2. Technical/physical colour models: They describe a colour as a mixture of three primary colours (Fig. 1). The differences between the individual models lie in the selection of the primary colours and the type of colour mixture. The RGB basic cube and YIQ model are important for colour television.

3. Perception-oriented colour models: The technical/physical colour models are orientated to the requirements of output devices and transmission technology. But they are less suited to direct colour definition by the user. Colour models were therefore developed, which work with dimensions corresponding to human perception, namely shade of colour, lightness and saturation. Two groups can be differentiated depending on the description of these three dimensions:

– numerically symbolic colour description (HLS model),
– colloquial colour description (CNS model).

A model consequently gives a simplified picture of a complete set, leaving out many parameters. A danger in such simplifications lies in the fact that one begins to think monocausally or that conclusions are drawn, which would have looked different with a view of all the variables. For this reason, however, each model

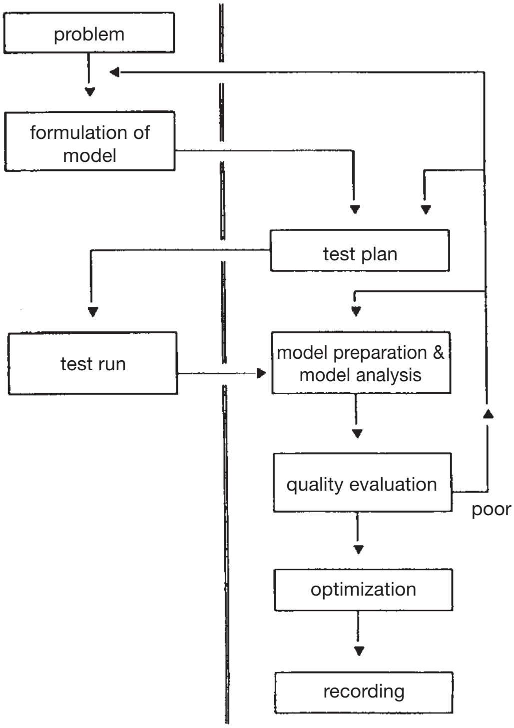

Fig. 2: Strategy diagram of a computer-controlled development process (left: data of the developer; right: the software [APO]).

presentation must be verified in the natural system, i.e. compared with measurements and experiments.

II. Process models: A process model is understood to mean a framework of technical correlations, which is more or less consistently capable of describing the behaviour of a process, e.g. a dyeing process. The mathematical description of a process is always the acknowledged aim in the natural scientific disciplines. In order to achieve this aim, a deterministically characterised solution strategy is required, which so to speak represents the tool, with which a mathematical process model is produced. Assuming that adequate practice-relevant measuring methods are available for the quantification of target demands, the question arises as to which statements are expected from the model to be constructed. Some essential ones are listed below:

- the behaviour of the target dimensions should be comprehensible in a mathematical equation in the technically relevant working area;
- the resulting model equation should reproduce the simplest possible correlation between influencing and target variables, objectively and comprehensively;
- the deviations between measured and design values must be minimal;
- the model equation should be numerically stable, which means that a slight change in the measured data does not result in a change to the model equation;
- the error existing in the measured data must be quantifiable so that a forecast for the process using a probability, adequate for the practice (e.g. 95 %) is possible.

The expectations for a general strategy can be formulated as follows (Fig. 2):

- the strategy must be independent of the technical problem to be dealt with at any one time;
- minimum expense for maximum information gain must also be guaranteed for multi-dimensional problems;
- the main variables of a process system should not only be recognisable, but also quantifiable;
- practical knowledge already available in the form of measured data should be capable of being transmitted into a new testing programme without loss of information.

The statistical planning of experiments and analysis is a solution strategy, which optimally meets all the demands previously made, but never replaces the problem engineering and the associated creativity of the developer. The more complex such process systems are, the more advantageously such methods are used, where the development of environment-oriented process conceptions are concerned. Therefore the objective demand here is in the position of having to be competitive with new process concepts within a few months with processes which have already been producing optimally for years (according to Marte).

Modified biochemical oxygen demand test (BODT, so-called closed bottle test), in which is indicated the measurability of the → Biochemical oxygen demand (BOD) utilised in the microbial oxidation of organic substances and the % measuring result of the theoretically necessary calculable oxygen demand for final oxidation, i.e. mineralisation of the test substances (% BODT). With this method, the BOD_5 value comes to hand incidentally as it were.

Modified cross-section fibres → Profiled fibres.

Modified fatty chain products E.g. → Soaps with modified fatty acid residues.

Modified fibres Viscose, high tenacity and high wet tenacity fibres with a particular structure caused by spinning in the presence of → Modifier (small additions of aliphatic amines, polyamines, quaternary ammonium compounds, polymers of ethylene and propylene oxide amongst others). These altered spinning conditions produce new valuable properties with suitable drawstretching: higher strength, higher working capacity, denser, homogeneous cross-sectional structure (all enveloping structure), lower swelling power and better wet tear strength.

Modified fibres and textiles Variously shaped group, which includes numerous industrially implemented new developments and new trends at the experimental stage. These can be differentiated between a) total or partially chemically modified fibres with lasting or almost permanently altered properties resulting in possible uses, for the latter, and b) causing various deposits and coatings.

Modified resins → Alkyd resins.

Modified starches All products for which only a gradual change of the characteristic properties is carried out for native → Starch (e.g. pregelatinised starches), and thus cleavage of the polymer chains or the reaction of functional groups should not take place to any determinable extent using chemical methods. The transition from a “modification” to starch decomposition is fluid. Decomposed starches are produced when principal valencies of native starch are split. This is carried out, for example, under the influence of oxidising agents so that the starch oxidation products are already attributed to the starch derivatives.

Modified starches, pregelatinized starches According to different processes broken down starches, which already swell more or less strongly when stirred with cold water and produce starch preparations with adhering properties. Usually short boiling is enough to obtain low-viscosity solutions for use in sizing and finishing. The ratio of modified starch : potato starch : dextrine approximately 1 : 3 : 2. The most widespread use of starch is based on its capacity for water absorption and its swellability. Air-dried starch particles rapidly swell in suspension in water, and its diameter increases by approximately 30–40% (Fig. 1).

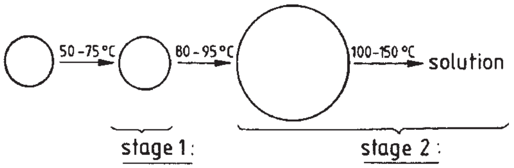

Fig. 1: Diagram showing the visible changes during swelling of the starch granule (van den Berg).
Stage 1 = from the natural granule to low swelling (reduction in refractive index); stage 2 = strong increase in swelling, poss. until solution is achieved.

During heating while carefully stirring, the shape and optical properties remain until suddenly irreversible changes set in at a specific temperature. The particles start to lose their double refraction and swell up considerably. This temperature range of approximately 10°C, in which all particles go through this process, is called the gelatinisation temperature. The swelling of the particles steadily increases with further heating, they lose their irregular morphology and look like a pair of bellows. The increase in the optical transparency, solubility and viscosity occurs simultaneously. The viscosity reaches a maximum when the entire space is filled with swollen particles. The diffusion of a part of the amylose from the particle starts in this stage. Before they burst, the particles can absorb 20–40 g of water per 1 g of starch. Above this critical point, the particles break up and the viscosity falls sharply. The second stage of gelatinisation, at which a true homogeneous solution is produced, is at more than 100°C, at approx. 120°C for potato starch and not until around 150°C for amylose-rich starch.

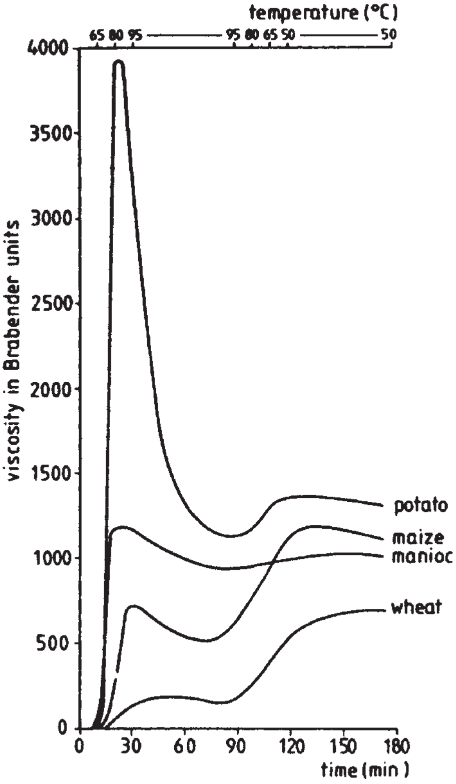

Fig. 2: Increase in viscosity of different starches during gelatinization (van den Berg).

Measurements on the Brabender viscoamylograph, which are carried out using a standardised time/temperature programme, are suitable for the characterisation of the gelatinisation process of different types of starch (Fig. 2). Potato starch shows a particularly high viscosity and swelling. This is possibly connected with its phosphate content. The association with regard to phosphate-free cereal starches would be lowered by the repulsion of the loaded groups.

The gelatinisation properties become lost by mechanical damage to the starch particles, e.g. in dry milling. Acid pretreatment results in lower swelling, presumably due to the increase in crystallinity. The transmission to gelatinisation is interpreted as a melting process. If the starch suspension is tempered, i.e. held for a longer time just below the gelatinisation temperature, the otherwise broad temperature range of the swelling (55–65°C or 62–72°C) is increased and shifted to the upper temperature limit. This observation is explained by a recrystallisation of defective crystalline. The actual melting point of the pure starch crystals in water is somewhat higher than the gelatinisation range reveals. In the first stage of gelatinisation,at 50–70°C, the starch crystallites melt and form a polymer network. At this temperature only amylose goes into solution, but a large part still remains. In the second stage, at approximately 100°C, the network is separated and a solution of amylose and amylopectin is finally obtained (according to Burchard).

Modified yarns → Textured yarns.

Modifier Modification agent, in → Modified fibres these assume important structural modifying functions as spinning auxiliaries, which result in the slowing down of the conversion on the spinning bath/thread surface and thereby encourage the formation of all cover fibres with improved dry and wet properties.

Modular construction principle Construction principle, in which systems are constructed from the smallest possible number of standardised machine elements assemblies.

Modulus (Latin: modulus = measure, scale), characteristic numerical measurement for particular property of a material (material constant), e.g. the ratio between loading/elongation as an elasticity modulus (→ Tensile elasticity).

Modulus of elasticity → Tensile elasticity.

Mogador gum → Gum arabic.

Moghan carpets → Knotted carpets from the South-East Caucasus. Moghan Steppe. Medium high wool pile with approximately 150 000 knots/m^2. Coloured design with a lot of bright yellow in the bright variation of geometric flourishes, flower and animal motifs.

Mohair (WM), one of the → Natural protein fibres, hair from the Angora goat (Turkey and South Africa). The microfibrils (keratin intermediate filaments KIF) are chiefly parallel to the fibre axis in the cortex of mammal hair. X-ray diffraction patterns were obtained from a large selection of mammal hair and all produced the A-keratin diagram. The quality of the diffraction pattern, which is obtained in the radiography of wool is not as good as that of mohair, which has an absolute helix proportion of 35%. This is one of the reasons for the fact that researchers, who deal with the molecular structure of wool and hair, readily study mohair fibres. Its wear resistance is a characteristic of mohair. That is why mohair fabric is always used when durability is the prime requirement. Mohair can be dyed easily and has a natural lustre. The surface of the fibre is covered in epidermal scales, which are much more tightly connected with the fibre stock than wool scales (→ Wool structure). There are only approximately half as many scales as on the wool fibre (see Fig.). The overlapping is slight so that the fibre has a soft handle. Light is easily reflected from the surface so that mohair has a characteristic lustre. Two typical textile properties of mohair are:

- lustre and soft handle as a result of the scale structure of the fibre surface,
- good breaking strength and wear resistance.

The scale edge height of mohair, in comparison to 1.07 µm for Australian wool, is 0.4 µm. The remarkable abrasion resistance and wear resistance of mohair items can be put down to the regular structure of the cortex. The individual cells consist of approximately 0.2 µm wide macrofibrils in the cross-section. The macrofibrils are in turn bundles of 10 nm fine microfibrils in a hexagonal pack. This structural arrangement is found in the low-sulphur keratin fibres, which supply highly informative radiographs with many radio reflexes. The microfibrils or keratin intermediate filaments (KIF) represent approximately 60–70% of the fibre mass. These KIF are mainly responsible for the stability of keratin fibres against elongation and drawstretching. The chemical sub-units of the individual KIF are 8 keratins with molecular weights of 40–70 Kilodalton. Each keratin consists of a central alphahelical rod domain of 311–314 amino acid residues. The central rod domain is flanked at both ends by regions, which vary both in their size and in their chemical character.

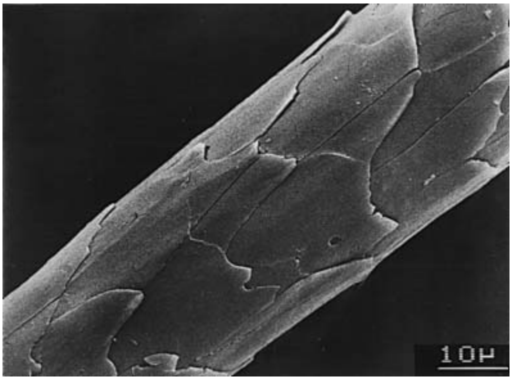

Fig.: SEM image of a mohair fibre under strong magnification.

Mohr bleach Combination bleach for cotton fabric in three stages:

1. pre-boil grey fabric in (used) peroxide bleach liquor.
2. chlorine bleach with sodium hypochlorite.
3. peroxide bleach (used liquor is used for each following batch).

Mohs' hardness scale (MH), → Hardness scale in accordance with Mohs.

Moiré effects are produced by interference from two linear systems. Moiré interferometry processes, which are used for the testing of surfaces, offer extensive detection. These processes are based on the fact that the overlay of the transmission functions of two equal, easily bent together, optical gratings produce characteristic intensity patterns in the form of light/dark stripes (see Fig.).

In screen printing, moiré effects can in particular be put down to the fact that the thread system of the mesh and the fabric to be printed knit into each other. A certain screen angle of the combining linear systems can prevent the appearance of moiré. Moiré is produced in roller printing if very fine longitudinal stripes are printed on coarser fabric qualities. In order to avoid this, the fabric is calendered before printing. In decatizing,

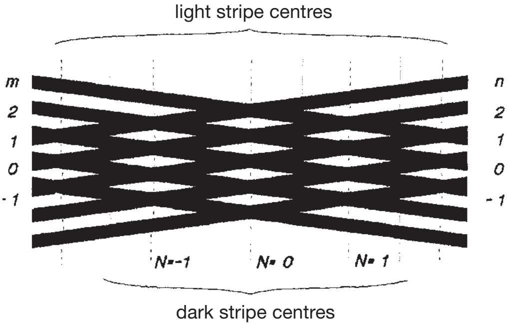

Fig.: The generation of moiré effects by inclined grid patterns.

moiré is produced in the interaction of the weft threads of wool fabrics and cotton back grey (worn out).

Moiré fabrics (from French: marmoire = marbled), most easily ribbed material (silk or viscose filament) with imprinted (lustrous) pattern effects, in plain, satin or twill weave, predominantly one colour and → Changeant. Antique moiré: with indefinite linear guidance, produced by pressing two material webs lying on top of each other. Renaissance moiré: with stronger “soaking”. Application: for garment, furnishing, upholstery fabrics and similar.

Moiring (watering), aims at production of wave-shaped → Moiré effects (so-called “soaking”), which occurs due to partial even printing of weft ribs on viscose and silk fabrics. Real moiré without repeat of figures is produced by calendering with ribbed rollers and possibly following outside passage of an irregularly perforated edge, whereby weft threads are shifted from their position and the moiré effect is increased. Work also takes place on the normal calender and/or the plate press by straining two material lengths lying on top of each other or a piece folded lengthwise. Designs running symmetrically to the centre of the material are produced in the latter case by unfolding. False moiré is produced on the embossing calender using moiré embossings. The pattern is repeated after each roller convolution. Embossing moiré (also washfast using synthetic resin application) can be produced in designs using impressive matt/lustre effects by fabric passage between steam-heated engraved steel roller (guide according to design size 1 : 2 or 1 : 3) and 2- or 3-times larger paper roller. If using ripple engraving (instead of correctly using circular or diagonal ripple) a rib fabric is processed using transverse ripple (parallel to the roller axis and thereby parallel to the ribbed fabric); a second, unwanted so-called mock moiré effect is produced as a fault within the embossed moiré. Ciré moiré: → Embossing. Besides desired production of the different moiré effects, moiré formation should still be referred to as a fault: This is produced, for example, by uneven setting of the fabric on the crabbing jack, on the dye beam, etc. generally appearing irregularly or even regularly as cloudy, more or less lustrous, pressure marks in the fabric. An unwanted moiré effect may also appear during combining or laminating if the type of weft and weft number meet unfavourably.

Moist-cure process → Wet crosslinking process.

Moist dwell process Fixation of compounds (e.g. resin finishing agents) by dwelling of the fabric in a moist state. →: Wet cross-linking process; Cross-linking.

Moisture (moisture content). Humidity, being moist, light dampness, water (vapour) content.

Moisture absorption and X-sectional swelling of fibres → Swelling.

Moisture absorption of fibres Approximated average values in % at 65% relative humidity and 20°C (→ Moisture behaviour of fibres and yarns).

alginate	20.5

W = water retention capacity as a %.

that in a growing proportion of man-made fibres the capacity to transport moisture also increases. This can essentially be put down to the fact that the capillaries existing in the yarn are not closed by swellable fibres. The moisture waste transport can be eased by construction; if, e.g., locally effective suction properties are required (such as in dusters), this can be adjusted by using cellulosic man-made fibres or cotton. The moisture waste transport is not, however, as frequently assumed, dependent on the higher moisture absorption in natural and cellulosic man-made fibres, but on the construction of suitable pores in the yarn or textile fabric.

The moisture waste transport mechanism is regarded as a function (individual and interaction) of chemical, physical and textile-mechanical factors. Moisture transmission and fibre swelling can have a contra-rotating effect in strongly swelling fibres (e.g. in regenerated cellulose): a strongly swollen fibre will delay the capillary moisture waste transport (= decelerated transport from the moist to the dry phase). In less swelling fibres, however, (e.g. man-made fibres) the actual moisture waste transport can be put down to the wicking along the smooth fibre surface area.

Moisture content control in drying occurs in accordance with the measured values determined in → Moisture content measurement; either alleviated by optical indicating devices, which report the crossing of the moisture vapour tolerance, by hand (speed and/or temperature regulation), semi-automatically (transfer or pushbutton operation of a servomotor in operating range) or fully automatically (change in speed via contact-released, gradual impulses). In control systems, the simplest impulsing is carried out via synchronous motor or via relay. Its constants and the respective operating conditions reveal whether manual control or a fully automatic system is more advantageous for a drier. The medium throughput time = medium fabric run speed is decisively divided by fabric length found in the drying zone. The inertia of all the control processes caused by the throughput time should thereby always be considered.

Moisture content in solvent vapour space is the relative humidity in the vapour space in closed systems above a solvent liquor, depending on the type of dry cleaning process according to experience in equilibrium with the humidity of the fabric and the solvent, so that one can practically directly infer the humidity in the vapour space from the fabric humidity (→ Moisture content measurement).

Moisture content measurement A distinction must be made between the determination of the moisture content of air and the substrate humidity.

I. The measurement of the humidity is carried out by means of →: Hygrometer and/or Psychrometer (thermohydrograph). The measurement of the relative humidity of air carried along in dried textile fabric and/or an air flow sucked through by the fabric can either be carried out mechanically by means of a micro-hygrometer or indirectly electrically, e.g. by means of resistance measurement of a cellophane strip.

II. The determination of the moisture content of textiles is carried out:

– Directly by drying out and according to differential weight determination (→ Conditioning).
– Directly by infra-red absorptive water determination with the aid of a special hygrometer.
– Indirectly by electrical measuring methods.

The indirect method has the greatest significance for production. Different variants are distinguished according to the following measuring principle:

a) Measurement of the electrostatic charge, whereby one makes use of the fact that when drying mobile material lengths (chains, fabrics, etc.) a static charge occurs dependent on the respective moisture content of the textile, which is lower in damp fabric and higher in dry fabric.
b) Measurement of the electrical conductivity (resistance measuring principle). Small changes in the textile moisture content hereby correspond in accordance with the order of magnitude of changes in the electrical resistance.
c) Capacitive measurement of the dielectric properties of the textile material (dielectric constant and/or dielectric losses), which also alter with the water content because the capacity of the continuous condenser field also increases with the textile moisture content, whereby dielectric losses are naturally also increased.
d) Microwave moisture measurement for water quantities between approx. 20 g and more than 30 g of water (of approx. 20–300% relative humidity for moderately heavy fabrics). Principle: coupled electromagnetic microwaves produced in a general reflex klystron (approximately 3 cm in size) are directed towards the damp fabric. The water present there absorbs a part of the waves. The re-

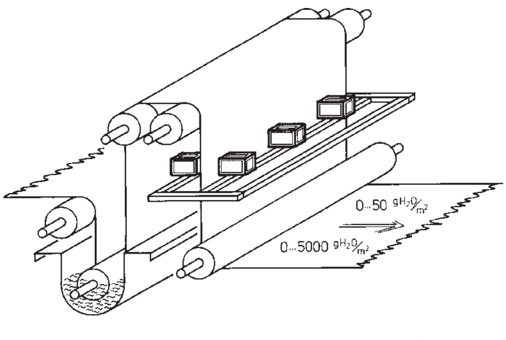

Fig.: Moisture content measurement on a running fabric by means of microwave absorption (Pleva).

mainder is reflected and absorbed in a receiving hollow conductor. The absorbed energy is a measure of the humidity (see Fig.).

Moisture content measurements have great importance in guaranteeing an optimum cleaning effect in dry cleaning, which (apart from dry-cleaning detergent) requires a variably optimum water content in the solvent depending on the type of fabric. The hair and special membrane hygrometer or electric conductivity measuring instruments are chiefly used for this, either to measure the liquor or the air in the vapour space above the solvent. The devices assume from experience that an equilibrium is formed between the water content of the fabric, that of the liquor as well as that of the vapour space above the solvent, during the cleaning. The balance between water content of the fabric and water content of the liquor is carried out relatively rapidly. Correspondingly lacking water can consequently also be rapidly replenished using a suitable device. Certainly the equilibrium between liquor and vapour space is adjusted somewhat more slowly so that work takes place with a certain delay. With small lithium chloride measuring plates, which are distinguished by quick reading, 10–15 s are required with sufficient ventilation in order to get close to the upper range value at 90%.

Moisture content measuring of circulating air in driers Control of the exhaust air damper position via measurement of the moisture content of the circulating air in the drying machine, comparison of the actual value with the given desired value in the microprocessor and instruction on the servo component (see Fig.). (→ Exhaust air moisture measuring systems).

Moisture content of air → Air humidity.

Moisture content of textiles is dependent on fibre hygroscopicity (→ Moisture absorption of fibres) and → Air humidity. The hygroscopicity varies according to fibre origin, can increase up to 40% in animal fibres and up to 32% moisture content in cellulosic fibres, without being noticeable by touch, and is normally approx. 4% (polyamide) to 0% (polyethylene) in synthetic fibres. Moist air thereby encourages a weight increase and dry air a weight decrease (air conditioning system). The determination of the actual moisture content (conditioning), i.e. referring to air dry “as-delivered” weight of the material, is therefore important in order to establish the actual dry weight at any one time and to guarantee the normal standard weight using agreed → Moisture regain. On the other hand, the moisture content determines the drying speed and is in a direct correlation with swelling processes, dye affinity, cleaning ability and the like.

Moisture regain (moisture percentage figure, regain), customary moisture percentage, as regain to the dry weight determined by → Conditioning in order to correspond approximately to the normal moisture content of the fibres at 65% relative humidity, which is, however, only partially accurate. The following regains in % are customary, for example:

18.25	wool combed top, worsted yarn
17.00	wool carded yarn
15.50	worsted yarn with 25% wool
14.00	reclaimed wool
13.75	jute

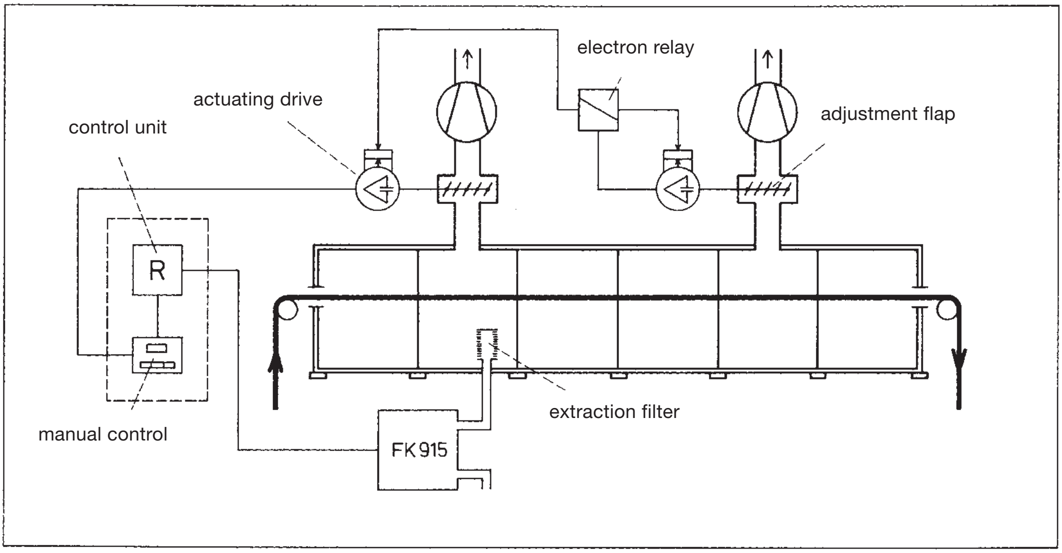

Fig.: Measurement and control of moisture content in circulating air (Pleva).

1.50	polyester staple fibre; polyethylene; elastane

Moisture-Register Device for electronic moisture content measurement.

Moisture transmission in bed textiles The view exists that man-made fibres with their low moisture absorption would be inferior to hygroscopic natural fibres and viscose regarding moisture transmission. This view is disputed by physical measurements. The moisture transmission via fibre material (depositing of the absorbed moisture) can practically be ignored on the basis of diffusion constants; however the water vapour diffusion is roughly 250 times faster through air than through a fibre material. The layer thickness and consequently the air volume are determining factors. Another moisture transmission is carried out via the fibre surface area. Electrical wicking measurements have shown that man-made fibres can transmit the moisture via the fibre surface due to their particular surface. This helps to achieve a true moisture concentration gradient from the bed core outwards to the ambient air containing less moisture.

Nonwovens weighing 200 and 600 g/m^2 with polyester proportions of 100, 50 and 0% (polyester/hygroscopic fibres) were tested regarding their water permeability. The thickness of the nonwovens (approx. 20 and 40 mm) is expressed; but the different moisture absorption of different types of fibre cannot be determined. The moisture transmission is dependent on particular physical factors and less on the moisture absorption of a fibre. Dry heat and dry skin are crucial for the "cosiness" of a sleeping person, i.e. a thermoregulation demanded by the sleeper without switching on the organism (indifference range for cosiness in the bed). This contemplation of the sensation of cosiness is valid in the heat generation for a normal person (no special meals or excessive taking of alcohol) and a draught-free dormitory of approx. 15°C.

Moisture transmission mechanisms of tent fabrics Without considering the area of application, it is the aim of many textiles to facilitate a moisture transmission through a solid substrate, which separates 2 climatic zones from each other (Fig. 1). The humidity of an interior (climatic zone 1) should diffuse outwards (climatic zone 2) and a moisture build-up should thereby be prevented and/or reduced by condensation. Water vapour permeability, water vapour absorption and water vapour depositing mechanisms should be considered for this. These mechanisms are controlled by different factors, which have a different effect. The following are decisive factors:

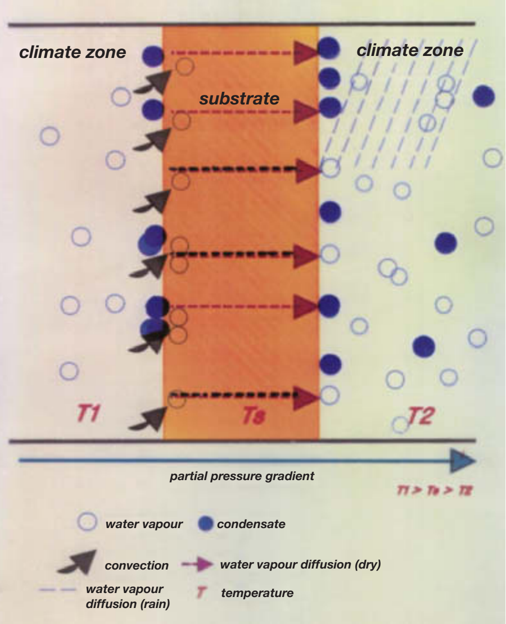

Fig. 1: Water vapour diffusion and condensation on a solid substrate.

- design of the transmission medium,
- temperature ratios,
- humidity ratios.

Each material has a characteristic water vapour transfer resistance (R_{et}), which is determined by thickness, type of polymer and structure. The higher R_{et} the lower the water vapour permeability in general applies. But the R_{et} is not solely responsible; the swelling behaviour of the textile material is also a crucial factor, as swelling closes the textile pores and the water vapour transmission is thereby reduced. Hydrophobic man-made fibres have proved to be advantageous, as they hardly have a swelling capacity. A textile simultaneously assumes a buffer effect in order to reduce condensate formation. In the buffer effect, a distinction should be made between liquid water and water vapour. Both properties can be described using constants. Water vapour transmission is only guaranteed via a sufficient vapour pressure gradient between both climatic zones. This vapour pressure gradient results from the relative humidity and temperature of the ambient air, which are at work in climatic zone 2, and the evaporation, sweat evaporation, water vapour convection, water vapour condensation, water vapour diffusion and core temperature, which predominate in climatic zone 1. The temperature difference is the driving force of water vapour transmission and determines the limit of the area of application depending on the external air humidity.

In a tropical climate, for example, "breathable" materials lose their advantages, as the temperature and humidity ratios of both climatic zones are reversed. Their use in extreme negative degrees is likewise dubious. Tests using tents at –17°C external temperature have shown that the early saturated external air and the large temperature difference encourage the condensation of the water vapour. Interior humidity arising excessively, e.g. due to heavy perspiration, cannot escape quickly enough so that a moisture build-up can hardly be avoided. Ice layers formed can additionally aggravate water vapour transmission. At the same humidity saturation in the climatic zones, the vapour pressure is adjusted corresponding to the temperature and can facilitate transmission at moderate temperatures. A temperature difference of approx. 15°C should be guaranteed for the moisture diffusion. Condensate is formed in just such a system, as the moist, warm air is abruptly cooled down on the colder substrate surface. However not only is the temperature gradient, but also R_{et}, responsible for the condensate formation. A loss of comfort cannot be absolutely determined at the start of the condensate formation. The condensate formation strongly increases only at a temperature difference of approx. 10°C. The substrate temperature is increased and the vapour pressure gradient falls due to the heat released in the condensation, but this shift does not have a significant effect on the cooling capacity of most materials. Fine condensate films can however increase the R_{et} as water vapour barriers. Only isolated materials improve their water vapour permeability with mounting condensation or wetting. Water films on the outside also represent an additional resistance. The surface character has an effect on water vapour permeability via the water repellency effect here. Different materials accordingly show different properties under water repellency. Some products, which show a good water vapour permeability in the dry state, still only show reduced results in rain. The water vapour permeability falls by 30–70% depending on the material, although the effectively driving force increases, if cooled by rain from outside. This phenomenon is different however in the various "breathable" materials. Distinctions are made in principle between two fundamental concepts, which can produce moisture transmission through solid substrate:

1. Controlled use of porosity (Fig. 2).
2. Permeability through functional polymer systems with defined molecular structures in compact systems.

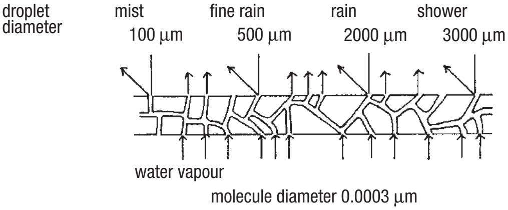

Fig. 2: Moisture transport through a porous system relative to molecule diameter.

The combination of water impermeability and water vapour permeability of porous systems is based on the possibility of using pore structures, whose open pores are larger than water vapour molecules, but smaller than drops of water. The following work according to this system

– microfibre fabric,
– laminates with microporous membranes,
– microporous coatings.

The capillary suction effect and the micropores allow adsorption and diffusion of the water vapour. The water vapour permeability of microporous systems is determined by the pore structure and is relatively independent of the layer thickness. The various porous systems are considerably differentiated in their pore structure, i.e. cell wall thickness, pore distribution, pore size and pore number. So, for example, thicker films usually have a heterogeneous pore structure with thin cell walls, while thinner films are constructed from smaller cells with a homogeneous structure. Fine pores with thin cell walls have a positive effect on water vapour permeability. In microporous systems the danger exists that water is pressed through the channels at high pressure. Rain can penetrate the outer fabric pores especially through friction points, thereby block them and cause a condensation of the incident vapour. The surface of microporous systems is sensitive to soiling, amongst other things residues, e.g. of washing agents, which cause a blockage of the pores and thereby restrict the diffusion. Residues remaining on the surface after salt water evaporation likewise make the water vapour permeability drop considerably.

Moisture vapour transmission →: Moisture behaviour of fibres and yarns; Diffusion mechanisms in dyeing; Migration.

Molality (kilogram molality, weight molality), → Mole/kg of solution (not per 1 solution as in → Molarity).

Molar % Molar percent = 100 x → Mole fraction.

Molar concentration (MK, molar solution), contains 1 → Mole (or one mole multiple or one mole fraction) of a substance dissolved in 1 l water. An example for sodium chloride (NaCl) is illustrated in the Table.

substance	atomic weight	mol	MK	semimolar 0.5 molar or m/2
Na	23.00	58.46 g	58.46 g/l	58.46 : 2
Cl	35.46			29.23 g/l

Tab.: Molar concentration of sodium chloride.

Molarity (litre molarity, volume molarity) →: Mole/l solution; Molar concentration.

Molar percent → Mole fraction.

Molar solution → Molar concentration.

Molar weight → Molecular weight.

Molded garments Textiles, which are brought out of the tubular form into the physically suitable form using mechanical/thermal deformation, e.g. for ladies' wear.

Mole (mol), → Molecular weight in grams. 1 mole of any material you like nonetheless contains individual molecules.

Molecular alignment of water repellent finishes It is typical in water-repellent finishings of textile fabrics that the hydrophilic residues of the finishing products (paraffin distillates, silicones, fluorocarbon polymers, etc.) are taken up by the surface of the fabric or knitgoods. The hydrophobic residues of the substances are then aligned so that they point towards the air (see Fig.).

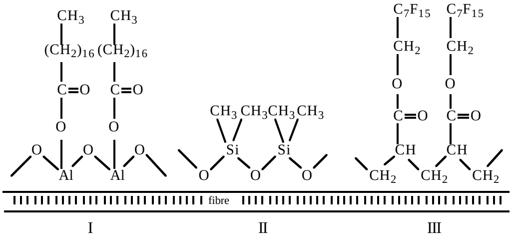

Fig.: Alignment of various water-repellent agents on the fibre surface.
I = aluminium salt/paraffin emulsion; II = dimethyl polysiloxane; III = fluorocarbon polymerisate.

Molecular dispersivity → Dispersivity.

Molecular engineering Production of → Fibre engineering using modified technical generation and chemical structure.

Molecular formula → Formula, chemical.

Molecular Modelling Became possible due to the development of theoretical chemistry, computer technology as well as screens capable of graphics. Complex calculations enable the spatial expansion of molecules, their surface area or their molecular volume, their electronic properties, such as chemical reactivity, distribution of atomic forces, electrostatic potentials, water-repelling properties amongst others or molecular dynamics to be determined. The chemical formulae are firstly depicted on the screen. The structures calculated by the computer are then shown three-dimensionally on the graphic terminal. These molecular images can be enlarged, reduced, shifted and rotated in all directions (Fig. 1). The most likely molecular geometries can be studied by minimising the molecular energies.

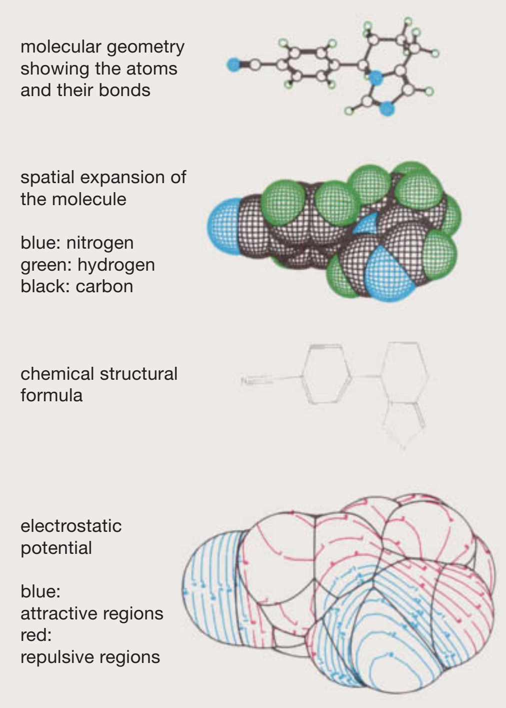

Fig. 1: Different methods of representing a molecule with the aid of "Molecular Modelling" (molecule CGS 16949A = active substance against tumours) (by Ciba-Geigy).

Molecular Modelling is therefore in simple terms a modern molecular modular construction, with which it is possible to reproduce realistic molecules. The use of such a program is not only limited to the mere view of one fact; with its aid you can additionally calculate the optimum geometry, binding intervals and binding angle in a molecule as well as electrostatic and Van der Waals forces. Information about how a molecule actually exists is obtained from this. The possibility of indicating or predicting particular properties of a molecule also exists. Such calculations are not only limited to individual molecules. Complete molecular bonds and their connections with each other can also be shown on the

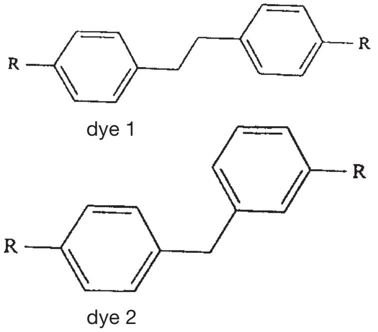

Fig. 2: Comparison of two dye molecules.

screen. An example from dye research should clarify this: Two dyes (Fig. 2), which only differ in their structure by one methyl group, behave completely differently in dyeing. While dye 1 uptakes well on cellulose, dye 2 almost completely remains in the liquor and hardly shows interaction with the substrate, although the residues R are the same in both cases. With the aid of molecular modelling it is clear that dye 1 is completely planar and can therefore enter optimum interaction with the planar cellulose, while dye 2 is angled and cannot therefore stick on the cellulose.

So the molecular dimensions of dyes can be deter-

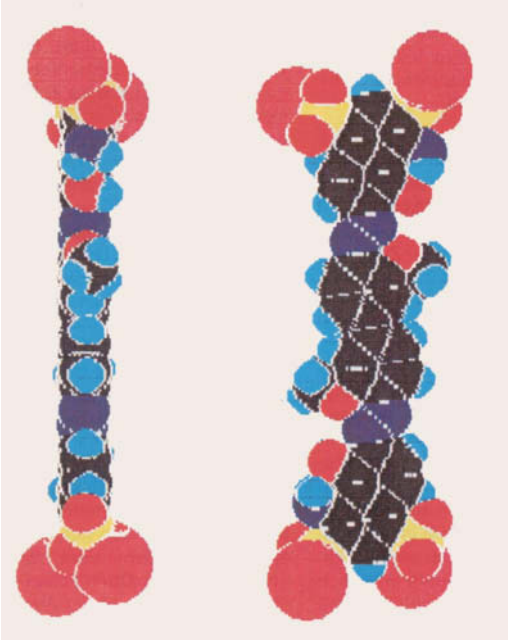

Fig. 3: Molecule conformation of C.I. Direct Blue 1. Red = oxygen; black = carbon; yellow = sulphur; violet = sodium; dark blue = nitrogen; blue = hydrogen (by Flath).

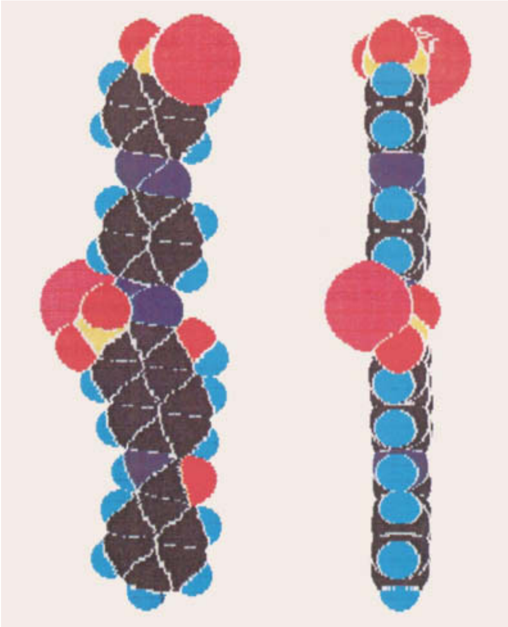

Fig. 4: Molecule conformation of C.I. Direct Red 81 (by Flath).

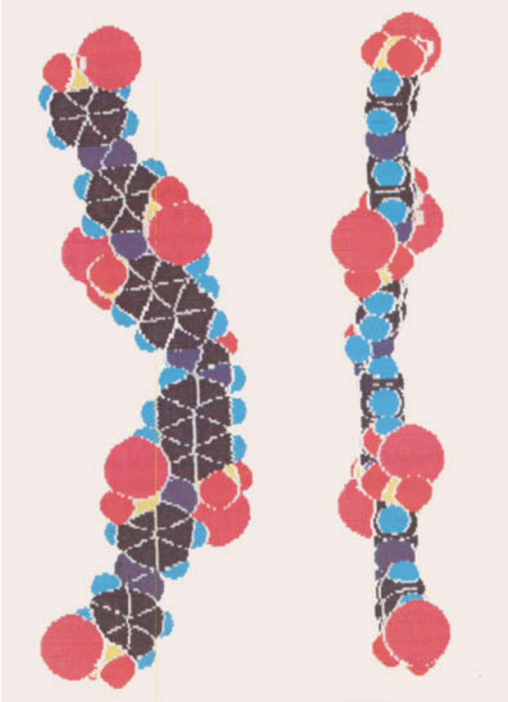

Fig. 5: Molecule conformation of C.I. Direct Red 80 (by Flath).

mined using computer simulation. The molecular conformation, which corresponds to an energy minimum (Figs. 3–5), is iteratively determined. The area of the dye molecules is calculated from the molecular dimensions. The proof that direct dye molecules exist as planar molecules, which was determined as the most favourable conformation energetically, could, for example, be produced by such calculations. They can be taken up in parallel by the cellulose chains and are then linked with secondary valency.

