwisted thread with polyamide threads "sewn in".

Malimo fabric → Stitched-bonded composites made from oversewn warp/weft thread layers, very similar to woven fabric; chiefly made from viscose staple fibre, cotton (for towels, sheets, etc.) and carded/worsted yarn (for clothing and interlinings).

Malipol fabric, → Stitch-bonded fabrics as a combined stitch-bonded yarn composite fabric type. Conventional textile fabrics (e.g. viscose staple fibre) with pile loops (1–7 mm) threaded to one side of the fabric using stitch bonding and the back of the fabric covered with stitches. I.e. chain plush fabric with pile threads bonded using stitch formation in contrast to tufted fabrics, where loops sewn in have to be bonded with adhesive on the back. Application for Terry fabric goods, duvets, furnishing fabrics, carpets, rugs, coat fabrics in types of fleece and velour, car upholstery and technical textiles.

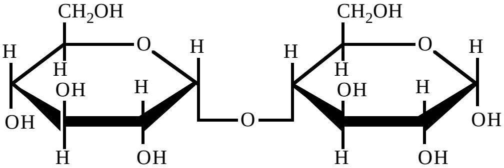
Maliwatt fabric → Stitch-bonded fabrics made out of oversewn nonwovens, with/without binding bonding; for interlinings, felts, upholstering fabrics, coating base for artificial leather, technical purposes; also layered agents for clothing fabrics, raised lining fabrics and artificial leather.

Malt Aqueous extract from germinated cereal grains (barley); contains amylase and maltase as diastatic, starch degrading (condensing via dextrines to maltose) enzymes (ferments). → Malt diastases.

Maltase A glucosidase as an enzyme of malt (malt diastases), which the starch decomposition (into maltose) already effected by the amylase continues to form glucose.

Malt diastases Obtained from germinating barley; consist of α- and β-amylases (→ Diastases). The effective malt diastatic enzyme decomposes starch into maltose. Effectiveness: pH of 4.5–6.2, 50–65°C and quantities of 3–20 g/l of sodium chloride addition have an active effect. Alkali, copper, tin and lead salts act as enzyme poisons. Malt diastases are very suitable for the production of sizing and chemical finishings, but also for desizing. When using diastases and surfactants, it should be considered that soaps and fatty alcohol sulphates are inhibitive. Ethylene oxide adducts have favourable compatibility.

Maltose (glucose, α-glucoside), $C_{12}H_{22}O_{11} \cdot H_2O$.



Easily water-soluble, sweet-tasting starch decomposition product, which is further decomposed by the enzyme of the malt (amylase) and by maltase into two molecules of α-glucose.

Management Intellectual leadership of a company with the aim of economic and ecological optimization of flows of energy, material and above all information in textile processing. The management develops programmes for market processing and controls a product policy geared to it. Production planning by the management comprises strategic and tactical methods. Logistics and quality assurance support management in the handling of application engineering. Management systems (e.g. Fig.) are chiefly supported by EDP for the optimization of the flow of information. Organigrams based on this help management to make decisions.

Manchester velvet → Genoa cord, named after the English city.

Mandrel Thread shaft for transmitting a rotary motion.

Mandrel jack Machine for fitting printing rollers on mandrels onto the steel shaft.

Mandrel removal from printing rollers Removal of steel mandrels from the tapered insides of engraved printing rollers after completion of printing is achieved in a hydraulic forcing machine (or forcing jack).

Manganese Mn; atomic weight 55; white, brittle metal; melting point 1240°C; tarnishing in rainbow colours during heating; rapidly evaporating at 1900°C; very soluble in thinned acids. Valuable component of chrome manganese steel (→ Stainless steel). Valency of 2, 3, 4, 6, and 7. Hydroxides of Mn(II) and Mn(III) have a quite strong alkaline effect, of Mn(IV) approaching neutral, of Mn (VI) and Mn(VII) pronounced acidic (permanagate acid $HMnO_4$, as the main substance of potassium permanagate, is a strong acid).

Manganese brown (manganese bistre, deep brown) → Mineral dyes. Significance: as a result of fastness and easy dischargability using reducing agents (tin salt, sulphuric acid) previously applied to wool, cotton fabrics, for travelling rugs and skin imitations.

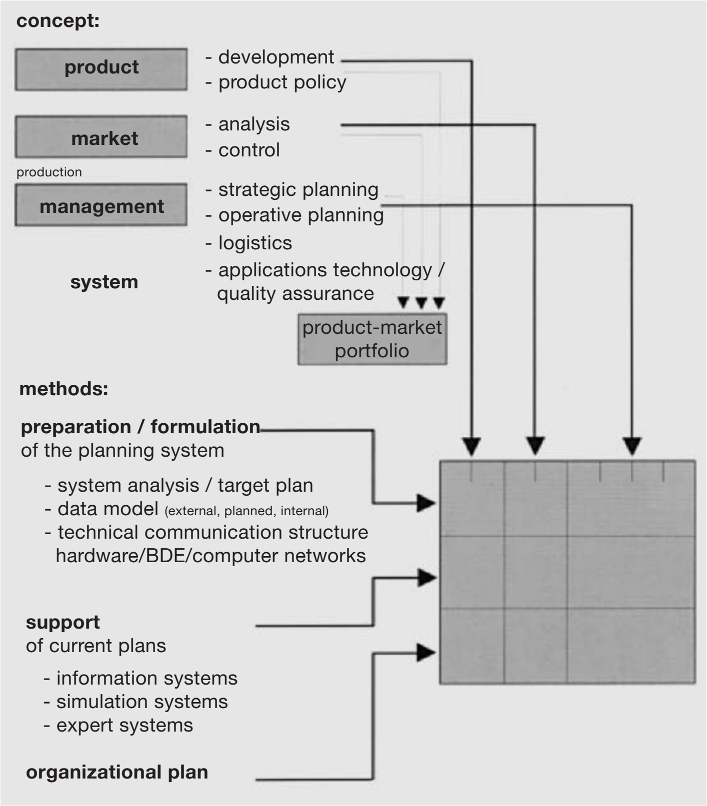


Fig.: Decision-making concept for the management in a production plant.

Production: Impregnate with extracted manganese salt, intermediate drying, caustic soda liquor passage (condensate of manganese hydoxide), oxidizing agent: bleaching powder solution (calcium chloride hypochlorite) or potassium dichromate (formation of managanese peroxide).

Manganese in water supply Encourages all kinds of catalytic fibre damage, unclear white fabrics, dull, cloudy, misdyeings, stains, etc. Nuisance even superior to iron. With 0.1 mg/l of manganese this water is ruled out for numerous finishing purposes. (→ Water demanganizing).

Manganese soap,

Formation similar to → Lime soap through water hardening salts.

Mangle Machines used for → Mangling. Basic types:

1. Bowl mangles: in the form of suction, single-bowl, double-bowl, multi-bowl and add-on mangles; constructed in small, medium and large units.
2. Steam chest mangles (smooth steel cylinder as smoothing body) for high volume industrial use.
3. Some multiple-bowl mangles have automatic feed and delivery units.

Mangle bowl (batch roll), fabric batching roller (made of wood or iron) for → Mangling (modular mangle).

Mangling,

I. Chemical finishing character work. Intended for the woven fabric (linen, less often cotton) to be treated with a simili gloss or handle improvement:

1. modular mangling, whereby the fabric wound on skeins is exposed to the pressure of a heavy module which goes to and fro. The effect is influenced by how tightly the fabric is wound on the skeins;
2. roller mangling, whereby the fabric continuously passes two or more heated rollers with adjustable pressure;
3. calender with 2 or more rollers, whereby mostly only elastic rollers are used.

A similar extensive finishing effect can also be achieved using the → Rotary cloth-press.

II. Mangling of washing as a combined smoothing and drying process in laundries, whereby washing is “mangle-dried”.

Manila fibre (abaca, banana, maguey, musa fibre), a → Bast fibres from the tropical fibre banana (Philippines, Central America). Yellowish-white, yellow to reddish. Specifically light. Fibre bundles 2–5 m long and 0.2–1 mm thick; individual cells 3–12 mm long and 0.016–0.032 mm Ø. Longitudinal strength 40–75 cN/dtex, transverse strength much weaker. Resistant to moisture and sea water. Structure: 63% cellulose, 10% water, 1.4% water-soluble, 0.2% fats and waxes, 25.4% pectin/hemicellulose/lignin, 1.2% ash (grey). Dyeable using cationic, vat, acid, sulphur and direct dyes. Application: for ropes, nets, strings; yarns for bags, mats, braids, etc. (→ Tagal); finer yarns with silk also for shirts, etc.

Man lock → Sampling lock.

Man-made fibre alloys → Polymer mixtures.

Man-made fibre generations,

I. Fibres of the 1st and 2nd generation: 1st view: fibres of the 1st generation: original fibres neither chemically nor physically modified in the first “year of their life” after discovery. Fibres of the 2nd generation: further development using physical and/or chemical modifications in the manufacturing process. 2nd view: only chemical modification (grafting and bicomponent structure) results in “fibres of the 2nd generation”, while physical modifications and depositing substances provide “made to measure chemical fibres”.

II. Chemical fibres of the 3rd and 4th generation: chemically or physically modified types of conventional chemical fibres, i.e. synthetic fibres created for a very specific requirement profile (→ Fibre engineering).

Man-made fibre manufacture From the melting or concentrated solutions of usually macromolecular substances and also from which some low molecular compounds (honey, soap solutions) can remove threads. So thread formation is not a special property of macromolecular substances. But the threads only have a low mechanical strength naturally. If the thread material consists of long molecule chains, these are partially oriented when drawing. The resulting fibres have a higher strength. But only some fibres show such high strengths that they are suitable for textile or industrial use. Chain-forming macromolecules are therefore the first prerequisite for fibre formation. Heavy branchings degrade the thread formation and mechanical properties, as fewer points of contact per unit length are possible between the chain molecules. A certain minimum degree of polymerisation should be available for thread formation for the same reason. The tear resistance is practically equal to zero with small degrees of polymerisation. This minimum degree of polymerisation is lower, the stronger the interactions between the chains are, i.e. the more polar the groupings are and/or the more easily the macromolecules can crystallise. But crystallisation is not an absolutely required prerequisite for the formation of fibres. For example, bristles for brushes, etc. are produced from the non-crystalline polystyrene. A cristallinity which is too high is even less desirable, as the fibre then becomes brittle.

The spinning jet nozzles for the spinning of man-made fibres are manufactured from metal plates with the finest bore holes (cross-sectional diameter of approximately 0.05–0.12 mm). These apertures were usually bored previously; now they are pierced without exception or produced using laser beams. With a spinning jet nozzle diameter of ca. 1–5 cm the number of apertures for viscose is between 16–120 and more; this number is considerably larger for synthetic fibres and is somewhere between 1000–5000 and more. Previously a gold/platinum alloy was mainly used for the nozzle base; now the silvery white precious metal tantalum, which is more mechanically robust and also more corrosion-resistant, is preferred.

Due to the considerable advances in nozzle manufacture, the fineness both of filament and staple fibre products can be as varied as you like. Fibres of the fineness of natural silk and finer (microfibres) and the thickness of the coarsest wool or animal hairs can be produced. The thickness of man-made fibres is geared to the purpose. It is given in dtex. The entire range, in which man-made fibres are produced today, is between ca. 1–45 dtex; for microfibres < 1 dtex. This produces a significant scope regarding the fineness and adaptability to natural fibres. Most products, which endlessly come on the market, are multi-thread or multifilament. Viscose filament, for example, consists of 16-120 individual filaments; the synthetic fibres, however, usually only have 6–18 individual threads. The fineness of multifilament man-made fibre yarns is given by two figures, e.g. 120/40; the first figure (here 120) signifies the total titre; the second figure (40) indicates the number of individual filaments. If you divide the total titre by the number of filaments, you get the individual titre. So in this case 120 : 40 = 3. The so-called B types (man-made fibres for the cotton sector) are normally in a fineness range from 1.1–2.75 dtex. The W types (wool types) start at about 2.75 dtex and reach up to about 33 dtex for particularly coarse products. Finenesses of more than 11 dtex are usually only used for the carpet industry (T types). A particularly popular fineness in the

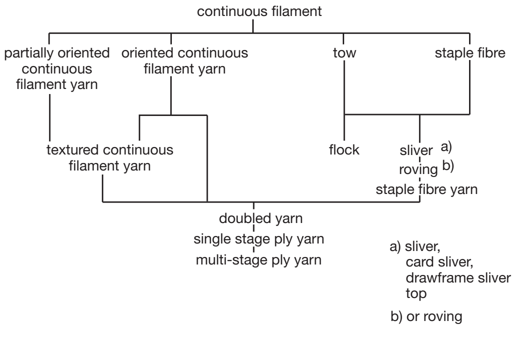

Fig.: Man-made fibre forms (according to BISFA).

outer clothing sector is 4.1 dtex. This corresponds approximately to a wool fineness of AA.

Just like the fineness, the length (staple) of the fibres is also adapted to fit further processing and/or the natural raw material in question. The fibres which firstly come out of the nozzles as filaments are cut to particular lengths using cutting machines. The length ranges from approximately 30–250 mm. A cut length of 30, 40 or max. 60 mm is usually selected for the B types. For the wool sector, the fibres are cut at 30–80 mm (usually 60 mm), if they are to be processed in the carded yarn process and at 100–150 mm (usually 120 mm) if they are to be processed in the worsted spinning process. Just as one frequently chooses the fineness somewhat finer than the natural product, one tends to use man-made fibres, which are somewhat longer than the natural products; this applies in particular when the natural raw material is relatively short (as e.g. for cotton or reclaimed wool). They can then be spun more easily.

With regard to purity, man-made fibres are an ideal spinning material, as they are not contaminated by shell or leaf remains, burrs, dust, etc. as are natural fibres.

The surface of man-made fibres may be smooth or rough, as it can be given a scarred effect. Highly glossy, glossy, matt and deeply matt threads can be produced. While a high gloss is regarded highly for certain fabrics, it is not to be desired in other cases and is felt to be chilly, greasy and cold. Instead of the previous, less resistant post-delustring the so-called delustring in spinning is used today. Finely distributed substances, e.g. titanium dioxide, are hereby mixed in the spinning solution before spinning out. So they are not on the fibre surface, but in the fibre substance. The most varied gloss levels, which are very natural, can be achieved with the corresponding dosage rate.

Spin dyeing is a similar process to delustring in spinning, i.e. coloured pigments are added to the spinning. So the spin dyed products already come out of the nozzle dyed. The particular advantage of this is that this type of dyeing is cheaper than all the others. Furthermore, it is possible to repeat these colours in a constantly even shade. Finally, these spin or nozzle-dyed products have unusually high colour fastnesses, especially friction, water, washing, sweat and light fastnesses.

The possibility of texturing exists in order to adapt fibres, which are used in the wool sector, as far as possible to natural wool. The appearance, handle and above all the thermal retention of the finished goods is determined to a high degree by the crimp. The artificially produced crimp is, however, not as resistant for all products as for natural wool, but considerably more durable for synthetic fibres than for the materials made from regenerated cellulose (the worst being acetate). Distinctions are made, e.g. between torsional crimp texturing (false twist texturing), stuffer-box crimp texturing, air bubble texturing or knitted setting texturing processes. A resistance to the mechanically produced crimp can be achieved for most thermoplastic synthetic fibres using thermal treatment.

While the moisture absorption of man-made fibres from natural raw materials (e.g. viscose 10–13%) is normal to good, practically all fully synthetic products characteristically only absorb very little moisture (→ Moisture absorption of fibres). With a moisture absorption of 4–4.5% in standard atmosphere, polyamide products are still relatively favourable, as polyester and polyacrylonitrile products only absorb approx. 1–2% moisture content in standard atmosphere. The low moisture absorption of synthetic fibres is, for example, also the reason why these products tend to be processed using wool, which is very attracted to moisture, in order to create compensation as regards this. The drying time of products naturally also depends on the moisture absorption. The low water retention is therefore the reason why materials made from synthetic fibres dry so quickly.

With the very considerable increase of man-made fibres in the textile industry amongst other sectors, technical terms, which give cause for uncertainities, were often used. The BISFA therefore considers it advisable to define in summary the names of the various manifestations of man-made fibres acknowledged as correct by experts (see Fig.).

Man-made fibres Generic term for chemically/ technically produced textile fibres:

I. Made from natural polymers: →:Regenerated cellulose; Man-made protein fibres; Mineral fibres.

II. Made from synthetic polymers (→ Synthetic fibres): →: Polycondensation fibres; Polymerization fibres; Addition polymers.

Man-made fibres (Fig. 1) are, as products of modern big industry, in contrast to natural fibre materials. They not only intrude upon the areas of application of natural products, but have also developed new areas and have been promoted to an indispensable factor of the economy and human life. Robert Hooke (London) had already referred to the exhaustion of lime-like materials for threads for the first time in 1665. The invention of nitrocellulose in 1845 by Schönbein, the artificial cel-

lulosic threads of the Frenchman Chardonnet and the proof of the solution of cellulose in cuprammonium hydroxide are milestones in historical development. But only through the introduction of long, chain-forming molecules were the scientific foundations created for a suitable theory. Staudinger coined the term of macromolecule, which is still valid throughout the world today. The years of origin for synthetic polymers are generally 1920 to 1930. The basic characteristics of a fibre-forming substance were found here: the availability of macromolecular chain molecules and the ability of these molecules to store themselves together in bundles, which guarantee a sufficient transverse strength from mutually effective attraction forces (secondary valency bonds). A synthetic fibre came onto the market for the first time in the middle of the 30s with polyvinylchloride fibres. The pioneering work of Carothers, USA (polyamide 6.6), Schlack, IG Farbenindustrie (polyamide 6), Whinfield and Dickson, England (polyester) and Rein, IG Farbenindustrie (polyacrylonitrile) formed the foundations for today's synthetic fibres. The construction of numerous manufacturing plants and the continual increase in the production opportunities available made the man-made fibre industry into an economic factor throughout the world (see Fig. 2) without which the provision of humanity with textiles and the considerable increase in consumption due to the growing world population is no longer conceivable. 4 main types (see Table) have developed amongst the large number of possible fibre raw materials. This includes the regenerated or transformed cellulose products, the polyamides, polyesters and polyacrilonitriles. Besides that, fibres made from polypropylenes have even taken a notable upturn. The remaining polymer systems have only achieved partial success in certain sectors due to very specific properties, such as the polyvinylchloride fibres, polyvinylalcohol fibres or elastomer filaments such as polyurethane, as well as some newly developed special fibres for technical textiles.

year	cotton	wool	synthetic fibres	cellulose derivatives	total
1980	14,0	1,6	10,7	3,6	29,9
1985	15,6	1,7	12,8	3,3	33,4
1990	16,5	1,7	14,5	3,3	36,0
2000	19,0	1,7	17,5	3,8	42,0

Tab.: Increased man-made fibre consumption in millions of tonnes (world-wide) compared with wool and cotton; silk production per year: 50 000 tonnes.

In nature, the organic molecules represent the essential ingredients of life. Amongst them the linear forms of the macromolecules of cellulose and man-made solids have a significant importance as a fibre substance. It it therefore understandable that empirical tests to manufacture artificial fibres began with these natural materials. Particular successes were, however, only achieved with cellulose, which still has great economic importance as a raw material today. The term man-made fibres was coined in 1950 for previously customary terms such as synthetic fibres, created fibres, industrial fibres, etc. This phrase thereby represents the new

million tonnes cotton production

Fig. 2: left-hand side: Economic importance of man-made fibres (1970–2000); right-hand side: cotton production (1997–2000), source: ICAC, Washington.

generic term for all types of fibre, which are created industrially, independent of whether they are manufactured as filament or cut, made of animal, plant or mineral raw materials. That is why they also include the synthetic fibres. Their number and importance has grown significantly since rayon staple fibre, as there are several hundred different types of man-made fibre throughout the world.

Cellulose is normally the starting material for the so-called man-made fibres made from natural polymers. It is, for example, found in the wood of beech and spruce trees, while the raw products for synthetic fibres are chemical substances such as phenol, benzene, acetylene, chlorine, hydrocyanic acid, etc. These materials do after all also derive from nature, namely petroleum, calcium carbonate, sodium chloride, etc., but they were obtained using chemical transition processes. All the products, so not only the filament threads, but also the cut fibres, are basically manufactured in a filament spinning process. While the filament, i.e. endless products, are left in this form and wound on cones, the staple fibres are tear-converted or cut to the desired length with the aid of trimming machines so that they can be spun together with wool, cotton, flax, etc. or also on their own.

Man-made protein fibres (protein man-made fibres, regenerated protein fibres), nozzle-spun man-made fibres made from natural polymers on base of protein solids:

I. Vegetable origin: vegetable protein fibres such as →: Zein; Arachin fibre; Glycine.

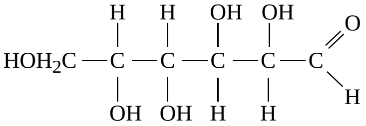
II. Animal origin: animal protein fibres such as →: Casein; Fibroin.

Man-made protein fibres are generally distinguished by heat, pleasant handle and elasticity. Depending on hardening they are remarkably resistant to rot and moth attack as well as not being inflammable. They are outstandingly suitable for mixtures with wool and viscose fibres (encourage richness, improve handle and wool-like character, reduce tendency for creasing). Generally very good resistance to diluted and weak acids strong acids have a damaging effect. Fairly resistant to weak alkalis, having a cold and short effect. Concentrated alkalis, particularly hot, have a swelling to destructive effect. Dyeing reaction: extensively like chlorinated wool. Bleaching is possible using sodium hypochlorite, peroxide or sodium hydrogen sulphite. As man-made protein fibres promote the felting process of wool, they were useful in the hat and felt industry, otherwise only as fibre blends.

Man-made protein fibres, distinguishing tests Boiled in 0.1% ninhydrin solution for 1–2 min fibres appear dyed as follows: groundnut protein fibres = greyish brown, zein fibres = grey-blue, milk casein fibres = faint purplish blue, soya fibres = undyed.

Man-made staple fibre Designation for staple fibres of the man-made fibre type. Opposite → Filament.

Mannose (D-mannose), $C_6H_{12}O_6$; molecular weight 180.16.



Belonging to the simplex sugar types. Occurring as a component of similar sugar polysaccharides, e.g. predominantly involved in the structure of → Locust bean flour (galactomannan, carob). In its pure state (commodity) white, sweet-tasting crystal powder, easily water-soluble.

Mannuronic acid →: Polymannuronic fibre; Alginic acid.

Manometer, pressure gauge Pressure gauge for gas, vapour and air pressure (also fluid pressure), which exceeds or falls below normal pressure.

I. Fluid manometer: Simplest type (similar to → Barometer) as an open U-tube filled with fluid (mercury, paraffin oil or coloured kerosene), connected on one side or (for differential pressures) on both sides, board-mounted, mm pitch, reading off the level stand above and below (rounded distance). Only for low excess pressures (often below 1 bar).

II. Diaphragm pressure gauge: oval housing, air-tight clamped diaphragm (corrugated sheet metal), one side with overpressure connection, another side with pushbutton, little gear wheels, pointer and calibrated measuring scale.

III. Tube spring manometer: tube spring bent in three-quarter circle (Bourdon tube) with oval cross-section made of brass or (for maximum pressure) bored steel tube, one side above with excess pressure connection, other side closed with lever-operated transmission, counting segment, gear wheel, pointer and calibrated measuring scale.

II. + III. for high-pressure measurements in autoclaves and similar also (remote) indicating as well as using a contacting device to control industrial machines or indicating devices; or also (tele)typing.

MA process Low wet pick-up process as an impregnation process with only low pick-up of finishing liquor, thereby shorter drying times. Fabric spreads across roller (applicator roller or inching roller), which dips into the liquor on the underside and possibly on the top side (see Fig.) and delivers this in a controlled manner to the fabric. Speed range of 0–150 m/min. For fabric finishing, knitgoods and application of chemicals in printing (2 phase vat printing). The MA technique can be used for very absorbent fabric; the liquid uptake is thereby only ca. 35%, compared with 60–70% for the padding. → Low wet pick-up.

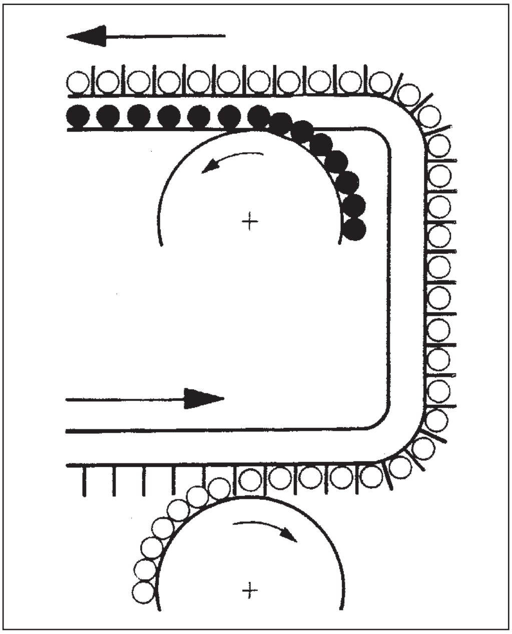


Fig.: Two-sided wet pick-up in the MA process (Triatex).

Marangoni effect According to the discoverer of the described "self-extension effect" of foam lamellae film damaged at one place, whereby a new film surface of higher surface tension and smaller area coverage with surfactant molecules develops there (see Fig.). This results in surfactant molecules immigrating from the environment with low surface tension and thereby carrying along the underlying fluid with their hydrophilic groups to fill the areas which have become thin (self-healing).

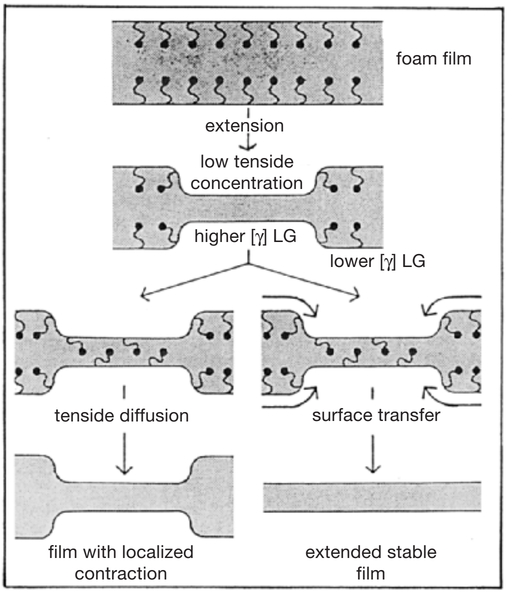

Fig.: Diagram showing surface elasticity and the Marangoni effect.

Marbled soap Soap, which is produced via the dilution taking place in the soap type (refined core-glued deposit) during cooling. This partial dilution gives rise to the formation of transparent or, with dye addition, coloured strands in the soap.

Marengo Suit and coat material (similar to fine → Loden), not a fabric quality, only a colour description. This concerns very dark-coloured, almost black materials, which are brightened up by a small white component of 1–4% (= radial-line colour). The four-weave symmetrical twill is almost exclusively found as a weave. There are marengos both in worsted yarn warp and weft and in carded spun yarn in both thread systems. There is therefore a distinction between worsted yarn and carded yarn marengos, the worsted yarn marengos are generally lighter and either barely finished or only lightly meltonated. The carded yarn marengos are practically in nearly every type of weight, above all for winter coats, and furthermore in all kinds of chemical finishing. The predominant marengos are qualities of merino-fine overcast wool, which are usually wool dyed. You can have part coloured marengos, but the white component must then either consist of resisted wool or synthetic fibres, which cannot be dyed when applying wool dyes.

Marengo yarn Black and white mottled yarn, e.g. made of wool or silk (worsted or carded yarn).

Marginal lye Electrolyte solution of a concentration above which soap is insoluble, below which it starts to dissolve. Its concentration depends on the nature of the solid matter used, the electrolytes and the temperature.

Mark Withstand capability of a print paste; perfect mark of a print paste when printing corresponds to a sharp vertical outline. → Print definition.

Market analysis Systematic/methodical examination of the position of individual companies in market events. A necessary prerequisite for the conception and business policy of a company, besides the monitoring of the market for the creation of market transparency. Implementation to a certain extent with own staff, but mostly with specialist institutes or market analysts/consultants. A product-oriented company management solely concerning optimisation of products and the technical manufacturing processes is no longer adequate today. The marketing area is gaining importance and so is the "buyers' market". The marketing idea is developed against this background. One definition is: market planning, a term for a sequence of functions, which consolidate all the efforts of the company to the one aim of serving the customers in order to guarantee that the customer receives:

- what he wants,
- where he wants it,
- how he wants it,
- when he wants it.

So in marketing the needs of the purchaser are the focal point, to be distinguished from the term "selling", which regards the needs of the seller as having priority. An effective marketing policy requires decisions in the marketing area. However, these are often related to the future and therefore tainted with a rather uncertain character. In order to make decisions as rationally as possible requires reliable information, which is used and/or interpreted, as well as corresponding methods. This information requirement is met by a partial function of marketing - market research. Market research is occupied with customers' wishes and modes of behaviour, competition measures, effect of own marketing policy measures, technological, legal and social trends.

Market research should be described as an interdisciplinary science, whose main sources are economics and social sciences. But other sciences are also included in order to do justice to the complexity and multi-layeredness of the task, which provides market research. This is how mathematical statistics and probability theories, for example, have become major industrial instruments of the market researcher. If any information is gathered for purely marketing policy purposes, one talks of marketing research. Market research, however, deals with the collection and processing of data gathered from the market for any purposes you like. The Figure clearly shows the delimitation, which is fluid, however.

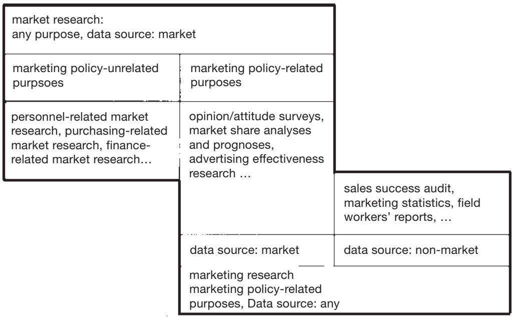

Fig.: Definition of market and marketing research.

Capital goods belong to producer goods - goods, whose purpose lies not in consumption, but in a longer-lasting use; so they wear out quickly and are not destroyed in use; a relatively high price should be supplied to the purchaser for their acquisition. Capital goods are, for example, furniture, machines and equipment, vehicles and similar. Consumer goods are, however, intended for consumption and are perishable; they are subject to consumption or destruction. The creation of the need for consumer goods applies to the human personality in all its levels of existence and in its social interconnections. The following sciences are therefore enlisted for the gathering and interpretation of data in consumer goods market research: biology, anthropology, psychology and sociology. The buying decision for investment goods is dependent on other criteria, which are of the technical/economic kind. This market is, however, not always as clear as the consumer goods market. It shows more market dependencies, as the national economic degree of integration is larger for capital goods. That is why it can be affected by more subsidiary economic developments and departmental economic trends. Another important distinguishing feature of capital and consumer goods is the structure of demand. While you almost exclusively find a polypolitical demand for consumer goods, complete market types such as buyer's monopoly, oligopoly and polypoly appear for capital goods. In contrast to capital goods, the circle of consumers for consumer goods can often be determined easily according to general characteristics such as gender, age, income, etc. You can usually form really homogeneous customer groups for marketing according to this. The circle of potential consumers for capital goods is, however, dependent on internal conditions, i.e. on specific functions of production. To this is added the fact that the capital goods themselves are distinguished by a great heterogeneity. Against this background it also turns out that the apparatus for the respective branches of market research can differ now and then. Secondary research dominates the field of capital goods market research, whereas primary research is of greater significance for consumer goods market research.

A specialist institute for technical market research, for example, offers ascertainment of the following data:

- total size of the market,
- regional marketing potential,
- own market share,
- market development tendencies,
- number of competitors,
- market share of competitors,
- advertising expenditure of competitors,
- distribution methods of competitors,
- prices and terms of competitors,
- structure of marketing channels,
- importance of marketing channels,
- description of purchaser circles (structure of customers),
- production methods and systems,
- design characteristics of rival products,

- marketing prerequisites for new developments and diversification,
- site selection criteria.

The marketing planning process demands help from market research for the following phases:

1. registration of the current market situation of the company (market diagnosis).
2. assessment of the probable market and sales development (market forecast).
3. determination of marketing aims.
4. decision on marketing strategies.

Research on demand, purchasing power and rivals are very significant for sales market research. Ecoscopic and demoscopic analyses are thereby applied. The competitive analysis is thereby essential for the assessment of the market and competitive position of the company concerned, unless this concerns a monopoly-type structured market. The following information is of importance for this: the number of competitors and their competitive intensity (market shares of competitors, market structure of rival firms and reactive competitive behaviour). Besides the competitive analysis, the analysis of your own operational market position is of importance for drawing up a complete picture of the market. It includes research into:

- the market shares,
- the consumer circles,
- the change of brand, the commitment to a brand,
- the consumer satisfaction,
- the product images,
- the degrees of information,
- the opinions and feelings,
- the trends,
- the potential market position.

Besides market diagnosis, the second task of market research consists in the market forecast. Forecasts show developments, which are the most probable according to the level of knowledge at the time of the forecast, i.e. currently effective influence factors are transferred to the future development. The following types are distinguished:

- national economic and business management forecasts,
- short-, medium-, and long-term forecasts,
- qualitative and quantitative forecasts,
- overall and partial forecasts,
- supply and demand forecasts.

The following procedures can be applied for this:

1. Extrapolation procedure, which is based on the tracking down of legal restraints.
2. Econometric procedure, whereby a relationship system is established between several explanatory sizes and their factors of influence.
3. Intuitive procedure: scenarios, i.e. presumable plots, are hereby drawn up on the basis of particular basic estimates.

Forecasts should have accuracy and reliability, which is, however, always in relation to coverage and detail. However, forecast errors, which can be characterised as data, modelling or assumption errors, may always occur.

The implementation of market research tasks can be carried out by the following institutions:

- operational market research,
- market research institutes,
- economic research institutes,
- advertising agencies,
- associations,
- marketing consultants.

In general it can be said that operational market research has the following advantages:

- better familiarity with the problem to be settled,
- better possibilities for co-ordinating market research activities,
- better exhaustion of information from the decision maker,
- often longer experience and specialist knowledge of the line of business,
- better information and data protection after conclusion of the project.

The following are considered as disadvantages:

- operational blindness,
- methodical backwardness,
- influence of results from internal authorities.

There are the following advantages for external research:

- use of specialists,
- greater objectivity in research,
- comparability with results from other investigations,
- better control and use of more recent research methods.

However, the danger hereby lies in the commercialisation and with that the setting of a goal operating on a profit basis.

Market research as such is a complex area. The objective of an individual market analysis is dependent on the customer. A businessman is, for example, interested in the behaviour of competitors, market shares, buying motives, differences in price and quality for the consumer. The instruments and methods of market research are therefore also very diverse and should always be selected against the background of the facts to be investigated. Key data of the market and/or market phenomena, often statistical, can usually be ascertained from already published sources. This is called secondary research or ecoscopic market research (desk research). On the other hand, behaviour of market participants must be directly investigated by the relevant persons. This concerns primary research or demoscopic market research (field research). Secondary research deals with collecting and evaluating information already available. Internal management data such as sales and order statistics, cost accounting, list of customers, customer correspondence, representatives' reports, after-sales service reports and purchasing reports are considered for this as well as external data such as official statistics for sales and prices, brochures, catalogues, annual reports, business newspapers, trade journals, directories and manuals, office addresses, trade fair catalogues and visits. Databases represent an important instrument in this connection, for example, complete register of all industrially active firms in Germany. Secondary research requires a far lower expenditure of money and time than primary research. Primary research is always carried out starting on the basis of the secondary data collected. One cannot usually do without a certain amount of primary research, as, for example, the existing sources do not go deep enough, one requires particular information immediately or else subject-related information about market participants in the real sense of demoscopic market research is required.

Marketing Concept of market-oriented business management, → Market analysis. The extensively small to medium-sized structured German textile and clothing industry sees itself exposed to dynamic changes in the market situation, which increasingly aggravates a monitoring of the market only using the traditional aids. The marginal conditions of marketing are essentially determined by the quicker fashionable change, the decline in established consumer groups. Information about the partners in the "textile chain" (raw material production, spinning, textile surface production, finishing, garment manufacture, trade, consumer and disposal) directly influence the distribution and marketing of a company. → Market analysis.

Marking → Sighting.

Marking chalks Are used for marking/sighting piece goods in the finishing phase. Consist of dye pigments stored in wash-active substances. Should not be decomposed during operating processes before the piece washing (e.g. steaming, burning at high temperature, etc.); otherwise risk of dye fixation on the fibres.

Marking colours Marking pencils, inks, → Textile markers.

Marking inks →: Chalk dyes; Laundry markers, but also dyes, which are applied to yarns for labelling without being fixed properly. Must therefore be easily washed out.

Marking machine,

I. For fabric faults, are used in combination with corresponding recording devices on inspection and measuring machines.

II. Are used for the labelling of individual pieces such as shirts, etc.

Marking of grey fabrics is used for marking/sighting as a grey material preparation in textile finishing using description or stamping (→: Textile markers; Stamping inks); also analogous to dry-cleaning and laundry (→ Laundry marker).

Marking off in wet goods Bleeding or destaining of colorations and printing in fabrics laying on top of each other in a wet or moist state.

Marl yarn (Fr.: twisted),

I. Marl ply-yarns: double or multi-thread tightly twisted ply-yarns, whose individual threads consist of contrasting colours, which gives a speckled appearance to the fabrics manufactured from them. The handle of these fabrics is usually somewhat harder due to the tight twisting. Marl ply-yarns are typically more often found in the following fabrics: cord, fresco and tropical, coat gabardines, whipcord and in particular in twists. Marl ply-yarns are manufactured in both worsted yarn and carded yarn techniques. Marl ply-yarn made from polyamide is important for carpets.

II. Woven fabric: no designation for a particular fabric quality, but only type of design. The name implies that marl ply-yarns have been used in the chain and in the weft, but only in the chain in many cases.

Marocain → Crêpe Marocain.

Marquisette Transparent net curtain fabric in gauze weave, fine thread, gauze-like; smooth, patterned, embroidered; mostly cotton (e.g. Swiss marquisette), cupro filament or synthetic fibres; for net curtains, curtains, furnishing and clothing fabrics (also made of silk).

Marseilles soap Fatty, mild → Soap made from olive oil, cotton oil, etc., white or green, bar or needle-shaped.

Marvel-Meter Instrument for the mechanical counting of stitch courses in any kind of stitch products, from the finest 75 g weight to coarsely knitted batch fabrics; fast and reliable, without special previous knowledge.

Masked fatty acid products → Fatty acid condensation products.

Mass (unit of measurement), basic dimension of → SI units using the base unit → Kilogram. The base unit 1 kg is the mass of the International Kilogram Prototype (original kilogram, mass kilogram). The unit already contains the prefix "kilo" so that no other prefixes may be used for multiples or fractions of the unit. The following are permitted as special names:

1 gram 1 g = 10^{-3} kg and

1 ton 1 t = 10^3 kg = 10^6 g = 1 Mg (megagram).

Mass action, law of puts pure, solid silver chloride (sediments) in equilibrium with its aqueous, saturated solution, so this heterogeneous equilibrium is described by the phase transition:

$$\mathrm{AgCl\ (solid)} \rightleftharpoons \mathrm{AgCl\ (aqueous)}$$

whereby the symbol AgCl (solid) resp. AgCl (aqueous) signify the neutral silver chloride in the pure solid phase resp. in the liquid mixed phase, which is made up of the electrolyte silver chloride and the solvent water. As silver chloride is only diluted in water to a small extent, it is called a not easily dissoluble salt. In the aqueous phase, the dissolved neutral silver chloride AgCl (aqueous) dissociates in accordance with the following chemical homogeneous reaction:

$$\mathrm{AgCl\ (aqueous)} \rightleftharpoons \mathrm{Ag^+ + Cl^-}$$

As this dissociation reaction is almost completely executed, the equilibrium is extensively at the end of the ions. If the concentration (molarity) of the undissociated silver chloride, the Ag^+ ions and the Cl^- ions in the aqueous solution is described using $c_{AgCl(aq)}$, c_{Ag^+} and c_{Cl^-}, the law of mass action for the reaction corresponding to the normal quotient notation for the equilibrium concentrations of the types of particle, which are left and right in the reaction equation, is as follows if the ideally displaced solution is assumed:

$$K_c = \frac{c_{Ag^+}\, c_{Cl^-}}{c_{AgCl(aqueous)}} \cdot \frac{1}{c^*}$$

K_c is the equilibrium constant for the reaction in the concentration scale and c^* a standard value of concentration, e.g. $c^* \equiv 1$ mol/l. The equilibrium constant for the given medium (e.g. water) generally depends on the temperature and (in condensed phases) slightly on the pressure. It is, however, independent of the presence of other electrolytes, even if these in turn contain types of particle, which participate in the reaction in question.

The concentration of dissolved complete electrolytes is constant for given solvents in saturated solutions at constant temperature (and constant pressure) – saturation concentration. The concentration of the undissociated silver chloride $c_{AgCl(aq)}$ consequently also represents a constant in this respect in the above example due to the equilibrium. With saturated solutions, the equilibrium constant and the concentration of undissociated electrolytes is therefore summarised by the definition:

$$s \equiv K_c \cdot c_{AgCl(aqueous)} \cdot \frac{1}{c^*}$$

The dimensional size s means solubility product. From the previous equations there follows:

$$s = c_{Ag^+} \cdot c_{Cl^-} \cdot \frac{1}{(c^*)^2}$$

Silver ions react in aqueous solution with ammonia under formation of a complex in accordance with:

$$\mathrm{Ag^+ + 2\ NH_3} \rightleftharpoons \left[\mathrm{Ag\ (NH_3)_2}\right]^+$$

For this equilibrium, which is extensively on the right end in the silver diamin complex, the law of mass action assuming an ideally displaced solution in the concentration scale is:

$$\left(K_c^{I}\right) = \frac{c_{[Ag(k)]^+}}{c_{Ag^+} \cdot (c_{NH_3})^2} \cdot (c^*)^2$$

whereby $c_{[Ag(k)]^+}$ and c_{NH_3} respectively signify the concentration of the silver diamin complex and the ammonia. The equilibrium constant KS_c^I of the reaction of silver ions with ammonia is called the stability constant of the complex or complex-forming constant. If ammonia is added to the saturated aqueous solution of silver chloride with sediment considered at the beginning, complex formation occurs. The silver ions used in this are subsequently delivered by the dissociation of the silver chloride. The undissociated silver chloride AgCl(aq) required for this is, for its part, made up of solid silver chloride. On the whole, the sediment is thereby fully or partially dissolved depending on its mass. Sum of the reactions results in the following for the gross reaction in the solution:

$$\mathrm{AgCl\ (aq) + 2\ NH_3} \rightleftharpoons \mathrm{Cl^-} + \left[\mathrm{Ag\ (NH_3)_2}\right]^+$$

The following applies for the equilibrium constant of this reaction under the conditions introduced above:

$$K_c^{II} = \frac{c_{Cl^-} \cdot c_{[Ag(k)]^+}}{c_{AgCl(aqueous)} \cdot (c_{NH_3})^2} \cdot c^*$$

The concentration of the undissociated silver chloride $c_{AgCl(aq)}$ now also represents a constant in the presence of the sediment silver chloride for a given solvent, at constant temperature (and constant pressure). For this reason the definition

$$K_c^{III} \equiv K_c^{II} \cdot c_{AgCl(aqueous)} \cdot \frac{1}{c^*}$$

is introduced. It results in

$$K_c^{III} = \frac{c_{Cl^-} \cdot c_{[Ag(k)]^+}}{(c_{NH_3})^2}$$

Use of the previous equations in this respect leads to:

$$K_c^{III} = K_c^{I} \cdot s$$

The correlation enables the equilibrium constant K_c^{III} to be calculated for the known concentration of chloride ions c_{Cl^-}, the silver ions in the diamin complex $c_{[Ag(k)]}^{+}$ and the ammonia c_{NH} in the solution mixed with ammonia with sediments made of silver chloride. The stability constant K_c^{II} of the silver diamin complex is available from this in accordance with the equation for the given solubility product s.

Mass coloration (spin dyeing). In this process (Fig.) also called jet dyeing, finely distributed dye pigments, which withstand the thermal and chemical demands of the spinning process, are added to the spinning solution/melting of synthetic fibres. Used, for example, in polyamide for upholstery fabrics, carpets, floor carpeting, automobile articles; in polyester for upholstery fabrics, menswear, work clothing.

1. Continuous process: dye is introduced to the already formed polymer (solid or molten state). Dye in powder or granule form is continuously distributed using dosage pumps and then mixed with polymer granules or chips, which supply the melting equipment (extruder or fixed melting furnace), or directly with molten polymer. Process is simple and flexible, but results in great variations in bright colours. Dyes (liquid or in paste form) are dispersed in binders (polymers of different molecular weights or polyethylene glycols of high molecular weight) and are injected into the molten polymer using additional extruder, which directly supplies the main extruder, in which polymer granules are melted.

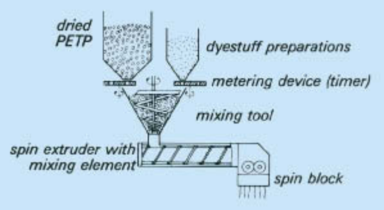

Fig.: Spin dyeing.

2. Discontinuous process for polyester: in a unit of production for the manufacture of polyester granules, the polyester chips are dried in a vacuum for several hours at 140–180°C in rotary driers or tumblers and at the end of this process specially selected dyes are added; they are fixed on polyester granules via thermodiffusion. Suitable process for the manufacture of small quantities of spin-dyed fibres/threads.

3. Discontinuous process for polyamide: Polyamide granules are simultaneously washed and dyed in the aqueous medium. After several hours drying at 180°C, it is melted under the same conditions as colourless granules. Granule dyeing is carried out in a machine with bath circulation.

It is indeed difficult to determine the cost difference between spin-dyeing and conventional dyeing even with only 10% accuracy; but it is estimated that the spin-dyeing of polyamide and polyester is 20–30% cheaper than dyeing according to normal processes. In addition, spin-dyeing has ecological advantages as well as simplicity and precision of technology. However, this type of dyeing cannot react to fashion trends in the short term and is therefore chiefly used for standard articles.

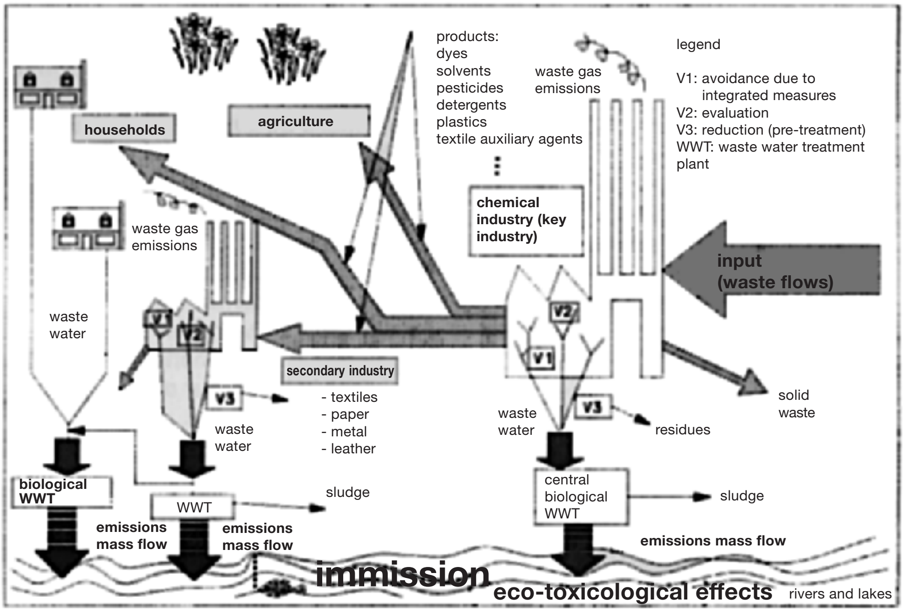

Fig. 1: Mass flows in the economic system (principal sketch diagram, according to Schönberger).

Mass flow In all areas, business with the associated process technology is linked to mass flows (material flows). The exhaust gas, solid waste and waste water accumulating from this are undesired mass flows. The wide use of raw materials and the application of products represent mass flows, which are normally desired or wanted (Fig. 1). Not only in the textile industry are undesired mass flows the subject of environmental protection efforts. It is necessary to avoid, exploit and reduce these and/or change these in the direction of better environmental compatibility. These aims can only be achieved cost-effectively and efficiently if the existing mass flow ratios are recorded and shown in detail. This should lead into a synchronisation of mass flow and associated flow of information (quantity and quality of the mass flow at the location x at the instant y) as is striven for and executed by the material flow logistics on the production side. In textile finishing, such an assessment and/or synchronisation can only be worked out relating to a procedure or process depending on the process stage due to the more or less strongly variable production processes. I.e. process-related emission factors should be established (in waste water quantity/kg of substrate, g of operating material in the waste water/kg of substrate, type of making up of finished textiles, application technique, etc.).

The initiative for recording the emission mass flows (environmental audit) should come from the individual textile finishing business itself with the aim of hurrying along the further reduction of the emission mass flows autonomously. This autonomy is legally supported by the self-monitoring regulation simply in Baden-Württemberg. The “general and production-specific self-monitoring” amongst others should be carried out in accordance with appendix 3 of this regulation (item 2.1 of appendix 3). According to this, the waste water-related materials used in production should be recorded at the internal waste water accumulation points according to type, quantity and composition (used material list). Self-monitoring also includes the following examinations at the waste water accumulation points from a drawn off waste water quantity of 50 m^3/day, in the field of textile finishing from 200 m^3/day:

– waste water accumulation according to type, composition, quantity, specific waste water load;
– the operating processes, in which specifically loaded waste water or cooling water accumulates;
– the possibility of improvement in waste water sepa-

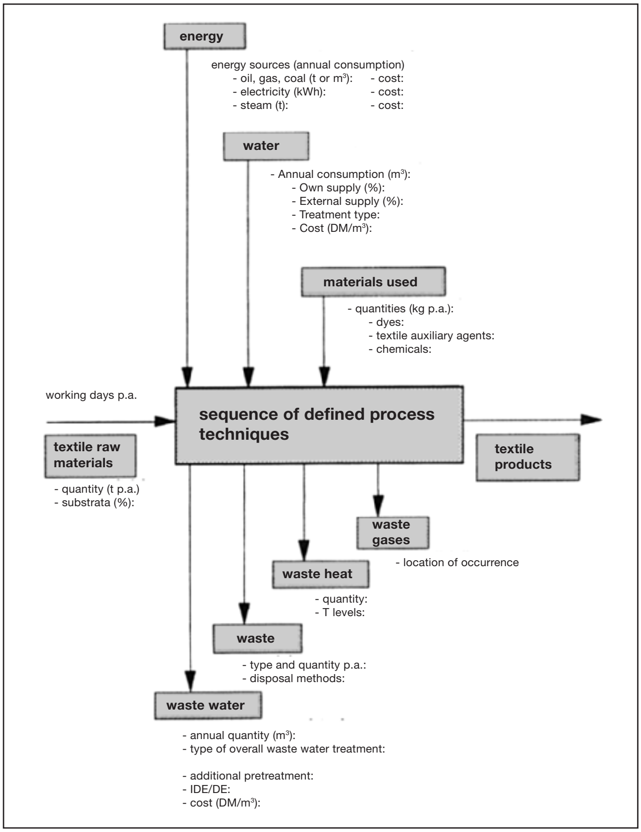

Fig. 2: Textile finishing operations: annual energy and mass flows (according to Schönberger).

ration (e.g. production waste water, waste water containing cyanide or chromate, rinse water, concentrates, etc.) and in segregated steam treatment;

- the possible measures for avoiding and reducing harmful pollutant loads within the meaning of § 7a WHG (Germany's → Water Resources Law);
- peculiarities, defects, possible remedial measures.

Waste water register is the synonym for the raising and representation of internal waste water/mass flow ratios. It should firstly be effectively drafted in a rough form, i.e. for the mass flows flowing within a year. As all energy and mass flows within the production flow together, this balance should be represented for all media (waste water and solid waste, exhaust gas and energy). While the annual survey of energy and mass flows shown in Fig. 2 is useful, this is only the case to a limited extent for considerably shorter periods of time (e.g. individual days). The reason lies in the continuous change in production (annual cycle, change of substrate, etc.). Finally a process-related stock-taking must be worked out as a very detailed plan concerning the determination of process- or procedure-related emissions factors, which are joined together to form a whole, the waste water register (multiplied with the respective substrate quantities and EDP supported).

So-called integral, all-media programmes for their avoidance, exploitation and reduction are possible on the basis of known mass and energy flow ratios. Unique solutions for the reduction of the emission mass flows associated with exhaust gases, solid waste and waste water are normally too uneconomic. Integral, all-media programmes also include energy flows. This will also be necessary in the future due to the Heat Utilization Ordinance (according to Schönberger).

Mass flow ratio in heat recovery (K), the ratio of the masses (m^2/m^1) indicates what proportion of fresh air (referring to the quantity of outgoing air) is supplied to the driers. K = 0.5 therefore means that 50% of the exhaust air filtered from the drier can be replaced by fresh air from the heat recovery plant.

Mass per unit length → Linear density of fibres and yarns.

Mass spectrometry Accelerated, positively charged particles are separated by a magnetic field proportional to their mass in the mass spectrometer. A mass spectrometer consists of the four functional areas of supplying samples, ionisation, mass separation and ionic detection. A fine molecular flow runs from the intake system into the ionic source and vertically meets an electron beam there, whose energy at 70 eV is:

$$M + e \longrightarrow M^+ + 2\,e$$

The molecular ions are accelerated and focused after abstraction of one or several electrons with 2–10 kV. The speed of the ions is thus:

$$z \cdot u = \frac{m \cdot v^2}{2}$$

$$v = \sqrt{\left(\frac{2 \cdot z \cdot u}{m}\right)}$$

z = ionic charge,
m = ionic mass,
v = ionic speed,
u = accelerating voltage.

The radical molecular ions which arise break into fragments, which are separated in the homogeneous field of approximately 1 teslar strong electron magnets based on their mass. The following applies for the deflection radius:

$$r = \frac{m \cdot v}{z \cdot B}$$

B = magnetic field strength.

The following results from this together with the first (speed) equation:

$$\frac{m}{z} = \frac{r^2\,B^2}{2\,u}$$

The masses of the fragments are determined by measurements of the deflection radii in the analyser part. Magnetic returns on the structure of the substance can be made from the fragments obtained in the analysis of the spectrum obtained, as this chiefly fragments at the weak bonded points.

Mass transfer kinetics Diffusion processes, whose mass transfer kinetics are associated with complex correlations, run both in dyeing (dye from liquor in fibres) and in washing (dirt from fibres in liquor) and in drying (water vapour from fibres in drying room). Dyeing processes in particular are extremely complicated procedures in their totality. In order to be able to understand them, you not only have to know the physical and chemical properties of the dyes and the substrates to be dyed; you also have to develop ideas as to how the diffusion and adsorption processes run physically and chemically. With the exception of pigment dyeing, all the other dyeing processes are based on sorption processes, whose transport processes are preset and which are often accompanied by chemical reactions. It is therefore difficult to describe these dyeing systems and the phenomena which arise in experiments accurately. Models, hypotheses and theories are needed for this. The more detailed such models are, the better the correspondence is between their statements and the experiment, but the more complicated are the formulae and equations necessary for their mathematical description as well. Finally, the mathematical terms are so complicated that approximation procedures (i.e. new hypotheses) are required to solve them, in which the model is however simplified again. There is no generally applicable dyeing theory where all the phenomena can be described clearly.

Interactions occur between the dye in the liquor and the dye on the fibre when dyeing cellulose fibres using direct dyes. In order to achieve a particular shade of colour, several dyes are normally needed, but the components influence each other mutually in such a combination. It is difficult to predict how a component of a mixture reacts in the equilibrium bath separation from the dye behaviour of the individual dyes. For prescribed calculations you can also recognise how these interactions should be included with the aid of colorimetry.

The affinity of the dye to the substrate is not only critical for the position of the equilibrium as a driving force in the dyeing process, but also for the kinetics of the dyeing process. The idea of Gouy-Chapman is used as the useful model for determining the dye equilibrium, in which the substrate is considered as an adsorbing surface. The following term is differentiated for the equilibrium distribution of a dye in a combination:

$$\ln (C_f/C_b) = A_0 - A_1 \cdot \frac{1}{\chi} - A_2 \cdot \frac{1}{\chi} \cdot \sum z_i \cdot C_{fi}$$

C_f, C_{fi}, C_b = equilibrium constants on the substrate and in the dyebath.

A_1, A_2 = constants to be determined in the experiment. They determine the electrostatic interaction between dye and dyed substrate. A_1 contains the charge-density, which should be considered as the parameter for the charge state of the substrate. A_2 contains the specific surface, which is accessible to the dye anions and represents another criterion for the dyeability of the substrate.

$\frac{1}{\chi}$ = Debye length, i.e. the distance from the surface according to which the potential is lowered to $^1/e$.

z_i = numbers of charges in the dye anions.

A_0 = standard affinity

This equation can be used for
- affinity tests,
- interpretations of diffusion coefficients,
- detection of interactions in the combination dyes using direct and reactive dyes,
- determination of the surface charge and internal dependence on the pre-treatment,
- computer colour matching of combination dyes.

The following material balance applies for the computer colour matching of any direct dye involved in a combination:

$$E = C_f + V \cdot C_b$$

E = dye application (g/kg),
V = liquor ratio (l/kg).

Using this equilibrium system, the applied dye C_f can be calculated according to an iteration principle. A high bath separation is not always desired due to the unfavourable levelling behaviour associated with it. In these cases the salt addition can be, which is required for a planned bath separation, calculating using the above equations.

Problems do not only arise when dyeing with dye mixtures, but also when dyeing with substrate mixtures (e.g. cotton/viscose). If both substrates are dyed in separate baths, the difference in the shade of colour is less pronounced than when dyeing out of a common bath, in which the viscose fibres really absorb a dye more deeply than cotton. If the substantivity characteristics A_0, A_1 and A_2 of both dyes are available on both substrates, this situation can be recorded arithmetically.

The following equation system applies for each dye involved in the combination:

for substrate 1:

$$\ln (C_{f1}/C_b) = (A_{01} - A_{11}) \cdot \frac{1}{\chi} - A_{21} \cdot \frac{1}{\chi} \cdot \sum z_i C_{fi1}$$

for substrate 2:

$$\ln (C_{f2}/C_b) = (A_{02} - A_{12}) \cdot \frac{1}{\chi} - A_{22} \cdot \frac{1}{\chi} \cdot \sum z_i C_{fi2}$$

and the material balance:

$$E = m_1 C_{f1} + m_2 C_{f2} + V \cdot C_b$$

m_1, m_2 = percentages by weight of substrate 1 and 2 resp. (kg/kg); ($m_1 + m_2 = 1$),
C_{f1}, C_{f2} = dye absorbed by substrate 1 and 2 resp. (g/kg),
C_b = dye concentration in the dyebath (g/l).

The mass transfer between textiles and liquor is one of the most important process elements in textile finishing. In order to make the process kinetics controllable, adjustable and optimisable, it is necessary to know the transport mechanisms, the kinetic constants and the position of the exchange equilibria. In contrast to simple chemical reactions, which occur in the homogeneous phase, textile finishing processes take place in the heterogeneous phase. The phase surface between the fluid phase (liquor) and the solid phase (substrate) is a char-

Fig. 1: Formal description of the mass transfer system.

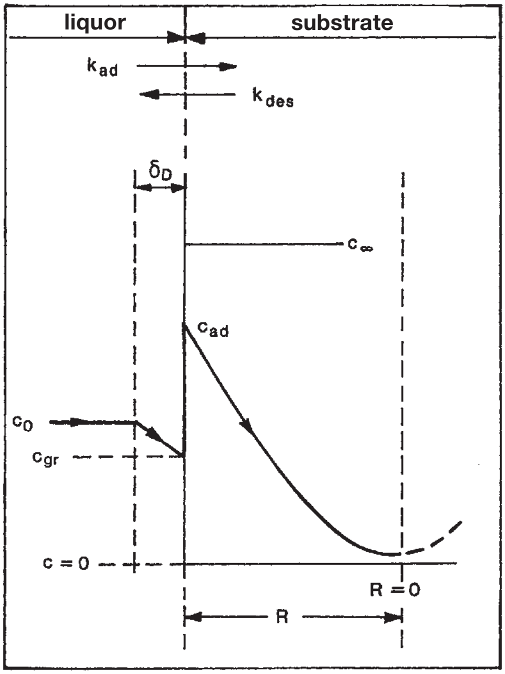

Fig. 2: Schematic diagram of the radial concentration profile on the substrate surface (Gerber).

acteristic feature. The mass transfer equation, which describes the mass flow from phase 1 into phase 2 (see Fig. 1), contains a kinetic term (the mass transfer coefficient β), a material-specific term (the surface range O) and a concentration term, which is also a measurement of the motive power of the mass transfer. The mass transfer causes a drop in dye concentration on the substrate surface range. This concentration deficit is in practice compensated for by the impinging flow of the substrate surface range. The strength of the hydrodynamic boundary layer is important in this connection (see Fig. 2).

A diffusion boundary layer forms into a transport resistance through mass transfer. The actual importance of liquor convection lies in the clearing away of this boundary layer and in the replacement with fresh, unspent liquor (liquor exchange). The strength of the diffusion boundary layer is critical for influencing the speed of this mass transfer. The hydrodynamic boundary layer is thick in laminar flow; thinner however in turbulent flow. Great impinging flow accelerates the finishing process. Unlevel dyeing may also be flow-dependent. The accuracy of test dyeings is therefore crucially determined by the adjustment of the flow profile in the laboratory.

Convective diffusion is the most efficient model for mass transfer in textile finishing processes: The competition between transport mechanics in the direction of convection (flowing liquor) and transport mechanics in the direction of diffusion (exhausting dye) represents the transport mechanics from the phase limit. The knowledge of the speed law of dye uptake under the current dye conditions in the fibre/liquor/degree of dye system is crucial for the optimised arrangement of dye processes. The test dyeings necessary for this, in particular for short dyeing times, require a defined sample packing and impinging flow of the fibre surface range.

Dyeings show that the integral dye uptake does not directly depend on the time in the form of R(t). The dyeing process can be treated from a formal, kinetic view as a dilution of two simultaneously accessible reservoirs for the dye. The integral dye uptake is described by:

$$\begin{aligned} c\ (t) &= c_1\ (t) + c_2\ (t) \\ c_1\ (t) &= c_1, \infty \cdot [1 - \exp(-k_1 \cdot t)] \\ c_2\ (t) &= c_2, \infty \cdot [1 - \exp(-k_2 \cdot t)] \\ c_F, \infty &= c_1, \infty + c_2, \infty \end{aligned}$$

c(t) = dye concentration on the fibre at the moment t,
c_1 (t), c_2 (t) = dye concentrations in reservoirs 1 and 2 at the moment t,
k_1, k_2 = speed constants in partial processes 1 and 2,
c_F, ∞ = dye concentration on the fibre in equilibrium,
c_1, ∞, c_2, ∞ = equilibrium concentrations in reservoirs 1 and 2.

The numerically determined speed and equilibrium constants represent characteristic properties of the liquor and the substrate. They give the access to the simulation of the dyeing system. The bath exhaustion of a separation dyehouse can be calculated in the same way as the exchange factor for continuous dyeing. Models of a cotton dyeing process derived from experiments can be explained by the morphological structures of fibres, whereby the quickly accessible reservoir represents the primary wall and the slower accessible the internal surface range of the secondary wall (Fig. 3).

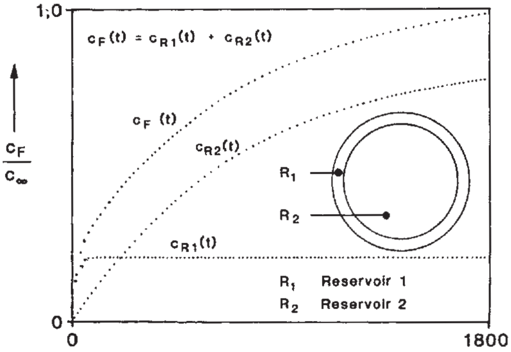

Fig. 3: Model of the substantive dyeing of cotton (according to Elgert).

The time/temperature programme is not predominant when simulating the dyeing process on the screen, but the exhaust curve. It clearly indicates the mass transfer between the liquor and the fibre material. In order to make it more clear, it is shown in time-lapse photography. So a process simulation tries to calculate an exhaust curve (i.e. “mass transfer”), which lies as closely as possible to the curves for control dyeings, from a few parameters for dye, fibre material and dyeing processes. The example of polyester bath dyeing using good combinable disperse dyes shows how you can construct a dyeing process simulation, how it works and for what you can use them. The prerequisites for the validity of the mathematical model are

– uniform fibre material,
– dyeing using disperse dyes according to the exhaustion process,
– finite bath,
– constant heating-up speed or constant (isothermal) temperature,
– process control in which no noticeable unlevel dyeings arise,
– constant liquor ratio.

A mathematical model for the transfer of the disperse dye between liquor and polyester material is the basis. It is based on the “dispersion depot” of dye in the initial dyeing range (DD range) and on the solubilised dye in the final dyeing range, which is exhausted (SE range). Building on a few functions, the DD/SE model, which assembles the dyeing process as made of two successive ranges, was constructed:

1. Disperse dye depot (DD range): the dye is available as a dispersion, turns into a solution from this monomolecular (at any rate low molecular) state and covers the fibres in this state. The concentration of monomolecular dye in the liquor remains roughly constant corresponding to an infinite bath due to rapid dye delivery from the “dispersed dye” depot. The rate of dyeing increases through constant heating up of the liquor. The course of the exhaust curve is either approached by a logarithmic function or by an ascending e-function (DD/SE model):

$$\mathrm{CTX}\ [\mathrm{g/kg}] = A \cdot (e^{-\mathrm{FSV} \cdot \mathrm{ZTM}} - 1)$$

CTX = dye concentration in textiles,
FSV = dye loss,
ZTM = (dyeing) time in min

2. Range of fully solvatised dye and the exhaustion of the bath (SE range): when the dispersed dye is used up by the exhaustion, only dissolved (solvatised, solubilised) dye remains and the bath is exhausted. The rate of dyeing continually decreases until it reaches equilibrium. The exhaustion can be described using an e-function, which approaches the final bath exhaustion as the threshold limit value:

$$\mathrm{CTX}\ [\mathrm{g/kg}] = C_\infty + (1 - e^{-k^* \mathrm{ZTM}})$$

The transmission point between both ranges (DD, SE) is macroscopically the turning point of the exhaust curve and microscopically the dissolving point (temperature, concentration) of the disperse dye, which indicates that the depot is used up.

The DD/SE model (Fig. 4) can be put to good use in numerous respects:

– time/temperature programmes can be constructed in order to produce exhaust curves;
– Knowledge about the mass transfer system can be extended;
– it is useful as an original test tool for detecting faults and for optimising practice dyeings;
– it illustrates representations of curves;
– Parameters are obtained, which bring extended knowledge, e.g. with regard to dye (diffusion constant and solubility), auxiliaries (dispersing effect and hydrotropic property) and fibre material (glass transition temperature range and accompanying activation energy).

Diffusion processes also operate in drying processes with characteristic mass and energy transfer kinetics. If a heating wire is centrally stretched out and heated in a

Mass transfer kinetics

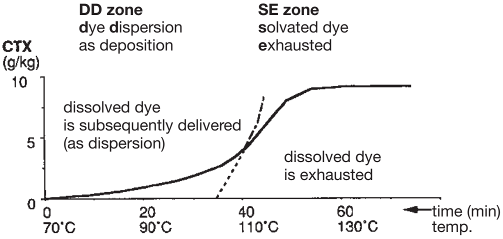

Fig. 4: Disperse dye deposition (DD) and bath solvation and exhaustion (SE) zones in the polyester process.

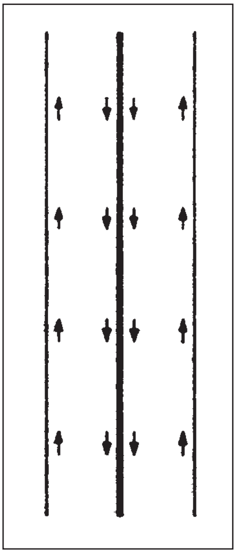

Fig. 5: Convection currents in the thermodiffusion pipe.

narrow, vertical tube with the aid of a weight, thermodiffusion takes place in the temperature difference between the cold wall and the hot wire (Fig. 5). This convectional flow is directed against gravity, i.e. upwards, near the hot wire; correspondingly downwards in the cold sheath of the tube. So, all in all, a flow of components, which endeavour to accumulate in the warmer part of the equipment in the thermodiffusion, continually takes place upwards and a flow of other components downwards until a more stationary state is reset.

Energy is consumed in the heating of air dry textiles through the heating up of fibres and through the volatilisation of the relatively low moisture content available. Instead of the specific heat c of the moist textiles, its reduced specific heat c_r is however authoritative for quantitative statements on the drying of a fibre. This should be interpreted as follows: the initial moisture content f_0 [kg/kg] is reduced to f [kg/kg] in air dry mass which occurs. The volatilisation and binding heat r' [kJ/kg] is the expended heat of volatilising: $(f_0 - f)\,r'$.

The heating-up time of the textile results from:

$$\frac{\vartheta(x,\tau)}{\vartheta_A} = f\left(Bi,\ Fo,\ \frac{x}{s/2}\right)$$

$\vartheta(x,\tau)$ = difference between the actual temperature t (x; τ) defined in place x and time τ and the constant ambient temperature t_U, so i.e.
$\vartheta(x,\tau) = t(x,\tau) - t_U$

a = temperature conductivity, represented by the term
$a = \frac{\lambda}{c\,\rho}$

λ = thermal conductivity of the material;

c = specific heat of the material;

ρ = material density;

ϑA = initial difference between fabric and ambient temperature, i.e.
$\vartheta_A = t_A - t_U$;

Bi = dimensionless number, characterised by the relation
$Bi = \frac{\alpha s}{2\lambda}$;

α = heat transmission number;

s = fabric thickness;

Fo = dimensionless criterion, defined by the relation
$Fo = \frac{a\,\tau}{(s/2)^2}$

τ = heating-up time sought for textile fabrics.

Thermal diffusion develops when temperature differences are balanced in gases. Convection is then the transfer of heat energy, which is accompanied by a flow. Exogenous forces may intensify the convection. Forced flow can appear as an exogenous force. So, for example, turbulence is a motion state (flow) of gas with statically unordered character of paths of gas molecules, which flow forming whirls. Flow through a tube is turbulent when the Reynolds number Re_{krit} becomes = 2320 with an irregular stenter. Turbulence develops from the laminar boundary layer (on an interface). The layers of a stationary moved gas phase slide past each other without whirl formation with pure laminar flow.

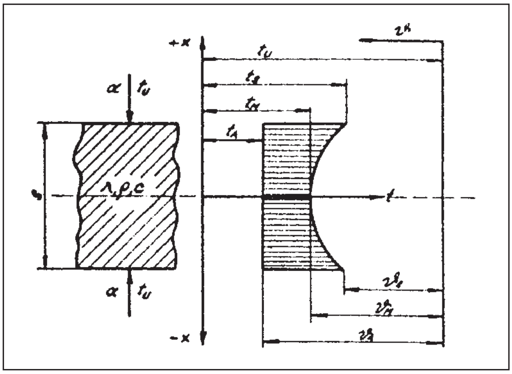

Fig. 6: The temperature profile in a textile fabric during heating.

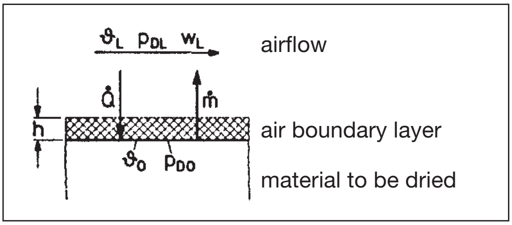

Fig. 7: Heat and fabric flow in the first drying section.

Two opposite flows flow through the laminar boundary layer of a moist textile which is heating up: the heat flow $\dot{Q}$ and the mass flow $\dot{m}$. In the 1st drying phase the volatilisation takes place on the surface area of the material (Fig. 7). This process is caused by heat transfer from the hot air via the boundary layer to the surface area and by transport of the vapour formed via the boundary layer to the air, whereby only the boundary layer appears as resistance. These processes can be described by the following equations:

$$\dot{Q} = A \cdot \alpha\,(\vartheta_L - \vartheta_O)$$

$$\dot{m} = A \cdot \frac{\beta}{R_D \cdot T}\,(p_{DO} - p_{DL})$$

$$\alpha = \frac{\lambda_L}{h}; \quad \beta = \frac{D}{h}$$

A = fabric involved in the transfer [m^2],
α = heat transfer coefficient [$W/m^2\,K$],
β = mass transmission coefficient [m/s],
ϑ_L, ϑ_O = temperatures of the drying air and the material surface area [^oC],
ρ_{DO}, ρ_{DL} = partial vapour pressure on the surface area and in the drying air resp. [N/m^2],
λ = thermal conductivity in the boundary layer [W/mK],
D = diffusion coefficient [m^2/s].

The state of the drying medium is described by the temperature ϑ_L and by the prevailing partial vapour pressure ρ_{DL}. The state of the drying material is determined by its temperature ϑ_O and the prevailing vapour pressure on its surface area ρ_{DO}. An equilibrium must exist between supplied heat and volatilised water quantity in the steady state, i.e.

$$\dot{Q} = \dot{m} \cdot r$$

and so

$$\dot{m} = \frac{A}{r} \cdot \alpha\,(\vartheta_L - \vartheta_O)$$

The scale of the heat transmission number α is chiefly determined by the intensity of the spray system, by the nozzle geometry as well as the distance between nozzle and fabric. So the heat transmission number is in the end a drying constant, as is the exchange area A (drier size), so that at constant spraying only the temperature difference (ϑ_L - ϑ_O) determines the transferable heat quantity and therefore the rate of evaporation. The heat and mass flow and/or the rate of drying may be determined from external conditions alone in this drying phase, i.e. independently from the material properties of the drying material. An increase in the rate of drying can therefore only be achieved by

1. increase in the temperature and partial vapour pressure difference between material surface area and air.
2. increase in the heat transmission and mass transmission values by increasing the speed of the drying air, which impinges the surface area, whereby the boundary layer thickness and therefore the resistance becomes smaller.
3. increase in the area involved in the heat and mass transmission.

(according to Dierkes and also to Gerber, Elgert and Rüttiger).

Mastic Greek tree resin; transparent drops, pea-size, pollinated outside, pale yellowish green (rarely reddish), malleable/sticking together when chewed. Bitter aromatic taste, glass gleaming break, softens at 80°C, melts at 105–120°C. Soluble in ether, benzene, xylene; partially soluble in alcohol, acetone, chloroform, turpentine. Distortions: often due to sandarac gum (never round drops, long stems, not softening when chewed, but powdery, only partially soluble in ethereal oils, much cheaper), colophony also powdered (solubility, high acid value), synthetic green dyeing using indigo. Easily soluble in ether, benzene ether and oils; up to approx. 90% in cold water. Application: dammar resin.

Matelassé Jacquard double cloth made from 2 chain and 3–4 weft systems, whose patterned fabrics emerge malleable, as if “padded”; resin finished. Application: coats, suits and garments, furniture covers.

Material,

I. (from Latin: materia = mother fabric), raw material, material, auxiliary, e.g. fibre material, dyeing material, sample material.

II. Generally, in the sense of → Woven fabric.

Material balance Concerns balancing of operational input and output values of dyes, chemicals, auxiliaries, work procedures, water (→ Waste water balance), etc. Intends to establish by product which substances accumulate in what quantity at which location. The resulting secondary products produced in the decomposition show how these react with the remaining constituents in the air and waste water. Helps to grasp

Material balance

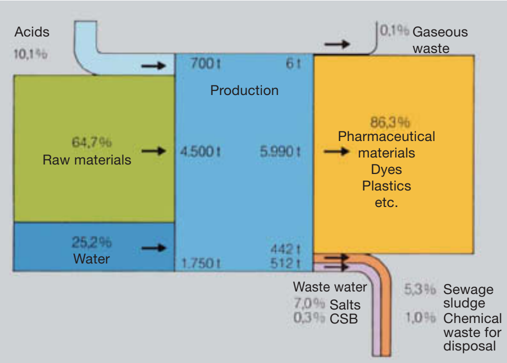

Fig. 1: Material balance in the Hoechst main factory in t per day (excl. fuels, cooling water, domestic-type waste, packaging and similar).

specific measures for the reduction of the waste water and exhaust air load and to prevent ecologically harmful waste materials from forming unchecked. In a dyeing recipe, for example, the kg input of dyes, chemicals, textile auxiliaries, water, etc. are balanced against the kg output of decay rate as waste water (salts, organic substances, water), exhaust gas (e.g. chlorine, ammonia) and any remains as solid waste (→ Ecological problems in textile dyeing, printing and finishing). In recent years, exhaust air cleaning plants, waste water treatment and waste incineration have been developed, which are connected to the production procedures. Pollution control does not however firstly start with the later disposal of exhaust air, waste water or solid waste, but already in the optimisation of production procedures. Only through this is it possible to consider all the factors such as also saving raw materials and energy. Though not all environmental problems can be solved by new procedure plans in accordance with the principle of reducing residues. You cannot completely do without connected measures. The following therefore applies:

- to develop and apply procedures, with which as little waste as possible is produced; waste is always lost raw material.
- reprocessing, recycling and reuse of waste; raw materials are also reclaimed here, but often at great expenditure.
- improvement in the processes for waste water treatment and cleaning exhaust air.

However each of these measures precedes a material flow absorption. The resulting product quantity diagram (Fig. 1) represents on the left all the output materials used in a process or in a finishing business; on the right all the finished products are listed together with the by-product level and as quantitatively as possible on both sides. Conclusions for suitable improvements can be drawn from the balance.

Zero values of emissions cannot be achieved thermodynamically. They still occur in the material flow of a large chemical plant even after pollution control measures

- in exhaust gas up to 0.1%,
- in waste water up to 7.0% as salts and 0.3% as organic added stabilisers,

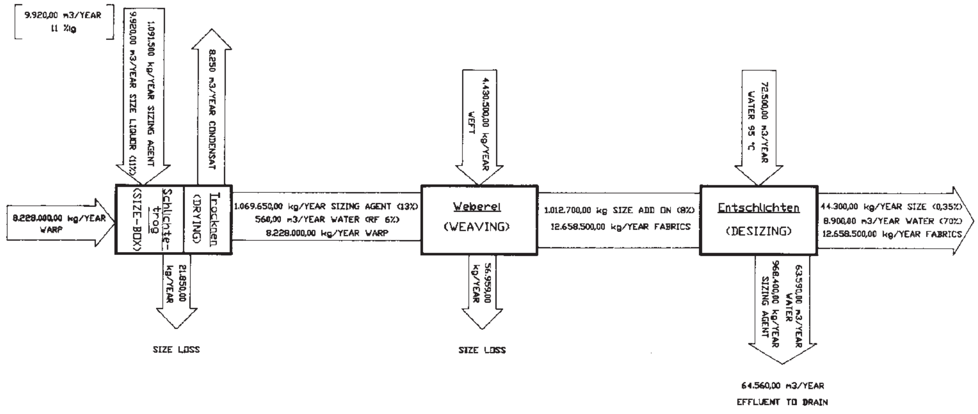

Fig. 2: Material balance without recycling of sizing polymers for a weekly production of 780 000 m fabric.

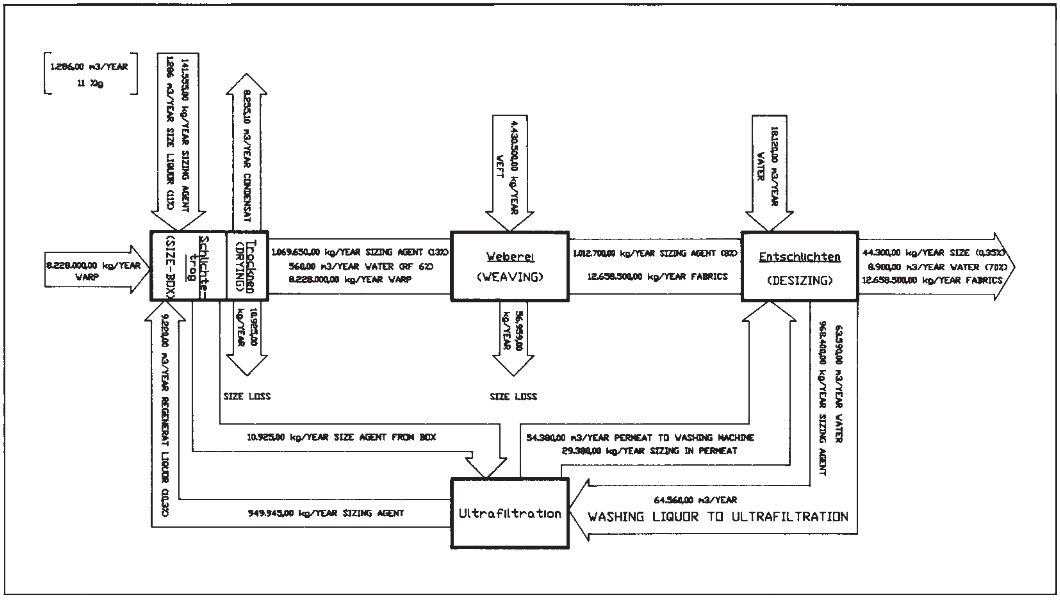

Fig. 3: Material balance with recycling (by GTV) for a weekly production of 780 000 m fabric.

– as waste, i.e. 5.3% sludge, 1.0% chemical waste to the waste disposal site.

In order to install size recycling between desizing and weaving preparation (Fig. 2), a material balance should be constructed beforehand, which can be compared with the success of the size recovery (Fig. 3).

Material carrier is used for the absorption of the dyeing material in the form of crosswound yarn packages, tubeless cross-wound yarn packages (bobbins), card slivers, spinning cake, loose material (loose stock), hank yarn and woven ribbons in circulating liquor machine dyeing.

Material ecology concerns the ecological aspect for materials, whose evaluation should in future no longer be restricted solely to its technical use in the completion of conventional material testing, but should also consider the damage to the environment. Production and products should be sustainably environmentally compatible.

Material flow The logistics in an industrial undertaking are the planning of demand, output, time and space as well as the monitoring and implementation of a planned material flow in view of the optimum cost. The term “quick response” is increasingly gaining in importance in the fashion-oriented market event and requires quick reaction to customers’ wishes exploiting logistic and economic material parameters of the sales market. Fig. 1 shows the material flow in a hypothetical textile operation from the order to the delivery, in a simplified form.

The production process in a yarn dyeing business is multistage and has different processing stages and times depending on yarn quality and requirements of the finished product. The path, which the raw yarn takes from delivery to the finished dyed package, is shown in Fig. 2: Material flow for a yarn dye works. Each package must be individually picked up at least twice, but in most cases 6–10 times, depending on the process. For a production of 10 000 packages per day, this results in more than 60 000 necessary operations. So, a total weight of more than 60 000 kg must be moved. Another 6–12 transport operations of pallets, boxes and dye carriers are added to this. These figures clearly show that transport and handling are labour-intensive and a considerable cost factor in high-wage countries. It is also physically hard and unattractive work.

The dyeing process lasting 4–8 hours operates fully automatically in many dyehouses on the basis of process control as well as automated chemical metering and a colour kitchen. The following manual operations are still required:

– monitoring of the process run on the PC usually centrally in the head dyeing office.
– loading and unloading of the equipment as well as designs by the operator.
– possible weighing up and release of dyes and chemicals according to the recipe in the colour kitchen, if this is not already automated as well.

Such an equipped dyehouse can be operated using 2–3

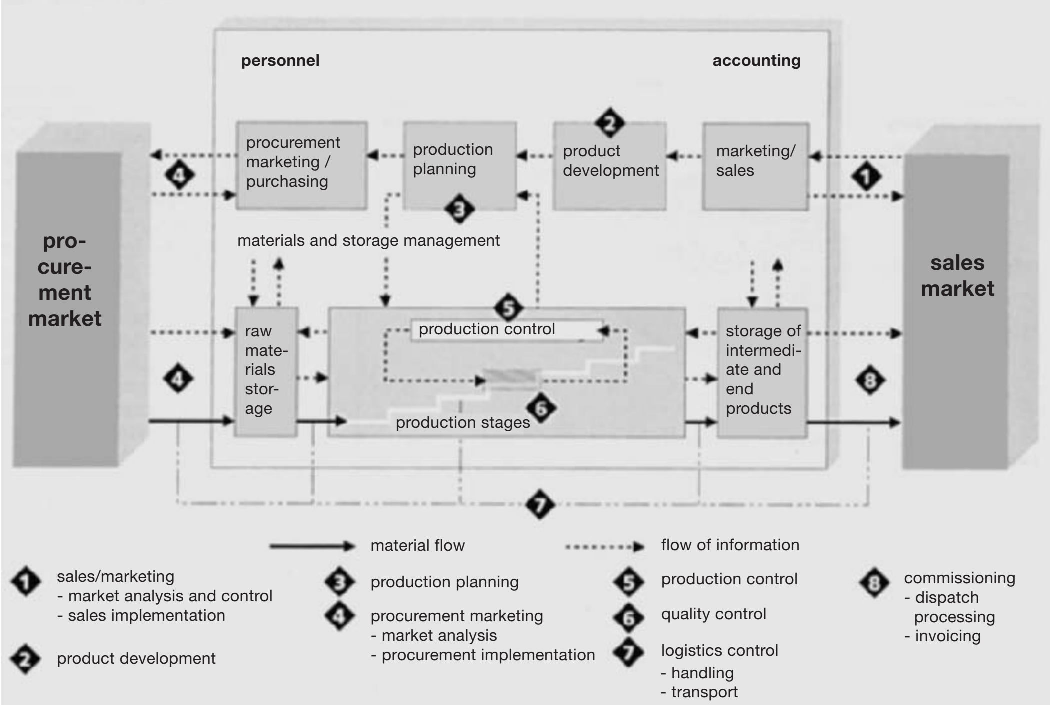

Fig. 1: Material flow in a hypothetical textile plant (according to Bug and Fischer).

persons, 10–15 machines and an ejection of approximately 3–4 tonnes per layer.

Materials Business and technology place ever more varied demands on materials. The areas of application and correspondingly material properties required are becoming more diverse with the increasing expansion of technology in the field of human life. Materials in their conventional form could not however or only incompletely satisfy these requirements. The resulting adaptation of materials to the altered conditions resulted in a multitude of previously unknown types of material: firstly completely new materials; secondly modifications of known materials; and finally combinations of materials with the purpose of uniting the properties of several materials in one. The so-called → Composites represent one section of the last group – combinations of a particular type of materials with the aim of the best possible adaptation of a material to its purpose.

There has not been a standardised and generally applicable definition of the term material until now; in general a material is understood to mean such which is used for the mechanical production of necessary items provided that it is an essential component of the end product. Material is a generic term for all material assets somehow used with regard to production in the manufacturing process, which are effective in the production process through the use of their material substance. In the broader sense, all material agents, which are also used outside the productive sphere to achieve some purpose or other, whereby the use of the material substance is not necessarily required, are thus summarised.

Each material holds a functional purpose; it is only useful due to its purpose. An absolute “material” is inconceivable without relation to a purpose. Nothing at all alters the fact that one and the same material may well serve several purposes. A material is therefore a technical processing material with at least one purpose. The concept of the quality of a material should correspondingly be tackled, namely as the degree of its suitability for the respective purpose. As a material may be good for one purpose, but unsuitable for another, an absolute definition of quality cannot be defined either. A strict relation to the purpose should be observed.

The properties inherent in a material stay together in a very particular proportion, which can only be modified in relatively restricted limits. The reason for this low modifiability mostly has its roots in the nature of the material; the range of modification is correspondingly of varying breadth for the different materials. The often mutually dependent material properties therefore stick together in a more or less fixed combination,

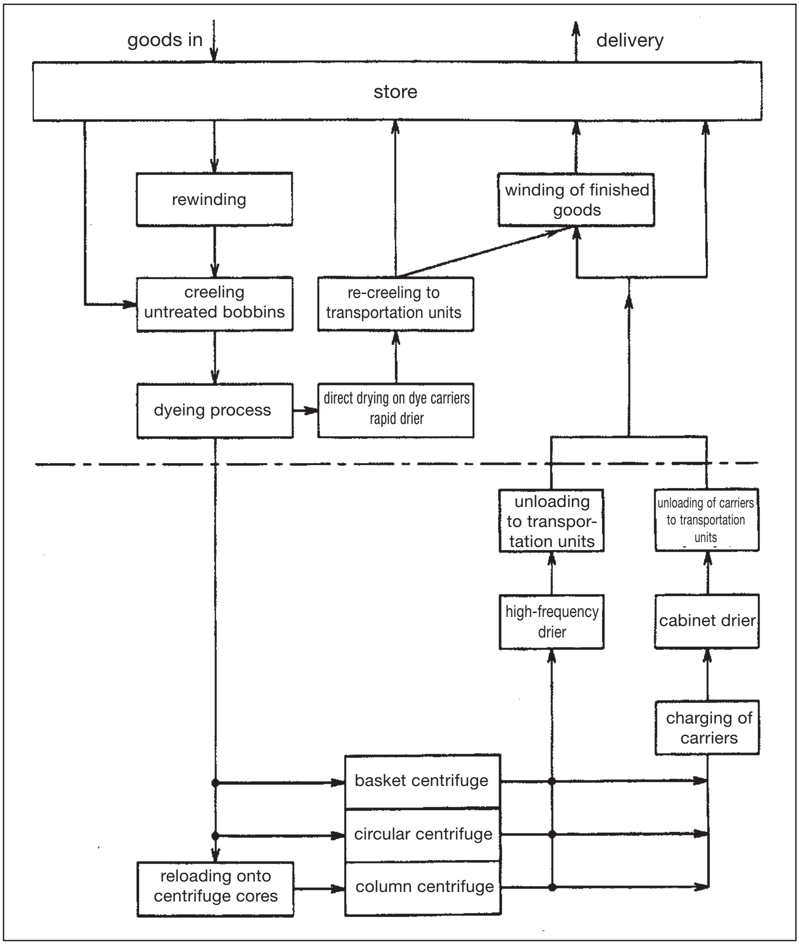

Fig. 2: Material flow for a yarn dye plant (Scholl).

which in its totality only corresponds exactly to the requirements of the purpose in exceptional cases. Rather deviations will appear in many points, which reduce the degree of suitability of the material. If these properties could be altered in isolation, it would be possible to achieve the most extensive adaptation to the purpose and thereby increase suitability through gradual modification of the original material. Partial alteration is hardly possible, however, due to the fixed combination of the properties to each other mentioned; the change of one property simultaneously also causes the alteration of others. In the manufacture and processing of some materials it is possible to achieve a partial preference of the properties regarded as particularly important by using particular technical processes. So growth of property is attempted: partial change of individual material data. As this concerns the attempt to improve the quality of a material, whereby the nature of the material extensively remains unchanged, the term “compensation” seems made for it. This term was previously almost exclusively used in the special treatment of steel; it has its alternative in the aimed property change of textile fibres in the term “textile finishing”.

The paramount importance of materials for the development of humanity is expressed in the names Stone Age, Bronze Age and Iron Age for the three great historical periods of development. Although it has become uncustomary amongst the people of the modern age to name periods of time after the most important materials, these have not lost any of their importance for the technical, civilisation and cultural progress. Not only the fact that they change the living and working habits as previously, more than ever they stimulate growth in many sectors of the economy and become breeding-grounds for new technologies and the starting point of a new quality of life.

Fundamental new discoveries and economic advances in the field of solid-state physics and chemistry were the prerequisite for the development of a multitude of new and improved materials. Newly developed, extremely sophisticated research methods have provided a very crucial contribution to this in the last 30 years. The most important contribution to science thereby consisted in the resolution of the correlations between the externally measurable properties of a material and its molecular structure, the inner structure. This structure is also often described as inner architecture. Science demonstrated that the inner architecture of materials consists of a hierarchy of structural levels constructed on top of each other. The big differences in the behaviour of the different materials could only be explained using the decoding of the detailed molecular structure and this highly complicated architecture.

The precise geometric arrangement of the atoms in the crystal lattice of crystalline materials including the exact atomic intervals even for the most complicated structure can, for example, be explained using the methods of solid-state research. The physical properties, which an ideally structured crystalline material might have, can be calculated in advance from this with the aid of computer programs. The pure research has also led to a better understanding of the correlations between the chemical structure and the spatial packing of molecules as well as the macroscopic properties in the field of polymers. This opened up new paths for the development of more innovative and improved materials. The conformation, i.e. the spatial arrangement of polymer molecules, can be determined with the aid of modern spectroscopic methods, such as the two dimensional nuclear magnetic resonance spectroscopy. The "molecular modelling" allows the motion processes within macromolecules to be studied and important characteristics to be derived from it. Shape and preferred mutual arrangement of macromolecules can be calculated and graphically shown as a bar or collar model using the "Computer-aided Molecular Design" (CAMD). Over and above that, motion processes in macromolecules, such as are triggered by an increase in temperature, can thereby also be tracked dynamically on a screen. The long-term goal of this still dawning development is to give valuable advice on the synthesis of new polymers to the chemist through continual dialogue with the theorist. It is important for the understanding of the behaviour of ceramic materials to clarify the influence of foreign matters in material molecules. They may appear as contaminants and lead to a reduction in quality or even unusability. Or they may be added to materials with the aim of improving certain properties. Just one foreign particle of a few thousandth millimetres in diameter may be a trigger for the breakage of a ceramic component with mechanical loading. When milling silicon nitride in a steel mill, e.g., contaminants with microscopically small iron particles may arise in the material powder due to abrasion. These in turn endanger the durability of the turbo-charged rotors made from silicon nitride. Conversely the specific adding of foreign, inert materials, i.e. those incapable of reacting, often leads to composite materials, whose positive properties are added. Another cause of changed properties in materials may be the exchange of existing atoms with foreign ones. The consequences here are sometimes beneficial, sometimes disadvantageous as well.

Materials handling technology In the clothing industry the automatic handling of individual parts through production and in intermediate storage is state-of-the-art. Semi-finished and finished products are also transported in spinning and additionally in weaving using suspension materials handling technology. In finishing plants materials handling technology is, however, rather unusual due to the multitude of finishing steps and the varying processing sequences.

Material, textile Fabric, material, e.g. dyeing material, cleaning material, textile material; should always be regarded as fibre loading in the technical finishing sense.

Matrix (Lat.: mother substance),

I. So-called cement substance in → Wool structure.

II. Ordered diagram of values for particular calculating rules, location diagram.

Matrix fibre → Bicomponent fibres, from M/F (matrix-fibril) type.

Matrix-fibril bicomponent fibre (ultra-bicomponent fibre, Island in the sea fibre), a real multi-component fibre in accordance with the matrix-fibril type. After the release of the matrix component, fibres with a fine titre, whose number and titre are pre-programmable, remain in a high yield.

Matrix-fibril fibres (→ Bicomponent fibres of the M/F type), several fine filaments (fibrils) are pressed out of a nozzle hole in the lattice, i.e. simultaneously and in a relatively large titre, and distributed into individual filaments (fibrils) in a subsequent step in the process. The individual filaments thereby consist of a matrix (e.g. polyamide) and fine fibrils (e.g. polyester). The matrix component selected is generally as small as possible. It amounts to 5–20% of the fibre depending on the titre and area of application. The matrix-fibril fibre can be separated relatively easily on the basis of the only low adhesion between polyester and polyamide. This takes place via shrinkage processes of one of the two partners with the aid of suitable solvents (Figs. 1–2) via treatment with alkaline solutions or via thermal-mechanical influences, e.g. on the hot plate of a texturizing machine. Combinations of several basic polymers are possible, in so far as the splitting up permits its mutual adhesion, i.e. if they are sufficiently incompatible with each other. The so-called orange profile type has proven to be particularly suitable in the polyester/polyamide 6 combination, amongst many cross-section and polymer options.

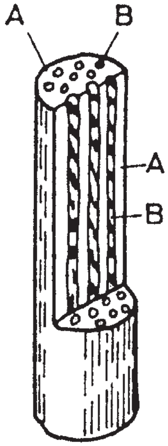

Fig. 1: Structure of the initial multi-component fibre. Multi-component fibre of polymers with varying solvent solubility (by Atzo).
A = embedding component (matrix) is soluble; B = capillary fibrils.

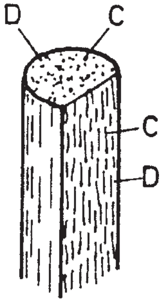

Fig. 2: Structure of the capillary fibrils B (from Fig. 1).
C = superfine fibrils (approx. 0.1 dtex); D = embedding matrix components, also soluble (usually with A).

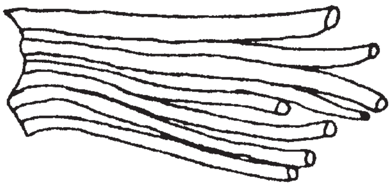

Fig. 3: Superfine fibril bundle after solution of the matrix (Akzo).

Yarns made from medium-sized bicomponent filaments can be texturized. The polyamide matrix melts locally using the correspondingly adjusted thermal treatment, whereby the direct compound of both polymers is transformed into a selective one (Fig. 3). The filament yarns can also still be processed without a coating as chains on all weaving machines, in this form. The selective connecting points between the matrix and the fine fibres are forced open in the finishing of woven fabric by triggering the different shrinkage behaviour of both polymers. Yarns then consequently exist with essentially more individual filaments than in yarn or fabric manufacture. In the case of a filament yarn of 50 dtex f 15, whereby the 15 individual filaments have a cross-section of a “6 orange”, there are 90 fine polyester filaments and 15 polyamide fibre-style fabrics (Figs. 4–5). Such filament yarns give fabrics new properties. Not only is the handle influenced, but the visual effect is also altered and the wearing comfort made of manufactured textiles. (→ Microfibres).

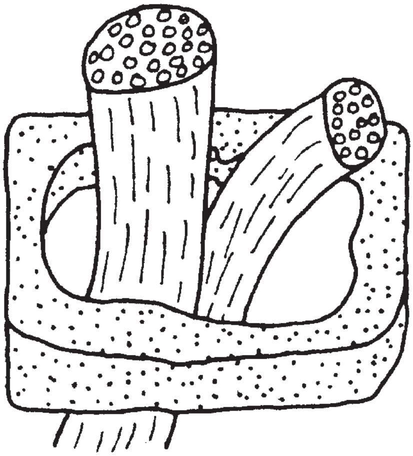

Fig. 4: Ultrafine fibres in bundle form before leaching out of the matrix (Akzo).

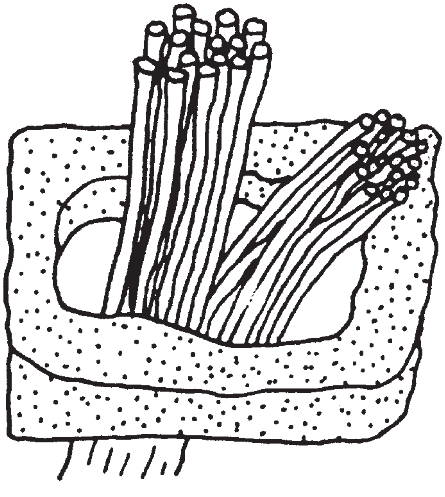

Fig. 5: Fibre following leaching out of the matrix (Akzo).

Matrix memory Magnetic structural memory. The rows and/or columns are represented by conducting or live circuits, for example, of a central memory. Exactly one memory cell of the matrix memory is activated by exciting a column or row circuit. It is also used as read-only memory.

Mats Pile-free, usually braided or woven underfloor coverings made of bast fibres. Also made of gum, plastic and fine metal filaments as door models.

Matting of wool The undesired → Felting of wool.

Matt printing → Pigment printing.

Mattress ticking Made of cotton, viscose, linen union and more rarely pure linen. Shank and Jacquard patterned fabrics are distinguished. The shank fabrics are self-coloured, coloured in stripes or they show a small figure design. The Jacquard materials have a large figure design. Markedly high strength values (mattress drill) are required from these materials. Twill and satin are considered as a weave. The Jacquard materials usually have a 5 or 8 shank chain satin in the base; the formation of figures takes place using the weft effect. Mattress ticking is difficult to obtain on the market as fabric by the meter, as these linings are usually sold in finished fitted form.

Matt white printing Printing using pastes, which contain white pigments and binders. Often used on dyed material.

Mauritius hemp (fibre), similar to sisal → Hard fibre, which is longer and more flexible than this, but has lower strength (approx. 10–20 cN/tex); not a type of hemp. Occurrence: Mauritius (aloe fibre), Brazil (pita fibre), Central America (fique fibre), West Indies and East Africa inter alia. Used for rope goods and sackcloth.

Mauveine (aniline purple), first synthetic (cationic) dye, which the then 18 year old Perkin discovered by chance in 1856 (called aniline purple, later mauveine, Perkin's mauve, Perkin violet) and a few years later industrially manufactured on a large scale, whereby he also thoroughly understood how to solve the application problems.

Max. International abbrev. for maximum, maximum peak value.

Maximum immission concentration Permitted immission concentration for air polluted substances, which may have an effect on the environment outside workplaces. These values apply to single appearance in the atmosphere. Maximum immission concentration k limits the permitted peak concentrations to 10–30 min. max., while maximum immission concentration d represents permitted average concentrations for 24 h in the atmosphere. (→ TLV values).

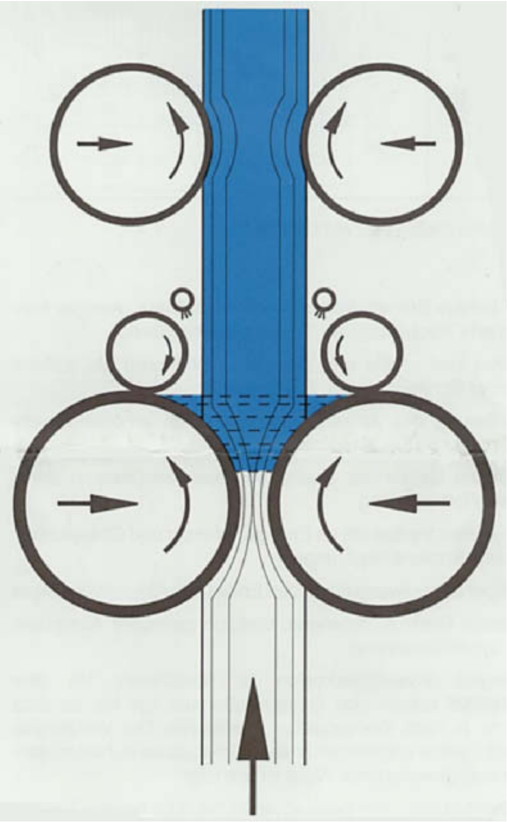

Fig.: Maximum liquor pick-up by a fabric in the Optimax unit by Menzel.

Maximum pick-up More than 100% of liquor application (compare →: Low wet pick-up; Addition high-wet pick-up). Using special machines (see Fig.), a fabric is loaded with as much liquor as it can just carry without dripping before it then, for example, goes into a steamer.

The classic wet-on-wet impregnation technique avoids intermediate drying, e.g. between the enzymatic desizing and the following peroxide bleaching. This thermal treatment is not only expensive, but detracts from the final quality of the pre-treated fabric by reducing the absorbency, the whiteness and by the insolubility of the remaining contaminant. Various measures are necessary in order to obtain uniform, reproducible effects in the classic wet-on-wet application (e.g. frequent checks of chemical concentrations). The continuous process requires the use of highly concentrated liquors in order to keep the concentration of the products in the saturator constant. The liquors are often at the limit of stability. At the end of the treatment, 500–2000 l of liquor are conducted into the waste water each time. Modern plants, on the other hand, work using a wet-on-wet maximum pick-up of 150% and a residual liquor of less than 101. The pre-treatment cycle is also simplified and the quality of the bleached fabric and the process safety are improved.

For each textile substrate, there is a limit of the application value dependence of the water of crystallization absorbed on the cellulose, the liquor withheld in the capillaries of the fibrils or in the holes of the textile structure as well as the liquid absorbed on the surface of the fabric through adhesion.

In classic liquor exchange, the cooled fabric is squeezed off up to 70% in the ca. 1000 l capacity saturator and is then padded using a liquor application of 90%. This produces a difference in the liquor pick-up of 20%. In order to prevent the dilution of the liquor as a result of the continuous throughput of the fabric the addition liquor must be increased by the factor 100 : 20, i.e. fivefold. In the maximum pick-up technique, however, the desized, washed and still warm (90°C) fabric runs into the ca. 10 l capacity applicator for a liquor pick-up of ca. 80%. This produces a final pick-up of 70% + 80% = 150%. The addition liquor is considerably less concentrated (100 : 80 = approx. 1.3-fold), so considerably more stable.

In the liquor exchange process, the NaOH and the hydrogen peroxide concentrations must unconditionally be monitored by titration in order to guarantee the reproducibility of the effects. The equilibrium is slowly adjusted and can be changed rapidly. No titration is necessary in the maximum pick-up technique because the system is very precise. The liquor pick-up corresponds to 70% water + 80% liquor = 150% liquor pick-up. The liquor is supplemented in fractions of a second. Finally this system leads to a better quality, but also to a better uniformity, reproducibility and safety in the continuous bleach.

Characteristics of a maximum pick-up bleach path: The contact time between fabric and liquor is between 0.2–0.4 s, so there is no risk of peroxide decomposition. The advantage lies in shrinking in the steamer in the warm state and starting the bleaching early. Dosing of the liquor application is possible, as the liquor can be changed easily. Thanks to the automatic dosing, the recipe can be aligned with the fabric in less than 5 s by varying all the concentrations of the products via a computer. The input in the steamer must be matched. In order to prevent the bleach liquor from dripping, it is necessary to fit the deflecting cylinder horizontally (close to the entrance of the steamer). This design prevents the loss of liquid. The small pools which develop promote the ingress of the bath into the heart of the fibre for a better bleaching. The fabric impregnated with 150% has no direct contact with the cylinders in the steamer. The chemical recipe is structured so that foam formation is prevented in the applicator, but it forms a fine foam layer between the textile materials and the rollers in the steamer. There is therefore no direct metal/fabric contact and the risk of rope creases and abrasion marks are thereby reduced. The first wash liquor after the output from the steamer is regarded as an extension of the steam chamber. The bleaching reaction continues on the basis of the active product residue still remaining on the fibre. Caustic soda liquor and washing agents ensure better hydrophilic properties, peroxide and stabiliser for a higher degree of whiteness.

In less than three years, six different systems have been developed and introduced into industrial production:
- Flexnip System (Küsters),
- Optimax System (Menzel),
- Booster System (Benninger),
- Super Sat System (Babcock),
- Dip Sat System (Max Goller engineering works),
- Raco Yet System (Kleinewefers KTM).

(according to Fornelli).

Maximum pressure → Air pressure.

Maximum workplace concentrations → TLV value.

Mazamet wool → Sweated wool from Southern French town of Mazamet, where most Australian sheepskins come to be processed.

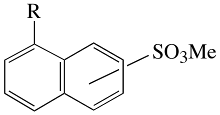
MBAS Methylene Blue active substance, so-called methylene blue test as a dye reaction for certain chemicals (e.g. anionic surfactants). Is used in the determination of biodegradability (→ Surfactant biodegradability, evaluation of). Restricted area of application. MBAS sludge degradation performance gives MBAS g, which are degraded per kg of activated sludge solids each day.

MD → Modal fibre, → Standard abbrev. for textile fibres, in accordance with the → EDP code; → CMD.

Md Elementary symbol for mendelevium (101).

ME → Metal fibres, → Standard abbrev. for textile fibres, in accordance with the → EDP code; → MTF.

Me Conventional abbrev. in standard chemical formula (similar to → R), whereby Me designates the cation each time; normally (alkali) metals, but also (for cationic) organic bases, e.g. RCOOMe type = soaps.



alkyl naphthalene sulphonate

Meander open-width scouring machine Multiple passage of textile layer via low gap saves liquor with a good liquor exchange. The principle: counter-current liquor from above, product from above; multiple squeezes, high liquor exchange, low water consumption.

Measurable variable regulator Regulator, in which measuring sensors and information processing section are united in one device and the information transfer between them does not take place using electrical signals. Typical for regulators for the processing of temperature, pressure, differential pressure and liquid level. A measurable variable regulator is a definite purpose regulator and only geared to a measured variable each time. Location is measuring point of the controlled variable.

Measurement and control Measuring instruments should provide information about the state of the finishing system via suitable sensors. They should put transmittable numerical values (process sizes) in the place of intuitive logging by human sense organs. Costs are not primarily caused by microprocessors or microcomputers, but chiefly due to the use of suitable sensors and control elements. The main emphasis is regarded as the purchase of regulating and control elements such as control valves, motors and variable speed, flowmeter for the recording of liquor circulation and liquor motion values, etc. The availability of the correct measuring probe for a finishing process decides as to whether the process is controlled or regulated using automation. In controlling (Fig. 1) a particular function is given between two variables (e.g. temperature/time). No degradation is, however, obtained about the success of the action (typical example: bath exhaustion due to heating-up rate). Only that sensor, which provides measuring information directly about the success of an action (e.g. transmission measurements of the dyebath), can reach the control unit (microprocessor) usefully amplified. A new action (→ Automatic control systems) takes place via the servo component after a variance comparison.

The degree of → Automation is clarified in the example of the stabilization of concentrations (NaOH, H_2O_2) in a pre-treatment path. The principle of control can be applied as the simplest action for the maintenance of the liquor concentration for liquor with a flat concentration profile, uniform movement and constantly remaining disturbances. An empirically determined quantity of liquor is thereby adjusted in proportion to the quantity of fabric put through. The speed of a driving roller on the bath can, for example, be selected as a measurement for the quantity of fabric. It can either be coupled mechanically via a gear drive directly to a dosage pump conveying the liquor addition or given “an electrical wave” to the pump via a pulse generator.

Actual values determined “off-line” (in the laboratory) or “in-line” are only used to control the proper sequence of the control system. Another step to increase the reliability of a process exists in the use of a manual regulation system. It is based on a comparison of the actual value with the desired values carried out periodically discontinuously on manual correction of the deviations which appear. The manual regulation system can be very usefully combined with a control system. The last stage in the automation of process control is the actual automatic control system. The actual values input in a control unit are continually compared with the likewise input desired values. Any difference arising (the control variation) is immediately and automatically removed using corrective action. Fig. 2 illustrates such a closed control circuit.

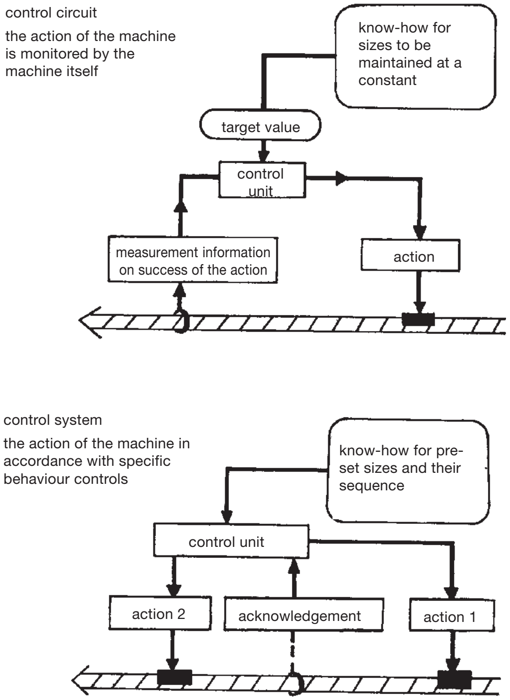


Fig. 1: Comparison of control circuit and control system as principal elements of automization.

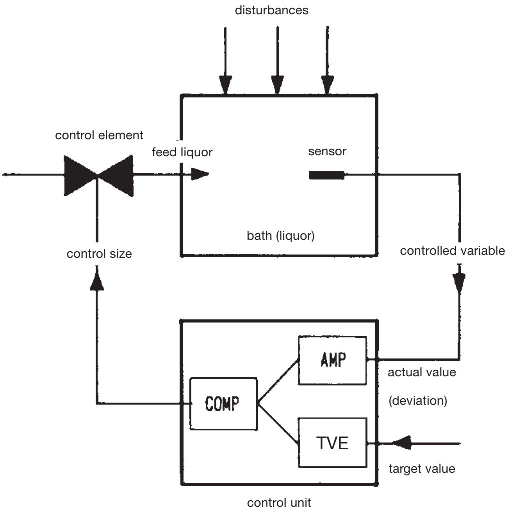

Fig. 2: Closed control circuit.
TVE = target value emitter; AMP = amplifier for the actual value detected by the sensor; COMP = comparator of target and actual values.

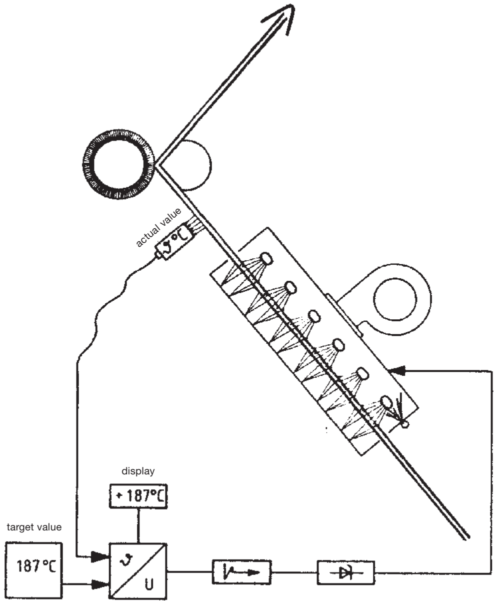

Fig. 3: Control of a thermal treatment process (pile brushing) by measurement of the effective surface temperature (Sistig).

These wet chemical explained principles can also be transmitted to physical dimensions, e.g. the temperature (see Fig. 3). This should be clarified by the example of the fabric humidity measuring device from Pleva. It is based on the principle of microwave adbsorption via water. A specialised oscillator on a semiconductor basis produces microwaves in the region of 10 GHz. This high frequency current of only low power (approx. 5 mW) is radiated via a transmitting head to the fabric to be measured. The accompanying reception head is fixed to the other side of the fabric. A part of the radiated microwave energy is absorbed on the metering pipe between transmitting and reception head depending on the quantity of water molecules. The absorption is thereby a measurement for the absolute water content of the fabric, which is given in scale divisions of 0–100 or via calibration in g H_2O/m^2. The percentage fabric humidity can easily be calculated using the known weight per square metre of the dry fabric.

Water molecules absorb microwave power due to its high permanent dipole moment, which originates from the spatial arrangement of the oxygen atom and the two hydrogen atoms. This dipole moment depends on the binding form of the water; it is different for different fabrics (cotton, viscose, synthetics, blends). Calibrations, which allocate the humidity values in g H_2O/m^2 in scale divisions to the humidity values displayed, are therefore required for the exact determination of humidity. In practice though, it has been shown that an optimum value of humidity is determined in scale divisions only once per batch. This optimum value is then the desired value of the humidity for every later production of this batch. The measurement is contact-free, non-destructive and also does not give rise to effects harmful to health. No kind of protective precautions are required.

An automatic control system for the dye padder dependence on the three measured values of the microwave measuring device requires three control circuits (Fig. 4). As these control circuits mutally influence each other via the dye padder rollers, an automatic con-

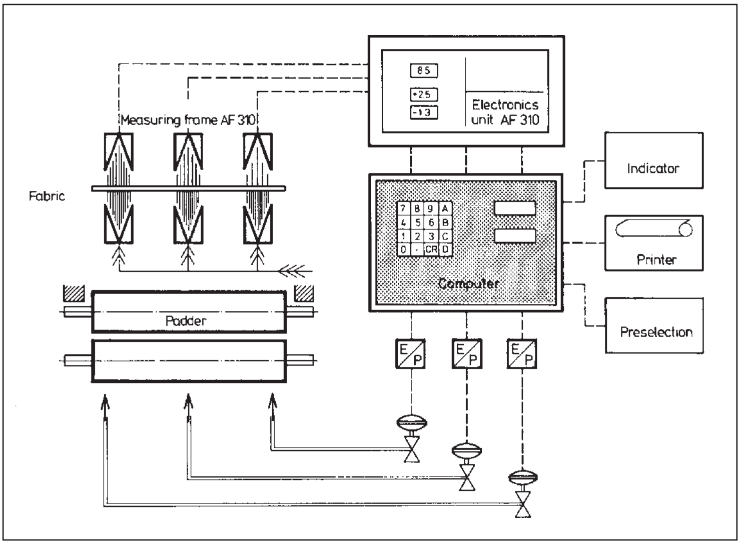

Fig. 4: Measurement and control with microwave measuring unit (AF 310 by Pleva) and computer for constant squeezing by a pad.