The planarity in the molecule C.I. Direct Red 81 (Fig. 4) is ideally shaped, for example. There are deviations from the ideal state in the larger molecules. While the phenyl and naphthalene rings are completely even, a bend in the molecule is caused by the azo group each time, as these groups only permit an arrangement bent at the side. The sulphonic group is a sterically demanding group, which always stands out from the molecule. This protrudes from the side elevations of the molecules (according to Cohen, Dörr and Flath).

Molecular weight (molar weight, mol. wt, MW), sum of the individual → Atomic weights of a → Molecule. Example: 1 molecule of water (H_2O) = 2 x 1 (atomic weight of the hydrogen) + 16 (atomic weight of the oxygen) = molecular weight of 18. In practice: 2 g of hydrogen + 16 g of oxygen = 18 g of water, or water consists of 11.1% hydrogen + 88.9% oxygen.

Molecular weight distribution of polymers Only molecular weight average values can be indicated for most man-made polymers due to their molecular irregularity (poly-dispersivity). The most important averages are:

$$\bar{M}_n = \frac{\Sigma\, n_i M_i}{\Sigma\, n_i} \qquad \text{(number average)}$$

$$\bar{M}_w = \frac{\Sigma\, m_i M_i}{\Sigma\, m_i} = \frac{\Sigma\, n_i M_i^2}{\Sigma\, n_i M_i} \qquad \text{(weight average)}$$

n_i = number of macromolecules with the molecular weight M_i,
m_i = mass of macromolecules with the molecular weight M_i.

Molecular weight average values say nothing about the distribution of individual molecular weights in the sample. The ratio of $\bar{M}_w$ and $\bar{M}_n$, which is described by

$$\frac{\bar{M}_w}{\bar{M}_n} = \quad \text{Q as a polymolecularity index or}$$

$$\frac{\bar{M}_w}{\bar{M}_n} - 1 = \quad \text{U as irregularity}$$

in contrast supplies a dimension for the width of the molecular weight distribution.

The polymolecularity index (or the irregularity) of macromolecular compounds depends on the mechanism of their synthesis and fluctuates to a great extent. For molecularly regular substances

$$\bar{M}_w = \bar{M}_n \text{ and with that Q = 1 and U = 0 resp.}$$

Q (and/or U) say nothing about the specific form of the molecular weight distribution though. To determine it, the polymer should be taken apart into fractions as molecularly uniform as possible, whose molecular weight averages are then determined. The following can be related to the fractionation:

- gel permeation chromatography,
- ultracentrifugation,
- extraction fractionation,
- precipitate fractionation.

Molecule (Lat.: molecula = small mass), smallest viable unit of a chemical substance, which consists of two or several → Atoms of the same or different type, e.g. hydrogen gas H_2, oxygen O_2, ozone O_3, water H_2O (made from 2 atoms of hydrogen and 1 atom of oxygen), sulphur dioxide SO_2 (made from 1 atom of sulphur and 2 atoms of oxygen), etc. → Macromolecules.

Mole fraction → Mol number of the component of a mixture and/or solution divided by the total mol number. The sum of the mole fractions is always equal to 1. If however you make them equal to 100, one talks of molar percentages.

Moleskin a weft atlas fabric made from cotton material; sometimes strengthened with an additional under-weft. The left side has a napped and/or emerized surface in the nature of a suede fabric.

Molisch's test For the testing of carbohydrates and/or their derivatives (e.g. methylcelluloses, cellulose glycolates, etc.). Two drops of a 10% solution of α naphthol in chloroform are added to the solution to be tested and carefully lowered using concentrated sulphuric acid; a reddish violet ring is produced on the interface of both liquids. This reaction also takes place in the presence of proteins. Distinction: leave solution with reddish violet ring for 10 mins, then shake it. Deep blue dyeing of the whole solution = carbohydrates and/or their derivatives. Faint purplish brown dyeing = protein.

Molleton Long-haired, soft wool material (lightly milled) with slightly visible weave under the hair surface; also in cotton, then thicker (e.g. →: Beaver cloth; Kalmuck). The cotton molleton materials in practice represent a heavier type of beaver; they are also occasionally described as heavy flannel. They are also found in plain fabric and twill; raw dyed, bleached white and piece-dyed, more rarely designed yarn dyed. Heavier qualities are produced using backing weft. Molleton materials are always raised on both sides.

Used as lighter duvets, padding materials, children's drawsheets, principally dyed as window display materials and for carnival costumes; in addition as decatizing fabrics for wool fabric kier decatizing.

Mollier diagram Gives information about steam conditions by means of isobars and isotherms. Describes the correlation between heat content (i) and entropy (s) of the → Steam.

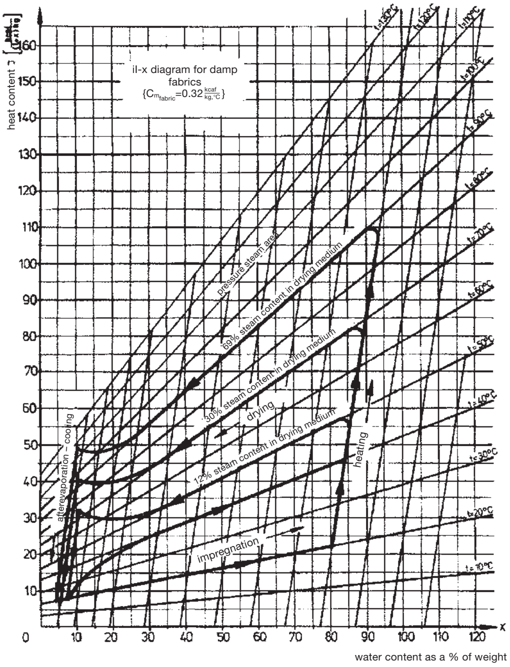

Fig. 1: Impregnation, heating and drying in i-x diagram for damp fabric lengths.

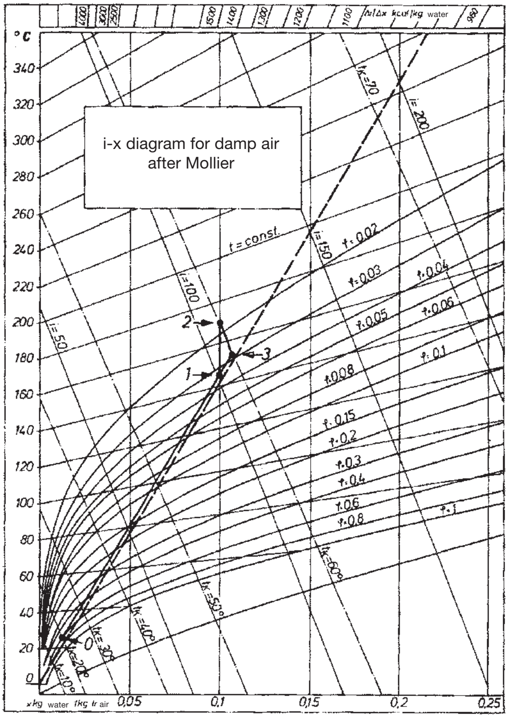

Fig. 2: Mollier i-x diagram for damp air.

With the aid of the Mollier diagram (Fig. 1) it can be shown how the heat content increases during impregnation with increasing water content in the system; heating-up when drying further increases the heat content of the system until this again decreases along the isotherms of the wet bulb temperature with decreasing water content when drying.

The heat content of the dry air (point 2, Fig. 2) is that which is blown from the nozzles of a stenter onto the fabric; this is connected to point 3 by a line of constant heat content (i = const.). The temperature of e.g. 170°C in point 2 can be directly measured easily: point 1 is exactly below point 2 on a line x = const. and in addition on the connecting line of point 0 and point 3. It describes the state of the air before admission into the heater in the drier and is produced by mixing the air streaming out of the fabric guide with fresh air from outside. If a parallel is drawn via the zero point of the diagram to the connecting line 0 → 3, this indicates the theoretical heat consumption on the edge scale when drying. The specific drying capacity increases and is reduced approximately proportionally to the difference between air temperature and wet bulb temperature in point 3.

Mol number Weight of a chemical, divided by its → Molecular weight.

Molten beads Drop-shaped end of thermoplastic fibres as a result of local heat effect, e.g. in burning tests, through singeing, ironing too hot or due to sparks flying. Compared with non-singed fibres, molten beads behave differently in dyeing and appear darker with the same dye content. Regarding this, particularly delicate polyamide and polyester fabrics are therefore singed after dyeing, frequently in fact not until after intermediate shearing.

Molten-metal dyeing machines First generation of continuous dyeing machines for piece goods, in which the heated metal was used as a divider and fixing section.

Molten metal dyeing process → Standfast molten metal dyeing process.

Molten Metal Process → Standfast molten metal dyeing process.

Molten metal, temperature effect on fibres Fibres are without exception not so strongly affected in molten metal as in water vapour treatment, as a result of a lack of water.

Mol. wt. → Molecular weight.

Molybdenum Mo, atomic weight 96, silvery white metal, melting point 1900°C. Forms numerous compounds less important for textile finishing. However particularly increases the acid resistance in steel alloys (molybdenum, chromium molybdenum, chromium nickel molybdenum, chromium nickel molybdenum copper steel, etc.; → Stainless steel).

Momme Japanese silk weight = 3.675 g. Momme number: weight of original Japanese silk for 1 yard length.

Monforizing Continuous mechanical shrinkproof finish on the monforizing system, consisting of padder as a damping system, nozzle dryer as a pre-drying system, palmer with overfeed device and felt calender for final drying. – Manuf.: Monforts.

Monfor-Matic Computer-controlled guidance system for heat treatment machines (e.g. stenters, hotflue, etc.) with processing sequence of measured values on screen in vertical arrangement (linearly indicating diode instrument); for central analysis and display stages of treatment sections. Mode of operation contactfree, maintenance-free. – Manuf.: Monforts.

Mono- (Gk.: mónos = alone), prefix with the meaning one, individual, single.

Monoacidic Designation for bases with an effective hydroxyl group, which can be ionised and replaced by acid residues, e.g. caustic soda liquor NaOH with hydrochloric acid produces sodium chloride NaCl.

Monobasic Acids with an effective acid hydrogen atom, which can be ionised and replaced by metal, e.g. hydrochloric acid HCl → NaCl Sodium chloride; Nitric acid HNO_3 → $NaNO_3$ Sodium nitrate.

Monocarbamates → Dimethyl-(mono-)carbamate.

Monochromatic Monochrome, light from a sole wavelength. Monochromatic microscope lens systems are only altered for a single light wavelength (usually 275 nm) and are particularly suitable for microphotography in short-wave UV light.

Monochromatic measuring arrangement → Polychromatic and monochromatic measuring arrangement.

Monochromatism → Colour blindness.

Monoethanolamine bisulphite (MEAS). Organic reducing agents for the permanent wool setting of surfaces and creases.

Monofilament Single-nozzled → Filament, i.e. single-nozzled capillary filament; single-threaded; individual thread. Artificial horsehair, bristles, tapes. Opposite →: Multifilament; Oligofilament.

Monofilament gauze Produced from monofilament polyamide or polyester fibres and usually calendered in accordance with particular processes. Monofilament gauzes have the advantage that they can be processed with less dye application. Thereby less “smearing” and sharper contours can be achieved. Advantages compared with multifilament fabrics:

- higher tear strength,
- greater abrasion resistance,
- greater open area,
- higher knit number possible,
- and lower squeegee printing pressure required.

Monofilament yarn In accordance with DIN 60 001 → Filament yarn made from only one filament. Monofilament yarns are spun by means of extruders, pressed through spinning heads and immediately drawstretched (Fig. 1). After the relaxation, the yarns are wound on a reel. Distinctions are made between homogeneous and heterogeneous monofilament yarns (bicomponent yarns, Fig. 2).

Monomer (Gk.: one-piece, one-part), basic chemical module (individual molecule) of the → Macromolecules. Opposite of → Polymer. Monomer units of polymers are e.g. glucose (cellulose), ethene (polyethylene) and caprolactam (polyamide).

Monomolecular layer consists of only one molecular layer. Under certain concentration conditions as

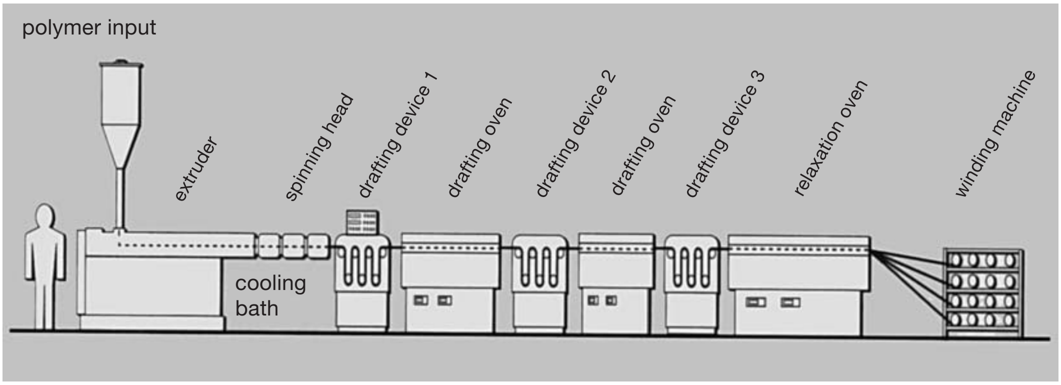

Fig. 1: Plant for the production of monofilament yarns of polyester or polyamide (by Reutter).

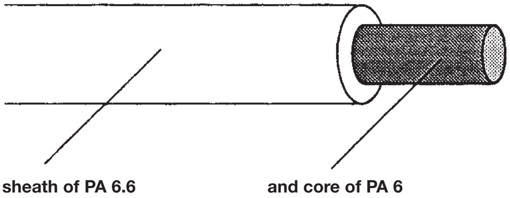

Fig. 2: Bicomponent monofilament yarn (by Reutter).

an adsorption layer is, for example, restricted to the "thickness" of a tenside molecule. In addition plays a large role in corrosion and in dyeing.

Monophosphates Salts of tribasic monophosphoric acid (orthophosphoric acid) H_3PO_4. The following, for example, are distinguished according to the number of H atoms replaced with monovalent metal.

1. Monosodium monophosphate (primary orthophosphate): NaH_2PO_4.
2. Disodium monophosphate (secondary orthophosphate): Na_2HPO_4.
3. Trisodium monophosphate (tertiary orthophosphate): Na_3PO_4.

Monsanto crease photographs → Photographic standards for fabric creasing.

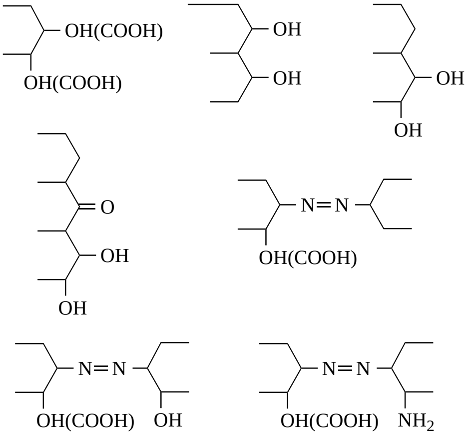
Mops (type of steaming table for napped fabrics). Designation for the steam table used particularly in the finishing of brushed fabrics, which is built on in many cases.

Moquette,

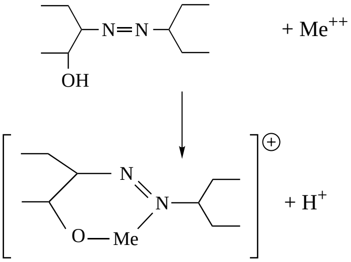
I. Colourfully patterned → Plush, manufactured using several pile warps or by printing (print moquette), then with smudged pattern contours; for upholstery covers, divan covers and similar.

II. Single-coloured, densely woven velour wire carpets. Designation also for carpets with corresponding appearance manufactured in a different way, e.g. flocked carpets.

Mordant-attracting groups in the dye molecule Molecular particles of dyes, which can have some influence on secondary valency bonds due to a particular configuration with metal ions so that insoluble colour lakes are produced. Chiefly "neighbouring" hydroxyl groups (–OH) and carboxyl groups (–COOH), which, for example, always appear in a neighbouring position in azo dyes in the –N = N group as the following overall view of the most important configurations shows schematically.



The metal mounting via e.g. chroming or aftercoppering takes place in accordance with the principle of salt formation in phenols, whereby a metal equivalent (Me) takes the place of hydrogen in the OH group each time, which is however connected to an inner complex salt here under formation of new ring systems with the dye. Simplified schematically this looks as follows in azo dyes:



Mordant dyes → Mordant-attracting groups in the dye molecule.

Mordanting Predominantly pretreatment, in some cases also aftertreatment, using mordanting agents (easily hydrolyzable acid or basic salts) in order to make fibres either susceptible to certain dyes or to fix such dyes more fastly (→ Colour lakes). Application for mordant dyes.

Mordants as resist agents in the dyebath → Retarding agent for fibres.

Mordants for animal fibres E.g. fur, pelts, goat hair such as mohair, hare hair and/or felting wool. Are used to increase the swelling capacity and alleviate milling in order to encourage the formation of felt.

Mordants for mordant dyes Fatty mordants and → Metal mordants for mordant and chrome dyes.

Morin Chief component of → Fustic; Flavone derivative. Crystal needles, colourless, shiny, difficult to dissolve (1 : 4000 in cold water), easier in hot water, alkalis, alcohol and acetic acid. Is used in alcoholic solution (1 knife point of morin + 50 ml of ethanol) as a specific aluminium test (still in dilution 1 : 10 000 000) = green fluorescence.

Morpholine (tetrahydro-1.4-oxazine), colourless liquid; density 0.998. Boiling point 128.9°C. Soluble in water and alcohol. Properties: solvent (for resins, waxes, shellac, many dyes, etc.), emulsifier, anti-corrosion agent, vulcanisation accelerator; intermediate product for fluorescent brightening agents, tensides, corrosion inhibitors, dyes and/or special reagent for zinc, copper, various man-made fibres (→ Morpholine Test).

Morpholine Test For the rapid identification of certain man-made fibres. The following characteristics result when immersing in morpholine (morpholine): polyvinylidene chloride fibres: slightly darker, after a few minutes morpholine becomes opaque and dyed almost black. Polyvinyl chloride fibres, post-chlorinated: dissolve clearly reddish brown. Polyvinyl chloride fibres, not post-chlorinated and vinyl chloride vinyl acetate copolymer fibres: no effect.

Morphology (Gk.: morphe = form/shape; logos = science), science of structure, shape formation and surface structure, e.g. of textile fibres. The morphology of a fibre loading is of particular importance to the finisher, i.e. for example the order structure and the clearance volume.

Fig.: Morphology of a fibre arrangement using the example of a rope.

The entropy of the fibre arrangement as well as the fibre distribution in the cross-section are substantial for the character and structure of a yarn. The yarn shape and the changes in this influence the physical properties and the technological characteristics of a textile. Besides such yarn structure parameters, the yarn diameter is an important parameter, which gives information about the proportion of air in the thread and/or about the packing density of the fibres in the thread in conjunction with the yarn count. Yarn finishing and completion processes often cause the fibres to compact as well as give an improved parallel layer of the fibres in the yarn as a result of post-drawstretching.

Mosaic printing → Roller printing.

Moss crêpe (mimosa), small patterned garment crêpe with mossy character made from viscose delustred in spinning.

Mote knife → Doctor blade.

Motes Appearance of fault in cotton in the form of fibre knots felted into each other as growth motes (skin residues, unripe and dead cotton, moisture effects, etc.) or processing motes (torn and spun together, chiefly ripe fibres, which are produced in the ginning and on the carding machine). This also includes the so-called small husk motes with fragments of outer husk and with them frequently complete bundles of → Cotton fibre tufts.

Mothproofing Mothproof finishing, is directed towards the garment, fur moth (and/or their larvae), the anthremus, attagenus beetle, etc., which live as → Textile parasites on keratin-containing substances (wool amongst other protein fibres, fur, duvet feathers, etc.). Countermeasures are (→ Insect repellent finishes):

I. Cold storage rooms: temperatures between 0–6°C do not cause any killing off, only a kind of “hibernation”.

II. Respiratory poisons: work very vigorously, e.g. ethylene oxide, hydrocyanic acid, carbon disulphide and similar. Less harmful odour poisons (camphor, naphthalene, and paradichlorobenzene) only work in a higher concentration, repel the larvae, but do not kill them off.

III. Contact poisons: neurotoxins, which enter through orifices of the body, paralysing and later have a deadly effect. Application in the organic solvent by spraying.

IV. Oral poisons: colourless compounds, which originate from a) aqueous, neutral or acid solution similar to dye, either combined in the dyeing and/or afterwards or in conjunction with wet aftercleaning; b) from organic solvents in the style of an impregnation.

Mothproofing agents should also protect against carpet beetles amongst other harmful insects. Insecticides are more or less poisonous. This applies in particular to the dieldrin banned in many countries. There is an intensive search for new, non-poisonous products. The synthetic pyrethroids also seem to be problematic. They are fish poisons as well, but can at least be removed from waste water. Pyrethroids have a satisfactory protective effect against moths, but only in high concentrations against carpet beetles.

Approx. 30 species of moth larvae and approx. 15 species of beetle larvae are counted as keratin-digesting insects. To combat these insects, contact poisons and products, which work on the digestive tract, are distinguished. The latter should be favoured because contact poisons can also be poisonous to other living things. The effect of the digestive enzymes of moths and beetles on a feed protection finishing of wool only shows to advantage in the consumption of the treated wool by the animal. A finishing is ineffective, if the bond between wool and product is not digestible. Digestion of the delicate group of the finishing by the insects however results in the release of the poisonous insecticide in the digestive tract of the insects. A mechanism of the digestion disrupting products should not only protect wool textiles against moths, but also against being eaten by carpet and fur beetles. A mothproofing agent is not necessarily also effective against the latter. The use of insecticides is prohibited due to their toxicity. So products based on DDT (dichlorodiphenyltrichloromethane), pentachlorophenol or dieldrin are ruled out.

Mothproofing fastness is chiefly based on biological tests with larvae from selected wool parasites. An extensively precise and clear definition of as many test details as possible (test animals, age, size, number, test climate, etc.) is desired. It should be shown whether a mothproof finishing has the effect of preventing feeding and if necessary also of killing off against the most important wool parasites and whether the protective agent is applied in sufficient quantity. In other cases, statements as to what extent the protective treatment shows particular fastnesses (e.g. wash, dry cleaning, ironing, water, light, perspiration fastness, etc.) are desired, or is not volatile, i.e. produces sufficient durability in normal storage.

Motif print Self-coloured or two-colour, if necessary, also multicoloured print of individual figures, emblems or strokes with the aid of printing screens of different sizes, usually in accordance with the pigment printing process. Predominantly made from tricot on semi-finished or finished products.

Motion study → Method study in accordance with → MTM system by means of → TMU units.

Motive power engineering The stepless adjustment of a motive power (rotational speed and torque) on the finishing machine can be carried out using several alternative motive power techniques:

- mechanical (adjustable gears),
- electrical (motor speed variation).

Distinctions are made in the following → Gear drives:

- gear drives with friction wheels,
- gear drives with V-belts (Fig. 1),
- ball-socket adjustable gears (up to 3 kW),
- contact gears (up to 150 kW).

Two kinds of current determine the types of electric drive with speed adjustment:

- d.c. shunt-wound motor with thyristor feed,
- three-phase induction motor with static frequency converter.

The output of the engine is achieved by resetting a reduction ratio in the coupled variant (Fig. 2).

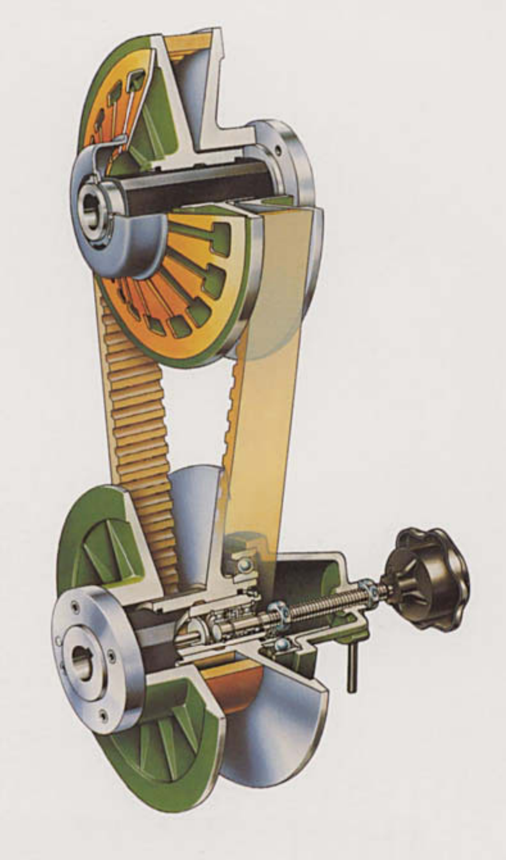


Fig. 1: V-belt adjusting mechanism (Lenze).

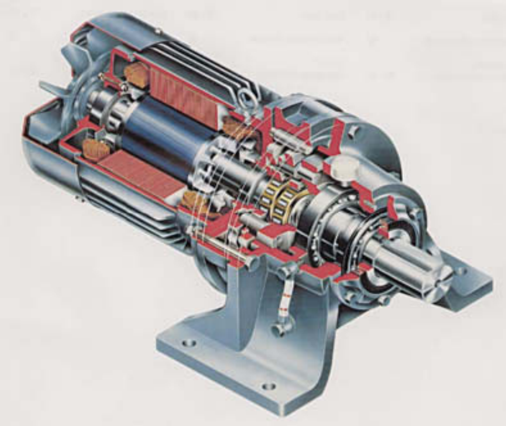

Fig. 2: Electric motor and transmission coupling (cyclic transmission) with transmission ratios of 6 : 1 to 119 : 1 in a single stage.

Mottled Mixed (bright/dark), speckled, checked. → Colour blend.

Moulding Seamless shaping of textiles made from thermoplastic man-made fibres.

Moulds (hyphomycetes) belong to the lowest group of plants. Hyphomycetes (eumycetes), those subordinated sprouting fungi and/or → Yeasts (saccharomycetes) and furthermore aquatic fungi (phycomycetes) are of particular interest to textiles. The fungus substance, in contrast to bacteria, consists of a connecting braiding (mycelium) of usually widely ramified fungal filaments (hyphae). Almost all moulds form → Spores, either in the hyphae inner (sporangia), on particular fruit bearers (conidia) or by hyphae decay (oidia). These fruit forms are already visible when enlarged by a magnifying glass and give affected textiles the most characteristic dyeing of mildew stains (→ Microbial damage to textiles). Moulds can

- live on textile finishings, i.e. a) destroy sizes and finishes (mucoraceae, individual fungi imperfecti) and b) additionally also destroy textiles through excretions (Aspergillaceae, penicillia, fungi imperfecti, etc.).
- attack textiles a) through excretion of cellulose splitting enzymes (→: Cellulase; Cellobiase); b) after caustic soda pretreatment of textiles; c) through pH pretreatment of textiles; d) through acid ↔ alkaline pH shift, in which possibilities of development arise for further types of fungi and bacteria.

Mountain flax → Asbestos fibres.

Mousseline → Muslin.

MP, abbrev. for → Melting point (floating point).

MPI (Multi Product Injection), liquid injection device for the programmed dye and chemical addition for dyeing and finishing processes (see Fig.). Funnel-shaped containers with measuring scale, rinsing ring and programmable quantity control, dosage pump with overload protection. Equipment made from rustproof stainless steel. Types for 100, 250, 500 l. Can be connected via threaded coupling to any dyeing machine. – Manuf.: Thies.

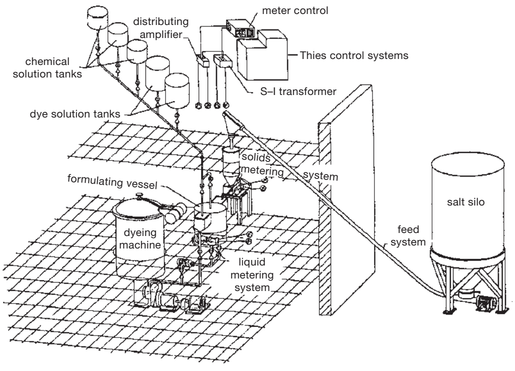

Fig.: Dyeing plant with stationary MPI installation (Thies).

MR Process (Menschner, Rotta), for wool fabric fixation. An enhancement in the quality of wool fabrics is possible in the MR process through the combination of physical treatment and chemical finishing. The MR stabiliser/MR finish finishing system is offered by the chemical factory Theodor Rotta under the name Rotta-Fix MR and Rotta-Finish MR. The use of these products facilitates the creation of the quality of wool items. The textile material obtains a shiny fabric surface. The handle is spring elastic. The process is adjusted into the normal finishing sequences. The fabric ready for fin-

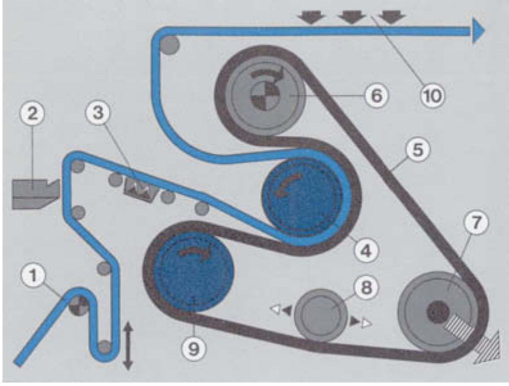

Fig. 1: Cloth passage diagram for the MR process in conjunction with the Contipress pressing and fixing machine (Menschner).
1 = pretreated cloth length; 2 = rotary dampening (WEKO); 3 = steaming table; 4 = heated effect roller; 5 = pressure belt; 6 = drive roller; 7 = tension roller; 8 = pressure belt control roller; 9 = heater roller for pressure belt; 10 = cooling zone.

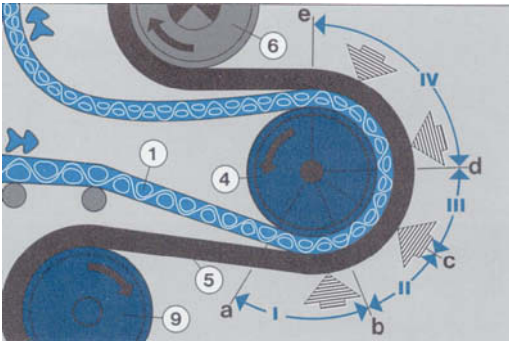

Fig. 2: Dimensional change during MR Process. Temperature differences in the cloth: I = pressing and heating phase; II = wet steam zone; III = saturated steam zone; IV = steam vapour zone (superheated zone).

ishing is padded with reducing agents and then dried. After shearing, it is sprayed with water by means of a special spraying device from WEKO (Fig. 1), and treated on the pressing and fixation machine Contipress (Menschner) using pressure and temperature (Fig. 2). In connection the fabric obtains a finish decatizing. The humidification of the fabric is necessary for the activation of the MR stabilisers. It is carried out directly before the Contipress with the aid of rotor moistening. The amount of humidity can be adjusted in a reproducible way. The application is carried out contactless and evenly. The rotor moistening takes place directly before the Contipress so that the moistened fabric side can enter into the core area of the Contipress in the shortest way.

Ms → Mulberry silk, → Textile fibre symbols, in accordance with DIN 60 001 until 1988, from 1991 → SE.

MSI Magyar Szabványügyi Intézet, Hungarian Standards Institute; → Technical and professional organizations.

MS Process (Micro-Stretching) → ML Process.

MST Labels for contaminant-tested textiles by the “Verein für verbraucher- und umweltfreundliche Textilien”. → Ecolabels.

MSZH Hungarian Standards Association; → Technical and professional oganizations.

MTF → Metal fibres, → Textile fibre symbols, according to DIN 60001 T4/08.91.

MTM (Am.: Methods-Time-Measurement), system of predetermined times in the → Method study in accordance with processes analytical to movement. Is assisted by the → TMU units (Time Measurement Units = 0.036 s). Organisation: German MTM Association, Hamburg.

Mucilages Plant products supplying mucilage, especially from → Algae, lichens and mosses, which in particular include →: Agar agar, Hai-Tao, Iceland moss or even carob extract and carragheen. Used for finishing purposes.

Mucoraceae (Lat.: mucor = mildew), genus of sizing and finishing destroying → Moulds.

Muff Loose → Tubeless cross-wound yarn package without batch centres for textured yarns. Can be dyed both in accordance with the packing system and in accordance with the creel system in the circulation machine. Short muff: height approx. 15 cm, 650–800 g; long muff: height approx. 25 cm, 1440–1700 g.

Muffle-Furnace Test Method for testing the burning properties of textiles, in which spontaneous combustion is determined in a hot furnace.

Muga silk → Wild silks from the muga or Moongaspinner (India). Quite similar to tussah silk, very tough. Colour depending on food greyish white, yellow and reddish.

Mukeka Mutono Special Special creasing and tying technique.

Mulberry cottonized bast fibre (cottonized mulberry bast fibres), cottonized fibre bast made from the bark of the mulberry bush (tree). White, silky sheeny, soft fibre of cotton-like staple length. Manufactured in Italy.

Mulberry silk (pure silk, natural silk). That → Silk, which is spun by the caterpillars of the silkworm (bombycidae, genus of scaled fliers, order of lepidoptera), also mulberry silkworms, in the form of threads, which form a cocoon. The mulberry silkworm runs through four stages during its development (Fig. 1): egg, larva (caterpillar), pupa, butterfly. After mating, the female lays 300–500 eggs, from which in the spring approx. 3 mm long and 0.45 mg heavy, black haired caterpillars hatch after a few months of hibernating. These so-called little darkies feed almost continuously. They live exclusively on the fresh leaves of the mulberry tree (monis alba). In the following 4–6 weeks, the caterpillar multiplies its net weight several times by absorbing food. Within 5 life stages, it firstly sheds its skin four times and develops into an 8–9 cm long and 4 g heavy caterpillar. Matured the caterpillar covers itself with a cocoon by spinning, which should protect the defenceless, immovable pupa against enemies and atmospheric influences. The caterpillar hereby excretes a sticky secretion solidifying in the air through two apertures located on the lower lip. It continually swings to and fro by its head and lays the thread in even, figure of 8 movements around itself. Within 3 days, the silk caterpillar fixes double threads hanging together in an average of 2000 m into a tight cocoon. After 3 days of rest in the finished cocoon the caterpillar sheds its skin for

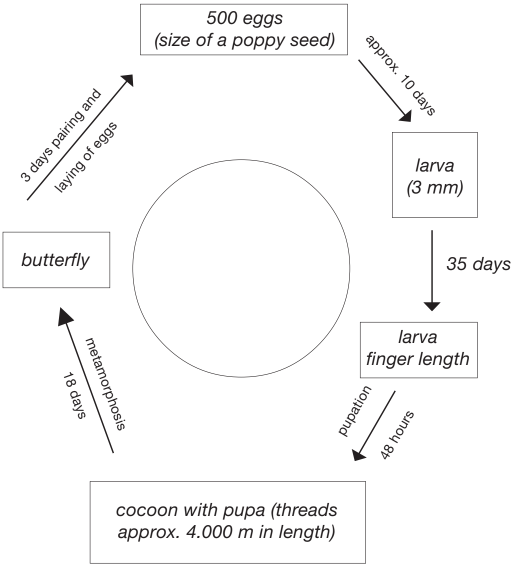

Fig. 1: The life cycle of Bombyx mori.

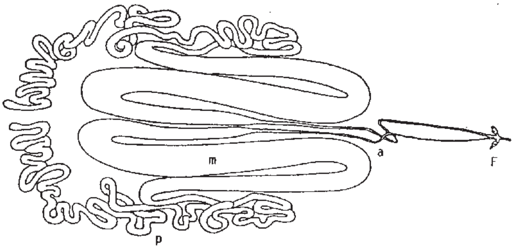

Fig. 2: Silk glands of the Bombyx mori larva.
F = Filippis gland; a = outer gland zone; m = middle gland zone; p = inner gland zone.

the last time. It thereby changes into the pupa, which already has the first signs of wings, legs and antennae of the later butterfly. After a further 2–3 weeks, the butterfly slips out of the cocoon, which was previously softened by the secretion of a proteolytic liquid and made accessible at one place.

The mulberry silkworm moth is an inconspicuous night butterfly. The animals are greyish white, ungainly with short wings; they can neither feed nor fly properly. Its lifespan is not more than 2–4 days and exclusively serves reproduction. The male dies immediately after mating. The female lays the eggs 10 hours after mating within 2 days and dies as well. The metamorphosis of the silkworm moth is concluded with the laying of the eggs.

The silk caterpillar has a pair of silk glands (Figs. 2 and 3), which are tubular shaped and consist of 2100 cells for the biosynthesis of fibroin and sericin. A back, middle and a front section are distinguished in each gland. The fibroin molecules are biosynthesised in the back section and sezerniert in the lumen. The silk fibroin exists there as 30% aqueous solution (liquid silk). This is transferred into the middle section and stays there until the moment of spinning (reservoir). Three kinds of sericin are biosynthesised and sezerniert in the middle section in order to wrap up the fibroin. The water gradually migrates into the sericin layer from the fibroin solution; the fibroin thereby becomes thicker and forms liquid crystals. Both flows from both glands meet near the spinning gland. That is why a raw silk thread consists of two fibroin threads. When the “thread” issues from the spinning gland it is stretched, whereby the chains are oriented in parallel so that the hydrogen bridges can then “click shut”. The hydrated hydrogen molecules are thus displaced and the resulting product is insoluble in water.

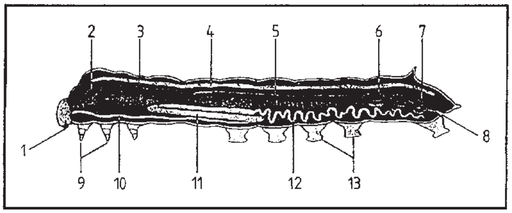

Fig. 3: Internal structure of the silk larva.
1 = mouth with spinning tubercle; 2 = pharynx; 3 = front intestine; 4 = heart; 5 = stomach; 6 = large intestine; 7 = rectum; 8 = anus; 9 = breat limbs; 10 = spin gland secretin segments; 11 = gland reservoir; 12 = gland ducts in pairs; 13 = prolegs.

The spinning speed is 1 cm/s over 2–3 days. The transformation of liquid silk into silk fibres is carried out using mechanical forces. Of the approx. 1000–3000 m long threads of the cocoon, only one part is regularly wound and unbonded; so it is only possible to unwind one part. The winding occurs in a way that, after killing the caterpillars using heat, the cocoons are soaked in hot water and lightly brushed. The origins of the threads thereby remain hanging on the bristles; the thread origins exposed by this are bundled and afterwards led to the reeling. The grège silk is obtained from reeling and twisting. As the fibre material of the sticky layers of the cocoon cannot be unwound, the sticking substances should only be removed in order to be able to obtain the silk described as floret or schappe.

Mule yarn Single, more or less (loose) twisted cotton weft yarn for soft materials, as a filling weft and similar.

Mull Soft, smooth, very light, thinly set (cotton, viscose or silk) fabric, similar to → Muslin (but denser and stiffer); also finer qualities than → Organdy, bleached, printed - brocaded - embroidered. Application: for blouse materials. Mull is also used for dressing material and nappies as a highly porous, plain woven cotton fabric (e.g. with 28 threads/cm^2). The thread density is from time to time so low that the total of warp and weft threads on a cm^2 is sufficient as the quality number. As a point and dot mull for curtains in broché design.

Multiaxial fabrics The structure results from several layers of monoaxial fabrics (fleeces, fabrics; see Fig.) arranged shifted together. The resulting physical properties such as strength and extensibility are clearly above those of monoaxial arrangements.

Multi-Bath process American description for multi-purpose baths, which facilitate various finishing stages in one bath.

Multi-bath washing for laundry The total standing liquor is drained for each individual washing/rinsing cycle and fresh water admitted for the next work operation. Processing in the single- or multi-bath process. Opposite → Flow washing process.

Multicellular Multicell, e.g. viscose fibres with a thin cell wall structure and triangular diameter.

Multi charge sewerage filter is used as a continuous → Sewerage filter. It is accumulated from charge

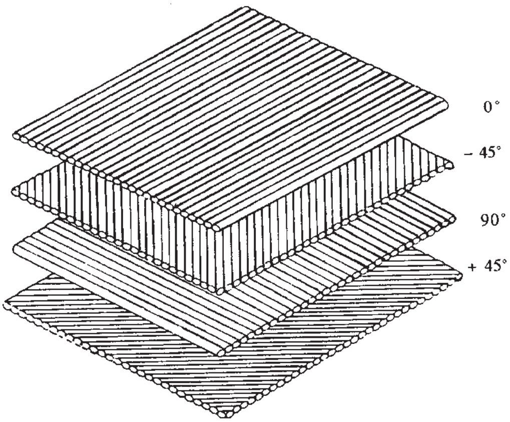

Fig.: Multiaxial composite material.

to charge as long as dirt together with filtering powder addition falls onto a basic layer until the flow output has reached a minimum value. The basic layer can also be repulsed mechanically by the filter elements for every charge in order to form a new filter layer together with other filtering powder additions during re-accumulation. As the flow output decreases with increasing number of charges, the multi charge sewerage filter must be dimensioned relatively large in order to obtain a satisfactory sewerage effect. So that the re-accumulated filter layer does not fall from the elements, low overpressure should always be present in the filter. Multi-charge sewerage filter cleaning and/or filter cake removal is in general carried out by mechanical devices or by rewinding.

Multicolour-Designer Device for the production of multicolour effects by means of 1–2 rotary screens. In the screen inner, scanned fully flat open or provided with patterns, a sealed print paste application part is located on the screen with specific apertures for the individual conducting of the print pastes across the whole fabric width. The print paste application part is axially pushed to and fro in the screen using a control mechanism. Stroke and stroke speed can be controlled steplessly. For the production of TAK and space effects (→ Space dyeing). – Manuf.: Mitter.

Multicoloured effect Achievement of heterochromatic marks using discharges, printing, fixation differences, resists, weaving and similar on textile fabrics.

Multicolour effects Multicolour effects on textile fabrics; e.g. →: Colourcraft process; Differential dyeing or also spray dyeing effects, e.g. on fabrics in special machines (Figs. 1 + 2).

Multicolour effects, space-dyeing Colour effects in various shades of colour, which are achieved by multicolour printing, by print paste application of different dyes, by exhaust dyeing processes on fibre blends, for which different types of dye are in one bath, or by → Space dyeing.

Fig. 1: Spray dyeing plant for multicolour effects.