Measurement and control

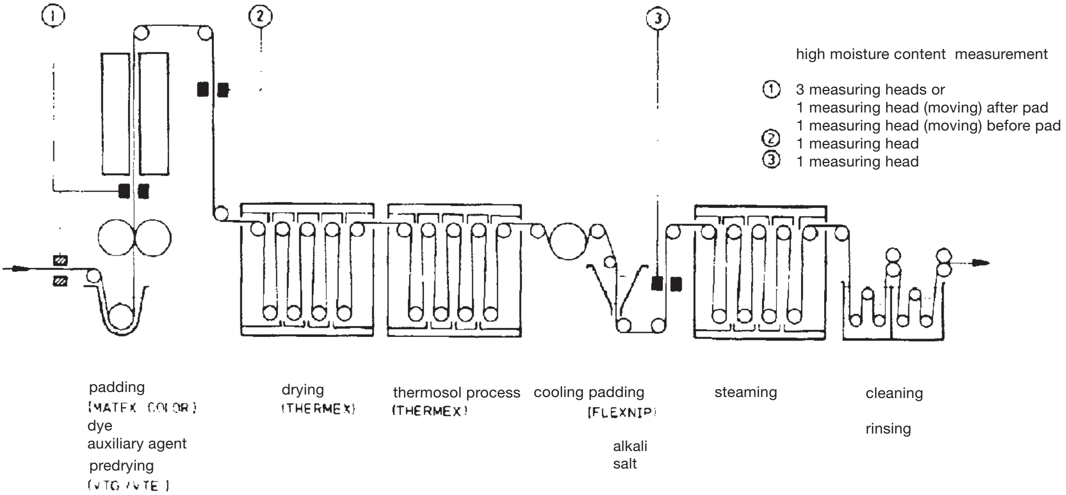

Fig. 5: Measuring device arrangement for the whole continuous process, controlling high moisture content in the Thermosol/ pad steam process.

trol system with three separate, conventional control units can only be realised with extreme difficulty. The automatic control system has proved to be favourable with the aid of a computer. The control diagram is valid in principle both for changes of the nip profile produced on the dye padder pneumatically, hydraulically or by shifting. Computers, which produce the connection from the AF 310 to the respective dye padder and regulate it, are offered on the market by Küsters, Kleinewefers KTM and Monforts, amongst others. Over and above that, Cintex offers a stand-alone, computer-aided automatic control system. Padders already available were automated for textile plants using this automatic control system together with the AF 310. The automatic control systems offer a choice of two control variants:

1. automatic control system for the humidity values centre, left difference and right difference edge dependence on the desired values stored per item.
2. adjustment of the padder to the normal squeeze pressure level (per item) and control of the edge deviation at given values. In most cases, it is controlled at the same pick-up on the edges or at a somewhat higher pick-up on the edges, always with reference to the centre.

The complexity of a continuous dyeing plant requires several control points (Fig. 5):

1. measurement and monitoring, if necessary, control of the liquor pick-up according to the padder either by microwave measuring instruments or by differential weight measuring instruments.
2. measurement, monitoring and control of the residual humidity in accordance with the IR pre-drying section using microwave measuring instrument or isotropic radiation measuring instrument.
3. measurement, monitoring and control of the liquor pick-up in accordance with the chemical pick-up before the steamer using microwave measuring instrument.

Each machine must receive the information about the machine setting to be corrected from a piece identification system. Batches to be processed differently can, for example, be clearly identified with the aid of a barcode applied to the fabric adjacent card in connection with a seam detector. Data required for the process (Fig. 6) is retrieved from the computer (1) or input via the terminal (2). The correct setting, for example, of the calender and control of the

– positioning of air coolant nozzles (3),

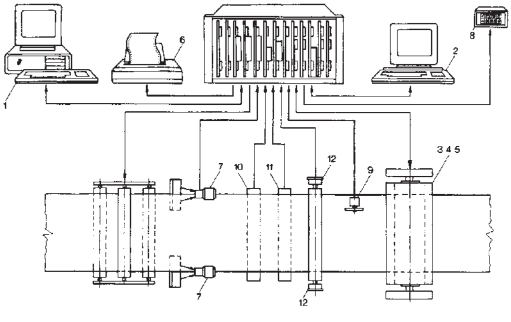

Fig. 6: Diagram of a calender with Elcom 18 (Mahlo).
3, 4 + 5 = control elements on the calender;
7, 9, 10, 11 + 12 = sensors.

- selection of the press width (4),
- roller temperature (5)

are then carried out automatically.

Operating conditions and actual values of the plant are continually displayed on the terminal. A matrix printer (6) creates a protocol of the measured values. In addition to this, the possibility exists of outputting the current fabric width determined using CCD cameras (7) via a digital remote indication (8) to any point of the machine desired. The fabric length is determined with the aid of an incremental probe (9). The active operator guidance using modern visual display units guarantees a real dialogue with the plant and thereby safer operation during the entire process. The Elcom 18 system also integrates the signal processing of the metal detecting device (19), the seam detector (11) and the fabric tension measuring instrument (10).

In order to achieve an optimum exhaust air moisture in drying machines, a control diagram has proven itself in most cases, as is shown in Fig. 7. The moisture content of the circulating air is measured in the first third of the drier, starting from the material infeed. The greatest water evaporation arises here due to drying technology reasons and thereby the highest humidity. The measuring instrument provides the control unit with the actual value. In order to achieve the desired value of humidity, the exhaust air quantity is controlled by means of a variable-speed exhaust air fan or by opening and closing operations of shutter butterfly control valves with the aid of stepping motors.

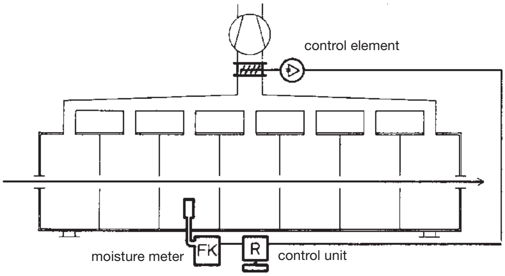

Fig. 7: Control diagram for circulating air moisture content.

The automatic positioning shown in Fig. 8 measures the temperature difference between supply air and return air and produces a thermal image of the process in the cage stenter from this. Control functions, which optimise the positioning process, are derived from this. The process is shown as a thermal balance in the screen display (top left), which correlates in the individual fields with the effective fabric temperature. The setting of the stenter chain running speed is directed accordingly so that the fabric to be dried does not run out of the frame overdried and the necessary contact time is satisfied at the heat setting temperature.

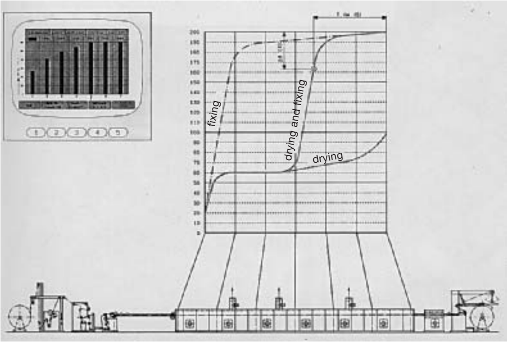

Fig. 8: Brückner automatic fixing unit Type BFM/CM.

Measuring cell Arrangement in which a property of a measured material is determined in a closed vessel. Flow measuring cell: the measured material hereby flows through the cells; thermal conductivity and conductivity measuring cells. Measuring cells with electrodes are → Measuring chain.

Measuring chain Combination of two electrodes, which are connected to each other electrolytically via a measuring medium either in the process flow or inside a → Measuring cell. It is used for the measurement of electrochemical concentrations and/or activity. There are: combined measuring chains, pH measuring chains, redox measuring chains and conductivity measuring chains.

Measuring geometry Term from the field of colorimetry; describes the type of illumination (diffuse or directed, e.g. at an angle of 45°) of the sample to be assessed colorimetrically (see Fig.: Measuring geometries in colorimetry) and the position of the measuring instrument to the illuminated sample. The measurement can be carried out perpendicular to the sample (0°) or minus 8°. The illumination and measuring directions can also be interchanged.

Measuring machine The → Length measurement of textiles is subject to legal provisions in many countries. In the territory of the FRG, fabric measuring machines must comply with the provisions of the “German calibration regulation”. The measurement determined by the machine may not exceed a difference of $\pm 2^0/_{00}$ for the new calibration or $\pm 4^0/_{00}$ for the recalibration compared with the value ascertained by hand according to the “German calibration regulation”. If you want to attain a precise measurement result for all types of fabric, the measured material must be brought over to the measuring device without any longitudinal stretching and carried out using it. The most important prerequisite for the calibration measurement is an off-circuit fabric guiding system. It is attained by the two reflection optics (R) in the infeed and exit of the machine. These cause the fabric to be relaxed between the

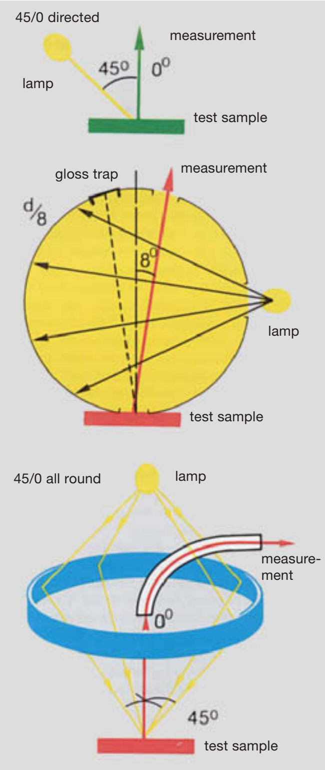

Fig.: Measuring geometries in colorimetry.

thread-up roller (A) and the measuring roller (B) contact-free. After the measuring, the fabric between the measuring roller (B) and the rolling device (C) can also be continued alternatively relaxed or under low tension depending on the application on the ready rolled bales. To avoid measuring errors an additional contact-free relaxation device can be provided for very strongly extendable hosiery goods using self-extension on the path from the thread-up roller (A) to the measuring roller (B), which works in the same way as the aforementioned relaxation and ensures a sag in the section of fabric (F) (see Fig.).

Processing of a reflection optic: A light signal with 2.4 kHz modulation frequency is thrown onto the fabric in a bundle. The fabric is moved below the focal point of the optics. The reflected quantity of light increases with the decreasing distance from the focal point until the operating point is reached. It is so low that a fabric sag is always secured. So if the operating point has been reached, the thread-up roller (A) is coupled around for a short time at a somewhat higher speed and the sag is enlarged again. A clock work mechanism accordingly opens the quick coupling again and the roller (A) is again turned more slowly than the measuring roller (B). As soon as the fabric sag is too low again, the

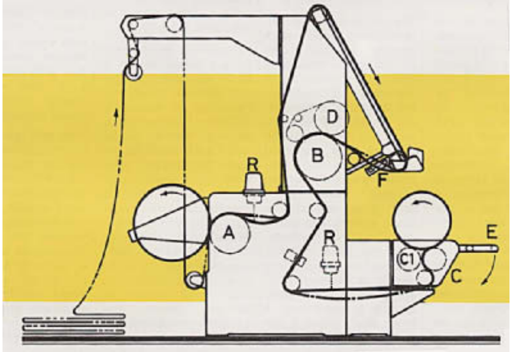

Fig.: Calibratable measuring machine (also used for synchronized rolling) for fabrics (Type MBW, formerly Monforts).

same operating sequence starts again. The reflection optics are independent of fabric colour and artificial light. The reflected signal is amplified in a narrow-band booster, which exclusively considers light impulses with the frequency of 2.4 kHz. The function described here correspondingly applies to the sag between (B) and (C) as well. If the machine runs in reverse operation, the clutches at (A) and (C) reverse their functions. So it is guaranteed that the fabric also reaches relaxed into the measuring device (D) in reverse and a precise length measurement is carried out in accordance with the regulations of the “German calibration regulation”. A transportable belt drives the measuring wheel (D) using fabric speed. The transportable belt lies on the fabric wrapped around the measuring roller (B). An electronic pulse generator, which gives a pulse per cm of transported fabric, is located on the measuring wheel axis. The meter is operated by a particular stepping motor, which absorbs the pulse and takes one step after each cm of fabric passed. The meter and measuring wheel drive are thereby separated from each other. There are no friction moments between the measuring wheel and the meter, which could result in a distortion of the result. Several meters can be arranged at any point you like in this separate type of drive.

Measuring sensors Measured quantity detectors, probes or sensors. The measuring sensor is a component in the signal flow path of a measuring device. It converts the characteristic of the measured quantity into the characteristic of another more favourable quantity to be processed. Measuring sensors, which provide a digital measuring signal, are particularly significant.

Measuring tapes Made of paper, are in exceptional cases inserted in the fabric batch in the batching process.

Mechanical breaking Finishing character work, which aims at mechanical loosening of the fabric structure, i.e. "breaking" the hardness caused by finishing application, tightening and drying, which consists of fixed thread and fibre bonds. Result: softer, fuller handle. The simplest mechanical breaking devices are blunt metal rails arranged perpendicular to the fabric run, which are used for very heavy linen and cotton fabric as well as tapes. The stud roller breaking machine (see Fig.) consists of two series of wooden rollers adjustable back to back and provided with round-headed nail mounting, which set the circulating fabric in revolution and this is thereby broken on all sides. The so-called patent finishing machine with needle rollers is similar. With the grooved roller breaking machine, the breaking effect is achieved by a number of driven grooved rollers, chiefly in the weft direction. The cylindrical blade breaking machine, however, only has up to three rollers with blunt steel blades arranged helically, which work against the fabric run using quick self-drive; particularly suitable for velvets. In all the devices described, the fabric throughput is repeated until the desired suppleness is reached. Similar effects are also possible on the jigging stenter.

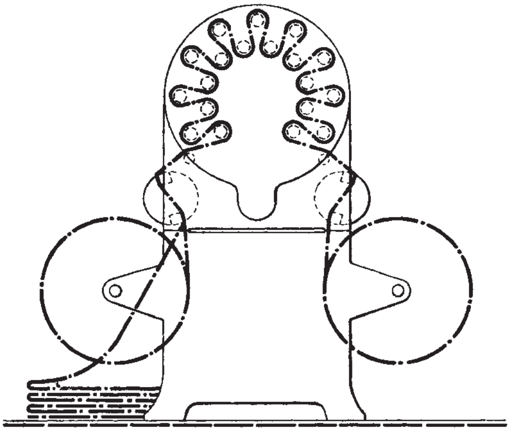

Fig.: Spiral roller mechanical breaking machine (Menscher).

Mechanical properties of fibres,

I. → Tensile strength: parallel orientation of polymer chains in the direction of the fibre axis causes the mechanical properties to be strongly anisotropic. The high axial strength is accompanied by relatively low knot and loop strengths in most fibres. The axial strength is routinely determined on fibres. The stress-strain diagrams (Fig. 1) result from the measurements. The tensile strengths refer to the cross-section; the titre (tex) should therefore be known. The ultimate load is divided by the titre and so the tensile strength or breaking strength is obtained in cN/dtex.

II. →: Loop strength and Knot strength: This is lower than the axial strength in most cases. The values are around 50–90% depending on morphology and stiffness.

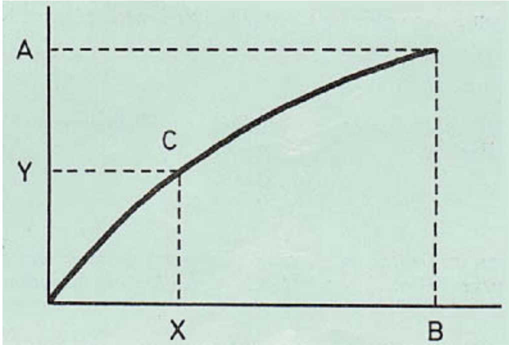

Fig. 1: Stress-strain curve of a fibre.
A = Force in cN/tex (stress at break); B = extension in % in relation t the original length (extension at break).

III. → Elongation: This describes the percentage ratio of length change during a tensile load to the original length without load.

IV. Initial module: The fibres are rarely loaded to breaking point in use. The initial part of the force/extensibility curve (Fig. 2) provides the important technologically significant initial module (M_i). The initial module is a measure of fibre stiffness and characterises the fibres in the field of Hooke's behaviour. The initially straight part of the force/extensibility diagram is small, but only here should a direct proportionality between force and extensibility be recorded. Tab. 1 compares several fibres with known materials.

V. Proportionality limit: The point in the force/extensibility diagram where the proportionality stops is described as proportionality limit (Fig. 3).

The deformation (extensibility) is elastic up to the proportionality limit. The fibres are capable of return-

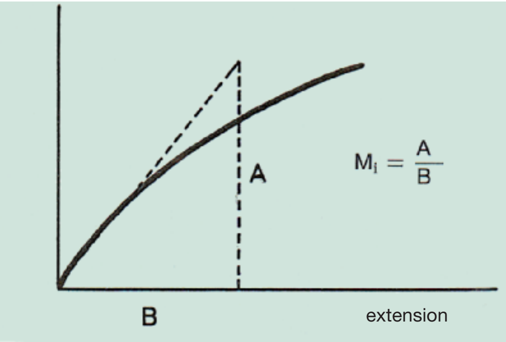

Fig. 2: Strength plotted on the ordinates (in cN/tex) against extension (in %) to explain the initial modulus (rise shown as dotted line = tangent to the curve through its origin).

	density kg/dm^3	modulus cN/tex	tenacity cN/tex	extension at break %

(24°C, 65% rel. moisture content, 30 s rest period, gauge length 5 cm; filament yarn).*

ing to their original length by unloading after a delay period. If the fibre is loaded (extended) beyond the proportionality limit, a deformation remains after the unloading.

VI. Energy capability: The surface under the force/extensibility diagram corresponds to the energy, which has to be applied in order to tear the sample. It is a measure of tenacity.

VII. Recovery capacity: If fibres are loaded beyond the proportionality limit and held there for a short time (e.g. 30 s), then unloaded, a deformation is produced. The tension decreases during the holding period and the polymer chains are displaced. The phenomenon is stress decay (tension drop). After unloading, the fibres have a permanent deformation, whose magnitude depends on the extensibility originally applied in the test. A so-called hysteresis curve develops (Fig. 4). The recovery capacity (just as ultimate load and module) varies with the speed of elongation, temperature, humidity, etc. Tab. 2 illustrates some values of the recovery capacity.

Mechanical resist → Resist printing.

Mechanization Creation and application of devices and methods to lighten heavy or tiring physical work and to increase productivity of labour. Mechanization is a preliminary stage towards → Automation serves rationalization and is used where considerable advantages can be achieved quickly using simple means, or automation at a given time appears possible for economic considerations, but not yet realisable.

Mechanochemistry According to Speakman concerns the derivation of mechanical properties of fibres from the chemical fibre structure. Mechanochemistry tests therefore provide insights into interactions between different influences, to which a fibre can be exposed, and changes to its textile behaviour.

Me-Complex dyes → Metal-complex dyes.

Medallion carpets have perfectly circular or elliptical motif on self-coloured primary backing in the centre of the carpet. Similar designs can be found along the edge of the carpet or in the corners.

Medical fibres →: Antimicrobial fibres; Antibacterial textiles.

Medio yarn Single cotton yarn of medium twist. Application as warp and weft yarn.

Medulla Medullary cord or medullary canal (in → Wool structure), inner central pores, filled with a network of cell walls. Unbroken (lattice medulla) and broken (fragmented, ladder medulla, the latter with one or several rows) occur.

Medullameter For testing wool samples for medullary cell content (→ Medulla). Wool impregnated with benzene or dichlorobenzenes is laid on non-reflecting plate, covered with glass plate and illuminated by two 100-watt lamps. Depending on wool quality the light reflected is released in a photocell current, which, increased by tubes, displays the test result on a specular galvanometer.

Medullary canal →: Medulla; Wool structure.

Medullary cord → Medulla.

Medullary rays are seen with the naked eye on decorticated trees as lens-shaped stains or short strokes (bands running horizontally), which continue in the direction of the centre of the tree (medulla). This applies as analogue for bast stems (→ Flax stem structure). Medullary rays aid the plant in the transport of carbohydrates from the so-called starch sheath (innermost cell layer of the bark) via the bast area to the cambium.

Medullation "Hairiness", in the sense of wool fibres with → Medulla, so-called hairlike fibres, hairs containing medullary cords.

Mega- (Gk.), unit auxiliary for a million times = 10^6; e.g. MJ.

MEK Max. permissible concentration of harmful emissions in the exhaust air. Can be determined on the basis of the → Maximum immission concentration, in view of the chimney height. So an MEK of ca. 40 kg/h of trichloroethylene or tetrachloroethane and 50 kg/h of benzine is produced from an exhaust gas conduction height of, e.g., 10 m.

Melafix process was used for the controlled chlorination of wool by adding chlorine acceptors to the chlorination bath. The chlorine was taken up by dispersed melamine compound and (controlled by temperature control) released. Thereby wool chlorination in the fibre-gentle acidic range. Effects: felting and shrink-resistant finish, increased dyeability with preservation of the wool fibre structure. – Manuf.: Ciba-Geigy.

Melamine (2, 4, 5-triamino-1, 3, 5-triazine, cyanuric acids, cyanurtriamide), product of polymerisation of → Dicyandiamide, from which 3 molecules are cyclically stored together as 2 molecules of melamine. White crystalline powder, water-soluble. With formaldehyde forms the chemically important finishing condensation products of → Melamine-formaldehyde compound.

Melamine-formaldehyde compound Condensation product made from melamine and formaldehyde (→ Methylol melamines). Melamine-formaldehyde compounds with methanol partially or completely etherified (→: Methoxymethylmelamines; Self-crosslinking resins) are important. Application as finishing agents, particularly for permanent calender effects, as binder of pigment colorants and finishing agents in hydrophobic finishing, in dry cross-linking (see Fig.).

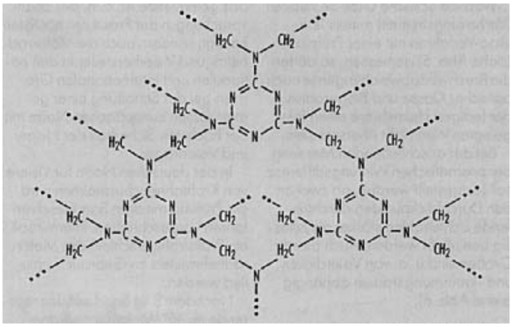

Fig.: Possible structure of a hardened melamine resin (part).

Melange flocking Flocking or flock printing using blended flock material.

Mélange yarn Mélange yarn made of bleached/unbleached or treated/untreated fibres, which only appears mottled after dyeing.

Melissic acid $C_{29}H_{59}COOH$; constituent of →: Beeswax and Carnauba wax (for chemical finishing, sizing, etc.).

Melt blowing process A filament spunbonded process, which allows the fine-titred filament (usually 0.07–0.40 dtex) to be directly converted into a fleece (see Fig.). Such fleeces are thereby most likely comparable with textile fabrics due to their pronounced soft handle with highly specific surface area, which are manufactured from microfilament yarns using conventional thread and fabric formation technologies. The prerequisite for a wide application is, however, that it manages to reduce drastically the high specific energy consumption, which is essentially caused by the firstly principle-conditioned application of > 200°C hotter and accelerated air for the filament drawing at a speed of 15 000–20 000 m/min. At any rate ca. 6 times as much energy is consumed solely for the production of the highly accelerated hot air streams with ca. 6 kWh/kg of fleece as is consumed for the conversion of the same melting into wound up threads in high-speed spinning at 6000 m/min. A quantitative comparison

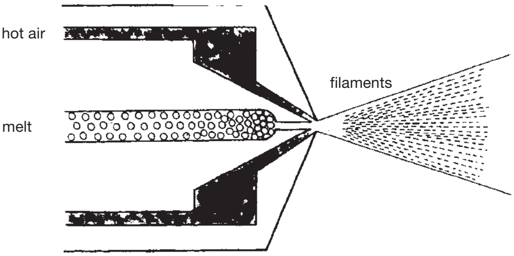

Fig.: Melt blown spinning nozzle.

naturally depends on concrete technological conditions (fleece fabric mass, filament fineness, plant formation, type of polymer), but in principle applies qualitatively in the mentioned order of magnitude.

Melt coating Process for the coating or laminating of fabrics, knitgoods, paper with high polymer thermoplastics (see Fig.), which are melted in granule form in a roller slot and so applied on the coating substrates.

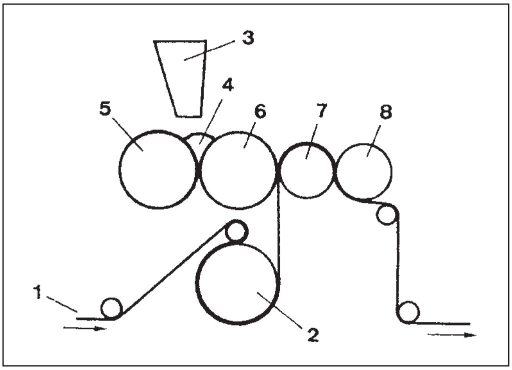

Fig.: Roller melt coating plant.
1 = fabric; 2 = preheater roller; 3 = granulate feed hopper with metering screw; 4 = thermoplast; 5 = melt roller (moveable); 6 = melt roller (fixed); 7 = take-up roller; 8 = embossing roller.

Melt-flow index (melt index), quantity in g of a condensed substance (e.g. thermoplastic) at a set temperature, which is squeezed through a nozzle per unit time using standard force. A high melt-flow index corresponds to low melt viscosity of the molten substance, in the case of a sealable polymer identical to good (hot)sealability: indicates quick penetration of the thermoplasticated coating material in fabric to be sealed, i.e. good adhesion.

Melting Transmission of a material from a solid to a fluid aggregate state. Opposite: → Freezing point.

Melting point Material-specific temperature of → Melting. The so-called → Softening range for thermoplastic fibres is found before the melting point.

Melton Named after the English town of Melton in the county of Leicestershire. Wool carded yarn fabric (occasionally also worsted yarn goods), which have a lightly matted surface on both sides due to milling. Depending on the strength of the milling process (lightly meltonated, semi-meltonated, fully meltonated), the fabric bond disappears more or less strongly under a tangled, flat fibre pile. Used for men's suits and costumes.

Melt-spinning process Spinning process for the manufacture of synthetic fibres by forcing out the viscous polymer melt under pressure from round or profiled nozzle channels, whereby the escaping fusible thread is stripped downwards at high speed, is firstly tapered, then becomes solid on a cooling system and finally reaches the vented organ (yarn package winding machine) (Fig. 1). The → Drawing of synthetic fibres, which can also be combined with the melt-spinning process or stretch texturizing using the texturizing process as drawing in spinning, mostly follows as the next processing stage.

The principle of the melt-spinning process for thermoplastic high polymers has been well-known for half a century. Its technological and technical development

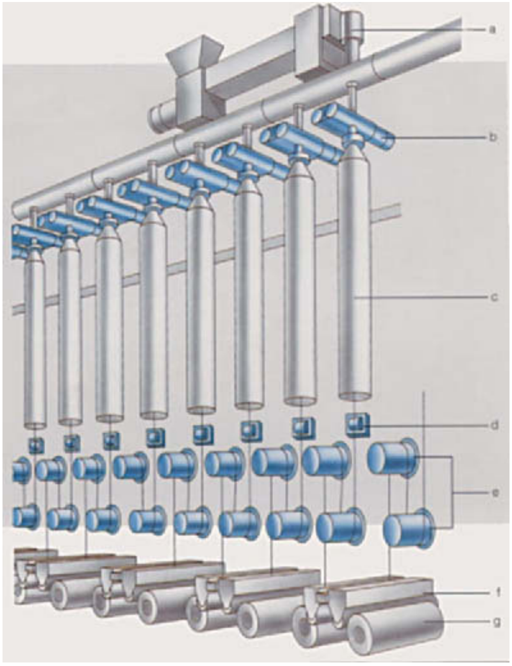

Fig. 1: Diagram showing a spinning-drawing-winding machine.
a = extruder; b = extrusion pump; c = cooling shaft; d = finishing rollers; e = godets; f = traversing; g = winder.

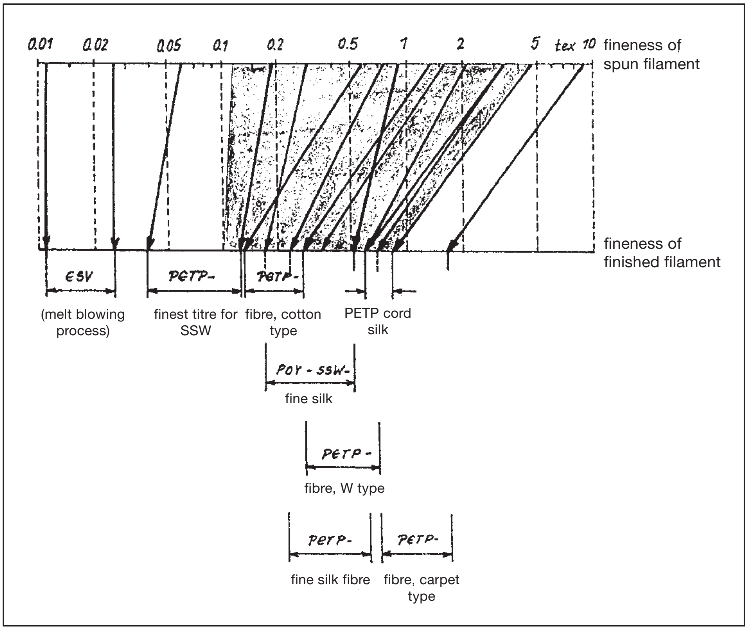

Fig. 2: Melt spinning of polyester; elementary filament fineness ranges.

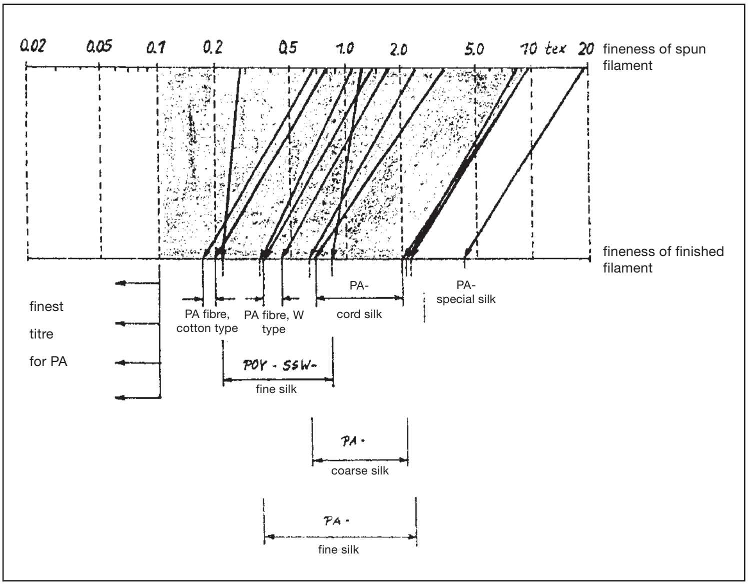

Fig. 3: Melt spinning of polyamide; elementary filament fineness ranges.

has lasted just as long, stemming from the first industrial origins of rust spinning up to today’s extruder spinning with its varied polymer-, technique- and range-specific production lines for fibre manufacture. The (provisional) last step in the current technology level is the different variants of high speed spinning process (→ High-speed spinning). If you include the fine filament, coarse (cord) filament and staple fibre spinning process or the variant of continuous filament spunbonded processes in the class of melt-spinning processes, different parameters result for each, which also determine the potential limits of continuous filament fineness in a specifically different way. In this connection, it is critical whether the demand for continuous and stable ability to wind up the filaments exists (indispensable for most spinning processes) or whether this does not completely apply (continuous spunbonded processes in accordance with the compressed air, suction-air or melt-blown principle).

The ranges of continuous filament finenesses of the threads are entered in Figs. 2 + 3 on the basis of the commercial range of polyamide and polyester fibres currently available. Each drawing contains two fineness co-ordinates. The continuous filament finenesses of the threads are applied on the top axis as they develop in the unstretched or partially stretched state in the spinning shaft, i.e. as they have to be manufacturable in the melt-spinning process. The continuous filament finenesses of the finished threads or fibres are applied on the bottom axis as they are presented for texturizing, yarn manufacture or surface formation or as they are merged directly into a textile surface (continuous filament spunbonded) in a more or less stretched out state.

The connecting arrows between the two fineness axes show which stretching ratio should be realised between the spinning and finished thread structure for the individual threads or fibre ranges. You can see whether this concerns a classic multi-stage spinning and stretching process or a high-speed spinning process from the angle. The figures show that threads, which are varied in their continuous finenesses by more than two powers of ten (> factor of 100), can be produced in melt-spinning processes realised today. The underneath hatching delimits the ranges, which are described in the thread formation catalogue. This range is somewhat larger for polyamide than for polyester, but for both fibres the fact that the extremely coarse and fine titres are not recorded first of all applies (according to Beyreuther).

Melt transfer printing → Transfer printing, in which all grades of dye are embedded in a fusible resin on the carrier (paper) and the dye is transmitted onto the textile via the phase of the molten resin under the effect of the temperature.

Melt viscosity → Viscosity characterised by the → Melt-flow index. Hot melt adhesives on a polyamide or polyester basis have a precisely definable melting point. But the melt viscosity curve (see Fig.) is more important for workability with laminates.

Membrane Taut skins or skin, permeable, impermeable or semi-permeable. One also talks of membrane in the radial layer structure of fibres. →: Intermediate membranes; Selectivity; Semi-permeable.

Membrane filtration, molecular filtration Increasing demands on product characteristics and the trend for ecologically compatible manufacturing processes necessitate a complex treatment of process flows in many sectors of the industry. The use of membrane filtration here proves to be a particularly promising solution approach. This process, also called ultrafiltration, is thereby understood to mean a technique for separating released or suspended substances from liquids, dependent on the size or the molecular weight. New ultrafiltration membranes and modules with high chemical and thermal stability are particularly suitable for sophisticated applications. The thin, asymmetric structure of the active membrane surface and the tangential flow facilitate a high flow rate (see Fig. 1). A surface layer formation normal in conventional filtration can consequently be reliably avoided by different methods (Fig. 2).

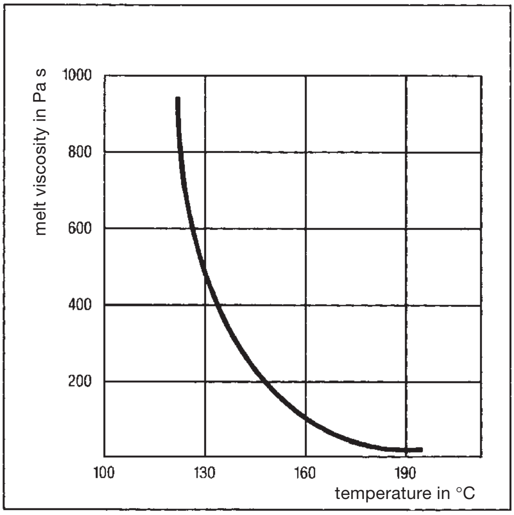

Fig.: Melt viscosity in relation to temperature.

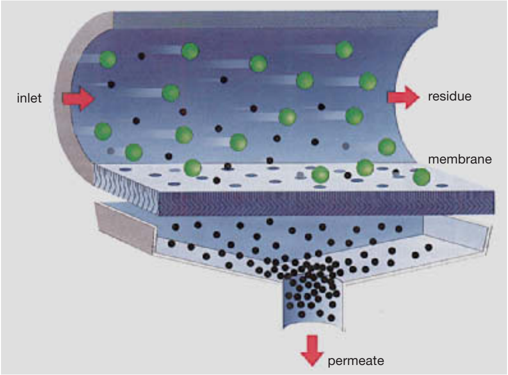

Fig. 1: Membrane filtration (according to Hoechst).

Membranometer Device for assessing the foam stability of detergent solutions by measuring the strength of surface skins.

Mepasin C_{13}–C_{16}; hydrogenated → Fischer-Tropsch waxes. Boiling range 220–280°C. Iodine number 10. Raw material for sulphonation products.

🟥 **Microfiltration**

Microfiltration membranes are capable of retaining particles of about 0.05 microns or larger. Smaller particles (e.g. salts, sugars and proteins) pass through the membrane. The operating pressure for microfiltration usually is 0.1-3 bar.

🟨 **Ultrafiltration**

Particles of about 0.005 microns (MW > 1000 Dalton) or larger are retained by ultrafiltration membranes. Low-molecular substances (e.g. sugars and salts) pass through the membrane. The operating pressure for ultrafiltration is 3-10 bar.

🟩 **Nanofiltration**

Water, monovalent ions as well as low molecular weight organic compounds (MW < 250 Dalton) pass through nanofiltration membranes. Bivalent ions (e.g. $MgSO_4$) are retained or allowed to pass, depending on the type of membrane. The operating pressure is usually 10-30 bar.

🟦 **Reverse osmosis**

Reverse osmosis membranes practically only allow water to pass through them. Salts and dissolved organic substances with a higher molecular weight than 50 Dalton are retained almost without exception. The operating pressures used for reverse osmosis usually vary between 20 and 60 bar.

Fig. 2: Waste water treatment by membrane filtration.

Mepuquat chloride 1.1-dimethyl-piperidinium chloride; bioregulator for the inhibition of unwelcome lush, vegetative growth functions of cotton plants.

Mercaptans (thiols), type R–SH; organic compounds corresponding to the alcohols in which S appears instead of O, e.g.:

CH_3–S–H	methylmercaptan
C_2H_5–S–H	ethylmercaptan
$C_{12}H_{25}$–S–H	dodecylmercaptan

Are highly volatile, have unpleasant odour and light acidic reaction. Mercaptan salts are called mercaptide (type R–SNa). Disulphide (type R–S–S–R_1) is produced from mild oxidation, which, e.g., includes the cystine of wool, while sulphonic acids (R–SO_3H) are formed from stronger oxidizing. Alkylated mercaptans are → Thioethers.

Mercaptoacetic acid → Thioglycolic acid.

2-mercaptoethanol HO–CH_2–CH_2–SH; seldom used reducing agent in water-soluble sulphur dye.

Mercaptophthalocyanines → Phthalocyanine dyes.

Mercerizing Treatment of cotton yarns, fabrics and knitgoods with cold, strong caustic soda liquor under tension. The process is based on the observation (Fig. 1) that cotton fabrics shrink under the influence of liquor, increase in density and strength and show an increased dye uptake ability. Mercerizing is an important

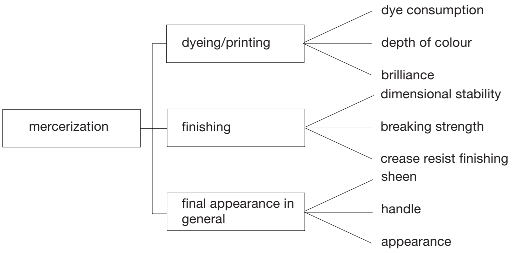

Fig. 1: Effects of mercerization.

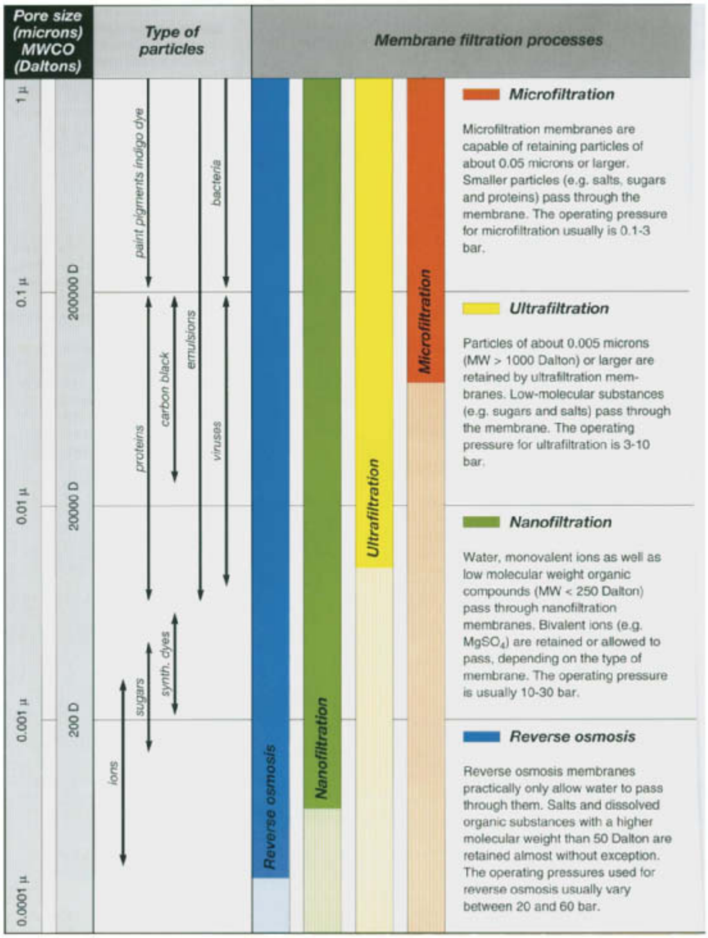

🟧 **Microfiltration**

Mercaptophthalocyanines → Phthalocyanine dyes.

Mercerizing Treatment of cotton yarns, fabrics and knitgoods with cold, strong caustic soda liquor under tension. The process is based on the observation (Fig. 1) that cotton fabrics shrink under the influence of liquor, increase in density and strength and show an increased dye uptake ability. Mercerizing is an important

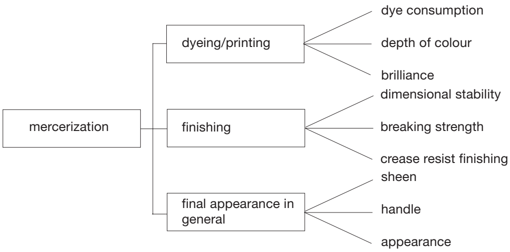

Fig. 1: Effects of mercerization.

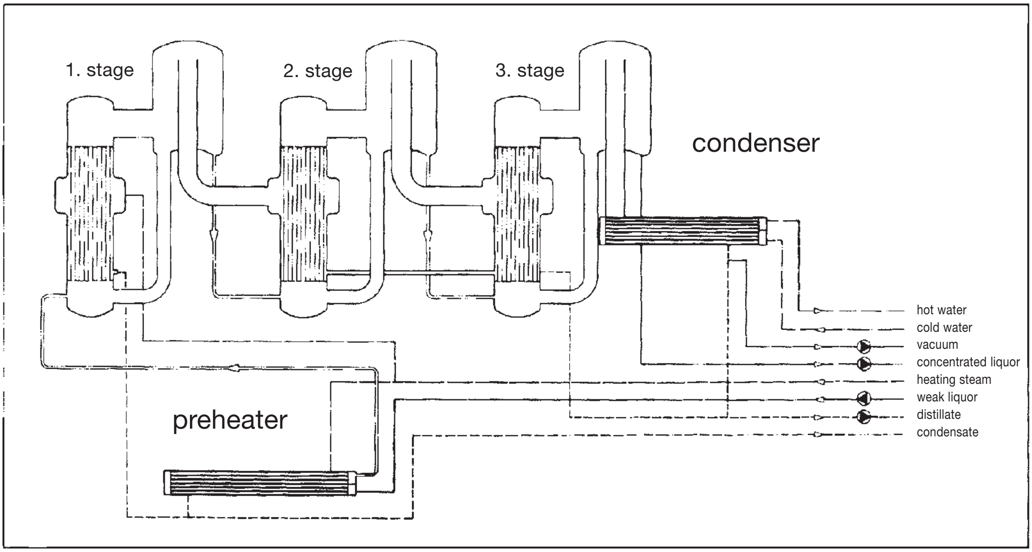

Fig. 2: Evaporation plant for recycling of mercerizing liquor (Kasag).

operation for cotton finishing to achieve a resistant silk shine and good handle without all the fundamental processes being understood. Yarn mercerizing is labour-intensive, self-dyeings on yarn mercerized knitgoods also usually break down somewhat fitfully and streakily. That is why the mercerizing of fabrics is better. Knitgoods can be mercerized both in an expanded state and in tubular form. Chain mercerizing machines can also be used for the expanded form as they are used for fabric. The mercerizing of tubular knitgoods is distinguished from cut or flat-knitted knitgoods.

Mercerizing is carried out in the following steps:
- impregnating with liquor (e.g. mercerizing of grey goods: 20 m/min, 20°Bé, air strake),
- stretching,
- scouring under tension (up to 7°Bé),
- souring off (1st section 80°C water and steam; 2nd section: 50°C acetic acid),
- rinsing (20°C).

If cotton is cold mercerized in its raw state, a liquor-resistant wetting agent must be added to the liquor. Products previously manufactured on a cresol basis have meanwhile been replaced by cresol-free ones (waste water pollution). The waste lye produced during scouring has a strength of up to 9°Bé when applying the counter current principle and is reused for scouring. In large-scale plants, the purchase of an evaporator system, amongst others, pays off (Fig. 2).

If an evaporator system is available for the washing water, non-foaming wetting agents should be used. The degree of mercerizing is expressed by the so-called “barytes number”. The more strongly the cotton is mercerized, the more it absorbs barium hydroxide. A shine which has a completely different intensity may however be detected at the same barytes number. For mercerization it is crucial that the scouring of the liquor is carried out under tension. The treatment of cotton fabrics in caustic soda liquor of mercerizing concentration, but without tension, also called “slack mercerization”, is more correctly described as → Causticizing. The properties of the cotton fibres are altered under the influence of strong caustic soda liquor as follows:
- the cuticle is destroyed,
- the cross-section becomes larger and assumes perfectly circular forms (Figs. 3–4),
- the lumen disappears,
- the spiral windings loosen,
- the fibre length is shortened by 20–25%,
- change in the macromolecular structure,
- orientation of the crystallites in the direction of the fibre axis,
- increase in the inner fibre surface,
- increased reactivity,
- improvement in the effect of resin finishings,
- higher resistance to attacks from chemicals, micro-organisms, sunlight and weathering,
- increased dye uptake ability (up to 25%),
- increase in the tear strength of individual fibres,
- better dimensional stability.

The chemical processes of mercerization have still not yet been clarified precisely. The following parameters are important:

1. Provenance: This has little influence on the mercerizing effect.

2. Caustic concentration: Caustic soda liquor of 28–32°Bé proves to be most effective, i.e. liquor with a

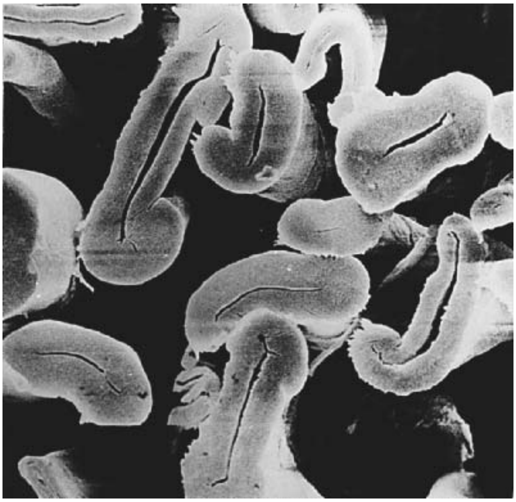

Fig. 3: Electron microscope image of natural (untreated) cotton fibres in section, magnified x 2200.

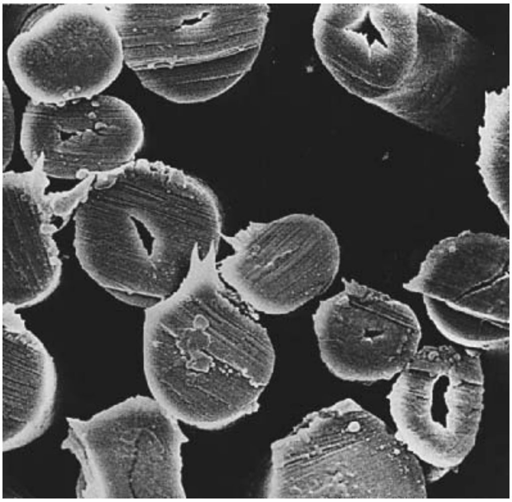

Fig. 4: Electron microscope image of mercerized cotton fibres in section, magnified x 2200, which are suitable for anticrease finishing.

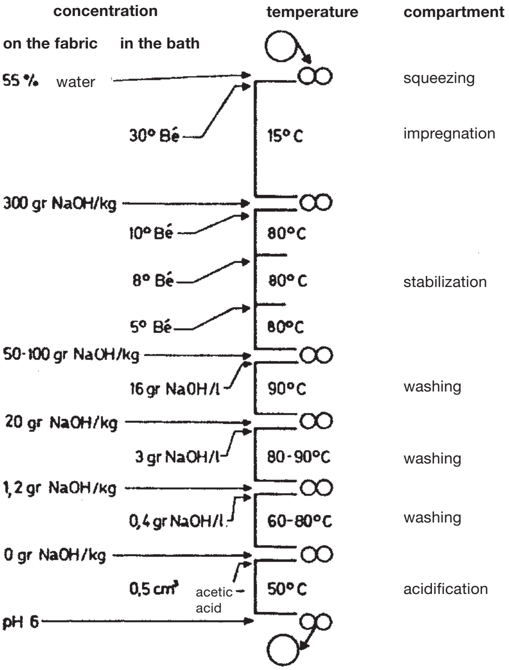

Fig. 5: Sequence of the classic mercerization process, diagram.

270–330 g/l sodium hydroxide content. This applies to the mercerization of dry fabrics. The cotton hereby absorbs more alkali than corresponds to the liquid quantity absorbed. The concentration decreases. Reinforcement under constant monitoring is required. There are fully automatic control devices for this. This advice should be observed to an even greater extent, if moist fabric is being mercerized.

3. Temperature: The principle that the lower the temperature, the higher the shine is not tenable in this form. It has been well established that the cotton swells to a maximum at 12–15°C. For this reason, mercerizing plants have often been provided with a liquor cooling unit. However, the heavy swelling of the wetting zones of the yarn then prevents a further ingress of the liquor so that the fibres remain more or less unchanged there. An increase in the liquor temperature to 50–60°C (hot mercerization) produces lower swelling, but complete penetration of the yarn, whereby optimum shine should be achieved. Fig. 5 shows the temperature profile in the individual steps of a classic mercerization of fabric.

4. Time: Normal values are 30–60 s of effect. The quicker the liquor penetrates into the fibre core, the shorter the time can be. One way of doing this is the addition of suitable wetting agents; another possibility exists in the use of heat (thermotex process), i.e. the fabric is highly heated shortly before admission into the liquor. High liquor temperature also results in quick penetration. As the penetration for dry fabric is also a matter of its air-containing capacity, one tries to carry out ventilation. Kleinewerfers has developed the vacuum method for this, by equipping the liquor padder with a suction cap (vacuum mercerization). Instead of the suction cap, Brugman ventilates the fabric by means of the “mach nozzle” (Fig. 6) and steam.

5. Tension: To achieve max. effects, the scouring of the liquor must firstly be carried out under tension. The

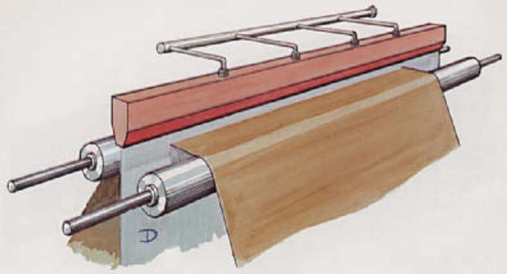

Fig. 6: Mach nozzle device by Brugman (Almelo): Steam (D) is blown at high speed through the fabric, which is then immediately impregnated with mercerizing liquor.

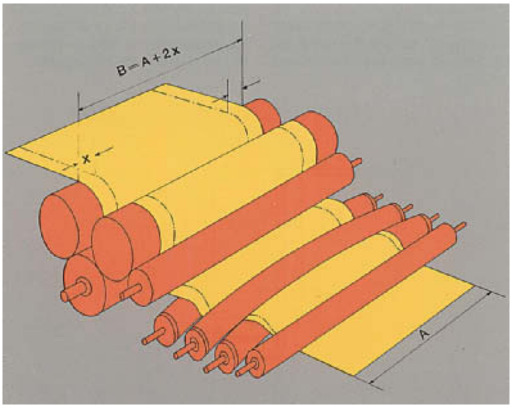

Fig. 7: Expanding rollers in the first rinsing bath (stabilization) of a roller mercerization plant by Kleinewefers KTM.

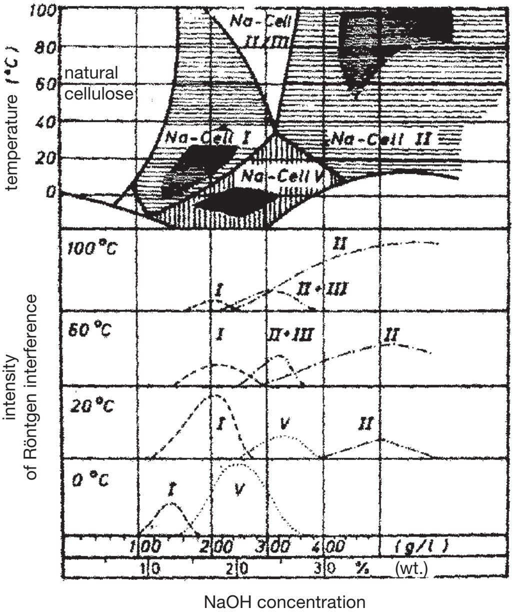

Fig. 8: Phase diagram for mercerization.

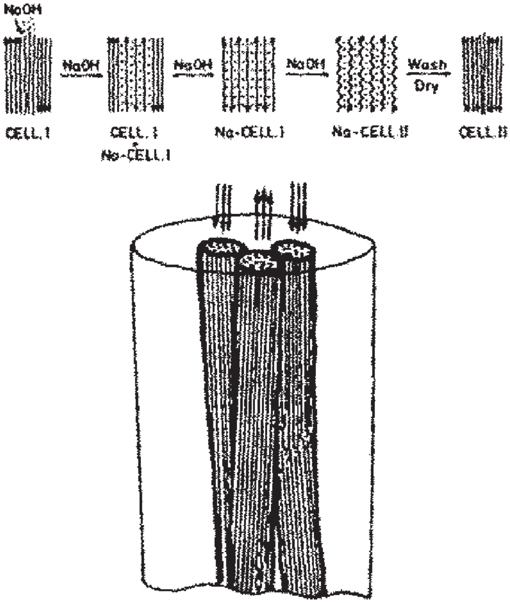

Fig. 9: Mercerization represented in model form.

installation of effective expander rollers in the first rinsing section (Fig. 7) (stabilization section) of chainless fabric mercerizing machines is therefore important. The fibre swelling of the cotton in caustic soda liquor is a fundamental prerequisite for successful mercerization. The swelling of the cotton fibre and its structural change during treatment with caustic soda liquor produce the far-reaching property changes that are striven for. Depending on the caustic soda liquor concentration and temperature, sodium cellulose is formed in the reaction between cotton cellulose and caustic soda liquor analogue to the phase diagram in the cotton fibre (Fig. 8). Alkali cellulose I is produced during causticizing with 16–18% NaOH, while the cotton cellulose reacts with 21% (and higher concentrations) of caustic soda liquor to form alkali cellulose II. Before these products, but after equilibrium adjustment can be recorded, complex preliminary stages, which determine the kinetics of the conversion, occur in the heterogeneous system of fibre/liquor.

The following knowledge is considered fundamental: Because the fibre is already heterogeneous in itself as a morphological structure, the different layers are variably sensitive to the reaction conditions of the caustic soda liquor effect. The spiral-shaped structure and the contra-rotating direction of rotation of the fibril bundles in particular (Fig. 9) make the cotton fibre considerably more resistant to a slip in the fibril bundles than, for example, comparatively regenerated cellulose fibres. The interfibrillar spaces between the microfibrils (consisting of crystallites and misordered areas), which represent the sub-units of the fibril bundles, play a particular role in the swelling of the cotton fibre.

An electric potential (the zeta potential) is formed on the fibre/liquor interface because water molecules from the liquor are orientated to the fibre surface due to their dipoles. Tied up functional OH groups may dissociate on the fibre surface. Dissolved ions are selectively adsorbed in the liquor: caustic soda liquor is present in the diluted solution (Fig. 10) dissociated as a hydrated ionic couple (below 100 g/l); due to their large diameter these elements cannot penetrate into the orientated areas of the fibre. The number of available water molecules is reduced with increasing NaOH concentration because, from 150 g/l of hydrated ionic couple, hydrates are formed by diminishing diameters. The swelling maximum is therefore reached at 180 g/l. From 200 g/l, an accumulation of hydrated dipole hydrates starts in the undissociated liquor and finally undissociated, non-hydrated NaOH molecules are produced via dipole hydrates without water, which would be mobile. These processes influence the electric transition work in the diffuse double layer. So a reduction of the negative zeta potential of the fibre results from the effect of caustic soda liquor on cotton until a limit is finally reached at 17% NaOH.

The increase in the fibre diameter (swelling) as well as the contraction in length to be observed clarify the anisotropic behaviour of the cotton fibre. An asymmetric pressure is built up in the fibre due to a Donnan equilibrium because the fibre surface (as a semi-permeable membrane) only allows the colloidal ions to diffuse through into the fibre and so it “inflates” itself. This behaviour of the cotton is irreversible, as a transition into hydrated cellulose and later into alkali cellulose is carried out by absorption of water. The resulting swelling is carried out intercrystalline from 5% NaOH effect. Higher caustic soda liquor concentrations produce lattice transitions in the cellulose.

The inner fibre surface, pore structure, hydrogen bonds bonding form, the degree of order (radiographically), or, in summary expressed in the sense of pretreatment and “the accessibility” of the cotton is altered by the respective alkali treatment. The increased dye uptake produced by the mercerizing, for example, is firstly based on this increased accessibility (e.g. at the same percentage, radiographical crystallinity in comparison to the untreated cotton due to a larger number of smaller crystallites). Secondly, the light from the rounder fibre after mercerizing is less diffuse, but reflected in a more bundled way (so with less light scatter), which supports the detection of increased dye uptake in the sensory impression of “colour”.

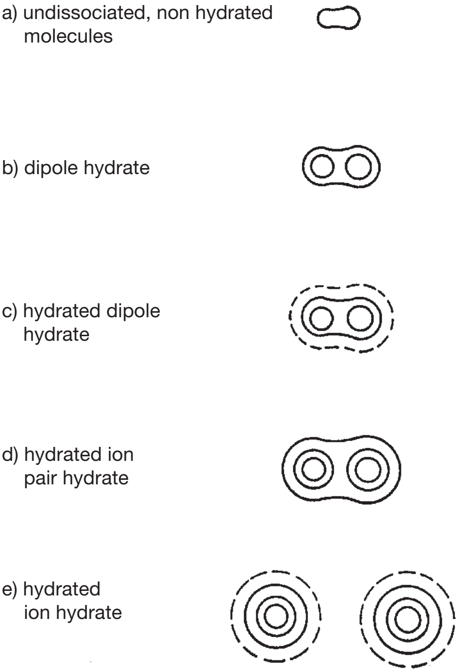

Fig. 10: Size of the caustic soda molecule in water, with decreasing concentration from a to e.
a = 0.1–0.5 nm; b = 0.5–0.8 nm; c = 0.8–1 nm (from 200 g/l); d = 1–1.5 nm (from 150 g/l); e = 1.5–2 nm (< 100 g/l).

Mercerizing can be carried out within different stages of finishing:

- as a grey good,
- after desizing,
- after desizing and scouring,
- after bleaching or between two bleach stages,
- after dyeing.

A double mercerization is sometimes also applied, i.e. a) mercerization of the raw fabric and b) mercerization after desizing, if necessary after desizing and kier-boiling. The decision depends on the requirements of the finished result of the fabric. Disadvantages of the mercerizing of grey goods: Complete penetration of the yarns rather difficult using liquor; soiled liquor, which can lead to discoloured fabric; reuse of the waste lye restricted. The increase in shine using mercerization should be greater the weaker alkaline the scouring was. Increase in shine produces a souring off between scouring and mercerization. If materials from unevenly spun yarns are to be mercerized, it is often advantageous to carry this out only after dyeing. The fabric pattern looks more even; the knops of dead cotton thereby also almost completely disappear. The dyeing must withstand the liquor and acid treatment. The latter should, if necessary, be left out.

Mercerizing

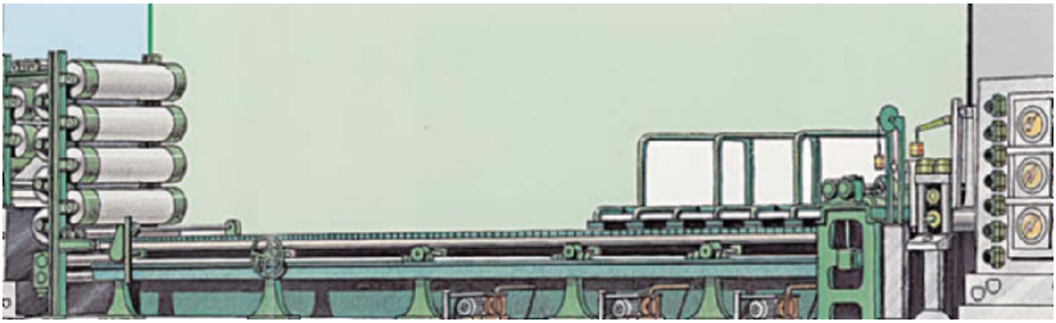

Fig. 11: Typical working line on a chain mercerizing machine (Morrison).
Left: lye impregnation zone with dwell time on cylinder rollers; centre: washing out on a stenter frame; right: start of rinsing.

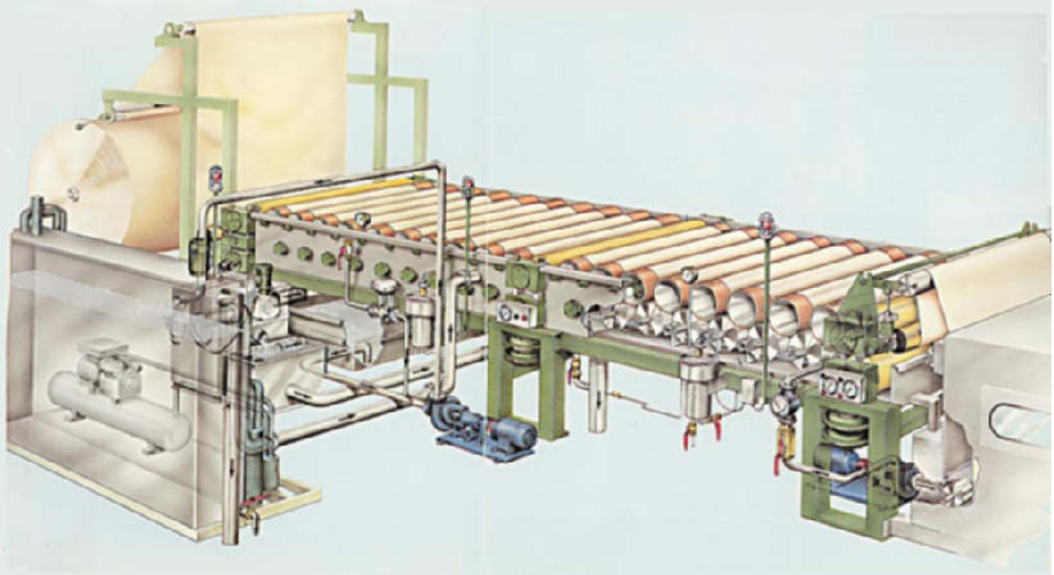

Fig. 12: Roller mercerizing machine by Brugman.

In some cases mercerization is carried out after dyeing and handle modifying finishes. This is the case when the tear strength and abrasion resistance of crease-resistant finished fabric is to be improved.

Two systems are in use for the mercerization of fabrics under tension:

- chain machines,
- chainless machines.

In less common chain machines (Fig. 11), the fabric is held on both corners by a clip chain after impregnation on a padder. The chains are brought closer to each other on the stenter infeed and then spread as far as the necessary width of the fabric requires. In the last third of the span, rinsing is carried out using hot water until no more shrinkage can occur after the tension has stopped. The rest of the liquor is removed in the following lye extractor. In this device, washing takes place in accordance with the counter current principle using hot water and an 8–10% strong waste lye is thereby obtained. After rinsing, it is soured off and the acid is washed out again. For economic reasons hydrochloric acid or sulphuric acid is used (the latter however only if soft water is available) or (with less risk during drying) acetic acid. For better impregnation with liquor, two padders are usually used, whereby a series of transition drums is connected between the two. The effective time is thereby extended. Chain mercerizing machines are chiefly suitable for the mercerization of knitgoods, if they are to be dyed evenly afterwards.

Chainless mercerization machines operate according to a different principle. The fabric runs across a system of rollers (Fig. 12) through the liquor and the so-called stabilizing section, in which so much liquor is rinsed away (Fig. 13) that it no longer shrinks in the subsequent lye extractor. The rollers lie closely next to each other or on top of each other so that the fabric has no possibility of shrinking. If need be, width losses can be compensated for by the installation of an overstretching field with expander rollers (Fig. 14) in the centre of the stabilizing field.

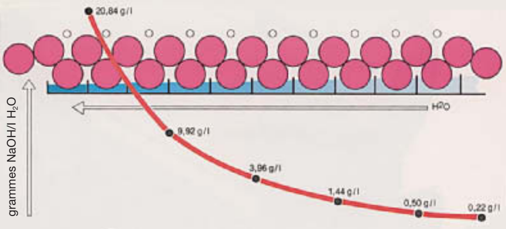

Fig. 13: Process of washing out the caustic soda in the stabilization section of a roller mercerizing machine by Goller.

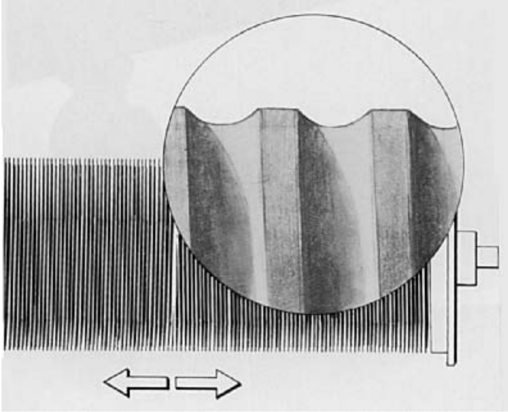

Fig. 14: Expander roller with ripples on the Goller roller mercerizing machine to ensure contact during fabric transport.

Benninger (Fig. 15) developed the two-stage process (1st stage hot impregnation, 2nd stage cold-swelling under stenter stretching, scouring on stenters and rollers). The result is the combined roller chain mercerizing machine "Dimensa", whose chain stenter part was developed in co-operation with Brückner. The "Dimensa" in principle consists of five modules:

1. In the impregnation zone, the fabric is brought into contact with 60°C hot caustic soda liquor (of mercerizing liquor concentration). The preparation of the liquor takes place in an under tub (the impregnating tub), i.e., only so much stock liquor and water is mixed as is consumed in the impregnating tub. Diluting heat is produced during the preparation of the hot liquor so that the liquor only has to be heated by 40°C to 60°C. The process of mercerizing liquor consumption is monitored and controlled in an extensive measuring and control system. Concentration measurements, level stage measurement and temperature measurements function for control circuits.
2. Subsequent to the hot impregnation, the fabric runs through a roller mercerizing section with two large cooling rollers. If good penetration of the fabric took place in the hot impregnation section (under simultaneous influence of the fabric shine), the fabric should now swell to a maximum at a lower temperature because swelling is an exothermic process. The mercerizing liquor concentration is not altered in this cooling and dwelling range.
3. The first part of the stabilizing zone, the span, which has 3 m long mobile arms, stored in a stiff, but adjustable in width in stentering, then follows. Hot weak liquor is applied in a spray box across the whole cloth width in order to start the stabilizing process.
4. The cloth then goes over into a normal roller mercerizing zone.
5. The process concludes with a roller vat.

The advantages of the "Dimensa" process are in the width constancy of the cloth; the untreated width can be fixed easily. It is debatable though whether with common material, which tries to engage up to 15% in width, an intensive stretching process does not stretch fabric sections on the selvedges more than in the middle of the fabric. The "Dimensa" process at least offers the possibility of pulling adjusted cloth correctly as in a loom to the untreated width and so save a drying operation.

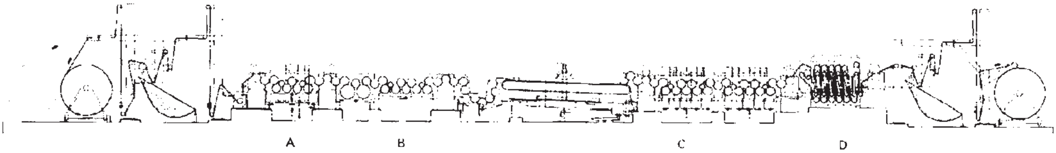

Fig. 15: Stenter frame and roller section of the "Dimensa" by Benninger (all elements with contact fabric transport). A = impregnation; B = cooling; C = stabilization on stenter frame; D = rinsing.

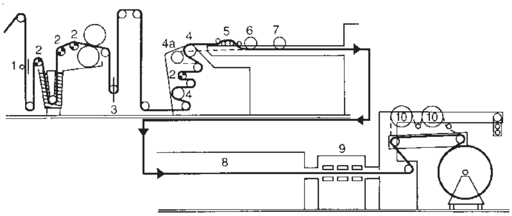

Fig. 16: Mercerization on the stenter frame by Sandoz. 1 = stretcher; 2 = expander roller; 3 = floating roller; 4 = drawing roller; 4a = drawing roller lowered for direct fabric feed; 5 = finger spacers; 6 = shrink roller; 7 = rotary brush; 8 = drier; 9 = cooling zone; 10 = cooling drum.

The purchase of a mercerizing machine is a financial problem in small production plants. Dornier built a special device for small batches. The fabric is impregnated with the liquor, rolled under pressure, then rewound on a second roller. After the rewinding, which is carried out from roller to roller in constant direct contact and consequently prevents a shrinkage in the weft direction, lye extraction takes place by spraying hot water under the same conditions. Another plant is the “Mercerizing centrifuge” of Kleinewefers-Jaeggli, in which the cloth impregnated with liquor is rolled up onto a perforated drum and washed in accordance with the principle of the Dokken washing machine and hydro-extracted by centrifuge.

In the Sandoz SM process, application is on the stenter (Fig. 16). As only a slight change is necessary, existing machines can be used without any problem. The infeed system, needle bonding or clips, all metal parts of the stenter, which come into contact with the alkaline impregnated textile, must consist of stainless steel. The brush trim in the punching may only contain polyamide brush hairs. The rubber in the squeeze rollers must have an alkali resistance of at least 23°Bé NaOH. The SM process is suitable both for flat knitgoods and cut circular knitted fabric and for fabric made from cotton and cotton fibre blends. The application technique includes padding at room temperature, stretching with controlled width, drying at 130°C and intensive scouring. The result is a very good dimensional stability with a high uniformity of fabric structure and high shine. As with all foulard processes, the conditions should be kept as constant as possible (liquor level, NaOH addition of 25°Bé, temperature). After the padding, chiefly the knitgoods shrink very considerably. The infeed phase (before the drying system) is carried out under stronger longitudinal tension. The width tension should be applied in such a way that the fabric is also pinned down in a heavily tensioned state, but without producing clip defects. When drying, the following rules of thumb should be observed for the dimensional stability and correct setting of the knitted geometry: width tension of 5–10% across the desired final width plus 3 cm for selvedge cutting (single jersey). The longitudinal tension is 20–30%. The adjustment of the width and longitudinal tension is a matter of experience and depends on the final dimensional stability, knitted geometry and final weight per square metre. A stenter with 4–5 drying sections is suitable for the application of the SM process. The drying takes place at max. 130°C in a stretched state; the tension is crucial for a good shine. You recognise the complete drying by the alkali-conditioned uniform yellow tone. The cloth is then rolled up in a cooled state; this can also be plaited down for knitgoods. The temporary low strength of alkali treated cloth in the dry state should thereby be considered. In the subsequent scouring, the cotton attains its original strength again, the yellow tone completely disappears, and the textile obtains the properties of a mercerized fabric. The adjustment of the knitted geometry runs uniformly in knitgoods, which helps to avoid listings when dyeing. The risk of selvedge condensing (Fig. 17) exists on conventional chainless mercerizing machines. This irreversible damage is based on the diverging shrinking behaviour of the centre and outside. The outside shrinks unevenly greater than the centre. A safe mercerizing of cut cloth is only possible on chain mercerizing machines or on stenters in accordance with the SM process.

A lot of interest exists in the true mercerizing of tubular knitgoods; if the stabilizing does not take place under tension (inflation of the tube), it is effectively only causticized. The Caber merceknit process (Fig. 18) acts as a pneumatic expander for the purpose of radical tension of the tube during stabilizing. Sperotto-Rimar is trying to achieve this effect by inflating with air (Fig. 20). But Dornier puts the most elegant solution into practice with a reworking of the Spreiz system: Dornier previously stretched the tube during stabilisation and rinsing with rings, which were expandable in the diameter. The cloth then stuck to the rings, especial-

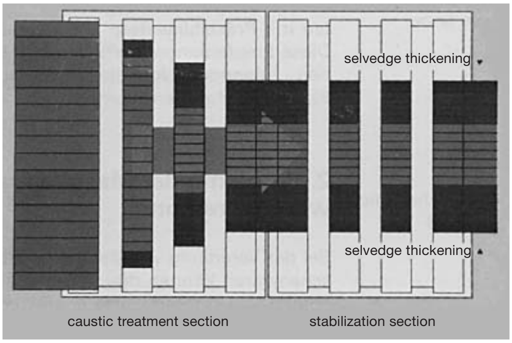

Fig. 17: Diagram of selvedge thickening in the case of a conventional, non-chain mercerizing machine.

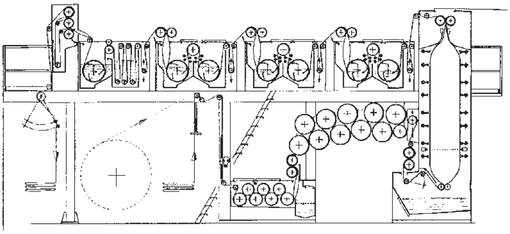

Fig. 18: Caber mercerization plant for tubular goods.

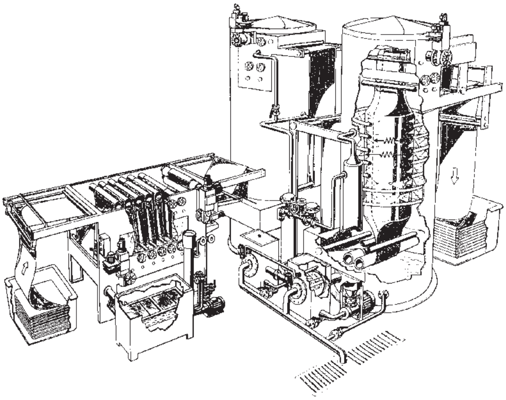

Fig. 20: Sperotto-Riemar mercerization plant for knitted goods in tubular form.

ly during rinsing, and a considerable longitudinal expansion was experienced. Dornier filled the extendable rings with a lot of rollers (Fig. 19).

It is said of the chainless machines that the knit formation between centre batch and lateral batch precipitates somewhat differently. This should be the case less often with chain machines. For this reason, the slitting of tubular knitgoods is dispensed with and a tubular fabric mercerizing machine is used.

The firm Coats firstly used liquid ammonia instead of caustic soda liquor for mercerizing cotton yarns. The Norwegian textile institute in Oslo developed the "Tedeco" process for fabric, also known by the registered designation "Duralized" in conjunction with permanent-press finishing. Liquid ammonia has a temperature of 33°C at normal pressure and penetrates cotton immediately. Up to more than 90% can be reclaimed. The equipment must be completely closed. Monforts also constructed systems for fabric. Before the fabric enters the ammonia, it must be cooled. After immersion a looping section follows, then the economiser, in which the greatest part of the ammonia vaporizes, a stretching wheel and finally a rinsing device with hot water. The effect should be just as good as in mercerization using caustic soda liquor. Caustic soda liquor should have more of an effect in the intermicellar region of cotton fibre and ammonia in the intramicellar region. With this system, it should be noted that the treatment part is just as expensive to purchase as the recovery system for the volatile ammonia. A schematic comparison of the mercerizing process might look as follows:

Decrease in shrinkage:
NaOH (20°C) → NaOH (90°C) → NH_3.
Increase in swelling speed:
NaOH (20°C) → NaOH (90°C) → NH_3.
Intensity of structural change:
NaOH (20°C) ← NaOH (90°C) ← NH_3.

A non-uniform mercerizing effect can be seen in non-uniform dyeing. Causes:

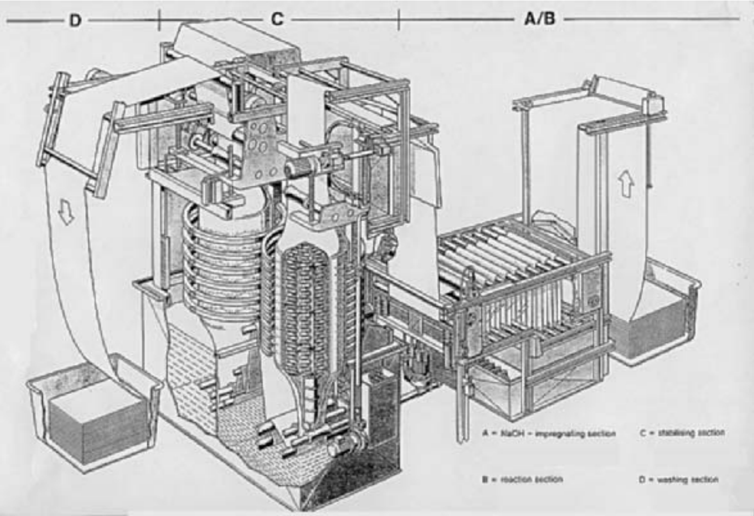

Fig. 19: Dornier mercerization plant for tubular goods with contact fabric transfer.

- non-uniform moisture content (water spotting stains);
- creases, which appear during mercerizing, cannot be removed;
- oxycellulose formation, if washed cloth is left not completely alkali-free;
- hydrocellulose formation, if acid is inadequately washed out and the cloth starts to dry.

Mercerizing of cotton blends: The sensitivity of most regenerated cellulose fibres (except HWM fibres) compared with higher alkali concentrations necessitates extreme caution when mercerizing mixed spun yarns of cotton and viscose. Mercerization incidentally only makes sense for this blend if the viscose fibre content does not considerably exceed 50%. The polishing effect of this treatment is hardly noticeable otherwise. But mercerization in these cases is accompanied by a much better tone-in-tone dyeing of both fibres. Viscose fibres have a solubility optimum in caustic soda liquor of 13°Bé at 20°C. The soluble component in viscose fibres is 5–45% depending on origin. The solubility is less in hotter liquors, greater in colder ones. If moist yarns or fabric are mercerized from cotton/viscose, these run through twice the dangerous concentration range of 13°Bé for viscose. That is why it is better to dry it beforehand. The rinsing process is altered compared with the treatment of pure cotton in that it is washed immediately with very hot water (50–80°C) in order to achieve a throughput of the danger zone as quickly as possible. Mercerization with caustic potash solution is less critical, as viscose fibres swell significantly less in that than in caustic soda liquor. However, as the effect on cotton is less, one works with mixtures of both liquors. Protection of the viscose fibres can be achieved by adding 40–50 g/l of sodium chloride to the caustic soda liquor. Mixed fabric made from cotton and polynosic fibres can be mercerized without special measures. Certain differences should though exist between polynosic and HWM fibres in their reaction to mercerizing liquors. Mixed fabrics made from cotton/polyester are also possible for mercerizing in a high proportion of cotton. There are no particular precautions to take for this. A partial mercerization of cotton takes place, if the cloth is impregnated with mercerizing liquor, dwells for 5–15 min without tension at 65°C and is then washed off. Simili mercerizing is merely a calender treatment on a grooved calender. The mercerizing of linen hardly alters it; however, it has been established that linen fabrics treated with crease-resistant resins and then mercerized obtain a better handle and better abrasion resistance (both in the treatment in caustic soda liquor and in liquid ammonia).

Mercerizing of grey goods → Mercerizing without prior kier boiling, scouring or other wet treatment; → Dry mercerizing.

Mercerizing plants Depending on which batch size you want to mercerize, you can fall back on small systems such as Minimerc from Menzel (Fig. 1) or on large systems such as Dimensa (Fig. 2) from Benninger (combined roller chain type), Flexnip addition pick-up from Küsters (Fig. 3) (roller type) or the classic chain mercerizing machine (Fig. 4) from Farmer Norton (with impregnating section, stretch stenter entry zone, stabilizing zone in the needle field and rinsing machines as horizontal and vertical width washing machines) (→ Mercerizing).

Both optimized chain mercerizing plants (Fig. 5) and roller mercerizing plants (Fig. 6) are in operation today. New types of roller arrangements (Fig. 7) have also become known in chainless mercerizing plants.

Mercerizing position in cotton pretreatment → Mercer, John.

Mercerizing wetting agents The effectiveness of strong alkaline treatment baths used in mercerizing depends on how quickly the liquor impregnates the textile material, i.e. the fibre, the fibre lattice (yarn, ply-yarn), the textile fabric (woven fabric, hosiery goods), in which cellulose penetrates and due to whose swelling a shrinking process is triggered in the longitudinal direction of the fibre, which is transmitted to the textile material and by which more or less extensive prevention of the actual mercerizing effect is achieved. The shrinking process, i.e. the change in length over time, should therefore be regarded as a measurement of the effectiveness of a mercerizing wetting agent.

You cannot do without a wetting agent in raw cotton mercerizing. Lack of foam and shrinkage behaviour are important characteristics of the varied demands on such a wetting agent. The formulation of a mercerizing wetting agent using biologically degradable, end-group sealed non-ionic tensides as a defoamer has the following result:

- applicable in mercerizing and causticizing,
- good shrinkage wetting behaviour,
- low foam development,
- rapidly biologically degradable (OECD screening test: > 90% MBAS or BiAS acceptance; closed cylinder test: > 60% BOD_{30}/COD).

An automated method in accordance with Landolt is used to measure shrinkage wetting behaviour. The Landolt measuring tube (see Fig.) consists of a glass tube with a built-in guide rod, equipped with a double temperable sheath. The tube is filled with the mercerizing liquor, in which the yarn is given. A polished piece of metal is located at the bottom end of the yarn sample. This moves upwards when the yarn shrinks. A photocell tracks this movement; the data is processed in a

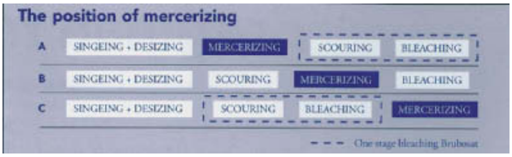
computer and displayed on a screen via a displacement sensor and analogue/digital converter.

Mercer, John in 1844 observed the prerequisites, which led to → Mercerizing named after him. The first patent followed in 1850. The simultaneous tension required for polishing was only discovered in 1890 (Lowe) and technically utilised from 1895 (Thomas and Prevost in Krefeld).

Mercerizing can be carried out at various stages during pretreatment: After desizing, after scouring or after bleaching (Fig.). Each of these process sequences has its own merits.

A. After desizing: Pollution of the caustic can be caused by the continuous build up of size extracted from the fabric, thus causing lifetime reduction of the caustic liquor. However with this option maximum lustre is achieved.



The position of mercerizing

A	SINGEING + DESIZING	MERCERIZING	SCOURING	BLEACHING
B	SINGEING + DESIZING	SCOURING	MERCERIZING	BLEACHING
C	SINGEING + DESIZING	SCOURING	BLEACHING	MERCERIZING

- - - One stage bleaching Brubosat

Fig.: Mercerizing position in cotton pretreatment.

B. After scouring: After mercerization the washing off of the caustic has to be sufficient to obviate irregular bleaching. To prevent catalytic damage during the bleaching process extraction of iron has to be guaranteed.

C. After bleaching: When mercerizing after bleaching contamination of the mercerizing caustic is prevented, however, the whiteness as well as the absorbancy might suffer. Care should be taken to have sufficient washing capacity to prevent yellowing.

Wet on wet or wet on dry: Mercerizers are suitable for both wet on wet and wet on dry applications.

Hot or cold mercerizing: Between 12° and 15°C cotton fibres swell to their maximum which prevents deep penetration of caustic at these temperatures. Furthermore cold caustic also has a far higher viscosity than hot caustic therefore penetration of the fabric is much easier at higher temperatures. Cold mercerizing results in a higher degree of swelling but with the risk of uneveness, especially on heavier fabrics. Hot mercerizing gives deep penetration with quick uniform swelling without the need of wetting agents thereby reducing the required length of the mercerizing section. Overall dyestuff savings are comparable, dyestuff absorption is equal but dyestuff yield improves at lower temperatures. No differences in lustre are observed between 10° and 45°C but above 55°C lustre is significantly reduced. Stability of the cloth is not influenced by temperature but handle is much softer at higher temperatures.

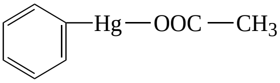
Merchant converter Commercial contractor, who purchases raw cloth or warp-knitted fabrics and has these dyed and printed by a commissioned finisher according to his instructions and then resells them; without his own production.

Mercury (Lat.: hydragyrum), Hg, atomic weight 200.6; density 13.6. Only fluid metal, with a silver glance, regularly expanding up to 100°C; freezing point –39°C; boiling point 360°C; low quantities already evaporate at room temperature; resistant to air. Soluble in diluted nitric acid and hot, concentrated sulphuric acid (mercury vapours are very toxic). Ion compounds: mercury valency of 1 (mercuro and/or oxydul salts), valency of 2 (mercuri and/or oxide salt); both highly toxic. Mercury iodide (yellow when heated) forms with potassium iodide in caustic soda liquor, releases Nessler's reagent (for the testing of ammonia and ammonium salts = blackish brown dye). Use as a metal: barometers, thermometers, mercury steam lamp (short-wave ultraviolet radiation) and artificial daylight (for the colour matching of dyed/printed samples) and analysis quartz lamp (quartz mercury burner for luminescence analysis). Alloys: amalgams. Powerful disinfectant; analytical reagents, etc.

Mercury column (QS), abbrev. for mercury column in units of measurement for pressure.

Mercury porosimetry A purely scientific method to determine the → Pore volume of textiles, pore diameter and pore volume distribution in the fibre due to the toxicity of mercury. Mercury can only be squeezed into the fibre by applying pressure due to the unwettability.

Mercury salts, organic The mercury phenolates and above all phenylmercury acetate were interesting for textile chemistry; but toxic.



All these compounds were important preservatives as well as products for microbisidal finishing.

Mercury vapour lamp → Ultraviolet lamp.

Merino fibre Fine crimped → Wool (see Fig.) from the Spanish merino sheep, yarns from this (also wool union knitted and hosiery knitted yarns) and fine worsted fabrics with a slight shine (also similar to cotton and wool union merinos). Structure → Hierarchical fibre structure.

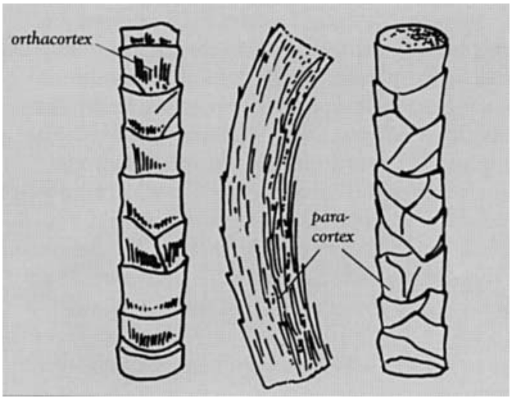


Fig.: Typical appearance of the merino fibre.

Mersolate → Sulphonic acids.

Mesh fineness For the labelling of the finenesses of → Screen mesh materials, are used for different systems depending on material: silk bolting cloth (screen silk): numbers 0–25 (8–16 for finenesses of 50–200 stitches per inch; 8–11 for normal design; 11–14 for sharp contours and 15–16 for the finest half-tone drawings). Phosphor bronze: mesh finenesses lie between 90 and 350 threads per inch (110–180 as normal fineness, 200–350 for the finest designs). Synthetic fibre threads: labelling according to threads/cm (12–200).

Mesh number Parameter for screen mesh, which indicates the number of openings/inch (= 2.55 cm), is however only meaningful using the diameter of the individual openings (see Fig.). As with constant mesh number the screen throughput is proportional to the opening diameter; besides the mesh number the screen manufacturer publishes a whole series of additional information, such as:

- hole diameter,
- number of holes per cm^2,
- throughput in %,
- type of hole distribution,
- vertical and horizontal hole geometry.

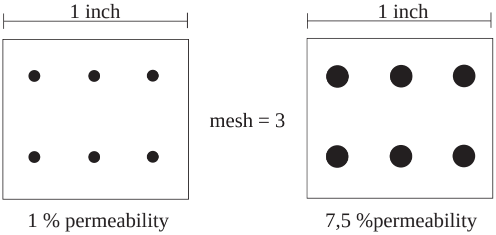

Fig.: Permeability (in % area) with the same mesh number, dependent on the diameter of the openings.

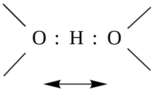
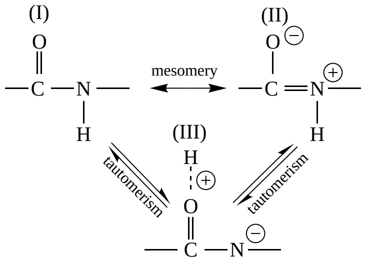
Meshtester Device for measuring rotary screens for screen printing with regard to manufacturing-related differences in the open area.

Mesomeric resonance is present in homogeneous molecules, which may have different chemical bonding structures. To an extent they form a bastard structure of atomic bond with a partial ionic character, which merges due to transfer of electrons flowing into each other, which however does not result in any change in the composition of the molecule. Mesomeric resonance is favoured for molecules from different atoms and also atoms lying particularly close to each other, whose unsymmetrical arrangement gives cause for a shift of developing dipole forces, as for example happens in hydrogen bonds, where the hydrogen (more precisely a hydrogen proton) swings to and fro between two oxygen atoms. [Distinction: mesomery = electrons migrate; → Tautomerism = atoms (usually hydrogen) migrate].



Mesomeric resonance occurs diversely in the interaction of fibres and dyes with conjugated double bonds. Hydrogen can be added to different molecule parts in tautomerism, which then easily leads to a transfer from the system of the alternating double and single bonds, whereby varied zwitterionic states can be observed and also correspondingly shifting electrical attraction forces are triggered between the fibre and dye. In the following example of another similar limit formula, attention is paid to the whereabouts of the hydrogen on the polyamide molecule and the load ratios conditioned by it, which are of course only effective at the shortest distance:

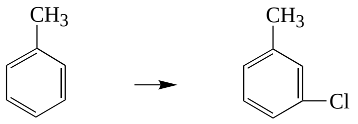


It should be understandable that such a delicate fibre system may have a strengthening effect with regard to dyes with similar resonance structures. This then easily leads to unpleasant differences in the shade of colour. So, shifting resonance structures are consulted for the plausible explanation of the phenomenon of some dispersion dyes, which dye different types of fibre in accordance with the same dyeing principle in varied shades of colour.

Meta- (Gk.),

I. prefix for inorganic compounds, which are produced via heating and release of a molecule of water from the aqueous ortho compound, e.g. metaphosphoric acid HPO_3 (from $P_2O_5 + H_2O \rightarrow 2\ HPO_3$).

II. as a designation for the isomeric status of substitution products in compounds of aromatic nuclei (compare →: Ortho-; Para-), e.g.:



toluene metachlorotoluene

Meta-acids/salts → Acid anhydrides.

Metabolites Living cell components for the reaction control of the metabolism, e.g. ferments and vitamins. Metabolites emerge as intermediate or finished products in the biodegradation of waste water contents.

Metabolite test As with surfactant degradation via those metabolites in → Waste water treatment plants, but also occurs in water under the influence of micro-organisms, the legal regulations (MBAS or BiAS analysis) in corresponding products found to be biologically soft and biodegradable must require an almost complete biodegradation (→ Surfactant biodegradability, evaluation of). The metabolite test looks into the phenomenon that the surfactant degradation does not necessarily have to be complete either; stable intermediate stages (metabolites) might remain. Waste water is led in circulation for several weeks in the waste water treatment plant simulation test for this (see Fig.) and each time new tensides and new waste water materials are added. Even the smallest quantities of stable metabolites have to be increased ever more in this way and become able to be tested. If a tenside passes this test, it is considered to be completely biodegradable. The limits of the evidence of this test are reached if the test compounds are not easily dissoluble or if intermediate products, which are not easily dissoluble or are strongly adsorbing, are formed in the degradation process. As a modification of the coupled units test, the metabolite test is a test system in which precipitation and/or adsorption of not easily dissoluble substances (on the activated sludge) might feign a degradation.

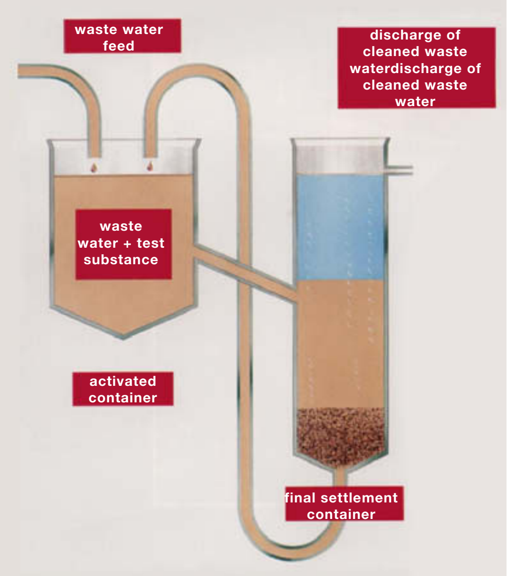


Fig.: Metabolite test as a laboratory-scale sewage treatment plant: the biological decomposition process of tensides in the course of operation of a communal sewage plant is successfully and realistically represented by the sewage plant simulation test (source: Henkel).

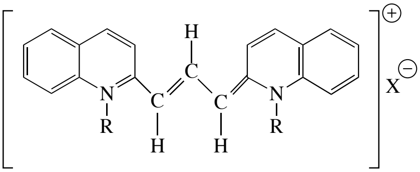
Metachromasy Property of certain dyes to show a different shade depending on concentration, aggregation, solvents and substrate. If, for example, you place an alcoholic solution of pinacyanol in sufficient concentration in a reagant glass here, this appears dark red in the inspection.



pinacyanol

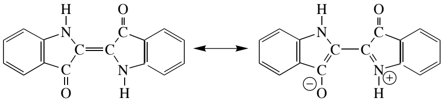
The thin layer, which flows down on the glass walls after the solution is tipped out, is, however, blue. This is a result of different strengths of absorption of different wavelengths of light by the dye. Red is not noticeably absorbed. The strongest absorption of the dye is in the orange parts of the spectrum at about 605 nm. The absorption subsides in the shorter wavelength range, but is still strong enough that with sufficiently large layer density or concentration the eye can no longer distinguish light let through here. So only red light is let through. By reducing the layer density, green and blue rays still have an effect on the eye as well, which results as the colour effect of blue.

By measuring the ratio of the noticeable (I_0) to the let through light intensity (I) for all the wavelengths of the spectrum, e.g. for the infra-red and ultraviolet area as well, the so-called extinction coefficient ε, which is defined as follows by Lambert-Beer's Law, can be determined:

$$\log \frac{I_0}{I} = \varepsilon \cdot c \cdot d$$

c = concentration in mol/l,
d = layer density in cm.

The graphical representation of the dependence on the extinction coefficient of the wavelength or wave number is called absorption curve. So this absorption curve is a material constant, with whose help the dye can be characterised and information on its structure can also be obtained. The absorption spectrum is only a constant in a diluted gas state. In solution or even in an adsorbed or crystallised state, the absorbing molecule is in interaction with neighbouring molecules and more or less alters its structure through this and thereby its absorption spectrum as well. This means that the colour of a dye is in no way invariable. So it has been known for a long time that dyes with asymmetric load distribution, so-called merocyanine, can sustain considerable colour changes in polar solvents. This is the cause of the change from blue to red in indigo: indigo can be recorded in different mesomeric formulae (polar and unpolar), whose weight is shifted depending on the polarity of the solvent, e.g.:



The absorption maximum is shifted between tetrachloride hydrocarbon and aniline by approx. 1000 cm^{-1}.

Water has a distinctive structure due to the hydrogen bridges, which are formed between the isolated electron pairs of oxygen and the hydrogen atoms of neighbouring water molecules. The order is certainly not complete so that it can be increased on surfaces, e.g. on the hydrophobic surface of dye molecules and macromolecules. But this means a degradation in the entropy. This system tries to balance this entropy degradation by reducing the surface, i.e. the addition of the dye is encouraged on the macromolecule. This effect is by far the greatest as a solvent in water. If you are dealing with even, two-dimensional molecules as with dyes, a reduction in the surface can also be carried out by stacking several dye molecules on top of each other, i.e. by an aggregation. In fact, a lot of dyes tend to form such aggregates just in water. Usually dimers appear as the first stage of aggregation. As the electron system of a dye molecule can be regarded as an electron oscillator, the splitting into two frequencies normal for such systems is carried out in the combination of two such oscillators with the same natural frequency, in a higher and a lower one than the one in the single oscillator. If the dimer molecule has a high symmetry, a transmission moment, corresponding to a strong light absorption, only remains for the higher frequency. The absorption band observed in the dimering is, compared with that of the monomer, shifted in accordance with short waves. A slight fault in the aggregate symmetry due to substitutents on the dye molecule also makes the long-wave shifted band appear weak.

The shift of the bands to the short-wave side of the spectrum is generally about 1000–1500 cm^{-1}, but increases, as with thiocarbocyanin, up to twice the amount by increasing the aggregate through further increase in concentration, whereby a limit is clearly reached. The dye molecules, which show such aggregations in aqueous solutions, are generally cations or anions with corresponding counter ions. It can be demonstrated that the dye ions are stored directly together even with the same charge. But through molecular weight measurements and measurements of the circular dichroism when using optically active counter ions it can be shown that the counter ions on the polyion are held in the aggregates and thereby extensively compensate the charges. The dye salt is completely dissociated in smaller concentrations of dye, for which there is still no aggregate formation, as the molecular weight measurement also shows (according to Scheibe).

Meta-formaldehyde → Trioxane.

Metal alcoholates Type R-Ome (→ Alcoholates). Conversion products between lower aliphatic → Alcohols and Alkali metals or polyvalent → Metals. The most well-known chemical textile auxiliaries are →Aluminium alcoholates as solvent impregnating agents. Metal alcoholates are normally easily decomposed via humidity, which is why a stabilising stage is carried out by means of conversion of the metal alcoholates (using acetylacetone, acetoacetic acid ethylester or higher fatty acids). The impregnating effect is thereby certainly worse the more absorbed alcoholate groups are converted to metal.

Metal-complex dyes Dyes of a different constitution with metal absorbed in the molecular complex, which gives the dye additional properties (light, wet fastnesses, bonding possibilities on the fibre).

I. Acid 1 : 1 metal-complex dyes: monoazo compounds with sulphonic acid groups, which contain one chromium atom per dye molecule (chromium complexes). Shades usually dull. They are chiefly dyed on wool, partly on silk and polyamides. They have to be dyed from a strongly acid bath and show very good levelling power under these dyeing conditions. Good to very good light fastness as well as good wet fastnesses. Well suited to carbonized piece goods. Quantity of sulphuric acid can be reduced by specific auxiliary products. Sensitive to metal-complexing agents.

II. 1 : 1 : 1 metal-complex dyes: mixed complexes made from one coloured, one colourless component and one metal central atom (variation from 1 : 2 complex).

III. Soluble 1 : 2 metal-complex dyes: Contain two-tone components and a metal central atom. With ionized, acid water-soluble groups or methylsulphone, alkylsulphone or sulphonamide groups. They are dyed onto wool, polyamides and silk. Excellent light fastness, very good wet fastnesses (better than I.). Potting fastness better than I., but not as good as after chrome dyes. Tendency to streaky dyeing on polyamides. Application on wool, neutral or weakly acid, together with levelling agents. Shades usually dull.

IV. Dispersed 1 : 2 metal-complex dyes: Do not contain any water-soluble groups and are applied as disperse dyes on polyamides. Good light and wet-fast, building up to the deepest tones. Tendency to streaky dyeing in brighter shades. Usually dull tones.

V. Pre-metallized direct dyes: Direct dyes, which contain one or several complex-dependent metal atoms in the molecule. Widely distributed in the highly fast to light direct dye ranges. Usually copper as the metal. In direct dyes capable of after coppering, which e.g. contain o.o-dioxyazo groups, the copper atom is not applied during the dye production, but only after the dyeing process, using after coppering.

VI. Phthalogen metal-complex dyes: Group of dyes, which are used with the blood dye haemin and the vegetable dye chlorophyll. They have a 16 element aromatic band and are usually present as metal complexes (copper, cobalt, nickel). Depending on additional groups, which are annexed to the phthalocyanine nucleus, pigment, direct, sulphur, vat and reactive dyes are produced. The → Phthalocyanine dyes synthesised on the fibre also belong to this group. Various phthalocyanine derivatives are subject to phototropism, especially if dyeings and prints are finished with synthetic resin.

Metal complex dyes 1 : 2 type Two dye molecules go onto a chrome atom, as is the case in weak acid attracting 1 : 2 metal-complex dyes. → Chromium-complex dyes.

Metal-complexing agent → Complexing agent.

Metal content of cotton Native cellulose fibres, such as cotton, contain different quantities of metal depending on their origin, absorbed as feldspars $K[AlSi_3O_8]$ and/or $Ca[A1_2Si_2O_8]$ (potassium and/or calcium aluminosilicate) as well as their weathering products, the aluminae with the general empirical formula $(K_2H_3O)_y\{Fe_2(OH)_2[Si_{4-y}A1_yO_{10}]\}$ (y = 0.7–0.9). Different quantities of metal cations: Mg, Ca, Ba, Fe,

Tab.: Metal content of different raw cotton provenances (source: Wurster, Janssen and Rath).
n.a. = not available.

Mn, Cu are found absorbed in the aluminae. The table shows the metal content of different raw cotton origins.

Metal detecting device Device for the local monitoring (detecting) of the smallest particles of leading metals to prevent damage to calender bowls and shearing blades. Used at fabric speeds up to 400 m/min.

Metal detectors are metal detecting devices for the purpose of tracking down and removing metal parts dragged along (e.g. wire card teeth) in order to prevent damage to finishing machines. Tracking down metal even in heavily scutching, thin textile webs, already at 1 mm ∅ and at a speed of 2–360 m/min. Besides manual detecting devices, there are fixed installed detecting devices, which still respond to iron particles of 10 mg at fabric speeds of 400 m/min.

Metal fatty alcohol sulphates → Fatty sulphuric esters.

Metal fibres (MTF, ME), textile processed metal filament and staple fibres. Recently spinnable cut forms of metal filaments or → Metallized yarns, e.g. up to 5–15% compared with other long staple fibres in fashionable glitter effect yarns. Metal filaments are manufactured from high-grade steel filaments in the nozzle extraction process. Uniformity, high strength, abrasion resistance, electrical conductivity, temperature resistance, low extensibility. Chiefly used as an addition, e.g. in carpet yarns; prevents electrostatic charge. After sizing, 100% yarns can be processed in weaving and knitting. Steel filaments are, e.g., used for tyre cord.

Metal flock → Flock made from metal powders.

Metal foil printing Works according to the transfer printing technique. Fabrics are firstly pre-printed with adhesive and afterwards treated together with the metal foil in a transfer calender (see Fig.).

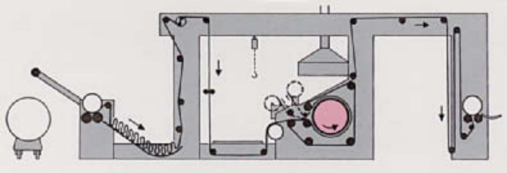

Fig.: Calender for metal foil printing (Stork).

Metal frames for screen printing have displaced wooden frames due to their dimensional stability. They are manufactured from tubes with different profiles. Besides square and circular profiles, above all A and W profiles have been established.

Metal indicators For complexometry using complex ions and similarly acting dioxy dyes, barbituric acid derivatives, etc. The metal complexes of these metal indicators are coloured differently from the free dye acids as a result of changes to the resonance system caused by complex formation. The metal complexes hereby usually behave in a somewhat less stable manner than the corresponding complexes with, e.g. Komplexon. From this, it is used in such a way that a trace of metal indicator is added to the metallic salt solution to be titred (buffered with ammonia and ammonium chloride to ca. pH 9–10), whereby the colour of the free dye acid is altered to the colour of the metal dye complex. This solution is then titred with a complexing agent solution.

Metallic contaminants in textiles Comparatively simpler identification by careful bleaching in a very short liquor with alizarin. Contaminated metals thereby act as a mordant. So, a fixed dyeing is produced on the relevant areas.

Metallic soaps Water-insoluble, fatty acid metallic salts, usually of aluminium for impregnating purposes or of magnesium for sealing and weighting agents; (with addition of fatty alcohol derivatives) as a bleaching stabilizer.

Metallic yarns From a textiles point of view, it is more correct to say → Metallized yarns.

Metallizable dyes Contained in the dye molecule → Mordant-attracting groups, which can form metal complexes (so-called colour lakes) with metals (metal mordants or metal salt aftertreatments). Examples: madder red, turkey red, logwood, alizarin red, mordant dyes, chrome dyes, aftercoppering dyes. The dye metal complex brings a colour change and has improved fastnesses in comparison with the original dye.

Metallized yarns (metal spun yarns, tinsel threads), products for textile purposes made from or with copper, brass, aluminium, silver, gold and similar, in different fineness, length and make-up.

I. Endless yarns: made from metal rods drawn through a narrowing bore hole made of steel or diamond. Are woven directly or with wool, silk and similar.

II. → Metal fibres.

III. Flat thread (tinsel, lametta, Plätt, Plätte, Plasch, Rausch): produced from endless yarns via band-type rolling out, possibly also imprinted or corrugated (frisé). Material description given by m/kg.

IV. Spiral filaments (purls, Kanetillen, Canetillen or helical tinsel yarn): pure metal filaments, produced by the helical re-winding of a needle, which is later pulled out.

V. Metallic yarns, wrapped in viscose, acetate or other plastic films and similar.

VI. Metallic spun yarns: different techniques, e.g. helically rewound textile yarns with tinsel (such as cotton, linen, viscose filament, etc.; or with coloured silk as so-called lustre yarn, with pearly ply-yarn base yarns as a flickering diamond yarn) or conversely tinsel gimped with e.g. finer viscose yarn or aluminium twist finely gimped with narrow little cellophane bands as an alucell, or tinsel lightly twisted and twisted into viscose yarn for example, also in variation with non-oxidizing metallic yarns.

VII. Metal yarn: Metallized textile yarns, e.g. galvanically produced (yarns previously made dominant) or with additives from atomised cathode metal in vacuum on acetate threads and similar, also similarly cut from films of polyesters with metallic vacuum, or impregnated with mixtures from metallic dust, acetate cellulose and similar. The content is guaranteed for real silver or gold twist respectively. Gold twist mostly consists of silver with gold plating. Fake gold threads (so-called simili or cement), for example, consist of copper with zinc coating (brass layer) and fake silver twist of copper with silver coating. Fineness given in nm diameter.

Application: variedly for party clothing, cocktail dresses, theatre clothing, effects in fashion clothing, deco furniture materials, in splendid knitting, hosiery goods, knits, trimmings, amongst others.

Metalloids → Non-metals.

Metal mordants for mordant and chrome dyes Chiefly chromium, aluminium and iron salts; for special cases (in alizarin indigo print) also nickel and zinc acetate as well as cobalt acetate (for nitrose beta-naphthol printing). Lacquer formation with mordant dyes generally takes place most easily using acetates, reduced using lactates, more or less incompletely using oxalates, tartrates and citrates.

Metal powder printing (→ Bronze printing), designing technique for the manufacture of gold, silver and graphite printing effects in hand block, screen, spray or roller printing. Precursor of → Pigment printing. Fixation of metal powder usually with aqueous plastic dispersions.

Metal powders (bronze colours), powdered metals of copper (alloys: gold bronze, bronze, German silver), aluminium (silicon alloys), also gold, amongst others. Usually coated with a fine layer of grease on the market. Shines metallically; in the most varied colours, either produced by heating, light-resistant tarnishing colours (yellow, red, orange, brown, violet, etc.), or dyed using cationic dye (so-called patent bronzes). Application: metal powder printing, amongst others. Fine powdered qualities, which are somewhat more matt in tone, but rather tend to be used less in film screens or added to roller engravings, are preferred for this.

Metals Chief representatives aluminium, barium, beryllium, lead, chrome, iron, gold, iridium, cadmium, calcium, potassium, cobalt, copper, lithium, magnesium, manganese, molybdenum, sodium, nickel, palladium, platinum, mercury, radium, silver, strontium, tantalum, uranium, bismuth, tungsten, zinc and tin. Heavy metals (density > 5): lead, iron, gold, cadmium, copper, manganese, nickel, platinum, mercury, silver, tungsten, zinc and tin. Light metals (density < 5): aluminium, barium, potassium, calcium, lithium, magnesium, sodium, strontium and titanium.Precious metals: gold, platinum and silver. Precious metals do not form any oxides in moist air or when heated. Properties: metals can be melted and thereby mutually dissolved into each other in any required ratio (alloys). Oxygen compounds: → Oxides (basic character). Hydroxide compounds: → Bases form (OH) ions; hydroxides are produced with acid salts. Exceptions: dependent on simultaneous presence of oxygen atoms and hydroxyl group, with increased number of oxygen atoms in aqueous solution. Tendency to weaker release of OH ions and stronger release of hydrogen ions. Hydroxides of metals with a valency of 1 and 2 therefore produce strong bases, metals with valency of 3 produce weak bases, and metals with an even higher valency produce acids.

Metal salt treat of dyes or dyeings This means treatments in the style of → Chroming (pre, single-bath, afterchroming) and aftercoppering (→ Aftercoppering dyes) in cellulose dyes.

Metal spangles → Glitter pigments.

Metal yarn → Metallized yarns.

Metameric index Two samples, which, for example, have the same colour in daylight, possibly have a different colour when the illumination is changed, if they have different spectrum reflection curves and are therefore metameric. A metameric index is used for the quantitative labelling of this undesirable property, e.g. in order to discover the sample which shows the smallest metamerism, when comparing several colour recipes for the post-dyeing of a pattern. If both samples do not have a colour difference in daylight D65 ($\Delta E = 0$), the metameric index of this sample pair for an illumination change from D65 to another light source is equal to the colour difference of the samples in this other light source. The metameric index is, for example, determined in the colour recipe calculation in this way, as the colour recipe of the post-dyeing is so determined that the colour in daylight D65 agrees with that in the pattern. In determining the metameric index for a washed out colour recipe in comparison to the pattern, even though perhaps only small, a colour difference will also always exist in D65.

Metamerism is based on the fact that two shades matching in daylight appear to be different in other light (e.g. artificial light) (→ Colour stimulus), e.g. exhibit a shade change from red to blue. Explanation: The summary of the colour effects determined by the reflectance curve is the function of the observer and the light energy coming into the eye, as long as the surfaces under the reflectance curve of both shades are equal, if not identical. If the observer or the light is changed, the areas are no longer offset and the shades are different. In order to prevent metamerism, the reflectance curves of both shades must be very similar, but preferably the same.

Metamerism can be explained colorimetrically with the aid of the tristimulus values X, Y and Z. Two patterns are the same at a particular illumination, if their tristimulus values are equal for this type of illumination. This condition is obviously met, if both patterns show identical reflectance curves. Equal tristimulus values may however also be reached with different reflectance curves for a particular light source, as this merely concerns cumulative values for the X, Y and Z values. It is well known from dyeing practice that a particular colour pattern can be set using different dye combinations. So orange/red/blue, for example, can be set so that both dyeings show the same shade in daylight, i.e. that the tristimulus values for daylight (D65) are equal. Because the reflectance curves of both dyeings are different, however, the tristimulus values are also different for the other light sources and both dyeings therefore show different colours with other light sources.

Metaphosates Condensate phosphate with ring structure. Do not have any complex-forming powers (potassium metaphosate and sodium hexametaphosate). Typical metaphosates of the $(NaPO_3)x$ type are cyclic polyphosphates, so not identical to the structure of the Graham's salt type of long chain polyphosphates, also called hexametaphosphate.

Metastable states Designation for pseudo-equilibrium systems, which do not decay in a particular temperature range, in which they are thermodynamically unstable, such as metastable foams.

Metering Metering is understood to mean the measurement of an amount of substance. A dose, which may be a substance, but also energy, is added to another amount of substance. Each measured amount of a dye or textile auxiliary in textile finishing should therefore be understood as a dose, which is supplied to a medium, serving the finishing of textiles in some way. If one talks of metering as finishing processes today, this is usually thought to mean a dose of liquids or solids distributed into a corresponding medium over a certain period of time, in non-observance of the full meaning of the origin of the word. Some meterings already practised are shown in the table, whereby the types of dose, their control size and, in so far as they are known, the processes are listed.

Dose	Control parameter	Dye system	Process
Energy	Temperature (K)	Disperse dyes	SDC system (Thies)
	Frequency (Hz)	All	
	Voltage (U)	All	
Salt	Quantity/time	Substantive and reactive dyes	MPI system (Thies)

Acid	Quantity/time	Acid dyes	Dosacid (Ciba-Geigy AG)
	pH		

Tab.: Some examples of the use of metering processes and their application in the dyehouse.

Controlled addition of dyes or chemicals to finishing liquors is gaining ever more importance because manual metering is no longer suitable for the accuracy and cost demands of modern textile finishing. In the simplest case, substances are linearly metered (amount/time diagram); but dyes and scrooping agents are usually metered on a sliding scale, while salts, acids and alkalis tend to be progressively metered. The metering of chemicals and auxiliaries represents an important constituent of chemical engineering in continuous pre-treatment. The control and monitoring of a continuous chemical process is therefore more difficult compared with discontinuous processes in which the process conditions such as fabric speed, fabric throughput and liquor exchange may fluctuate widely in an impregnating dwell process. However, the quality and regularity of a pre-treatment is directly dependent on the control of the chemical process. Metering systems for pH regulation of the dyebath are important in the discontinuous type of dyeing. The solid metering of salt is also gaining in importance.

The classic system of chemical metering (Fig. 1) is the control of a continuous system via the decreasing liquor level in the impregnating section. Simple mechanical float switches or electrical level probes are chiefly used for detecting the liquor level. These level controllers operate a solenoid valve, metering pumps or other dosing systems, which is metered through the fabric proportional to the liquor abduction. The dosing should be increased as a function of the difference in squeezing in a wet-on-wet impregnation. The dosing

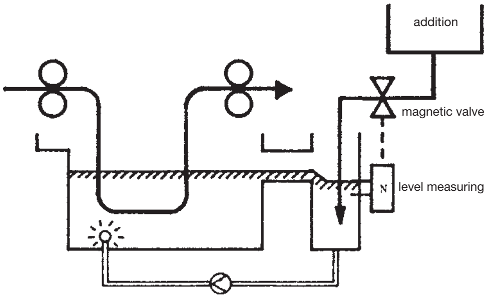

Fig. 1: Level controlled metering system.

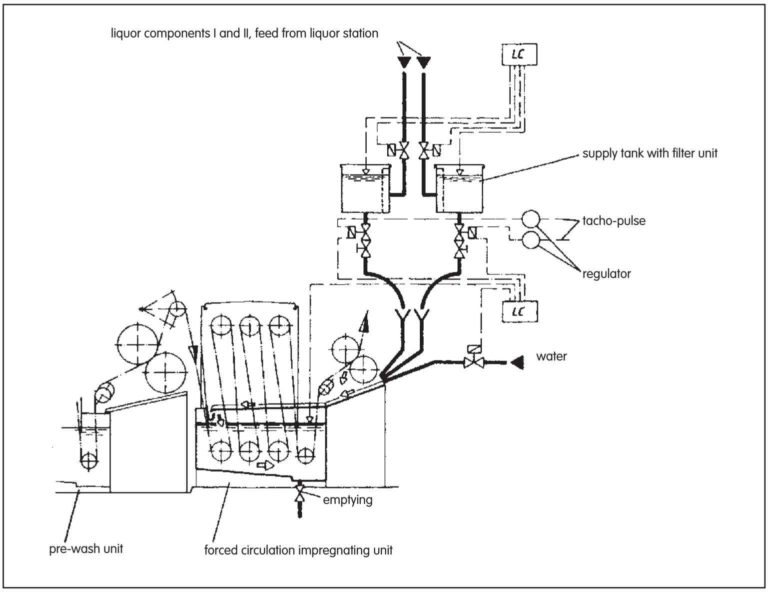

Fig. 2: Wet on wet impregnation with the Polykomat automatic metering unit as a speed-proportional metering system.

factor is only dependent on the difference in squeezing, but not on the liquor exchange factor.

The speed-proportional metering system is just as widely used. A pulse generator, which is normally fitted to a roller of the impregnating padder, sends a pulse to the metering pump in accordance with a particular meter number. This starts to operate within a set time interval, whereby the metering time should be adjusted via a pulse generator. The maximum metering time per pulse is generally 10 s. and the pulse spacing is 10–20 m. Speed-proportional metering systems such as the system from Texicon operate according to the same principle, except that measuring cylinders are used instead of metering pumps. Prescribed chemical volumes are prepared in these cylinders and called for by the pulse generator (Fig. 2).

The systems mentioned so far, in each case require a titrimetric control to determine the chemical content in the impregnating liquor. Metering systems with an automatic concentration measurement make these methods superfluous and facilitate an automatic control of the dosing. The chemical content in the impregnating section is detected by a measuring cell and a concentration meter. A measuring transducer then controls the dosing via valves or metering pumps. This involves an actual/set value comparison, i.e. true automatic control in the closed control circuit.