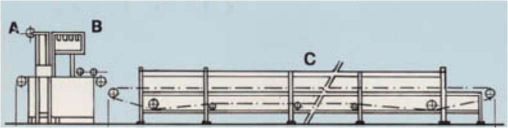

Fig. 2: Multicolour patterning plant.
A = material feed, poss. folded; B = Spray head for microprocessor-controlled application of five dye application liquors; C = steam tunnel.

Multicolour printing from one printing roller → Orbis printing.

Multicolour process Single-bath dyeing method for attaining multicolour effects on 100 % wool. Principle: simultaneous attainment of 2–3 tone-in-tone or contrast dyeings in one dyebath. Purpose of the process: processing of untreated compared with pretreated (prechromed and/or resisted wool) into yarns or fabrics/hosiery goods and subsequent dyeing. “Resisted” wool is only approximately half as deeply stained as “prechromed” wool. The multicolour process has found its way into the practice, but requires precise knowledge of the behaviour of the individual dyes. → Differential dyeing.

Multicolour Rapid-Printing machine for sample purposes can accept up to 8 printing rollers and produces application-oriented printing result. It is thereby not necessary to fit the printing rollers on mandrels. These are secured on the central cylinder by means of plug-in bearings. The doctor blade is shaped in such a way to save the print paste colour box that it can directly accept the print paste and dispenses using a colour furnisher roller. Approx. 75% of the print paste quantity otherwise required can thereby be saved.

Multicomponent fibre → Bicomponent fibre made from various synthetic fibre components of the matrix-fibril type.

Multienzyme complex Enzyme producers offer enzyme mixtures for the entire degradation of vegetable cell walls, which are manufactured from a chosen cultural root of the aspergillus group. This multienzyme complex has pectinase, cellulase, hemicellulase, protease and in low quantities amylase and lipase activity. It is used for the processing of cereal and for the production of beer, alcohol and starch.

Multi fibre Fibre blends, e.g. cotton/synthetic fibre blends.

Multifibre strip The wet fastness requirements of textiles were in a way carried to such extremes by Marks & Spencer that the position was selected as a model: A white textile gets into a large washing batch of coloured articles wash, which is subject to a 100°C wash. The white textile is simulated using a narrow textile carrier, on which all possible types of fibre are made up in a white form. This “multifibre strip” is suspended in the wash test of a dyeing, whose wet fastness should be tested. The dye migration conditions (diffusion ratios) are naturally optimum in that way so that this fastness to washing test represents an extremely rigorous test.

Multifilament (multifil), multi-nozzled → Filament, multi-threaded. Opposite: → Monofilament.

Multifilament gauze Polyamide or polyester gauze manufactured from multifilament fibres. Polyester gauze is preferred due to its good light resistance, low extensibility and good elasticity.

Multifilaments → Multifilament.

Multifilament yarn In accordance with DIN 60 001 B1. 2: → Filament yarn made from several → Filament.

Multifunctional clothing should, for example, protect against heat, cold, gases, colloid dusts, radiation, simultaneously being permeable to water vapour and body heat, and being electrically functional (cannot be found by radar and similar).

Multifunctional processes Multipurpose processes, which combine different finishing stages into one single process, e.g. bleach and dyeing combined or dyeing and finishing combined processes.

Multi-level drier In contrast to the horizontal or flat stenter, which needs a lot of space, the multi-level drier (see Fig.) has the advantage of carrying fabric in the stenter in several levels from top to bottom through the convective drier and consequently of being space-saving.

Multilobal Multi-lapped; e.g. cross-sectional forms of → Profiled fibres.

Multimetal machines Machines made from multimetal designs, e.g. older double drum machines, whose outer drum sheath consists of galvanised sheet steel and of copper in the inner drum.

Multi-Pass-System For the extension of rotary screen printing application using roller screens with standard diameter in order to produce designs with a large register (even more than 5 m). Is based on the draining of the print heads independent of each other corresponding to the preselected program, in which, depending on the pattern to be printed, the screen is disengaged after one or several roller revolutions and automatically stops. – Manuf.: Reggiani.

Multiplexer Circuit route, which selects a particular actuating signal from x actuating signals through default of an address and switches to the corresponding output terminal. Is used as an external measuring-circuit selector, forced value selector and power supply unit for connecting devices in the 2nd interface system to an EDP system.

Multipolymer fibres → Copolymer fibres.

Multipore fibre → Imitation suede.

Multi Product Injection → MPI.

Multiroller (dye multiroller), multi-roller milling and dyeing machine for hat bodies. Is used for simultaneous milling and dyeing in one operation. Slowly run-

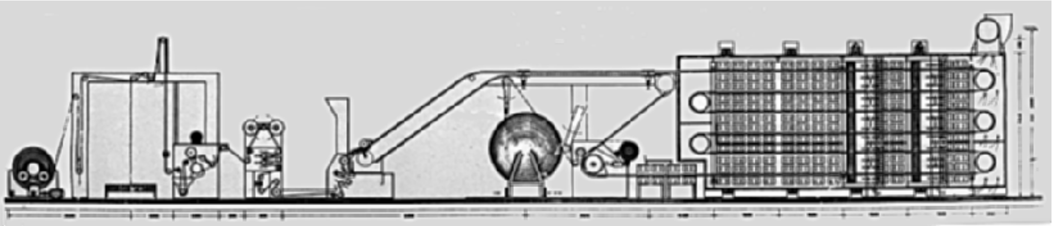

Fig.: Multi-level drier KM 15 (Krantz) as tenter frame.

ning roller aggregates, between which the hat bodies are continually sprayed with the dye-containing milling liquor. The squeezed off liquor flows across a collection tank, is reheated there and again is usedfor spraying, etc. Already $^2/_3$ ready milled fabric is advantageously used and starts with dyeing and weft milling at 50°C (max. attainable temperature approx. 85°C). Approx. 20% additional dye consumption should be considered. The dyeing should be completed after approx. 3 hours. Cost-efficient because the combined operation is feasible. Manufacturers of hat finishing machines have adopted the multiroller principle in multiple adapted form for their designs.

Multistage stenter For the stretching and treating of web shaped fabrics through the drying zone in repeated fabric forward and return stroke. Air supply parallel or vertical. Tension chains offset vertically (→ Tier drier).

Mungo Designation for class III (made from milled fabrics) sorted → Rags and → Reclaimed wool produced from them.

Mushroom Apparel Flammability Tester Flammability tester, developed by American National Bureau of Standards.

Mushroom reaction → Fibre damage (cellulosic fibres), tests for.

Muslin (Mousseline), named after the city in Iraq referred to as Mosul or Mossul. Only fine, single, softly twisted worsted yarns made from almost all fibres are considered for this type of fabric. The fabrics are fairly loosely adjusted and produce relatively light dress materials of soft, flowing drop in conjunction with the fabric weave. Bald finishing. They are typically printed, previously even printed by hand to some extent.

Mussel silk (byssus silk, sea silk, etc.), natural silk-like hair of different large ham mussels (Mediterranean, Normandy) belonging to the → Natural protein fibres, which are held tightly on the rocky ground with the fibre tuft produced and are torn off there. Reconditioning by kneading by hand using soap, carding, drying, washing using citric acid and hot platelets. Outer smooth, gold shimmering gloss, colour brown to olive-green. 2–3 threads of mussel silk are twisted with a thread of natural silk. Precious, rare material. Production barely 200 kg/year. Application: (Italy) for shawls, stockings, gloves, bags, etc.

Mustard gas protective finish Referred to as fabric impregnation against the poison gas, mustard gas (dichlorodiethyl sulphide), is 2.4-dichlorobenzylbenzoeacidchloramide (2.4-$Cl_2C_6H_3N(Cl)COC_6H_5$). Mustard gas protection with 35.5 % chlorine (23.5 % available chlorine); reacts with the poison gas into oxidised and chlorinated products, which should prevent the formation of skin blisters. Typical example from the field of use of technical textiles as protective textiles.

MUT (environmental-friendly textile label). Label for textiles kind to the environment, awarded by the Verein für verbraucher- und umweltfreundliche Textilien. → Ecolabels.

Mutagenic agents (Lat.), substances hazardous to health, which damage hereditary factors and trigger mutations, i.e. can cause changes in hereditary makeup. Mutagenic agents also partly act as → Carcinogens.

Mutarotation Is the optical change in rotation up to an upper range value occurring in the solvent state in sugars, in which e.g. the normal δ-glucose is produced from α-glucose and β-glucose (inversion).

MW Abbrev. for → Molecular weight.

MWS (metres head of water). Metre water column. Unit for → Pressure (-heights, liquid columns) no longer is use. 10 MWS = 9806.65 Pa.

Mycelium → Moulds.

Mycotoxins Collective description for infectious diseases caused by fungi. → Antimycotic finishing.

Myria- (Gk.), unit prefix for ten thousand times, factor of 10^4; e.g. myriagram of magnesium.

Myristic acid, $C_{13}H_{27}COOH$. Constituent of coconut oil. Application: for the manufacture of textile auxiliaries.

Myrobalans Tannin-containing, small rock hard fruits (Bengal, India) and/or fruit parts or their extract. Good myrobalans have a wrinkled exterior and contain 38–40% tannin; worse are smaller, unwrinkled with 25% tannin content. Stoned myrobalans have approx. 50–53% tannin content, 24–34% liquid and 65% solid extracts. Good myrobalans correspond approximately to $^1/_3$ tannin. Used as tannin for tanning.

N

N,

I. Chemical symbol for nitrogen (7).

II. Unit symbol for → Newton.

n Unit sign for → Nano- (billionth) factor 10^{-9}.

Na Chemical symbol for sodium (11).

Nacré (Fr.), nacré print, flowing print; like mother-of-pearl.

NALCC A leading American specialist textile cleaning organization; → Technical and professional organizations.

NALI English textile cleaning specialist organization; → Technical and professional organizations.

N-Alkoxymethyl-compounds Compounds with one or more N-Alkoxymethyl groups, $–N–CH_2–O–R$ (e.g. $R = CH_3$). Used inter alia as crease resist finish, e.g. → Dimethoxymethyl-4.5-dimethoxyimidazolidon.

Nanking yellow → Iron buff.

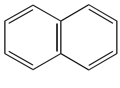
Nano- (Gk.), Unit sign for billionth = 10^{-9}, e.g., 1 nm = 10^{-9} m.

Nap cloth (floconné, Fr.: flocon = flock), the term used to describe thick, soft double fabrics (900–1000 g/m^2) made from carded yarns usually of high quality merino wool. The typical appearance is achieved by a separately-inserted 3rd weft thread, the nap weft, which is a long float thread, later napped (thus also called the "raised thread") giving rise to fluffy tufts of hair on the surface of the fabric. Depending on weave, comes in ribbed, diagonal or herringbone effect; wool-dyed or piece-dyed. Used for high-quality men's coats.

Nap finish machines Mainly → Brushing machines for the production of brushed or napped finishes on grey goods. In the widest sense they also include → Raising machines.

Naphtha The term for crude oil or certain crude oil fractions.

Naphthalene $C_{10}H_8$,



consisting of two contiguous benzene rings. A product of crude oil (rare) and coal tar. Small white laminations with a distinctive smell. Insoluble in water, soluble in organic solvents. Hydrogenation products →: Decahydronaphthalene; Tetrahydronaphthalene. Application: an essential base material (e.g. alkyl naphthalene sulphonic acid), as moth repellent, fire lighter, heating fuel, etc.

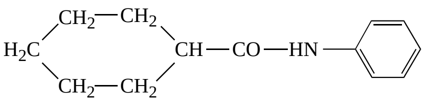
Naphthalene process A pad steam process for the continuous dyeing of loose wool, with the addition of emulsified naphthalene.

Naphthenes → Alicyclic hydrocarbons.

Naphthenic acids Light, saponifiable oils with an unpleasant odour, derived from mineral oils or the products of dry distillation of brown coals, bituminous shale etc., with the general composition:

$$C_nH_{2n-1}–COOH \text{ or } C_nH_{2n-3}–COOH$$

Goods (mercerizing), wetting, dispersion, emulsifying and washing agents are water-soluble alkaline (sodium salts = strongly foaming soaps), ammonium and particularly triethanol amine salts, whose unpleasant odour has prevented their widespread use in Germany. Good mercerizing wetting agents and emulsifiers also include the naphthamides, e.g.,



and their sulphonate products. Similarly, sulphonated wash-active substances are also obtained from oxyethylated naphthenic acids (e.g. ethanglycol naphthenate). Many metal naphthenates (containing copper, iron, aluminium, lead, zinc, etc.) are excellent antibacterial agents and are used as active substances against microorganisms, rot and decay in textile finishes. Naphthenic acid esters are also used as softeners for synthetic resins.

Naphthol dyeing process Naphthol dyeing is carried out on the fibre by combining (coupling) two soluble components, a naphtholate and a diazotized base. The base is either diazotized in the dye shop itself, a complicated process, or obtained from the dye manufacturer as a stabilized diazotized fast colour base, the dyeing salt. There is a large number of combinations, capable of achieving bright yellow, orange, scarlet and red shades which are not available in the vat-dyeing ranges, and more muted burgundy, brown, navy blue and black shades. Naphthols are characterized by good fastness, in particular fastness to boiling. Some combinations are also weather-resistant. The dyeing technique for naphthol dyeing requires promoting the main reaction to form an azo dye, and avoiding the secondary reaction of hydrolysis to a compound no longer suitable for coupling (Fig. 1).

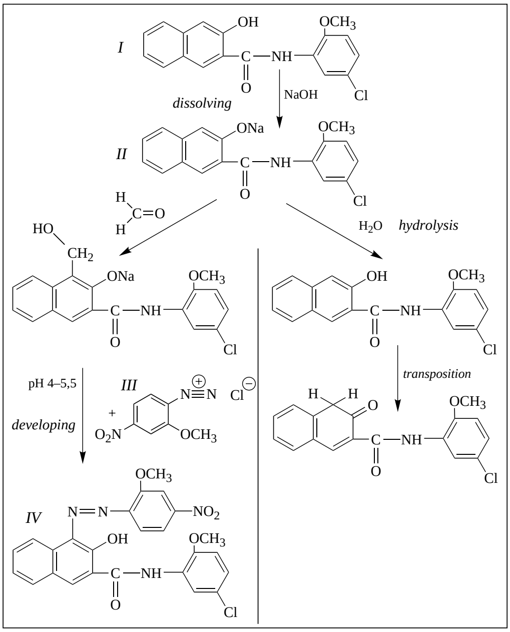


Fig. 1: Chemistry of naphthol dyeing using the example of Naphthol AS (Hoechst).
I = Naphthol AS-CA as grounding components;
II = dissolved naphtholate; III = fast red salt B in the developing bath; IV = dye pigment.

This is done by interim stabilization of the naphtholate with formaldehyde. Particular attention must be paid to the stoichiometric calculation of the developing components (also called diazo components, in the form of fast colour salts or fast colour bases) and the impregnating components (also called coupling components, Fig. 2), which join together to form depth of colour, given in grams of fixed naphthol per kilogram of goods. The dissolving instructions for naphtholates and for fast colour salts (or the solution and diazotization of the fast colour base) must be adhered to precisely. In the exhaust method on the jig or in yarn dyeing the selected liquor ratio must be adhered to precisely, in particular when impregnating, as the proportion of impregnating components absorbed by the fibre determines the depth of colour. As the relevant recipe preparation is complicated, special computer systems are available for naphthol dyeing.

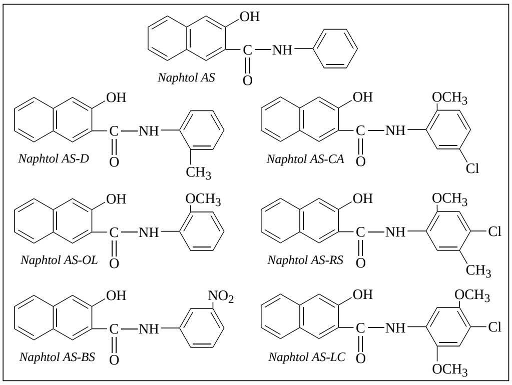

Fig. 2: Coupling components by Hoechst.

Naphthols can be applied using the exhaust method or padding, with the two-bath method, i.e. impregnation and developing carried out separately. In the exhaust method, in order to obtain a good abrasion resistance of the dyeing, the excess naphtholate must be removed after impregnation and before coupling. Depending on the equipment, this is done by squeezing, wringing or, even better, rinsing. This is possible due to the affinity of the majority of naphthols. Yarns to be dyed are on cross-wound package or warp beams. In certain cases, warp yarns are also dyed with naphtholene in the size, e.g. for denim articles. In yarn dyeing, the two-bath method is largely replaced by a single-bath method. By using specific recipes, it is possible to apply moderate- or high-affinity naphtholates and dyeing salts together in a bath containing dispersant, and promote coupling by the addition of an acid. There is also a semi-continuous process for knitted goods whereby pre-treatment and impregnation take place on hanks (e.g. in a winch beck). The goods require intermediate dwell time in watertight carriages, as they need to be completely covered by the impregnation liquor in order to exclude the hydrolyzing influence of atmospheric carbon dioxide. Wet-in-wet, following thorough hydroextraction, the developing bath is applied to the loop on the padder. A semi-continuous process is also used for impregnation on the jig with subsequent developing of the goods following intermediate drying in a continuous plant with developer bath section. In a fully continuous process (Fig. 3) the fabric is impregnated on a pad and developed following interim drying in a padding section with the diazotized fast colour base or fast colour salt. There is another classic process involving impregnation on the pad – hot-flue drying with cooling stage or airway as a wet-in-wet

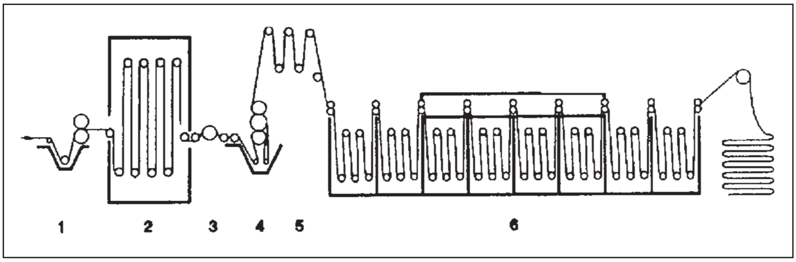

Fig. 3: Diagram showing the continuous process with naphthol dyes (with intermediate drying). 1 = pad for grounding; 2 = hot flue; 3 = cooling roller; 4 = 3-roller pad for developing; 5 = skying; 6 = full-width washer with eight compartments.

process – pad developing – airway – full-width washing machine. One type of single-bath process is discontinuous pad-batch dyeing. Naphtholate and fast colour salt are padded together and the goods left to dwell for 1 hour at 40–60°C. The coupling then takes place by means of passage through a bath containing acetic acid and sodium chloride at 80°C for 10–15 seconds. In all processes, following coupling a boiling bath with soap or a special dispersant is essential.

I. For wool: impregnation only in a sodium carbonate bath at 35-60°C, with the addition of formaldehyde, sodium chloride and protective colloid. Interim rinsing in cold sodium carbonate. Developing as described above, pH 5.5–6.5, temperature 20°C. Post-treatment at 40–50°C with detergent and ammonia, then a fresh bath at 80-85°C with detergent and acetic acid. Careful selection is essential, especially in the case of diazo components, as these are absorbed by damaged wool. As the process takes place in the alkaline region, the wool is likely to be damaged.

II. For silk: for boil-resistant, strong shades on yarns. Impregnation with naphtholate, protective colloid and sodium chloride at 20–25°C. Interim treatment: spinning. Cold developing with fast colour salts or diazotized fast colour base, with the addition of sodium chloride and acid. Warm post-treatment with hydrochloric acid, finally rinsed twice in a detergent bath, rinsing, finishing.

III. For acetate: for cross-dyeing-fast special-effect yarns. Limited selection of naphthols. Impregnation at 75°C with naphtholate and fast colour base in dispersed form. Interim treatment: rinsing. Developing: diazotizing with sodium nitrite and hydrochloric acid, cold. Post-treatment: rinsing, soaping, sodium hydrosulphite bath. Sodium nitrite may also be added to the impregnation bath, and after cooling to 45°C, diazotization may be carried out by the addition of formic acid. The disperse diazo dyes recommended for the dyeing of polyester may also be used for acetate. Dyeing temperature 105°C.

IV. For polyamide: of little significance. Procedure as for acetate, but with increased quantities of nitrite.

V. For polyester: the disperse diazo dye group is particularly suited to the dyeing of polyester loose stock, for later spinning together with other fibres. Deep dyeing with good fastness is achieved. The usual range of naphthols cannot be used for polyester. Special dyes are used, consisting of blends of naphthols with fast colour bases in disperse form. Impregnation is carried out under HT conditions or with the addition of a carrier, diazotized at temperatures of 80–100°C. Post-treatment: rinsing, reductive cleaning with caustic soda and hydrosulphide at 80–85°C.

Naphthol dyeing test in UV light Place a test dye sample in a 50 ml beaker, and fill with sufficient blank vat to cover the sample (36 g/l caustic soda, 35.5% and 24 g/l sodium hydrosulphite); boil until the original dye appears a dirty yellow; remove the sample with a glass rod, squeeze the sample out on the glass side of the beaker, place on a round filter paper (preferably on a glass base) and leave to dry. Examine the test samples under an analytic quartz lamp: strong luminescence indicates naphthol dyeing.

Naphthol preparation Firstly the necessary naphthol components are applied to the fabric, usually through padding. After drying, the second components, the fast colour base or the fast colour salt are applied together with the padded base.

Naphthols,

I. A designation of hydroxy-derivatives of naphthalene with one or more OH groups. They are used as intermediate products (α-naphthol, β-naphthol) in dye synthesis (→: Phenols; Cyclic hydrocarbons).

II. Developing dyes (obsolete ice colours), produced on the fibre, usually by means of a two-bath application, they are insoluble azo dyes from naphthols (primers) and fast colour bases or dyeing salts (developers), with around 2000 combinations possible. An essential class of dyes for cellulose fibres, especially for deepest red, scarlet and claret shades, which are not available in vat dyeing ranges. Can be used in exhaust dyeing and padding processes and also for “dyeing in the size”. Of lesser significance for wool, wool/cellulose, silk, acetate and polyamide. Dispersion diazo dyes have been specially developed as naphthol preparations for the dyeing of polyester. A range of special naphthol classes is used in printing.

Naphthols – colour scale Of greatest significance for red shades. Paranitraniline red has been superseded by naphthols. Naphthol dyes and prints (around 2000 different dye combinations: yellow, scarlet, red, claret, brown, blue, green, olive, violet, black) possess good properties to produce deep shades and often a high degree of brilliance.

Naphthols – fastness on cotton, wool, wool/cotton Largely dependent on the components (naphthols and fast colour bases/salts) which are used to produce the insoluble azo compounds. Naphthols achieve, to an extent, the highest levels of fastness and can then be labelled with the indanthren product designation.

Naphthols in direct printing,

I. Base printing: The goods are padded with naphthol (low affinity because of the subsequent removal of non-printed areas) and dried evenly (hotflue, drying cylinder). They are then printed with printing dye paste containing thickened dye salt (fast colour salt) or a dye base diazotized in the printing dye paste (fast colour base); they are then boiled with soap with an alkali additive.

II. Naphtholate print: Only suitable for patterns with very low cover. The fabric is printed with naphthol dissolved in caustic soda, thickened and as far as possible, dried, padded with dyeing salt or diazotized dye base, treated in a hot sodium disulphate bath, rinsed and boiled with soap.

III. Process without naphthol basis with steam or wet development:

a) Printing with a combination of naphtholate and antidiazotate: thickened dye, caustic soda and weak oxidizing agent are printed and then dried. The non-developed antidiazotate can be converted into a developable diazo compound by lengthy airing or steaming and subsequent passage through a hot electrolytic bath with the addition of organic acids (formic acid, acetic acid) or by steaming in acid ager, rinsing and boiling with soap.
b) Printing with a combination of naphtholate and diazoamino compound: thickened dye, wetting agent and caustic soda are printed, dried, with acid bath treatment (passage through a hot electrolytic bath with organic acid or steaming in acid ager). Conversion of the stable diazoamino compound into developable diazo compound. By using a developer in place of the caustic soda in the printing dye paste, fixing can also take place using neutral steam. Finally rinse, then boil with soap.
c) As b) with neutral, fissile diazoamino compounds. Fixing by neutral steaming.
d) Printing with a combination of naphtholate and antidiazosulphonate. Also fixed using neutral steam.

IV. Printing of prepared azo dye with alkaline fixing: only of historical interest. Splitting off of water-soluble components by saponification.

Naphthols in discharge printing Because of their chemical structure, naphthols are excellently suited to the dyeing of white and coloured dischargeable grounds. There are only a few exceptions where the dischargeability is insufficient or the dyes cannot be discharged at all. The special suitability of naphthol dyeing for discharge dyeing is a result of the high wet fastness properties and the ease of splitting of the azo pigments with the help of reducing agents. The advantages are also apparent in the discharge dyeing of deep dye shades, for which the colour fastness salts derived from aminoazobenzene are used.

Naphthols in resist printing Their significance has been substantially reduced by the application of modern discharge agents.

I. White resist: thickened aluminium sulphate, possibly with the addition of organic acids (e.g. tartaric acid).

II. Coloured resist: preferred with reactive dye in resist printing. The goods are printed, dried, briefly steamed, padded with slightly thickened variamin blue, ventilated, rinsed briefly, immersed in a boiling bath with sodium disulphite, rinsed, boiled with soap with sodium carbonate.

Further options: vat dye with potassium sulphite and zinc oxide added to the usual printing dye paste. Vat leuco ester, e.g. application of the ammonium chloride process with the addition of aluminium sulphate. Pigment dye with the addition of organic acid. Mordant dye with the addition of oxalic acid, potassium sulphite or sodium thiosuphate.

Nap velours A napped fabric, usually wool, in which the raised fibres all lie in a parallel direction. Opposite → Upright pile velvet.

Narrow fabric → Ribbon.

Narrow fabric accumulator A device for collecting the fabric by depositing it in transverse folds on a continuous conveyor belt.

Narrow fabric dyeing Narrow fabric lengths are wound into hanks and dyed in a circulating-liquor machine like yarns on sticks or wound directly onto bobbins. Wider narrow goods are dyed by the continuous process.

Narrow fabric finishing Narrow fabrics are woven in working widths of up to 300 warp threads, but usually as narrow textiles substantially less in width, on special looms, and it is in this form that they must be heat-set or crease resistant finished (possibly following pre-treatment and/or dyeing). This is carried out on cylindrical dryers, around which the narrow fabric passes several times (see Fig.).

NATA "National Association of Testing Authorities"; an Australian textile testing body based in Chatswood. → Technical and professional organizations.

National Cotton Council of America An information bureau for cotton processing based in Washington, USA, with branches in many countries. → Technical and professional organizations.

National Institute of Drycleaning (NID). An

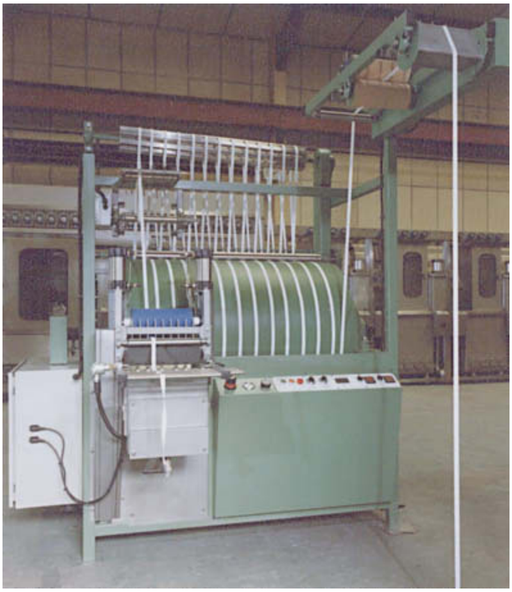

Fig.: Webtex narrow fabric finishing plant (left: entry; right: exit).

American dry-cleaning organization founded in 1972. → Technical and professional organizations.

Natural (Lat.), original, e.g. cotton can be called a natural cellulose fibre in contrast to regenerated cellulose fibres (viscose, acetate). Natural protein fibres are wool and silk, in contrast to man-made protein fibres such as casein fibres.

Natural cellulosic fibres belong to the group of natural → fibre materials of vegetable origin:

I. → Vegetable hair fibres: →: Cotton; Kapok.

II. → Bast fibres: →: Flax; Hemp; Jute; Kenaf; Kendyr fibre; Nettle fibres; Ramie; Rosella; Sunn fibre; Typha fibres; Urena fibres.

III. → Hard fibres: →: Agave fibres; Alfa grass; Bromelia fibres; Coir fibres; Henequen; Manila fibre; Mauritius hemp; Sea jute; New Zealand flax; Palm fibres; Panama; Pine apple fibre; Raffia bast; Sanseviera fibre; Sisal; Yucca fibres.

IV. others: → Paper yarns.

Natural colour The colour of undyed textile goods prior to dyeing, which needs to be taken into account when formulating the recipe. Sample dyeing is essential.

Natural dyes There is a vast number of plants whose extracts can be used for the dyeing of wool, silk cotton and linen; there are also a few examples of dyes of animal origin. Different parts are used depending on the plant, whether the whole plant, the bark, the heartwood, the leaves, the roots or the fruit. For various reasons, e.g. due to the dyeing behaviour, the fastness or the biological availability, only some of these have gained widespread acceptance as dyes. Some examples are given of the natural resources necessary for obtaining some dyes of plant and animal origin:

1. Cis-bixin (annato) from the seed pods of the fruit of the rocou tree, for food, oils, margarine, cheese rinds etc. One tree yields 1–3 kg seeds; 100 kg seeds yield 120–160 g pure cis-bixin. The annual harvest in Central and South America is approx. 500 t seeds.

2. Carminic acid (cochineal) is obtained from the female cochineal insect (coccus cacti) and is used as a wool, silk, food and cosmetics dye. 1 kg of dried female insects (approx. 140 000) equal to 50 g pure dye. Insects reared on plantations can be collected approx. 3 times per year; those living wild approx. 6 times per year. In opuntia plantations, still in use today, 1 ha yields approx. 300 kg cochineal per year.

3. Carotene is obtained mainly from carrots, red palm oil and pumpkin seeds, and is used primarily for food and pharmaceutical purposes. 1 t of carrots yields approx. 67 g pure carotene.

4. Carthamine is obtained at quantities of 0.2–0.3% from flowers of the safflower (carthamus tinctorius). The flowers also contain 30–36% worthless safflower yellow, which must initially be removed by extraction with water.

5. Curcumin occurs in the root tubers of the curcuma genus, native to east Asia. 30–50 g pure dye are obtained by extraction from 1 kg of the dried drug; this is used for dyeing wool, cotton and silk in yellow, in red to brownish-black shades.

6. Euxanthinic acid is obtained from the urine of cattle which have been fed on the leaves of the mango tree. The yield is 50 g per animal per day. The land of origin was India, although the practice was banned prior to 1930 on animal protection grounds. Euxanthinic acid was once a highly prized yellow artists' pigment.

7. Fustine and fisetine, obtained from young fustic (tanner's sumac). 1 kg wood dust yields approx. 40 g dye.

8. Haematin from logwood (campeachy), the heartwood of haematozylum campechianum. It is obtained from 10–12 year-old trees. The reduced form hematoxylin is present in the wood, so that in order to obtain the substance, the heartwood, cut into blocks, is left to season for approx. 1 year, or is artificially oxidized by fermentation. A faster oxidation is also possible using nitrites, chlorates or chromates. A consumption statistic from 1950 shows that approx. 30 000 t of logwood was shipped from Campeche (Mexico), representing worldwide consumption. At that time logwood was used in larger quantities in the textile industry to achieve fast blue and black shades on polyamide.

9. Hypericin is found in the ratio 1.2–1.5 g/kg in the dried, ground flowers of St John's wort. Depending on the mordant it produces yellow, pink or blue-black

shades, and without mordant reddish-purple shades on wool.

10. Indigo is obtained from East Asian Indigofera genus and European woad (isatis tinctoria) and dyes wool and cotton (principle dye used for jeans). 100 kg of the indigofera plants yield 1.5–2 kg raw dye, with a pure content of approx. 20%. The content is much less in woad.

11. Juglan is found in the ratio approx. 2 g/kg in fresh walnut shells. It give a brownish-yellow dye on wool, or pink if an aluminium mordant is used. It is also used for colouring in cosmetics (sun protection lotions).

12. Kermesic acid is a derivative of anthraquinone, which is obtained from the kermes insect (kermes ilicis or kermes vermilio). A dried kermes insect contains approx. 1% kermesic acid. The kermes insect lives on the kermes oak, quercus coccifera, native to the Mediterranean lands. Kermesic acid and carminic acid also occur in so-called St John’s blood, obtained from the Polish scale insect (prophyropus polonicus). The insects live on the roots of a type of carnation (scleranthus perennis), requiring the plants to be dug up, the insects collected and the plant replaced.

13. Madder dyes are hydroxyanthrachinones, obtained from the root rind of various plants of the Rubia genus, e.g. madder (rubia tinctorum). The roots contain approx. 1.9% dye, which occurs either free or in a glycoside compound.

14. Laccaic acid, consisting of at least 4 components, occurs at 0.5–0.75% in sticklac, the raw material of shellac, which is obtained from the Coccus laccae insect. It gives wool a red colour using aluminium or tin mordant.

15. Lawson is obtained from henna and is suitable for the dyeing of wool and silk, and as a hair colour. The dried leaves contain approx. 1% henna.

16. The example of archil, which is obtained from a slow-growing lichen native to southern lands, shows how excessive use and over-exploitation in the Middle Ages has led to an enduring shortage of the dye plant.

17. Phoenician purple (6,6’,-dibromic indigo) is obtained from the shell Murex brandaris, or other types, and is used to dye wool and silk. 10 000 of these molluscs would yield approx. 1.2 g pure dye. Excavations have shown where ancient dye shops would have been sited, from the quantities of broken shells found.

18. Rutin is contained in the leaves, flowers and fruits of numerous plants, e.g. types of buckwheat and Chinese yellow berries. The rutin content varies and can be as much as 27%. It give a citrus yellow colour to wool and silk with an alum mordant. It used to be used in China to dye the Mandarins’ robes.

19. Saffron is obtained from the stigmas of crocus plants and is used to dye silk as well as a food colouring. It takes 70 000–80 000 stigmas to yield 1 kg saffron, which contains approx. 10 g crocin and approx. 60 g crocetin, the actual dye. The city of Basle owes its status as a city to the saffron trade (Sewekow) (Tab. 1).

dye	name	occurs in/as	fibres	ecological/toxicological implications
red	purple	gland of the murex shell approx. 8 million shells for 1 kg dye	wool, silk	
	cochineal	cochineal insect approx. 2 million insects for 1 kg dye, 1 ha supplies 300 kg C	wool, silk, after preliminary mordant with metal salts	potential allergen, heavy metals
	kermes	kermes scale insects and other scale insects (1% in the dried insect)	the same, where necessary with preliminary mordant with metallic salts	heavy metals
	madder	outer root of the madder plant approx. 50 kg roots for 1 kg dye	wool, silk, cotton, linen after preliminary mordant with metal salts	metals
blue	indigo, woad	leaves and flowers of the indigofera or woad plants approx. 300 kg indigofera or 900 kg woad for 1 kg dye	wool, silk, cotton, linen after fermentation vat (urine, dung) and air oxidation	
yellow	saffron	stigmas of crocus plants approx. 1 million flowers for 1 kg dye	silk	
	weld	flowers and leaves of the mignonette plant	wool, silk	heavy metals
brown	redwood	as brazilin in Caesalpina species	wool, silk	heavy metals
black	logwood	heartwood of the Campeach tree	wool, silk	
	iron + tannin	gallnuts	wool, cotton, linen

Tab. 2: Light fastness of some natural dyes (denoted in accordance with the blue scale) (according to Sewekow) with essential mordant metals.

The following dye categories are recognized:

I. Cationic dyes (barberry).

II. Direct dyes (curcuma, archil, safflower).

III. Mordant dyes (logwood, cochineal, fustic, catechu, kermes, madder, Persian berry, lacdye, quercitrin, redwood, sandalwood, weld).

IV. Vat dyes (indigo, Phoenician purple, woad).

Natural dyes only allow limited fastnesses and muted shades. The "old dyeing methods" were very well-developed, but usually extremely complicated. With the advent of synthetic dyes, their variety, consistent composition, greater purity, simpler, more reliable application and lower price, in addition to the necessary fastness, ensured their supremacy.

Naturally-occurring dyes display many disadvantages in comparison with their man-made successors; many of them have an adverse effect on the environment, either during manufacture or processing. The quality is variable and often insufficient. thus wash- and light-fastness can often be a problem (Tab. 2).

In addition there is not such a rich choice and they are unsuitable for many synthetic fabrics. They are also often substantially more expensive, and often cannot be produced in the quantities required due to insufficient natural resources (e.g. cultivation space or suitable environment).

Natural fibres Textile fibrous material of natural polymers of plant, animal and mineral origin. →: Fibres; Mineral fibres; Natural cellulosic fibres; Natural protein fibres.

Natural gas A substance obtained from the earth, consisting mainly of hydrocarbons, it is gaseous and flammable under normal pressure and temperature conditions. The composition is generally consistent within a natural gas field, but may vary from field to field. The main component of natural gas is usually methane, but may contain hydrocarbons of high molecular weight to a greater or lesser extent, capable of whole or partial separation by condensation. Natural gas is categorized as "dry" or "wet"; the latter is also known as petroleum gas. Natural gas may also contain: nitrogen, carbon dioxide, inert gases, and possibly also oxygen. It is mainly used as a source of primary energy for housing and industry, and in power stations for the generation of electricity.

Natural protein fibres Fibrous materials of animal origin belonging to the overall category of natural fibres. They are subdivided into the following groups:

I. Wools and hair: sheep's wool (→ Wool), camel wools (→: Alpaca; Llama hair; Vicuna; Guanaco), →: Camel hair; Hare and rabbit fibres; Angora rabbit hair; Goat hairs (→: Mohair; Cashmere; Cashgora; Tibetan cashmere), other hair (→: Dog hair; Human hair; Cattle hairs; Horse hair, Hog's bristles).

II. → Silks: →: Mulberry silk; Wild silks (→: Anaphe silk; Eri silk; Fagara silk; Muga silk; Tussah silk; Yamamai silk), other silks (→: Mussel silk; Spider silk).

Natural resins → Resins.

Natural rubber (polyisoprene). Typical properties: Shore hardness range 30–90 A, excellent fabric bonding strength and abrasion resistance, moderate to good resistance to acids, poor resistance to solvents (aliphatic, aromatic hydrocarbons), good against oxidation (ozone = poor), poor against the effects of sunlight and flammability.

Natural Sharling The designation for a fine, resistant but soft wool fibre obtained from a type of Merino sheep reared in Australia. The animals are kept in individual enclosures and receive a controlled daily amount of food. The fibres are particularly uniform. The fibre yield is 72%, compared with 65% from animals put out to pasture. The fibre is similar in appearance and handle to cashmere, although it has a different structure.

Natural silk → Silk.

Natural surfactants → Natural tensides.

Natural tensides Surfactants are necessary in nature (e.g. milk emulsifiers). Vegetable glycosides (sa-

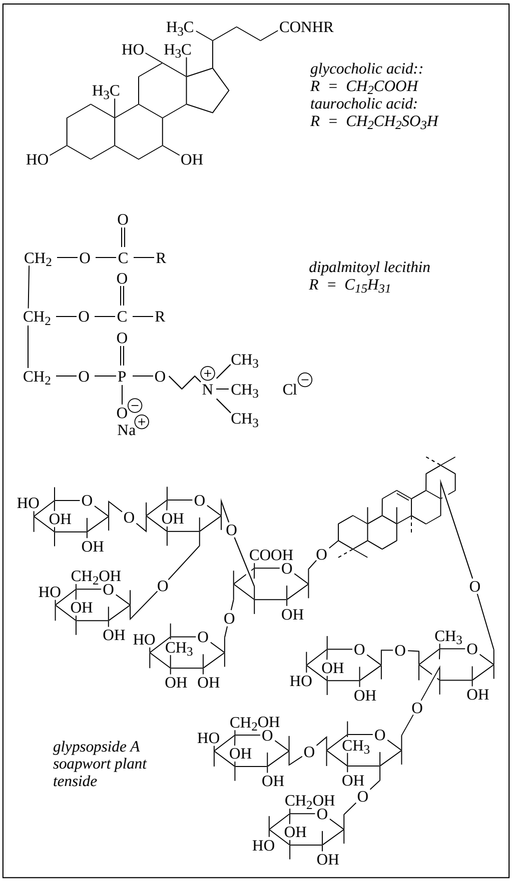

Fig.: Molecular structure of natural tensides.

ponines) occur in soapwort (Fuller's earth) and panama soap; they were formerly used for washing and cleaning because of their surface active, foam forming properties. Natural surfactants often have such a complicated molecular structure, in that hydrophilic and hydrophobic components are not obvious at first glance (Fig.).

Natural textiles Primarily a marketing term, but of genuine technical significance due to systematic awareness of ecological issues. Ecologically aware textile production seeks to label textiles which have been produced with minimum adverse impact on the environment. Thus natural textiles are defined as follows:

- Natural textiles: garments made from pure, untreated natural fibres, or those which have been dyed but without chemical treatment.
- Natural fibres: fibres of animal or plant origin (wool, silk, natural cellulose fibres, not mineral fibres or regenerated cellulose), preferably cultivated without the use of pesticides.
- Untreated natural fibres: neither resin finished nor chemically treated (from antifelt to silk weighting).
- Natural fibres without finish: unbleached, plant dyed, unadulterated fibre surfaces for skin contact, without the influence of chemicals, resin coating or toxic substances, on the properties of the natural fibre. Lubricants (paraffin lubricants) and sizes (modified potato starch) must be capable of washing out.
- Guaranteed free from residues: analytical inspections of each new yarn batch for raw material residues (pesticides, herbicides, formaldehyde etc.) by independent bodies.

Framework conditions:

- Obligation to declare: Textile labelling acts, declaration of any deviation.
- Quality development: influences on the production of raw materials such as good animal handling practices, ecological plant cultivation.
- Marketing methods: ecologically aware marketing and distribution (outlets dealing in natural fabrics and textiles).

Natural wax → Wax.

Nb, Cb The chemical symbol for niobium (41), also known as columbium (Cb).

NBS,

I. National Bureau of Standards, Washington, an American textile research body; → Technical and professional organizations.

II. New British Standards.

NBS Unit → Colour difference formulae.

NCH Standard abbrev. for non-carbonate hardness, permanent hardness.

Nd Chemical symbol for neodymium (60).

NE Dutch patent.

Ne,

I. Chemical symbol for neon (10).

II. English yarn count, → Linear density of fibres and yarns.

Neale process The use of sodium hydrosulphite in combination with sodium boron hydride in vat dyeing.

Near infrared reflection measurement (NIR). In contrast to the usual procedures involving analysis of wavelengths, in near infrared reflection measurement a continual optical spectrum is evaluated using statistical chemometric procedures, as even in the near infrared area the absorption of all relevant components overlaps to such a great extent that only by registering the whole spectral range can a clear statement be made on the components to be determined.