The concentration measurement is carried out by

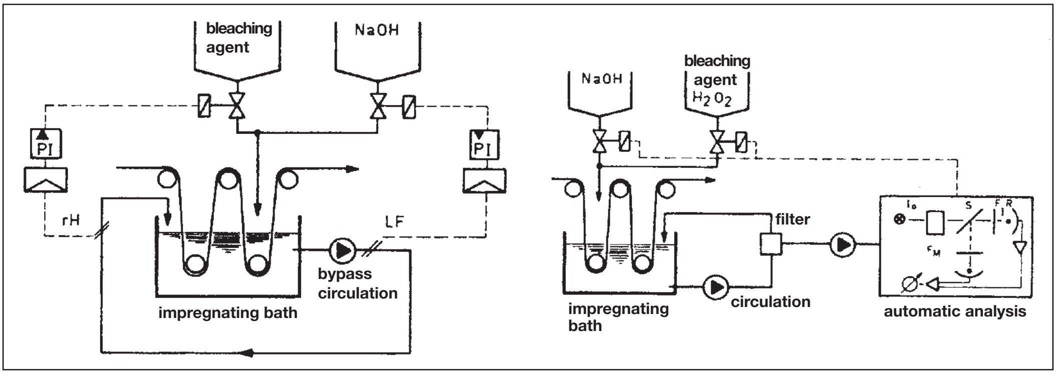

Fig. 3: Comparison of the in-line measurement of redox potential (rH) and conductivity (LF) for metering bleaching agent and caustic soda (left) with on-line measurement by thermometry (right).

devices, which automatically titre (on-line) liquor samples in given intervals of time or, for example, carry out heat-tone measurements by continuous flow of the liquor sample (on-line thermometry). Conductivity and pH devices are chiefly used for determining the concentration of caustic soda liquor (in-line measurement). This method can of course only be put into use if “titreable” chemicals are available in an impregnating liquor or the conductivity measurement is significant. Other recipe components such as stabilisers, complexing agents or washing agents need to be combined with the measurable chemicals, if the whole system is to be automatically controllable (Fig. 3).

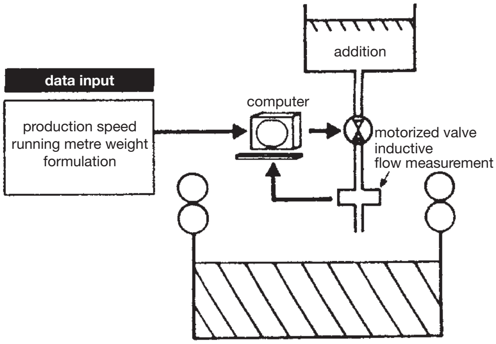

Fig. 4: Computer controlled quantity-proportional metering system.

Important new developments in metering technology are computer-controlled, quantity-proportional metering systems (Fig. 4). From the input data of production speed, running meter weight and recipe the computer calculates the chemical quantities/h required. The metering is carried out via motorised valves; the chemical flow is detected and re-registered by inductive flow measurement. Permanent control of the chemical quantities being added is possible using this system; the motorised valves are controlled by set/actual comparison by the computer. No mismetering can take place if the fabric data has not been input, as the computer will not let the system start.

Metering roller → Applicator roller.

Metering station Plant for the metering of particular quantities of dye and chemicals. Supplied as a ring main via mixing station or metering unit directly to the dyeing plant (see Fig.).

Metering systems for dyes and chemicals are used for mixing chemicals according to prescribed recipes. The mixture is intermittently or continuously dosed into the process. The term “metering” has become a term in wet finishing. In the following “metering” is understood to mean the addition of a given quantity of solid or liquid active material to a liquid treatment medium (dye or treatment liquor) over a period of time (metering time). According to this definition, the term “metering system” covers the metering volume, metering concentration, metering mechanics, metering curve as well as the type and composition of the metered substances.

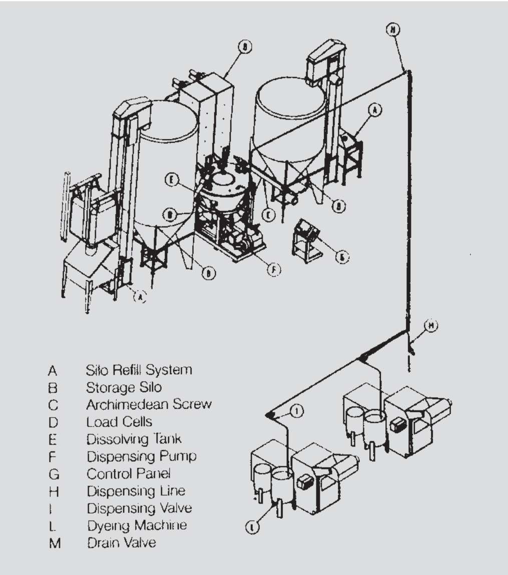

Fig.: Lawer Silos-Dos-System a typical metering station for dyestuffs.

Two types can in principle be distinguished:

1. metering systems for the stabilisation of a given active concentration in a treatment system in continuous use (continuous process).
2. metering systems for the control of a dye or reaction system with increasing treatment concentration (batch-wise treatment, exhaustion process).

The first case is used, e.g., in the bleaching and washing baths of continuous plants with automatic hydrogen peroxide, pH and surfactant control using metering pump systems. The second case, e.g., forms the basis of the metering dye process in the exhaust dyeing of cotton with reactive dyes or in the metering of acid for the dyeing of wool and polyamide or of silk with acid and metal-complex dyes. Over and above that, the metering principle can in general be used for the control of exhaust dyeings by means of electrolyte and dye metering. Both systems can be controlled, i.e. via monitoring points and feedback signals, or programmed. Programmed means metering according to a given volume/time-plan without feedback signals.

Apart from the weighing of dyes in dyeing, the weighing of print pastes (Fig. 1) (volumetrically or

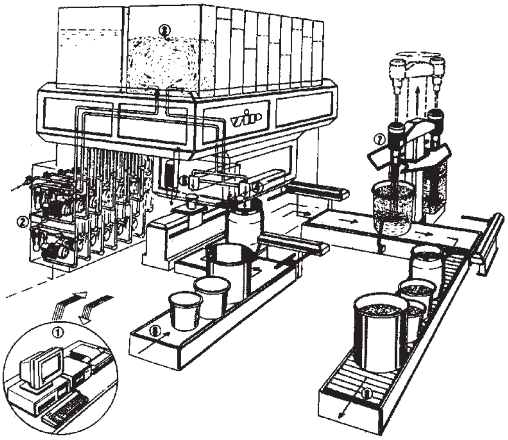

Fig. 1: Automatic dye kitchen for printing (according to ViP). 1 = computer control and monitoring; 2 = circulation and filtering system; 3 = storage tank for dyes and thickeners; 4 = compact metering block with steplessly controllable valves; 5 = automatic sample quantity metering and mixing system; 6 = bucket conveyor belt; 7 = Duplo-robot stirrer; 8 = bucket removal belt.

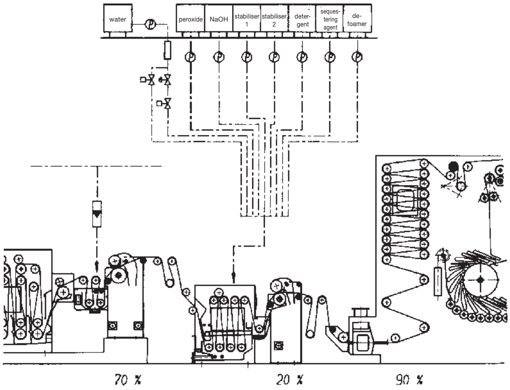

Fig. 3: Liquor application with the impregnation stage of Küsters cotton pretreatment.

gravimetrically) and the distribution of chemicals delivered to dye batches (Fig. 2) is also controlled by metering plants.

A wet-on-wet impregnation is, e.g., carried out in the vat impregnation in the roller vat (Fig. 3). 60–70% water is input, which must be exchanged with the chemical concentration of the impregnating bath. The mixing of both liquids and the additional liquor quantity of 10–20% applied onto the fabric via the squeezing unit of the impregnating vat require an injection of a liquor concentrated by about 4–5 times (concentration factor refers to 100% liquor pick-up, calculated on the dry weight of the fabric) to achieve the necessary quantity of chemicals. This liquor exchange requires expensive devices for metering. The high chemical concentrations necessitate a separation of chemical preparations in different vessels to avoid premature decomposition of the bleaching agent. The hydrogen peroxide on the one hand and the alkali with the stabilisers and surfactants on the other should be prepared separately. The selection of auxiliaries is however, restricted by this, for example, surfactants do not always show the high alkali resistance demanded or it has to be bought at the price of a loss of cleaning effect. The separated preparations have to be mixed via multicompo-

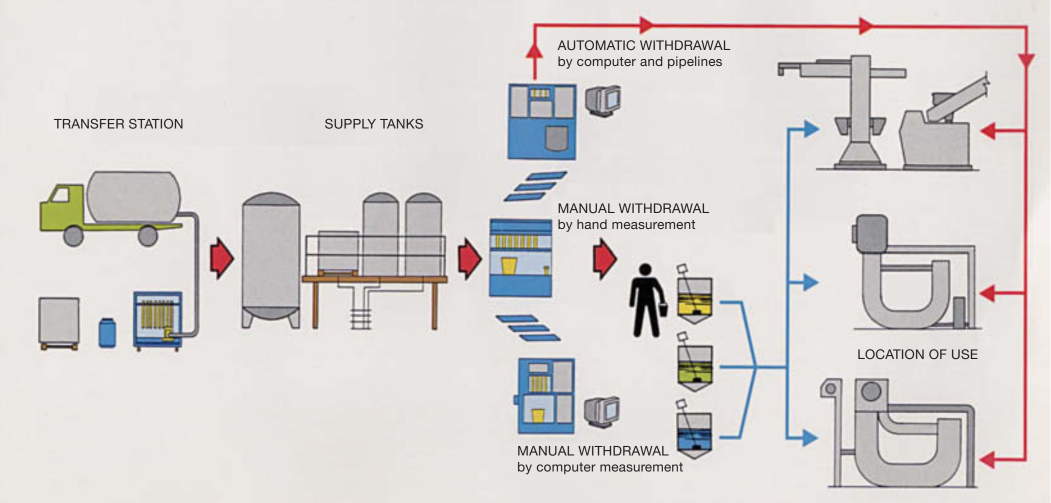

Fig. 2: Metering technology in a dyehouse (according to Meter).

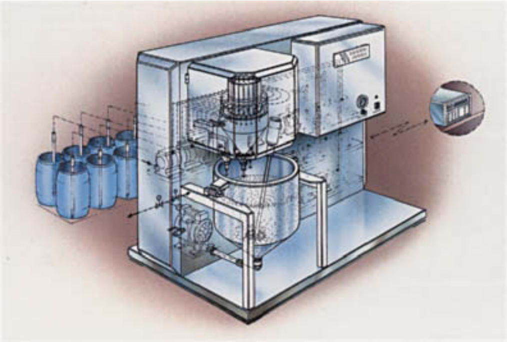

Fig. 4: OCD metering unit (van Wyk) for padder trough.

nent metering pumps shortly before being added. Quantity and mixture ratio can only be determined via costly, permanent bath control (titration).

If padders are to be charged with liquor before stretching, it is best to use fully automatic metering (Fig. 4) to reduce the residual liquor quantity. Fully automatic on-line metering systems for chemicals are based on the principle of gravimetric measurement in order to achieve a better measuring accuracy than in volumetric processes. With their aid, completely mixed preparations of 200 l can be prepared from a maximum of 20 chemicals and water. Each chemical is pumped directly from the vessel or the drum in which it was delivered by a pump. These quantities are directly delivered to the processing machines. The plant is controlled from a microprocessor terminal, which is set up close to the processing machine.

High wet pick-up plants, such as the Flexnip (Küsters), are most effectively charged with the aid of a continuous metering and mixing plant in continuous cotton pre-treatment (Fig. 5).

Metering system with proportioning cylinders A system for metering specific quantities of dyes and chemicals using proportioning cylinders with a content of e.g. 251 for each product. Sampling cylinders up to 500 ml are also available for very small quantities.

Metering technology for reactive dyeing The dyeing of cellulose fibres using reactive dyes can in principle be carried out according to two different types of process:

1. temperature controlled dyeing processes.
2. pH controlled dyeing processes.

In the temperature controlled dyeing process, exhaustion and dye fixation are controlled by the temperature and in the pH-controlled process by the alkali addition.

It is the purpose of the metering systems in reactive dyeing to systematize the alkali allowance and to programme the dyeing process as a preliminary stage to automation. Programming means replacement of the manual implementation of dyeing by a fixed programmed processing sequence, i.e. an industrial production principle instead of workmanship. Programming means adapting the most important process steps of dyeing, fabric quality and circulating time of the fabric to the dyeing machine The depth of shade, fixation efficiency in exhaust dyeing (substantivity), rate of reaction (reactivity) and the setting yield should also be considered.

That is why besides chemical and technical reasons, the development of metering technology in the plant also has economic and logistics grounds. The main argument is the improvement in reproducibility through

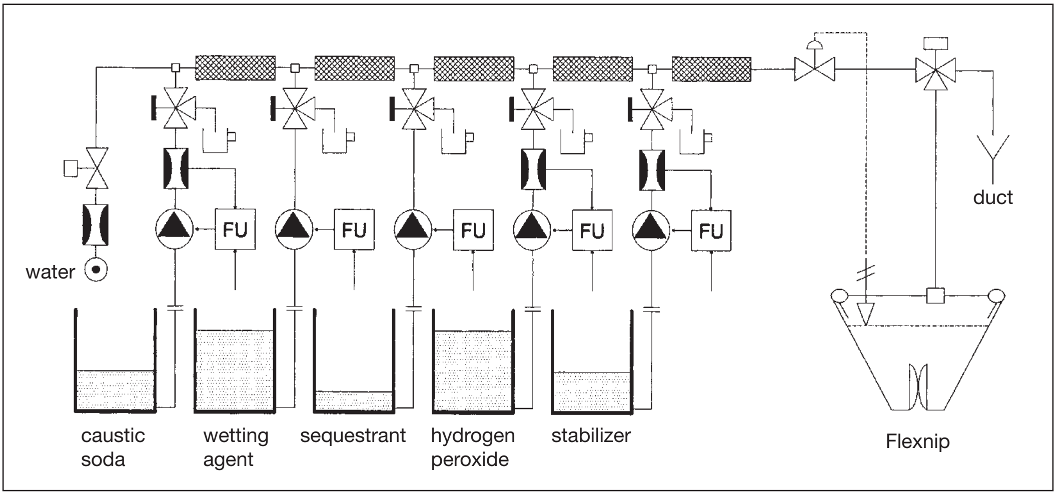

Fig. 5: Contidos continuous metering and mixing unit (Küsters).

reduction of the estimation margin by operating staff, simplification of the remaining manual operation, reduction of chemical and energy consumption and reduction of the proportionate labour costs per dyeing. The most important technical reason results from the better distribution of chemical additions to liquor and fabric, i.e. better mixing during introduction into the dye liquor and thus prevention of local over-concentrations, which may lead to precipitation and separation of dye and auxiliary. The kinetic task of alkali metering is the control of the rate of reaction using programmed pH build-up in the dyebath.

Metering processes in reactive dyeing can be subdivided into different groups:

1. dye metering.
2. salt metering.
3. alkali metering.

The individual metering steps can be carried out one after the other or simultaneously. Non-metered and metered allowances can also be combined. Attempts to improve the evenness via slow injection of dye solution to salt and alkali containing dye liquors has already been undertaken in the initial phase of reactive dye development, in particular in the field of yarn dyeing. The metering systems familiar today use different metering curves. A metering curve is thereby understood to mean the delivery rate of the metering pump as a function of the metering time. Progressive, linear and combined progressive/degressive curves were described for dyeing using reactive dyes and their suitability for dyeing cellulosic fibres and their blends with reactive dyes were investigated. Both stationary and mobile equipment were designed for solid metering. Solid metering, for example, permits the metering of sodium dithionite in vat dyeing and sodium chloride in reactive dyeing or in dyeing using direct dyes. The electrolyte to be dissolved is fed via a mixed head in a secondary circuit with a solvent channel, in closed machines, and by flexible delivery trunking to the heating panel in open machines. The same microprocessors are used for control as in liquid metering. Solid metering facilitates the automatically metered salt allowance during the dyeing processes in the dye run, a step which is otherwise difficult to implement.

Metering technology for solvent process machines is used for product blending, after treatment process and finishings by pre-selected addition of product quantities at the required moment. Automatic metering using dosing system (see Fig.) is the most efficient.

The fundamental part is a metal cylinder with moving pistons: piston stroke and delivery rate are precisely adjustable (scale with direction guide), check valves control the suction and metering process. The suction is achieved by spring or air pressure and the metering by air pressure. The air for the metering process is provided via a solenoid valve. The product to be metered gets to the operating cylinder via a suction pipe. Air pressure forces the piston down and forces the product through the metering pipe to the pump suction. By this method the product reaches the fabric mixed with the circulating solvent. There are dosing systems with different delivery rates which can be matched with the requirements of the machine depending on its size; varying with regard to requirements and any other required combinations.

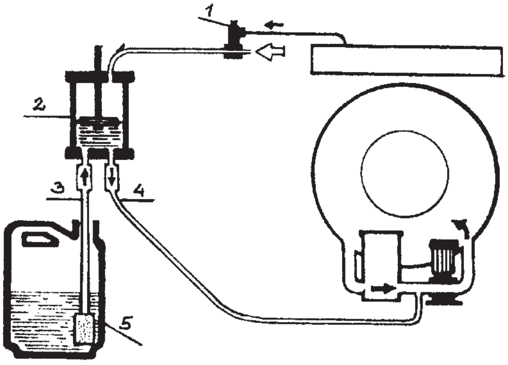

Fig.: Automatic chemicals metering for dry-cleaning.
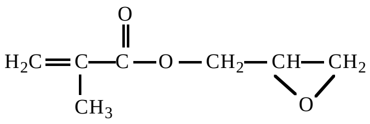
1 = air magnetic valve; 2 = metering unit; 3 = suction line; 4 = metering line; 5 = product container.

Methacrylic acid → Polyvinyl derivatives.

Methacrylic acid glycidol ester (GMA, methacrylic acid glycidol ester, methacrylic acid-2 epoxypolypropylene ester, 2-propenoic acid oxyranylmethyl ester), monomer compound with 2 reactive groups, colourless liquid, almost odourless. Universal self-crosslinking agent for plastics (e.g. polyethylene, polyester, polypropylene), varnish resin on acrylate base, self-adhering adhesive substances; is used in fibre chemistry to modify wool, cotton, polyacrylonitrile, cellulosic fibres, e.g. by deesterification of methyl methacrylate using → Glycidol.



Methacrylic resins → Acrylate polymers.

Methanal → Formaldehyde.

Methanation in the biogas process Biogas is produced everywhere where organic material is microbiologically decomposed by the exclusion of air (anaerobic). This natural process has already been used on a commercial scale for several decades in sludge digestion towers for treating excess sludge from waste water treatment plants with the aim of disposing of the sludge. Anaerobic stimulation has gained increasing importance in recent years as a useful addition to the existing oxygen-supported activated sludge process in waste water treatment.

While the activated sludge process in principle concerns cold (biological) combustion, the biogas process can be understood as cold (biological) pyrolysis. The advantages of the anaerobic method lie in the fact that

- the energy intensive oxygen input can be dispensed with,
- less excess sludge is produced,
- instead of this, biogas is produced, the energy of which is usable,
- instead of an oxidative mobilisation of heavy metals, the result is their reductive precipitation as a sulphide.

The disadvantage of the anaerobic method lies in the high sensitivity to fluctuations in degradation conditions. The degradation chain requires balanced cooperation of the different microorganisms in order to avoid substrate limitation and product inhibition. Firstly, complex organic molecules are hydrolytically separated into soluble low molecular compounds. An acid (in particular, acetic acid) is added to them with simultaneous formation of hydrogen and carbon dioxide. The last step involves the actual methane formation. Besides the broad spectrum and the different generation periods of the micro-organisms involved, as well as the complex interactions between fermentative acid formation and methane recovery, the regulatory role of the hydrogen on the acetic acid formation by the acetogenic micro-organisms, dictated by thermodynamics should still be considered. While acetic acid degradation is independent of the partial hydrogen pressure, high partial hydrogen pressures encourage methane formation from hydrogen and carbon dioxide. The transition from propionic to acetic acid is, however, thermodynamically impossible under these conditions. If more propionic acid is formed by the series-connected materials in the microbiological food chain than can be degraded in further behaviour, this will lead to an accumulation of propionic acid (souring of digester doors). So what matters is that a narrow “thermodynamic window” is set regarding the hydrogen concentration, for which the methanation of hydrogen still functions on the one hand, while the propionic acid degradation is not yet inhibited. In practice, this can be implemented using a microbiological population as active as possible regarding hydrogen recycling (according to Aivasidis).

Methane → Saturated hydrocarbons.

Methane hydrocarbon → Saturated hydrocarbons, which are all derived from the first link in the methane series.

Methanoic acid → Formic acid.

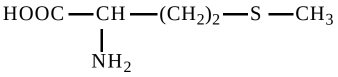
Methanol (carbinol, wood spirit, methyl alcohol), CH_3OH. Molecular weight 32; clear as water, easy and flexible liquid, boiling point 64.8°C; miscible with water, alcohol and ether; toxic; flammable with bluish flame. Wood spirit also contains acetone and methyl acetate. In liquids containing benzene, 20% addition removes the benzene odour. Different compared with → Ethanol: with sodium tetraborate addition and ignited, green flame colour is immediately produced (only after addition of concentrated sulphuric acid by ethanol). Application: added to the wet fabric in textile finishing during the rapid dry process (→ Remaflam process, Hoechst) and burned off for the purpose of shock-like evaporation of water, which should prevent the migration of the dyes.

Methanol/Water flashpoint Important for carrying out the → Remaflam process (Hoechst). Methanol combusts under certain physical conditions. Methanol vapour or the vapour escaping from the methanol/water mixture can, however, only be ignited if its temperature is above the flashpoint. A pad liquor with 35% volume of methanol must firstly be heated to approx. 35°C in order to achieve an ignition of the methanol vapour. As the pad liquor is submitted to the padder at max. 30°C, the temperature should be increased by IR radiators. These are medium-wave radiators, whose wavelength is chiefly tuned to substances containing OH groups. The ignition of the methanol vapours takes place for each batch to be dried and the flames are on the fabric guiding side, but the flame also effects the other side of the fabric. After passing the IR line, the fabric which is enclosed by flames enters the combustion chamber. The evaporation of the pad liquor from the fabric initiated by IR radiators is then continued by heat, which is released by combustion of methanol. The lower thermal value (= combustion heat minus condensation heat of the water component) of methanol is approx. 19 510 kJ/kg. The heat radiation from the steel duct walls is also added to the energy available from the combustion chamber of the Remaflam system. Hot air conducted in reverse by the principal of counter currents is used, which results in the energy released from combustion process being used most in the most efficient way.

Methenamine In the USA, normally in the → Pill test for the testing of flammability, especially of carpets.

Methine group (–CH=), hydrocarbon group with double bond; chromophor.

Methionine A sulphur-containing → Amino acid (monoamino-monocarbon acid), included in wool (0.71%), also identified in silk (2.59%).



$$HOOC-\underset{\displaystyle NH_2}{\underset{|}{CH}}-(CH_2)_2-S-CH_3$$

Methods engineering is used for work intensification and work rationalisation. Handles all the issues concerning time studies, job evaluation, work flow studies and technical workplace structuring. The transport technology in a company is a typical example of methods engineering, because, besides many other factors, time studies and workplace structuring are influenced.

Method study Economically useful application of the timing diagram (→ TMU) within the framework of the → MTM system. For example, the machine manufacturing industry today sells machines and automatic machines, whose machine basic times (t_G) are very low, which are, however, not always effective in business practice, i.e. in some cases, technical parameters, but not yet the desired reduction in working time. Manual times (t_H) may be too high as a result of poor workplace and method study or non-observed work study points already in the machine development. This makes a considerable proportion of the t_H times, minimised by high technical expenditure, economically ineffective.

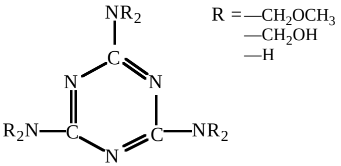
Rules for method study:

1. the most important point is the median plane (symmetry plane of the human body). Frequent or significant movements should be on or at this plane.
2. working methods should be organised rhythmically (countable phase time of a simple rhythm), advisably with slightly bent arm.
3. location of tasks so that good visual control is possible.
4. movements using the forearm as much as possible, for flexibility in change of direction and in the course of circular movement.
5. shape of movement (orientation of direction) and result of movement (structural orientation) should be in harmony with each other; a rational working method follows from this.
6. work tasks reaching behind should be avoided (costly body movements).

It can be seen from this that many work organisation aspects should be considered for optimisation of tasks.

Methoxyl content (methoxyl index), content of the methylcellulose in CH_3O groups. Plays a special role in the evaluation of solubility properties.

Methoxymethylmelamines Completely or partially etherified with methanol → Melamine-formaldehyde compounds; liquid, stable under storage conditions, depending on the degree of methylolation and etherification. Tri- to hexamethoxymethylmelamine used for finishing effects resistant to 100°C wash, no loss of strength from chlorine retention, however occasional yellowing tendency.



Methyl acetate (acetic acid methylester), formula: CH_3COOCH_3. Molecular weight 58. Density at 4°C = 0.9562; boiling point 57.5°C. Soluble in benzine and chlorinated hydrocarbons, also slightly in water. Application: carrier substance for water-soluble, non solvent-soluble substances in volatile organic solvents, for spotting agents, etc.

Methyl alcohol → Methanol.

Methylaminoacetic acid CH_3NHCH_2COOH. Belongs to the amino acids. Colourless crystals; easily soluble in water, less soluble in alcohol. Used for the pulping of vat dyes; as a stabiliser for diazoamino compounds; as a sodium salt for the purposes of wetting, dispersing and washing.

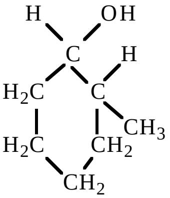
Methylanon → Methylcyclohexanone.

Methylcellulose (cellulose methyl ether), corresponding to the 3 OH groups existing in the cellulose molecule per glucose unit, the etherification using methoxy groups CH_3O can lead to mono-, di- and trimethyl celluloses. The products are water-soluble with a low methoxy content (approx. 5–13%), but insoluble in 5-12 % caustic soda liquor. The products are soluble in cold water with a medium content (approx. 15–25%), but are insoluble in a hot water and alkali solution. The products are soluble in solvents with a high organic content (more than 23%). Tri-methyl cellulose (approx. 45%) is soluble in many organic solvents. Used variably for permanent finishings, sizings, thickeners (especially for pigment printing), adhesives, etc.

Methylcellulose test on textiles Solution of 0.5 g of benzamide indigo blue RRLS to 1 l of distilled water. Load fabric sample, treat for 3 mins, rinse, perhaps dry. Methylcellulose contents are (on every fibre material) immediately dyed dark blue, which is clearly visible under a magnifying glass, but most certainly microscopically. Starch is stained to an extent by this, but not cellulose glycolate.

Methyl chloroform → Trichloroethane.

Methylcyclohexanol (methylhexalin, hexahydrocresol, heptalin), molecular weight 114; density 0.93; boiling point 160–195°C; flash point 68°C; evaporation number 807. Mixture of three isomeric hydrogenated cresols. Colourless liquid with a typical odour. Not very water-soluble, soap-soluble solvent for fats, resins, etc. Used for fat-solubilising soaps and spotting agents.



Methylcyclohexanone (methyl anon), formula as → Cyclohexanone, where hydrogen was replaced by CH_3. Is used as a solvent for fats, oils, resins, chlorinated rubber and polyvinyl chloride.

Boiling range 168–178°C; density 0.910–0.918, flash point 53–55°C; evaporation number 50. Primary product for synthetic resins and synthesis of polyamide 6.

Methyl dye Blue and violet cationic dyes.

Methylene blue active substance → MBAS.

Methylene blue method is used for the control and determination of the concentration of cleaning boosters in organic solvents in dry-cleaning. Most cleaning boosters are anionic compounds, either alone or mixed with non-ionic surface-active substances. These (e.g. alkyl sulphates and/or sulphonates or aralkyl sulphonates, etc.) react in aqueous solution with cationic compounds or pyridine (cetyl pyridinium chloride) as follows: a certain quantity of solution from a cationic substance is added to a mixture of several ml of liquor with anionic dry-cleaning detergents, chloroform and an aqueous acid solution of methylene blue. Two layers are obtained: an upper one containing water with a methylene blue colour and a lower chloroform layer, which should have the same blue colour as the upper layer at the end of the reaction. Pure chloroform, indicator solution (sulphuric acid solution of methylene blue) and titration solution (approx. 1% solution of cetyl pyridinium chloride) are required for titration. Depending on the concentration of dry-cleaning detergent in the liquor, e.g. 5 ml of liquor is added (at 0.5–1% dry-cleaning detergent content) or 1–2 ml (at 2–4% dry-cleaning detergent content).

Methylene blue number characterizes the content of the carboxyl groups in damaged cellulose (oxycellulose). Wash out sample in diluted methylene blue solution and determine the dye uptake using colorimetry of the dyebath before and after washing out. More accurate, but more awkward is the → Reversible methylene blue method.

Methylene blue test For the testing of:

I. Oxy- and photocellulose. Wash out using methylene blue (cationic dye), rinsing with hot water. With damaged material, a lasting blue dye occurs (not however to undamaged cellulose).

II. Acid, alkali and mechanically damaged wool. This has improved dye affinity (test by counting the darker and brighter fibres under a microscope).

III. Linen compared with cotton: after washing out and thorough washing, linen remains permanently dyed, cotton does not.

Methylene blue-potassium cyanide reaction For the testing of glyoxal and glyoxalmonourein, mix the test solution with 1 drop of 1% methylene blue solution and 10 drops of 1% potassium cyanide solution. Glyoxal decolours the solution at room temperature, glyoxalmonourein during heating and glucose only after addition of caustic soda liquor.

Methylene blue-sodium hydroxide test For the testing of reducing sugars. Mix test solution with 1 drop of 1% methylene blue solution and surplus liquor of concentrated caustic soda liquor, then heat carefully without shaking. Aldoses are available when the solution is dyed. Alternate shaking with air and heating makes the colour appear and disappear until the aldose has been consumed. Simple aldehydes do not give this reaction in practice.

Methylene chloride → Dichloromethane.

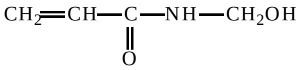
Methylene dyes Blue and green cationic dyes.

Methylethylcellulose Cellulose ethers of combination dyes (→ Cellulose derivatives).

Methyl green Green, cationic dye (heptamethyl-p-rosaniline chloride). Application: methyl green test; for the dyeing of bacteria (microscopy).

Methyl green test → Alkali traces in textiles.

Methylolacrylamide Besides the N-methylol group, also contains an acrylamide group, toxic. Used, amongst other things, as resin finishing agents in the so-called ambivalent crosslinking, usually together with cyclic N-methylol compounds. Finishings with moderate dry, but outstanding wet creasing angles, soft, smooth fabric handle. After-washing required.



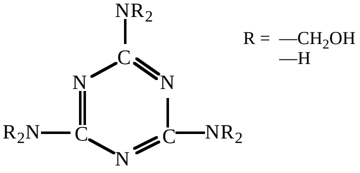
$$CH_2{=}CH{-}\underset{\displaystyle \overset{\|}{O}}{C}{-}NH{-}CH_2OH$$

Methylolamide group Reactive group of numerous self-crosslinking resins and reactive resins. → N-methylol compounds.

Methylolation Introduction of → Methylol group, e.g. conversion of NH-group containing compounds with formaldehyde to → N-methylol compounds.

Methylol group $-CH_2OH$. Component, of e.g. urea and melamine resins as well as numerous reactive types.

Methylol melamines → Melamine-formaldehyde compounds. Aqueous solutions of methylol melamines, less stable under storage conditions, self-polymerization in storage, therefore usually in powder form; only a few resin finishing products on a methylol melamine base (→ Methoxymethylmelamine).



Methylol ureas → Urea-formaldehyde compound.

Methyl orange (golden orange, helianthine, orange III, orange IV D), cationic orange dye; extremely sensitive to acid. Sodium salt of p-dimethylaminoazobenzene-p sulphonic acids. Soluble in water, insoluble in alcohol. Application: methyl orange test (change in colour at pH 4).

Methyl orange test is used (with 0.1 g to 100 ml of water) dissolved as an indicator. Reaction to alkali pale yellow; to mineral acid traces rose coloured. Neutralisation point: orange. Change to red/yellow at pH 3.1–4.4.

Methyloxyethylcellulose → Oxyethylated cellulose.

Methylphenyldiisocyanates Synonym for → Tolylene diisocyanates.

Methyl red Cationic red dye, p-dimethyl-aminoazobenzene-o-carboxylic acid. Soluble in alcohol and acetic acid, almost insoluble in water. Used as an indicator (0.5% alcoholic solution) in the titration of weak bases. Yellow in alkali solution, red in acid solution (change in colour at pH 4.2–6.3).

Methyl sulphinyl carbanions are produced in basic solution of → Dimethyl sulphoxide (DMSO) during action on, e.g., acid azo dyes. Cause increase in solubility and change in colour (halochromic effect), which is reversible and/or destructible through oxidation (air affect). Acceptance of a donor/acceptor complex formation.

Methyl violet Cationic violet dye. Mixture of salts containing hydrochloric acid from tetra, penta and hexamethylpararosaniline. Soluble in water; sensitive to acid. Used as cationic dye for dyeing and printing. Dye for inks, ink pads, typewriter ribbons, photocopy paper, etc. As an indicator (→ Methyl violet test).

Methyl violet test Indicator for traces of acids, which results in violet/greenish yellow change of colour occurs in the pH range 3.2–0.1. pH 3 violet; pH 2 blue; pH 1 green; pH 0 yellow.

Metre (m), unit of length; defined as the distance, through which the light in a vacuum passes during an interval of $^1/_{299792458}$ of a second.

Metre length Amount, e.g. of dyed or printed fabric in m.

Metric count (Nm) → Metric number.

Metric number (metric count, Nm), a mass-related length for the → Linear density of textile fibres and yarns. The designation Nm is permitted under the new law of units of measurement, as it derived from SI basic units such as mass and length. A larger Nm corresponds to a finer yarn. As this system is however contrary to the → Tex system (a large number indicates a thick yarn) and by using the designation Nm a risk of confusion exists with Nm = Newton · metres, the metric number should not be used any more as an indication of yarn fineness.

Metric system All metric systems, which are based on a metric basic unit. There have been various metric systems until now, such as the technical metric system, absolute metric system, etc. An international agreement describes the → SI System of Units. In contrast to this is the → Non-metric measuring systems from the Anglo-American and East Asian areas.

Mezzera continuous scouring machine (Mezzera/Hinnekens open width scouring machine), very common; is used (in warp and weft) for the untensioned continuous desizing, scouring and crêping of fabrics in the flat condition for a long period of immersion (see Fig.). Normal length 8 or 12 m for fabric widths of 1.2 and 1.6 m. A centrifugal pump provides continuous filtered liquor circulation from the main dyeing vat to the pre-wetting and guiding device (ventilation and drainage of the heavier liquids alleviate the formation of fabric loops). Separate after-flow tanks. Fabric inlet and outlet with centering device, outlet point with squeezing mangle. Two stainless steel chains with stainless steel bars move in the long main tank. The bars are led through a rack gear system so that they are, at times raised and then quickly drop and simultaneously move forward. In this way, besides the benefit of being washed, the fabric is removed from the bars and support points are avoided. – Manuf.: Mezzera.

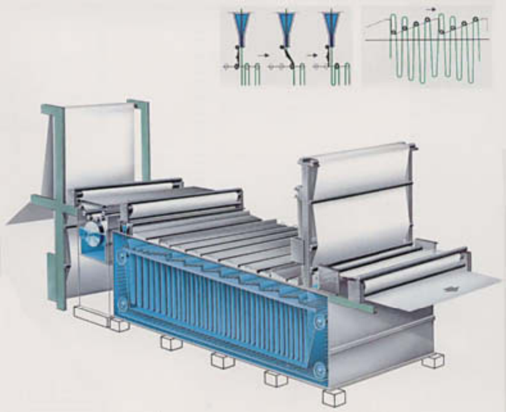


Fig.: Mezzera boil-off machine.

MFA Multifibre Agreement (MFA), refers to the World Textile Agreement (in 1974 by approx. 50 countries, in Geneva) on cotton, wool and synthetic fibres.

Mg Unit symbol for magnesium (12).

MgH magnesium hardness Standard short designation for → Magnesium hardness.

MH Abbrev. for Mohs' hardness scale, → Hardness scale.

Micellar bundle Bundled micelles, which consist of so-called fibrils, for example in → Wool structure. One talks of →: Micelles; Crystallites; Individual fibrils.

Micellar chain Designation in crystalline cotton structure for →: Micelle; Crystallites.

Micellar forces → Secondary valency forces.

Micellar network structure → Cellulose.

Micelles (→ Crystallites), smallest cell organisations of crystal lattice ordered ranges, like the three-dimensional order system.

I. In cellulose made from several → Lamella. (cellulose chain lattices), similar in wool structure (also silk structure) of → Keratin sheet structure grown in parallel on top of each other. Micelles form the next large organisational structures in individual fibrils, fibril bundles, spindle cells and individual fibres.

II. Tenside chemical: ordered aggregation of molecules (Fig. 1) and/or ions, which are formed above a certain critical concentration up to high molecular systems, e.g. with hexagonal rod packing (Fig. 2) (→ Critical micelle concentration).

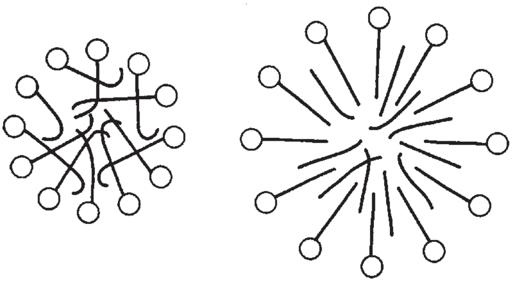

Fig. 1: Micelles of tenside molecules.

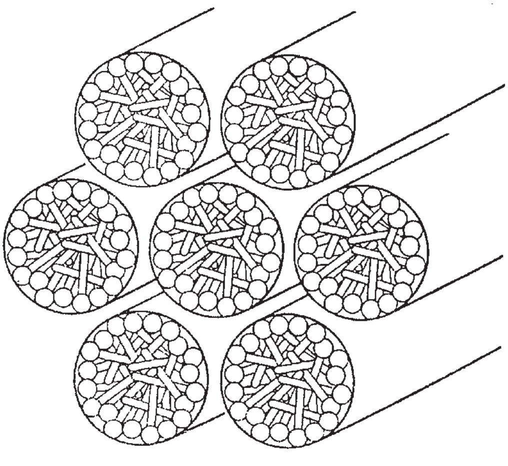

Fig. 2: Structural model of tensides. In dilute aqueous solution individual molecules are present, which form spherical or lamellar micelles as the concentration increases.

Micelle starches Starches reduced in their micellar size by steam, pressure, heating or mechanical measures. Particularly well suited to sizing purposes; therefore important for size boiling.

Micro- (Gk.: mikrós = small),

I. Prefix for compositions with the meaning “small”, “low”, “fine”; e.g. microfibres; microprocessor, etc.

II. Unit prefix for one millionth = 10^{-6}; e.g. µm.

Microbes Smallest micro-organisms. Appear in so-called colonies (→: Bacteria; Sarcina; Spores), which appear as worsted skin (→ Yeasts) or grass (→ Moulds), as fermentation, rot, disease exciters (→ Pathogenic bacteria) and textile parasites.

Microbial damage to textiles Generally promoted by a high moisture content, relatively high temperature, individual optimum pH (for bacteria pH 7–8.5; for fungi pH 4.5–7.5) and especially in a contaminated state. In principle, microbial damage from →Moulds (mildew stains) and → Bacteria may arise, contained by → Enzymes produced on both sides.

I. Protein fibres: wool is preferentially damaged by a group of so-called earth bacilli (aerobic and anaerobic, forming spores), but also by pathogenic types of bacteria (pus producers) also especially skin and hair fungi and by excreted proteolytic enzymes. Wool damage from fungi can, in fact take on the greatest proportions, however the predominant types of fungi only live by attacking fibre foreign substances and wool fat. Microbial damage goes beyond local or premature wear and tear to complete disintegration of the wool fibre (like splintered wood under the microscope, then complete splitting into individual fibrils). Alkaline washed, inadequately spun wool is particularly at risk. Alkaline oiling produces similar susceptibilities. Vat dyed wool is also considered as having increased susceptibility. Acid dyed wool is protected as long as there is still a relatively strong acid reaction. Chromed wool is particularly resistant however. Microbial damage to silk occurs more rarely.

II. Cellulose fibres: earth bacilli and numerous moulds as well as enzymes variedly excreted from both (especially cellulase and cellobiase) act as marked cellulose destroyers. There are also pectin-consuming bacteria, which destroy bast fibres. Usually cellulose fibres, which are in equilibrium with relative humidity of 100%, are chiefly attacked by fungi, but also some types at low humidity. Temperatures of 25–35°C encourage the growth of most cellulose destroyers. Water super-saturated fibres also increase the tendency of possible bacteria attack. The fungus resistance increases in cellulose with higher orientation and crystallinity towards

1. viscose
2. mercerized cotton
3. native cotton
4. ramie;

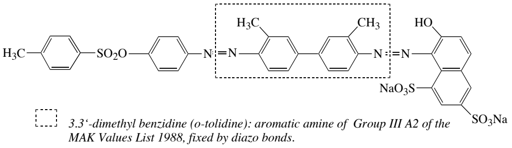
it also increases with increasing fibre lignification of cotton, hemp, jute, manila hemp and sisal hemp. The microbial damage which occurs can lead to complete fibre degradation in cellulose fabrics. It usually occurs in a locally restricted way and causes loss of weight and strength until the yarn breaks. Cellulose destroying and denitrifying waterborne bacteria and waste water fungi from the so-called sapropel together with cellulose degrading enzymes (cellulase, cellobiase) act on fishing nets, ropes and such, whereby considerable strength loss may occur. The so-called decomposability increases from flax, hemp, cotton and manila to sisal.

III. Synthetic fibres are generally considered to be microbe-resistant.

Microbiological degradation A substrate is biologically decomposed by biocatalysts (enzymes), which are produced by micro-organisms. This degradation may occur aerobically or anaerobically, but always takes place in the presence of water as a reaction and diffusion medium.

I. Degradation of fibres: protein fibres are easily microbiologically degraded by proteases. Cellulases microbiologically degrade fibres on a cellulose base, i.e. cotton or viscose. The main chain, the backbone of the polymer, should contain heteroatoms if a microbiological degradation of synthetic fibres is to take place. A conclusive reason for the resistance of many synthetic polymers to microbiological attack results from the theory of evolution: There is no selection print available for the degradation of such substances as long as they are missing in the environment of the corresponding micro-organisms. For polyamide, it has been proven in various works that the ease of microbiological degradation is controlled by the chemical structure of the environment of the amide bond and the hydrophobicity of the polymer. Polyamide is not generally degradable; nevertheless microorganisms, which, when growing cause corrosion to the surface of the polymer, have become well known.

II. Degradation of dyes: azo dyes have a high economic importance in the dyehouse and are currently indispensable with regard, for example, to light fastness and colour palette. Several primary products for the manufacture of these dyes as well as physical/chemical cleavage products, in particular, those on a benzidine base and microbiological degradation products in this substance class, may be carcinogenic. Although the waste water pollution caused by such dyes is comparatively low, the relevance of this problem is given on the basis of the toxicity which occurs (also bacterial toxicity amongst others). The microbiological degradation of azo dyes shows that the azo formation of these compounds can be split in this way (Figs. 1–2) and in addition complete mineralisation can be achieved with aerobic treatment. Such degradation is known to occur due to both bacteria and fungi.



3.3'-dimethyl benzidine (o-tolidine): aromatic amine of Group III A2 of the MAK Values List 1988, fixed by diazo bonds.

Fig. 1: Cleavage of tolidine dyes (Acid Red 114).

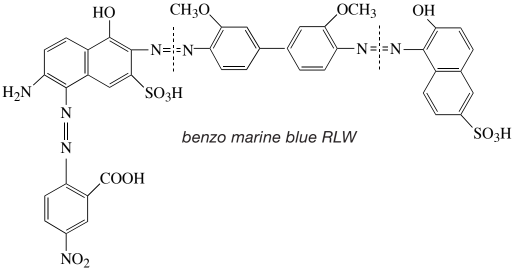


Fig. 2: Cleavage dianisidine dyes (Direct Blue 160).

III. Degradation of surfactants: due to their large scope of applications and their disposal via (predominantly municipal) waste water, surfactants are one of the important ecologically relevant substances, whose environmental compatibility must be guaranteed. The deciding criterion for the whereabouts and thereby, a possible harmful effect on the environment, is biological degradability as the chief mechanism of waste water treatment in waste water treatment plants and the self-cleaning processes in surface waters as well as possible toxicity in the metabolites produced. The degradability of anionic and non-anionic surfactants is regulated by the surfactant regulation. Accordingly, surfactants used in detergents and cleansing agents must on average be biologically degradable by at least 90%. This requirement is considered to be observed when a single test results in at least 80%. The corresponding test and analysis processes are stipulated precisely. The test is usually carried out in the OECD screening test, a static test with a mineral medium and the surfactant as a single organic source of nutrients; an 80% degradation must take place within 19 days after inoculation with waste water bacteria. If this limit is not clearly reached, the result is decided by identification of the surfactant degradation in a waste water treatment plant simulation test, the OECD confirmatory test. Here the surfactant is tested under continuous test conditions (the duration of stay of the test compound in the test system is 3 hours on average) in the presence of a high surplus of easily degradable compounds, i.e. under realistic competitive conditions. The biodegradation is measured each time with the aid of so-called substance group-specific analysis procedures, which permit a quantification of the a or n surfactant proportion still present. The property of anionic surfactants is hereby used with methylene blue, or non-ionic surfactants with Bismuth iodide, to form a complex so that the surfactant degradation is given as the acceptance of methylene blue active substance (MBAS) and bismuth active substance (BiAS) respectively. The so-called primary surfactant biodegradability is determined in the statutory degradation tests described using the MBAS or BiAS acceptance, as the surfactant molecule has already been altered by the first biological degradation steps so that essential properties of the initial compound, such as surface activity and, particularly important ecologically, aquatic toxicity, have disappeared or are drastically reduced. Commercially used surfactants normally consist of a multitude of homologous (in the C chain of different length) and possibly also isomeric (in different positions of the C chain, e.g. substituted by a phenyl ring) individual compounds. As a result of these different structures, the individual compounds also differ in their primary degradation and toxicity properties, whereby a contrarotation of both effects exists: The slower degradable individual compounds are less toxic than the quicker degradable ones.

The surfactant tetrapropylene benzene sulphonate (TPS) was a “hard” surfactant causing foam mountains on rivers at the start of the 60s, i.e. only inadequately degradable biologically due to its branched bulky structure (Fig. 3).

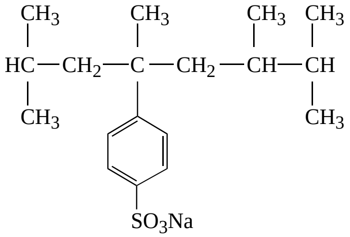

Fig. 3: Structural formula for the tenside tetra propyl benzene sulphonate (TPS).

It was replaced by a “soft” surfactant, a linear alkylbenzene sulphonate (LAS), which is very much more easily degradable due to its straight chain structure (Fig. 4).

In principle, tests on the total degradation of compounds were carried out in comparable tests as those described, i.e. in simple discontinuous screening tests (test of ready biodegradability) and in the waste water treatment plant simulation test (e.g. coupled units test). The fundamental difference however lies in the fact that the criteria for the final biological degradation are used as a set of criteria, i.e. the mineralisation of the test substance into carbon dioxide, water and possibly salts as well as the assimilation into biomass. The analytical apparatus for final degradation detection extends from the measurement of the mineralisation parameters “CO_2 production” and “biochemical oxygen demand” (BOD) to the complete determination of mineralisation and assimilation by measuring the acceptance of the dissolved organic carbon (DOC). The final degradability of the test substances is usually tested in one of five different tests of ready biodegradability recommended by the OECD and established in EC-wide chemical legislation. The test substance also represents the only source of carbon for the degrading bacteria stemming from environmental media (waste water, rivers and soils). According to the criteria of the OECD, compounds with a mineralisation rate (CO_2, BOD) of > 60% and a DOC acceptance of > 70% are considered as quickly and completely degradable under environmental conditions. If primary and final degradation data of surfactants are compared with each other, it can be established that an extensive degradation to the natural finished products also normally takes place in surfactants with a high primary degradation so that no durable degradation products can ultimately accumulate in the environment. The degradation reactions of a surfactant are shown in the example of the LAS already mentioned (Fig. 5).

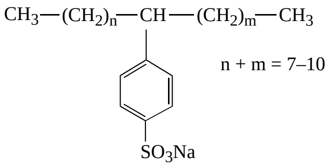

Fig. 4: Structural formula for the tenside alkyl benzene sulphonate (LAS).

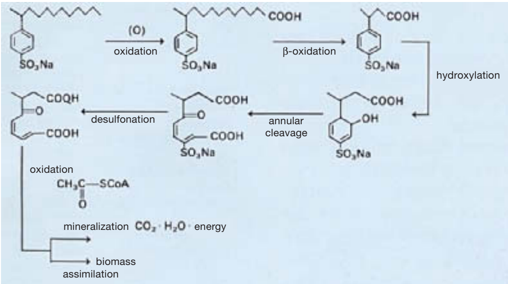

Fig. 5: Biological decomposition of a tenside.

The biochemical reaction proceeds in two sections and starts at the alkyl chain. Firstly, a terminal CH_3 group is oxidised to the carboxyl group and then the alkyl chain is shortened in C_2 steps into a branch (this reaction takes place quickly, partly in the sewerage system before the waste water treatment plant). The following opening circle starts with a hydroxylisation of the aromatic circle, which is simultaneously opened and desulphonated. The subsequent degradation of the now aliphatic compound happens quickly as in the alkyl chain, e.g. as β-oxidation and the compound is either completely mineralised or converted to cell substance by assimilation. The acute aquatic toxicity of surfactants, measured as LC_{50}/EC_{50} (concentration in which 50% of the organisms survive in the fish and daphnien test), is, apart from a few exceptions, above 1 mg/l. The use of highly toxic surfactants is, however, justifiable if their good primary and final degradation behaviour is warranted due to the crucial importance of biodegradation in the environmental compatibility assessment of surfactants.

Microbiological degradation in biological waste water treatment is tied to a particular $BOD_5 : COD$ ratio. The following should apply:

– approx. 0.5 in domestic sewage,
– < 0.5 in commercial sewage,
– > 0.5 in sewage from the food and drinks industry.

Small values of the ratio indicate that organic materials exist, which are barely degradable or degradable with difficulty. It should be considered that, in many cases, organically contaminated industrial sewage is concentrated. In order to create favourable conditions for biological cleaning, a dilution using purified water or operational waste water should be carried out. The oxygen consumption in the aerobic biodegradation of organic contents occurs in two stages (Fig. 6). The degradation firstly attacks in the carbon-containing compounds, which are finally converted into CO_2 and H_2O. This stage takes at least 20 days. In the second stage, the nitrification of nitrogen compounds occurs; this is carried on over several months. The oxygen absorption in aerobic degradation for urban waste water is shown for various temperatures in Fig. 7.

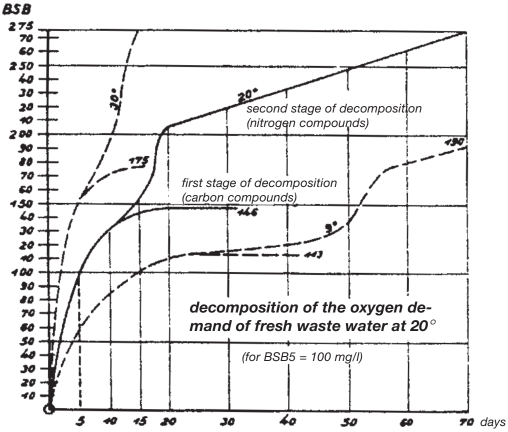

Fig. 6: Process of oxygen absorption during aerobic decomposition of municipal waste water (according to Meinck et. al.)

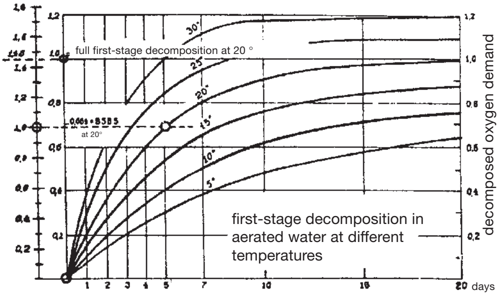

Fig. 7: Oxygen absorption during aerobic decomposition, dependent on temperature.

Furthermore, the oxygen consumption of 1 kg of activated sludge per hour at max. substrate breathing and endogenous breathing dependent on the temperature is shown in Fig. 8.

Only 5–15% of the oxygen in the air can be used bacteriologically so good ventilation must always be ensured if a high degradation performance is to be achieved. If a nutrient solution is produced without inflow and outflow, the following phases of growth can be established in the micro-organisms (Fig. 9):

1. Initial phase: The enzymes required for the degradation of the water contents are formed.
2. Exponential phase: Nutrient is amply available so that growth is determined by the max. division rate. This is known as “substrate breathing”.
3. Stationary phase: The number of cells remains, as the nutrient supply is restricted. The endogenous breathing (internal breathing of the separate cell substance) increases while the substrate breathing steadily decreases.
4. Dying phase: Nutrients are lacking. The microorganisms oxidise their own cell substance. Endogenous breathing chiefly exists.

The metabolism of the micro-organisms show coupled degradation (dissimilation) and construction (assimilation) processes. The metabolism processes are a branched and multiply coupled system of individual biochemical reactions. The conversion of waste water contents is thereby carried out in many small steps. The surmounting of an energy threshold is necessary for each such kinetic step, since the reacting substance must be transferred in a reaction-prepared state. This process is tied to the presence of enzymes, which are produced by the micro-organisms. A well-established theory on enzyme catalysed reaction, stems from Michaelis and Menten. The substrate S, contained in the waste water to be converted, enters into a complex with the enzyme E, wherein it is transferred in a reac-

Microbiological degradation

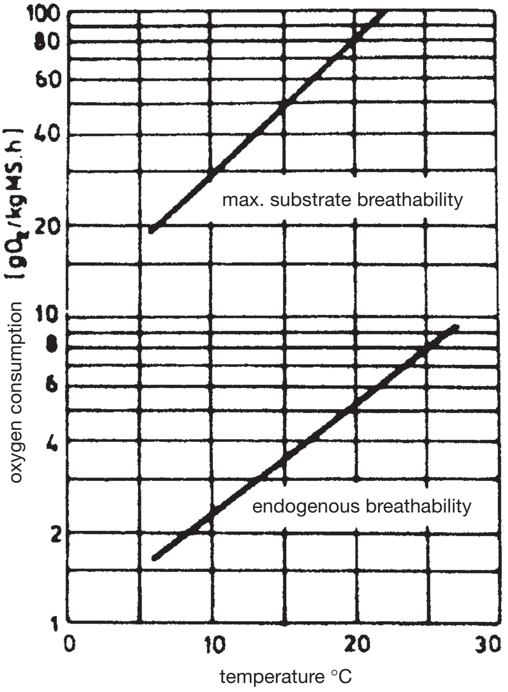

Fig. 8: Oxygen consumption (in relation to 1 kg activated sludge and one hour) for maximum substrate breathability and endogenous breathability in relation to the temperature.

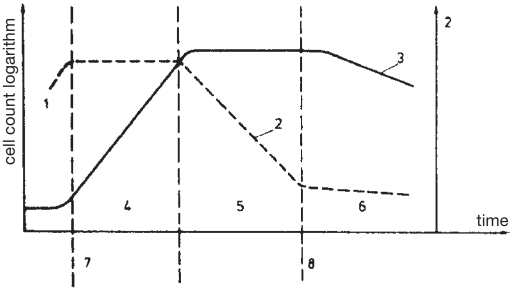

Fig. 9: Growth phases of the microorganisms and oxygen consumption.
1 = start-up phase; 2 = 0_2 consumption; 3 = cell count; 4 = exponential phase; 5 = stationary phase; 6 = slackening off phase; 7 = substrate breathability; 8 = endogenous breathability.

tion-prepared state. This facilitates the decay of the substrate. The enzyme is not consumed as a typical catalyst in the reaction. So the following can be formulated:

$$S + E \underset{k_2}{\overset{k_1}{\rightleftharpoons}} ES \overset{k_3}{\rightleftharpoons} E + P$$

P = product,
k_{1-3} = speed constants.

The transitory change of the substrate concentration can be written as the familiar Michaelis/Menten equation in the form:

$$v = \frac{dS}{dt} = V_{max} \frac{[S]}{K_m + [S]}$$

K_m = Michaelis/Menten constant,
t = reaction time,
V_{max} = theoretical max. degradation speed.

V_{max} is achieved when the total enzyme quantity available, saturated with substrate and known as ES. K_m and V_{max} characterise the substrate. It is recognised that a high S causes a high degradation speed for the substrate. So the biodegradation of waste water contents can be quantitatively formulated kinetically. The kinetics of the substrate degradation characterised by the BOD is particularly interesting. The equation of the BOD curve is known as Henry's equation. This can be written as follows:

$$S(t, y) = \frac{K_m}{V_{max}} \cdot \ln \frac{L}{L-y} + \frac{y}{V_{max}} - t = 0$$

L = BOD final value, referring to the zero point of the reaction,
y = oxygen consumption, referring to the zero point of the reaction.

It should be ensured that the pH remains in the 5–9 range in biological waste water treatment. It is of interest that the temperature dependency of the kinetics of biological waste water treatment is small so that no great differences occur in the degradation rate between summer and winter. There are several equilibrium ratios to calculate in biological waste water treatment, which are established within the framework of the nutrient substrate/substrate consumption relation of the organism. There is a "food chain" for the heterotrophic organisms, which leads from the nutrient substrate contained in the waste water to lower organisms (bacteria) and from them to ever more highly organised micro-organisms. Each type of microorganism, which is feeds on bacteria, is dependent for its reproduction rate on the bacteria.

These kinds of relationship in technical/biological cleaning are shown in Figs. 10 and 11. The technology of microbiological degradation in biological waste water treatment processes has meanwhile achieved a high level; these processes are chiefly used in municipal waste water technology. Endeavours are currently being made to use these degradation processes for undiluted industrial sewage as well. There are essentially three possibilities for the microbiological degradation of industrial sewage:

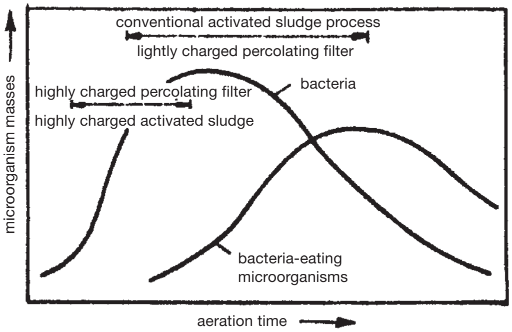

Fig. 10: Areas of growth phases of bacteria and bacteria-eating microorganisms in activated sludge plant and lightly charged percolating filters.

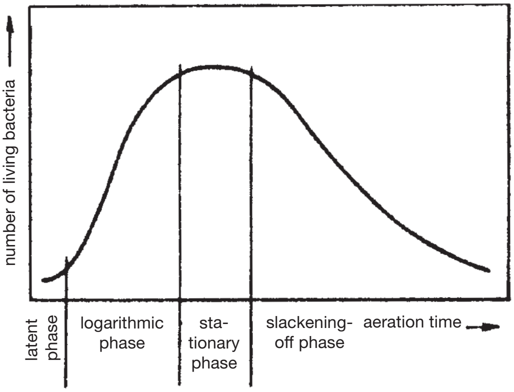

Fig. 11: Growth pattern of bacteria and bacteria-eating microorganisms in relation to the aeration time.

1. Natural processes, which are generally based on agricultural waste water exploitation and the use of sewage ponds. These processes are carried out in the natural habitat for economic use.
2. Technical processes, in which percolating filters and activated sludge plants are used.
3. Combination of these processes.

The country treatment of waste water has increasingly declined due to the increasing amounts of waste water and the steady fall in land areas available. A great cleaning effect is achieved by the festing technique, which accompanies mineralisation processes. It should, however, be noted that a large part of the bacteria dies in the upper soil layers, in which solar radiation plays a fundamental role. The draining of waste water, which is rich in E. coli, must be excluded from the harvest rhythm in order to avoid damage to foodstuffs. Not all waste water is suitable for agricultural use. The use of sewage in agriculture is standardised in the FRG. A much practised type of waste water treatment is the use of waste water ponds. They can absorb relatively large amounts of waste water over many days up to several weeks. A degradation of the organic contents also takes place on an aerobic basis as long as a sufficient oxygen absorption is guaranteed from the air across the water surface. Additional oxygen supply can be achieved through addition of oxygen-saturated surface water as well as algae multiplying under light irradiation. Several pond stages have been tried and tested. So-called refining ponds are occasionally connected. In special cases, waste water ponds can be used economically as fish ponds. Aerobically effective microorganisms from solid filling materials (e.g. mineral silicate, clinker, pumice, stone, etc.) are held as practically favourable in the percolation filter process; they are cleaned by rinsing with waste water. A mucilaginous lawn of microorganisms, nematodes and insect larvae is formed in the percolating filter material. So industrial sewage can be well treated (usually within the framework of a small waste water treatment plant).

Microcapsule Incorporation of dyeing auxiliaries. → Encapsulated dyes.

Microclimate,

I. Air moisture temperature and air moisture temperature ratios, which are employed in sections of a larger environment (e.g. in warp shed in comparison with warp barn).

II. Definitive for comfort. Not only important for clothing, but also for bed textiles. Concerns climate situation between textile (clothing) and human skin. Applies to the climate under the clothing, in contrast to the so-called ambient climate of the person, which does not correspond with the micro climate of the head and hands (normally unclothed), with regard to humidity and/or vapour pressure. → Clothing physiology.

Microcomputer A small computer, whose complete components are manufactured as integrated circuits, e.g. as control for machines and systems for fully automatic programming, especially temperature control. Can be connected by external data carriers.

Microcomputer process control Two main components: devices (hardware) and programs (software). It offers considerable advantages: e.g. supply of considerably more extensive and thereby more effective information on complete events in and on machines or systems. Cost advantages at switchgear cabinet level from saving the logic connections. Absence of auxiliary control relays and proportionate assembly costs. Many functions previously using individual electronic control can be monitored and/or controlled, combined in microcomputer process controls.

Microcosm The exploration of the world is carried out in two opposite directions and thereby also opposite dimensions. The macrocosm is the research aim of a large group of scientists and engineers. The greatest extent of the cosmos is the aim of the research of these researchers. They work in light year dimensions with gigantic telescopes and radio telescopes, whereby the inconceivable limits of their work is currently at about 10 billion light years. Spiral nebula, milky ways, quasars, pulsars, novas and supernovas are their research projects, amongst others. The other group of physicists and engineers is working in the field of pure physical research of the microcosm. The examination of the laws within the smallest dimension of the subatomic world is the research aim of these theorists and experimenters. The smaller these dimensions are, the larger and more expensive the measuring instruments. Gigantic microscopes, so-called particle accelerators and accumulator rings, facilitate advancement into inconceivably small, but measurable dimensions (Fig. 1).

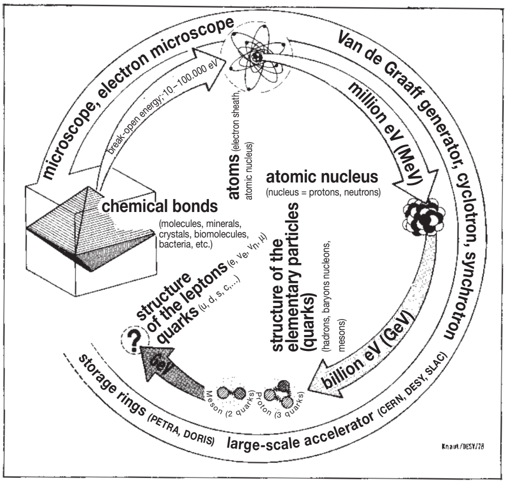

Fig. 1: Advancing through a microcosm.

In the course of the history of research, man has tried to analyse matter in ever smaller components in the search for the atomos, the indivisible. It has thereby been shown that larger forces and equipment are required for the "separation" of structures, the smaller the structures are. It was a long way from the magnifying glass to the accumulator ring. Breakage, fine grinding or crushing are sufficient to examine crystal structures or biological structures in the macroscopic area. In the atomic and sub-atomic area, however, an investigation of the structures only succeeds by bombarding these objects with very high energy particles. These particles must be accelerated at very high energy (almost at the speed of light). They thereby obtain a very high "breakage energy". They overcome the inner atomic forces, and can, for example, penetrate a proton or neutron, and "scan" these particles and analyse their structure.

Forces exist between the particles of an atom, whose examination, amongst others, is one of the main tasks of pure physical research. These four forces are:

- nuclear energy (powerful energy or powerful interaction),
- electromagnetic energy,
- weak energy (weak interaction),
- gravitational force (gravitation).

In elementary particle physics it can be estimated that, on the basis of theoretical and experimental results, a "combination" of the electromagnetic force and the weak force exists. An essential element of this combination lies in the fact that the effect of the forces is traced back to a homogeneous exchange mechanism. It seems that the forces can be traced back to the exchange of fixed particles [gluons (g) or photons (light particles)] and between two structural particles [e.g. electrons (e) or quarks (q)] (Fig. 2). Nuclear energy is distinguished from electromagnetic energy in that in nuclear energy the gluon is responsible for the effect of the force as a fixed particle and the photon (light particle, gamma particle) is responsible for the effect of the force in electromagnetic energy. The gravitation (mass attraction) has been known for the longest time of all the forces. But it is so weak compared with the other inner atomic forces that it does not play a role in elementary particle physics. It only appears in "large" masses, e.g. in the movement of celestial bodies.

The familiar Einstein equation $E = m \cdot c^2$ states that

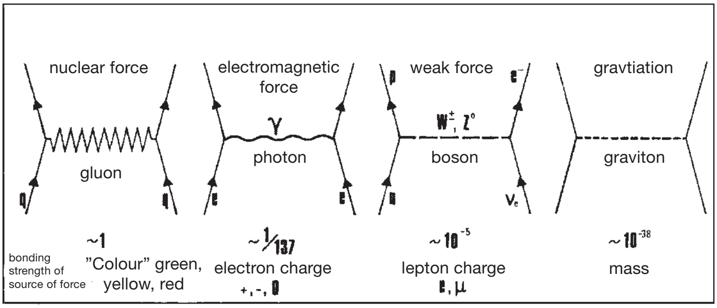

Fig. 2: Dynamic effect between two structural particles by exchanging a bond particle.

the energy of an accelerated particle is composed of the particle mass, multiplied by the square of the speed of light. The faster a projectile is accelerated, for example, the higher is its energy at impact. This acceleration is only possible in air up to a maximum speed. If, however, matter particles (e.g. electrons) are accelerated in a vacuum (maximum vacuum), they can be accelerated almost to the speed of light. The laws of “classical mechanics” no longer apply, however, but those of “relativity mechanics”. According to this law the particles do no not increase in velocity as they approach the speed of light, but instead become heavier, i.e. they increase in mass. Highly accelerated electrons have a high energy force based on their high energy (= mass), which is absolutely essential for the investigation of the structures of matter. After the Second World War, pure physical research became an important area of modern physics. The rapid development of ever larger particle accelerators and physical measuring instruments was a condition for penetration into the structures of the microcosm. Science and technology have pioneered new developments in recent decades and thereby for the first time facilitated the examination of this sub-atomic world. The particle accelerators thereby became gigantic microscopes for the examination of the laws within sub-atomic structures (according to Knaut).

Microcrystals → Crystallites.

Microdisperse (md.), range of vat dyes and disperse dyes as the fine dispersions of the standard size of 0.2 to a max. 1 µm.

Microemulsions Normal emulsions have a micelle particle size of > 300 nm (e.g. milk). Smaller particles < 100 nm lose their cloudy appearance and the resulting microemulsion is transparently bluish. There are even some with particle sizes < 10 nm. So you enter an area, in which the airborne form of the micellar microemulsion flows in a thermodynamically more favourable form, the so-called bicontinuum. The particle sizes of emulsions can be measured with the aid of photon scatter spectroscopy, also simply called laser measurement.

Particle sizes:

– normal, white	> 300 nm
– white to grey	300–100 nm
– transparent, bluish	100–10 nm
– as clear water	< 10 nm

The normal methods in practice for the manufacture of emulsions comprise a mechanical treatment with the addition of a corresponding emulsifier. Besides the simple mixer, high pressure homogenisation and shear emulsification are considered as mechanical treatment. High pressure homogenisation is, for example, used for the homogenisation of milk. Recently processes such as electrostatic or ultrasound emulsification have also increasingly been encountered. The manufacture of microemulsions proves to be considerably simpler: the emulsion is practically formed by itself in mixing the components together (the emulsifiers undertake the task of the mechanics and achieve the dividing work). One talks of so-called spontaneous emulsification. An increase in temperature produces an additional acceleration of the process. The essential manufacturing differences between micro- and macroemulsions are shown in the Table.

macroemulsions (more technical)	microemulsions (”high chem”)
less emulsifying agent	more emulsifying agent
a lot of energy	less energy
simple agitating mechanism	spontaneous emulsification, possibly with increased temperature
high-pressure homogenization	
shear emulsification	

Tab.: Differences in the production of macro- and micro-emulsions.

Clearly less energy has to be used for the manufacture of microemulsions than is customary for the manufacture of macroemulsions. The high stability of microemulsions can also be explained by this, which, compared with macroemulsions, are at a considerably lower energy level than the primary substances not yet emulsified, but already mixed together. The correlations are clarified by the energy diagram (see Fig. 1).

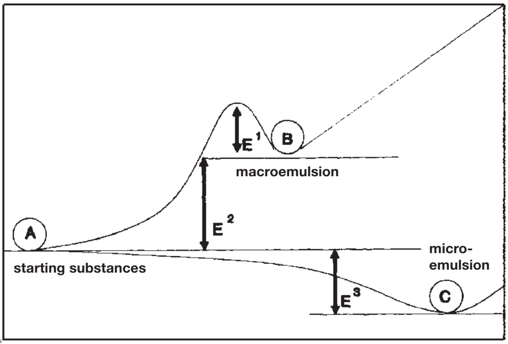

Fig. 1: Energy diagram of the emulsification process.

In Fig. 1 the primary substances already mixed together can be seen on the left. These substances can be transferred into a higher energy level by the addition of energy, where they are then relatively stable. The particles vibrate due to the inner energy available in the system. This vibration can be so strong that the emulsion again sinks to the old, lower energy level, which in practice means emulsion breakage. This is also called statistical fluctuation. It is a different situation for microemulsion: the primary substances move by themselves into a lower energy level almost without an external effect, where they then exist as a stable microemulsion. The emulsification takes place independently. Should the case then arise that the vibrations of the particles go beyond the normal framework, they always revert to the stable form of a microemulsion (according to Agster).

Microemulsions, for example, produce an outstanding soft handle, but the sewability is not noticeably improved. The fact that the particles can penetrate the centre of the yarn due to their size can be considered as an explanation for this, and has the effect that there is not the surface smoothness demanded, but rather an "inner softness" appears.

The soft and pliant surface handle and the excellent sewability of textile substrates finished with polydimethylsiloxanes (Fig. 2) made a significant contribution to their commercial use. Up to then, the novel handle could only approximately be achieved with any other class of chemicals. In the process chemicals sector too, the preparations of polydimethylsiloxane with colloidal silicic acid as highly active defoaming agent systems can no longer be dispensed with.

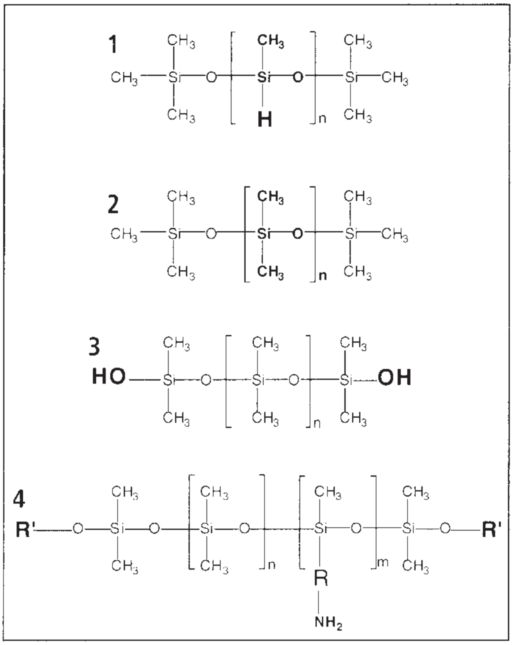

Fig. 2: Especially important silicone types.
1 = polymethyl-H-siloxane; 2 = polydimethylsiloxane;
3 = polydimethylsiloxane with end-positioned OH groups;
4 = aminofunctional polydimethylsiloxane.

New in the period which followed was the introduction of three-dimensional cross-linkable polydimethylsiloxanes with end-position OH groups (Fig. 2). In combination with organic tin catalysts and methylhydrogensiloxane as the cross-linker, highly elastic, wash-fast films could be produced, which became important in the rapidly growing market for leisure products and sportswear. In the coating field too, numerous application possibilities were developed from the solvent and aqueous phase based on OH end group-containing elastomeric silicones.

With the aminofunctional polydimethylsiloxanes, the large silicone producers' polymer chemists were able to improve the softening properties of the classic dimethylsiloxanes through the amino side groups. The familiar smooth, supersoft product handle can be achieved with the classic secondary emulsions produced from it. The same silicone oils, formulated into microemulsions, have a transparent to almost water-clear appearance, as the particle size lies – at > 40 nm – in the zone below the visible light wavelength.

On natural fibres, a filtration effect takes place during the application of classic, large particle macroemulsions. While the finishing liquor water penetrates into the fibre interior, the large silicone particles remain on the fibre and yarn surfaces, producing locally an increased silicone concentration in a kind of ring-shaped coating (Fig. 3). Due to their small size, the microemulsion silicone particles have much greater penetrating powers, and can therefore also penetrate the internal fibrillar structure of natural fibres. The resultant "inner softness" has a completely different handle.

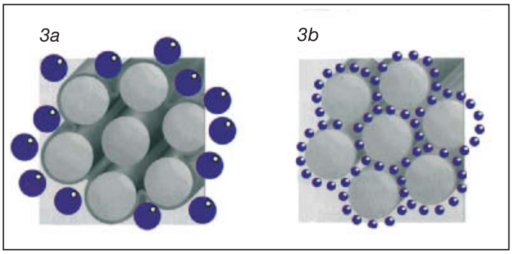

Fig. 3: Method of operation of macro and microemulsions on textiles.
3a = conventional, milky silicone emulsion, particle size > 120 nm, coats fibre/yarn = surface smoothness;
3b = fine particle, transparent silicone emulsion, particle size < 40 nm, penetrates fibre/yarn = inner softness.

Micro-encapsulation is a designation for the encapsulation of finely dispersed, fluid or solid phases by coating with film-forming polymers. With the aid of this micro-encapsulation technique, the most diverse substances can be converted into a dry mass, whose contents become free again as required using thermal, mechanical, chemical or enzymatic action. There are a variety of properties resulting from this, such as:

- conversion of fluids into solids,
- separation of substances reacting with each other,
- controlled release of active substances,
- reduction in the toxicity of products
- improvement in the processability of products,

permitting this technique to penetrate the most varied branches of industry, including the textile finishing industry (dyeing and printing) since its development in the 30s. The micro-encapsulation of water-soluble flame-retardant salts is called the typical application case, in which coating pastes can be added for roller blinds. The capsules only burst open and become active in case of fire and release the antimony- and halogen-free flame-retardant agents. The washing resistance of the finishing is the object of using micro-encapsulation in this case.

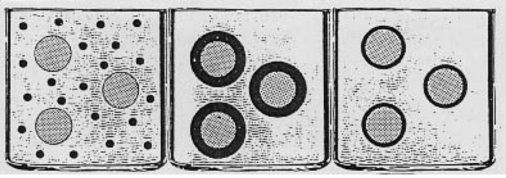

Fig.: Stages in the process of micro-encapsulation. Left: three-phase system; centre: deposit of the polymer protective coat on the raw material; right: fixing of the capsule.

Three non mixable substances are required for the manufacture of micro-capsules: a) the substance to be coated; b) a substance, which forms the coating, and c) a fluid medium, in which the coating takes place. Core material and coating material are found in the fluid substrate phase in a 1st process stage (see Fig.); water-insoluble substances are normally encapsulated in water and water-soluble substances in organic solvents. In the 2nd process stage, the coating material is deposited on the core material, i.e. it is adsorbed on its surface; there are a multitude of techniques covering this, such as emulsification, coacervation, interfacial polymerisation and additional polymerisation, etc. This adsorption is the necessary prerequisite for a technically applicable, effective encapsulation. In the last phase, the coating material should solidify by using thermal treatment, chemical cross-linking or water release.

Microfibres Finest fibrillar filament yarns (filaments) < 1 dtex (Fig. 1). In principle, three methods can be followed for titre refining:

1. Manufacture of microfibres in accordance with “conventional” spin technology and in a titre range from 0.3–1.0 dtex (main focus approx. 0.5–0.7 dtex in the West European market).
2. Manufacture of bicomponent fibres with a matrix/fibril arrangement. The basic aim with these yarns is suede or silk-like items (often also described as “supermicro” due to their fineness). They are still a speciality, due to their fineness, although they have already been on the market for two decades.
3. Titre refining via weight reduction of polyester fibres in the fibre surface. The alkali treatment of pol-

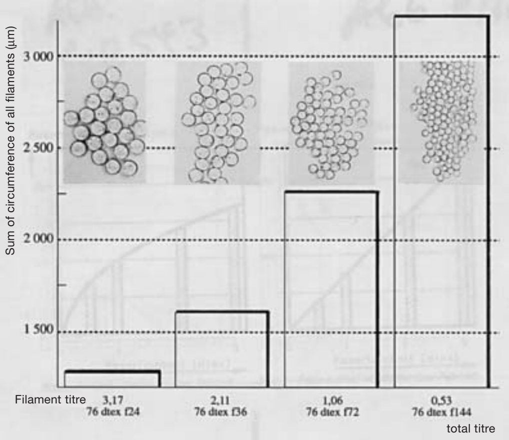

Fig. 1: Comparison in size of the individual filaments of a 76 dtex polyester filament yarn and the dependence of the filament circumference on the filament titres.

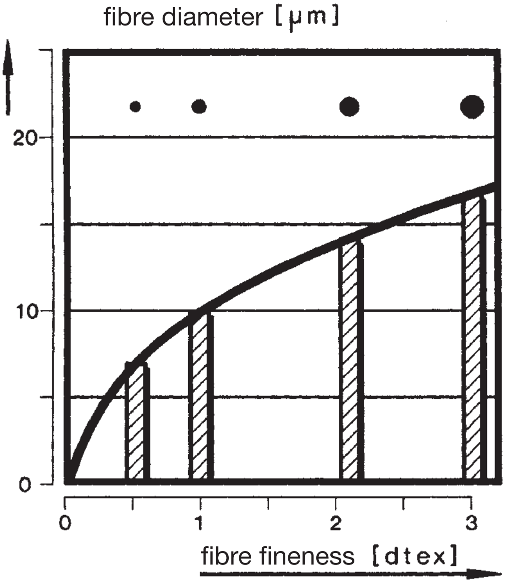

Fig. 2: Fibre diameter and fineness.

yester has been applied for the manufacture of silk-like crêpe fabric from wound up polyester filament yarns since the end of the 70s.

Finer titres increase the suppleness of the fibres, i.e. their flexing strength is extremely low. The size of the filament yarn is also strongly reduced, although the total titre remains the same. The diameter, the length of the fibres, their strength and modulus of elasticity as well as the size of the loading forces are important for mechanical stress and deformation of the fibres in processing. With reference to the fineness, the diameter shows a depressive curve (Fig. 2) corresponding to a root function, while the fibre cross-sectional area behaves linearly to the fibre fineness (Fig. 3).

Finenesses up to 1.0 dtex are recorded in the old and in the meantime withdrawn DIN 60 800. There has, however, not yet been success in establishing an exact definition for finenesses below this. The already prepared DIN 60 001 part 2 has not been published. For this reason, the following classification can only be viewed as a conventional classification for the practice, but not as the established standard.

Classification of man-made fibres according to fineness (see also Fig. 4):

fineness of the individual titre	conventional designation
> 7.0 dtex	coarse fibres
7.0–2.4 dtex	fine fibres (normal fibres)
2.4–1.0 dtex	very fine fibres
1.0–0.3 dtex	microfibres
< 0.3 dtex	supermicrofibres

Fabric made from microfibres: densely beaten microfibre fabrics are produced in parallel to membranes and coating systems. The high density of these fabrics is in particular realised by the fineness of the filament yarns. These fabrics can break down extremely hydrophobically due to a special treatment during the spinning out process. The water repellent effect is supported by application of the non-source synthetic filaments. This freedom from swelling inhibits the closing of the pores of the fabric by the effect of moisture, as is possible in hydrophilic textiles. Yarns made from the finest polyamide or polyester filaments permit fabric designs with up to 7000 filament threads/cm^2, whose superfine spacings allow the transport of water vapour, but prevent the penetration of water drops (Fig. 5). These fabrics are more suitable for the everyday, sport and leisure area, in which no specifically high demands are put on water-proofness and mechanical stability. Their water-proofness is attributed to that of laminates or coatings and diminishes again after care treatments and mechanical action. Application effects such as greasy contaminants, mechanical change, remains of wash-active substances and similar require regular care and additional impregnation, so a low product application, which does not bond the surface, should be carried out.

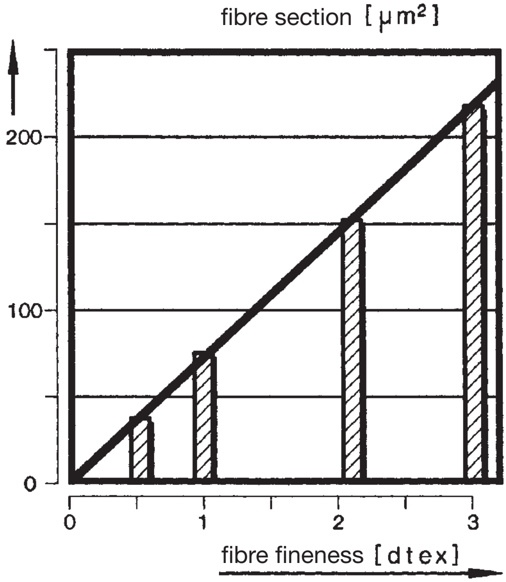

Fig. 3: Fibre section and fineness.

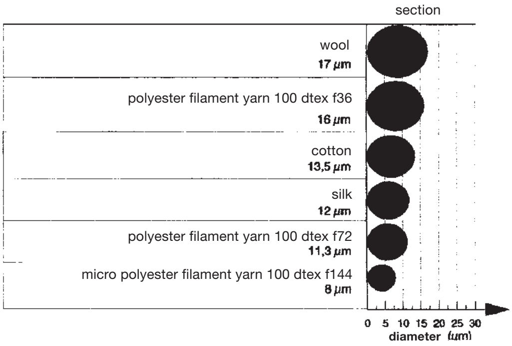

Fig. 4: Comparison of textile fibre diameters.

Microfibre fabrics are particularly suitable for sports clothing, for which functionality is relevant and four primary functions are demanded:

1. Good weatherproofing, e.g. wind-resistance (Fig. 6), is achieved using dense, but microporous fabrics; yarns with a large specific fibre surface area increase density and covering power, but at the same time produce a high porosity in the fabric, which even without coating achieves amazingly good serviceability.
2. Good thermal insulation, heat constancy and wearing comfort are determined by fine fibrillness, light

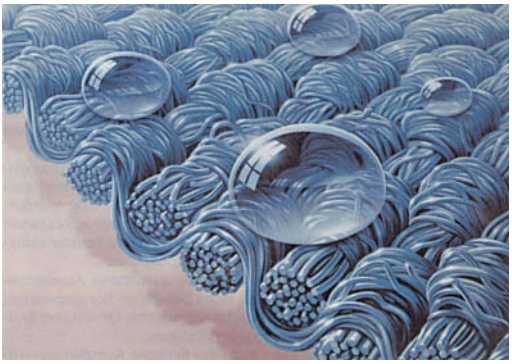

Fig. 5: The micro-fine fabric pores do not allow rain, mist and drizzle droplet, several times larger, to penetrate the fabric; cold bridges are eliminated (source: Hoechst).

Fig. 6: The large number of densely-layered microfilaments keep the wind away; cooling is thus avoided (source: Hoechst).

Fig. 7: Perspiration molecules quickly evaporate through the fabric pores which are thousands of times larger; the body temperature remains stable and the fabric stays dry inside (source: Hoechst).

weight, low moisture absorption, no swelling of fibres, good capillary moisture vapour transmission, softness and smoothness. Air pocket, material thickness and low moisture absorption play a key role in the effectiveness of insulation.

3. Good water vapour transmission (Fig. 7) is achieved using light, shape retaining, double flat knits made of texturized yarns with good capillary water transport capability on the inside and yarns made of water absorbing and water transporting fibres on the outside.
4. Optimum elasticity through selection of the correct yarn type and material design.

Microfibres, development history Microfibres have their origin in bicomponent microfibres. These fibres have a history going back as far as the 50s. The first group of bicomponent fibres appeared on the market around 1960. It had a simple compound structure similar to side-by-side and core/sheath compounds. Since then people have tried to duplicate the bicomponent structure in order to manufacture complicated fibres. Such “multi-layered bicomponent fibres” with more than 5 layers in one fibre had already been developed in 1965. They were split and so provided the first microfibres. Since the start of the 70s, microfibre technology has achieved five great innovations:

– imitation suede (Toray in 1970),
– silk-like materials (Kanebo in 1972),
– super high strength fabrics (Kuraray in 1981),
– 2nd generation artificial leather (Kuraray in 1981),
– high performance cleaning cloths (Kanebo in 1985).

Tab. 1 shows typical imitation suede made from microfibres. The most important and fundamental technologies for microfibres have been developed using these imitation suedes:

– spin technologies for multi-layered bicomponent fibres or spin technologies for fibres made of superfine titres,
– making (weaving, knitting, nonwoven technology),
– splitting techniques for multi-layered bicomponent fibres,

section	polymer	splitting	fineness (dtex)	structure
	PET/PS	dissolving	0,05–0,1	nonwoven fabric
	PET/PA 6	swelling	0,1–0,2	knitted fabric
	PA 6/PS	dissolving	0,005–0,01	nonwoven fabric
	PET/PA 6	mechanical deformation	0,24	loose-woven fabric, nonwoven

Tab. 1: Typical microfibres for imitation suede fabrics (according to Matsui).
PET = polyethylene terphthalate; PS = polystyrene

- surface raising,
- polyurethane impregnation,
- dyeing and finishing.

Imitation suedes are chiefly used for the manufacture of coats, jackets, gloves and upholstered furniture.

The 2nd development stage in the use of microfibres concerns silk-like materials for high-quality outerwear. The market has developed really slowly, but steadily. Tab. 2 shows typical microfibres for silk-like materials.

section	polymer	splitting	fineness (dtex)	remarks
	PET/PA 6	swelling	0,6	
	PET/llP	dissolving	0,2–0,3	mix with a common fibre

	PET/PA 6	mechanical deformation	0,23	
	PET	–	0,1	mix with a common fibre

Tab. 2: Typical microfibres for silky products (according to Matsui).
llp = easily soluble polymer

The 3rd stage in the use of microfibres concerns super high density, water repellent fabrics. Tab. 3 shows microfibres for these fabrics from different manufacturers. They are used in a large selection of high-quality sport and leisure clothing such as coats, down jackets, ski clothing, wind jackets and clothing for anglers. Radial bicomponent fibres, for example, are split using a chemical process for the manufacture of these microfibre products. During this splitting process, the polyamide is strongly swollen and shrunk, while the polyester only shrinks a little.

The 4th development stage in the application of microfibres concerns the 2nd generation of artificial leather using soft surface nap (see Tab. 4).

fibre type	section
radial fibre	
Island in the sea (multi-core)	
radial and hollow fibre	polymer blend	

Tab. 6: Typical microfibre composite structures (according to Matsui).

The 5th stage in the use of microfibres concerns high performance cleaning cloths. In 1981 Matsui found that microfibres have excellent wiping and cleaning properties. Tab. 5 shows typical microfibres for cleaning cloths from different manufacturers.

Splitting methods for composite fibres, which are used depending on the requirement profile of the microfibres, are chemical resolution, segmentation using mechanical deformation, chemical swelling methods as well as false twist processes (Table 6) (according to Matsui).

Microfibres, dyeing Compared with similar items made from polyester and polyamide yarns of normal finenesses, microfibres show a changed dyeing behaviour. The reason for this is mainly the enlarged fibre surface area. It produces an increased absorption and a greater exhaustion rate of the dyes at the start of the dyeing process, from which levelling problems result. In addition, the changed optics and the enlarged surface area result in an increased dye demand, which is 23 times the demand of classical fibres in microfibres made from polyester and twice the demand in microfibres made from polyamide (Fig. 1). The fastnesses of dyed microfibres can clearly differ from those of classic fibres. So the light fastness in particular may fail less depending on the depth of shade, material and finishing; a pH of the dyeing < 6 produces a deterioration in polyamide microfibres. The same applies for the wet fastnesses, chiefly caused by the increased dye demand and (in polyester fibres) the thermomigration.

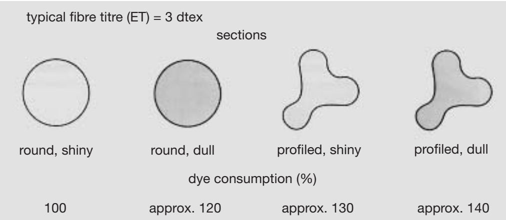

Fig. 1: Effect of the fibre section and the dulling on the dye consumption on polyester microfibres.

A calculation of the dye demand is possible according to Fothergill, if yarns from the same manufacturer or the same substrate are present (see Fig. 2):

$$C_2 = \sqrt{\frac{ET_1}{ET_2}} \cdot C_1$$

C = dye demand,
ET = individual titre.

The equation is only conditionally applicable, as fibre cross-section, delustring, spinning process, dye and similar also have an influence (according to Wiegner).

Microfibres, finishing A prewashing of the textile fabrics is required, as the warp ends are also sized in the field of microfibres. They are washed without tension in wide washing machines with vigorous liquor movement and sieve-drum systems. In special cases (e.g. for severely contaminated materials), the fabric should be treated and/or washed twice in accordance with the dwell process. After treatment, the material should be tested for remaining size residues. This can be carried out in accordance with a method using 1.4-dioxane iodine solution/boric acid. If size residues are established, 32.5% is post-washed before dyeing on the jet machine using 1.5–2 ml/l of caustic soda liquor (38°Bé), afterwards rinsed hot and cold and neutralised. Size residues may result in uneven dyeings, which can only be repaired with great difficulty or not at all. With perfect desizing, the material is dried at 140–150°C after washing. The free shrinking when dyeing the unfixed cloth attains the optimum density of the fabric. It is dyed on jet dyeing systems at high fabric speeds, which should be at least 250 m/min depending on machine type. In dyeings of microfibres, the light fastness of disperse dyes is partially degraded in comparison with normal textile polyester fibres so that a dye selection is required. If a setting process is carried out after dyeing, besides light fastness the dry heat setting fastness is also important.

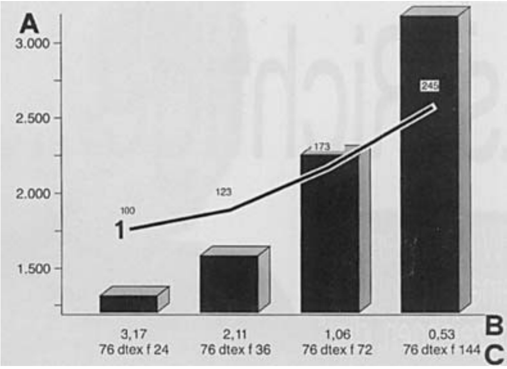

Fig. 2: Dependency of the filament circumference and the dye consumption on the fibre tire in the case of equal overall titre.
A = sum of the circumference of all filaments (mm); B = fibre titre (dtex); C = total titre; 1 = dye consumption (%).

In the re-adjustment of formulae, the dyer should also consider that, in comparison to normal polyester types, microfibres clearly require more dye. This may be between 30–60% depending on fineness. The main reason is the larger surface area of microfibres in comparison to normal coarser types.

A hydrophobic finishing may be carried out after drying. Afterwards it is calendered depending on the desired fabric result. Another post-condensing (post-shrinking) may be carried out on the stenters. The final finishing should be carried out so that the testing of the water impermeability is $\geq$ 500 mm water gauge in accordance with DIN 53 886 after the 5th wash, 3rd percolation.

Sports clothing and rainwear are to a large extent

windtightness, air penetration	10–20 l/m^2/s	0	0
watertightness	50–80 cm WS	up to 3 m WS	over 3 m WS

Tab.: Waterproofing options for microfibres.

manufactured from 100% microfibres (polyester or polyamide). Properties such as water vapour transmission, water impermeability, wind impermeability, but also soft handle and electrostatic properties are important. Fluorine chemicals are used for the water-repellent finishing, as normal silicones can reduce water impermeability via channel formation due to their gliding effect. The Tab. demonstrates the possibilities of water-repellent finishing. Besides the main functional focuses, surface structure is very important in today's fashion trend. Smooth or shifted (crusty, crêpe-like) surfaces may be determined by the pre-treatment and dyeing processes. Sanding and emerizing are either carried out before or after dyeing. The possible finishing operations are demonstrated in the Fig. Items made from or using microfibres are ideally suited to surface treatments due to their specific properties. It should, however, be observed that the fabric should meet certain requirements such as sufficiently high strength.

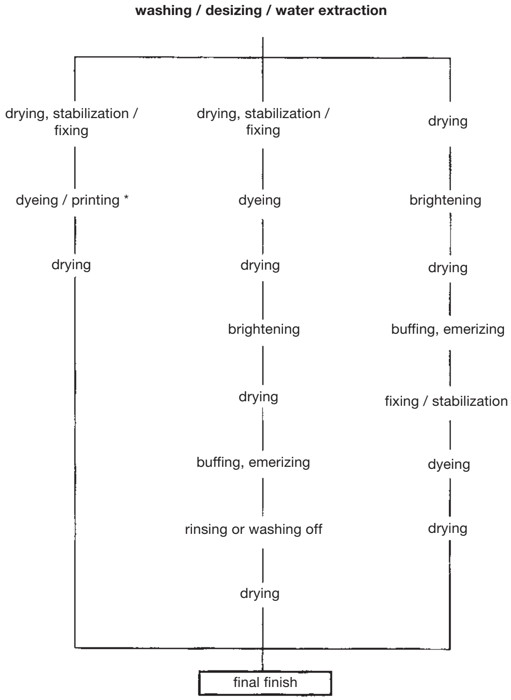

Fig.: Finishing sequence for microfibres (usual method depending on printing process).*

Leisure clothing and light coats are predominantly manufactured from blends of microfibres with cellulose fibres. The demands on wind and water impermeability are less high than for sports wear; softness, wearing comfort and functionality are however imperative. Surface treatments such as sanding or emerizing are the most widespread processes. With regard to the finishing operations, these operations differ only negligibly from those of sports wear. The sanding is normally carried out after dyeing, as the dyeing process may impair the effect on the cellulose part. Products, which do not have an influence on the water-repellent effect or can be washed out easily, should therefore be used as raising finishes.

Blends of microfibres with viscose (women's outerwear) or wool (men and boys' outerwear) are normal in the outerwear sector. Softness, wearing comfort and easy-care properties are the main requirements. While in women's outerwear the handle character should be "supersoft" to silky, soft and cosy is demanded in the men and boys' outerwear. The use of cellulose crosslinking agents cannot be avoided in most cases to achieve easy-care properties. Formaldehyde-free products should therefore be used with the ecology in mind and for wear properties. The quantities used comply with the respective fibre-blending ratio. Mechanical finishing is primarily important in wool blends. Chemical finishing thereby has a supporting effect for handle and volume variations.

In today's trend for casual combination fashion, trousers have a dual function: they are used as both leisure and business clothing. Trouser materials are offered in many blends. Cotton, viscose, linen and wool are the most popular components. The microfibre in the blend serves to improve the handle, wear properties and care properties of natural fibres without impairing their functionality. Emerizing effects are particularly fashionable in men's fashion. As dyeing chiefly takes place after emerizing, a mild "wash-out" effect corresponding to the trend in fashion results from this. Light, flowing qualities are to the fore in women's fashion.

Natural handle and wear comfort are the main qualities in using microfibres in shirts and blouses. Possible surface arrangements are sanding for "peachskin" or "angel's skin" and reduction of pilling and shaping for stylish effects. The finish should serve to emphasise the natural character. Silicon elastomer microemulsions are particularly suited to attaining a soft, dry and cool handle character. As shirts and blouses are manufactured in almost all possible blends, the final finishing should be matched with the blend component.

Napped knitgoods are another range of use for microfibres, which are used both in the leisure and sports sector due to their comfort and their good wearing properties. These fabrics are normally only napped after the dyeing process. While the requirements aim for a pleasant and soft, voluminous handle for leisure fabrics, water repellent properties are also demanded for sports items. This effect is normally produced using fluorine chemicals, as normal silicones result in an oily and less voluminous handle on these items. Easier care results as an additional effect (according to Gysin).

Microfibres, light reflection The total surface area of the fibre lattice or the textile fabric increases exponentially with the falling diameter of individual fibrils and/or with the decreasing titre, especially in finenesses < 1 dtex. A certain proportion of the incidental light is directly reflected by each fibre surface. The reflection of fibres of different finenesses is correspondingly different. This proportion is independent of a possible coloration, but depends on the specific expansion of the surface area. Only the light, which penetrates from the centre of the fibre outwards, is however determined by the light absorbing dyes. The relationship between the light reflected directly from the surface area and the light influenced by the dyeing coming from the centre of the fibre has a determining influence on the shade of colour and depth of shade. Fine fibres with a large reflection surface therefore appear brighter than the coarser fibres dyed with the same amount of dye. This relationship between the light reflected directly and the light returning from the centre of the fibre is altered with increasing depth of shade in favour of the surface reflection, as with increasing depth of shade less and less light is reflected back from the centre of the fibre. Conversely this means that it is more difficult to achieve deeper dyeings the finer the fibre and consequently the larger is the surface reflection.

Furthermore the optical impression of a textile fabric is strongly dependent on surface structure. If it is formed from fine fibres and is smooth, it has a rather mirror-like effect and reflects more light. Dyeing has a brighter effect, if a configuration is made from coarser fibres. The light is repeatedly absorbed in the larger spaces; the more open surface area has a darker effect. This effect also becomes greater with increasing depth of shade. So if textiles dyed with the same amount of dye appear brighter in finer fibres, a higher amount of dye is required in order to achieve equally deep dyeings.

Besides the diameter of a fibre, its cross-sectional form, its degree of delustring and its processing into fine or coarse threads and into smooth or textured yarns are also involved in the optical impression of a dyed textile material. These factors are not specific to microfibres. So a square cross-section, fibre pigmentation as well as crimping in the texturing process ensure higher light reflection, which likewise require higher amounts of dye for covering.

As a second phenomenon, the enlarged surface area produces a negative influence on the light fastness. Different yarn finenesses, degrees of delustring and cross-sectional forms have been known to be the cause of differences in light fastness for a long time. If the normal titres are shifted towards micro-finenesses, the quantity of outer fibre parts exposed to the light is increased by the denser, smoother fabric surface area. More surface is exposed to the light, which is interpreted as a bad light fastness mark because of dye destruction. The disperse dyes are however actually (provided they are the same polymer as the fibre) no less light fast in finer fibres than in coarser ones.

Microfibril composite fibre → Imitation suede.

Microfibril reconstitution Keratins consist of → Intermediate filaments, which are imbedded as a fraction lacking in sulphur in sulphur-rich surrounding proteins. This biological composite can only be fractionated by splitting (reducing) the cystine bridges beforehand and blocking the resulting cysteine. The protein structure denatures in this way because the higher protein structures (hierarchy) become lost. Both main fractions can be separated and are theoretically classified as follows:

a) microfibrils or intermediate filaments → SCMK-A fraction (s-carboxymethyl keratene A or B);
b) matrix → SCMK-B fraction.

A direct proof of this classification would exist if the fractions could be reaggregated individually, by recombining the disulphide bridges so that an analogy of the original components in untreated wool to the components obtained in vitro by reconstruction, would be possible via common morphological characteristics (comparison of electron microscopic photographs). The associated chemistry is designed for the separation operation and in the reconstitution as shown in the Figure.

The German Wool Research Institute has succeeded in reconstituting 10 nm of keratin intermediate filaments made of microfibrillar proteins lacking in sulphur, which exist in the unprotected thiol form. As the reaggregation tests were often carried out under the same conditions, the artefacts observed in the intermediate filaments by an electron microscope are of no concern. Furthermore it can be assumed that the intermediate filaments reconstituted in vitro are structurally identical to native intermediate filaments, as the primary material is pure microfibrillar protein, which was not isolated by partial enzymatic degradation of wool, but was chemically separated from the matrix proteins (according to van de Löcht).

Microfibrils → Individual fibrils.

Microflotation Process for the cleaning of waste waters. Removes approx. 99% solids and clears away approx. 90% phosphates.

Micro-Length-Stretching (MLS, MS). → ML Process.

Micron (My, M), 1 M = 10^{-6}m. Unit of measurement previously used, normally for coarser inner and outer fibre structures, also for colloidal states, coarser emulsions, etc. Today replaced in the metric system by µm (micrometre).

Micronaire value A dimensionless number characterising the fineness of cotton fibre. Additionally dependent on the maturity index, i.e. cotton with the same fineness, but different maturity index shows a different micronaire value. The principle of the micronaire measurement is based on the resistance which a loose fibre stock offers to a defined air stream. The finer the fibres, the greater is their total surface area for the same weight, the greater the air resistance and the lower the associated micronaire value. The value is defined on the Sheffield 60 600 micronaire device (standard device). All different devices must be calibrated to it. The micronaire value scale ranges from 2.3–8.0 (corresponding air stream of 9.9 to 60.6 l/min).

Microorganisms (→ Microbes), microbiology is the field of knowledge of small organisms (microorganisms) and consequently a branch of biology. As an example of special working methods, microbiology applies the determination of the germ number, the growing of bacteria and fungal cultures, and microscopy. Microbiology can be subdivided according to organisms with which it deals: bacteriology (bacteria, actinomycetes), algology (algae) and mycology (fungi). Another division option exists in applied microbiology depending on topics: e.g. medical microbiology, technical microbiology, food microbiology, soil microbiology and waste water microbiology. The microbiologist in textile materials testing deals with textile products or (generally) with problems in the textiles industry from the raw material via the finished product and its transportation to its wanted or unwanted destruction. As a biologist he has to rely on cooperation with textile experts. The textile material can be integrated into the human/microorganism correlation (see Tab.) because both bacteria and textiles operate close to the skin.

Microorganisms do not absorb their food via an internal digestive tract like animals and humans. They release chemicals and enzymes in the substrate thereby decomposing potential food outside their cell and absorb certain materials (building and working materials). The metabolism of microorganisms is dependent on water. Every metabolic action, even the depositing of chemicals (excretory products) and enzymes (exoenzymes) to the environment, only occurs with sufficient moisture. There are some special moulds, with an equilibrium material moisture of 65% relative humidity which is sufficient for their growth. In practice, a humidity of more than 80% aggravates the mould problem. With the corresponding humidity, potential nutrients (e.g. natural textile fibres, textile auxiliaries) already sprout numerous moulds, existing as spores in the ambient air into visible colonies and result in mould marks. With even higher humidity, e.g. in aqueous emulsions, numerous yeasts and bacteria also find sufficient moisture for growth. If there is enough moisture, microorganisms still require building and working materials (energy) for mass reproduction. The important destroyers amongst microorganisms in the textile industry (fungi, certain bacteria, Fig. 1) exploit organic substances (e.g. cellulose, keratin, softeners, starch, dust, etc.) both as energy and as a source of building material. From this, it follows that microorganisms can also grow on materials which are not nutrients in themselves. Surface dust contains sufficient organic material for growth. If such growth appears, the excretory products formed from this can also influence and destroy non-nutrients.

Temperature plays an important role in the growth of microorganisms. It is slower at low temperatures than at slightly higher temperatures. While growth is also possible at refrigerator temperatures, there is an upper limit: most destroyers cannot grow above 50–

Tab.: Microorganic interactions in the person/textile fabric system.

60°C. Some archaebacteria in extreme habitats are exceptions. Far higher temperatures are necessary to destroy microorganisms: dry heat of 160°C with an exposure time of hours or wet heat (water vapour) of 120°C in approx. 150 minutes. Spores are particularly resistant to heat distribution in fungi and bacteria.

I. Hygiene: the → Antimicrobial finishes of textiles include mildew-resistant finish, decomposition protection, hygienic finish (hygiene related textile finishing), the impeding and temporary prevention of mould marks (storage protection). The corresponding antimicrobes and addition finishings should be selected dependent upon the requirements of the protected textile (operating area, use, etc.). The disinfection of clothing is important as protection against infection by destructive pathogenic microorganisms in dry-cleaning. In hospital laundries, the disinfectants used in wash liquor must make bacteria, fungi or viruses harmless. The proteins in the cell wall and the cytoplasmic membrane are denatured by disinfectants as well as by the effect of temperature, i.e. the protein coagulates (clots) irreversibly.

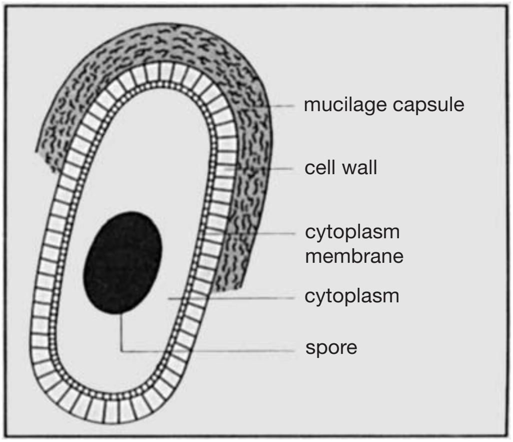

Fig. 1: Diagram showing bacterial structure.

II. Waste disposal: in working with microorganisms in activated sludge in →: Waste water treatment plants, it may be necessary to increase certain types of microorganisms. The search for microorganisms for the cleavage of compounds, which are difficult to decompose, may be carried out in accordance with two fundamentally different methods: continuous growing and vibration tests in charge operation. The latter concerns a sampling method with all its disadvantages: positive results are lucky, in which the chance of a hit with the number of tested microorganisms or the variety of inoculation materials used increases. It is, however, because of lack of available time not normally possible to exert selective pressure in the direction of the desired organism. Continuous growth can be cultivated (Fig. 2) to force a decomposition under aerobic conditions. A blend culture as complex as possible is thereby culti-

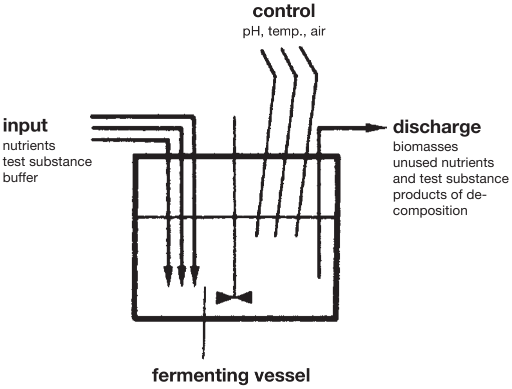

Fig. 2: Diagram showing continuous breeding of microorganisms.

vated over many generations and exposed to the compound to be decomposed. A compound is fed as a nutrient from which the culture can live. If this has a structural similarity to the test substance, the possibility exists that certain mutants can be adjusted to the decomposition of the latter. If the quantity of the nutrient is then reduced and limits growth, a selective pressure exists for mutants; i.e. those microorganisms, which may also decompose the test substance, have a growth advantage. There are also microorganisms, which live under oxygen expulsion, i.e. under anaerobic conditions. For denitrification, for example, reducing substances must be catalysed by enzymes, which come from bacteria. Finally microorganisms play an important role in waste dumps by causing decomposition. Certain types of finishing processes can thereby be toxins for the decomposing bacteria.

III. Fibre decomposition: the following are open to attack from microorganisms, if special preparations were not taken for their protection: wool, animal hairs, silk (somewhat more resistant), man-made fibres on a protein basis, vegetable fibres to a different degree, man-made fibres on a cellulose basis.

Man-made fibres on a synthetic basis such as polyamide, acrylic, polyester, polyvinyl and polyethylene fibres as well as copolymers made from these substances are more resistant to microorganisms. The following series was drawn up for the relative decomposition resistance of fishing tackle made from vegetable spun materials: flax → hemp → cotton → sisal → manila, whereby flax is decomposed most rapidly and sisal and manila most slowly.

The so-called skin and hair fungi mainly occur as wool-destroying fungi; there are predominantly such hyphomycetes in vegetable fibres, which are summarised by the trivial name “moulds”. They belong to a subdivision of the hyphomycetes, the so-called “eumycetes”. These microorganisms which cause the destruction of textiles can be found everywhere. Their spores can even be found in airborne dust. Their appearance is therefore described as “ubiquitous”. They are predominantly found in the earth’s crust and the bacterial content is therefore called “earth’s bacilli” or “earth’s bacteria”.

Even if microorganisms are not in a position to decompose man-made fibres, which are relatively resistant to bacteria and moulds, but does not prevent the bacteria and moulds and their spores from settling on these textiles and remaining viable. They can nevertheless proliferate substantially in the presence of a finish based on natural materials and mildew stains develop. Thus man-made fibres do not have any bactericidal or bacteriostatic and/or fungicidal or fungiostatic effect. They do not provide any culture media for bacteria either, if they are free of such finishes.

IV. Testing: in the → Soil burial enzyme test (decomposition test, mineral decay test) a test stripe of suitable size is used for the testing of tensile strength in germ-rich garden soil. The requirements of the soil mixture to be used is particularly variable. However, it is normal for all requirements that a finished test fabric made from a non decay resistant cotton should be totally decomposed in the burial period. It is more useful to standardise this control fabric than to stipulate a particular composition of the soil because the latter can only be maintained with difficulty. Therefore it pays to control of the activity of the test soil. The vessel, in which the test stripes are buried, should not be completely impermeable to air. According to all methods, a possible attack of the textiles by the microorganisms present in the soil should be retested by means of tearing tests and the designs new to the factory rechecked. If the drop in resistance is below 20% for a given period, the sample is normally regarded as sufficiently decay resistant (rot resistant or rotting resistant). It is customary in practice to extend the test to 4 or 6 weeks for textiles in particularly high demand (→ Rottability of textiles).

Good decomposition of cellulose fabric, which is demanded as a control material in various tests, cannot be considered as a comprehensive guarantee of good bacterial activity. The optimum humidities of the different destroyers present in the soil are too diverse for a defined humidity; both cellulose degradation caused by (aerobic) fungi and artificial leather degradation caused by bacteria require high humidity as an extreme substrate to be able to proceed equally optimally. For these reasons, the TEGEWA companies (loose interest cooperative of textile auxiliary competitors) is busy with two standard projects (as at August 1991):

- model standard to DIN 53 933 “determination of the resistance of cellulose containing textiles to microorganisms (soil burial test), part 1: test of a decay-

retardant finishing". After supplementary combined tests, the soil humidity was re-established and the implementation of the test altered, so that part 1 of the standard could be completed and is presently a yellow print. The "determination of the extended resistance of decay-retardant finishing" has been tackled in a combined test as part 2 of DIN 53 933.
- DIN 53 931 "determination of the resistance of textiles to moulds".

The microbiological textile test is an area with few internationally standardised methods due to the very specific form of the question. Numerous tests exist, which can be easily adapted to the current question. More extensive agreement in the acceptance of standard tests however exists in the degradability test of washing chemicals as well as other textile auxiliaries. The easy adaptability of methods is accompanied by the fact that results from different test cases may diverge as a result of small differences. Standardisation results in the fact that the differences are reduced and the degree of freedom in a test is reduced. Specialised microbiological knowledge also enables near-practice tests to be carried out for specific questions. In quality assurance tests, a selection should be made because of the wealth of possible tests. The support of several questions is thereby recommended: if both the bacteria and the mould and decay resistance are good, the forecast of microbial resistance can be made with greater certainty. In every discussion about preservation in the textile field it is important to know under which conditions microorganisms can grow. Dry storage is the safest preventive material protection against microbial destruction. If this cannot be implemented, an antimicrobial finishing as wash-resistant as possible can guarantee protection. A microbiological check of such measures, besides confirmation of existing protective agents, simultaneously allows the safeguarding of sufficient effect against test organisms or practice germs. In order not to use the antimicrobially effective materials in a way dangerous to the environment, besides clarifying compatibility for human health, the influence on the environment should also be given greater consideration (according to Nopitsch as well as Meyer, Raschle and Kuhlmann).

Micropore finishing Process in the finishing sequence to make films and coated textiles (artificial leather) additionally permeable to air and water vapour (sweat) but also keeps out heavy rain. Method of operation on layer starches of up to approx. 0.7 mm using electron beam bombardment, whereby up to 1 million micropores are produced per square metre. Polyacrylate, polybutadiene, polyurethane and certain polyvinyl chloride coatings and laminates are particularly suitable. Already manufactured textile materials are not suitable for this process.

Microporous coatings So-called "breathable" properties such as → Water vapour transmission and waterproofing should be achieved. This is possible using several processes:

I. Foam coating: porous structures were already being produced by foaming in 1950. Firstly, relatively stiff, non-breathing materials were developed, however. Foam coating in the fashionable, leather-like field achieved the breakthrough, where foam layers are provided with a top film. The foams can be manufactured in accordance with mechanical or chemical principles. The foaming process has a considerable effect on the foam structure and thereby on water vapour transmission. So, for example, thin films producable by the use of solvents are considerably "more breathable" than thicker ones made by mechanical foaming. Ecologically advantageous, purely aqueous systems have meanwhile also appeared. The foam layer produced when drying is usually condensed by the use of calenders and re-waterproofed or given a finishing lacquer (Fig. 1). This is absolutely essential, as the pores are somewhat larger than those of the remaining poromerics (15–50 μm) and therefore have relatively poor water impermeability. The number of pores is approx. 500 000 per cm^2.

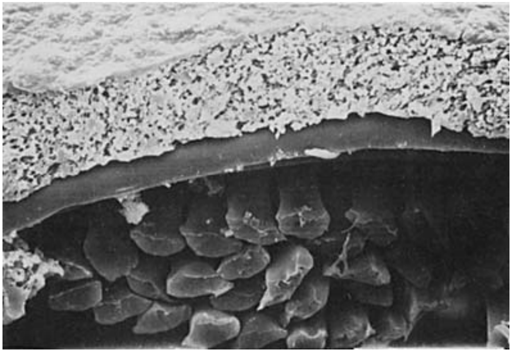

Fig. 1: Microporous fabric coating in section.

II. Coagulation process: microscopic pores are produced by controlled microphase separation, based on direct modification of polymer compatibility. Products manufactured by "coagulation" (precipitation, clotting) are distinguished by special softness and textile characteristics, unlike any other coating processes (Fig. 2). Three fundamental coagulation methods currently exist:
- DMF coagulation,
- thermo or evaporation coagulation,
- acid coagulation.

The sponge-like microporous coating film shows a structure connected with 0.2–0.3 μm pore sizes, which ensure water vapour transport as air conditioning channels. A "vapour starvation" of the coating paste should be prevented in the coating, as otherwise a more compact, non water vapour transmittable film is produced.

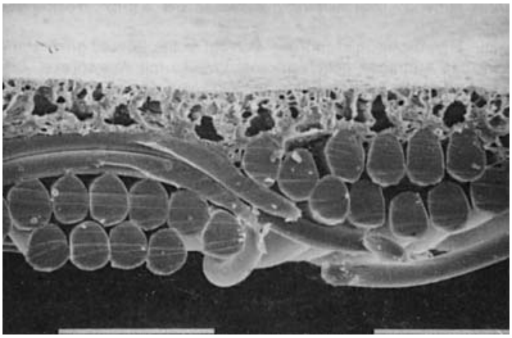

Fig. 2: Coating by the DMF coagulation process.

As a hydrophilic surface develops, using the polyurethanes normally applied, the coatings can be provided with a closed top film, which increases water impermeability. This top film thereby prevents the contamination of the coating from soiling and pore clogging.

a) DMF coagulation has been used since 1960 and is therefore the oldest process. Refined and transposable to other solvents, it is the most significant manufacturing method for microporous artificial leather (Fig. 2). Coagulation is based on the solubility of the polyurethane solvent DMF (dimethyl formamide) in water (Fig. 3), against which polyurethane is completely insoluble in water. The DMF is extracted in the coagulation bath by the water in the bath. A change in the solvent takes place by using the non-solvent, i.e. the solvent is successively extracted from the polyurethane while the polymer layer is increased by the use of water and the solubility of the polyurethane portion in the layer thereby diminishes. Finally precipitation and complete coagulation of the polymer occurs on the substrate. The plastic is combined to form a fluffy layer with a dense microporous structure. DMF residues should be removed in wash baths and rinsings, as otherwise they represent a risk to the cell structure during drying. Recovery of the DMF by means of a distillation plant is absolutely essential from an economic and ecological point of view. The process can be adapted to the desired targets using different solvent combinations or variations of the polymer system. The adjustment of the pore size and structure depends on:

- polyurethane concentration,
- solvent/precipitant ratio,
- temperature,
- other additives.