The PLS method is a statistical method based on Principal Component Regression (PCR) factor analysis, which is particularly suited to quantitative evaluation of the NIR spectra with heavily overlapping absorption bands. The bands are based on the molecular vibrations of the chemical components and can be identified as absorption bands in the infrared spectrum. The

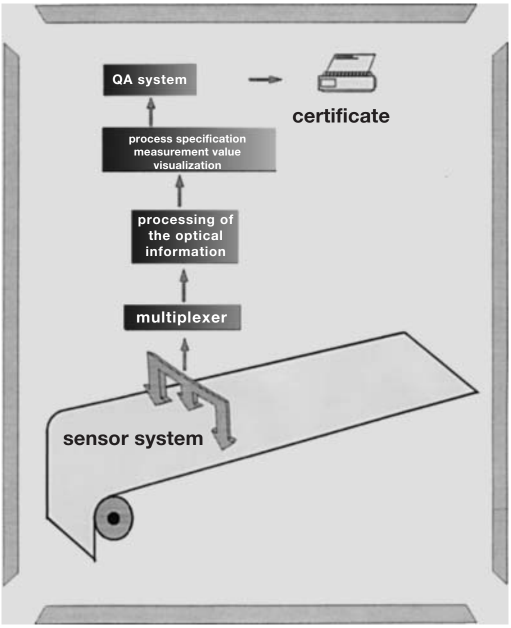

Fig. 1: Functional elements of near infrared reflection measurement (according to Schumacher-Hamedat) using a Qualimat 100i/3000i.

measuring process is based on the recording of a reflection spectrum in the near infrared range; this carries the relevant information for each process chemical. The basic principles of measurement value recording are shown in Fig. 1. The moving fabric lengths are exposed to radiation by special fibre optic bundles and the reflected radiation conducted to a spectrometer, where the optical information is split into its spectral components. An optical multiplexer means measurements can be taken at several points across the width of the cloth. It connects the optical fibres in sequence to the spectrometer.

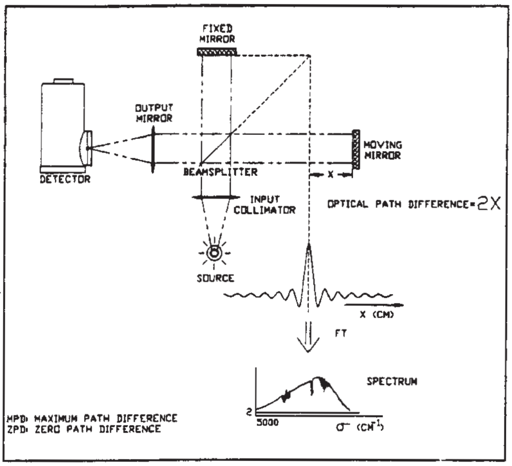

Fig. 2: Diagram showing the principles of a classic interferometer (according to Schumacher-Hamedat).

Possible spectrometers available include wishbone interferometer or grid monochromators. Unlike various other instruments, in the interferometer the optical frequencies are not separated.

The Fourier transformer-interferometer (Fig. 2) creates an interference effect by separating the primary radiation into two equal parts; a path difference between the two parts across a moving mirror with associated superposition produces in conjunction with the path difference what is called the “Interferogram”, which uses a mathematical algorithm, the Fourier transformation, to determine the spectral wavelength variation.

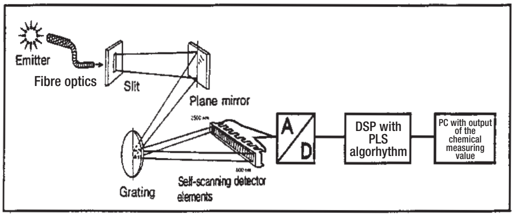

Fig. 3: Diagram showing the structure of a grating monochromator with detector elements (according to Schumacher-Hamedat).

The structural principle of a grid spectrometer with simultaneous array detection for the processing of optical signals is shown simplified in Fig. 3. The light captured by the fibre optic bundle is split into its spectral components (array) and transformed into electrical signals by a multi-channel detector.

Necked lamellar straight edge For napping the pile of fabrics with loose, slack and/or thickened selvedges, without these edges being cut by the blade (Figs. 1 and 2).

The straight edge is divided left and right for a length of 30 cm into 1 mm thick lamellae. At the point at which the fabric edges run over the shearing table, the lamella are automatically lowered. This gives rise to a greater distance between the lower blade and the surface of the fabric. It is not necessary to monitor the fabric edges or the shearing table. Loose, folded or thickened selvedges can slide beneath the blade without coming into contact with it. The lowering of the lamellae is controlled by two pneumatic fabric edge sensors placed immediately below the shearing table. The advantages over alternative systems include:

- the length of cloth does not have to be positioned precisely, and thus processing is safe even at high speeds;

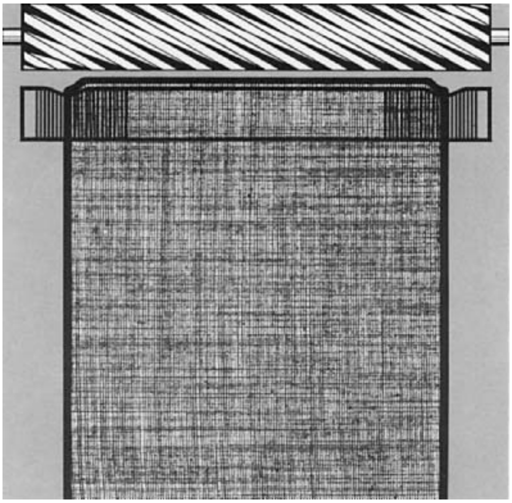

Fig. 1: Diagram of a necked lamellar straight edge.

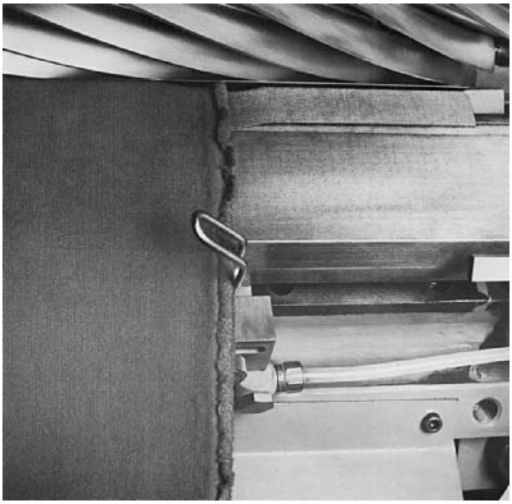

Fig. 2: Peerless selvedge automatism (Vollenweider) forming a necked lamellar straight edge for cutting machines.

- the length of cloth always runs centrally through the machine. It is not necessary to move it over to one side in order to keep the edge away from the cutting range of the blades;
- there is no need for the edges of two cloths of different widths to be sewn together precisely;
- the shearing table edge is not displaced to the side, therefore problems are less likely; particularly safe operation even at high speeds;
- the desired selvedge width which is not to be cropped, is adjustable.

Necking effect → Telescope effect.

Nederlandse Textielinstituut successor organization to the NVTC, member of the → IFVTCC. → Technical and professional organizations.

Needle bonding Fixing process for →: Tufted textiles; Needle punched nonwoven fabric, e.g. an alternate insertion and withdrawal of a number of needles in nonwoven fleeces, or similar in the case of napped needlefelt fabrics and batt-on-base woven felts.

Needlefelt fixing Following needling of folded fleece fabrics, which may be regarded as preliminary fixing, the fleece, in three-dimensional form as far as possible, must be fixed with binders. Fine fleeces (Fig. 1) are impregnated with foam, or by spraying the binder dispersion. Another form of fixing is bath impregnation with subsequent coagulation (Fig. 2). Less three-dimensional, i.e. smoother, needlefelt fabrics can also be fixed thermally (on calenders or by thermofixation).

Needle gauge The distance between the centres of two adjacent needles on knitting, needling tufting machines and similar. The number of needles in relation to a specific length (e.g. 10 cm) determines the gauge of the machine.

Needle pluck test A modified burning test for the detection of synthetic fibres spun from the melt (polyamide, polyester) which during the burning test can be drawn out by a needle to form a fine thread following melting, by a heated iron. The needle draw test does not work specifically with polyacrylonitrile, acetate and triacetate.

Needle punched carpets Textile floor coverings produced by the needling of bonded fibre fleeces (→

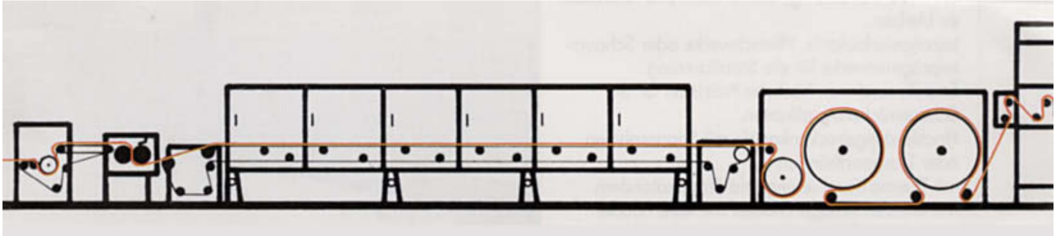

Fig. 1: Foam impregnation plant for needlefelt fixation of fine fleeces (Mohr).

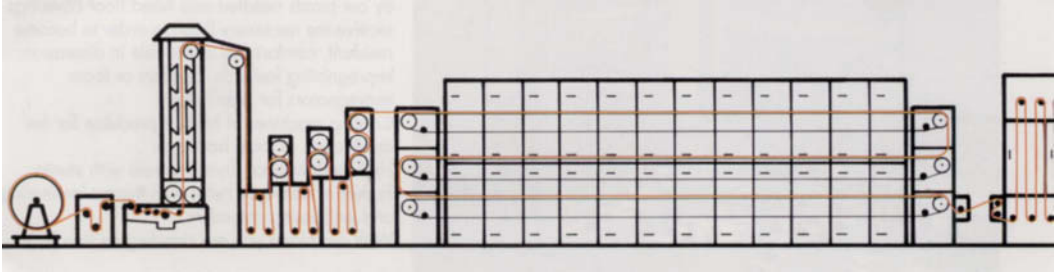

Fig. 2: Impregnation and coagulation plant for needlefelt fixation (Mohr).

Needle punched felt). May be composed of several different layers (top layer, lining, backing layer). The mechanical needle punching of the nonwoven fabric is known as pre-fixing. In post-fixing, binding agents are used. Nonwoven fabrics with a thermoplastic fibre content are fixed using heat treatment. The fixing needles penetrate the nonwoven fabric either vertically or at a slight angle. Special needles can be used to achieve special effects on the needle punched surface. In contrast to most other types of carpet the fibres are mainly horizontal. The backing is either embedded in the layers of the nonwoven fabric or forms the bottom layer for the needle punched felt. If embedded it is generally between one of the top layers and one of the lower layers, made from a combination of waste fibres. If the nonwoven fabric layers are to be needle punched onto the backing, a lining of cheaper material (e.g. nonwoven fabric made from waste fibres) can be inserted between the top layer and the backing, or stronger nonwoven fabrics or several nonwoven fabric layers of the same quality as the top layer can be bound together with the backing.

The top layer of needle punched felts mainly comprise different synthetic fibres, predominantly polyamide (sometimes up to 100%), which is particularly suitable due to its high wear resistance. In contrast to polyester, polyacrylonitrile and polyolefin fibres, polyamide fibres have a water retention value (10–12%), making floor coverings made from these fibres subject to stretching or shrinkage depending on the ambient humidity, which can lead to problems with regard to dimensional stability, particularly in the case of nonwoven fabrics. This problem can only be countered by full bonding. The biggest advantages of polyester and polyacrylonitrile fibres are their low moisture absorption rate (0.5–0.8 or 1.0–2.0%). Whilst they have been extensively used for tufting and weaving, they have to date, only rarely been used for the manufacture of needle punched felts, not least because of the dyeing costs. The polyolefins (especially polypropylene) are more widely used, either 100% or as a mixture with polyamide fibres for the top layer. Polyolefins absorb practically no moisture and have a water retention value of practically zero, which gives products made from these fibres an excellent stability regardless of ambient moisture conditions. The titre of the fibres usually lies between 17–20 dtex given a staple length between 40–100 mm. Hard-wearing needle punched felts may also be made from very coarse synthetics (up to 80 dtex). The lining and base layers are often composed of synthetic fibres, generally making use of waste fibres which can be obtained cheaply on the fibres market. Different processes variously make use of regenerated cellulose fibres and reclaimed wool. The backing used to be made from woven or nonwoven jute fabrics. For some time now increasing use has been made of woven or nonwoven polypropylene fabrics. Glass fibre backings are also used successfully for continuous and bonded fibre carpeting.

The nonwoven fabric may be produced either mechanically or by a pneumatic production plant. In the case of needle punched felts the proportion of pneumatically-produced goods is, for various reasons, very low, although they do have some advantages over nonwovens produced by carding. Thus, for example, there are no problems of substantial differences between longitudinal and transverse stability, as the fibres are applied by a flow of air and are thus laid down at random. On the contrary, in the case of a carded web the fibres are largely longitudinally arranged due to the carding process, resulting in a fabric which is substantially stronger in a transverse direction than in a longitudinal direction. This relationship can be enhanced even further by random carding. Special felting needles on the needling machine pass through specially-arranged holes or slits in the stripper plate into the base plate. The material to be needle punched passes between the stripper plate and base plate. The base plate takes the force and protects the material as the needle passes through, and the opposite forces as the needle is withdrawn are transferred to the stripper plate. The penetration depth of the felting needles is adjusted by raising or lowering the base plate. The fibres of the nonwoven material are captured by barbs on the felting needles and drawn through to the back of the fabric. A proportion of the fibres are thus reoriented from a horizontal to a vertical layer.

Standard needle punched carpets have a more or less open surface. Various attempts have therefore been made to improve the appearance of needle punched felts. This can be achieved by patterning using a further development of the needling technique. In order to achieve this pattern specially equipped needling machines are used in conjunction with specific types of needle. Loop, fork or side-hook needles are used to create looped, ribbed and velour surfaces. Needle-felt carpets are fixed mechanically and adhesively. It is the type of fixing which largely determines the use for which the floor covering is suited. The fibre bonding is generally achieved by means of polymeric dispersions based on polyacrylates or butadiene/styrol copolymers. In recent years carboxylized styrol-butadiene lattices (SBR lattices) have taken over in the market from the originally exclusively used polyacrylates. A further development of the SBR lattices is providing needle punched felt producers with products for finishing carpets which satisfy the most demanding requirements and are also sufficiently fade-resistant for most purposes.

Needle punched felt A nonwoven fabric, produced by needle punching transversely or diagonally → Bonded fibre fleeces with a backing layer or base fabric (Fig. 1). Needle punched felts are not considered → Felt in the usual sense, which represent textile fabrics whose composition and strength originate in the natural felting properties of wool and certain other animal hairs; rather they are fleeces compacted on needling machines and fixed with binding agents. They are made in a dry process by means of fleece carding. Fixing then carried out mechanically by means of alternating insertion and withdrawal of a number of suitable needles (Fig. 2) and then using an adhesive binding agent or a thermal process. Used for textile yarded or plate form goods as an underlay felt, padding felt, needle-felt carpet, etc.

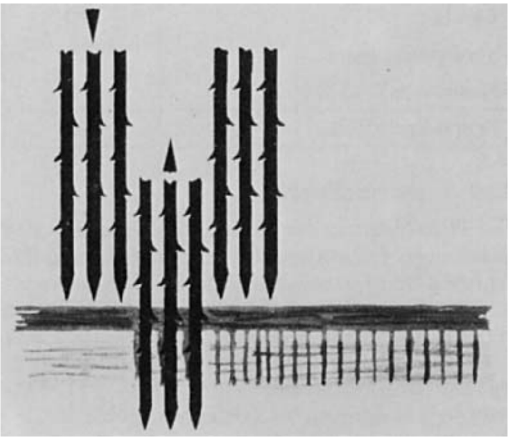

Fig. 2: Diagram showing the needle punching of fleece.

Needle punched nonwoven fabric → Bonded fabrics of the → Needle punched felt type and needle punched wadding. Fixed by needling with or without shrinkage or needling with thermoplastic bonding.

Needle roller bearing Miniature version of a roller bearing for the smallest rotating machine parts.

Negative process In contrast to other processes for the manufacture of screens for screen printing, the pattern section is projected onto the gauze in negative form. All those parts of the design which are to remain blank when applying the lacquer layer are fixed into the gauze in the form of exposed gelatine. Finally a specially selected lacquer is drawn over the gauze with an applicator. The lacquer penetrates all areas of the gauze; only the parts covered with the gelatine resist – the lacquer stays on the gelatine. Once the lacquer has dried the screen is immersed in water at 70°C and after a certain steeping time the lacquer layer on the gelatine can be removed. The same process is carried out for the back of the screen. Any residual gelatine is removed once the last of the lacquer has been cleared using an alkaline bath containing sodium carbonate or caustic soda, followed by thorough rinsing.

Neo-batiks A technically improved development of → Batik. Patterns in molten wax are applied to well-stretched textiles (usually natural silk), and aqueous or alcohol-based dye solutions applied with a cotton wool pad. It is then dried and the wax removed by dissolving in organic solvents, or by ironing between sheets of blotting paper. Then the fabric is steamed to fix the dye. In this way, combinations of wax resistance and different colour schemes can be used to produce unlimited effects.

Nephelometer → Turbidity meter.

Nernst's distribution law It is the case with all dissolved substances that the chemical potential in equilibrium must be equal in both solvents:

$$\mu_1 = \mu_1^* + RT \ln C_1 = \mu_2 = \mu_2^* + RT \cdot \ln C_2$$

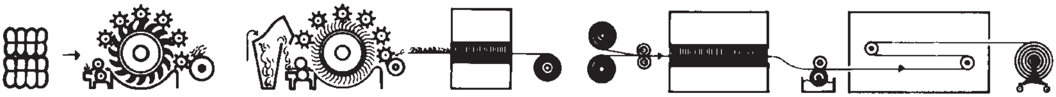

Fig. 1: Production of needle punched felt.

$$\ln \frac{C_1}{C_2} = \frac{\mu_2^* - \mu_1^*}{RT} = \text{const.}$$

and $$\frac{C_1}{C_2} = K$$ (Nernst's distribution law).

K = distribution coefficient,
C_1 = dye concentration in the fibre,
C_2 = dye concentration in the liquor,
μ^* = standard potential,
μ_1 = chemical potential solvent 1,
μ_2 = chemical potential solvent 2,
R = gas constant,
T = temperature.

Nessler's reagent For the detection of ammonia (in water) and for the detection of damaged cellulose (yellow to orange, later grey colouring).

NET (standard pressure increased temperature bleaching process). In contrast to HT bleaching this peroxide bleaching process does not require a pressure chamber steamer. The process is carried out using superheated steam without increased pressure, e.g. in a slightly modified Mather & Platt steamer (N = normal pressure, ET = elevated temperature).

Net curtain fabrics Fine, usually transparent fabrics made from suitable yarns. They must be washable and resistant to stretching and ironing; those made from synthetic yarns generally do not require stretching or ironing after washing. There are various different manufacturing methods for net curtain fabrics: looms (fine muslin, voile, etamine, marquisette, Madras), bobbinet machines, a form of bobbin lace machine (bobbinet, tulle and lace curtains), raschel knitting or crocheting machines (raschel or galloon curtains), knotted lacework machines or by hand (lace curtains), and embroidery machines (dotted muslin, burnt-out or air lace).

Net curtain finishing The finishing of these fabrics varies between extreme types. Net curtain fabrics are made, for example, on looms (voile, marquisette, etamine) or on special machines (tulle or raschel types). The former types are usually finished by separate finishing contractors, the tulles, however, by the manufacturers. Few specialist finishers have access to stenter frames up to 10 m in width and 100 m in length as is required for tulle finishing. Cotton has been widely replaced as a net curtain fabric by polyester or polyacrylonitrile. Polyamide is not sufficiently light-fast for this purpose. Raschel-type net curtains are made in widths up to 450 cm and in this width can be continuously washed, optically brightened or dyed in pastel tones with pigment dyes and fixed and finished on stenter frames. In the latter case, dyeing and finishing can be carried out in a single process. For heavily soiled grey goods or for the dyeing of fuller shades, beam dyeing equipment is used. The main finish to be applied is a dirt-repellent finish. Instead of flame-retardant finishes, flame-retardant fibres are used, e.g. Trevira CS (Hoechst), which also have the advantage of being easier to dye. The tulles, up to 10 m in width, are pre-cleaned, optically brightened or dyed using a deep winch beck. Fixing is carried out by saturated steam in autoclaves. The tulle is unwound to lie smoothly on a perforated cylinder. If the fabric is heavily soiled or needs to be bleached, it can be loaded into the circulation apparatus pack cylinder. Fuller shades can only be applied to polyester under HT conditions using beam dyeing apparatus. Finishes can only be applied to wide fabrics in hank form. The fabric is lightly squeezed, spun and stretched on the frame. For the finishing of cotton net curtain fabrics the usual cotton fabric finishing machinery is used.

Net textile weight A term in the German → Textile Labelling Regulations (TKG – Textilkennzeichnungsgesetz) for the overall weight of the textile raw materials used in the manufacture of a textile product, as the starting value for the weight proportions in percentages, where textile products made from different fibres are classified in decreasing sequence according to their proportional weight. Certain exclusions are made (cf. wording of Textile Labelling Regulations § 6, Sect. 1), e.g. components which are not part of the textile product, such as stiffeners, reinforcements, inserts and fillings, selvedges, facings, ornamentation, binder warp/weft for blankets, floor coverings, soft furnishing fabrics, the base layers of velvets, plush fabrics etc., and finishing agents (fatty compounds, binding agents, filling finishes) and similar.

Nets Generally wide-meshed fabrics which are produced by weaving, knitting, crocheting or on raschel looms.

Nettle fibres Bast fibres (stem fibres) obtained from the native stinging nettle or the Chinese nettle (→ Ramie); fine, strong, rough fibres.

Networking of CAD systems → Integration of CAD systems.

Network materials Due to their particular ductility, textile → Nets are well-suited to three-dimensional, structured materials, for example, impregnated with resin. After deep-drawing they are stabilized by curing (see Fig.: Three-dimensional, structured textile net fabric). Another production method involves the processing of fibres with different shrinkage rates.

Neutral affinity In connection with the dyeing of wool/polyamide blends, certain acid dyes possess a good neutral affinity, and are drawn into both fibres to a certain depth of colour from a neutral dye liquor, without the addition of acids or salts.

Neutral-exchanger → Ion exchanger.

Neutral exhaustion number As a term for neutral pick-up metal complex dyes, the expression is de-

Fig.: Three-dimensional, structured textile net fabric.

rived for what percentage is taken up of a dyebath developed to standard depth 1, at pH 7 and 90°C in 15 min on wool of a certain quality. The neutral exhaustion number characterizes very simply and precisely the homogenity in dyeing behaviour (→ Neutral affinity). (A better basis of evaluation is the ease of combination).

Neutral fats, neutral oils Fats in which all 3 OH groups of glycerine are always esterified with fatty acid esters, such as in liquid fats (olive oil and groundnut oil), which represent neutral oils.

Neutral(ization) A mutual saturation of acid and base until neutral reaction pH = 7 (equilibrium of H and OH ion concentrations). The result is a neutral salt. It is not substantially the latter, however, but in particular the H and OH ion combination “to water”, e.g.:

hydrochloric acid + caustic soda = sodium chloride + water

$$\mathrm{HCl} + \mathrm{NaOH} \rightarrow \mathrm{H}^+ + \mathrm{Cl}^- + \mathrm{Na}^+ + \mathrm{OH}^- = \mathrm{Na}^+ + \mathrm{Cl}^- + \mathrm{H_2O}$$

Neutralization of waste waters In textile finishing waste water is generated by a wide range of different process stages. Dyeing, printing and finishing cause different types of contamination of inorganic or organic origin. The degradation of organic substances can generally take place in biological treatment plant. In many cases the problem of waste water treatment in textiles can be solved by the factory neutralizing its own waste water and then discharging it into the public sewage system (see Fig.).

The Fig. shows a plan of a waste water neutralization plant. This example can be used to explain various problems and solutions which arise. The inflow (1) of waste water from various points during the works network passes first through a filtration plant (2) and then a grease trap. The pumping station (3) pumps the waste water into an equalizing and blending reservoir (4). Often, works generate acid and alkaline waste water at the same time or successively. In this case the tank not only has the function of an equalizing reservoir but this is also where the required self-neutralization of the water takes place. Depending on the local conditions, the water authority determines the permitted pH value for the water to be discharged into the public drainage network. In practically every case a pH adjustment is necessary to achieve this. This is the purpose of the reaction vessel (5) with agitator (6). For example, if the waste water pH value permitted by the local water authority lies within a range of pH 6–9, then in order to economize on acids and alkaline solutions this area will be fully utilized. The automation components are also

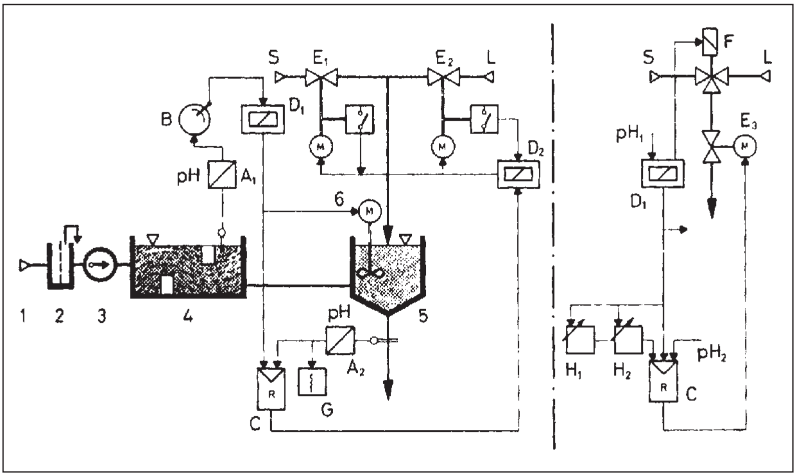

Fig.: Diagram showing a waste water neutralization system
1 = waste water feed;
2 = filtration plant/grease trap; 3 = pumping station;
4 = equalizing and blending reservoir; 5 = reaction vessel; 6 = agitator; A = pH value sensor; B = limit value warning; C = electrical control; D = auxiliary relay;
E = adjustment valve;
F = three-way magnetic valve; G = recorder;
H = target value adjuster;
L = caustic solution feed;
S = acid feed.

shown in the figure. In the equalization reservoir the pH is measured and the limiting value warning actuates auxiliary relay D_1 if the measured value is outside the permitted range. The agitator and controlller (C) are started by D_1. The control device works with a target value of pH 7 for the reaction vessel, for which the second pH value sensor is necessary. Additional substances for this controlled circuit are alkaline solutions or acids, which are added to the reaction vessel by control valves E_1 or E_2. These control valves are interlocked in such a way that only acid or alkaline solution may be metered (D_2). Once the pH tolerance range in the equalization reservoir is reached, the limit value warning (B) switches the control circuit off, both control valves are closed, and the agitator is switched off. The pH value is recorded by the recorder (G) for the purposes of plant monitoring and for the water authorities. The control circuit is therefore only operative if the pH exceeds or falls below the tolerance range. It controls the pH to a value of 7; the expected deviations from the target value do not, however, cover the full tolerance range. This automatic system can be improved even further, as shown in the right-hand section of the diagram: if, for example, the pH falls below pH 6, then the relay switch D_1 starts the control circuit and switches the control unit C to a target value of pH = 6. At the same time, the three-way magnetic valve F is actuated, so that only alkaline solution can be added to the reaction vessel through control valve E_3. By setting two target values, pH 6 or 9, it is possible to ensure that the permitted tolerance is fully utilized in the reaction vessel even during the control process. This concept also involves switching off the control circuit, as previously described, depending on the pH value of the equalizing reservoir, in connection with the closing of control valve E_3.

Neutralizing → Ion-exchange process.

Neutral milling → Milling.

Neutral point (→ Isoelectric point),

wool:	pH 4.9
silk:	pH 5.1
collagen:	pH 7.0

Neutral reaction Neither acidic nor alkaline, corresponds to pH = 7.

Neutral rinsing agent (neutral rinse), a neutralizing after treatment agent for washed items in the last rinsing bath.

Neutral steam process Neutral steam development for stabilized blends of naphthols and diazoamino compounds.

Neutrons → Atomic theory.

New tin A term (in the weighting of silk) for aluminium sulphate.

Newton In the → SI System of Units, the derived unit for force which imparts an acceleration of 1 m/s^2 to a body of mass 1 kg. 1 N = 1 kg · m/s^2.

Newtonian liquids The flow resistance defined by the Newtonian equation of proportionality between shear stress τ and shear rate (D)

$$\tau = \eta \cdot D \ (\eta = \text{const.})$$

is at a given temperature a material constant (Newtonian Flow) known as → Viscosity. For example: liquids of low molecular weight, thinned suspensions of spherical particles etc. Something approximating to Newtonian liquid properties are shown among thickeners, e.g. gum arabic. Newtonian behaviour is a rarity among solutions of high polymers, as most of these solutions are non-NF (non-Newtonian Flow, “apparent viscosity”, “intrinsic viscosity”) at higher concentrations; they do not fall within Newton’s Law. Here, η is not a material constant. Such liquids include, for example, colloidal solutions and suspensions at higher concentrations.

Newton’s Law of Viscosity → Rheological behaviour of solutions.

New Zealand flax or hemp (phormium fibre) → Hard fibres from various lily-type plants, most significantly Phormium tenax (New Zealand, Australia, South Africa, South America). Less valued when water retted. White, yellowish, brownish. Bast bundle 1–1.5 m long, fineness similar to flax. Bast cells 5–15 mm long, 8 – 19 µm wide. Strength 20–40 cN/tex. Applications: (often with manila or sisal hemp) binding twine, ropes, also for clothing, blankets, carpets and for the manufacture of core spun yarns with polyester/cotton.

NF,

I. → New Zealand flax or hemp (Phormium), → Textile fibre symbols, in accordance with DIN 60 001 T4/ 08.91.

II. → Non-ferrous metals.

III. French standard.

nf “Normal strength”, as opposed to hf “high strength”, additional designations for chemical fibres, which are significant when giving technical values.

Nf-metal → Non-ferrous metals.

NI Indonesian standard.

Ni Chemical symbol for nickel (28).

ni Abbrev. for → Non-ionic.

Nickel (Ni), atomic weight 58.7, silver-like → Metals; very ductile (can be hammered, rolled, welded); high strength; magnetic. Density 8.8; melting point 1452°C. Resistant to air, and to aqueous alkalis and acids. Easily soluble in nitric acid, more slowly in hydrochloric or sulphuric acid. Applications: as a metal, essential corrosion protection component in important steel alloys for equipment, machinery, linings, tanks, etc. Nickel salts as dye mordants, for analytical purposes, etc.

Nickel ammonium hydroxide Similar to → Cuprammonium hydroxide, but containing nickel sulphate instead of copper sulphate. Application: for dissolving or (quantitative) detection of pure silk among other fibres; wild silk and tussah silk remain undissolved.

Nickel screens are made for rotary printing using the discharge or rotary screen processes. Nickel screens cannot be recycled, i.e. cannot be re-used for other patterns. → Rotary screens for screen printing.

Night vision One of three components involved in the seeing process, in addition to the nerves and the brain, is the human eye. By multiplication of the spectral energy distribution of the light source with the spectral directional reflectance of the object being observed it can be calculated how much light of each wavelength is reflected and thus reaches the eye. If it is also known how the human eye reacts to light of different wavelengths, a statement can then be made on the perceived colour.

The light entering the eye through the pupil is bundled by the lens and generates on the retina an image of the object observed. The retina contains a large number of light-sensitive photoreceptor cells, called rods and cones. The conversion of the incoming light rays into nerve excitations is done by breaking down dyestuffs in the photoreceptor cells. All of the approx. 120 million rods have the same spectral sensitivity, which is many times higher than that of the approx. 7 million cones. It is therefore the rods which are responsible for night vision, i.e. for the perception of light/dark in low light conditions. In the case of higher light radiation, e.g. normal daylight, they are inactive and therefore of subsidiary colormetric significance. Because all rods have the same spectral sensitivity, → Colour vision is not possible. When the eye is adapted to bright light, e.g. in daylight, the less sensitive cones are responsible for transferring the visual impressions to the brain. There are three types of cone with a relatively broad but varied spectral sensitivity.

Nigraniline → Aniline black.

Nikki-plush → Circular-knit pile fabric (sheared plush). The grey cloth undergoes shearing during finishing, whereby the loops are cut to give a velvety look. The fabric has the elasticity of jersey. Used for outer clothing; also printed. → Circular-knit pile fabric finishing.

Ninhydrin reaction Triketohydrins, white crystals, soluble in boiling water. Only react with protein components and amino acids of low molecular weight. Identification:

I. Protein in a substance: dissolve as much of the substance as possible in a 10% caustic soda solution, boil for 10 min and adjust to pH 6–7 with acetic acid. Boil a few ml with 10–12 drops of a 1% ninhydrin solution for 1–2 min. Blue-purple colour after standing = protein.

II. Protein on the fibre: boil fibre in 1% caustic soda for 15 min, adjust to pH 6–7 with acetic acid and proceed as under I.

III. Triazone, primary amines and amino acids (e.g. in acid extracts of synthetic resin finishes): drop a few drops of solution onto filter paper, dry at moderate temperature, spray on both sides with ninhydrin solution (0.2 g ninhydrin in 120 ml n-butanol and 5 ml 10% acetic acid) and dry for 2 mins at 100°C. Triazone and primary amines (pale lilac), oxyalkylamine (reddish to violet-grey).

Niobium (Nb; columbium, Cb), atomic weight 92.91. Uses since World War II, includes use in German stainless steels as minor addition to stabilise the carbon content (known as carbide former), especially for equipment with working temperatures > 450°C.

NIOSH Abbrev. for National Institute for Occupational Safety and Health; → Technical and professional organizations.

Nip,

I. Passage of material (full-width piece goods) between two rollers, in pad dyeing, calendering and similar. The roller nip is the contact line between the two rollers which concentrates the pressure of the two rollers.

II. The gap between two nip rollers (Fig. 1). There are two types, hard nip rollers, as found in calenders (steel and flexible rollers) and elastic nips between two elastic rollers. An examination of nip formations (Fig. 2) shows a distinction between two limit cases of the elementary functions when padding:

1. Sufficient wetting in the chassis actually dispenses with the need for liquor to pass through the fabric in the nip, as the main role of the nipping process is the metering of the liquor in the goods.
2. If there is insufficient wetting the passage of liquor through the goods in the nip not only has the effect of metering the liquor, but also drives out the air (subsequent wetting).

The liquor pick-up (nip effect) in the nip is shown in the diagram (Fig. 3). The following basic functions are possible:

- compression of the textile goods in the gap between the rollers,

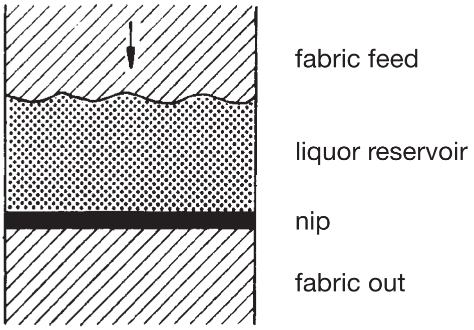

Fig. 1: Padding: nip structure.

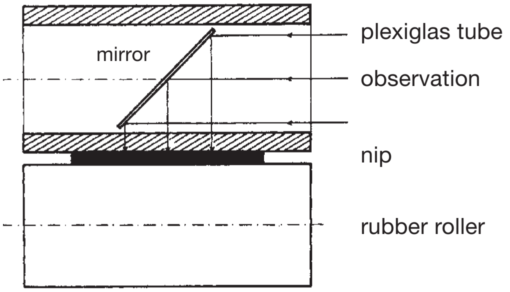

Fig. 2: Observation of the nip structure (according to Schollmeyer).

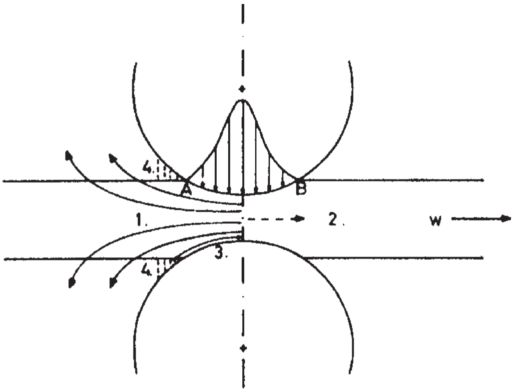

Fig. 3: Diagram showing the squeezing process in the nip. 1 = return flow of liquor; 2 = capillary transportation; 3 = return of liquor to be applied; 4 = liquor wrung out.

- return flow of liquor through the goods,
- capillary transfer in the direction of goods, velocity w,
- liquor adhesion return flow to the rollers,
- return flow of liquor squeezed out, etc.

During the transfer of the reaction mix after the nip, the basic functions take effect; these also play a part when dipping a roller:

- penetration of the fibre material by the water,
- penetration of the fibre material by the dye or the finish,
- evaporation of the water.

(according to Heidemann and Schollmeyer).

Nipco rollers Deflection-free (elastomer) rollers with hydraulic power transmission (see Fig.). Pressure generation with even pressure on outer mantle by means of individual hydraulic supports; load can be applied externally in groups, every 2000 mm, e.g. 5 zones. The Nipco calor roller can be precisely heated from the inside. Used for pads, calenders and other squeezing equipment.

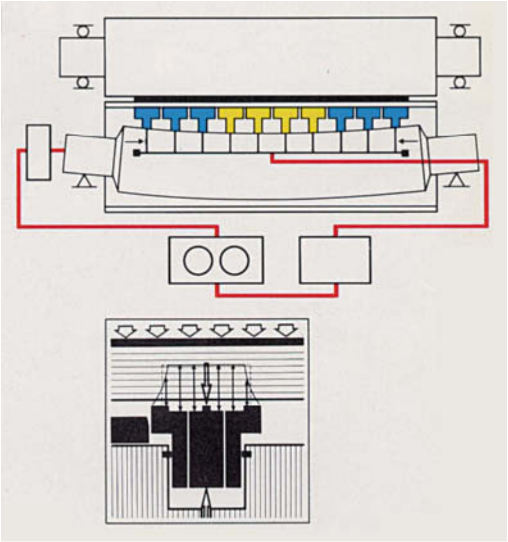

Fig.: Nipco roller system for the control of an individual preasure stamp (Kleinewefers KTM).

Nip padding A particular type of padding (see Fig., Krantz). With the two-roller pad the lower roller is wrapped with cloth and dips into the padding liquor; the fabric is passed between both rollers. Used especially in resist printing, as the short contact with the liquor prevents the resist from softening.

Nip pressure profile With the aid of, e.g. carbon paper, impressions can be obtained of the evenness of the squeezing pressure across the full width of the nip (see Fig., Kleinewefers KTM).

NIRC National Institute of Rug and Cleaning; until 1972 the American institute for carpet cleaning. Successor is → AIDS International. → Technical and professional organizations.

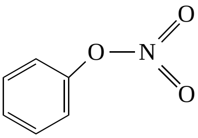
Nitrate discharges → Oxidation discharges for indigo ground.

Nitrate rayon → Nitro rayon.

Nitrates Contain the typical nitrate group $-NO_3$ or $-ONO_2$.

I. Inorganic salts of nitric acid of type $NaNO_3$; usually colourless (exceptions: iron, cobalt, copper and nickel nitrates, etc.); water soluble application as dye mordants.

II. Organic ester of nitric acid of type



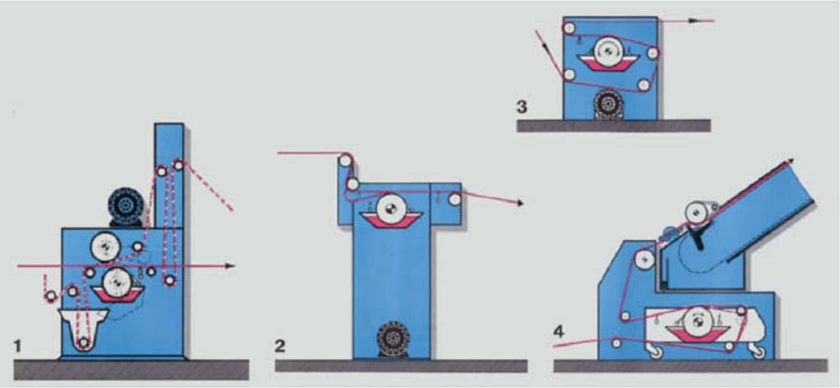


Fig.: Nip padding systems by Krantz. 1 = combined with two-bowl padding mangle; 2 = for the back of the fabric; 3 = for application on the top side of the fabric; 4 = in the fabric feed section of a tiered stenter frame.

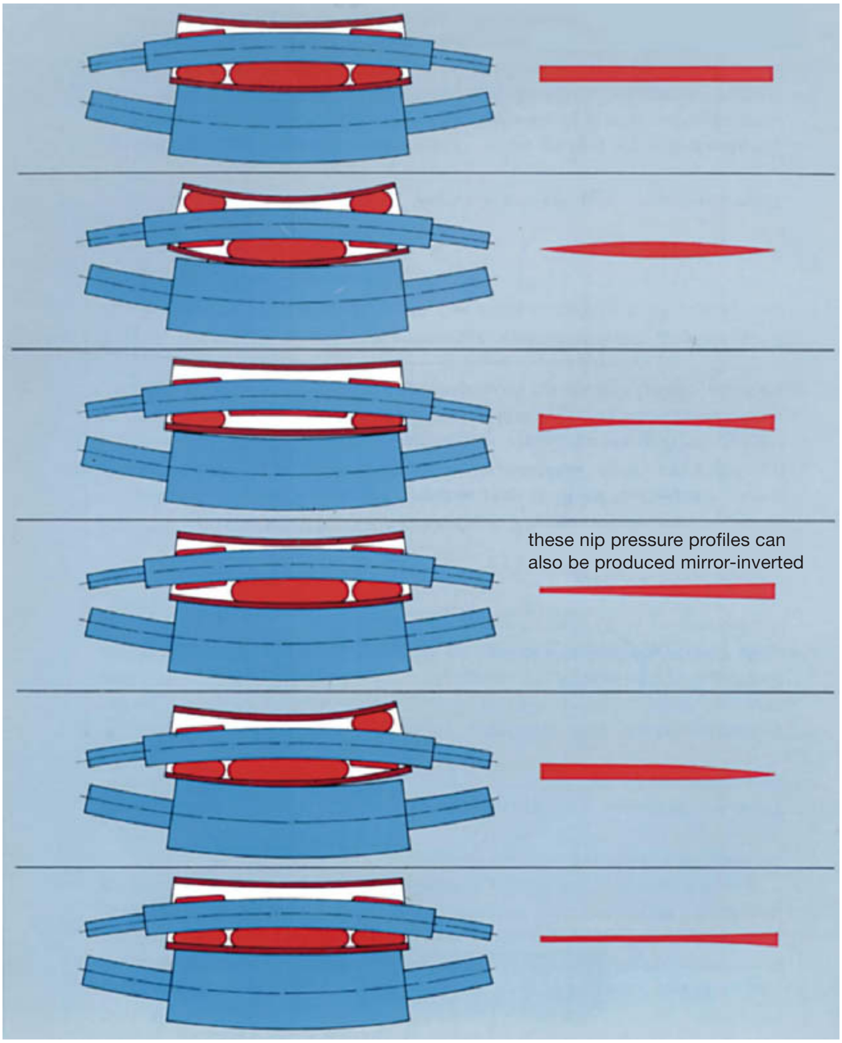

Fig.: Nip pressure profiles with a Bicoflex roller system (Kleinewefers KTM).