All parameters require extreme precision. It is a costly process, in which UV stabilisation and pigmentation of the polyurethane pastes are difficult. “Breathability” clearly exists in these materials, but the combination of water vapour transmission and absolute water impermeability demanded cannot be so easily achieved. The conflict is alleviated through the use of polyurethanes with hydrophobic elements. Another possibility is additional fluorocarbon finishing. Meanwhile polyamides from Japan capable of coagulating have also become well known.

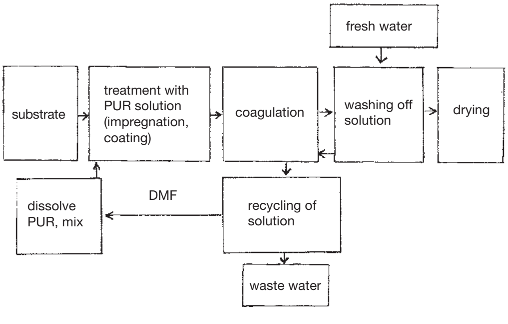

Fig. 3: DMF coagulation process.

b) Thermo and/or evaporation coagulation require lower machine investment than wet coagulation, as work can take place at the normal solvent coating plants and no DMF sewage is produced. Polyurethane is dissolved in an organic solvent and modified by a defined allowance of water and special additions so that a stable, easy to spread paste is produced in the form of a water-in-oil emulsion. The solvent is selected so that it firstly evaporates during drying. Through this selective evaporation, there is a steady decrease in concentration of the solvent and an increase in the concentration of the water. Finally the point is reached at which the polyurethane precipitates in a solid form under the formation of microporous structures from the aqueous medium. The water also only evaporates in the second drying phase. A partial temperature adjustment considerably alleviates the fractional evaporation. Long drying channels with at least three temperature zones allow the coagulation to be controlled by temperature and operational speed. As for all drying processes of polyurethane products, a temperature of 170°C should not be exceeded in order to prevent melting of the pores and thus their bonding. The structure of the dry coagulate ideally has finer cells than those of the wet coagulate. Individual item groups produce films of 25–50 μm thickness via different processes. The paste preparation, which requires the most meticulous care with regard to recipe, operational result and stirring intensity, needs special attention. An important parameter is the proportion of water in the formula, whose quantity is determined by microporosity. Referring to the polyurethane solution, the proportion of water is 40–70% so that the pore structure of such products varies greatly. By the increased addition of the non-dissolving proportion, the water vapour transmission can be increased by a certain amount. Further solvent addition does not however have an effect on porosity. Viscosity control of the coating paste is possible via water and/or solvent addition.

c) Acid polyurethane dispersions which can be coagulated, and which can be applied without solvent addition in accordance with conventional processes and which achieve similar results from the solvent coagulation, have existed since 1984. The polymers from these dispersions contain solubility switching groups, and have been converted into salts and lose their effect due to acidification. This acidification is the step, which triggers coagulation. It is not a gradual concentration shift as in DMF or evaporation systems, but a spontaneous coagulation based on the ion reaction. The products manufactured according to the acid coagulation process, show a remarkable water vapour transmission, but currently still unsatisfactory water impermeability, as coarse coagulation structures are produced. With increasing coating starch, water vapour transmission and water impermeability run contrary to each other This is the reason why a later water-repellent finishing is indispensable. This process is restricted to relatively open pore or voluminous substrates, which allow a satisfactory deposit of the coagulate. Furthermore no transparent films are produced. The relatively young acid coagulation process is still at the start of its development and can certainly be further consolidated.

III. Polymerisation accompanying pore structuring: According to this process of applied pastes, dispersions or solutions are applied, which first of all contain prepolymers and react to form microporous structures after application. The pore structure resembles coagulation porometrics. In this process, a solution of oligomers, monomers and photo initiators is applied. The relatively low molecular polymers, polymerise in seconds with their highly reactive functional groups using ultraviolet irradiation or electron beam bombardment. These are then no longer soluble in the solvent used and microporous structures are formed. The use of conventional apparatus, the versatile chemistry and high production speeds (approx. 100 times higher than in coagulation processes) allow the manufacture of inexpensive products. Another advantage is the usability of numerous plastics such as polyurethanes, polyacrylates and polyesters. The adhesion between substrate and monomer and/or polymer has a positive effect in the electron beam induced polymerisation reactions. A liquid monomer or oligomer surrounds the fibre better than a polymer dispersion, whereby the monomer can be adapted to the substrate more easily during the warp growth.

IV. Compact hydrophilic systems: new types of functional polymer systems with a sequential molecular structure combine the contrary requirements for water vapour transport and watert impermeability. In contrast to the microscopic dilution, in which microscopic pores are produced, a molecular dilution takes place in the polymer morphology. A polymer structure, e.g. in the form of a hydrophobic polymer matrix with hydrophilic channels, allows a high water vapour transmission, whereby the compact surface area guarantees water impermeability. The polymer chemistry opens up a broad spectrum through which the molecular combination of actually incompatible segments is possible. The principle of water vapour transport via complex molecular mechanisms has already been used for medical purposes, e.g. dialysis. As only certain hydrophilic polymers are in a position to transport water vapour in this way, only polyesters and polyurethanes are currently used. Their permeability is a fundamental material property and dependent on the diffusion coefficient and the solubility in water vapour. The diffusion coefficient is determined by the free volume of the polymer as a molecular parameter; the solubility is however dependent on the polarity, i.e. the functional groups. Polymers with different water absorption power and different swelling behaviour are available in the choice of suitable structural elements. The transport mechanism (Fig. 4) should be understood so that water vapour molecules landing on the hydrophilic surface are absorbed via hydrophilic polymer components. These may form weak bonds with the water vapour molecules and facilitate a diffusion along the molecule chain.

The direction of movement of the molecules is dependent on their concentration and speed. The higher the vapour pressure gradient, i.e. the moister and warmer one side is, the more the movement is promoted to the other side. Rising humidity increases the number of molecules which occur and increasing temperature increases their speed. The direction of move-

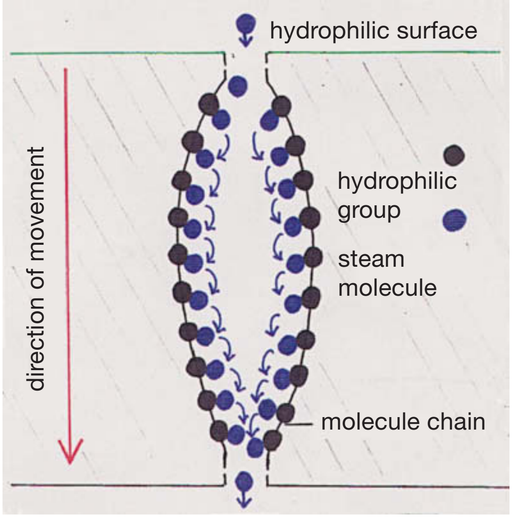

Fig. 4: Molecular steam transfer.

Next Page

ment can be promoted by a specific substrate structure; for example, coating strokes are structured so that their hydrophilic character is diminished from the absorbing to the emitting surface. The temperature mechanism does not allow any limitless use, as a reduction in operation may result from temperature and humidity ratios. The hydrophilic layers may be blocked by constant rain and prevent absorption of vapour or condensed liquid. This fall in the vapour pressure difference deteriorates the water vapour transmission on the one hand and increases the diffusion coefficient with the water content on the other. Swollen hydrophilic membranes transport more water vapour in a unit of time. The reduction in the partial pressure difference can therefore be compensated by the increase in diffusion speed.

a) Compact hydrophilic membranes: as with microporous membranes, the compact hydrophilic membranes can also be processed in a variety of ways. Laminates with top cloth, lining fabric or subcarriers permit numerous varieties of items. The polyester membrane from the firm of Akzo/Enka has been known in the market under the name Sympatex since 1984. Water vapour transport via the free hydrophilic groups of polyester molecule chains proceeds through the closed surface. The approx. 15 µm strong membrane is distinguished by an excellent watert impermeability of more than a 10 m water gauge due to its compact surface area and its functionality is not reduced by soiling to the extent as is the case for porous substrates. There are currently also hydrophilic compact membranes made from polyurethanes.

b) Compact hydrophilic coatings: the hydrophilic coating is the latest development in the field of “breathable” materials; it externally resembles the classic compact coating. Its hydrophilic molecule groups, e.g. polyvinyl alcohol or polyethylene oxide, facilitate water vapour transport through the intermolecular pores – the finest pores, which are set in the molecular structure. Dissolved polyurethane systems, which guarantee a good water impermeability in 30–45 g/m^2 of additive, are normally used. The water vapour transport of such systems is often inferior to that of the microporous coating, but individual manufacturers are already promising far better results. The polyurethane coating Witcoflex 971 from the firm Shirley-Baxenden promises a 50 times higher water vapour transmission than average microporous coatings. Other “breathable” polyurethane coatings are also possible with the Impraperm brands from Bayer AG, products from the Dutch company Stahl or the Belgian firm UCB. These compact films are often used as a top layer in a microporous coating in order to construct an absolute water permeability. Mostly thin films of 5–8 g/m^2 are applied. This strength should not be exceeded, as the water vapour transmission of the hydrophilic coating varies inversely proportional to the layer thickness. The layer thickness determines the density gradients of the material and thereby the rate of diffusion in these asymmetric coatings, i.e. a layer as thin as possible with molecular pores, which ensure water vapour diffusion and a porous substrate with macroscopic pores, permits rapid water vapour permeation. Surface dirt or detergents do not impair the strong, usually abrasion resistant coatings, as no pores can block up. Pump effects, as in macroporous systems, are not apparent and the hydrophilic polymers prevent an excessive formation of condensate through their “stepping stones”.

Microporous membranes The most well known is the Gore-Tex foil from the firm Gore, which has been known as an innovator in the field of “breathable” materials since the 70s. → Gore-Tex is produced by the drawing of partial crystalline polymer films made of polytetrafluoroethylene (PTFE), whose crystalline fibrils are separated in the stretching process under formation of microscopic pores. This thin membrane (approx. 25 µm) can be laminated on carrier textiles and used in the form of multi-layered laminates. The different designs may differ greatly in handle, case, function and area of application. The watertightness of such laminates is not problematic, though the laminate construction significantly determines water vapour transport. In particular the top cloth properties can, for example, reduce water vapour transmission by swelling and subsequent closing of the textile pores. The PTFE used, also known as teflon, provides a particularly hydrophobic surface, which supports water resistance and itself shows excellent water vapour transmission values. The evenly combined micropores (Ø approx. 0.2 µm) are approx. 500 times smaller than the finest mist droplets and 670 times larger than water vapour molecules. The proportion of pores is approx. 82%; that is approx. 1.4 billion pores per cm^2 so that active water vapour transport is guaranteed.

The use of membranes requires new operating processes, which give rise to additional costs. Strict guidelines, which are necessary to prevent damage to the membrane and subsequent leakage, should be observed especially in the seam processing. Their use permits high-tech functionality without influencing classic textile properties in an acceptable way.

The firm Gelman Sciences is promoting its microporous membrane Repel with properties similar to the Gore-Tex film, but at a considerably lower price. This “breathable” membrane (2 µm) contains approx. 1.7 billion pores per cm^2 and costs ca. a tenth compared with other membranes. This can be put down to low cost manufacturing. Other microporous membranes are the polyurethane membrane Porelle from the firm Porvair and Thintech, a membrane from the company 3M provided with an additional hydrophilic impregnation, as well as Sympatex (Akzo). → Microporous coatings.

Microprocessor systems Such systems monitor, control or regulate (depending on whether there is an

Previous Page

ment can be promoted by a specific substrate structure; for example, coating strokes are structured so that their hydrophilic character is diminished from the absorbing to the emitting surface. The temperature mechanism does not allow any limitless use, as a reduction in operation may result from temperature and humidity ratios. The hydrophilic layers may be blocked by constant rain and prevent absorption of vapour or condensed liquid. This fall in the vapour pressure difference deteriorates the water vapour transmission on the one hand and increases the diffusion coefficient with the water content on the other. Swollen hydrophilic membranes transport more water vapour in a unit of time. The reduction in the partial pressure difference can therefore be compensated by the increase in diffusion speed.

a) Compact hydrophilic membranes: as with microporous membranes, the compact hydrophilic membranes can also be processed in a variety of ways. Laminates with top cloth, lining fabric or subcarriers permit numerous varieties of items. The polyester membrane from the firm of Akzo/Enka has been known in the market under the name Sympatex since 1984. Water vapour transport via the free hydrophilic groups of polyester molecule chains proceeds through the closed surface. The approx. 15 µm strong membrane is distinguished by an excellent watert impermeability of more than a 10 m water gauge due to its compact surface area and its functionality is not reduced by soiling to the extent as is the case for porous substrates. There are currently also hydrophilic compact membranes made from polyurethanes.

b) Compact hydrophilic coatings: the hydrophilic coating is the latest development in the field of “breathable” materials; it externally resembles the classic compact coating. Its hydrophilic molecule groups, e.g. polyvinyl alcohol or polyethylene oxide, facilitate water vapour transport through the intermolecular pores – the finest pores, which are set in the molecular structure. Dissolved polyurethane systems, which guarantee a good water impermeability in 30–45 g/m^2 of additive, are normally used. The water vapour transport of such systems is often inferior to that of the microporous coating, but individual manufacturers are already promising far better results. The polyurethane coating Witcoflex 971 from the firm Shirley-Baxenden promises a 50 times higher water vapour transmission than average microporous coatings. Other “breathable” polyurethane coatings are also possible with the Impraperm brands from Bayer AG, products from the Dutch company Stahl or the Belgian firm UCB. These compact films are often used as a top layer in a microporous coating in order to construct an absolute water permeability. Mostly thin films of 5–8 g/m^2 are applied. This strength should not be exceeded, as the water vapour transmission of the hydrophilic coating varies inversely proportional to the layer thickness. The layer thickness determines the density gradients of the material and thereby the rate of diffusion in these asymmetric coatings, i.e. a layer as thin as possible with molecular pores, which ensure water vapour diffusion and a porous substrate with macroscopic pores, permits rapid water vapour permeation. Surface dirt or detergents do not impair the strong, usually abrasion resistant coatings, as no pores can block up. Pump effects, as in macroporous systems, are not apparent and the hydrophilic polymers prevent an excessive formation of condensate through their “stepping stones”.

Microprocessor systems Such systems monitor, control or regulate (depending on whether there is an

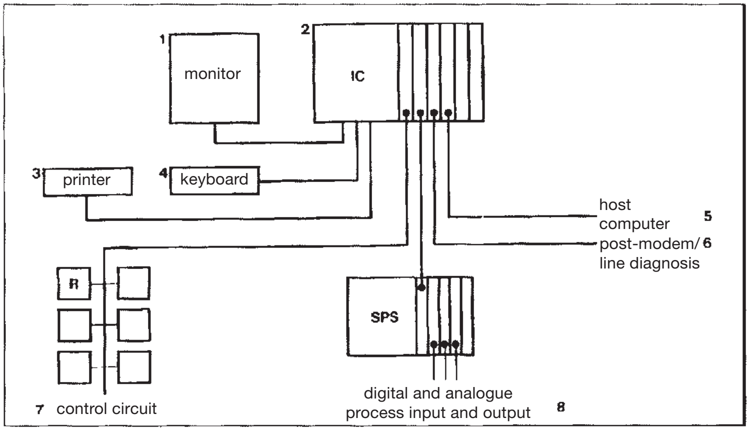

Fig. 1: Process automation of continuous plant, hardware system. 1 = monitor; 2 = industrial computer; 3 = printer; 4 = keyboard; 5 = host computer; 6 = post-modem/line diagnosis; 7 = control circuit; 8 = digital and analogue process input and output.

open or closed control circuit) important functions in the operation of a finishing plant or finishing machine. The hardware is divided into clearly defined modules (Fig. 1).

An industrial computer (IC) manages the process and fabric data, and exchanges data with other EDP systems. Storage Programmable Controls (SPC) are used at process measurement and control level. The regulating functions can be executed by software blocks or by interfacial controls. Stand-alone controls have the advantage that during computer malfunctions processing can continue using manually adjusted desired values. The SPC is equipped with digital and analogue cards in order to be able to issue the necessary control commands and receive process signals. The control information is generated in the IC from the fabric and process data and the operating mode (preparation/production) and handed over for implementation to the SPC and the controllers. The screens are connected to the computers, on which the machine operator observes the process and controls program execution. He/she inputs operator commands (Fig. 2) via the keyboard. The printer is used for the output of the production protocols and fault signals. This hardware must be supplied with appropriate software. A corresponding menu is set via function keys for the purpose of individual program execution. The process observer sees on the screen which tasks are available for the process and selects the next task in view of the information schedule and technological conditions. The data is automatically inserted in the mask “prepare next task”. The formulation of the process and the calculated liquor batch volume are printed out. Preparation processes are started and changes in process initiated from the mask “prepare next task”. The IC generates the control information from the fabric and process data and operator instruction (preparation/production/process change) and passes it for execution to the process measurement and control level.

Interactive programs lead the user in the interactive mode; he/she requires neither programming knowledge nor encoding lists. The consistent use of the menu technique alleviates the operation as well as the generation, management and running of the programs and permits adaptation of the control to the apparatus. By pressing

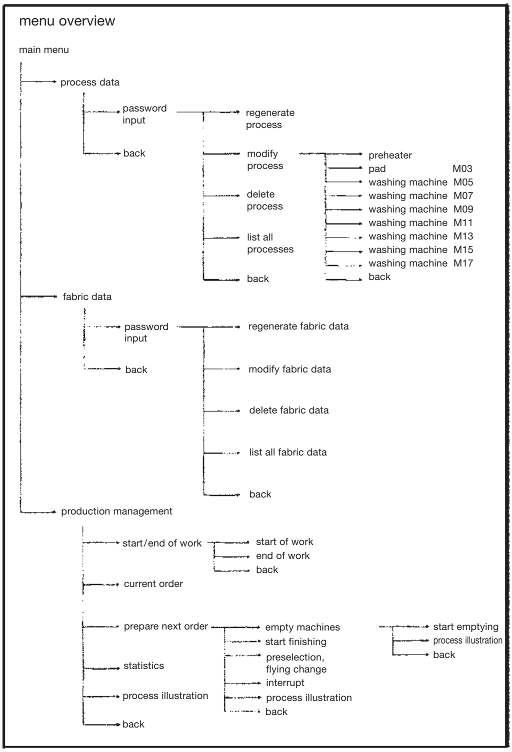

Fig. 2: Operating structure of a process-controlled continuous dyeing plant (Küsters process technology).

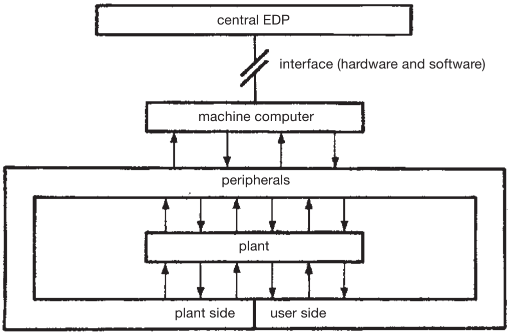

Fig. 3: Information flow system.

the corresponding function key, the control either splits into another menu or into a program routine. Distinctions are basically made between basic menus, program flow, program execution and service routine. The latter two are only accessible by inputting a password. An unauthorised change or correction of programs or machine settings is thereby prevented. All controllable functions appear in a logical sequence one after the other in plain text on the screen during the program generation, for example for a dyeing machine:

- fill dyeing kettle with water type 1,
- fill dyeing kettle with water type 2,
- fill secondary container with water type 1.

The person with authorised access compiles the required program steps via the function keys. The automatic system does not accept illogical steps; errors can be corrected immediately.

Systematic structuring and equipping with microprocessor systems as well as integration into the higher-level system is known as dyehouse management. After dyeing, the data is analysed and the batch data is fed back to the commercial EDP (Fig. 3). The dyehouse then also receives the necessary statistics. The provision of planning data for the commercial EDP is very important within the framework of batch preparation. The commercial EDP should know the need for dyes, chemicals, dyeing times per batch, etc. It asks for a planning recipe. This contains the quantity of fabric to be dyed, the colour and the possible pre- and aftertreament. The recipe with the necessary dyeing program, the demand for dyes and chemicals as well as the suitable type of machine and the time for the dyeing are then drawn in the technical EDP (Fig. 4). All this data (Fig. 5) is reported back to the commercial EDP, which works out the relevant dyeing tasks. As the commercial EDP usually also comprises the material management, the orders for dyes and chemicals can be initiated. Should this not be the case, the planning requirements and ordering can also be carried out by the technical EDP.

The dyeing tasks include all the important information for dyeing. Material, colours and possible pre- and aftertreatments then permit the selection of a suitable master recipe, which is transferred into a production recipe. The tasks for the weighing stations and the dyeing program are then gathered from the production recipe. The print-out of the necessary cards is carried out simultaneously. The respective operational progress status can be recognised by the commercial EDP at any time by feedback of the batch status. The production of the dyeing program from the recipe is optimum from this, if dyeing program modules parameterised at any time for individual treatment stages (such as the pretreatment, dyeing and aftertreatment) can be assigned. The recipe, which is organised into several treatment stages is on the left side. Parts of the necessary dyeing programs are shown on the right side. The dyeing program consists of the individual modules and the parameters with the data assigned from the recipe. So, in the example shown (Fig. 4), the gradient in the “colour” module is established at 1°C/min, the final temperature of 120°C and the retention time at 20 min.

The application of modules on the one hand and their parameterisation on the other permit very many recipes from the dyeing programs to be assembled from relatively few modules. The expense for the generation and maintenance of the dyeing programs is thereby considerably lowered and an optimum program can be produced each time without great expense.

Fig. 5 shows that the databases can be divided into three groups, which are product-specific, process-specific and machine-specific. The machine-specific data for example includes liquid level calibration curves for the machines to maintain definite liquor ratios, fabric

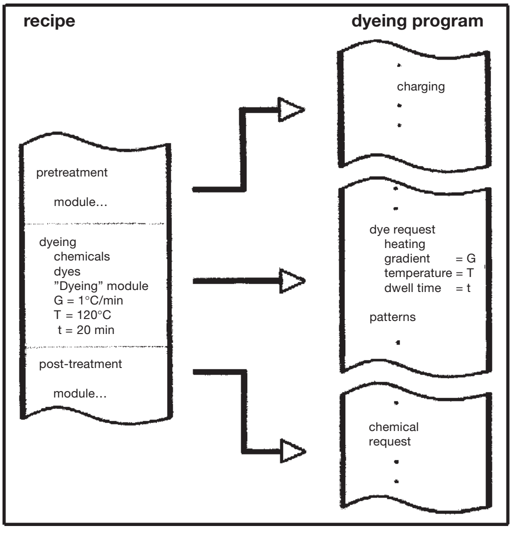

Fig. 4: Generation of the dyeing program for parametric modules (Then).

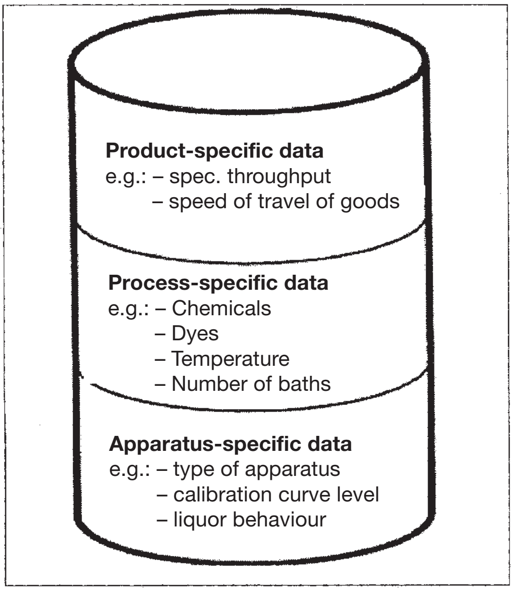

Fig. 5: Common database for recipe and dye program (Then).

speeds, flow values in yarn dyeings, etc. A common and comprehensive database therefore appears to be an important requirement when integrating dyehouse management and process control. The next processing sequence is, for example, the patterns. If there is a pattern, this is firstly assessed colorimetrically. It is thereby split into three categories:

- The pattern is within the tolerance limit; the dyeing is good.
- The pattern is outside the tolerance limit; an addition is possible.
- The pattern is outside the tolerance limit; a colour correction is not possible.

The work to be carried out can be selected accordingly and triggered at the measuring station in the integrated system. If the pattern is good, the module for the after-treatment in the machine control is started; but if an addition is necessary, a suitable addition module can be selected depending on the colour variation, transmitted to the control and started . The weighing is done on the scales in the colour kitchen. A comment that this recipe should be revised can furthermore be input in the master recipe. The response of the batch within the dyehouse is recorded in a batch report. The time period, number of additions and machine control are documented and permit a check of the dye behaviour at any time. Layer and long-term reports not only verify the production success. A comparison of the production in the recent past with the long-term statistics also results in a trend report. This brings an influence to bear early on in the production. User-friendly data and inquiries give considerable help in the analysis of the events in the dyehouse. Not only are the machines controlled by the computer work station in the dyehouse (Figs. 6–7), but also a connection to the colorimetry, weighing stations and the recipe management can be produced. The BEE cards can also be produced by a minor hardware expansion for the programming of individual controls; in the case of control centre failure, work should be continued using individual control (Fig. 8).

The situation in the textile industry with continually increasing demands on quality and the obligation to maximum operational efficiency with simultaneous demand for just-in-time production can only be managed with practical process automation. As production processes are extremely complex, the information from individual process units must be connected to network systems in order to exhaust all the possibilities of modern data technology to form production planning systems.

The workplace in the dyehouse will change and dealing with the microprocessor will become routine for the staff. This also necessitates training and further education of staff in order to be able to use the continually growing possibilities of automation systems by means of EDP optimally as (according to Hartmann and Quas).

Microscope A distinction is made between the → Light microscope and the → Electron microscope. Practical textile microscopy can be called on for clarifying numerous problems which occur in the manufacture and finishing of textiles. The identification of man-made fibre materials is becoming more and more complex with the increasing variety of new fibres and their processing into the most varied fibre blends. A differentiation in the various man-made fibres, especially in dyed items, is hardly possible any more without microscopic tests together with dissolving, swelling and dyeing reactions. In clarifying textile complaint and damage cases, extensive practical experience in all areas of textile manufacture are required in order to be able to evaluate the results of practical microscopic tests. Easy to operate working microscopes with a polarisation device are enough for practical textile microscopy, especially as these devices in many cases do not have to be operated by trained staff, but by semi-skilled technical assistants. An optical device with approx. 100–800 times magnification is adequate. But more important than the magnification is the resolution of the microscope. This is understood to mean the power of a lens system to make two object points lying close together separately visible. The resolution therefore depends on the strength of the lens systems, which depict a magnified, inverted image of the preparation. This image is made visible to the eye by the eyepiece, but no further resolution is carried out in detail by eyepiece magnification. A photo device is part of the basic equipment just as is a hot table microscope. This latter is necessary in order to be able to determine the melting range of synthetic fibres.

Microscopic Only recognisable under the → Microscope. Opposite → Macroscopic.

Microscopy In textiles, there is an indispensable specialist area of textile testing within the framework of identification, production (man-made fibres), item development, processing and damage information about fibres, yarns and fabrics. Technological tests provide information about textile physical characteristics, detect deviations from desired values, but are often only possible with the aid of the microscopy to allocate the causes. While the examination and description of vegetable and animal fibres were prominent in the beginning, textile microscopy set itself new tasks with the development and spreading of man-made fibres.

Clasification:

1. Light field microscopy with backlighting or front lighting for surface area tests and for the analysis of cross-sections.

2. Dark field microscopy, whereby the light, assuming the lens aperture is smaller than that of the condensing lens, passes the lens. The field of vision is dark. Only a part of the light scattered on structures and constructions reaches the lens and facilitates observation of the object. Structures on the surface, deposits of delustring agents, carbon black and dye dispersions as well as vacuum bubbles are very well reproduced.

3. Fluorescence microscopy is based on the phenomenon of photo luminescence. These tests are possible on preparations which contain substances which, with radiant exposure to high energy, short-wave UV light, convert this into long-wave, visible light. Devices for pick-up, of exciter and stop filters, as well as a light source (e.g. mercury high pressure lamp), which gives a high short-wave light content, are prerequisites.

4. Polarisation microscopy can detect the double refraction of man-made fibres and give information about the orientation of the chain molecules. The degree of orientation of man-made fibres can be influenced by the spinning speed and/or by the aftertreatment (drawing of synthetic fibres). Different tension or temperature ratios in subsequent processes (warp beam manufacture, sizing, fixation) also change the degree of orientation. Orientation differences in turn influence the dyeing behaviour and may consequently be cause for complaints. In addition, in polarised light, mechanically caused fibre deformations or filament breaks due to deformation zones in longitudinal fibre formation and texturizing processes can be detected with tension zones in the microtome cross-section. If an anisotropic object is brought into the optical path of the polarisation microscope at crossed polarisers, the ranges of the polarised light are shifted and appear coloured (interference colours) on a dark base.

5. Thermomicroscopy is used within the framework of the identification of man-made fibres for the analysis of substances adhering to fibres, e.g. oligomers/paraffin. Material-specific changes regarding shade transfer, softening and melting point caused by heat input are thereby also observed.

6. Scanning electron microscopy is being used to an ever greater extent. Besides research institutes, numerous laboratories work in the fibre industry using these devices. The high magnification in conjunction with high resolution at a depth of focus not attainable until now, facilitate representations of the topography of samples in their actual spatial form. The representations of → Scanning electron microscopes give insights into cross-sectional forms and surface composition of fibres and enable cause/effect correlations between process conditions to be recognised, from which, for example, measures for the yarn manufacture and/or aftertreatment can be derived.

Microscopy fibre cross-sections, preparation of Either (most effectively) by means of → Microtome or simplified in the following ways:

I. A carefully prepared fibre bundle (in which fibres are as parallel as possible) is pulled through a small pierced (0.5 mm diameter) supported metal sheet by means of a yarn loop so that the fibres fit tightly in the opening. Then the fibres are carefully cut off perpendicular to the fibre bundle on both sides of the small plate using a sharp razor blade. Cross-sections obtained in this way be assessed in the microscope at 250–400 times magnification. They can also be easily microphotographed.

II. In accordance with type I above, pull a fibre bundle through a stopper and then cut thin strips from the bundle. This method has the advantage of making several different cross-sectional forms in rapid succession from the same fibre material.

Micro-Stretching → ML Process.

Microtome Device for the manufacture of fibre cross-sections for microscopic work, e.g. without (manual microtome) or with mechanical blade guide (slide, pivot, automatic microtome).

Microwave moisture measurement is capable of measuring the moisture application behind the padder in continuous dyeing processes and of evaluating the measured values for the padder control. They can also be used to determine the residual moisture content be-

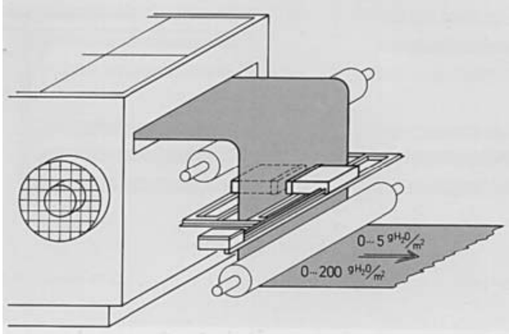

Fig. 1: Residual moisture measurement using the RF 110 microwave system by Pleva.

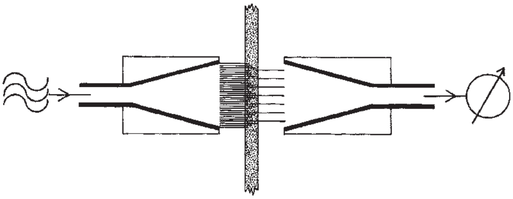

Fig. 2: Principle of moisture measurement using microwaves.

hind the stenter exit (Fig. 1). A defined microwave emission is thereby beamed onto the damp fabric. The proportion of microwaves not absorbed because of its density (Fig. 2) is measured and related to the humidity by calibration.

OH ions dampen radiated high frequency energy at microwave frequencies in proportion to the amount of radiation. In addition, they vibrate at a wavelength of approx. 1.7 cm in resonance with the excited energy and thereby consume a particularly large amount of energy as does every resonator. In this way it is possible to test humidity using microwaves and it is rather selective due to this resonance. These measurements are possible without contact; the cloth must be well controlled and maintained in a constant position. Humidity analyses can be carried out using different measuring arrangements both in the residual moisture range and with a high water content of approx. 20–400 g/m^2. The absolute water content is always indicated. So knowledge of the fabric weight is necessary for calculating the relative humidity. As the structure of the cloth and, to a certain extent also the type of textile material enter into the reading, item-specific calibration curves must be constructed (above all, in the residual moisture range, where only a little water is absorbed by the microwaves).

Different designs of device are on the market. One manufacturer allows the microwave energy to push repeatedly through the cloth when determining the residual moisture in order to increase the damping effect. Another guides the measuring instrument through a so-called pore resonator, in which the short waves vibrate as in a microwave oven. With high humidity, the waves are beamed onto the cloth from horn transmitters and again picked up behind by the similar elements. The measuring range limit is achieved, if so much water is found on the cloth surface area that it reflects like a sheet with high frequency energy. But if the deep humidity is distributed fairly evenly, the total amount of humidity can be measured using microwaves. The measuring accuracy is sufficiently good if measurements taken on the same cloth or different items are carefully calibrated. If extremely high accuracy is not required, a cloth-specific calibration can possibly also be dispensed with, at least for items similar to each other.

Microwave rapid laboratory method for CPB dye fixation The rapid laboratory method developed by Hoechst AG, in which the dwell time required in CPB dye fixation for the fixation of remazol dyes can be shortened to 4–6 min with the aid of normal microwave ovens. Reproducible recipe results, which are applicable to product batches, are thereby obtained.

Microwaves Electromagnetic radiation in the milli-, centi-, decimeter wave range (approx. 1 mm to 30 cm) and frequencies between 1–3000 GHz. → Radiation, comparison of different types.

Microwave treatment Fixation of dyes using microwave treatment. Continuous dyeing process for yarns, strips and fabric by means of microwaves. Dyes can be fixed in a continuous process using microwaves as a heat source (→ High frequency drying). A useful example of microwave treatment is its use in spinning. Honeydew in cotton fibres, amongst others, leads to stickiness owing to residue of plant sugars and insect secretions. The treatment process is based on the principle of evaporating the water on the adhesive particles by direct heating. The adhesive tendency is lost as a result of the drying out and/or embrittlement (see Fig.). As an energy source microwaves have the capacity of automatically having the greatest effect at the position of the highest water content. The heat takes effect chiefly in the adhesive particle and not in the fibre itself. The treatment system consists of a dissolving unit, the microwave element and an aperture cleaning unit.

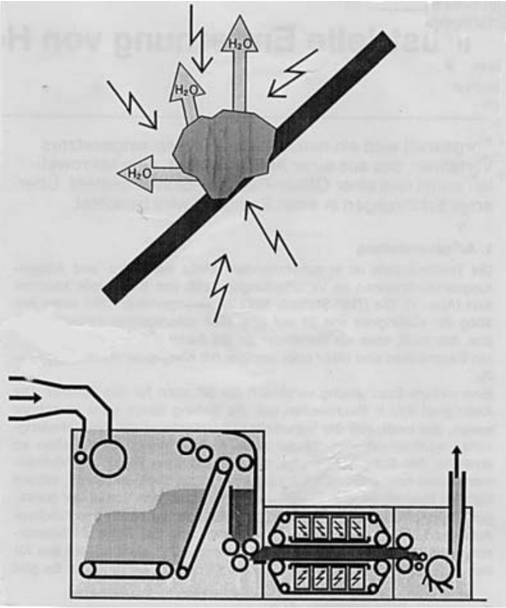

Fig.: Application of microwave drying for the removal of honeydew stickiness from raw cotton when opening bales.

The flocculent is formed into a wadding in the dissolving unit, which is led to the microwave tunnel and simultaneously compressed. A transport system consisting of two special-purpose strips continuously carries the compressed flocculent as wadding through the microwave tunnel. The microwave output is controlled at a given temperature profile. It is operated at a process temperature of 110–130°C. The released water vapour is dissipated via a ventilation system.

Microwax Shortened form for microcrystalline hydrocarbon wax made from de-paraffined products (paraffin gatch, petroleum gatch, etc.), obtained after de-oiling/cleaning. Colour black/brown/yellow/white; consistency sticky, soft malleable to hard. Has higher setting range/melting point of 55–90°C compared with commercial paraffins and a very fine crystal structure. Used for water-impermeable finishes.

Migration Migration power of a substance in or on the substrate from places of higher to places of lower concentration.

I. By levelling during the dyeing process (→ Levelling properties).

II. As a result of uneven drying in padding processes (→: Migration in intermediate drying; Dye migration in drying).

III. By contact with dyeings and/or prints with substrates, which have an affinity to the dyed and/or printed dye (e.g. with disperse dyes/prints in polyvinyl chloride coatings). Low wet pick-up processes avoid extensive migration compared with pad-dry condensation processes in resin finishing. A test of the migration of chemicals for resin finishing using a special-purpose staining technique (lattice test). The migration of dimethylol dihydroxyethyleneurea across the fabric cross-section and to the fabric surface area in the pad-dry condensation process was investigated by nitrogen and formaldehyde analysis as well as by colour measurement and was documented (resin migration). → Vertical migration.

Migration ghosting → Ghosting effects.

Migration in exhaust dyeing processes Controlled staining processes are mostly more economical through high standards and good reproducibility. They control the set up and/or fixation so that the cloth is almost equally dyed from the start. In migrating processes, however, a greater initial unevenness is accepted, which must be compensated for through migration. This requires good migrating dyes. Migrating processes may be more economical for unfavourable dyeing conditions (low liquor throughput, slow fabric run, etc.), as an almost identical staining would be time-consuming under these conditions. In many cases, migration processes are unavoidable, e.g. with fibre differences, temperature differences in the plant or with rapid filling dyes (such as vat dyes). The following applies for controlled staining processes: The filling only needs to be roughly controlled in order to avoid a filling which is considerably too fast (loss of time). The filling phase and the migrating phase are distinguished in a filling curve, as shown in Fig. 1. Uneven dyeings intentionally produced by migrating can be evened out in the too rapid filling phase.

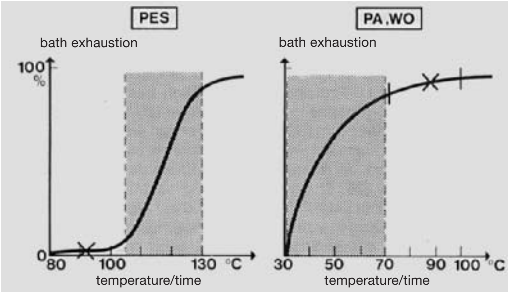

Fig. 1: Critical temperature ranges (dark) and idle times (x) in polyester or polyamide and wool dyeing.

Example: a dark yarn dyeing (100 parts = 2.5% dye made from yellow/bordeaux/grey) and a brighter yarn dyeing (70 parts of the same dye recipe) were wound on top of each other. This wound yarn package was then brightened on a blind dyebath boiling at pH 6 with the addition of 2% levelling agent and 10% sodium sulphate calcium. After cooling down to 60°C, the dyebath was adjusted to pH 4.5–5 using acetic acid and the wound yarn package washed out as normal (Fig. 2).

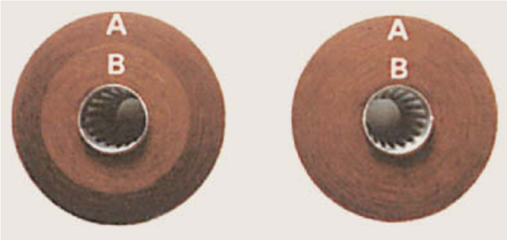

Fig. 2: Migration within a wound package.

Migration is understood as the evening out of inequalities, which are produced in fibres with the same dyeing properties through concentration or temperature differences in the liquor. The migrating power of dyes is normally tested by treating a (close to the equilibrium) pre-dyed fibre sample with an undyed one in the same bath and measuring the cross migration of the dye. Migrating curves are produced, as shown in Fig. 3.

The ratio of the quantity of dye $M_{F,2}$ on the previously undyed sample to that on the pre-dyed one $M_{F,1}$ according to a particular time t_M is described as the migrating power.

Migration in exhaust dyeing processes

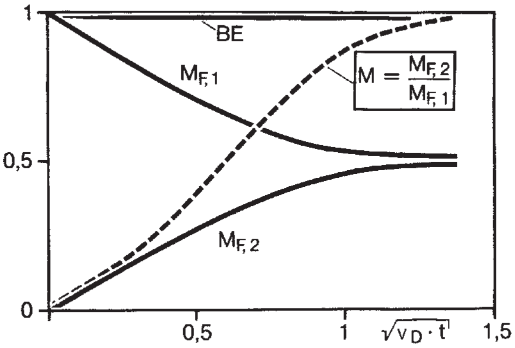

Fig. 3: Migration of a dye from the pre-dyed fibre 1 to the initially undyed fibre 2 in a fresh bath.
M = migration pattern; $M_{F,1}$ = Dye quantity in fibre 1; BE = bath exhaustion; V_D = diffusion speed; t = time.

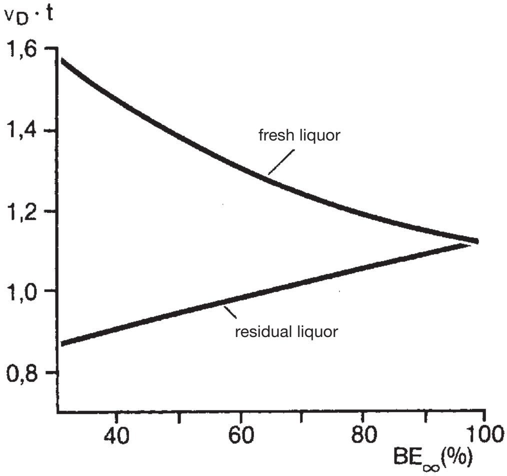

Fig. 4: Effect of the bath exhaustion BE_∞ on the time to 90% equalization through migration (i.e. until M = 0.9 is reached), expressed by the dimensionless parameters $V_D \cdot t$.

$$M = \frac{M_{F,2}(t_M)}{M_{F,1}(t_M)}$$

Some laws of the migrating process can be recognised by simple model calculations. With well-mixed liquor, the diffusion of the dye from the pre-dyed, into the initially undyed fibres, is determined by speed. Assuming Fick´s diffusion with the same constant diffusion coefficient D for both fibres and Nernt’s distribution equation, the following applies: the levelling time t_M is inversely proportional to diffusion speed v_D until a certain value of M is reached

$$t_M \approx \frac{1}{v_D}$$

and incidentally depends on the equilibrium bath exhaustion at the end of the migrating process BE_∞ and the liquor concentration at the start. The influence of BE is shown for two cases in Fig. 4.

A flat geometry (film) was assumed; but the same type of image is obtained for regular cylindrical fibres: with high bath exhaustion, BE t_M is almost independent of this. With migration in the residual liquor, t_M increases with increasing BE. With migration in a fresh bath, however, t_M is greater the lower is BE , i.e. more dye is desorbed in the bath. So migration tests in the fresh bath can be misleading. With uneven dyeings, evening out via migration is carried out considerably more slowly and is slower the lower the liquor flow. The cloth movement promotes migration to a different extent depending on dye and migrating conditions. The liquor may not be regarded as ideally mixed. Through the migration, inequalities to be evened out are produced by concentration or temperature differences in the liquor. This is also expressed in the fact that the measured migrating values of dyes do not only depend on the diffusion coefficients, but decrease much more strongly with increasing affinity (bath exhaustion) (Fig. 5).

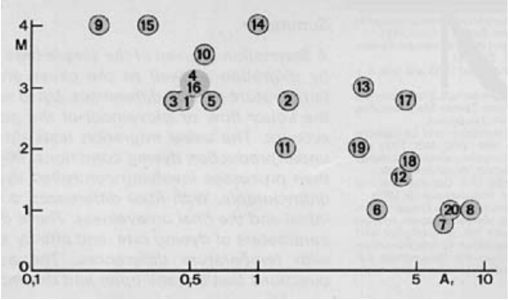

Fig. 5: Measured migration tendency M of acid dyes on polyamide against relative affinity A_r of the dye.

Three parameters are definitive:

- the diffusion speed v_D,
- the bath exhaustion parameter

$$b_M = \frac{RE_{outer,\infty}}{(BE_\infty)^{\frac{1}{n}}},$$

- the flow parameter

$$s_M = \frac{U}{v_D} \cdot b_M \cdot w.$$

(according to Hoffmann).

Migration inhibitors Substances, which are added to the pad liquor in order to prevent the migration of dyes when drying. The alkaline saponification of polyacrylonitrile facilitates the manufacture of water-soluble products, which can be used as migration inhibitors in the thermosol dyeing process. The molecular weight often results in a solution viscosity which does not satisfy technological standards. Control of the viscosity of these solutions using cross-linking agents is therefore recommended. It is possible to use water-soluble acrylic polymers modified with formaldehyde as migration inhibitors in thermosol dyeing. The structure of the polymer film, on which the fixation of the disperse dyes is carried out using heat treatment, considerably influences their yield. The opinion is thereby held that the fixation process is accelerated by the presence of a film with a porous structure. The use of crosslinked polymers can result in an increase of the fixation ratio of the disperse dyes, because of the existence of microgel particles. It is assumed that the volume of these particles is impervious to the disperse dyes, consequently their fixation takes place in practice from the phase with increased concentration.

Migration in intermediate drying is due to too little substantivity of the dyes under drying conditions and also to high moisture absorption. Migration tendency is greater in polyester/cellulose blend fabrics than in cotton and is encouraged by uneven drying. The smaller the particles of the dye the stronger the migration during drying. The coarser the yarn or the more densely beaten the fabric, the stronger the migration effect. Recommendations for avoidance: as little liquor pick-up as possible during padding. Resting of the damp fabric after padding or drying. Effective drying evenly across the whole width of the cloth. Avoid shock drying. Use products, which cause a change in the particle size under drying conditions. Only use wetting agents as far as necessary.

The pad liquor is more or less homogeneously distributed across the cloth after leaving the padder. Drying only starts on the top and/or bottom of the fabric. The liquor migrates from the fabric inner to the drier surface due to heat, whereby the substance is accumulated on the fabric surface. The migration ends when the fabric is so far dried that the coherence of the liquid phase is broken. As long as the liquid flow to the fabric surface is not interrupted in the first drying phase (70–30% humidity in the cloth), the so-called migration threshold will not be exceeded, i.e. the particles dissolved in the water (e.g. finishing chemicals) are borne along to the cloth surface and accumulate there (uneven distribution). This migration stops when the evaporation of the water transfers to the centre of the fibres, as through low wet pick-up or high squeezing effects (e.g. with the Roberto roll), no more surface water is available.

The types of migration can be subdivided in summary as follows:

1. Migration of the liquor to the fabric surface from less rapidly drying to rapidly drying places: “listing or centre run” (surface migration), or from one side of the fabric lagging behind in the drying through to the more rapidly drying side: “side uniformity” (fabric migration).
2. Migration of the particles dissolved in water on fabrics from the centre to the evaporation surface.
3. Liquid migrations as a result of concentration differences.

In all three cases migration is caused by the drying of the padded textiles. After impregnating the fabric with a solution, the liquid is held in capillary pores in the centre of the textile material. The evaporation of the water during drying firstly takes place on the fabric surface, then the liquid is further conveyed by capillary forces. The particles dissolved in water are rinsed onto the fabric surface together with the liquid. A back diffusion of the material particles is carried out by the concentration difference developing between inner and outer as long as one capillary is filled with liquid. But the back diffusion stops when either the liquid column breaks or when the particles dissolved in water become so large that they can no longer move due to lack of space. The migration is completed when the evaporation of the water only takes place from the centre of the material, i.e. the moisture content break point is reached, and the further conveyance of the liquid into the fine capillaries is completed.

Apart from migration from the fabric centre to the fabric surface, the types of migration shown in Fig. 1

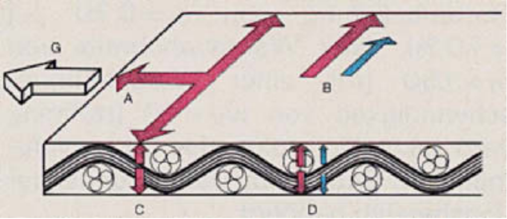

Fig. 1: Diagram showing the migration types during pad-dry processes (according to Somm).
G = fabric length (direction of travel); A = horizontal migration (cause of uneven fabric appearance); B = selective horizontal migration of the individual components of a dyeing (cause of dichroism and uneven fabric appearance); C = vertical migration (cause of listing and two-sided dyeing); D = selective vertical migration (cause of side-to-centre shading and shade differences).

are above all of interest to the dyer. A vertical migration can take place when more heat or earlier heat is supplied to the textile material from one side rather than from the other side. This then leads to “two-sided effects”. Stripes which occur during drying can be put down to the fact that front and/or back sides over the width of the textile material dry alternately stronger and weaker. A selective migration can take place, when in a dye combination the individual components of the dyeing are conveyed to the surface of the textile material length at different speeds. This uneven conveyance leads to shade shifts and an irregular cloth profile. In horizontal migration, the migration of the particles take place mainly on the surface of the textile material. In structured textiles, thin places dry sooner than thick ones, through moisture vapour transmission and dye conveyance which is effected from the thicker to the thinner places. The appearance of a so-called “wet” cloth profile can be put down to this reason.

Migration during drying can only occur when particles dissolved in water (e.g. finishing chemicals) are carried along in the liquid flow in the capillaries, which lead to the surface. The migration stops when the so-called migration threshold has been reached. The end of the migration varies greatly with respect to the material. In hydrophobic fibres, the proportion of surface moisture is considerably greater than in hydrophilic fibres, which have a large proportion of swelling moisture. The end of the migration or the migration threshold is an important criterion for the characteristics of the migration; several values are therefore given in the Table.

	end of migration (migration threshold)	water retention property
viscose	40 %	85 – 100 %
wool	36 %	42 %
cotton	21 %	45 %
polyamide	10 %	13 %

Tab.: Comparison of water retention properties and threshold value of the water content below which no further migration will take place on drying.

The drying conditions play a big role in all the possibilities. So it can be established that migration increases with growing evaporation performance, i.e. the more heat is carried over to the textile material to be dried, the more intensive the water evaporation is and therefore more particles can be transported to the surface of the textile material. A very large migration can be expected in the high performance convection dryers familiar today, also in the IR pre-dryers with a maximum drying performance of approximately 10 kg H_2O/m^2. Only low migration values can be expected with low air movement (circulating air distribution) and high relative humidity (i.e. with low drying performance). The migration drops off with falling moisture content of the material, i.e. the migration is at its greatest after the padding at the start of the drying process.

The migration decreases with an increasing degree of saturation of the drying air, caused by the reduction in the evaporation rate. It would be possible theoretically to control the evaporation rate via the saturation value. The more moisture there is in a drier, the higher the wet bulb temperature, which in turn can be equated to the fabric temperature. As this fundamentally concerns the reaction of hydrophobic and hydrophilic fibres to the migration, this factor can be classified under the physical factors. If a solution migrates in material not capable of swelling, an increase in concentration occurs on the surface of the fabric while a decrease in concentration takes place in the fabric core.

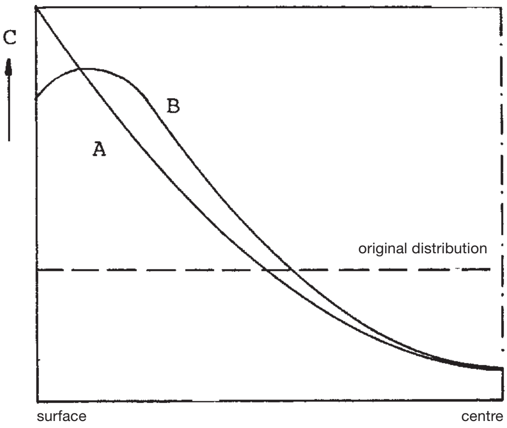

Fig. 2: Migration properties of a solution in non-swellable textiles (according to Junginger).
A = solution fully saturated; B = solution not fully saturated

Fig. 2 demonstrates the concentration profile of a completely saturated and a non completely saturated solution in the cross-section of the textile material not capable of swelling. In curve A, an efflorescence or precipitation of the super-saturated solution occurs in the second drying phase, which can only occur in the advanced drying stage in curve B. In a textile material capable of swelling such as wool, a capillary moisture movement is only possible up to the value of the swelling humidity. This humidity combined with swelling can only be removed in the vapour diffusion way, i.e. the substances dissolved in this swelling humidity cannot migrate, but result in a basic concentration value.

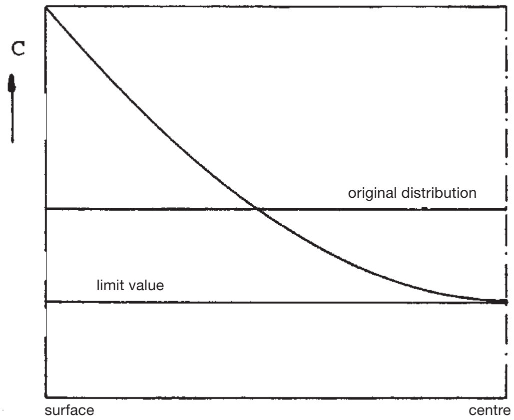

Fig. 3: Migration properties with a swellable textile (according to Junginger).

The distribution corresponds to the representation shown in Fig. 3.

A series of test methods, which can fundamentally be divided into two groups, is available to test the migration behaviour in a laboratory:

1. The migration takes place similar to the practical conditions in the hot air flow, such as: pocket and/or sandwich test, watch-glass test, hair-drier test.
2. Drying takes place at room temperature or given temperature without air movement in the drying cabinet, such as glass plate test, crease test, etc.

Migration in polyvinyl chloride Resistance of the colour of textiles to migration in polyvinyl chloride layers, which contain softeners. White pigmented polyvinyl chloride film is placed on a glass plate and the sample spread on it. A quantity of softener corresponding to the weight of the sample is evenly dripped on, the test specimen covered with a second glass plate, loaded and kept at 80°C in a hot cabinet for 3.5 hours. Then the sample is removed, the polyvinyl chloride film rinsed with petroleum benzine (petroleum ether) and dried. The staining is assessed using the grey scales.

Migration propensity of dyes Capacity for → Migration, in order to even out concentration differences. The levelling capacity of dyes is not only dependent on dye properties, but also on the textile material and dyeing process. The migration propensity of dyes is jointly responsible for their → Levelling behaviour. (→ Dye migration in drying).

Migration test The colour measurement should be partly consulted for an analysis of these tests, but colour measurement is a surface measurement and does not provide reliable evidence about dye distribution, other suitable methods are sought (→ Levelling property test).

I. Modified migration test in accordance with Baumgarte (Fig. 1): the fabric to be tested is laid in nine layers and crease-free samples, 5 x 10 cm, are punched out, so that it can be ensured that the layers have close contact with each other. Afterwards the sandwich samples are stored in a standard atmosphere over night. The air conditioned samples are then immersed in the liquor to be tested in the horizontal knuckle padder and immediately squeezed on the laboratory padder (80% squeezing effect). The pad liquor generally contains 20 g/l of dye. The sandwich is fixed between two Teflon sieves for intermediate drying in the laboratory drier in order to prevent flapping. The Teflon sieves are dimensioned so that they can be pinned down onto a stretching frame. The drying time is adjusted to the desired residual moisture, which can be ascertained gravimetrically.

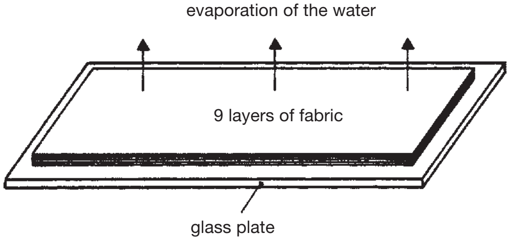

Fig. 1: Model test for dye migration (according to Baumgarte).

II. Sandwich test (Fig. 2): three fabric sections of 15 x 30 cm are padded and then closely fastened on top of each other on a pin frame. This is then dried in a hot air flow under precisely defined conditions. It is fixed, reductively cleaned or boiled with soap depending on the dye classification. The outside of the fabric (1, top or bottom), the middle fabric layer (2) as well as the inside of the fabric (3, top or bottom) are assessed.

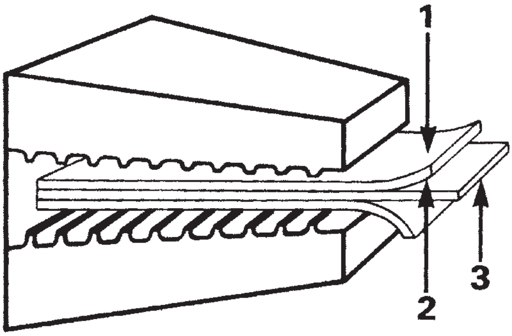

Fig. 2: Sandwich test for migration (according to Somm).

III. Clock-glass test (Fig. 3): a clock glass of approx. 10 cm in diameter is laid onto a padded fabric pattern run into the drier in a horizontal position. The drying is carried out similarly as in II. It is reductively

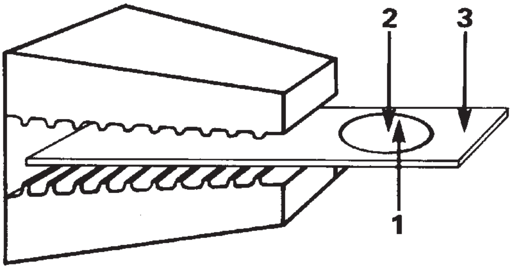

Fig. 3: Clock-glass test for migration (according to Somm).

cleaned or boiled with soap depending on the dye classification. The clock-glass underside (1), the clock-glass covering (2) as well as the top side of the fabric (3) are assessed.

IV. Hair-dryer test (Fig. 4): a padded fabric is laid onto a wire grid and dried from above using a hot air hair-dryer at a distance of 20 cm. The front and back of the fabric section are assessed with regard to difference in depth of colour or shade of colour after drying.

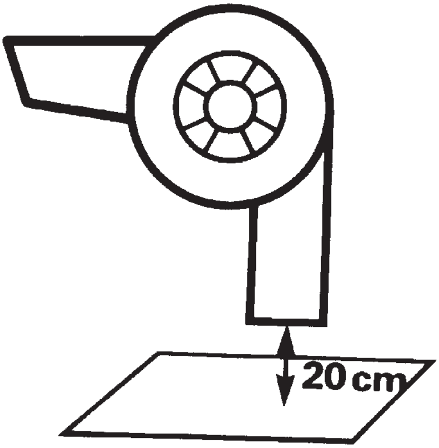

Fig. 4: Hair-drier test for migration (according to Somm).