The presence of an oxygen (O) bridge is characteristic. In contrast to the → Nitro compounds, this compound as an ester is responsible for the fast decomposition of the nitrates when boiled with acids and alkaline solutions (phenol, nitric acid).

Nitric acid HNO_3. Molecular weight 63. Combines with water to form two hydrates: $HNO_3 \cdot H_2O$ (known as orthonitric acid, also written as H_3NO_4) and $HNO_3 \cdot 3\,H_2O$, the more stable, more important form (actual nitric acid). Salts: → Nitrates. Belongs to the strongest mineral acids. Dissolves most metals except gold (aqua fortis). Applications: the bleaching of silk, fibre identification.

Nitric acid/nitric oxide HNO: hyponitrous acid, salts = hyponitrites ($Na_2N_2O_2$). HNO_2: nitrous acid, salts = nitrites. HNO_3: nitric acid, salts = nitrates.

Nitric acid solubility test For the identification of synthetic fibres.

I. The following are insoluble in hot 10% nitric acid: viscose, casein, polyvinyl chloride, polyacrylonitrile, polyester and polyamide. Soluble: polyvinyl alcohol.

II. The following are insoluble in cold nitric acid: wool, silk, cellulose, casein, polyester, polycarbonate, polyvinyl chloride, polyvinylidene chloride, polyethylene, polypropylene, polytetrafluoroethylene, m-aramide. Soluble: acetate, polyamide, polyurea, polyvinyl alcohol, polyacrylonitrile.

III. The following are insoluble in boiling concentrated nitric acid: polycarbonate, polyvinyl chloride, polyvinylidene chloride, polyethylene, polypropylene, polytetrafluoroethylene. Soluble: wool, silk, cellulose, casein, triacetate and 2.5-acetate, polyamide, polyacrylonitrile, polyester, polyvinyl alcohol, polyurethane.

Nitrification Oxidation of ammonia released by decomposition of biological substances containing nitrogen to form a nitrate, which occurs through the action of aerobic, nitrogen-fixing bacteria (nitric bacteria) (→ Nitrogen elimination). Through aerobic and anaerobic decomposition organically linked nitrogen in waste water is transformed into ammonia ions. From this stage of oxidation, in the presence of specific bacteria (nitrosomonas, nitrobacter), the nitrogen is combined with oxygen from the air in higher degrees of oxidation. The following reactions thus take place:

nitrosomonas:
$NHS_4^+ + 1.5\,O_2 \rightarrow NOS_2^- + H_2O + 2\,H^+ + 230\ \text{kJ}$

nitrobacter:
$NOS_2^- + 0.5\,O_2 \rightarrow NO_3^- + 75\ \text{kJ}$

In good nitrifying plant nitrite is no longer detectable. Nitrite is produced, but is converted to nitrate almost immediately by nitrobacter. The same equations are produced by the whole reaction:

nitrosomonas + nitrobacter:
$NH_4^+ + 2\,O_2 \rightarrow NO_3^- + H_2O + 2\,H^+ + 305\ \text{kJ}$

Nitrite and nitrate are formed when the BOD_5 of the waste water falls to around 20 mg/l. Nitrosomonas and nitrobacter are autotrophic bacteria which assimilate carbon dioxide with the assistance of the energy obtained from the nitrogen oxidation. The prevailing opinion is that the named bacteria react sensitively to higher concentrations of the waste water contents, so that nitrification should only take place if the carbon compounds are largely decomposed, i.e. the nitrite or nitrate content only increases substantially in the case of low end BOD_5. During nitrification there are free protons, which correspond to an acidification of the waste water. Alkalis need to be added to neutralize.

Nitrile alloy American term for synthetic modacrylic fibres of a type in which the improvement of the dyeing behaviour of single-polymerizing compounds (approx. 10% N vinyl pyrrolidone) in the fibre molecule appears equally concentrated. Thus a more regular copolymer fibre is produced than is the case with irregularly modified polyacrylonitrile fibres. Thus a nitrile alloy has considerably more cross-linking hydrogen bridges, which in addition to notably good dyeing properties (also well-suited to anthraquinoid vat dyes) is particularly noted for its mechanical properties (see Tab.).

	Nitrile alloy	Unequally spaced copolymer (otherwise similar chemical composition)
density	1.19	1.17
moisture absorption	2.5 %	1.6 %
boiling water 6 min.	approx. 1 %	approx. 8 %
shrinkage 10 h	approx. 2 %	approx. 12 %
softening	254°C	> 253°C

Tab.: Properties of nitrile alloys.

Nitrilotriacetic acid (NTA), $N(CH_2COOH)_3$, used for complexometry and as a waste-water chelating agent. Iin the latter case at temperatures above 10°C full decomposition takes place both in sewage treatment plants and in river water, only partial decomposition at around 10°C, whilst at temperatures below 5°C it stops completely in river water and to a large extent in sewage plants. Nitrilotriacetic acid, as a potential phosphate substitute, possesses calcium compound-forming properties, but unsatisfactory biodegradability (after adaptation 3–74% BOD_{30}) and also negative toxicological effects through remobilization of mercury and cadmium compounds from sediments (redox potential ~ 100).

Nitrilotriacetic acid salts (aminotrimethylcarboxylic acid salts), salts from → Nitrilotriacetic acid, $N(CH_2COOH)_3$. This organic chelating agent, one of the → Aminopolycarboxylic acids is, in the form of sodium salts, resistant to boiling and alkalis. It displays maximum effectiveness at 70–100°C. Magnesium hardness only occurs with application of heat, but, not as calcium hardness, also in caustic alkaline solution.

Nitrite-containing untreated water Evident from traces of yellow staining of animal fibres. This in turn leads to divergent, dull dyeing (the effect of light can cause colour transformation to brown), dye alteration or destruction, general dyeing difficulties, difficulties with tone-in-tone dyeing of blends, changes in coupling dyeing, etc.

Nitrite reaction For the detection of urea, thiourea, dicyandiamidine, glyoxalureine in, e.g., synthetic resin finishes: approx. 5 ml of an acid resin extract is mixed with 1 ml conc. hydrochloric acid and 2–3 drops of approx. 0.1 n sodium nitrite solution. Every 3 min during the 15-minute process, a drop of the test solution is applied to potassium iodide paper. The blue colour is evaluated immediately thereafter. If the colour gets progressively fainter on each application until it fades away completely, the outcome is positive. In addition, if dropped onto a glass surface, nitrogen bubbles form. If the reaction is positive, but without nitrogen bubbles, this means the presence of nitrosamines, which are formed from imidazolidones and pyrimidones which react easily with nitrous acid. They are finally identified by the following reactions:

I. → Diphenylamine sulphuric acid (deep blue colour).

II. → Liebermann’s indophenol reaction (purple, deep blue colour).

III. Dimethylaniline test: add 1 drop dimethylaniline and a little conc. hydrochloric acid and warm. Yellowish-red nitrodimethylamiline hydrochloride.

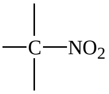
Nitrites Salts of nitric acid (HNO_2). A typical example is → Sodium nitrite, $NaNO_2$. Nitrites are usually colourless (exceptions: cobalt, copper, nickel nitrite, etc.) and easily soluble. Easily decomposed when heated. Application: for diazotizing.

Nitroaniline $C_6H_4NO_2NH_2$: (ortho-, meta-, para-) nitrified → Aniline. Crystalline intermediate products of dye synthesis.

Nitrobacteria Micro-organisms (e.g. bacterium coli commune, typhus bacillus) which oxidise organic nitrogen compounds (ammonia, nitrites, etc.) in the ground, ground water, etc., to nitrates. Nitrobacteria are of significance in connection with the water supply for textile processes.

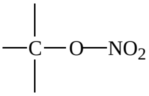
Nitrocellulose,

I. An erroneous term for → Cellulose nitrate. This is not a → Nitro compounds.



$$-\overset{|}{\underset{|}{C}}-NO_2$$

but a cellulose nitrate



$$-\overset{|}{\underset{|}{C}}-O-NO_2$$

A typical ester of cellulose, with characteristic sensitivity when boiling with acids and alkalis.

II. Not a homogeneous chemical compound, but a combination of various highly nitrified cellulose molecules. Cellulose dinitrate = collodion cotton, cellulose trinitrate = “gun cotton”. Nitrogen content 12.6–13.4%, in collodion around 10–11%. Fibrous, similar to cotton. Density 1.66. Easily flammable. Insoluble in cold and hot water. Further details → Collodion cotton. Solvent: esters, alcohols, ketones, oxyethers, very readily soluble in cyclohexylacetate. Thinner: benzene, benzine, toluol, carbon tetrachloride, ethanol. Application: fixing of the thickening agent for pigment, bronze and lacquer printing, and in large quantities for lacquer manufacture.

Nitrocellulose colours A sub-group of → Colour lake substance of colour pigments in collodion or nitrocellulose varnishes.

Nitro compounds contain the typical nitro-group $-NO_2$, e.g. nitro dyes, usually acid yellow or orange dyes. Other nitro compounds are nitrobenzene, nitrophenols, etc. In all nitro compounds the $-NO_2$ group is always immediately bonded to carbon (thus in contrast to organic → Nitrates), which results in good chemical stability. Thus nitrobenzene is absolutely stable, i.e. indestructible, in the presence of acids and alkalis.

Nitrogen Symbol N, atomic weight 14.04. → Non-metals, gases; colourless, odourless, tasteless; suffocating effect; non-flammable at normal temperatures, fairly slow to react. Combines with hydrogen, oxygen, carbon, boron, silicon, magnesium, calcium. Compounds: with hydrogen to give ammonia NH_3 (ammonium salts, ammonium bases = hydroxylamine, hydrazine, organic amides; amines, acid amides). With oxygen to give oxides or -ous oxides (nitrous oxide N_2O, nitrogen oxide NO, nitrogen trioxide N_2O_3, di- and tetroxide $2\ NO_2 \leftrightarrow N_2O_4$, pentoxide N_2O_5), which react with water to give → Nitric acid/nitric oxide.

Nitrogen elimination The government regulations for the discharge of waste water into water systems place strict requirements governing the residual concentration of the nitrogen, especially in the form of ammonia derivatives. The introduction of nitrogen must be limited in those places where communal sewage treatment plants are already overloaded with this form of pollutant. Nitrogen compounds in waste water

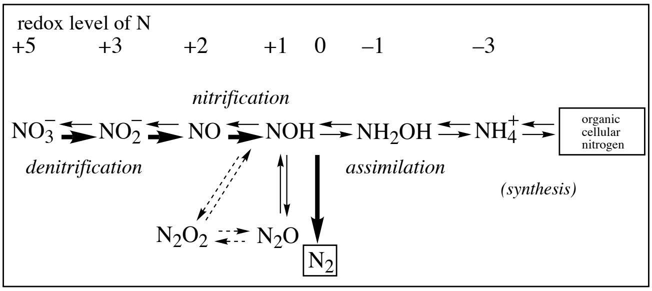


Fig. 1: Diagram showing the nitrogen compounds present during biochemical reaction in stagnant and flowing water.

arise from both organic and inorganic compounds, especially since nitrogen is one of the most important components of organic material. The total nitrogen content in unpolluted waters is practically always below 1 mg/l. If there is organic material in the water, this is ammonified by biochemical processes, e.g. in the case of protein:

proteins → peptones → polypeptides → amino acids → (urea) → ammonium.

Therefore prior to the introduction of the BOD$_5$ regulations, the ammonium-nitrogen content was used as the criterion for the evaluation of acute water pollution. In water systems and water treatment, nitrogen compounds constantly undergo biochemical transformation. The most important reaction stages of the chemical processes are nitrification, denitrification and assimilation (Fig. 1).

A range of adverse effects of the various nitrogen components includes:

1. Any ammonium nitrogen reaching the outfall is oxidized there to nitrate nitrogen; the necessary oxygen is drawn from the water, causing the oxygen content to sink below the necessary minimum in critical situations.
2. The increase in nitrogen can contribute to the growth of algae.
3. Depending on the pH, ammonia can be toxic to fish, and high concentrations of ammonia can also have a toxic effect on nitrifying bacteria.
4. High concentrations of nitrates, and in particular nitrites, in the drinking water pose a health risk to the public. Nitrates can lead to cyanosis in young babies. In addition nitrates and nitrites can contribute to the formation of carcinogenic nitrosamines.

Consequently nitrogen elimination is very important. As the chemical processes necessary for the removal of the dissolved nitrogen are not economical to implement due to the high solubility of the NH_4^+-, NO_2^-- and NO_3^--ions, nitrogen is eliminated using the self-cleaning biochemical processes of the water. The majority of nitrogen compounds are removed as a result of the nitrification and denitrification. The elimination of the ammonium nitrogen present in the pre-settled waste water therefore takes place in two stages. In the 1st stage of nitrification, the nitrogen is oxidized from the reduced form (oxidation number –3) to nitrate (oxidation number +5). This anaerobic process is followed in the 2nd stage by denitrification, which takes place under anoxic conditions, i.e. in the absence of free molecular oxygen, but in the presence of nitrate. The nitrate nitrogen is hereby partially reduced to molecular nitrogen (oxidation number 0), which as a free gas (N_2) can easily be removed from the water due to its low solubility. The high oxygen requirement of the 1st stage and the complete absence of oxygen in the 2nd phase require a separation of the process into two reaction areas. The microbial decomposition of the organic carbon compounds in the waste water, which is also required, can take place simultaneously with the nitrification, or in a prior biological cleaning process.

1st stage: the nitrification in the aerobic biological waste water treatment first takes place when the carbon-containing compounds have largely been decomposed. Nitrite and nitrate are only formed once the BOD$_5$ of the waste water has dropped to approx. 20 mg/l. The nitrification is linked to the metabolic processes of specific specialized types of bacteria; nitrosomonas (NM) and nitrobacter (NB). Both are autotrophic bacteria, which assimilate carbon dioxide using the energy obtained from nitrogen oxidation. The following reactions take place:

$$NH_4^+ + 1^1/_2\,O_2 \rightarrow NO_2^- + H_2O + 2\,H^+ + 230\,kJ$$

$$2\,H^+ + 2\,HCO_3^- \rightarrow 2\,CO_2 + 2\,H_2O$$

The protons formed by ammonium oxidation immediately undergo further reactions and destroy the carbonate-hydrogen carbonate buffer of the waste water, which can lead to a pH < 5.5. Alkali must be added for neutralization purposes. The further oxidation of the nitrite to nitrate can only be carried out by bacteria of the nitrobacter species:

$$NO_2 + {}^1/_2\,O_2 \rightarrow NO_3^- + 75\,kJ$$

Thus a total of 2 mol oxygen is needed for the full nitrification of 1 mol ammonium. In good nitrification plants, nitrite is not detectable, as it is immediately oxidized by nitrobacter. The high degree of specialization of the nitrifying bacteria requires a special environment, the maintenance of which is the defining influence on the degree of nitrification obtainable.

Nitrogen elimination

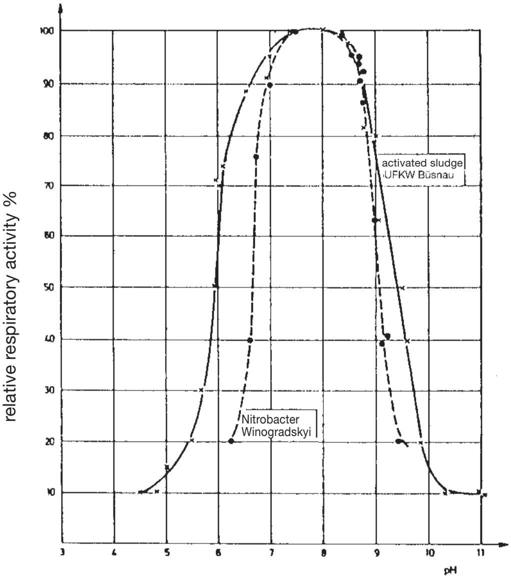

Fig. 2: Respiratory activity in relation to pH for a) activated sludge of the Büsnau training and research sewage treatment plant at Stuttgart University and b) Nitrobacter Winogradskyi.

Most microorganisms have a clear pH optimum, which is even more marked in the case of nitrifying bacteria. Fig. 2, shows the respiratory activity of activated sludge bacteria and nitrobacter, in relation to the pH. The optimum pH range is relatively narrow and in the case of activated sludge, bacteria and nitrobacter lie in the weak alkali range, for nitrobacter at approx. pH 7.5–8.3. Outside this range there is a sharp decline in the respiration activity. Therefore it is especially important to control the pH for the nitrification stage, particularly since the pH can fall due to nitrification because of insufficient hydrogen carbonate buffer; in certain circumstances optimum nitrification may only be maintained by the controlled addition of, e.g. sodium carbonate.

All nitrifiers are obligate aerobic bacteria, which makes it essential to ensure a sufficient oxygen supply to the system. The oxygen concentration of the water should, therefore, be constantly maintained above 2 mg O_2/l. The growth rates of the nitrifying bacteria lie well below those of the other waste water bacteria. At a temperature of 20°C nitrosomonas has a growth rate of $\mu = 0.34\ d^{-1}$ and nitrobacter of $\mu = 0.14\ d^{-1}$. The slow multiplication means that the bacteria are easily washed out of the system, which can only be compensated for by the age of the sludge. Nitrifying bacteria are limited in their biotic activity in the presence of organic, biodegradable substances in the water, so that nitrification can only take place in the case of low biological charging or residual charging. A range of heavy metal ions such as hydrogen sulphide, mercaptane, aliphatic amines and other toxic substances can upset the nitrification process even in very low concentrations. Sudden changes in temperature and other changes in the environmental conditions can also lead to an immediate reduction in the nitrification rate.

Technical nitrification may be carried out either by carbon oxidation in an aerobic, biological treatment plant, or as a separate process. The separation of carbon and nitrogen oxidation allows, above all, a separate control of the influential parameters of pH and oxygen content by intensity of aeration, which is significant for the optimization of the nitrification process. Fixed-bed reactors (e.g. percolating filters), which enable immobilization of the nitrifying bacteria, are particularly suited to separate nitrification. The good adhesive properties of the nitrifying bacteria types mean they can increase and multiply whilst fixed to the carrier without substantial losses by washing out. Also, in a fixed-bed reactor, a system with a longitudinal throughflow, they have more stable living conditions than in a fully mixed activated sludge suspension with free-floating micro-organisms. This is of great importance to bacteria as sensitive as nitrosomonas and nitrobacter.

2nd stage: The denitrification can be carried out by a number of heterotrophic activated sludge bacteria. Under anaerobic conditions the free molecular oxygen is substituted by nitrate or nitrite oxygen as the electron acceptor.

$$NO_3^- + 5\,H^+ \rightarrow 1/2\,N_2 + 2\,H_2O + OH^- - 360\ kJ$$

Many facultative heterotrophic bacteria may convert without difficulty to adaptation from oxygen breathing to nitrate respiration in an anaerobic environment. This respiration, termed denitrification, equates biochemically to oxygen respiration. It is effective to the extent that it reduces the proportion of free oxygen. Despite biochemical equivalence of the respiration systems, the enzymes formed need not be identical, as the tendency towards denitrification is linked to adaptive enzymes. Furthermore an electron donor is necessary to augment the redox processes. This may be made available in the form of organic carbon compounds, which are either present in the activated sludge or are added from outside. Due to its low cost and fast, full decomposition, methanol (CH_3OH) is often used for this purpose:

$$5\,CH_3OH + 6\,NO_3^- \rightarrow 3\,N_2 + 5\,CO_2$$

$$+ 6\,OH^- + 7\,H_2O - 750\ kJ$$

This reaction is slightly alkaline and leads to a slight increase in the buffer capacity in accordance with the following equation:

$$5\,CO_2 + 6\,OH^- \rightarrow 5\,HCO_3^- + OH^-$$

In contrast to nitrification, denitrification is not carried out by specialist bacteria and therefore does not require any special environmental conditions. The dependency of the respiration performance of denitrifiers corresponds in general to that of an activated sludge. As the affinity of the electrons to molecular oxygen is essentially higher than to nitrate oxygen, effective denitrification can only take place in the complete absence of free oxygen. As the denitrification tank has to be operated anaerobically, instead of by aeration, a slow agitator is installed which ensures thorough mixing and prevents the sludge from settling out. It is therefore possible to use fixed-bed reactors which through intensive bacterial growth give high volume-specific denitrification rates.

The ammonia desorption is a physical-chemical process for the elimination of nitrogen. Using this method, nitrogen can simply be removed from the waste water in the form of ammonium. Organic and oxidized inorganic nitrogen components are not included. It is therefore only usefully applicable for waste water which is already ammonified, or industrial waste water with high ammonium content. In the neutral range ammonium nitrogen is present in the form of the ammonium ion (NH^+_4). If the pH increases into the alkaline range, the dissociation equilibrium is shifted to free molecular ammonia (NH_3):

$$NH_4^+ + OH^- \rightarrow NH_3 + H_2O$$

Given a pH of 10–11 (Fig. 3) approx. 80–90% of the nitrogen components are present as ammonia. This is useful in ammonia desorption, in that the free ammonia is desorbed and released in the form of a gas. This process, described as “stripping” involves an internal contact between air and waste water, which enables the release of gaseous ammonia into the atmosphere.

Desorption plant is similar in construction to an industrial cooling tower. A strong fan provides the necessary air input, and an inbuilt grid system ensure the separation of the water flow into small droplets with a large surface area. Ammonia is very easily soluble in water, so that desorption requires a great expenditure of energy. The strong temperature dependency of the solubility of the ammonia requires, for example, for a 90% ammonia desorption at pH 11 and 0°C, almost 6000 m^3 air per m^3 waste water; at 20°C the requirement is still around 2200–3700 m^3 air per m^3 waste water. Ammonia desorption can be particularly economical if used in conjunction with lime phosphate precipitation, as this process gives a pH of practically 11. However limestone deposits can lead to problems of blockages.

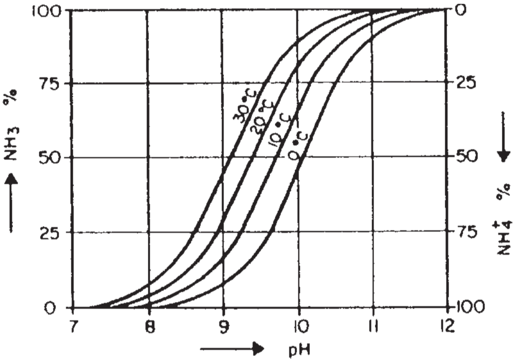

Fig. 3: Dissociation equilibrium for ammonia in relation to pH and temperature.

Nitrogen oxide gases (NO_x), gas combinations containing nitrogen oxide. Arise, e.g. when diazotizing and as gases from combustion (→ Exhaust gases). They are given the symbol NO_x, as their precise composition with relation to the proportions of NO and NO_2 is usually not known.

Nitrogen oxides Oxygen compounds of → Nitrogen, such as NO, NO_2, N_2O_3. Component of → Nitrogen oxide gases. Grouped in combustion gases under the designation $(NO)_x$, as the precise composition is generally unclear.

Nitrogen shock cooling If woollen fabrics which are overdried are treated with liquid nitrogen (see Fig.), the fabrics are shock cooled and when thawing are very moisture absorptive.

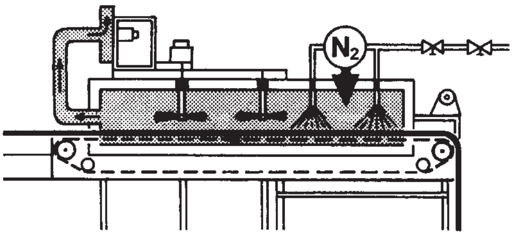

Fig.: Shock cooling with liquid nitrogen (N_2).

Nitrogen test in resin finishes,

I. Caustic soda test: boil a small fabric sample (approx. 3–4 cm^2) in a test tube with approx. 4 ml 32% caustic soda: released ammonia (positive nitrogen test) can be determined by the smell, with pH paper or by distillation with Nessler’s Reagent (yellowish-brown precipitation).

II. Thiocyanate test: finely grind a test sample in a mortar with sodium thiosulphate, then heat in a crucible on a sand bed until the solids start to burn, then boil off the residue with the addition of water; test the thiocyanate formed with ferric chloride: red coloration = positive indication of nitrogen. If nitrogen is indicated, the following could, for example, be present (without formaldehyde): polyamide and polyacrylonitrile and (if formaldehyde is also shown positive) amide resins; apart from any fibres which may upset the reaction such as cotton, polyamide, polyacrylonitrile.

Nitrogen test on damaged wool The usual methods for the detection of soluble nitrogen (sun-damaged, acid or alkali damaged wool) by the melting of the substance using sodium metal and the transfer of the sodium cyanide formed into Berlin blue, is often not appropriate in the case of dyed woollen materials. The process known as the micro-Kjeldahl process is acceptable.

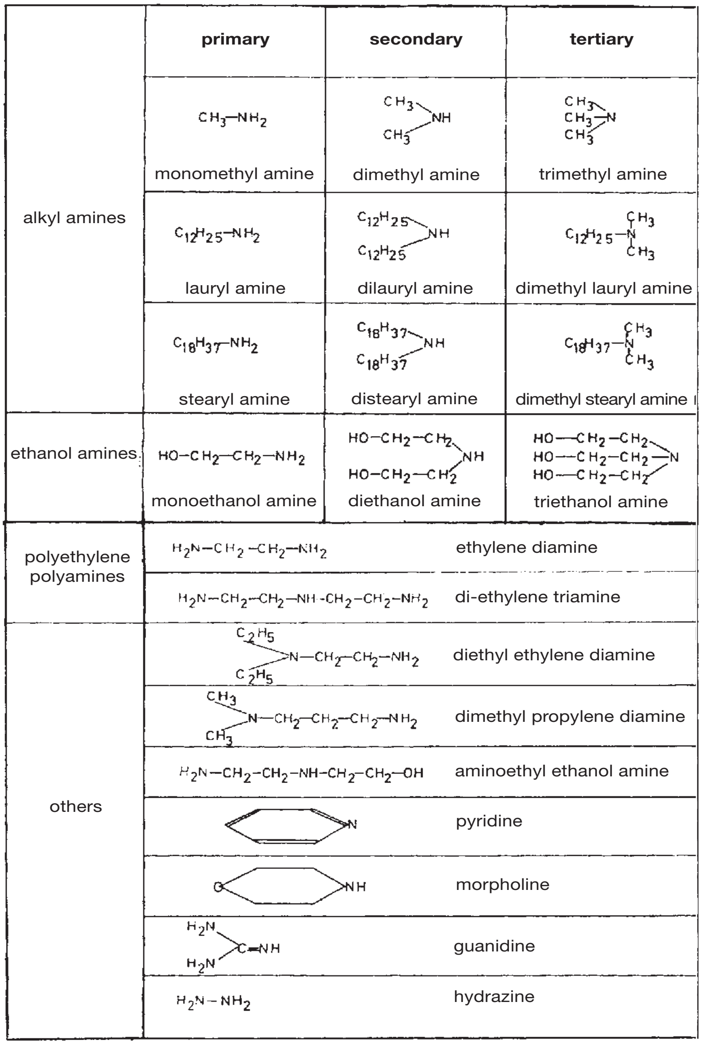

Fig.: Amino components in fabric softeners.

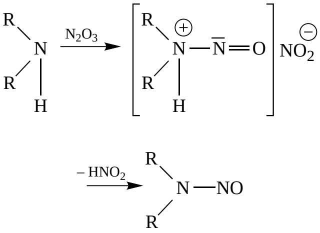
Nitro rayon (Chardonnet rayon), the first man made fibre (1884 by the Earl of Chardonnet). Produced from → Nitrocellulose, using ethanol and ether. → Man made fibres.

Nitrosamines Alkyl derivates of the type R–NH–NO, play a part, e.g. in the coupling of naphthol dyes. Softener on the basis of secondary and tertiary amines (see Fig.) may provide the chemical basis for the formation of nitrosamines during application.

Because of pronounced basic properties, high volatility, an intense smell and latent risk of formation of nitrosamines, effective measures during storage, transport, processing, operations and disposal are essential. Particular attention should be paid to the risk of nitrosamine formation of secondary amines with nitrous gases, as this is recognised as extremely carcinogenic in many animal species:



Nitrous acid treatment The introduction of the nitros group (NO) into an organic compound, e.g. through the effect of nitrous acid.

Nm,

I. → Metric number.

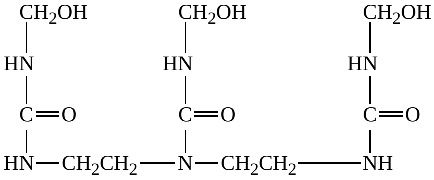
II. Unit of newton multiplied by metre, as a unit of torque.

N-Methylol compounds Compounds with one or more M-methylol groups $–N–CH_2OH$ (reactive group for crosslinking reaction). Produced by replacement of formaldehyde with appropriate compounds containing NH or NH_2 groups. There are two different types, linear (e.g. dimethylocarbamates) and cyclic N-methylol compounds (e.g. DMEU) with at least two functional groups, also etherified, $–N–CH_2–O–R$, (R usually CH_3). Applications include as crease-resist agent, of which it is the most important class of compound, e.g. →: Urea; Melamine-formaldehyde compound.

N-methylol group → N-Methylol compounds.

N-methylolacrylamide → Methylolacrylamide.

N-methylolpolyethyleneureas A crease-resistant finish; products of the reactions of polyethylene amines or imines, urea and formaldehyde, e.g. from diethylene triamine, urea and formaldehyde:



$$\begin{array}{ccccc} CH_2OH & & CH_2OH & & CH_2OH \\ | & & | & & | \\ HN & & HN & & HN \\ | & & | & & | \\ C{=}O & & C{=}O & & C{=}O \\ | & & | & & | \\ HN & -CH_2CH_2- & N & -CH_2CH_2- & NH \end{array}$$

NMMO-Cellulosic fibre The NMMO process is a solvent spinning process in which a Lyocell fibre is produced from cellulose in only a few stages, without the supplementary addition of chemicals (see Fig.). The technique represents a solution to the environmental problems caused by the usual methods (waste water and air emissions).

NMMO stands for N-methyl morpholine oxide, a cyclic amine oxide, in which cellulose is very soluble. The production of this solution with NMMO makes it

fibre types	NMMO	Giza 70*	viscose	Modal
FStr. (cN/tex) fibre strength, dry	45	34	26	35
FEI. (%) fibre elongation, dry	12	8	17	14
FStr. (cN/tex) fibre strength, wet	39	41	14	20
FEI. (%) fibre elongation, wet	19	21	7	8

Tab.: Comparison of fibre properties (Giza 70 = long-staple Egyptian cotton).*

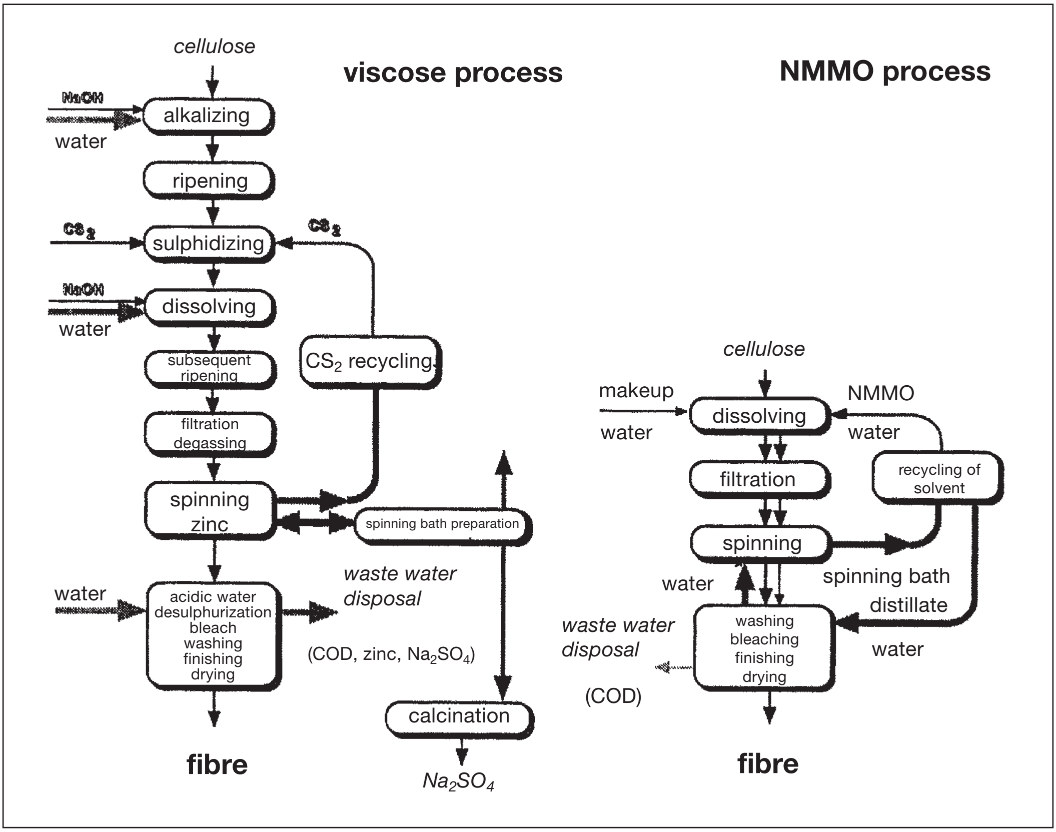


Fig.: Comparison of the viscose and NMMO (Lyocell) processes (Lenzing AG).

possible to regenerate the spun fibre in a precipitating bath of water without additional chemicals. Moreover, the aqueous NMMO solution can be re-used for the production of further solutions. This gives rise to a practically 100% closed circuit. The resulting Lyocell fiber properties are listed in the Tab.

NMR Spectroscopy (Nuclear Magnetic Resonance). This is used to determine the structure of substances. Pauli postulated isotopic spin to interpret the hyper-fine structure of atomic spectrums as early as 1924. In 1945, the first successful nuclear magnetic resonance tests were carried out on condensed matter. Bloch and colleagues observed proton resonance on a water sample in what was by today's standards a weak magnetic field as a small wide lobe on the oscillograph screen. In 1952, Bloch was awarded the Nobel Prize for Physics together with Purcell, who had observed the phenomena of nuclear magnetic resonance at the same time on solid paraffin.

Natural frequency is dependent on the chemical environment of the nucleus under observation, conditional upon the shielding of the electron shells. This chemical displacement, measured in ppm, is the basis for the use of NMR in chemistry. Several nuclei, e.g. protons, in a molecule also display a characteristic interaction which is expressed in the spectrum as a fine splitting of the resonance lines. The extent of this bonding and the multiplicity of the splitting provide a wealth of information on the number and type of adjacent nuclei as well as the number, type and geometry of the bonds between the nuclei within a molecule. The three values which can be extracted from a spectrum - position, intensity and bonding - are the corner stones of NMR spectroscopy structure analysis in solutions.

The actual sensor, isotopic spin, is a natural phenomena within the module. NMR spectroscopy can in principle be carried out on all nuclei which have a nuclear magnetic moment. In the classification of elements, there are 116 magnetically active nuclei, although only a few achieve the high sensitivity of protons. The strength of the magnetic moment and the natural frequency of the NMR-active isotopes are crucial here. In organic chemistry, C-13 NMR is of the greatest importance along with H-1 NMR. The natural frequency of the NMR-active carbon isotope C-13 is 1.1%. If the magnetic moment, which is smaller than that of protons, is taken into consideration, this means lower sensitivity by almost ten to the power of four. However, C-13 NMR has formed the basis of routine spectroscopy for a long time. Apart from the wide and increasing use of metal-NMR, F-19 NMR, P-31 NMR gained importance at an early stage and Si-29 NMR, N-15 NMR, O-17 NMR and H-2 NMR have only become significant with improved measuring technology. The introduction of the pulse Fourier transform technology (1966) had two consequences: NMR-spectroscopy of rarer nuclei was considerably extended and completely new measuring methods were developed.

With conventional pulse spectroscopy, a high-energy high frequency pulse is used to excite isotopic spin, the response of the released sample is detected inductively and registered on a time-dependent scale. The spectral information is obtained as a function of a frequency from the time function of the macroscopic magnetisation using Fourier transformation. If two or more pulses, which follow on from each other in a defined and gradually extended time interval, are adjusted for excitation, another frequency axis is created; the resulting range is therefore three-dimensional (intensity as a function of two frequencies) and is generally recorded as a contour line diagram (contour plotting). The bond relationships of the protons to each other or together with other nuclei can be made visible across the entire molecule, the spatial environment can be observed and dynamic processes can be detected and characterised. The three-dimensional structure of proteins can be clarified. This variety of methods and the resulting density of information on the molecular structure is unique to molecule spectroscopy. (according to Deusch).

NNI A Dutch standards body; → Technical and professional organizations.

NO Abbreviation for Norwegian patent.

No Chemical symbol for Nobelium (102).

No-Dip process in dry cleaning Based on the principle of cleaning drums which work without dipping (→ DIP process). As the dirt released is immediately removed from the machine to the filter, the risk of greying of the goods is substantially limited. As it operates without liquor and increased fall height, the no-dip process causes increases mechanical friction and thus an enhanced cleaning effect. In the case of chlorinated hydrocarbons is only recommended for particularly badly soiled goods, but not for delicate clothing.

NOEC (no-effect concentration). When surfactants are biologically degraded, for example, the first stage of the oxidation can be at the hydrophobic end of the chain:

The surfactant loses its effectiveness as a surface-active substance, i.e. if during biodegradation the surfactant concentration drops below a certain level,

– it is no longer detectable using the usual tests,
– it no longer foams,
– it is no longer toxic to fish.

No-Gel A foam carpet backing without gelling agent.

No-Gel-Foam A foam of natural or synthetic latex (for carpet backing, e.g. tufted pile), which is directly vulcanized in a single stage. The process is selected on the basis of the latex type and crosslinking system. All generally have high proportions of extenders from 150-220 parts per 100 parts latex solids and specific soap systems as foaming agent. In the case of no-gel foam based on cold latex, the foam system is derived from combinations of sodium sulphosuccinate and (particularly in the case of low litre loads) additional sodium lauryl sulphate. No-gel foams, of good foam structure, can also be produced on the basis of carboxyl latex, either sulphur or resin cross-linked.

No Iron Another term for crease resist finish. The literal expression of the purpose of this finish: no ironing is necessary after the washing process. The most frequently-used term is → Wash and Wear.

Noir reduit (steam black). Oxidized → Logwood extract for printing.

Noise emission Since the introduction of the German “Noise” Accident Prevention Regulation (Unfallverhütungsvorschrift “Lärm”; VGB 121) on 1.12.1974, ear protection must be provided for noise levels of over 85 dB(A), and ear protection must be worn from 90 dB(A) and above (→ Noise protection). Within a transition period of 3 years, i.e. by 1.12.1977, all employees working in noisy areas (levels assessed at ≥ 90 dB(A)) had to be given precautionary tests which would establish any hearing impairment caused in the past. In practice the wearing of personal ear protection does not guarantee freedom from the risk of hearing impairment.

Noise meter → Sound level measurement.

Noise protection Existing regulations require that machine manufacturers and operators increasingly reduce noise emissions from machines and noise immissions at the workplace (→ Industrial noise pollution). The EU Directive on protection against noise at the workplace, which has been implemented in Germany in the revised version of the Regulation for the Prevention of Accidents (UVV – Unfallverhütungsvorschrift), “Noise”, and the EU machine protection directive which was subject to national legislation up until the end of 1992, in particular give rise to considerable obligations relating to noise protection with which companies must comply. An example is the duty to declare noise immissions in the operating manual. Various methods of measuring noise levels are given in the applicable statutory regulations relating to industrial noise protection. A distinction can be made here between the following range of tasks:

– measurement of noise immissions,
– measurement of noise emissions,
– noise analysis for noise reduction.

Measurement of noise emissions and immissions should be clearly distinguished - noise emissions relate to the noise radiating from a machine, and noise immissions relate to the effect on the environment. A distinction can therefore be made between the two in terms of their objective: Measurement of noise emissions is used to assess a source of noise whereas measurement of noise immissions assesses the effect on humans. Both are directly related, thus it is possible to calculate e.g. the noise immission at a specific point (e.g. on a production line) if the noise emissions of all the machines together with the acoustics are known.

1. Measurement of noise immissions are necessary e.g.

– to recognise any potential risk to hearing at the workplace,
– to ascertain noise hazardous zones,
– to select suitable forms of ear protection,
– to test whether warning or danger signals can be detected sufficiently well in a noise hazardous zone,
– to check compliance with the limit values of 55, 70 and 85 dB (A), differentiated depending on activities and use of space as specified in the workplace directive (§ 15).

Procedure is described in DIN 45 645, Part 2.

2. Measurement of noise emissions is particularly significant for assessing new installations. According to the EU Directive 86/188 on the protection of employees against noise or the German Regulation for the Prevention of Accidents (UVV), “Noise”, the operator must find out about the anticipated noise emissions before purchasing a machine and must only purchase a machine which is in line with technical regulations. To support the operator, → VDI guidelines for certain groups of machines are available in Germany which give information on the status of noise reduction technology. For the textile machinery group, there is for example VDI guideline 2572, “Noises from textile machinery and in textile machinery halls and measures to reduce noise”. In Germany, it is also possible for a test institute approved under the Industrial Safety Act to assess whether a machine corresponds with the latest technology in terms of noise emissions. The test institute is also obliged to record and assess the noise emissions during the voluntary prototype test of a machine as stipulated by the law (GS-label = safety approved). Practical implementation of the measurement of noise emissions is described in Standard DIN 45 635. Parts 1–9 deal with different framework measuring methods, comparable with ISO 3740 to 3747 (according to Maue).

Nomad carpet → Oriental carpets, plush-like, with pile cropped to a greater or lesser extent, warp, weft and knotted sheep or goat wool pile (100 000–300 000 knots per m^2). Mainly narrow pieces (prayer mats, rugs, mats). Design (work of nomads) differs slightly in pattern, width, colour, often distorted and creased.

Nominal blending ratio (DIN 60 003), the given ratio of the fibre types used in a textile product.

Nominal diameter The approximate internal diameter of pipe connections, bracings, etc., in mm or inches. It is the determining dimension for the statement that parts of a specific nominal diameter fit together; whether they are functionally accurate is another matter.

Nominal pressure The maximum permissible → Working pressure in bars at 20°C. It is therefore sufficient when denoting the application range of a pipework component (piping, fittings) to give the nominal pressure.

Nominal temperature The temperature given on measuring instruments at which they should be used. If not given, it is 20°C. If two temperatures are quoted, this means the limits of the temperature range in which the appliance should be used.

Non-coagulating thickener Usually wheat starch or starch ether, which, depending on the printing process are mixed with various coagulating thickeners. Application in direct printing with vat dyestuffs following the 2-phase process.

Non-contact measurement → Temperature measurement.

Non-crystalline → Amorphous.

Nondrying oils These include e.g. olive oil and groundnut oil; mainly consist of → Oleic acid (linoleic acid in a few cases, probably never linolenic acid). Although unsaturated (fatty acid) compounds are also included, the oxidation capability (iodine number) of oleic acids is too low for them to be classed as drying at normal temperatures. → Oils, oxidation of oils.

Non-dyeing polyamide → Differential dyeing polyamide system.

Non-ferrous metals (NF metals), in particular chromium, copper, manganese, molybdenum, nickel, tungsten, vanadium. They are important as additives in the production of stainless steel or plated steel, in order to increase the corrosion resistance against atmospheric and chemical effects. Application: plant and machinery engineering.

Non-flatspotting is achieved, e.g. by polyamide 6.6 cord yarns, which are used in vehicle tyres as cord lining. → Flat spotting is avoided or substantially reduced by modification of the polyamide by means of an increase in Young's modulus, yield point and increased structural stability at elevated temperatures. Measures of this kind include: treatment with di-isocyanate, blending of the polymer with polyester, co-polycondensation with specific aromatic dicarboxylic acids and possibly the development of new aromatic polyamides.

Non fuming spinning oils A slogan in the synthetic fibre industry for spinning oils which are not, or are only slightly volatile or fuming; e.g. based on sebacic acid ester.

Non-hardenable synthetic resins Such as → Phenolic plastics.

Non-ionic Does not form ions, e.g. nonionic surfactants.

Non-ionic surface-active compounds → Surface-active compounds, which do not form ions in aqueous solution. The water solubility is determined by functional groups which have strong affinity to water.

fatty alcohol ethoxylate	$R_{Alkyl}{-}O(CH_2CH_2O)_nH$
alkyl phenol ethoxylate APEO	fatty acid ethoxylate	$R_{alkyl}{-}COO(CH_2CH_2O)_nH$
fatty acid alkylol amide	$R_{alkyl}{-}CONH{-}CH_2CH_2OH$
fatty acid alkylol amide ethoxylate	 $R_{alkyl}{-}CON{<}^{(CH_2CH_2O)_nH}_{(CH_2CH_2O)_nH}$
fatty amine ethoxylate	 $R_{alkyl}{-}N{<}^{(CH_2CH_2O)_nH}_{(CH_2CH_2O)_nH}$
polyalkylene oxide block polymer	 $HO(CH_2CH_2O)_x{-}(\underset{CH_3}{CH}{-}CH_2O)_y{-}(CH_2CH_2O)_zH$
fatty acid ester of sorbitol	
Tab. 1: Typical nonionic surfactants. (APEO is no more used.)

One of the most significant areas of application of non-ionic surfactants (Tab. 1) is as the raw material basis for washing and cleaning agents. In the case of constant hydrophobic chains, the pure surfactant properties, such as foaming behaviour, wetting action, emulsifying action, dispersing effect, and also solubility, etc., increase in their effect as the degree of ethoxylization increases, then either reaching a plateau or possibly falling away (e.g. washing effect). A special use for low-foam surfactants is as cleaning agents for automatic cleaning processes which operate under high pressure. In the case of industrial cleaning processes such conditions are often more marked, also, strongly alkaline liquors are often present. In addition to ethylene oxide-propylene oxide block polymerization, non-ionic surfactants also include closed end group fatty alcohol alkoxylates (the free OH group at the end of the alkoxylate chain is blocked by the relevant chemical reactions, so that low foaming properties and surfactant properties remain intact with small amounts of colour). Low-foam surfactants have a low cloud point, as they only possess low foaming properties above the cloud point. In the textile industry there are numerous examples of the application of non-ionic surfactants: in addition to their use as cleaning agents, they are used e.g. for the pre-treatment of wool, as a wetting agent, levelling agent, finishing agent, softener, lubricant and spinning oil; in every case because of their surface-active character. It is not always the cleaning effect which is of most importance. There are also many tasks in which non-ionic surfactants are absorbed in the substrate and thus do not enter the waste water. Such surfactants are also extremely useful for emulsifying processes. → Biodegradation is a prerequisite for their use. Among numerous analytical methods the Wickbold method has been developed to such an extent that a waste water analysis can detect 0.01 ppm, i.e. 1 millionth % (Tab. 2).

	BOD after 30 days (%)	degradation according to Wickbold (%)
fatty alcohol + 10 EO	80	98.5
fatty alcohol + 30 EO	57	98.1
nonyl phenol + 9 EO	1	33.7

Tab. 2: Biological degradability of nonionic surfactants.

Typical non-ionic surfactants with favourable ecological properties can be found in the following application examples:

When dyeing knitted cotton goods it is often essential to prewash the material to be dyed. Surfactant compounds based on hydroxy compound ether sulphates combine a wetting, emulsifying and dispersant effect. Dyeing processes can be carried out without the need for precleaning and bath changes. When mercerizing raw cotton the use of wetting agents is still necessary. Closed end group non-ionic surfactants represent biodegradable foaming agents which can be specially combined to form products for use as low-foam wetting agents in caustic treatment and mercerization. During production and processing of synthetic fibres, difficulties arise in the majority of cases due to electrostatic charges. A particular problem is the decreasing antistatic efficiency of antistatic finishes with time, especially in the case of polyamides. By using specific ether sulphonates it is possible to retain the antistatic effect on materials of polyamide fibres practically unchanged even after a storage times of several months.

Nonionic tensides → Non-ionic surface-active compounds.

Non-iron Textiles which, subject to compliance with certain care instructions, and following either dry cleaning or machine washing, fulfil specified minimum requirements for dimensional stability, colour fastness and smooth drying. Non-iron is a special feature of easy-care articles which applies exclusively to washable garments, signifying that no additional smoothing of the article after washing is necessary, provided the care label instructions are followed.

Non-iron finish → Resin finishing.

Non-metals (metalloids), Main examples: arsenic, boron, bromine, carbon, chlorine, fluorine, helium, hydrogen, iodine, nitrogen, oxygen, phosphorus, selenium, silicon, sulphur, tellurium. Oxygen compounds of non-metals have the character of → Acids. Hydrogen compounds are gaseous. Contrast → Metals.

Non-metric measuring system In contrast to the metric system (based on m, kg, s) the non-metric, or Imperial System is based on ft, lb, s. In order to achieve unity in measurement practice, the non-metric system should no longer exist, but only the SI system of measurement. However, the non-metric system is widely used in the USA, UK and East Asia. For conversions, see → SI System of Units.

Nonpolar bond → Atomic bond.

Nonpolar group An organic (surfactant) molecular component with electron distribution without appreciable dipole moment. Limited affinity to organic solvents of low polarity and thus lipophilic in character.

Nonpolar organic compounds → Dipoles.

Non-shrink finish Chemical and/or mechanical process for the dimensional and form stabilization of textiles, prevention of inability to retain size and shape (shrinkage) under conditions of heat, dampness and wetness.

Above all in the case of products of regenerated cellulose, repeated swelling and drying leads to shrinkage. To a lesser extent this also applies to natural cellulose products. Fabrics and knitted goods of synthetic fibres are given a non-shrink finish by heat-setting (thermosetting). Natural silk woven fabrics (with the exception of crêpes) do not tend to shrink due to the low swellability of the silk. Woollen woven fabrics are stabilized by crabbing, i.e. treatment with boiling water or steam and subsequent rapid cooling with cold water. The non-shrink finishing processes are principally divided into mechanical and chemical processes, with the combined process also of significance. These processes not only prevent shrinking, but also give other useful usage and care properties.

I. Chemical non-shrink finishes use chemical processes to limit or remove the fibre-specific causes of shrinkage.

a) In the case of cellulose textiles, shrinkage is most closely linked to the extreme swelling behaviour of the fibres. Reduction of swelling by → Resin finishing.
b) In the case of wool textiles the shrinkage is linked among other aspects to the felting of the wool. Reduction of the felting tendency of the wool hair is achieved by using enzymes, plasma, synthetic resins, oxidizing agents; → Antifelting finish.

II. Mechanical non-shrink finishing uses physical measures in the final finishing to equalize the tensions in the fibre material caused by the manufacturing process, and to remove the foreseeable normal shrinkage which may occur during making up or use.

a) For cellulose textiles, dryers are generally used which, to a great extent, enable pre-shrinkage by tensions in the fibres caused during manufacture (width shrinkage, overfeed). → Compressive shrinkage is largely limited to cotton (→ Compressive shrinkage processes). Size changes of ± 1% after boil washing can be achieved under optimum conditions.
b) For wool textiles compressive shrinkage processes are less common, usually only used as measures for tension compensation (→ Relaxation shrinkage).
c) For synthetic fibres → Heat setting.

Non-slip finishing of carpets Best achieved, e.g. with plastics, as backing finish (→ Backcoating of carpets) or by means of sprinkler, brushing machine or spray gun. Significant as a foam coating, with waffle backing as slip protection, etc.

Non-torque yarn (torque-free yarn), a practically torque-free textured yarn of the stretch type. Produced (→ Torque yarn) by high-twisting, fixing and twisting twice in S and Z twist in a discontinuous or continuous (i.e. false twist) process or stuffer box, or blast-drawing process.

Non-uniformity Deviations or irregularities in the properties of materials, the opposite of → Uniformity. Calculated (linear non-uniformity) as average percentage deviation of the → Average value; → Coefficient of variation.

Non-wetting agent The opposite of → Wetting agent. A textile processing agent without specific capillary activity.

Nonwoven pile fabrics Textile pile goods which are not counted in the narrower classification of → Nonwovens. They have a pile which stands up from the back cloth (nonwoven or individual fibre textile), tied into the back cloth (knit or raschel process), worked into the back cloth, or bonded to the back cloth. Nonwoven pile fabrics have good pile fastness, good resilience, abrasion and tread resistance, can be cleaned. They are used in the pile fabric, furnishing fabric and floor coverings sectors.

Nonwoven quilt Thick → Nonwovens fleece for waddings, bonded by spraying mainly of acrylic polymers.

Nonwovens,

I. Textile fabrics of textile fibres in more or less random layers, which are held together by the adhesion of the individual fibres. They are categorized according to the manufacturing processes (mechanical, aerodynamic or wet/hydrodynamically formed nonwoven fleeces, → Spunbonded fabrics), according to the type of fixing (→: Needle punched felt; Wadding; Felts; Stitch-bonded pile fabrics; Knitted composites) and according to the lay of the fibres (orientated fleeces → Cross-laid nonwovens; Random webs).

II. → Bonded fabrics. In the USA they differentiate between “pure nonwovens” (see III below), i.e. “bonded fabric”, “bonded web”, “fibre fabric”, “fiberized”, and “semi-nonwovens”, i.e. all the remaining bonded fabrics. Articles may also be disposable, short-life and durable nonwovens. The choice of fibres, binding agents and processing methods is made accordingly.

One of many new developments is “Vaporweb” lightweight, breathable nonwoven produced by Reifenhäuser/TBA Nonwovens. The two companies have developed a lightweight, soft and extensible, breathable composite for use as a wet barrier in hygiene products. This spunbonded/film laminate is produced by the following method (Fig.):

- spunbonded manufacture by the “Reicofil” system (PP);
- extrusion coating of the film on the surface of the spunbonded ($CaCO_3$ filled polyolefin);

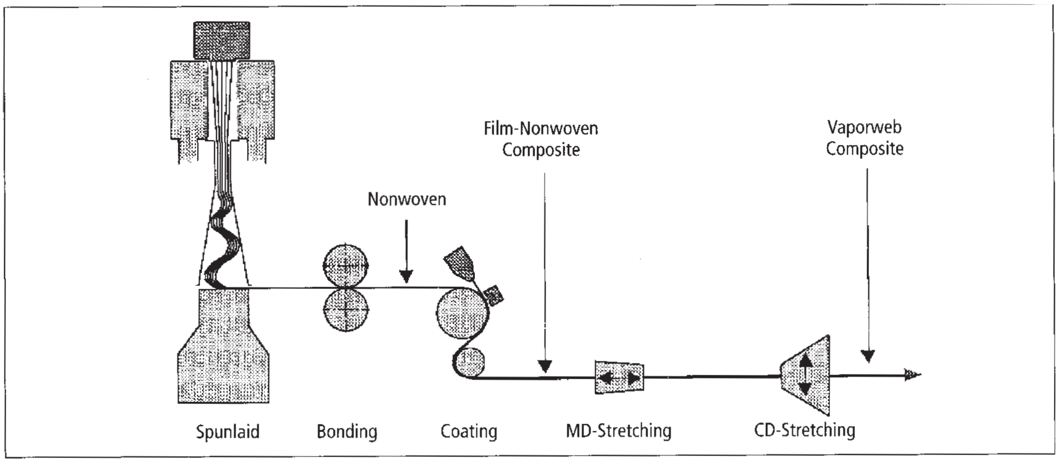

Fig.: Diagram of “Vaporweb” system design (Reifenhäuser).

- biaxial, longitudinal and lateral stretching of the composite.

The three-dimensional composite possesses the following functional characteristics:

- weight per unit area: below 30 g/m^2
- water impermeability: above 150 cm head of water
- vapour permeability: greater than 1000 g/m$^2 \cdot$ 24h.

III. Textile nonwoven fabrics with additional mechanical or physical-chemical fixing (DIN 6210). From the material feed (fibre blend) to the finished product, all processes are carried out continuously on nonwoven manufacturing lines at speeds of around 120 m/min. Reinforced nonwovens contain, e.g. yarns, woven or knitted fabric or net inserts (stitch-bonded nonwovens, knit bonded nonwovens, pile nonwovens, etc.). Nonwovens which are too stiff are slit (Breveteam process). Applications (Tab. 1): interlinings, household articles, needle-punched carpets, hygiene nonwovens, technical articles, etc.

process	production article
mechanical formation	nonwoven coatings nonwoven linings filters and felts nonwoven padding floor coverings domestic goods hygienic nonwovens medival nonwovens
aerodynamic formation	nonwoven coatings nonwoven padding industrial wadding
hydrodynamic formation	nonwoven coatings disposable goods special papers
spun nonwovens	nonwoven coatings book covers nonwovens for decoration nonwoven linings backing for tufted piles nonwoven reinforcings technical nonwovens nonwovens for clothing hospital nonwovens

Tab. 1: Uses of nonwovens according to type of manufacture (according to Enka).

The type of fibre has a substantial influence on the properties of the nonwoven. It is evident that a long "average free fibre length" will lead to a more fibrous, textile nonwoven than a small one. In addition to the bonding points, the fibre itself is of importance in connection with the nonwoven bonding. In the case of smooth fibres the free fibre length is naturally less than crimped fibres. In high-density nonwovens it is also less than in lower-density ones. In the case of parallel nonwovens the free fibre length is also less than in the case of random-fibre nonwovens, as there are very few fibre crossover points; rather the fibres lie more or less parallel to one another for their full length, promoting the formation of more extended, thinner bonding films. The ratio of the average distance between two bonding points and the free fibre length affects the properties of the nonwoven. In the case of smooth fibres this ratio will approach 1:1; in the case of crimped fibres, depending on the intensity of the crimping, it will vary substantially. The greater this deviation, the more flexible the nonwoven will be, as the fabric has to undergo extensive stretching before the fibres are fully extended between the bonding points. This also means that the deformation only starts at an extremely late stage at the bonding point itself. If the fibres referred to have a fixed crimp, the stress-strain diagram has a high value of elasticity, independent of the elastic properties of the bonding agent.

The most significant fibres are polyamides, polyesters, bicomponent fibres and for special purposes also natural fibres (and blends) (Tab. 2).

	1984		1990

Tab. 2: Fibres used in nonwovens (West Europe).

The basic difference between woven, knitted and braided fabrics, felts and other usual fabric types on the one hand, and nonwovens on the other, is the way they are held together. In the case of classic textile fabrics it is the friction between the individual fibre surfaces which ultimately holds the fabric together. The difference between the ways that classic textile fabrics and nonwovens are held together is the reason for the differences in mechanical behaviour between the two groups. So it can be said as a broad generalization that the flexibility of nonwovens is not as good as that of the woven, knitted, etc. fabrics. In the case of classic textile fabrics, in order to change the shape, e.g. creasing, a force is required which can overcome the friction between the fibres. Once the desired shape is achieved, the fabric remains in its new shape, as the individual fibres have been pushed against one another and now the same force has to be overcome to return them to their original shape.

In the case of nonwovens the force applied to change the shape must overcome the shear forces in the bonding agents and fibres. It is not possible to push the fibres against one another, as all the individual components of the nonwoven are held in their relative positions by the fixing process. A change in this arrangement would lead to destruction of the fabric. Because of the shear forces the "bent" fibres and bonding points caused by a change in shape seek to return to their original positions. Any change of shape to a nonwoven is therefore temporary, as it returns to its original shape with greater or lesser speed, as soon as the force causing the deformation is reduced or removed. A permanent deformation of the nonwoven is only possible by folding similar to the creasing in paper, which leads to a gradual deterioration of the nonwoven in the area around the crease.

Nonwovens manufacture Nonwovens are layered and mechanically or physico-chemically strengthened textile fabrics made of fibrous web. Using layering apparatus, the desired fabric weight is achieved by combining as many fibrous webs as necessary, which have been taken from several strippers (Fig. 1). This varies depending on the intended use between 15 g/m^2 (e.g. for so-called disposable textiles) to over 1000 g/m^2 (e.g. for floor coverings). Nonwovens manufactured from fibrous webs which are only combined lengthways have low lateral strength. Cross-laying is therefore used for articles subject to stress in all directions, i.e. strippers positioned diagonally to the direction of the web form other fibrous webs which are overlapped across the original web using layering devices as this moves past on a conveyor belt.

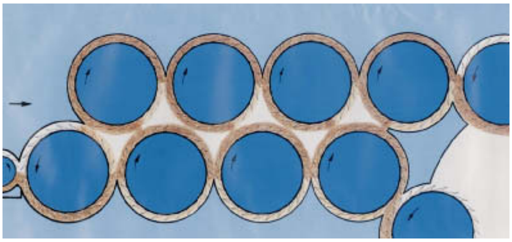

Fig. 1: Stripping the fibres for forming the nonwoven fabric (Turbo Lofter by Spinnbau Bremen).

The manufacture of fibrous webs therefore begins with the arrangement of the fibres being either flat or bulky. These may consist of staple fibres or filaments

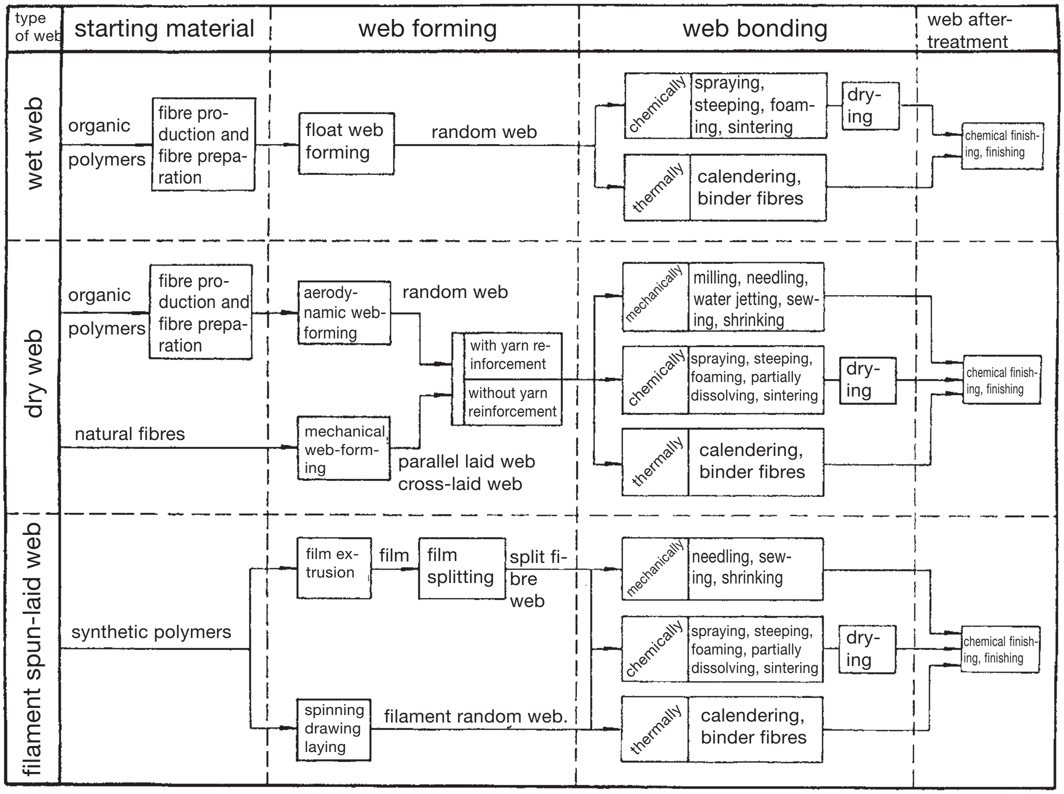

Fig. 2: Processing stages of various web forming processes (modified Bobeth diagram).

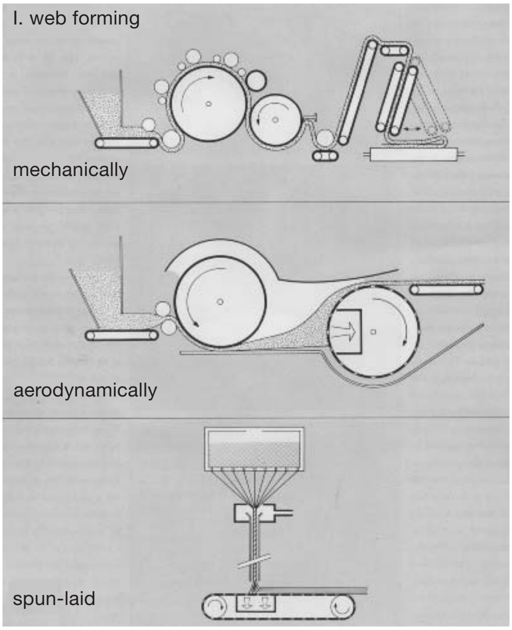

Fig. 3: Web-forming methods in accordance with the dry process (Groz-Beckert).

which are spun from melted polymer granulates. There are four different ways of forming a web (Fig. 2). Nonwovens are generally named after these methods (dry-laid manufacturing system, wet-laid manufacturing system, spunbonding method, other methods such as e.g. melt-blown); both aerodynamic web formation and the mechanical process are also important (Fig. 3). These processes, together with the formation of spun-bonded nonwovens, are classed as dry-lay processes, which should be distinguished from wet-lay processes (Fig. 4).

With nonwovens, the adhesion between the fibres or between the binder and the fibres is the base of the internal cohesion of the fabric. The smallest unit to determine the strength of nonwovens is the individual bonding point between two fibres (Fig. 5). A bond always signifies that the surfaces of two bodies have converged so closely that they form an interface. In order to enable this type of intensive contact, it is necessary for one of the bodies at least to be in a liquid state. The energy equation for this type of system is:

$$\Delta U_A = \Delta U_{S1} + \Delta U_{S2} - \Delta U_{S1S2}$$

U_A = adhesion energy,
S1 = solid,
S2 = bonded glue or melted, resolidified fibre,
S1S2 = interface.

The adhesion is independent of the surface properties of the substrate to be bonded and of the wetting angle of the liquid which wets them. As the adhesion between the binder and fibre or between melted and solid fibre during thermal strengthening is actually the basis for the inner cohesion of the nonwoven, the surface properties of the fibres are extremely significant. The larger the surface, the greater the adhesion. The fibre surface is not only significant for the bonding of the fibres in terms of its apparent size (round or x-shaped cross section), but also in terms of the capillary action which it may exercise on the bonding agent, thereby considerably increasing its actual effect. This type of effect occurs on substrates with a barky fibre sheath or a spongy surface.

Nonwovens are strengthened using the following methods:

1. bonding the fibres by printing, spraying, impregnating with binders (elastomers, bonding fibres, plastomers).
2. heat bonding (fusion) of thermoplastic fibres (binder fibres, e.g. made from copolymers) using the effect of heat.
3. heat bonding the fibres by spraying on binders using the effect of heat.
4. needle punching the nonwovens together (needle-punched felt).
5. fibre shrinking using the effect of heat and/or swelling agent.
6. effect of liquid jets.
7. etching, using admixes of soluble binding fibres, e.g. alginate fibres, bicomponent fibres, copolymer fibres, mixed polymer fibres, vinylal fibres.

Needle-punched nonwovens (also incorrectly referred to as needle felt) are obtained by inserting notched needles into the fibrous web (Figs. 6 and 7). If needles are used which are only effective for rehooking in one direction, fibres are also only pushed through the fibrous web in one direc-

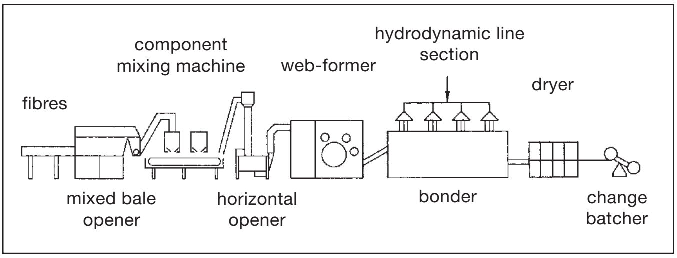

Fig. 4: Web-forming by the wet process (Wiesenbader).

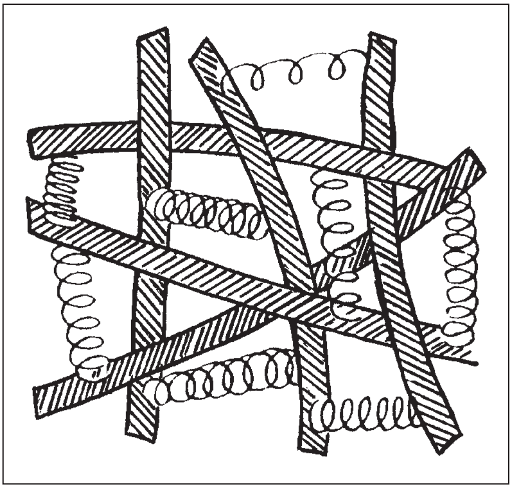

Fig. 5: Fibres in the ideal case with elastic bonds (by Enka).

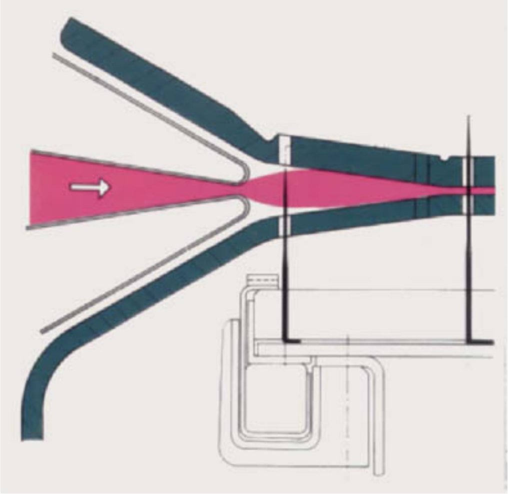

Fig. 6: Preneedling of the nonwoven fabric (by Asselin).

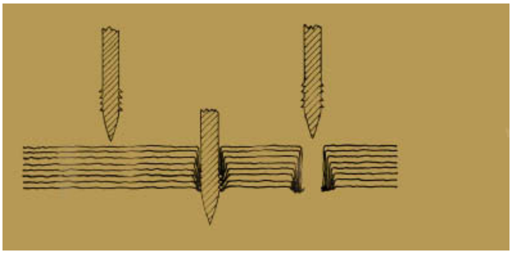

Fig. 7: Diagram showing the needle-punching of the fabric (by Bayer).

tion; the surfaces therefore have a non-uniform appearance. Strengthening is achieved as a portion of the fibres is pushed through the web itself and through the reinforcement fabric. Fibres from the fabric system are not incorporated into the web however, as this would cause a tendering of the reinforcement fabric (Fig. 8). The greater the number of needle holes per surface unit, the more intensive the strengthening achieved in this way. It must be noted that with a given fibre material, specific needles, constant nonwoven weight, etc. the strengthening can only be achieved up to a specific maximum. If this limit is exceeded, the effect is reversed: the nonwoven is “deneedled”, and this may in some circumstances result in the total disintegration of the nonwoven.

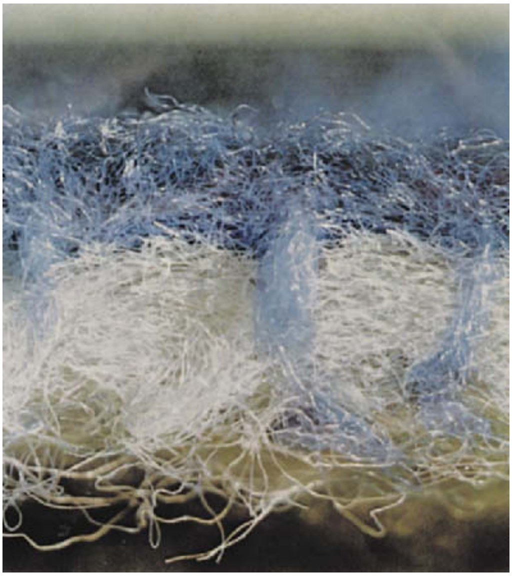

Fig. 8: Cross-section of a needle punched nonwoven fabric. Top layer Cuprama SK dyed. Base layer Dralon N (by Bayer).

The finer the needles and the fewer barbs they have, the higher the number of possible needle insertions per surface unit, if the maximum strengthening is to be achieved. The fineness of the needles also determines the character of the surfaces of the needle-punched nonwovens to a large extent. The selection of needles is dependent on the type of fibres to be needle punched. E.g. coir fibres are only strengthened with coarse, ultra-fine fibres using only very fine needles. Extremely hard needle-punched nonwovens or needle-punched felts are manufactured from ultra-fine fibres using extremely fine needles.

As it is impossible to achieve high-tenacity, hard and relatively dense products in this way in a single process, another method is used. The initial web is needle punched and an additional fibre web is needled onto this strengthened material. This process is continued until a product of the desired hardness, thickness and appropriate weight has been produced (Fig. 9). Where shrinkable fibres are used, additional compression can be achieved by a subsequent shrinkage process.

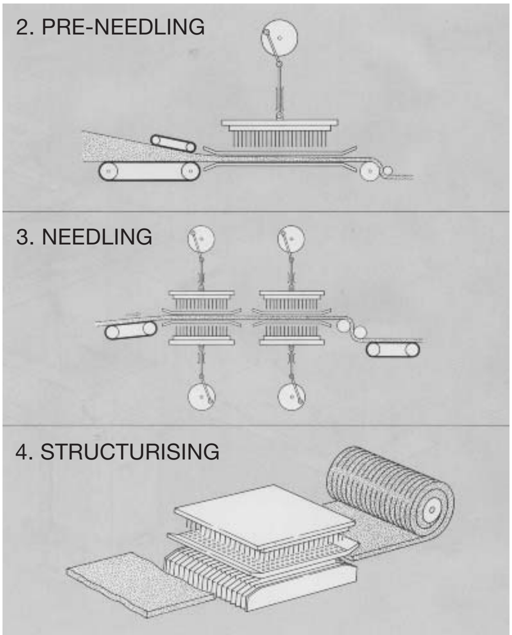

Fig. 9: Web needling for the purpose of mechanical bonding (Groz-Beckert).

Fibrous webs aligned in the machine direction can be better needle punched than those where the orientation runs transversely. The arrangement of the needles in the needle bed plays a crucial role here. In general, random webs cannot be needle punched as well as carded webs, as the proportion of fibres standing vertically in the web or the fibre lengths in the web which are required for strengthening using needling is not sufficient. It is difficult to catch these fibres with the barbed needles, and they therefore only form filling material in the finished needle-punched nonwoven.

Strengthening of the web is therefore an essential stage in the production of nonwovens. The choice of the web strengthening process is just as important in terms of the subsequent functional properties as the selection of fibres used. A distinction is made between three principal strengthening processes:

- chemical,
- thermal and
- mechanical strengthening.

It is possible to combine these types of strengthening. For nonwovens which are strengthened with thermoplastic fibres (thermal strengthening) or with chemical binders (binder strengthening), following carding and if nec. needling or other web formation techniques (wet, aerodynamic, spunbonded), synthetic fibres are mainly used.

Thermal strengthening takes place either on calendars or on sieve-drum driers as hot air fixation units, depending on the product. The type and proportion of thermoplastic fibres is set depending on the use (the proportion of thermoplastic fibres is generally in the region of 10–50%, 5–10% where prestrengthening occurs, and even up to 100% depending on the intended use of the nonwovens).

In addition to strengthening by heat bonding thermoplastic fibres, compressing swollen fibres is standard, as both of these manufacturing methods result in similar conditions in the finished nonwoven as fibrous webs strengthened using binders. Fibrous webs which consist entirely or partly of thermoplastic fibres can be strengthened using the effect of heat. The simplest method is formed by a passage between heated calendar rollers (Fig. 10). This method provides papery fabrics. Embossing rollers in a wide variety of sizes offer

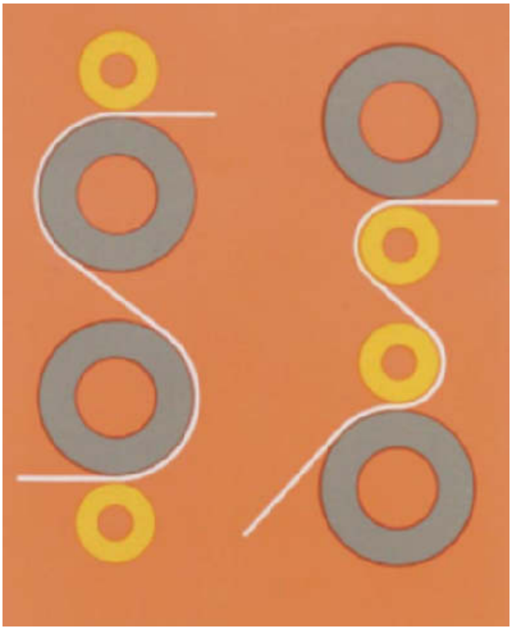

Fig. 10: Four-roller nonwoven calender by Kleinewefers KTM for thermal nonwoven bonding.

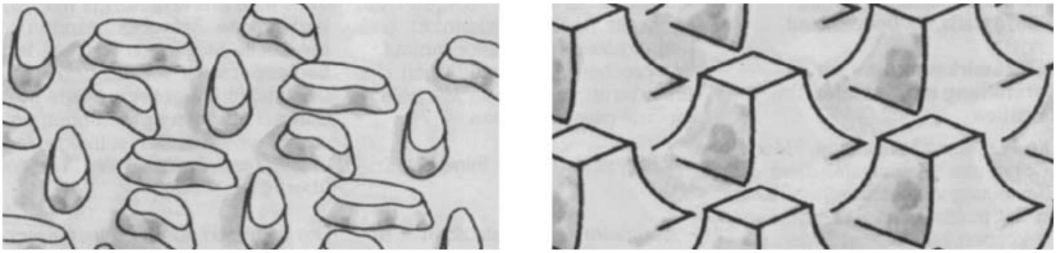

Fig. 11: Nonwoven bonding with embossing cylinders by Overbeck, Krefeld, Germany.

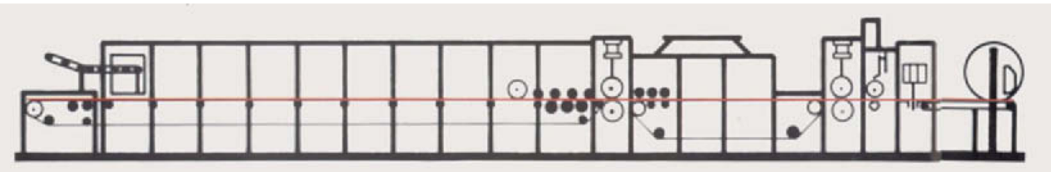

Fig. 12: Special thermobonding plant by Mohr set up as a perforated screen drier.

advantages in terms of web volume (Fig. 11) for all areas of application such as paper, nonwovens, cloth or leather.

If a felt calendar is used, where heat treatment occurs at extremely low pressure, a strengthened form is obtained without significantly reducing the volume of the finished product. There is also the possibility, in addition to the methods mentioned, of guiding preneedled nonwovens through a stenter frame at low tension. As only negligible pressure is exerted on the fibres during the heat treatment, a high volume nonwoven is obtained. The tension ensures that the fibres converge sufficiently closely together to guarantee good heat bonding between them. An alternative is the perforated conveyor drier (Fig. 12).

Compressing swollen fibres takes place in a similar way to heat bonding. The process simply takes place at lower temperatures, often at room temperature. Higher temperatures are used if the swelling agent or solvent is to be evaporated at the same time as compression. Often, the heat bonding and swelling process are combined, e.g. when compressing acetate fibres at higher temperatures following wetting with a small quantity of acetone. If cellulose which has been swollen in caustic soda liquor is used, a considerably higher degree of swelling is achieved below 20°C than at higher temperatures. The properties of the finished nonwoven are comparable to those of heat-bonded nonwovens.

Fibrous webs strengthened with binders are bicomponent systems. With heat-bonded or pressed nonwovens, the fibre acts as its own binder. However, it must not be forgotten that the swelling process or thermal treatment causes a modification of the fibre. It is always most likely that the degree of crystallinity of the fibres will be altered – reduced. The change to the fibre properties does not occur evenly – it is greater at the actual point of heat-bonding or bonding points than in the areas of the fibre which still retain their linear structure after the treatment. The term “bicomponent systems” can therefore also be applied to these nonwovens which are homogenous within themselves. The properties are extremely similar in the individual “components” (Tab. 1) and do not vary as much as fibrous webs strengthened using binders (Tab. 2).

high-pressure polyethylene	85–115˚C
low pressure polyethylene	126–135 ˚C
polypropylene	140–170 ˚C
polynitrilchloride	115–160 ˚C

bicompositional heterofil polyester	170–230 ˚C

Tab. 1: Binding temperature zones for some important connecting fibres.

Special cases of the fibre/binder/fibre systems include: strengthening fibrous webs with binders polyacrylonitrile using polyamide 6, polyamide 6.6 using polyamide 6 or heat bonding using thermoplastics which are incorporated into the nonwoven in powder, sheet or flake form (Fig. 13). In line with the latest technology, however, fibrous webs are predominantly

strengthened into nonwovens with binders which are available in the form of aqueous dispersions.

Nonwovens, shrunk Produced from nonwovens. Fixed by the effects of media which cause shrinkage (heat, chemicals).

Nonwovens with bilateral web Non-woven double-sided pile or loop fabrics of mechanically pre-fixed (needle punched) and additionally fixed nonwoven fleeces. The double-sided interweave of the fibres gives the substantially reduced fibre base layer relatively high strength, which can be increased even further by means of chemical or thermal binding agents. Up to 70% of the above fleece fabrics can be used for pile binding; pile height up to 18 mm per surface. Fibre tufts or loops then protrude vertically from the base layer in linear arrangement. Nonwoven fleeces of different colours can be used to produce interesting visual effects.

Nonwoven waddings For fills or waddings in all areas of clothing or textiles. Since the 1960s, synthetic fibre nonwoven waddings have replaced the grey wadding made from glued reprocessed yarns; moreover, they can be used for a far wider range of applications. Production: having formed a nonwoven fleece by carding, the fibres are pre-fixed by needles. The loose nonwoven fleece thus formed is sewed onto a textile base applied from below; in addition, the fibre stumps formed by the needle punches penetrate the textile fabric and it is usually “stitched”. It is easily observed that such nonwoven composite fabrics differ in their essential properties from nonwoven waddings (without backing material). This applies in particular with regard to the mechanical strength and the handle; however, it is sought to maintain the volume. The full bonding of the needled nonwoven fabrics is done using chemical or thermal bonding. The vast majority of the nonwoven fabric is bonded using binding agents, applied using aqueous dispersion. During production, first one side and then the other side of the fabric is sprayed and then dried. Condensation takes place immediately thereafter.

The chemical industry produces a range of binding systems suitable for nonwoven waddings, e.g. on the basis of (cross-linkable) butadiene styrenes, polyvinyl acetate, polyester or melamine resin. Those based on acrylic resin have proved particularly useful. There is a range of types of these to satisfy practically all requirements. Chemically, they are cross-linkable polymers on the basis of acrylic ethyl esters and butyl acrylates; they vary from extremely hard to very soft (adhesive). The binding agent strength (cohesive strength) is equal to the mechanical strength which the binding agent displays when subject to a particular load. This property is of particular importance in connection with the cleaning processes to which the nonwoven wadding may be subjected; it is in inverse proportion to the swelling capacity. In general it is the case that the harder binding agents show less marked swelling behaviour than the soft. Binding systems may be tested and evaluated for their specific swelling capacity, having regard to the optimum technology for the application. This is usually done using cast films which, using the parameters of temperature and time are subjected to simulated washing and cleaning processes. After drying the swelling subsides; however it must be assumed that binding agents which show marked swelling are not fully restored to their original cohesive strength or adhesion to the fibres.

With thinner nonwoven waddings, bonding fibres which provide an adhesive fibre-to-fibre bond are widely used. Bonding fibres (either in the form of fusible fibre or bicomponent fibres) provide thermal adhesion from their own substance. When heat is applied they become thermoplastically adhesive or melt. It is essential that whilst in this state they come into contact with one another and with the wadding, to ensure wetting. On cooling, they solidify, and an adhesive bond is produced. In the case of thin nonwovens, the contact is assisted by applying high mechanical pressure, e.g. by means of calanders. This method is not practical for nonwoven waddings, as the specific thickness needs to be maintained. In this case, the bonding fibres are used differently: the fibres are combined with approx. 10-30% bonding fibres. This is very expensive, as the mix must be absolutely homogeneous. After formation of the nonwoven fabric the material is lightly needled where appropriate and then subjected to thermofusion in a hot-air channel. The temperature applied here must be very precise, with a tolerance of ± 5°C, in order to avoid, for example, uneven shrinkage and to achieve an even bonding.

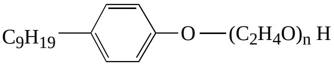
Thermofusion uses low-level forced convection of the air through the fabric from above. Factors are:

– the temperature used,
– the temperature generated in the nonwoven fabric,
– the dwell time.