V. Glass plate test: after padding, a fabric section of 9 x 9 cm is laid between two glass plates (A) of 10 x 10 cm, of which one has a hole with a diameter of 15 mm (B) in the centre. The edges of the glass plates are sealed with molten paraffin (C). After being stored at room temperature for 16 hours, the glass plates are separated and then the still damp fabric completely dried at room temperature. A fabric padded with the same liquor and likewise dried in the air at room temperature is used as the reference standard for the assessment. A comparison of the depth of colour between the reference standard and the “migrated” pattern on the covered places produces a dimension for the migration which has occurred.

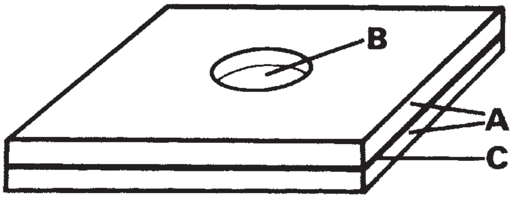

Fig. 5: Glass plate test for migration at room temperature (according to Somm).

VI. Crease test (“concertina test”): a fabric strip 75 cm long and 6 cm wide is padded and folded in book form. The small fabric staple length is dried between two glass plates in the drying cabinet at a given temperature.

Milas rugs One of the finest and most beautiful Anatolian → Prayer mats. Smoother, rather shorter pile with approx. 150 000 knots per m^2. Colourful, bright colours. Varied patterning varying from small flat stylised flowers to geometric shapes.

Mildew-resisting agent → Fungicidal finishes; Antimicrobial finishes.

Mild steel → Iron.

Mild washing agents Hard water resistant → Syndets for domestic washing. They are usually neutral.

Mild wash process for outerwear The protection of textiles against matting, shrinking, stretching and suchlike is hereby to the fore. These risks can be avoided by reducing the totality of the washing mechanics, but at the same time increasing the intensity of the mechanical effect. This can be achieved by using a washing drum with a large diameter for example, which operates with a pump speed corresponding to a transverse acceleration of 0.8–0.9 times gravitational acceleration at a reversing rhythm of 30–60 s interval and 2–5 s rotation (Miele Kreussler process). Outerwear, which had been reserved for dry-cleaning until now, can be washed using washing processes, which are carried out in washing machines using water with drum radius of 40–50 cm and are characterised by the fact that extremely long reversing pauses are used. These processes require completely new operating techniques and greater use of drying and ironing. In contrast to dry-cleaning, they have the advantage that water is used as a solvent. Even if still further optimisation is required, mainly in the field of drying, mild wash processes offer the possibility of completely re-structuring commercial textile cleaning (according to Hasenclever).

Milk of lime → Calcium oxide.

Milled composite fabrics → Bonded fabrics made from e.g. nonwoven wool (blends) bonded using felting and milling.

Mill engraving After producing the master pattern die (→ Pattern die) the actual mill engraving is carried out on the engraving mill (engraving machine). The hardened relief engraving is thereby pressed against a rotating copper printing roller with a thrust up to 7 tonnes until the required engraving depth has been reached. Mill engraving is precision work, as the repeats in height and width must turn into each other without any transition.

Milli- (Lat.), unit prefix for a thousandth = 10^{-3}; e.g. mg, ml.

Milling Matting and condensing (increased shrinkage in length and width) of wool piece goods (possibly also with a proportion of extraneous fibres) in the hot damp state, preferably of more open carded yarns. Milling is carried out in acid (→ Acid milling) and/or alkaline liquor. → Milling process.

Distinctions are made between the following:

I. Alkaline milling using excess sodium carbonate (+ olein fats + sodium carbonate = olein soap) or potassium carbonate and/or soap.

II. Neutral milling with as much sodium carbonate as is required for the saponification of the fatty acid content in the fats (fibre protection), milling auxiliaries. It is pre-washed for example (wool scoured) in "soap milling". In "fat milling, soil milling or soda milling" (raw fabric), fats capable of saponification must be removable in a maximum of 2–3 hours at approx. 3°Bé of sodium carbonate solution (otherwise fibre damage): milling in the "tanner". The latter always "fresh" (if too thin: soap addition; if too thick: no further soap). Grease milling requires special practical knowledge in order to prevent "burning of the dirt"; amongst prerequisites named for fabrics easy and difficult to mill. After 4 hours of milling using pH 10 sodium carbonate solution, approx. 30% area shrinkage; approx. 38% using potassium soap with same pH (→ Milling auxiliaries).

III. Acid milling of technical felting. Considerably higher densities of the felting are achieved than in alkaline milling.

IV. Milling in solvents (solvent milling, mixed phase milling, dry milling): finishing process carried out in tetrachloroethane, in which knitted, hosiery or woven textiles are milled with the addition of precisely metered quantities of emulsified water, i.e. shrunk, condensed and changed in their surface structure. The degree of milling can be precisely controlled by the quantity of water added and treatment time. Implementation in dry-cleaning machines of special design for knitted fabric finishing in a solvent. Milling in the solvent is also suitable for the matting of carpet yarns.

Milling auxiliaries (milling soaps) are used for the support of felt formation (thread end) in the milling of wool. This mostly concerns surfactants or preparations based on them. The action is based on an increase in wool suppleness and improvement of the sliding action at the same time. Suitable milling auxiliaries are milling soaps, triethanolamine soaps, further fatty acid condensation products and alkyl naphthalene sulphonates, possibly with inorganic or organic swelling compounds.

Milling calender Special calender for material pressing and milling to smooth fabric, in which e.g. needle bonded nonwovens and similar are pressed on the one hand, and on the other hand compact pores are converted into absorbent capillaries (handle improvement can also be analysed for fabrics/hosiery goods). Consists of a central cylinder (heated to a max. of 200°C) with several surface rollers (usually 8, heated/cooled), temperature and spacing are adjustable. As a laboratory and production machine (2–20 m/min) with/without batchers, also as part of a continuous plant assembly.

Milling dyes Colour fast for milling → Acid dyes.

Milling felt, Fulling felt Pressing felt → Felt.

Milling/felting theory The felting process was defined by Arnold for the first time in 1929. Felting is, therefore a "process for the connection of fibre materials and the formation of a homogeneous top layer from loose fibre materials by the use of friction, impact or pressure with the assistance of heat and moisture".

Witt had already put forward one of the first felting theories in 1888. He makes the flakey structure of wool solely responsible for the felting process in his so-called "mechanical sticking theory". This graphic model of the flakes mechanically sticking into each other is also still widely held today, although this theory is no longer valid. A short time later, Ditzel postulated that the flake structure of wool is a necessary prerequisite for the felting process because he had established that no felting of the wool could be observed if the flake structure is completely lacking. Wool has a direction-dependent coefficient of friction (Directional Frictional Effect, DFE, → Friction) due to its flake structure.

In contrast to Mercer, Speakman could not establish any better felting power using increasing DFE in his tests on the influence of elasticity in the felting process. From this he concluded that the DFE is not exclusively responsible for the felting process (→ Feltability of wool) The following three conditions should be fulfilled for the felting process according to Speakman:

- The wool fibres must have a flakey surface.
- The wool fibres must be easily elastic and easily deformable.
- The wool fibres must be able to return to the relaxed state from the extended state.

In contrast to Speakman, Martin holds the opinion that not only an extension of the wool fibres takes place during the felting process, but also a compression. The root ends are of great importance for the felting process in his theory. A clearly reduced felting tendency of the

Milling/felting theory

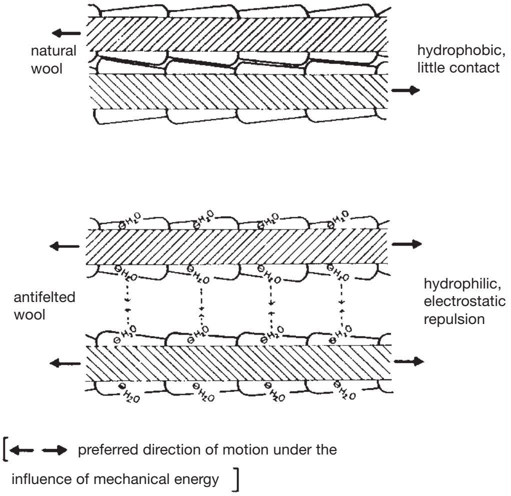

Fig. 1: Wool fibres are rendered hydrophilic through antifelt finishing, so that electrostatic repulsion in a fibre combination reduces compaction.

wool was observed by removing the flakes from the fibre roots. Speakman had already pointed out in his earlier works that a soaking of the wool fibre tips is necessary for the migration of the fibres in the course of the felting process. Rouette would also later confirm the influence of the soaked fibre tips on the milling process through treatment of wool fibre tips with H_2O_2. Speakman and Sun established a better feltability of the shorter wool fibres, while Sookne, Bogaty and Harris observed a better feltability of the longer fibres. Meichelbeck finally showed that the hydrophobic character of the flakes has influence on the milling process (Fig. 1).

The length milling process of a fabric is produced in the compression channel (Fig. 2), while the width milling process is realised through entré (Fig. 3). Laying the fabric hank (Fig. 4) prevents crease formation.

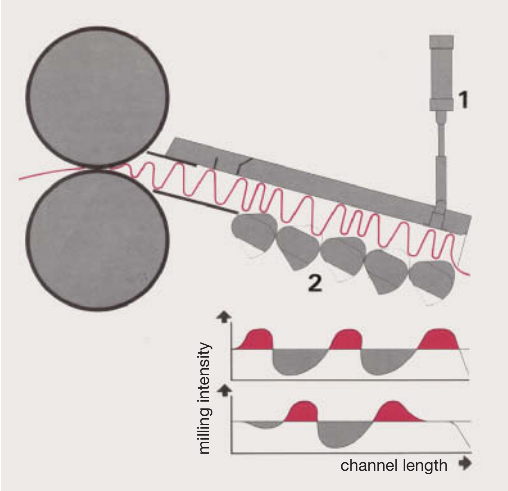

Fig. 2: Rhythmic compression and relaxation of the fabric to be milled in the compressing channel (Hemmer).
1 = pneumatic pressure cylinder; 2 = moveable elements for intensification of the rhythm of the movement.

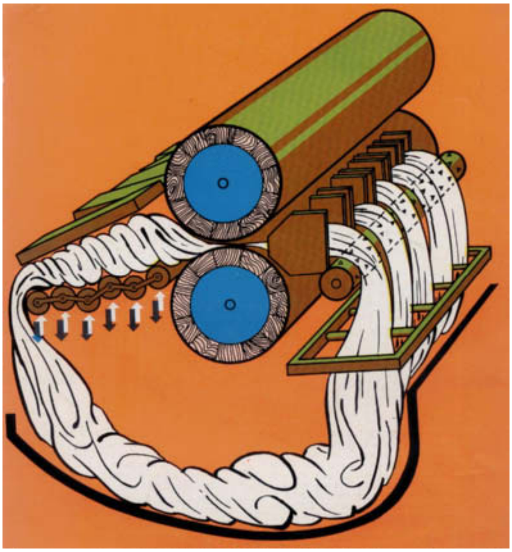

Fig. 3: Fabric hanks on entry into the feed systems of a mill (MAT).

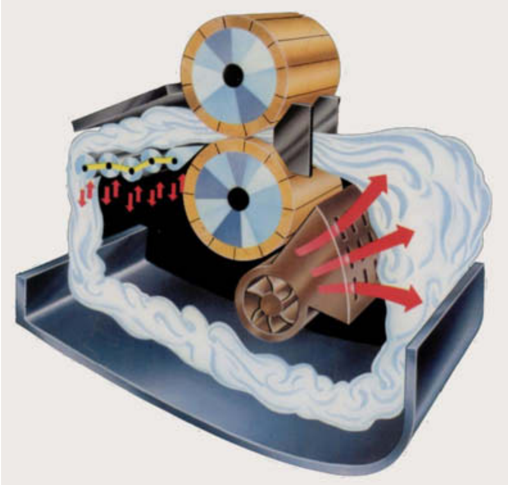

Fig. 4: Milling crease prevention by blowing the fabric hank with the objective of smoothing out creases (Turbomat).

Milling, light treatment,

I. Short → Milling (pre-milling): a) for the relaxation of wool (worsted yarn) fabrics; b) to achieve a particular fabric compacting and/or light felting of the fabric surface.

II. Addition of coloured fibre material (wool or foreign fibres) in the milling, which then stick superficially due to the felting power of the wool.

Milling lubricants → Textile lubricants.

Milling process includes the close connection of fibre material to a dense and hardwearing felt by the processing of loose fibrous materials by means of friction, shock and pressure assisted by moisture and heat. Felting is a specific property of wool, chiefly caused by its particular surface structure (→ Feltability of wool). As the flake cells overlap each other, as with roofing tiles, the friction resistance towards the fibre tip is lower than the reverse. The direction-dependent coefficient of friction (DFE) is obtained from this. The movement of a fibre swollen by moisture absorption under the effect of an external force, is steadily towards the root. In the opposite direction, the ratchet effect of the flakes hinders the migration of the fibre so that an irreversible shrinkage takes place.

Distinctions are made between the following:

1. Internal parameters of the felting:
   - flake structure,
   - hydrophobia of the cuticle,
   - longitudinal and transverse elasticity,
   - swelling,
   - fibre length,
   - fibre fineness,
   - grease content,
   - crimping,
   - yarn construction.
2. External parameters of the felting:
   - moisture content,
   - mechanics,
   - time,
   - pH,
   - temperature,
   - lubricants.

Untreated wool has a hydrophobic surface, in which the fibres tend to lie close to each other in water. This can be described as the start of the felting process. The longitudinal and transverse elastic properties of the wool fibre are causally related to the feltability. The fibres must be easily extendable and deformable since they are permanently extended during migration. While the root remains, due to the ratchet effect, the apical part (tip) must move up. This happens as a result of the fibre tangles being connected with the tip. Fineness, length, crimping and grease content have more influence on the quality of the felting than on the feltability. Fine fibres felt better with the same crimping. High felting speeds and high felting strengths are achieved at medium fibre lengths (25–50 mm). The felting power of completely de-greased fibres falls. Lubricants are used, which reduce the bending stiffness and so encourage felting. The fibre swelling indirectly influences the felting power because it has an effect on the elastic properties. The same applies to temperature. As regards the pH (Fig. 1) it is established that the felting power increases in the acid and alkaline range, while it is at its lowest at pH 5–7, i.e. in the isoelectric point range of the wool. The high densities, which are obtained in the acid medium, are no longer achieved in the alkaline one. Therefore fashionable woollen cloths are milled in an alkaline environment, while heavy technical felts are milled in the acid environment. Light furnishing felts made from nonwovens are produced using neutral milling.

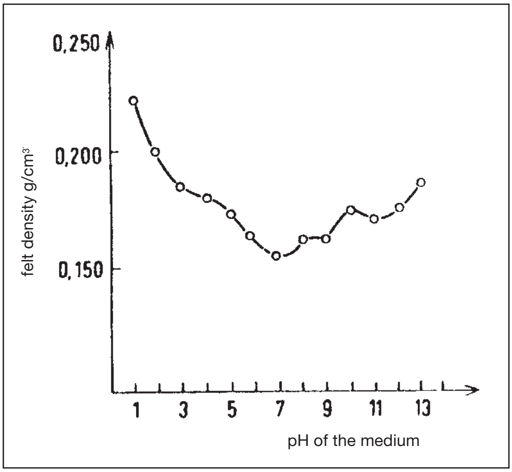

Fig. 1: Relationship of felting properties (Aachener shaking test) of loose wool to pH (according to Blankenburg).

Milling is understood to mean the processing of piece goods under extensively similar conditions such as in felting to increase the density and strength of the fabric (normally with a moisture content of 90–120% of the raw weight and at 30–35°C). The tasks of the milling process are character development of woollen items and preparation so that raw material strength is limited. Depending on the intensity of the milling process, a so-called pre-milled item is obtained, whose fabric weave can still be perfectly recognised, or a felt. In a core felt, the fabric is evenly felted in the cross-section; in a surface felt the top of the fabric only exhibits a random layer. In pre-milling the compression is achieved through relaxation and input of the piece goods in warp and weft direction. The number of warp and/or weft threads can be increased by a targeted compression to an extent, which cannot be achieved solely by fabric adjustment. Besides the compression of the fabric, a more or less strong matting is carried out by the milling. This further increases the mechanical union through the existing yarn and fabric bonds and so the fabric is made more resistant to wear.

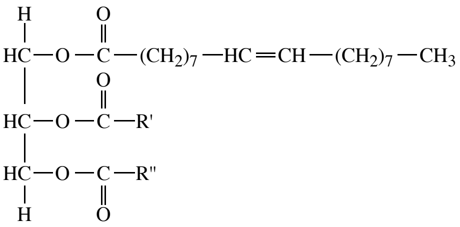
The area shrinkage, handle change (firstly soft due to relaxation, then firmer as a result of the increasing density) and air permeability, which decreases with the growing degree of felting, are standards for fabric compressing.

The milling processes are divided according to:

1. Dirt milling:
   - grease milling,
   - soap milling,
   - neutral milling,
   - acid milling,
   - special acid milling processes.
2. Milling of pre-washed fabrics:
   - soap milling,
   - neutral milling,
   - acid milling.

Natural wool chair fabric contains auxiliaries from the spinning and warp sizing in the weaving preparation, which must be removed in the washing and/or milling processes. The practical implementation of the milling process and the selection of milling method are therefore not only determined by the desired fabric result, but also by quantity and chemical structure of the spinning lubricants. Neutral oils, technical oleic acid (olein) and low-viscosity mineral oils are used as textile lubricants with and without the addition of emulsifiers.

Neutral oils, e.g. olive oils, contain a high percentage of dependent oleic acid.



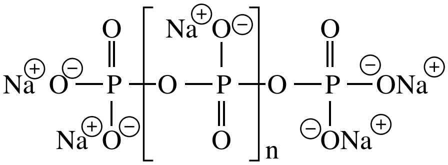
They have a good oiling property, but are not capable of saponification under normal washing conditions so they can only be removed with the aid of fat-solubilising soaps or emulsifiers. In order to facilitate their capability to be washed off , neutral oils are also available as emulsions.

- Technical oleic acid [$C_{17}H_{33}COOH$] has a satisfactory oiling property and can be saponified even in cold, alkaline liquor.
- Mineral oils [$CH_3(CH_2)_nCH_3$] can only be washed off in combination with emulsifiers. They are particularly valued as textile lubricants due to their good oiling property compared with metal and atmospheric oxygen.

Grease milling usually involves olein lubricated carded yarn fabric, whereby the spinning lubricant is saponified using sodium carbonate or ammonia. The soap formed by this is used for milling.

$$C_{17}H_{33}COOH + Na_2CO_3 \rightarrow C_{17}H_{33}COO^-Na^+ + NaHCO_3$$

Milling soap, sodium carbonate or ammonia and polyphosphates are used in soap milling. Through the formation of a lubricant layer on the fibre, the soap not only facilitates the throughput of the fabric through the milling instruments, but also reduces the fibre friction and so encourages the felting process. Alkali saponifies the olein present.



Polyphosphates are distinguished by:

- hardening and metal ion binding property,
- dispersing property,
- activation of wash-active substances,
- separate washing property,
- reduction of the turbidity point of soaps,
- emulsifying property,
- adsorption displacing activities (displacement of adsorbed soap residues on the fibre).

Chiefly mineral oiled or yarn dyed carded yarn fabrics and neutral oiled worsted yarn fabrics are treated in soap milling.

Neutral milling can be used should a non colourfast fabric be milled or only a low degree of felting is striven for. Carded yarn fabric, which contains an emulsifying spin oiling, can also be milled dirty at neutral pH. Synthetic surface-active substances are thereby used as milling agents. This, for example, includes fatty acid condensation products, fatty alcohol sulphates, alkyl naphthalene sulphonates, oil and sulphonated surfactants and/or sulphates (the long line in Fig. 2 symbolises a more or less long aliphatic hydrogen chain).

Acid milling is carried out at pH 2–4.5, adjusted by formic acid, with the addition of acid-resistant, synthetic milling agents. This milling process is chiefly used in felt manufacture (hats, technical felt), as particularly high degrees of felting can be achieved in the acid range; also in fabrics with a lack of colourfastness or with a large proportion of short fibres. Acid milling is the best method for mohair additions due to the low fibre loss.

Fig. 2: Surface-active agents for neutral milling.

Milling in is carried out in length and width one after the other by hammer milling (Fig. 3). Depending on how the piece has been laid in the tub, the impact of both hammers are either in weft or warp direction. Technical felts and felt slippers are milled in this way.

Width milling is effected by the pressure of the cylinders in cylinder milling (Fig. 4); length milling is however carried out by compressing the fabric together in the compression channel under the effect of the compression valve (Fig. 5).

Milling washing machines are fundamentally distinguished from cylinder mills only by the fact that the machine tank can be filled with liquor. The former were developed for reasons of efficiency in order to combine the processes of milling and washing in one type of

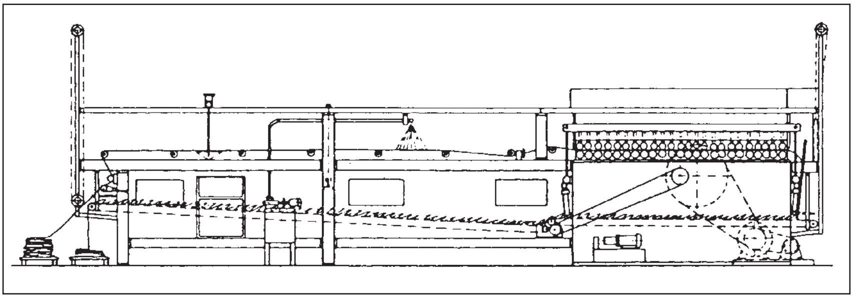

Fig. 7: Open-width milling machine.

machine, i.e. one operation. The models of different manufacturers are distinguished, amongst other things, by the cylinder coverings (plastic, wood, metal), the type of cylinder (continuous or disc cylinder) and the compression aggregates.

In order to guarantee a better hank layout for every hank revolution and to save sack sewing (sewing together of fabric selvedges into a tube), hot air at 40°C is blown by the turbomat (MAT) onto the fast running (600 m/min) hank, which is extensively unfurled by this before it again runs into the entrance. The name “Quatro Stagioni” (four seasons) expresses the widest possible application of this milling for all articles (light summer articles, heavy winter goods) (Fig. 6).

Furnishing felts made from wool fleeces are manufactured in a wide form on plate or roller mills (Fig. 7). Heavy carpet yarns can also be milled using peristalsis type movements in plastic tubes (periloc process, Fig. 8).

Additional elements in milling, such as the hank layout device from FAMIT (Fig. 9) or auxiliary elements in the compression channel (Fig. 10) support the milling process.

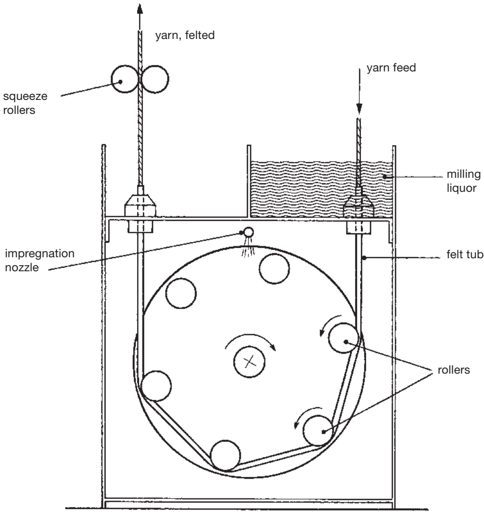

Fig. 8: Periloc process for the milling of yarn.

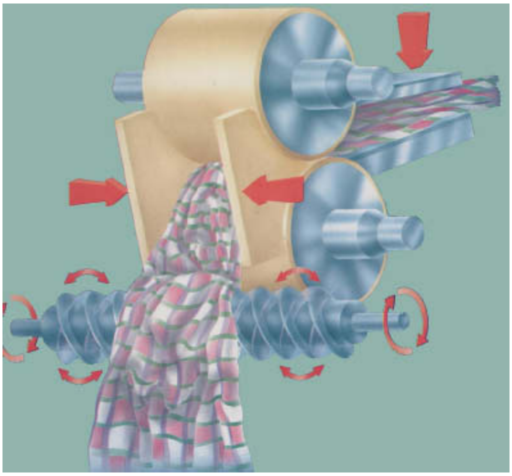

Fig. 9: FAMIT hank layout device.

Milling resist effects Milling of woollen items (woven or knitgoods) causes condensing of the textile fabric by felting. If you partially print on antifelting polymer fabric, the wool is resistant to milling at the printed places in the following milling. A fashionable surface structuring is obtained in this way. An antifelting paste is printed onto the untreated wool, as the application of oxidation processes, in particular the use of chlorine, is too problematic before printing. While it is customary to replace half of the resin proportions with a polyurethane polymer in the finishing of woven goods in order to achieve a softer handle, this is of little importance for knitgoods: the printed fabrics are then washed, which makes the handle soft again. To make the resin printable, it is prepared in the form of a print paste. The selection of the printing thickener is thereby important, as it should not interfere with the condensation of the resin and should be removed in the first washing and milling process. The market offers a broad selection of printing thickeners for the printing indus-

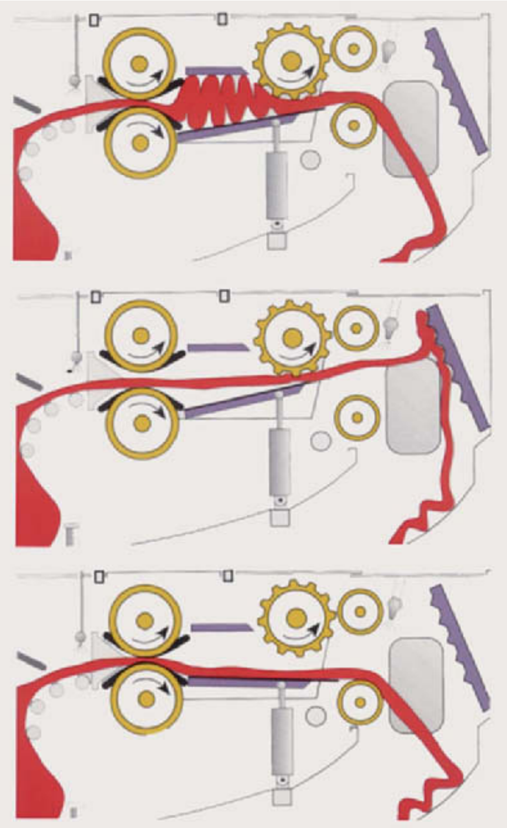

Fig. 10: CIMI auxiliary elements in the compression channel.

try, whereby "low solids/high viscosity" types with high profitability are preferred. Products on an alginate base are most suitable; others, which contain primary alcohols, may react with the resin and produce a hard handle in the fully finished part.

The preparation of the paste is carried out in steps; resolution of the thickener, addition of the diluted resin and the dissolved hydrogen carbonate shortly before printing, as the paste is only stable for approximately 12 hours after the hydrogen carbonate has been supplied.

Milling rig → Hole in milling.

Milling shrinkage,

1. Mark in a metre on grey goods in the sealing department. After milling, the difference between raw and finished length produces the felting shrinkage (in %, referring to the raw length).

2. Subtract percentage finishing loss (difference between raw and finished fabric weight) from the raw weight; divide the difference by the current finished weight per metre.

Millitron process Computer-controlled carpet spray printing, whereby dye solution is sprayed into the carpet pile from nozzles. As it is processed without screens, there is no contact with the carpet surface, therefore no deformation of the pile material and, when changing patterns, no machine stoppage. There are 100 nozzles on an area of 6.5 cm^2. The nozzles can be operated in a fixed or moving mode, continuously or intermittently. Operating speed: approx. 2–5 m/min.

Millon's reagent,

I. For the testing of protein substances (finishing analysis); reagent easily decomposable; always prepare freshly before use (consisting of 20 g of mercury and 40 g of nitric acid, heat in water bath until dissolved, leave for 24 hours, pour off precipitate; with protein, is turbid until precipitation, pink hue during heating); optimum pH range for reaction: neutral to weak acid.

II. For the testing of wool damage, i.e. degraded wool (reaction to the amino acid tyrosine). Boil sample with solution of mercury nitrate in nitric acid. This initially results in a white precipitate, which is then dyed reddish-brown (violet).

III. Testing of animal fibres (silk, animal hair fibres, casein) besides man-made fibres. It results in a red to reddish-brown hue when heated (animal fibres).

Mill scouring,

I. → Raw wool scouring (in contrast to → Backwash).

II. Washing of laundry in the → Laundry (in contrast to → Domestic washing).

Milnerised process Finishing process using application of resin finishing agents, catalysts and additives together with sizing agents and dyes on warp yarns made from polyester/cotton. Woven fabrics manufactured from this are firstly heat set and condensed at high temperatures (e.g. 185°C) and then washed. Final finishing with the same or other resin finishing agents (reduced amount of applications) concludes the finishing. Pigment colorant is used in this combination process for single-stage sizing, dyeing and after treatment. The process is for women's outerwear permanent-press items. After the weaving, it is rapidly processed on pin frames.

Mineral (Lat.: minera = ore mine), in German the term encompasses all natural constituents of the earth's crust, which are dug out. This not only includes materials of inorganic origin such as ores and the metals extracted from them, as well as rocks, salts, clay, mineral dyes, etc., but also organic decomposition products such as carbons, asphalt, mineral oils, peat, amber, etc. In languages other than German the term mineral is predominantly used for ore and rock.

Mineral acid hardness → Water hardness salts.

Mineral acids Inorganic, non-carbon containing acids such as →: Hydrochloric acid; Nitric acid; Sulphuric acid. Opposite: → Carboxylic acids.

Mineral dyes inorganic coloured pigments, known as so-called paints. Hardly used for textile dyeing and printing any more. The → Mineral khaki formed on the fibre is of some interest.

Mineral fibres (mineral and/or → Inorganic fibres),

I. From the group of natural fibres: → Asbestos fibres.

II. From the group of man-made fibres: other industrially produced fibres such as →: Glass fibres; Mineral silicate fibres (Rock wool); Slag wool; Metal fibres, etc.

Mineralization Biological degradation or biodegradation is understood to mean any transition of dissolved or solid substances by organisms into other compounds. Besides assimilation by means of photosynthesis, in which dissolved substances are absorbed in the biota, the biological degradation of organic compounds by micro-organisms such as bacteria and fungi is the most important process. Organic substrates are thereby oxidised, whereby the microorganisms use a part of the energy released for reproduction. This type of respiration is called mineralization. It consumes oxygen or, if this is not available, other oxidising agents such as nitrates, sulphates or already partially oxidised organic compounds. Simplified, these processes can be formulated as follows:

1. Aerobic respiration: Organic substances are oxidised; oxygen is reduced. Ideally the oxidation results in carbon dioxide and water:

$$<CH_2O> + O_2 \rightarrow CO_2 + H_2O$$

2. Anaerobic respiration: Organic substances are oxidised to carbon dioxide; carbon dioxide is reduced to methane (methane fermentation):

$$<CH_2O> + {}^1/_2\ CO_2 \rightarrow CO_2 + {}^1/_2\ CH_4 \text{ or}$$
$$<CH_2O> \rightarrow {}^1/_2\ CO_2 + {}^1/_2\ CH_4$$

with nitrate or sulphate:

$$2\ <CH_2O> + NO_3^- + 2\ H^+ \rightarrow 2\ CO_2 + NH_4^+ + 3\ H_2O$$

$$2\ <CH_2O> + SO_4^{2-} + 2\ H^+ \rightarrow 2\ CO_2 + H_2S + 2\ H_2O$$

These reaction sequences have been tested and are, for example, used for the biological treatment of waste water. Approx. 50% of the organic substrate is oxidised for the energy gain in aerobic respiration; the rest is converted into bacterial matter (sludge). However only approx. 10% of the substrate is converted into bacterial matter in methane fermentation (according to Kümmert and Stumm).

Mineralization of washed goods Appearance of a fault in cellulose fabrics (white washing) during washing in hard water with sodium carbonate addition, which converts sulphate hardness into calcium carbonate. The latter in particular is removed as coarse heat crystals and remains on the fabric. The sharp-edged crystals cause premature wear during use due to friction and abrasion. In the presence of soap, → Lime soap breaks down more rapidly, covers the calcium carbonate crystals and consequently reduces their cutting effect. Mineralization of washed goods is no longer a problem due to the increased use of softened water, addition of sequestering agents to the washing liquor and replacement of soap with synthetic detergents.

Mineral khaki Mineral coloured pigment. On cotton items in England, India and USA for tropical clothing, uniform materials, camouflage items, hunting shirts, tarpaulins and car covers, as extremely cheap, outstandingly light fast and good colour fast to washing (acids have a destructive effect though) as well as bacteriostatic, combined with a certain fullness and hard handle. An excellent camouflage dye for tropical uniforms and similar. Manufacture using blends of soluble chromium salts (higher quantity used results in greenish tone) and iron salts (higher quantity used results in brownish khaki). Process:

1. Impregnate on the 3 milling padder with the above blend (density 1.18).
2. Short steaming or drying (hotflue).
3. Passage through a) a bath (density 1.06) of 1 part caustic soda liquor 40°Bé and 3 parts sodium carbonate calc. (formation of chromium oxide and iron oxide on the fibre) or b) weak sodium carbonate solution and then diluted hypochlorite solution. Alternatively it is slowly heated to 80°C on the jigger using iron (II) sulphate and chromium salt; then follows rinsing, soaping, cold and hot final rinsing.

Mineral oil Usually carbon mixtures (benzine, benzene, petroleum, paraffin oil and vaseline oil), liquid, greasy or solid; insoluble in water, unsaponifiable. Application: benzine, benzene, oils: for lubricating purposes, oiling, etc.

Mineral silicate fibres Belonging to the group of mineral fibres; industrially manufactured fibres made from the melting of rocks. Only for industrial purposes.

Mineral wax → Ceresin wax.

Mineral weighting → Weighting of silk using inorganic salts (tin-phosphate-silicate weighting).

Mini-Fluid Doctor roll padder for energy-saving low wet pick-up of dyes, chemical and finishing liquors (see Fig.). Suitable for full immersion and roller application, consisting of colour box and kiss roll. Liquor quantity to the doctor roll is controlled by a magnetic beam. The liquor film is taken up by the continual material web and pressed into the fabric by the squeezing unit. A suction nozzle on the material edge accepts surplus liquor. Cleaning of the kiss roll by use of a cleaning device. Roller width 140–240 cm. Suitable for woven and knitted fabrics. Production speed up to 100 m/

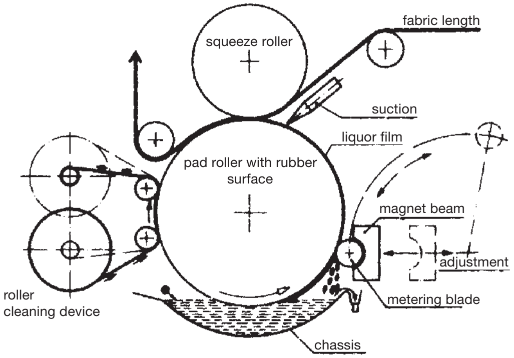

Fig.: Mini-Fluid product application by Goller.

min. Liquor application (using standard squeegee) 30–40%. – Manuf.: Goller.

Minimum film formation temperature (MFT, white point), below the typical temperature for the dispersion of a polymer, where only a white layer (white point) is formed during drying instead of a transparent/translucent, connected film. If, for example, a dispersion of white point (or MFT) is indicated at approximately 15°C, a clear, closed film is produced during drying at 16°C or above, against which a white, inhomogeneous layer is produced during drying at 15°C and below. The white point is always lower, the softer the film of a dispersion. The MFT is reduced by the addition of softeners, solvents, as well as acetic acid and similar. Field values of some important polymer dispersions are shown in the Table.

The respective particle sizes of protective colloid-containing dispersions (averagely or finely dispersed) play a role in this connection because particle sizes and their distribution decide jointly, with the emulsifier system, on the suitability of application of a dispersion (e.g. viscosity). The following processes take place in film formation during the drying of a latex application: very thin aqueous layers, so-called capillary layers, with a concave meniscus, are formed between the polymer globules (Fig. 1). The capillary forces squeeze out the water from the globular cluster and squeeze the globules even tighter together. If the polymer globules are too hard, nothing further happens. The water evaporates, but no film formation occurs. A densely packed globular cluster remains, macroscopically: a powder. If the globules are soft enough however, they are deformed under the influence of capillary forces. The contact areas become ever larger and many-faceted, geometric configurations, so-called polyhedrons, are formed from the globules, whose surfaces result from the geometric arrangement in the original globular cluster. The remaining water is thus completely displaced from the intermediate spaces and the polyhedrons themselves fuse with each other superficially. A polymer film is also produced: a matted globular cluster. A polymer globule, which consists of stretched, unsplit filamentary molecules, appears hard. If the macromolecules have lateral branches however, they

Minimum film formation temperature

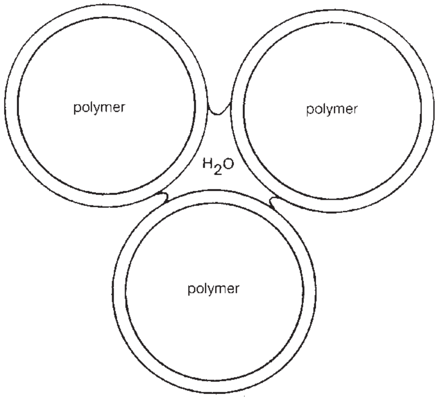

Fig. 1: Aqueous capillary layers with concave meniscus form between the polymer globules.

act as spacers. The polymer molecules can no longer lie so densely together, they remain mobile. Less energy is needed to push them apart. A latex particle, which consists of such well separated molecules, therefore normally appears soft.

Whether a polymer is in a state in which it can be described as hard or soft is also a question of the energy content. Only in the soft state are the small polymers mobile enough to felt with each other over the surface during close contact of two or several latex particles and so to weld the particles together. The temperature at which molecular mobility is only just sufficient for a film formation is the MFT. Only above the MFT does the welding of the latex particles into a relatively satisfactory polymer film take place. So much water is removed in the first stage of the drying process that a hexagonally compacted ball exists. In the second stage of the drying process, these balls should then fuse into a polymer film (Fig. 2). Three forces essentially work in this direction:

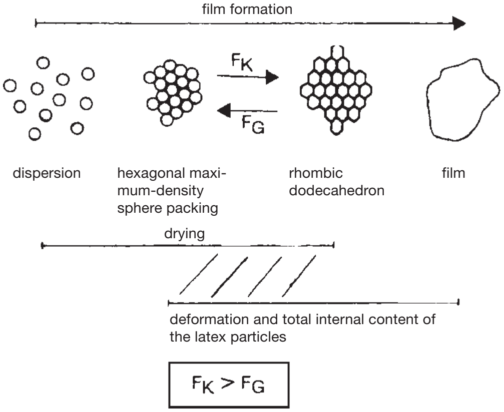

Fig. 2: Diagram showing film formation of latex particles. F_K = capillary pressure of the water; F_G = resistance of the polymer against deformation.

1. An internal pressure arises when two forces touch,

$$P_i = \frac{2\,\sigma}{r_k}$$

which tries to combine the balls into a larger ball. This internal pressure is higher the greater the surface tension σ and the smaller the ball radius r_k. The force F_i is equal to the product of pressure and area.

2. It can be seen in Fig. 1 that water capillaries with a concave meniscus are formed in the intermediate spaces of the globular cluster. The effective capillary pressure at the instant of contact of the balls is

$$P_k = \frac{2\,\sigma}{R}$$

So P_k is larger the higher the polymer/water surface tension σ is and the smaller the radius R of the capillaries. The capillary radius R can be converted into the ball radius r_k. The relation

$$R = r_k\left(\frac{2\sqrt{3}}{3} - 1\right) = 0.155\,r_k$$

for the same size balls is obtained, from which the above equation can be converted into

$$P_k = \frac{12.9 \cdot \sigma}{r_k}$$

So the capillary pressure is greater the smaller the latex particles are. If the polymer/water surface tension is approximately 35 dyne/cm (and the radius of the latex particles approx. 50 nm), the adjusted capillary pressure would be calculated at approx. 9 N/mm^2 under these conditions. In order to obtain the capillary force F_k, the capillary pressure must be multiplied by the area.

3. Intermediate molecular forces also work between the polymer particles. They may be dispersion forces, dipole forces, electrostatic forces, hydrogen bridges, etc. They all or some of them make a contribution, which supports the forces previously described. The quantitative recording of these forces is provided by the collective symbol F_{ZM}. The forces, which obstruct this process, certainly also hinder those forces, which encourage the coalescence of the latex particles. So the

polymer globules, as will any solid particle, also offer resistance to deformation. This resistance force is abbreviated to F_w. Finally the particles are given an electrostatic charge of the same denomination so that they can be generally stable as a dispersion. So Coulomb's repulsive forces

$$F_c = \frac{K \cdot e^2}{r^2}$$

counteract coalescence. These are greater the higher the particles are charged with a common denomination e and the smaller the distance apart of the centres of gravity of two particles r. So a coalescence of the particles into a polymer film only occurs, if

$$F_i + F_k + F_{ZM} > F_w + F_c$$

Only the capillary forces and deformation resistance are thought to play a leading role, so that the above unequal equation is reduced to

$$F_k > F_w$$

Accordingly, film formation is only possible if the capillary forces overcome deformation resistance. The deformation converts the hexagonally compacted ball into a complex of touching rhomboid dodecahedrons. Small particles in systems with a high surface tension are at an advantage.

Minimum ignition time → Ignition time.

Miscibility gap Components in solutions tend to be diluted at lower temperatures, while mutual solubility increases at higher temperatures, usually until complete miscibility (Fig. 1). Miscibility gaps frequently occur in compounds. These mixtures have a technical significance with regard to the equilibriums between the dissolved part and the non dissolved remainder. Restricted or varied solubility is exploited by separation via distillation.

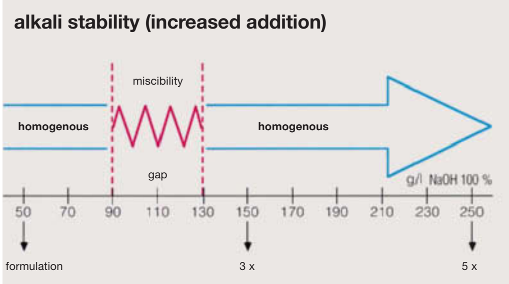

Fig. 1: Miscibility gap with increasing concentration of caustic soda.

The problem of restricted miscibility, which can assume varied forms, can be shown in the example of ternary mixtures. This is shown graphically in Figs. 2–5.

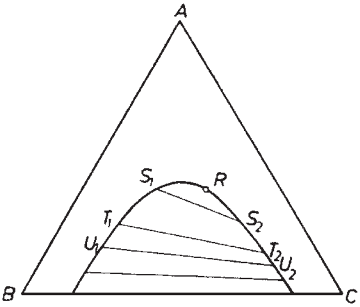

Fig. 2: Ternary mixture with a miscibility gap: the components B and C do not mix in every ratio. Phases belonging together (in equilibrium to one another) are linked by the connecting lines (tie lines) running through the miscibility gap zone.

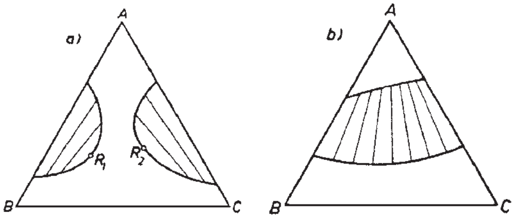

Fig. 3: Ternary mixture with two miscibility gaps: between A and B and between A and C. In a (left) the miscibility gaps are separated, in b (right) they have joined together. It is then no longer possible, starting with mixtures B + C, to achieve mixtures rich in A, or the other way round, unless (temporary) separation into two fluid phases takes place.

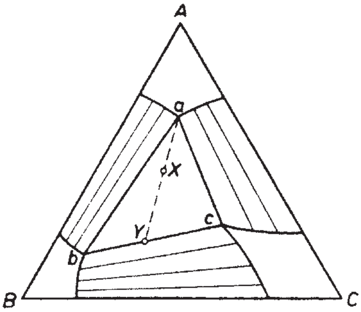

Fig. 4: Ternary mixture with three miscibility gaps: the miscibility gaps are so great that in inner zone abc, where the mixtures disintegrate into three coexistent phases according to the composition at points a, b, c. A mixture of composition X arises, which has a proportion at phase a, corresponding to line XY. The remainder, proportional by volume to Xa, disintegrates in relation to lines Yb and Yc in phases c and b.

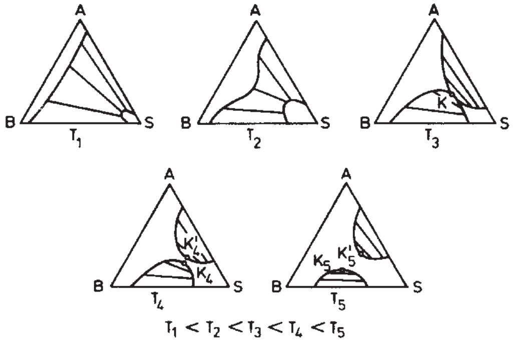

Example:	A nitrobenzene	$C_6H_5 - NO_2$
	B methanol	$CH_3 - OH$
	S isooctane	C_8H_{18}

Fig. 5: System with two miscibility gaps at high temperatures, which grow together at low temperatures.

The representation of the phase behaviour of binary systems of water and surfactants is temperature and concentration dependent in the phase diagram. The phases formed are, however, subject to changes in state.

The binary phase systems go through several phases depending on the parameters, temperature and concentration mentioned above. Besides molecular, micellar and inverse micellar solutions, single and two-phase liquid crystalline zones are also observed. A large concentration range is passed through in a comparatively short period of time, in particular in the evaporation of diluted surfactant solutions. It is possible to identify surfactant structures under polarisation microscopes and so it is possible to classify the phases.

The liquid crystalline condition is the classification for organic substances produced from solutions, which are plastic to liquid. They are found in so-called liquo crystals or in the mesomorphic state. Most surfactants form crystals with a defined quantity of water, which is divided into thermotrope and lyotrope. This intermediate condition is also described as the 4th aggregate state. The division of the liquid crystalline phase is arranged as follows: thermotropic phases are composed of anisotropic molecules and occur between the liquid and crystalline phases. They alter their structure under the influence of the temperature. Lyotropic phases have considerably more complex behaviour. Their aggregates form a dynamic system, which continually exchanges surfactant molecules with the environment. The mobility of the molecular amalgamations is temperature-dependent and results in polymorphism. Lyotropic phases show characteristic liquid crystalline behaviour in the presence of polar and continuous media.

If the molecules are mobile in two spatial directions in the liquid state and can rotate around an axis, this is described as a smectic state (Gk.: gunk, glue). If the molecules move in all three spatial axes and turn around an axis, this characterises the nematic state (Gk.: thread). Both disk and rod micelles are distinguished in the nematic phase. Besides nematic phases, cubic, in particular hexagonal and lamellar structures occur in the aqueous medium. Steric reasons are responsible for the formation of the liquid crystalline phases. The spherical micelle is the energetically most favourable form of isotropic solutions at low surfactant concentrations. These become anisotropic micelles during growth. They show inverse structures; with high surfactant concentrations. The continuous phase is no longer the solvent, but the surfactant. Cylindrical (nematic) and hexagonal phases are produced from rod micelles for surfactants with a voluminous head and a short alkyl chain. Depending on the chemical constitution (hydrophilic property of the head group and chain length) hexagonal and cylindrical phases can be produced, and disc micelles and/or lamellar phases formed. If nematic phases occur in the system, these can always be found in the concentration range below the lamellar and/or hexagonal phase. If a system forms both hexagonal and lamellar phases, the hexagonal phase is always present at low surfactant concentrations. Cubic phases may occur both before the hexagonal and between the hexagonal and the lamellar phases.

The phase behaviour of non-ionic surfactants in aqueous solution is very complex in construction. A reason for this is that miscibility gaps appear in non-ionic surfactants in aqueous solution. A dilution into two liquid phases occurs when heating such isotropic solutions at a certain temperature (dependent on the surfactant concentration). The phenomenon described characterises the dilution point or cloud point, which plays a crucial role in the washing effect. Besides the single-phase lyotropic range, several two-phase regions are present in small surfactant concentrations: a diluted liquid phase and a phase consisting of inverse micelles. An isotropic region is also present. Single-phase liquid crystal regions are present at higher surfactant concentrations. Viscous hexagonal phases are found in many systems, which are constructed from rod micelles, and the essentially light lamellar phase, which consists of a surfactant double layer (according to Schollmeyer).

Miss pinning faults (stenter miss clipping). Appearance of fault on fabrics due to occasional non-gripping of the fabric edges on the part of the clips on the stenter.

Mist → Fog.

Mixed bed exchanger → Ion exchanger.

Mixed catalysts in resin finishing So-called self-crosslinkers and reactant crosslinkers are used in the resin finishing of cellulosic textiles. The self-crosslinkers are chemically unstable and therefore their liquors can only be used over a short period of time. This problem is extensively ruled out in the use of reactant crosslinkers, as their chemical stability in the liquor is considerably greater. On the other hand however, this results in the reaction of the self-crosslinkers with the cellulose having less catalytic acceleration than that of the reactant crosslinkers. The selection of catalysts in resin finishing depends on the reactant crosslinker used. It also influences the condensation time and temperature required. Mineral acids and strong organic acids are unsuitable as catalysts, as they considerably accelerate the crosslinking reaction and simultaneously considerably damage the cellulose. Various metal salts are used as latent acid catalysts for this reason. They should only become active in condensation conditions. The activity of the metal salts depends both on the cation and the anion. In practice, various → Catalysts are used for resin finishing.

From the point of view of carrying out the crosslinking under the most mild conditions possible, in order to keep the damage to the cellulose as low as possible, catalyst systems consisting of magnesium chloride and other metal salts have gained importance in dry cross-linking. This increases the catalytic effect of magnesium chloride, as the addition of organic acids, such as oxalic acid, was tested for an increase in catalytic activity. An optimisation of the process parameters, such as temperature, condensation time and catalyst concentration, was carried out for some small crosslinkers regarding the result of resin finishing. Independent of pH the presence of phosphate ions increases the stability of crosslinking liquors due to interaction with the crosslinking molecules. The metal salts used as resin finishing catalysts have little influence on the stability of the crosslinking liquors. They almost exclusively catalyse only the actual process of resin finishing (according to Buschmann and Schollmeyer).

Mixed felt → Felt.

Mixed red Mordant dye in cellulose dyeing.

Mixed shoddy yarn Pure mixed shoddy yarn: soft, silky shining, usually mottled 2–3 fold wool yarn (→ Carded yarn). Also mixed yarns e.g. made of wool/cotton. Artificial mixed shoddy yarn: less valuable cotton weft yarn in a type of carded yarn.

Mixers and stirrers → Metering systems for dyes and chemicals.

Mixing → Metering station.

MK,

I. German abbrev. for “Metallkomplex” (metal complex).

II. → Molar concentration.

ML Process (Micro-Length-Stretching = micro lengthening), drop in tearing strength in weft direction is prevented through mechanical drawstretching.

An even drawstretching going beyond elastic elongation (Fig. 1) is carried out across the entire surface of the fabric and along the whole length of the weft yarns and individual fibres. This results in the rectification and re-orientation of the structure of the individual fibres, the fibres in the yarn and the yarns in the fabric. Application, e.g. on wet fabric. In resin finishing, usually after application of the finishing liquor for a short time before drying and condensing. A typical machine for the ML process is the Memotex system from Küsters (Fig. 2).

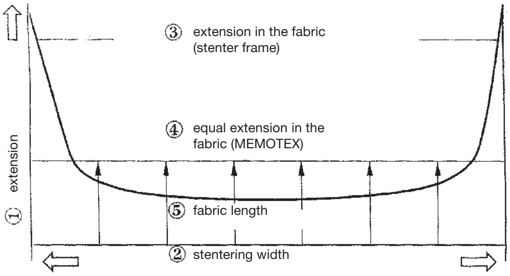

Fig. 1: Comparison of the tension in fabrics before and after ML treatment.

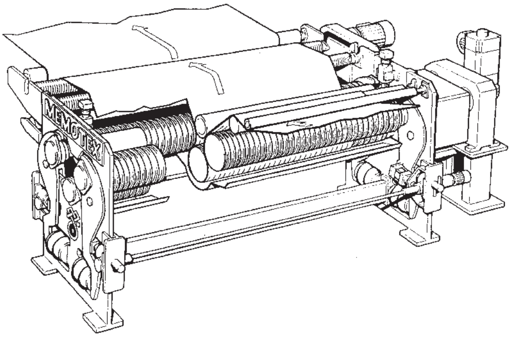

Fig. 2: Memotex plant by Küsters.

MLD Shortened form of minimum lethal dose (lethal limit), i.e. smallest known lethal basis for humans. In inhalation poisons, the criticality limit for gases, vapours and volatile suspended matter is usually given in ppm (cm^3 gas/m^3 air), for non-volatile suspended matter (dust, smoke, aerosol, etc.) in mg matter/m^3 air.

MLS → ML Process.

MM-co mercerising machine Mercerising machine operating continuously from spool to spool, especially for mercerisation, neutralisation and drying of cellulose ply-yarns (1000–2000 dtex). Useable fabric width of 480 mm, max. thread speed of 720 m/min. Chiefly consists of machine (with drive unit and spool feeding attachment in magazine design), two wet treatment chambers (yarn rollers, easily replaceable), electric hot air drier (circulating/exhaust air principle), winding head (also suitable for mock cake, with constant crossover angle) alternatively for conical or cylindrical spools (up to approx. 250 mm external diameter), electrical equipment (control equipment, thread monitoring, etc.). Central liquor treatment/distribution, extensive full automatic operation (processing sequence selection of shrinkage/stretching ratios, treatment time, etc.).

Mn Element symbol for manganese (25).

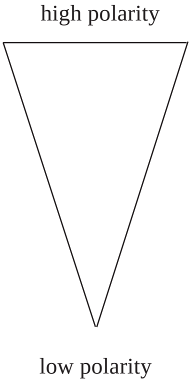
Mo,

I. → Mohair, → Textile fibre symbols, in accordance with DIN 60 001 until 1988, from 1991 → WM.

II. Element symbol for molybdenum (42).

Mobile solvents for thin layer chromatography are used as so-called → Eluents (mobile phase) for elution, whereby eluting effect of the mobile solvents increases with their increasing polarity. Selection of mobile solvents in accordance with the eluotropic series, thus for an unknown mixture, these mobile solvents are, to begin with, put in use one after the other (desired polarity can also be achieved by mixing):

bases
acids
water
methanol
ethanol
butanol
acetone
acetic ester
ether
chloroform
benzene
toluene
carbon tetrachloride
cyclohexane
benzine



Mock moiré effect → Moiring.

MOD Abbreviation for → Modacrylic fibres.

Modacrylic fibres (MA, MAC), modified polyacrylonitrile fibres made from 50–85% by weight acrylonitrile (copolymer fibres). Modified on the one hand for relaxing of the structure for improved dyeability or hydrophilic properties and on the other to also increases the flame retardant property. Other material properties are more or less affected because of this, and thus, advantages, such as reduced flammability, could also be connected with textile technology concessions.

Modal fibres (abbrev.: CMD, MD), regenerated → Cellulosic fibres with a high resistance and high wet modulus, manufactured by the addition of modifiers and by variable spinning speeds (wet elongation 15% at 2.25 cN/dtex load). This includes both → Polynosic fibres and → High wet modulus fibres. Modal fibres have a higher degree of polymerisation (DP 350–600), higher resistance, wet modulus, dimensional stability and alkaline resistance compared with normal viscose fibres. HWM fibres have lower alkaline resistance and lower brittleness compared with polynosic fibres (see Tab.).

The improved properties compared with the classic cellulose regenerated fibres are due to the clearly higher mole mass or chain length of the individual molecules and the more compact internal structure of the fibres, which come closer to the properties of cotton. A deceleration of the xanthate decomposition, caused by the addition of a modifier and the precipitation bath composition, results in an extension of the plastic state and in the possibility of a strengthened longitudinal orientation and the development of better internal structures. These developed structures play a crucial role in the finishing process. The deviating behaviour of classic regenerated and modal fibres is well known. One problem is the tendency for uneven dye uptake, which can often be recognised as colour streakiness. Local or temporary differences in the colloidal precipitation processes, delay and orientation processes, chemical decomposition of the xanthate as well as subsequent thermal effects, may constitute the cause of this.

Modal fibres, finishing In principle the same processes as for viscose and cupro fibres. Somewhat lower sensitivity to alkalis.

Models Scientific observations are often based on the idea of models or pictures, which exist in the human consciousness and help in thinking about the behaviour of nature. Model presentations of human behaviour are developed in psychology, and are used in thinking about the behaviour of a real human individual. A phys-

Tab.: Comparison of the properties of modal fibres with viscose or cotton.

icist, who deals with high energy elementary particles, develops his own model presentations for the behaviour of these particles, whereby the concept that there are elementary particles forms one of these model presentations. With the aid of models for systematic scientific testing or for better understanding of reality, it should never be forgotten that this cannot be a complete picture of reality, but the models only agree with reality in a specific area concerning a particular question. The scientific experiment is assisted by a model in order to analyse complicated connections, to organise them into smaller problem fields and to understand them with the aid of these simplified structures. So model tests do not help in recognising complex connections, but are used to test a section systematically and to find answers to questions, which are concerned with area. A good model is, therefore, useful because it is simpler than a natural example. The disadvantage that models cannot convey everything about the real system is accepted.

The classic form of an experiment is the one of designing a system in which all the factors are comparatively carefully verifiable and for which particular types of results can be looked for. The scientific method would therefore look somewhat like this:

– observation of nature.
– search for a theory (model),
– testing of the general validity of the model through experiment.

I. Colour models: The technology as “applied science” comprises the alignment of the methods and facts of science to a particular objective. As varied, for example, as is the use of the colour, so are the problems in colour definition, reproduction and perception also varied. Each colour can be declared in different colour models using different parameters. That is why there are different colour models, which can in principle be subdivided into:

1. Colorimetric models: In order to define colours in the textile industry, and also in other industrial sectors and/or to nominate for dyeing purposes; the CIE or CIELAB colour model is chiefly used (colour difference in accordance with DIN 6174).

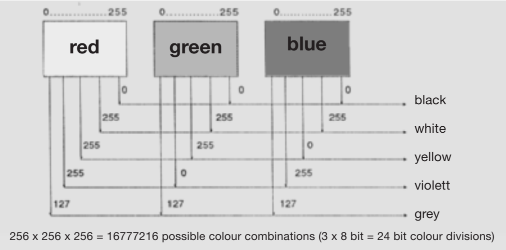

Fig. 1: Red, green and blue colour channels with 256 intensity gradations.