At the exit to the channel, the final process is the calibration of the nonwoven, still thermoplastically malleable, under minimal pressure between cooled rollers (according to Eisele).

Nonwoven, wet-laid → Nonwovens of short-staple polymer fibres, produced by spraying from spinning nozzles (polymer solution or melt) onto, e.g. perforated conveyor belt. Used for filter mats, insulation purposes, etc.

Nonylphenolpolyglycolether,



A product of addition of ethylene oxide to nonylphenol (→ Polyglycol ethers). A washing and wetting agent.

Normal humidity → Air humidity.

Normality → Gram equivalent per l solution; → Normal solutions.

Normal pressure → Air pressure.

Normal solutions Solutions with precisely determined contents for titration. The 1/1 normal solution (1 n solution) contains the → Gram equivalent or val of a chemical substance dissolved in precisely 1 l distilled water. 1 gram equivalent or val hydrochloric acid thus equates to 36.47 HCl, 1 gram equivalent or val sodium carbonate to 53 g Na_2CO_3. Both these quantities by weight when mixed will lead to mutual neutralization and produce neutral reacting sodium chloride, NaCl.

$$2\ HCl + Na_2CO_3 \rightarrow 2\ NaCl + H_2O + CO_2$$

If 1 gram equivalent or val is dissolved in 1 l water, this gives the normal solution. For a given acid, it is always of the same acidity, as it will always be of the same acidity for a given alkali. It therefore follows that every unit of a normal solution of any acid must also correspond to the same unit of any alkali for neutralization. Used in → Titration. Titration with normal solutions determines the potential → Hydrogen-ion concentration (practically equal in all acids), in contrast to the pH measurement, which determines the actual hydrogen ion concentration (dependent on the relevant level of dissociation).

$(NO)_x$ Nitric oxides which are generated by combustion processes at high temperatures. 90% of the pollutant particles in the atmosphere derive equally from traffic emissions and large-scale furnaces in heavy industry. Only approx. 8% derives from direct chemical production. In addition to benzpyrene, $(NO)_x$ play a substantial part in the combustion of natural gas. Like SO_2, these compounds are significant in smog formation. Sunlight causes them to split off reactive oxygen, enabling the formation of dangerous oxidants. NO_2 can be oxidised in air to N_2O_5, which forms nitric acid with water vapour. Precipitation contaminated with this acid contributes to acidification of the soil and surface waters. Nitric oxides from nitric acid production with amine components can be converted into carcinogenic nitrosamine compounds. Above all the burning of fossil fuels leads to the oxidation of more carbon and sulphur as well as nitrogen, the last particularly in internal combustion engines and thermal power stations. The majority of the main and subsidiary components of the atmosphere (O_2, N_2, CO_2, CO, NO, NO_2, SO_2, CH_4) form part of cycles, which are controlled by biological reduction and oxidation processes (photosynthesis and respiration, and their secondary or consequent reactions). At present, however, in industrial countries, there is an increasing tendency for the civil energy flux to be higher than the biotic. The gas and aerosol components come from various photochemically catalyzed oxidation processes. The reaction times for the oxidation of SO_2 mean that the more significant sulphur compounds remain in the atmosphere for max. of a few days; this corresponds to travel distances of a few hundred to over a thousand kilometres. The oxidative formation of HNO_3 takes place somewhat faster.

$(NO)_x$ can be reduced to nitrogen within furnaces (see Fig.) by ammonia (conproportioning):

$$(NO)_x + NH_3 \rightleftharpoons N_2 + x\,H_2O$$

Noxious (Lat.: noxa = injury), a generic term for substances used in the workplace which have a harmful effect on humans, which are not toxic (→ Toxic substances), but which nevertheless have a harmful effect on health or may affect performance. Of particular interest to methods engineers are non-toxic dusts, e.g. textile dust and dirt.

Nozzle-Test Used for the evaluation of the handle of textiles, in which the test sample is drawn through an eyelet.

NP Norma Portuguesa Definitiva; Portuguese standard.

Np Chemical symbol of Neptumium (93).

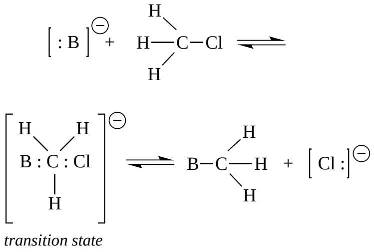
Nucleophilic reagents

Nucleophilic reagents If an ion or a compound with electron donator properties is sterically able to approach a homeopolar bond weakened by polarization, displacement reactions are possible (see Fig.).



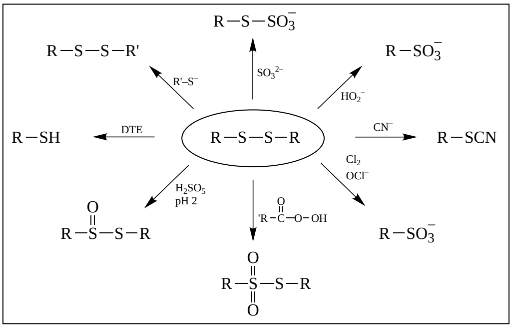


Fig.: Selection of different nucleophilic reactions of cystine sulphur.

Nuisance factor (NF). According to the waste water laws, the sum of the “nuisance proportion factors” for substances capable of precipitation (P), chemical oxygen demand (COD) and toxicity (T). The given quantity of waste water is multiplied by NF to obtain the value of the → Pollution index. → Waste water evaluation.

NZ → Sodium number.

NZSR New Zealand Standards Recommendation; the New Zealand standards mark.

O

O Symbol for the element oxygen (8).

o- → Ortho-.

Objectives of textile finishing In order to establish the sequence of operations for an article which is to be finished, first of all the target properties must be known. Depending on the use to which the finished article is to be put, different factors can determine the quality. The target properties can be divided into the following groups:

I. Visual appearance (eye)
II. Tactile appearance (hand)
III. Smell.
IV. Technological properties.
V. Environmental compatibility.

I to III belong in the subjective domain, and IV and V in the objective domain.

In the case of fashion articles, the emphasis is clearly on subjective visual appraisal (I). Usually one speaks of "attractive appearance, even finished quality, balanced design, level appearance, elegant drape", etc., i.e. evenness or unevenness in the sense of harmony or disharmony is a subjective measure of appearance. This evenness is the sum total of partial aspects, e.g. evenness of dyeing, of the fabric surface (geometrical structure), the thread distribution (thread structure), the surface structure (lustre), etc. All these partial factors thus form the totality of target characteristic I. Shade conformity (according to the reference specification) is a prerequisite; however, in connection with the appearance of the goods, it plays an important role in the overall impression.

The visual impression is followed by the handle (II). This characteristic is determined by the following factors:

- surface structure (lustre),
- stiffness (geometric structure, finish),
- thread distribution,
- thickness, etc.,

with the stiffness in turn also affecting the appearance (I), when one considers the suppleness, i.e. draping. Various factors thus influence the target characteristics I and II. If one orders the parameters and weights them with regard to target characteristics, a ranking results, depending on the article, e.g.:

1. geometric structure (incl. weak pleats, folds).
2. dyeing (cloudiness, skitteriness, etc.)
3. surface structure (lustre)
4. stiffness (finish)
5. thread distribution.

The ranking of factors can thus vary from article to article, since the target characteristic can only be evaluated subjectively, and people evaluate the influencing factors as an integrated target variable.

Furthermore, smell (III), e.g. the fish odour from resin finishing, and the technological data (IV), also play an important role. Usually, however, the technological data (IV) assume a secondary status, particularly in the fashion area, i.e. only when the first three areas have been fulfilled do they become co-determinants for the "quality" of the end result. A fabric with an uneven dyeing result (e.g. changes in shade from selvedge to centre) is generally not accepted, no matter how good the washing fastness of the dyeing. For the rest, the technological data such as tear strength, colourfastness, etc. depend predominantly on the substrate (material, dye) and on the process techniques of the individual operations, and therefore can be measured objectively. Increasingly, the environmental friendliness (V) of processes and products are the prime focus of interest. The aim should be to undertake ecological audits which attempt, viewed integrally, to weight all the influences in the overall production pipeline. (Source [in parts]: Loss).

Oblique-flow driers In conventional oblique-flow driers, after impinging on the goods in the space between the cloth and the nozzle boxes, the hot air emerging from the nozzles flows to the side, to the exhaust air ducts. The reversal of the direction of flow (Fig. 1) produces special aerodynamic conditions which affect the exchange of heat and substances. Heat exchange is accelerated, whilst substance exchange suffers under these conditions. For this reason, drier designers try to keep the route of the cross-flow exhaust air as short as possible by sub-dividing nozzle boxes, and to extract the heating medium directly after the cloth has been heated, via continuous extraction ducts (Fig. 2).

Connected nozzles of older driers, in which the hot air is supplied perpendicular to the run of cloth and the exhaust air is extracted laterally at the walls of the

Oblique-flow driers

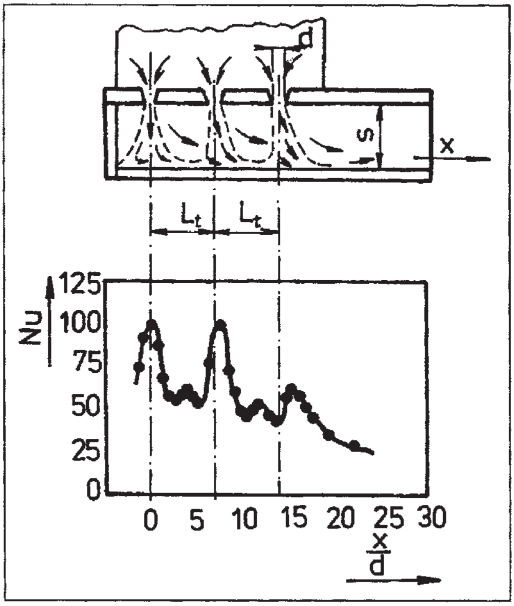

Fig. 1: Heat transfer caused by the crossflow in oblique-flow driers.

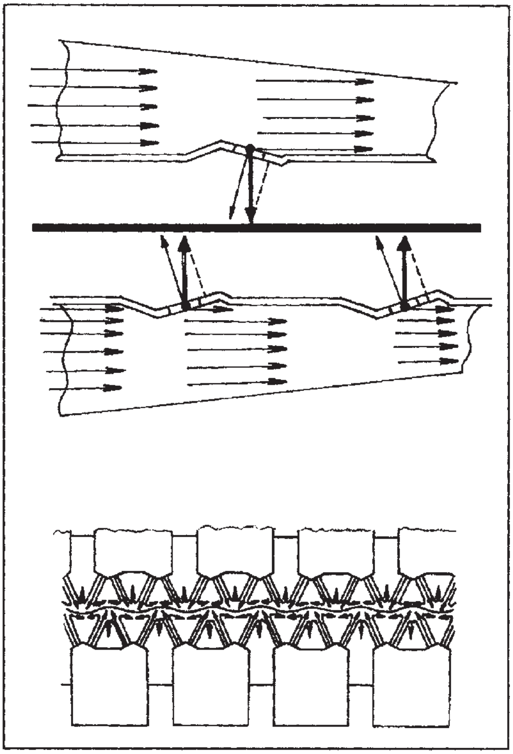

Fig. 2: Nozzle system with separate jet chambers (Krantz).

drying chambers, are no longer built. Compact nozzles still exist, but here too, the exhaust air is extracted directly in the blast zone.

The significance of turbulence lies in the following: the intensity of the substance exchange is influenced primarily by the transport coefficient in the flow field or in the zones subjected to the heating medium. The coefficient in turn is determined by the interaction of turbulence and flow rate of the impinging hot air. Alea (Italy) (Figs. 3 and 4) uses e.g. a parabolic profile of the hot air flow emerging from the nozzles, which is created with the aid of longer pipes in the nozzle system (Fig. 5).

Mixing the hot air flow with the ambient air increases turbulence, particularly at the walls of the drying chambers. This so-called “laminar” airflow system yields a considerable improvement in substance

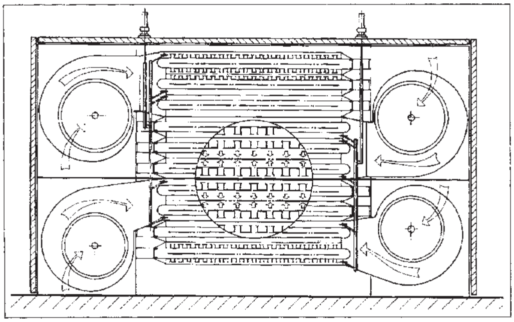

Fig. 3: Cross-section of a drier by Alea (Italy).

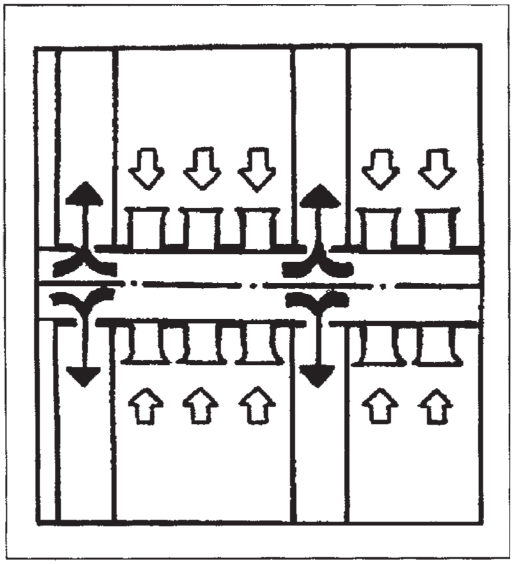

Fig. 4: A detail of the Alea system (Italy).

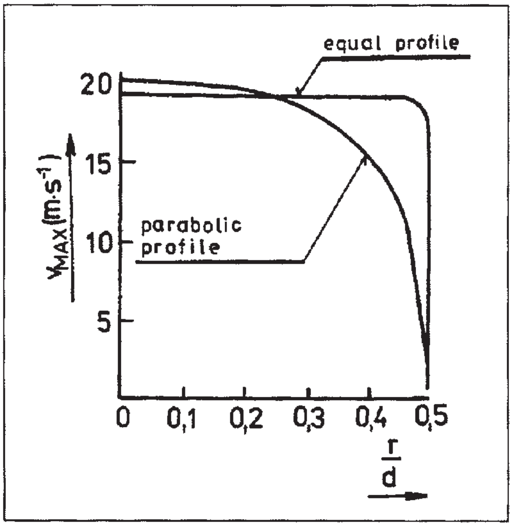

Fig. 5: Comparison of the flow velocities at the nozzle mouth for hot air streams having a parabolic and a cylindrical profile.

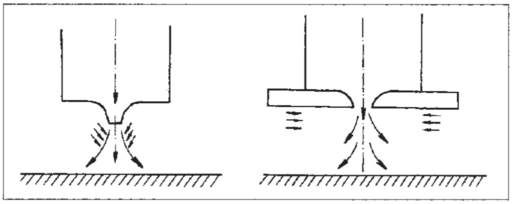

Fig. 6: Two types of nozzle.

exchange, i.e. by 30% in the slotted nozzles, and even up to 100% in the circular nozzles. The way in which the flow of hot air emerging from the nozzle outlets mixes with the ambient air is important. Mixing with the ambient air must take place directly at the nozzle outlet (Fig. 6, left). If this does not happen, i.e. if before impinging on the goods, the emerging hot air meets a barrier formed by the ambient air (Fig. 6, right), then inadequate mixing takes place, and substance exchange deteriorates.

The influence of turbulence and flow rate at various points in an oblique-flow nozzle system becomes particularly clear in relation to the effect of the so-called “inner” turbulences (Fig. 7).

Fig. 8 illustrates the system from Monforts: on the left is a universal system with circular nozzles for handling woven textiles and knits, in the centre, circular nozzles for suspended guidance of the goods to be dried. The system is particularly suitable for fine knits. For drying light woven textiles, Monforts offers a slotted orifice system (Fig. 8, right), which, thanks to the equilibrium between the individual aerodynamic fields, yields a level appearance of the goods after drying.

Good utilisation of aerodynamic conditions has been realised by Fleissner in the “Rotoswing” belt drier for knits. This is an oblique-flow drier characterised by movable slotted nozzles. The upper and lower jets periodically change their position relative to one another, thus effecting – by aerodynamic means – that the goods pass through the drier in a wave-like movement (Fig. 9). The result is evenly dried and shrunk knits. A pre-condition, however, is that the outflow speed out of the nozzle openings is uniform.

A tier belt drier from Monti (Italy) has been designed for handling tubular as well as open knit goods. Here too, the aerodynamics of the impinging air are used in order to give to the drying goods a wave-like movement. The slotted nozzle system with upper and lower nozzles offset relative to one another is shown in Fig. 10. In contrast to oblique-flow driers (with clip chains or needle chains, support rods or conveyor belts, etc.), in which the design of nozzle and air conveying systems for as great a drying output as possible, was the most important, in the case of tier driers the air circulation must be designed in such a way that floating and/or phase-shifted effects can be achieved.

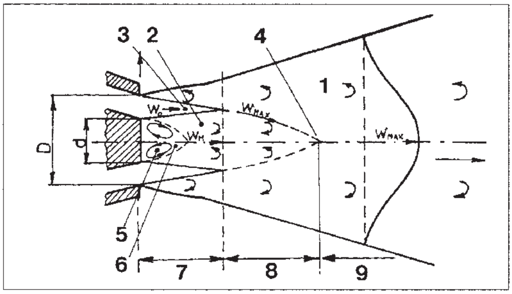

Fig. 7: Flow characteristics of a ring-shaped nozzle. 1 = outer mixing zone; 2 = inner mixing zone; 3 = active core; 4 = vertex; 5 = inner vortex; 6 = reverse flow zone; 7 = initial mixing zone; 8 = intermediate mixing zone; 9 = final mixing zone.

Oblique-flow driers

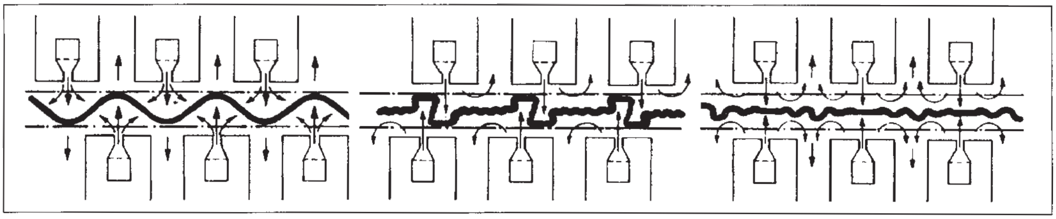

Fig. 9: Effect of the "Rotoswing" nozzle system by Fleissner.

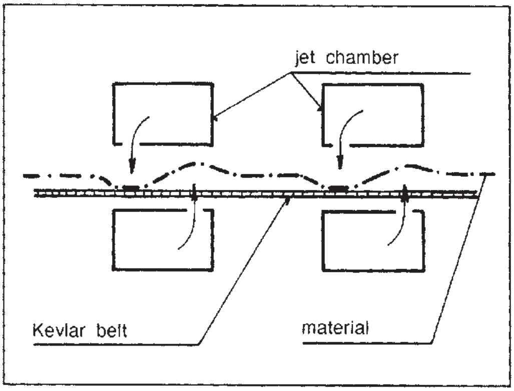

Fig. 10: Nozzle system by Monti (Italy).

In floating nozzle systems, both slotted and round nozzles are to be found. However, the nozzle outlets often have a special shape, by the use of flat plates or rollers (Fig. 11). Floating nozzle systems essentially differ from other systems through very precise control of the air circulation along the run of fabric. Included in this is a controlled quantity of exhaust air, through outlet air ducts equipped with slots and/or circular openings. In contrast to the circular jet fingers, in the Star-Jet system from Babcock (Fig. 12), after impinging on the goods each jet stream is led away by the shortest route, via the outlet tubes distributed on the jet body. The ratio between the jet supply and the outflow cross section is 1:18, compared with the usual ratio of approx. 1:5 in existing systems. The heating medium is supplied by means of special nozzle boxes of varied designs, which are assembled to form particular systems (Fig. 13). In this way, the uncontrolled flow of air above the run of goods perpendicular to the axis of the nozzle openings is eliminated.

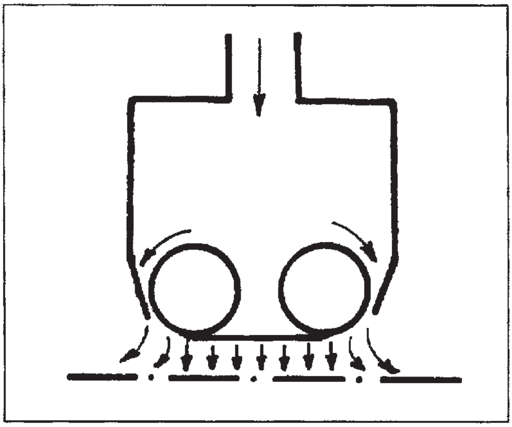

Fig. 11: Jet chamber with guide rollers.

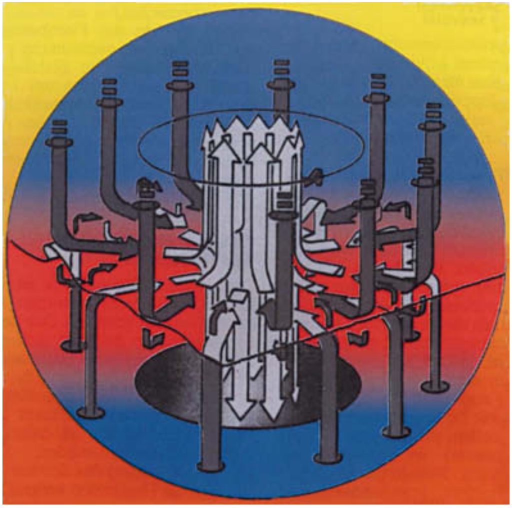

Fig. 12: Duett-1035 system by Babcock.

All floating jet systems use pressure or a pressure difference between the run of goods and the upper and lower jets in order to be able to guide the goods through the drier in a suspended state. The pressure difference can be achieved by various means; by casing the upper and lower nozzle chambers or with the aid of specially designed finger-like nozzle boxes which screen the two zones from one another, and thus create a partial pressure in the area of the run of goods. Particular attention

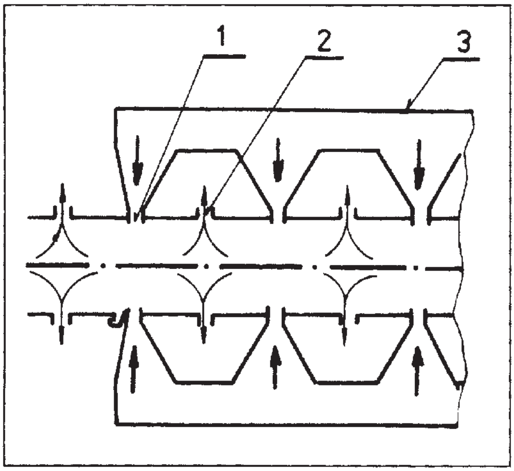

Fig. 13: Upper and lower jet chambers with facings.
1 = in; 2 = out; 3 = chamber.

is attracted by systems which use the “Coanda” effect to create the suspension (Fig. 14). In the drier from Elitex, rollers support the suspension, whilst circular nozzles yield a high drying output (Fig. 15). The Coanda effect is a phenomenon which can best be described as an adhesion of the run of fabric to the outflow of air (two-dimensional slotted nozzles). The fabric appears to be suspended on the jet system, lying above it.

Apart from the aim of creating state of suspension, other systems also aim at supporting the conveyance of goods by air flowing in the direction of the goods. This can be achieved either through suitable arrangement of the upper and lower jet systems, or through a special extraction system for exhaust air. In principle, the air conveying system of a floating drier barely differs from that of a regular oblique-flow drier. Only the control of the air circulation has been improved, via precise regulation of the drying medium flowing from the upper and/or lower jet systems, and through instruments for recording the total quantity of circulating air (Source: Krizek).

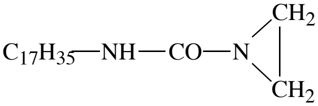
Occlusion (from the Latin occulus = “closed”). This relates to, for example, possibility of dirt adhesion for reasons of topography. Macro-occlusion: mechanical jamming of relatively large particles of dirt between the threads of a fabric and the fibres of the yarn. Micro-occlusion: jamming of the finest pigment particles (0.02–1 µm), which are nevertheless up-to-date in terms of washing technology, in the fine surface structure of the fibres. The existence of a micro-occlusion can be caused both by the core size distribution of pigment dirt, as well as by tears, cracks and pores appearing on the fibre surface. It can even be assumed that the micro-occlusion, in conjunction with the capacity of fine pigments to agglomerate, results in an adhesion which is extraordinarily resistant to surfactants, and which plays a not inconsiderable role in greying, particularly of cotton.

Occupational diseases in textile finishing →: Skin diseases; Solvent health hazards.

Octadecylethylene urea Textile auxiliary for soil-repellent finish and as a hydrophobic softener.



$$C_{17}H_{35}\text{—NH—CO—N}\begin{matrix}\diagup CH_2 \\ | \\ \diagdown CH_2\end{matrix}$$

Octet rule → Atomic bond.

Odorous substance complexes → Fragrant finishes.

Odour According to the present-day view, the receptor (= organ for receiving stimuli) appears to act in relation to the odour molecule like a key in a lock. Through the transportation of respiratory air, the odour molecules reach the upper nasal cavity (swirled by specially arranged cartilage laminae) to the smell receptors of the nasal mucous membrane (bearing around 20 million filament hairs), where they penetrate, are dissolved in the lipoid layer, and are passed to the brain as a physico-chemical (olfactory) stimulus through neuronal signals, for the purpose of transmitting odour-specific information. A wealth of theories are currently in existence, which do not satisfactorily explain the detailed sequence of perception of smell. → Osmophore.

Odour control Repellent or disabling effect achieved through odour, e.g. → Respiratory poisons for use against insects or microorganisms which damage textiles. Term is also used to describe a procedure to prevent the build-up of microbially induced odours by blocking microbial metabolism. → Hospital laundry.

Odour improvement Addition of odour modifiers to baths, e.g. in the case of sulphur dye baths, crease-resistant baths, etc. →: Deodorizing; Odour control.

Odour nuisance Environmental pollution is largely defined in the respective laws; these relate to the origin and action of pollutants in air, water and waste. The emission of pollutants can represent a nuisance even if, during emission, the source of pollution (introduction of pollutants into the environment) conforms to the law in respect of the amount introduced (e.g. in the case of emission of exhaust gases into the air which conforms to the Technical Instructions for Air [TI-air; TA-Luft] with regard to the permitted limit values). Odour nuisance in this sense is a cause for complaint. Typical odours are directly associated with textile finishing (e.g. in the vicinity of a wool finishing plant, due to the splitting of hydrogen sulphide derivatives in the wet-treatment of keratins; in carrier dyeing) or indirectly (e.g. in vehicles with a new interior trim which has been fixed with binding agents; evaporation in rooms with tufted, back-coated fitted carpets).

The human perception of smell is an extremely subjective matter. For a person to be able to perceive anything in the first place, the inhaled air must contain odour-forming components. For this, the concentration of these substances must be sufficiently high for the relative odour threshold to be exceeded. As a rule, even for intense-smelling substances, billions or even trillions of molecules are necessary. Despite this extremely high presumed figure, modern analytical chemistry has still not succeeded in making equipment to measure odours objectively. So we still have to assess odour by means of sensory test methods (olfactometry). There are three reasons for this:

1. The odour-forming components are often present in concentrations which lie well below the threshold at which they can be demonstrated. The nose is an extremely sensitive detector.
2. Many odours represent a combination of individual components.
3. It is extremely difficult to assign certain substances to a perceived odour.

The effect of scents on the area of the olfactory membrane is described by various theories, which differ in their views and nature:

- adsorption/desorption theory,
- enzymatic theory,
- oscillation theory,
- stereo-chemical theory,
- theory of functional groups.

Functional groups such as –OH, –OR, –CHO, –COR, –COOR, –CN, $–NO_2$ are → Osmophores with a pleasant smell, so-called euosmophores. –SH, –SR, –CHS, –CSR, –NC, $–NH_2$ on the other hand, are cacosmophores with an unpleasant odour. The threshold for a scent or a substance blend is that concentration which can just be perceived. A distinction is made between a non-specific threshold (an odour is registered) and a specific threshold (an odour quality is recognised). In the human sense of smell, the olfactory thresholds are subject to fluctuations which depend on various factors. Particularly important is the view that sensitivity to smell can be trained, but that on the other hand each act of smelling sets the threshold values higher for the one following immediately after. The olfactory thresholds for odour substances are subject to extreme variation; thus in the literature for ethanthiol, camphor, isoamyl alcohol, for example, $7 \cdot 10^{-6}$, $29 \cdot 10^{-4}$, and $11 \cdot 10^{-2}$ mol/l are given. Vanilla, whose threshold value is $33 \cdot 10^{-4}$ mol/l, is not infrequently used as a covering scent because it has an “empathetic” effect and in a subsequent act of smelling it pushes the specific value upwards considerably.

The organs of smell are localised in the nose. The olfactory region is an olfactory epithelium approx. 10 cm^2, which is equipped with $2 \cdot 10^7$ olfactory cells. It is located in the upper part of the nasal cavity, close to the brain. Even very weak external stimuli are thus directed there by the shortest route, and largely differentiated. In the case of corresponding olfactometric test methods, one must take account of the fact that molecules are only perceptible in terms of smell when they have a minimum vapour pressure; moreover, substances as gas must be water-soluble and fat-soluble, and contain osmophores. Sampling must be adapted to the application in question (ambient air of a textile finishing plant; the interior of a car; odour development of carpets in homes and offices). The evaluation by the persons doing the smelling must be independent of their mental or physical disposition. Grades of 1 to 6 are issued by 6 members of a team; the highest and lowest evaluations in each case are discounted, and the average is established from the remaining 4 grades. Grades are as follows:

1 = odourless
2 = perceptible, but not annoying
3 = bearable (limit value)
4 = annoying
5 = highly annoying
6 = unbearable

This elimination of the extreme values which have been found allows any possible temporary indisposition on the part of members of the smelling team to be taken into account. Up to the value of 3, grading is generally still tolerated, e.g. by the automobile firms, but “pungent” smells (such as those originating from HCHO)

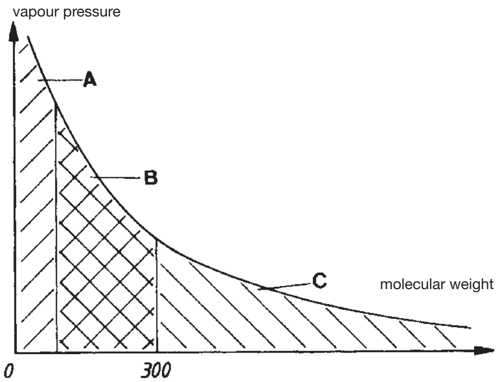


Fig. 1: Dependency of vapour pressure on molecular weight. A = odoriferous matter; B = condensable odoriferous matter, fogging relevant; C = fogging-significant substances.

would lead to rejection of textile furnishing materials. Odour development and → Fogging in furnishing materials for cars are, in the first instance, comparable processes in physical terms, since the relevant substances have to have a corresponding vapour pressure. The question of the transition range, namely concerning solids which are susceptible to both odour and fogging, is illustrated in Fig. 1 (source: Eisele).

When applying the preliminary coating of carpet backing, it was possible to determine the very intense-smelling 4-phenylcyclohexene (Fig. 2) by means of gas chromatography (imported into the process as an accompanying substance of styrene).

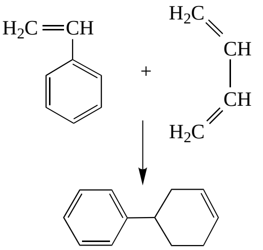

Fig. 2: Diels-Alder reaction during polymerisation of a carpet backing coating pre-coat.

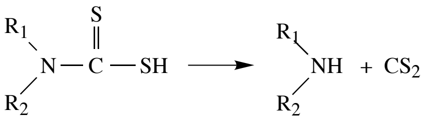
Vulcanisation pastes of foam coating (as main coating in carpet backing) contain – besides carbon bisulphide and sulphur dioxide – above all amines, which are very odoriferous. These are reaction products of vulcanisation paste constituents which allow dithiocarbamine acid to arise from the dithiocarbamates when the pH is lowered; this then reacts further:



$$(R_1)(R_2)N-\overset{\overset{S}{\|}}{C}-SH \longrightarrow (R_1)(R_2)NH + CS_2$$

Odour poison → Respiratory poison.

Odour threshold value The smallest concentration of gases or vapours which can still be perceived by the nose (→ Odour nuisance).

Threshold values of some substances (in ppm):

Ozone	0.02
Sulphur dioxide	0.3–1
Phosgene	0.5
Phenol	0.5
Hydrocyanic acid	1
Carbon bisulphide	1–2
Formaldehyde	2
Chlorine	3.5
Ammonia	5.5
Ethyl ether	50
Tetrachloroethene	50
Toluo	50
Trichloroethene	50
Carbon tetrachloride	70
Benzol	100
1,1,1 trichloroethane	100
Chloroform	200
Benzene	300
Dichloromethane	600
Methanol	2000
Liquid gas	5000

OE-spinning process (Open End spinning process). Besides increased output in ring spinning, outspinning has been brought a decisive step forward with the realisation of open end spinning. These methods owe their existence to the long-held desire to maintain the ready-cleaned cross-wound bobbin directly after the control section, i.e. without the entire preparatory spinning, ring spinning and rinsing machine. Various solutions have been proposed. The basis of all OE spinning processes is the separation of a fibre tape feed into individual fibres, which are given a twist through various media, and are spun continuously into an "open end" stripping thread.

The most important process, and one which has been introduced in practice, is rotor spinning. The essential features of a rotor spinning machine can be described as follows: The fibre tape is fed to a high-speed cylinder, and split into individual fibres. Compared with conventional spinning processes, a "break" takes place in the work sequence, i.e. the fibres are conveyed individually into an air driven rotor, with the rotor running at speeds of between 30 000 and 60 000 r.p.m. Under the action of centrifugal force, the fibres collect in a groove on the rotor wall to form a multi-layered, sickle-shaped fibre ring. This ring is drawn axially out of the rotor, from a drawing point, whilst maintaining the necessary twist. The yarn which is thus created can be spooled directly onto any material carrier. The maximum fibre length which can be processed is determined by the rotor diameter and the system resolution.

The majority of the machine types are designed for the short-staple range of up to 40 mm (in exceptional cases, up to 60 mm). It is therefore often cotton which is spun on these machines. The area of application covers both normal cotton yarns (so-called 3-cylinder yarns) and the condenser cotton yarns (2-cylinder yarns). When using fibre of a particular provenance, it should be noted that a raw material which is difficult to process in the drafting zone, and which has a high proportion of short fibres or a high degree of staple variation, produces a better result on the OE machine compared with the ring spinning machine. One must also take into account the fact that dust and pieces of husk collect in the rotor groove, and can detrimentally alter its shape, leading to a drop in yarn quality (moiré) and increased thread breaks. For this reason, the feed for the OE process has to be as clean as possible, i.e. the cotton band should contain little dust and pieces of husk. As mentioned above, the band which is fed in is split up into individual fibres. In the course of this, impurities can be removed easily. Fine dust and poorly adhering preparations (chemical fibres) are, however, not detected by a cleaning device, and have to be removed by good cleaning and carding in the case of cotton, or by a suitable preparation in the case of chemical fibres. A favourable design of the spinning organs, including the rotor, can help to overcome these difficulties, and enable problem-free operation with constant yarn quality.

For the purposes of assessment, two different OE machine types are distinguished:

a) As soon as OE machines are used without a cleaning unit at the spinning location, a very good cleaning and carding room is the main condition for perfect running behaviour and good yarn quality, particularly in the case of cotton, even when it has been selected from relatively clean provenance, so that in difficult cases duo-carding machines, possibly with squeezing rollers, can offer advantages.

b) With dirt separation at every spinning location, it is possible to remove a proportion of between 50 and 95% of the dirt contained in the tape, according to the Shirley analysis. Through this, the majority of thread breaks, which are caused by larger dirt particles, are avoided.

(Source: Cripps). → Air jet spinning; DREF, false twisting method.

OE-yarn → Rotor-spun yarn.

Off-line lubrication → Yarn lubrication.

Off-line testing In this form of in-house quality control, three methods are distinguished:

- Off-line testing with sampling and evaluation of the sample in a (separate) laboratory, so that the measurement results are obtained relatively late (DIN 38404 pt. 1/92).
- On-line testing (e.g. as adapted laboratory colorimetry) with sampling; direct regulation of the process is possible with a relatively slight time delay (→ On-line Quality Assurance).
- In-line testing (non-destructive) with immediate control by comparison of target and actual values (see Fig.).

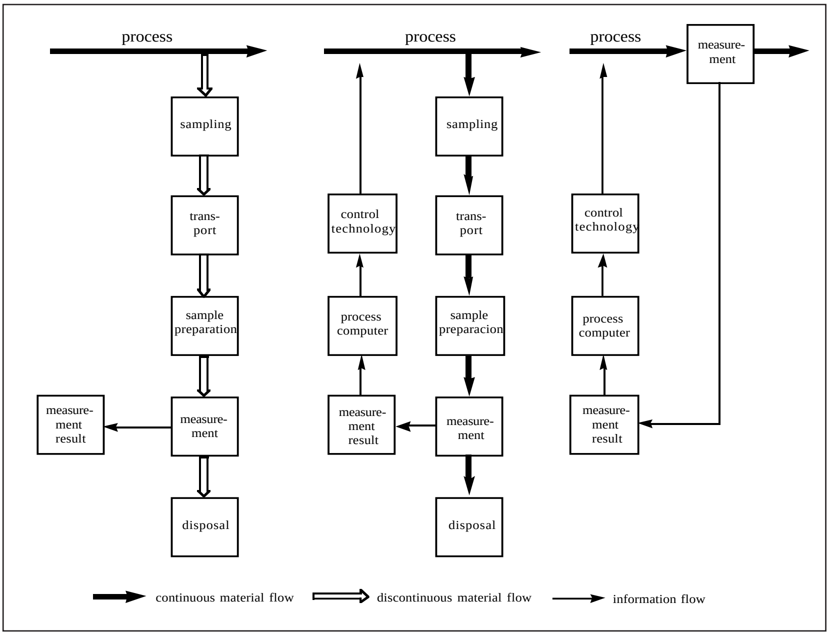


Fig.: Comparison of the material flows and information flows for off-line testing (left), on-line testing (centre) and in-line testing (right).

Offset printing The patterned coloration takes place indirectly via a rubber blanket, with printing colour paste being applied beforehand to the printing plate or roller, from the roller to the rubber blanket, and only then to the material which is to be printed. (see Fig.). During the printing process, the printing mould with the non-reversing image passes through the “moistening and dyeing unit”. Through moistening, the non-printing parts become dye-repellent, so that only the printing, water-repellent parts take up the dye paste. This dye paste is “deposited” on a rubber cylinder, which transfers the laterally reversed print image onto the running paper, with slight pressure.

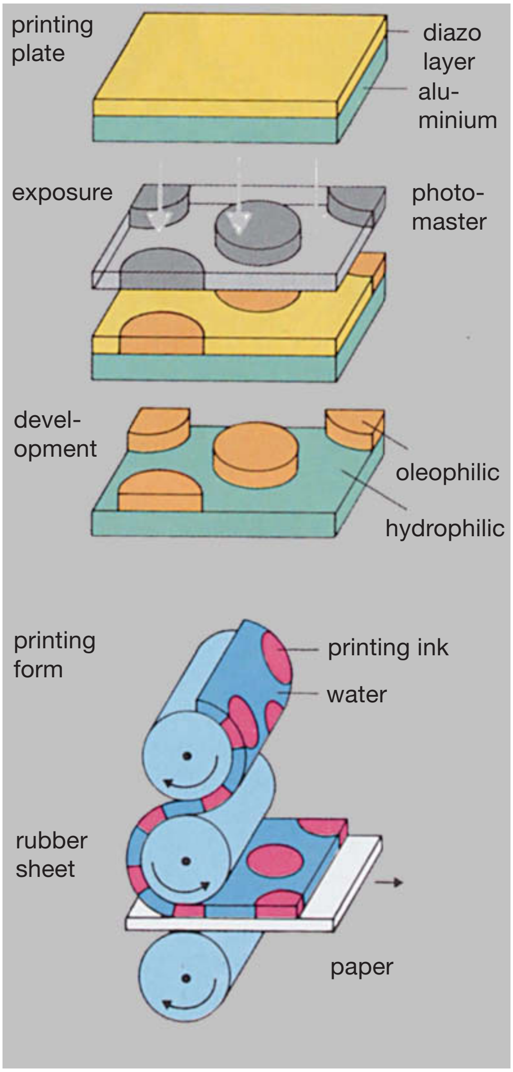

Fig.: Manufacture of an offset printing form and the principle of offset printing (source: Hoechst).

The process is begun by charging, which occurs as the printing plate is exposed in the automatic machine. Here, the surface of the photo-semiconductor layer is evenly charged electrostatically in the dark, under a high-voltage corona. In this state, the insulating photo-semiconductor layer acts like the dielectric of a charged capacitor. The next step is exposure. Here, the paper master of the printing side is illuminated. The reflected light reaches a photosensitive plate via a special lens. Through this, pairs of charge carriers are formed in the photo-semiconductor layer; under the influence of the electrostatic field they separate and migrate to the outer charges. These are neutralised, and the voltage of the capacitor collapses at the illuminated places, the “non-image places”. The charge image is developed with a toner which consists of resin particles with opposing electrical charges. Then follows a thermo-setting step, in which the resin particles are firmly anchored on the plate. Lastly, the photo-semiconductor layer is removed from those places not covered by the toner, by means of a de-sizing liquid, and the aluminium is exposed. The printing mould is thus ready for printing (duration approx. 3.5 – 7 min, depending on the type of automated device). With the largest types, 120 print plates in newspaper format can be produced per hour (source: Hoechst).

ÖFI Austrian research institute; → Technical and professional organizations.

Ohm (O or Ω) Unit of electrical resistance which yields a current strength of 1 A at a voltage of 1 volt; or the resistance of a mercury thread 106.3 cm long and a cross-section of 1 mm≤ at 0°C. The resistance is in direct proportion to the length, and in inverse proportion to the cross-section of a conductor. Resistance in ohms = length (m) multiplied by specific resistance in ohms (resistance of a substance of 1 m in length and 1 mm^2 cross-section) divided by the cross-section (mm^2).

Oil alkyds → Alkyd resins modified with → Fatty acids or → Resin acids.

Oil- and fat-soluble dyes These belong to the group of organic pigment dyes, usually (amino- and oxy-) azo dyes, but without a water-solubilising group. Soluble in fats, oils, waxes, lacquers, resins, (chloro-) hydrocarbons, alcohols, ethers, etc., but not in water. Oil- and fat-soluble dyes usually have a high yield (0.2 – 1 g is sufficient for dyeing 1 kg of wax). The dissolving process requires 30 minutes and more. Used for oil chalks, pigment and lacquer printing, fat dyeing in microscopy (Sudan Red test), dyeing leather fats, enhancing dyeings on coconut material, re-touching, etc.

Oil circulation heating (→ Circulating hot oil unit). In order to obtain a greater evenness of temperature in the stenter frame (Fig. 1), one can heat with hot oil, circulated by a pump, which has a flow temperature of around 40 – 50°C higher than the target temperature

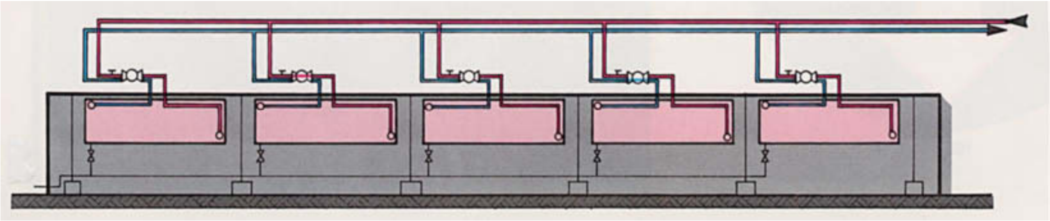

Fig. 1: Layout of heating pipes for the oil circulation heating of a horizontal stenter frame.

in the stenter frame, through separate heating (Fig. 2), i.e. where the frame temperature is 190°C, the oil temperature is approx. 240°C. Independent of boiler room.

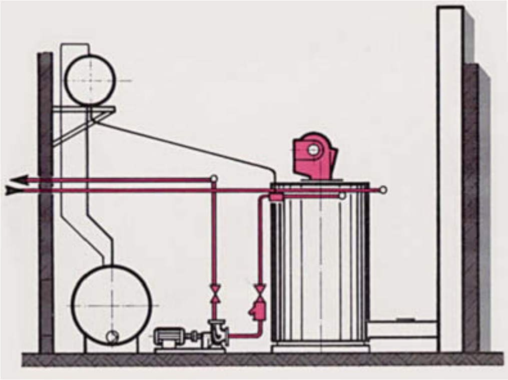

Fig. 2: Oil circulation heating boiler room.

Oil-colour solvent Special spot removers which can loosen even strongly resinified varnish stains, etc.

Oiled silk (insulating silk). Transparent, impregnated and printed fabric for raincoats, umbrellas, swimsuits, furnishing fabrics, etc. Manufactured according to a special process, such as elasticised urea resins. To avoid surface sticking, it is recommended that less elasticised urea resins are included, and that the mixture is thinned with alcohols or glycol ethers to immersion consistency. Usually dried at 80°C; this can also be accelerated by the addition of weak acids.

Oil emulsion → Emulsion system of water-in-oil (W/O).

Oil finish Finish with an oily, greasy handle, e.g. for anoraks. Originally, a non-permanent coating with vegetable oils. Permanent effects were only achieved through padding with → Silicone elastomers.

Oil-hydraulic batching drive Flexible drive for all winding operations with hydraulic motors, which guarantee the constant goods tensions for each winding size.

Oiling,

I. The preparation of man-made fibre continuous filament yarns, for the purpose of better processing in knitting (hosiery, warp knit and weft knit fabrics). Carried out on running threads, which pass through either oil-soaked wicks or rotating small rollers. The oiled thread is intended to preserve increased sliding properties and suppleness. Good removability by washing out is the main requirement. The oils used are mostly concentrated mineral oils with added emulsifier, for which oil sulphonates are suitable.

II. Preparation process for the willowing, carding and spinning of wool fibres or cellulose flocks or blends. Purpose: Increasing slding properties through → Textile lubricants with a film-forming characteristic which ensures an effective protective shell, lowers friction, and encourages stretching ability, flexibility, mouldability, etc. In the case of cellulose, there is in addition the elimination of electrostatic charges. Lubricant application for combed yarns 0.5 – 3%, carded yarns 8 – 15%, for reclaimed wool up to 30% (knits, etc. 6 – 7%, other used material mostly 8 – 10%). Oiling of synthetic fibres is neither customary nor necessary. In the case of wool blends, the wool is oiled separately beforehand, or – if this is not possible – the amount of oil is calculated only on the basis of the proportion of wool (according to experience, max. 4%). After dyeing or backwashing of combed tops, the preparations are washed out and have to be re-applied.

Oiling auxiliaries Added to → Textile lubricants, in order to facilitate the further processing of oiled fibres. Substances which are customarily used for this are mostly surfactants to promote the wetting, washing and milling characteristics, and to facilitate the removability by washing out. These include, amongst others, polyphosphates for easier washing out, reduced tendency to auto-ignition in the case of olein lubricants, and reduction of attack on metals.

Oil-in-water emulsion → Aqueous emulsion.

Oil repellence of textiles This is the capacity to withstand wetting and penetration by oily liquids. Oil is not absorbed, but is repelled in droplets. The effect is achieved by the application of oil-repellents in the oleophobic or oil-repellent finish. It is brought about by the fact that the forces acting between the oil-repellents and the oil droplet are weak in comparison with the forces acting within a drop of oil.

Oil-repellent → Oil-repellent finishing.

Oil-repellent finishing The textile auxiliaries used for → Water-repellent finishing are not sufficient to protect textiles against grease and oil stains. For this, special products are used, e.g. → Fluorocarbon polymers, which are used in the form of emulsion, sometimes in padding, sometimes in the exhaustion method. However, these products in turn do not provide a good water-repellent effect, which is why in practice oil-repellents and water-repellents are always used together. Some of the products available on the market provide effects which are resistant to washing and dry cleaning. Used with the → Soil release finish.

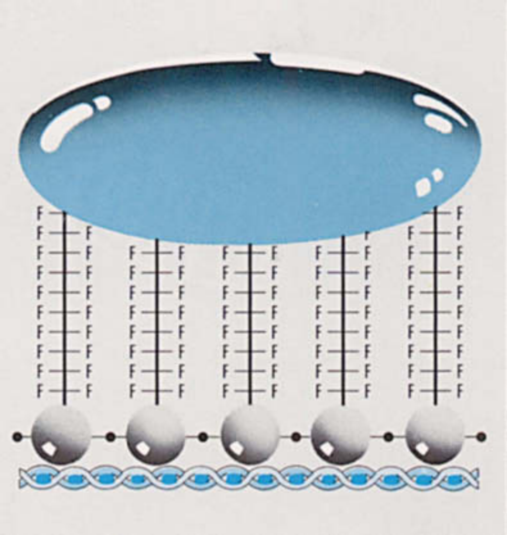

Fig.: The functional principle of an oil-repellant finish with hydro-fluorocarbon.

The synthesis technique of telomerisation used by DuPont provides access to perfluoropolymers. Sterically small base groups permit the arrangement of the fluoroalkyl chains close and parallel to one another, so that the result is oil repellence and water repellence (see Fig.). The high average chain length of 10–12 carbon atoms contributes to this.

Oils The composition and type of → Fats. There are (given corresponding presence of saturated or unsaturated → Fatty acids) →: Non-drying; Semi-drying and Drying oils. The drying property depends on the number of double bonds capable of oxidation in the fatty acids on which they are based (→: Oxidation of oils; Blown oils; Oil size). Chemical indices →: Iodine number, Acid value, Saponification number.

Oil separation from water Particularly from surface water and condensation.

I. Mechanical: (Preliminary removal of oil) Sedimentation basin (possibly introduction of compressed air, with addition of carbon dust, and subsequent filtration). Secondary removal of oil with special filters, e.g. filters with activated carbon. Principle and result: oil adsorption. Lowering of water velocity, constant change of direction, surface separation of the oil. Residual oil content approx. 1–5 mg/l.

II. Chemical: With sufficient alkalinity, e.g. with aluminium sulphate or iron salts; where alkalinity is too low, with added soda lye. Disadvantage: considerable enrichment of neutral salt. Principle and result: The precipitates which are created adsorb droplets of oil and drop out with them. Residual oil content approx. 1 mg/l.

III. Electrolytic: Condensation with soda lye slowly passes iron electrodes, and the oil precipitations which arise pass through gravel filters. Principle and result: destruction of the oil/water emulsion, separation, adsorption of basic iron salt separated at the anode, reduction of oil droplets. Residual oil content approx. 1 mg/l.

Oil separator Since oil has a lower specific gravity than water, it floats in an oil separator (see Fig.), if one leaves time for phase separation. If surfactants which have an emulsifying action are present in the oil/water mix, the emulsion separation is effected by means of colloidal chemistry; mechanical oil separation remains ineffective otherwise.

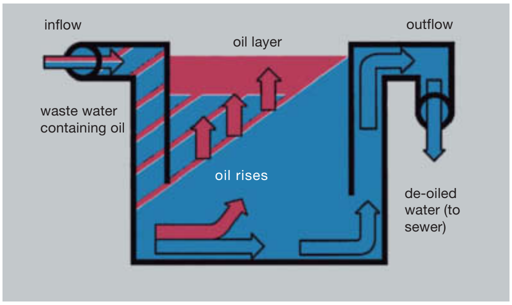

Fig.: The functional principle of an oil separator.

Oil size (linseed oil size). This was (and is) used for sizing viscose yarns with → Drying oils of the → Linseed oil type. This type of oil size is capable of oxidation, and polymerises, whilst absorbing oxygen, to form the characteristic “linoxyn skin”, which encloses the sized thread like a film. At the beginning of the 20th century, this oil size characteristic made a considerable contribution to the introduction of viscose yarns (highly twisted to non-twisted), which were prepared in this way for the warp stresses in the loom; it assumed particular importance for crepe articles and tightly woven fabrics (e.g. taffetas). The mills became independent of oil size, which had hitherto been indispensable, by the further development to full-width / warp beam size on special sizing machines, for they transferred the sizing of yarns from piece-work sizing shops directly to weaving preparation. Some disadvantages were eliminated, such as e.g. annoying oxidation risks and difficult de-sizing capability of the oxidised oil film. Oil size, these days is now barely of any significance. It is occasionally used for “end threads” or “selvedge threads”, as a substitute for highly twisted yarns, and in isolated cases as a viscose warp size for umbrella materials, with linseed oil size with paraffin and beeswax ensuring that a lasting water-repellent film is achieved.

In terms of the application technology, the following are distinguished:

I. Solution or dry oil size, type: Boyeux, Kress Special, Schetty, Swiss size. Principle: Linseed oil in organic solvent (benzene, trichloroethene, etc.), steep in the size centrifuge, spin, load in hanks, dry at 30–40°C in 48–60 hours, or according to method II.

II. Emulsion oil size (gamma size type): This served principally as a crepe yarn size, but did not become established as a general warp size. Principle: soak with emulsified linseed oil or similar in aqueous solution, centrifuge, spread, load in hanks, dry in 48–60 hours or (gamma method) in a shortened method according to the ozone oxidation method.

Oil size damage The main features of damage are e.g. the tendering of entire sections or localised areas, also differing strengths of outer/inner bobbin positions; auto-ignition through improper drying; warp streakiness through reduced stretching, sizing residues, yellowing, irregular crêpe effects in crêpe articles, etc.; brown spots, as local resin deposits through uneven drying, or residues or precipitations; sometimes considerably altered dyeing affinity.

Oil-soluble dyestuffs → Oil- and fat-soluble dyes.

Oil-solubler → Oil-colour solvent.

Oilstone (whetstone) → Levantine squeegee oil stone.

Oil tanning, chamois tannage → Tanning.

-ol Suffix in terms for → Alcohols and Phenols, usually appended to the name of the parent hydrocarbon in question; e.g. methane CH_4 = methanol (methyl alcohol) $CH_3\text{-}OH$; ethane C_2H_6 = ethanol (ethyl alcohol) $C_2H_5\text{-}OH$, etc.

Oleate Salt of → Oleic acid.

Olefin fibres → Polyolefin fibres.

Olefins (alkylenes, alkenes)**,** Unsaturated aliphatic → Hydrocarbons with a straight carbon chain and a double bond (type ethylene $H_2C{=}CH_2$). They contain 2 H less than the relevant saturated hydrocarbon, and thus correspond to the formula type C_nH_{2n}, and are characterised by the suffix “-ene” (formerly “-ylene”):

– derived from ethane $C_2H_6 \rightarrow$ Ethene C_2H_4;
– derived from propane $C_3H_8 \rightarrow$ Propene C_3H_6;
– derived from butane $C_4H_{10} \rightarrow$ Butene C_4H_8.

By splitting open the double bond, halogens are added:

$$H_2C = CH_2 \rightarrow CH_2Cl\text{-}CH_2Cl\ (C_2H_4Cl_2)$$

ethyl di-chloride

By contrast, unsaturated aliphatic hydrocarbons with so-called triple bonds are called → Acetylenes (alkines), and with 2 double bonds → Dienes (diolefins). Labelling of the C atom, on which the double bond is based, according to the following principle:

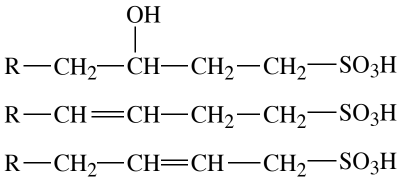
$$\overset{1}{CH_2}{=}\overset{2}{CH}{-}\overset{3}{CH_2}{-}\overset{4}{CH_3} \Longrightarrow \textit{1-butene, butene-1}$$

$$CH_3{-}CH{=}CH{-}CH_3 \Longrightarrow \textit{2-butene, butene-2}$$

$$CH_2{=}CH{-}CH{=}CH_2 \Longrightarrow \textit{1,3-butadiene}$$

1-configurations are also called α-olefins, etc.

Olefin sulphonate (α-olefin sulphonates, AOS, alkene sulphonates)



$$R{-}CH_2{-}\overset{OH}{\overset{|}{CH}}{-}CH_2{-}CH_2{-}SO_3H$$

$$R{-}CH{=}CH{-}CH_2{-}CH_2{-}SO_3H$$

$$R{-}CH_2{-}CH{=}CH{-}CH_2{-}SO_3H$$

Further development of washing agents based on → Olefins (α-olefins) through transformation with SO_3 and subsequent hydrolysis, where mixtures of hydroxy-/alkene sulphonates (among other formula types) arise. Designation as α-olefin sulphonates. Olefin sulphonates are among the most important detergent surfactants. The availability of the corresponding α-olefins is decisive for their introduction. Limited use of olefin sulphonate for detergents, flushing agents and scouring materials in the USA, Japan and Germany to date. Tests on the effective sulphonates of C_{14}-C_{18}-α-olefin mixtures yielded good washing power (low sensitivity to hardness, even at low concentrations); depending on the chain length, foaming problems can occur (foam inhibitor necessary). Olefin sulphonate mixtures with various other surfactants demonstrate synergistic effects and are particularly recommended (supplemented by other components) for well-foaming mild washing agents. Various olefin sulphonates no longer foam so strongly in the presence of sodium perborate in hard water at 60°C; the foam quickly collapses, which appears to be valuable for the manufacture of detergents for automatic washing machines. The ease of biodegrading of the olefin sulphonates must be emphasised: it is faster and more complete than for straight-chain alkyl sulphonic sulphonates.

Oleic acid (olein, $C_{17}H_{35}$–COOH) By-product of the manufacture of stearic acid. Colourless (pure state) to yellowish-brownish oil (unsaturated fatty acids; odourless; solidifies at 4°C, melts at 14°C; water-insoluble; forms easily soluble alkali salts (→ Soap). Used in: soap manufacture, lubricants for wool (absence of mineral oil, stearin, and similar substances which are difficult or impossible to saponify).

Olein (textile olein) Chemically non-uniform product. Main constituent: → Oleic acid and – depending on the raw material base (bone fat, tallow, train oil) – other (poly-) unsaturated (type: linoleic acid) and saturated fatty acids (palmitic acid, stearic acid). “Saponificate olein” (neutral fats and non-saponifiables) and “distillate olein” (more non-saponifiable, besides less neutral fat) are used for lubricants. The following is required for lubricant purposes: min. 99% total fat, flash point approx. 160°C, titre 10–17°C, acid value 175–195, saponification number190–205. Non-saponifiables 2–5%, ester number 2–5, neutral fat 2–5%. Iodine value 70–90, thiocyanogen value 75–85, metals less than 0.05%, Mackey test negative, discrepancy (difference between iodine and thiocyanogen values) 10.

Olein acid → Oleic acid.

Olein emulsions Commercially available lubricants in the form of compositions of olein soap.

Olein soap → Soap. Olein with special emulsifiers (mostly OE addition compounds), possibly with corrosion-preventing additives. With water, directly yields finely dispersed working emulsions.

Oleophilic Attracting oil; the opposite of → Oil-repellent (oleophobic). Some synthetic fibres, as well as cellulose and cotton which have been given a non-iron/crease-proof finish with synthetic resins, are strongly oleophilic, but also → Water-repellent (hydrophobic). Such materials are therefore easy to soil with oil, but difficult to wash with an aqueous liquor.

Oleum → Sulphuric acid.

Oleyl sulphate → Fatty alcohol sulphonates.

Olfactory (Latin: olfactorius = olfactory nerve; nerve for smelling). The characteristic of the olfactive (scent) which affects the olfactory nerve in the presence of → Odour.

Oligoester → Oligomers of polyester fibres.

Oligofilament Term used to describe a filament consisting of a few (2–16) continuous chemical fibres.

Oligomers (Greek: oligos = few, meros = part), few duplicated parts. Low-molecular attendants in → High polymers. Can be thought of as by-products not preventable by reaction kinetics (→ Pleionomers) in the synthesis of fibre polymers. Can be extracted using organic solvents. The structure is linear and cyclical.

A typical example is provided by oligomers contained at the level of 1–2% in polyester fibres, as e.g. dimeric and trimeric ethylene glycol terephthalate $(\mathrm{O(CH_2)_2O{-}CO{-}C_6H_4{-}CO})_{2-3}$. Cyclical oligomers have a strikingly high melting point (lowest members at approx. 70°C above that of polyester fibre), they sit firmly on or in the fibre, can be found frequently particularly after thermo-setting, cause annoyance through excessive dusting in re-spooling/twisting (abrasion products on thread guides and thread brakes) and – since they are specifically soluble at high temperature – as clouding deposits on dyed polyester fibres and at the edge of the dyeing machine, impair liquor circulation (Fig.) in wound package dyeing (filtered-off dye oligomer powder), reduce surface smoothness of yarns and the like. Remedy: dyeing time as limited as possible, carrier addition, relatively high use of dispersing agent (keeps oligomers in fine distribution); after dyeing has been concluded, drain the bath as hot as possible and rinse hot; after reductive washing off, conditions as intensive as possible; finish yarns before further processing; frequent cleansing (alkaline boiling) of dyeing machines, pipework, pumps, valves.

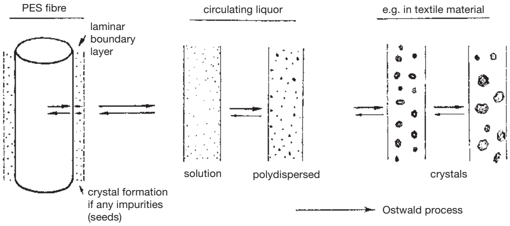


Fig.: Diagrammatic representation of the oligomer migration and crystallization process (source: Reinert).

Oligomer Test This test can be important for distinguishing oligomers as fibre abrasion products or as dyestuff dust. Demonstration is principally after extraction (see Fig.).

I. Cyclical oligomers show up in the polarising microscope as individual grains on a dark background.

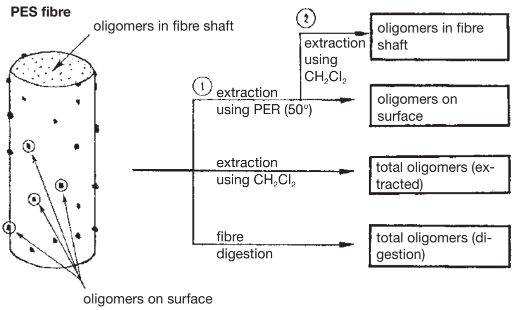

Fig.: Diagram of the process to obtain characteristic oligomer extracts.

Large amounts of oligomers on polyester satin which has been dyed black cause shadow-like patches, 100:1.

II. Oligomers in a mixture with 90 parts by weight of concentrated sulphuric acid and 10 parts by weight of water: polyester fibres are dissolved, cyclical oligomers simply swell.

III. Oligomers saponify in alcoholic potassium hydroxide solution to form terephthalic acid and glycol; separate terephthalic acid by precipitation with acid and cleansing through sublimation, dissolve the terephthalic acid obtained in diluted lye; with baryta water gives the specific crystalline form of barium terephthalate.

Oligosaccharides → Carbohydrates.

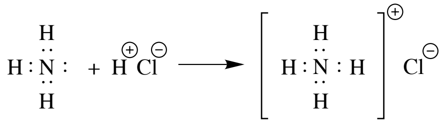
Olive oil lime soaps Mostly (more or less) thin-bodied special products, with a particularly softening or smoothing effect. Uses: (40%) as spool oil for viscose; finishing oil for silk, viscose etc. → Soap.

Ombré Colour effects yielded by continuous transition from light to dark and/or vice versa (shade, shadow), or from one colour (shade) to the next (variation shadow). They are achieved through → Dyeing of ombré or shaded effects, or also through special weave techniques (e.g. ombré weave).

O-Methylol compounds Compounds with one or more o-methylol groups ($–O–CH_2OH$), reactive group for cross-linking reactions (reactant resins), such as e.g. → Polyoxymethylenes (POM). Transformation products of aldehydes with alcohols, with at least two functional groups, also etherified, $–O–CH_2–O–R$, (R usually $–CH_3$). Used as resin finishing agents, e.g. dimethylol alkane diols; POM dimethyl ether.

Omnibus Short for omnibus designs: supply category for thermoprinting papers. Supplied to any number of firms, usually considerably cheaper. The opposite is exclusive designs: these are reserved for one firm or a certain small circle of firms, and are correspondingly more expensive; a minimum amount must be guaranteed.

Onium compounds (cation-active compounds), definition as → Complex compounds, in which the central atom effects one atom bond more than corresponds to the number of its valency electrons. The relevant anion is connected to the cationic complex via an ion bond. Ammonium compound derivation, e.g. of ammonium chloride $(NH_4)^+Cl^-$ in accordance with the following electron formula:



The proton thus pushes into the co-ordination gap of the nitrogen. Through this, via the free electron pair of the nitrogen, electrical resonance with the NH_3 group occurs, and an ammonium complex with a positive charge is created, i.e. a cation-active ammonium ion. Derivatives of this basic type are constructed analogously, and are generally referred to as onium compounds. Familiar ammonium compounds of this type are e.g. the cationic dyes. Since, in onium compounds, the cation represents the active constituent, the onium compounds used in textile finishing are termed cation-active (auxiliaries).

On-line Direct connection between data input and output (terminals) and the central computer which processes the data.

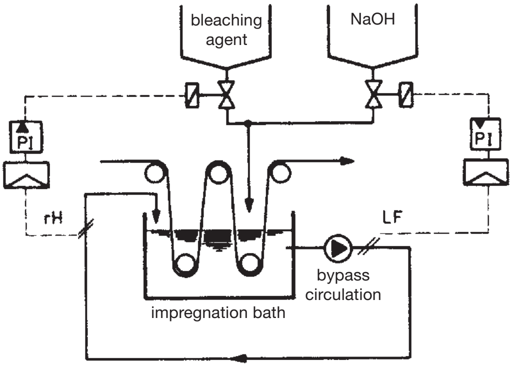
On-line controller Collective term for controllers on continuous runs of material. These include e.g. synchronous controllers, loop and tension controllers and band thickness controllers.

Online measuring probes Used in continuous processes for physical and chemical measurements (e.g. pH, redox, amperometry). As sensors, they have the task of bringing the measuring electrodes into contact with the liquid being monitored to obtain continuously reproducible measurements. Online measuring probes with an integrated mechanical cleaning system are designed to prevent soiling of the electrodes and are incorporated directly into the respective process cycle in either the main or the secondary flow.

On-line Quality Assurance → On-line quality control.

On-line quality control During the finishing process, on-line testing of the goods currently in production is used in order to prevent non-permitted variations in quality being produced at a production location (e.g. colour). On-line testing is thus an early warning system within quality assurance, to prevent “freak values”. If it consists of non-destructive measurement (i.e. without contact with the textile goods, or through direct measurement in the bath or in the bypass without liquor change), then this is in-line determination. The addition of soda lye and hydrogen peroxide in continuous pretreatment of cotton takes place e.g. after in-line measurement of the r_H value and the conductivity. The measurement of the so-called redox (oxidation reduction) potential takes place via a measuring chain, consisting of a precious metal electrode and a reference electrode (Fig. 1). The measuring chain potential is supplied to a measurement amplifier and a controller. The reference value of the controller is a redox potential based on practical experience. At the same time, the soda lye can be kept constant via conductivity measurement.

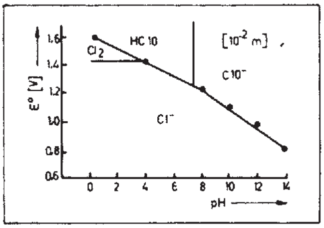
If in such a plant, a true concentration measurement – in each case during production – is to be the basis for the supplementation of chemicals used, then sampling of the liquor and its on-line titration with the loss of this liquor proportion must take place outside the plant, in its immediate vicinity, in a special analyser, in order to trigger the dosing via a control circuit (Fig. 2). The



$$E_{Rd} = E_0 + \frac{RT}{nF} \ln \frac{[Ox]}{[Red]}$$

$$OCl^- + H_2O + 2e \rightleftharpoons Cl^- + 2OH^-$$

$$E = E^\circ + 0.028 \log \frac{[OCl^-]}{[Cl^-]} - 0.059pH$$



relationship of redox potential of hypochlorite to the pH value

automatic analyser Concentromat ® ACC

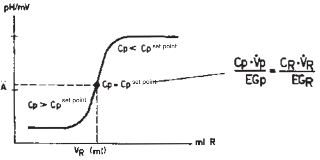

Fig. 2: The on-line principle for measuring and controlling the concentration of bleaching agent.
Cp = sample concentration (g/l); CR = reagent concentration (g/l); Vp = sample flow volume (l/h); VR = reagent flow volume (l/h); EGp = equivalent weight of sample; EGR = equivalent weight of reagent.

sample P is supplied in a constant amount to the mixer M1, via a pulse pump. The reagent R is likewise supplied to the mixer M1 via the variable output pump ST. The mixture now reaches the mixing cell MK, in which a pH or redox measuring loop is located. The measurement signal is supplied to an amplifier and a so-called internal controller R1. This controller R1 now regulates the reagent pump ST such that the mixture in the measurement cell MK is always at the neutral point. The reference value for the internal controller R1 is thus the neutral point of the corresponding titration. Under these conditions, the rotational speed of the reagent pump ST is proportional to the concentration sought. This signal is evaluated for the purpose of regulating the process concentration.

Off-line tests take place independently of the current process, in a laboratory separate from the process, on systematically-taken random samples which are not reusable. Its aims can include:

- detailed analysis of samples which were logged as defective during on-line testing;
- issuing of certificates for customers;
- production of internal statistics;
- establishing quality features which cannot be determined on the production machinery;
- checking the on-line system.

On-line control must take account of the respective inertia of the system. In the case of pH regulation, for example, the variables which influence the process control behaviour are the following:

- fabric characteristics, hydrophilic properties and the absorbency of the water/ethanoic acid mixture,
- placement of additives and the mixing process in the bath,
- measurement location,
- concentration of the added diluted ethanoic acid,
- pH of the water supplied,
- non-linearities (valve characteristics and pH curve).

Results obtained thus are shown in Fig. 3. Measurements are carried out every minute. It takes about 5–10 mins. to set the pH to a new value. Once the new value has been reached, there is stable control. The fairly long control time for a new value is due to the inertia of the system (determined by the ratio of bath content and the influx speed of the total liquids fed in, such as water, ethanoic acid). Trials with conventional PID controllers showed a slower or more fluctuating behaviour.

The problems with on-line colour measurement consist not just in how and with what scanning speed the measurement is to be made, but also in where the

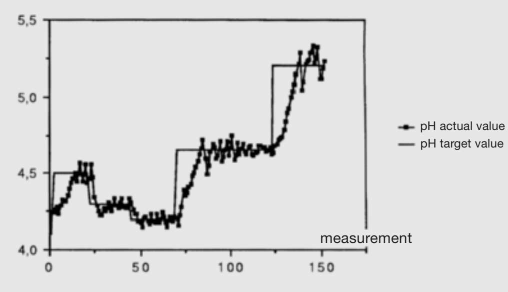

Fig. 3: On-line control of pH.

measurement is to be made. The industrial vat dye pad-steam process consists of the units illustrated in Fig. 4. The production sequence consists of pretreatment processes (washing, alkaline boiling off), which were carried out in the same plant before dyeing. After the fabric has been finished on this plant, it is then subjected to a thermal treatment (polymerisation or sanforisation machine). All that is of interest is the final colour. It makes sense to measure it after the last treatment and after a certain stabilisation time. Such measurements are carried out off-line, by the quality control staff.

These measurements provide information about the shade of the fabric, and are used in → Pass/fail tests or in corrections to recipes for the next dyeing. Since the number of such measurements is generally limited (they require the deployment of staff for cutting out samples for colour measurement), this leads to limited information about the causes of colour deviations. Moreover, they are not suitable for use in a control system for correcting colour deviations or for evaluating large amounts of data. The most suitable point in the dyeing process for predicting the colour which will finally result is the end of the continuous dyeing machine (point VII). Possible control corrections could be the liquor uptake (padder) or the addition of chemicals (reduction or oxidation agents). The reaction time between liquor uptake and colour measurement at the end of the machine is too great for effective control. Any change in liquor uptake which is necessary or which has been carried out is only registered at the end, after about 10 min. For this reason, additional measuring devices along the run of fabric can be useful for improving the overall control (e.g. measurement of the liquor uptake with the Mahlo or Pleva devices, air permeability, colour measurements in the wet state, pH or redox measurements). The colour measurements at the end of the plant are useful for correcting long-term deviations, for setting up reference values for critical control loops, or for setting up suitable control schematics.

When using colour measurement devices based on “reflectance measurement” in on-line operation, all efforts must be concentrated towards achieving the same dyeing conditions from the first to the last metre of the dye batch. This is particularly important for dyeing short lengths. Only when all these requirements have been met does it make sense to introduce the colour measurement device into the process, with the aim of measuring the current dyeing, and possibly of influencing the final dyeing result. Most colour measurement devices are concerned with evaluating quality in the final goods check, i.e. away from the production sites. Most measuring devices record the measurement value approx. 15–20 mm above the surface of the goods. If used on continuous dyeing plants, this would lead to the fear that problems could occur through heat radiation or re-evaporation from the goods. A measuring device which is suitable for this purpose should still be able to make measurements at a distance of 1.2–6 m from the goods.

A decisive factor for on-line colorimetry is the location at which the colour is measured. Depending on the measuring location, the run of fabric which is to be measured (e.g. polyester/cotton) in a continuous dyeing plant can be in the most variable conditions (Fig. 5).

– after the padder: wet (35–55% initial moisture content),
– after the IR pre-drier: damp (20–35% residual moisture),
– after the drier: residual dampness to absolutely dry (0–8%) and warm after the thermosol part: absolutely dry and warm,
– after the washing machine: wet (40–60% initial moisture content),
– after the drier: residual dampness to absolutely dry and warm,

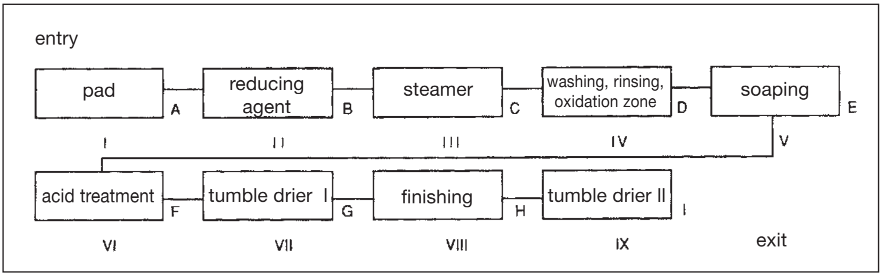

Fig. 4: Continuous dyeing facility.

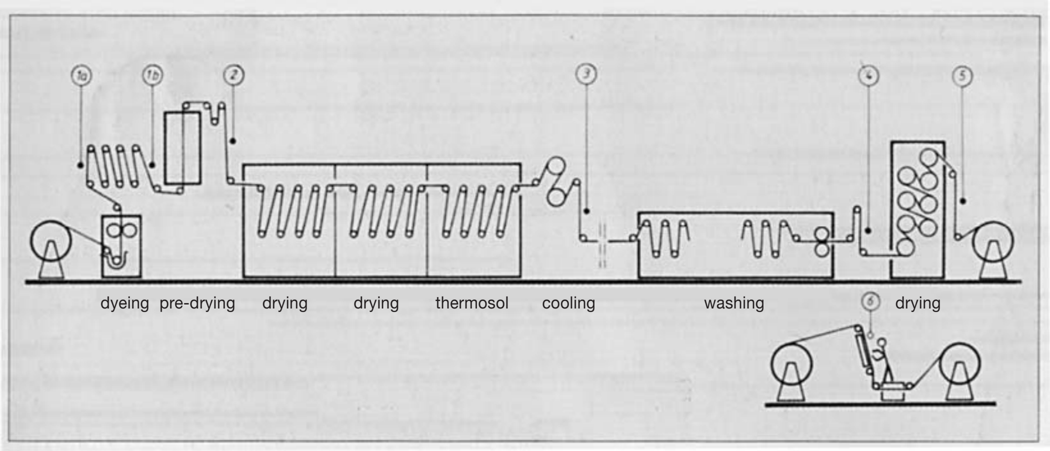

Fig. 5: Indication of possible dye measuring locations in a continuous dyeing facility (on-line) (Monforts).

– on the inspection table: cold (room temperature) and sometimes damp from storage.

Since the sample which is to be measured is compared with a standard, and this standard has to be prepared and worked out, it is to be expected that all the aforementioned states in which the goods might influence the colour appearance in comparison with a cold standard sample, damp from storage, to a greater or lesser degree. The use of on-line colour measurement devices in continuous dyeing makes sense where there exists a meaningful possibility of defining the standard clearly. Different levels of moisture and temperature influence the colour appearance so strongly that the measured values can be misinterpreted. Favourable measurement locations appear to be directly after the padder or in the finished goods inspection. With a perfectly-working drying and thermosol part, the colour evenness is preserved in respect of the edge/middle/edge difference. Any uneven colour result after the padder is partially alleviated by subsequent processes. The tendency of the dye liquor application appearance remains largely preserved right up until the finished goods stage. On-line colour measurement after passing through the padder can provide an early indication of defects or changes of shade from selvedge to centre.

Whilst pure on-line colour measurement technology is far advanced, and special pass/fail programmes for acceptance testing on dry runs of cloth are in the process of being developed, we still lack prospects of programmes which would put textile finishers in a position to provide the maker-up with information about the colour processability of a dye consignment. The maker-up must reckon with shade differences in the goods delivered, since in dyeing, for technical reasons it is not yet possible to avoid changes of shade within batches and colour deviations between batches to the desired extent. However, the processor would be well served with details of the bales of goods delivered which would tell him clearly which bales and bale sections can be processed together as one shade for making individual clothing items without the risk of visible colour differences appearing at the seams, and giving cause for complaint. This task must be taken on by colour sorting programs which, in the goods inspection system of the textile firm, are coupled with on-line colour measurement and pass/fail evaluation. For the textile finishing industry, this colour sorting would have the advantage that the time-consuming (visual or colorimetric) evaluation of the goods on the basis of sewing samples and their manufacture could be dispensed with (source: Jola, van Wersch, Rieker, D’Hulster).

ÖNORM Austrian standard.

Opal batiste Fine-filament, milky-looking cotton batiste, named after the semi-precious stone opal. Simple cotton yarns, usually maco yarns, are used for this. Finish: pre-mercerising, bleaching, acid treatment and final mercerising without tension. This creates a shrink effect which lends the fabric its milky appearance. Opal comes dyed, printed and embroidered in delicate colours, as well as in white. Used for summer clothing fabric, decorative aprons and in the cleaning industry.

Opal finishing → Transparent and opal finishes.

Opaline products → Pigment printing.

Opaque finish

I. In the case of thin knits, reduced transparency is often desirable, and this can be achieved through a calender process.

II. Black-out curtains are intended to prevent any light entering; this is achieved by coating.

Open area (printing screen) → Printing area.

Open-cell cellular material When → Foam lamellae (= closed-cell foam) are destroyed, or flow back into the cell webs at the end of foam formation, open-celled foam is obtained.

Open decatizing → Decatizing.

Open-end spinning → OE spinning process.

Opener (rope plaiting device) → Rope opener.

Opening, willowing In spinning technology, preparation on the → Plucker.

Open steam vulcanization → Vulcanize, to.

which one can make such detailed divisions in design and application technological aspects. This is made more complicated by the fact that many manufacturing firms would like to develop their washing machines into universal machines, and to do this they combine several otherwise specific features. The distinction between pre-washing and final washing processes makes classification possibilities even more difficult. It may therefore be helpful to summarise briefly the design principles for open-width washing machines known to date. Fig. 1 shows customary construction elements for open-width washing machines.

There is a trend towards open-width washing and automation of the construction of the open-width washing machine. Loop guidance of the goods in roller vats is partly replaced by horizontal goods guidance, with the direction of the run of goods running equally from bottom to top and vice versa. Any longer contact time between the goods and the liquor can be obtained by dwelling immersion in an accumulator. To intensify the washing effect, vibrators and/or increased pump output for forced liquor circulation is used (Fig. 2 and 3).

Open-width washing ranges Machines for continuous open-width washing are constructed of individual washing units, which are modules within a plant which are capable of washing functions (Fig. 1). The

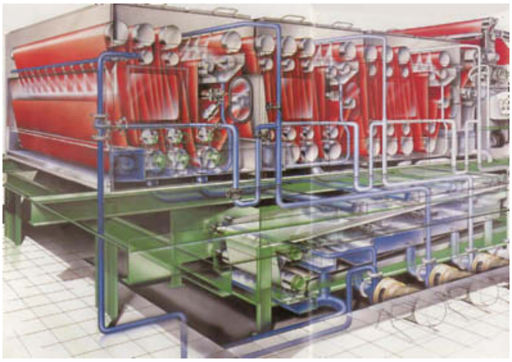

Fig. 4: Econ-Tex open-width washing machine (Babcock).

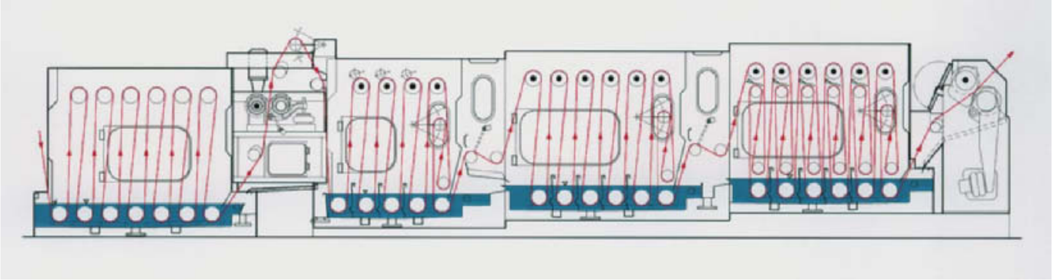

Fig. 5: Open-width scouring unit (Convi-Tex C from Babcokc).

sequencing of these units within a machine is variable. The individual units of a plant differ, to some extent, considerably, in terms of their guidance of goods and liquor, or else the same elements are used for each stage (Fig. 2). Large mechanical engineering firms include in their range, both horizontal and vertical open-width washing machines, as well as spray drum and perforated drum systems. In a conventional open-width washing range, the individual modules are set up from the back (goods exit) to the front, on modular foundations which rise step-like, so that the washing water flows against the goods step by step, with a natural fall (Fig. 5). The roller vats used in these open-width washing ranges (Fig. 3) represent the most important system of open-width washing machines. In the individual roller vat, also as a module in such a plant, the contraflow principle is realised by means of bulkheads and vari-directional liquor guidance.

The contraflow, which is regarded as essential, is created outside the liquor by means of laying-on rollers which lie on the upper guide rollers, loaded by their own weight. Through the laying-on roller's own

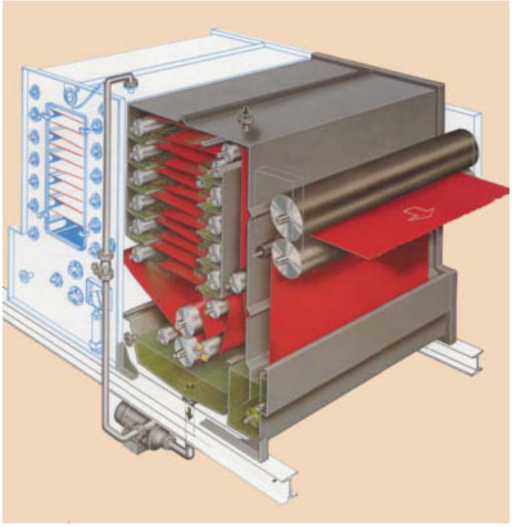

Fig. 7: Horizontal open-width washing machine (Kleinewefers KTM).

weight, excess liquor which is carried along by the goods is squeezed out and backed up to the extent that it flows down the ascending run of cloth in the form of a dense curtain of liquid. The high speed of the contraflow is calculated by adding the speed of the goods to the liquor which has been squeezed out. In the case of the “Econ-Tex” vertical open-width washing range from Babcock (Fig. 4), the goods run in a saturated steam atmosphere (virtually in a roller steamer). In relocating the standing baths of the roller vat from the goods compartment to below the machine, in order to carry out the contraflow and lint separation, the liquor is transferred by pumps from the liquor compartment into the respective goods compartment and back into the next liquor compartment. The overall contraflow liquor guidance thus has a strong liquor circulation superimposed on it. In each compartment, the liquor is brought directly into the nip between the goods and the rollers. The passage through the goods is effected at each deflection roller by the hydrodynamic print paste wedge and the effect of centrifugal force at each deflecting roller, particularly since there is no water back pressure (as in a roller vat on the lower deflecting rollers). Additional spraying tubes at the washing compartment exit support the washing action. Spraying tubes also support the liquor exchange at other points of the fabric passage (Fig. 6).

In horizontal open-width washing ranges (Fig. 7), which form the second most important group of open-width washing range types, the liquor flows down against the ascending goods under gravity. Here, the flow is forced through the goods in the nip at the deflecting rollers, which – in comparison with the passage through the goods in the areas between the deflecting rollers – leads to an increase of 0.2 l/m^2 per second (of a given fabric) to 1.2 l/m^2 per second. With raw cotton fabrics (not pretreated), problems can arise with this system, due to lack of through-flow, so that water pockets form.

In the third important group of open-width washing ranges, the perforated drum washing machines (Fig. 8), the liquor level in the interior of the drum is lowered

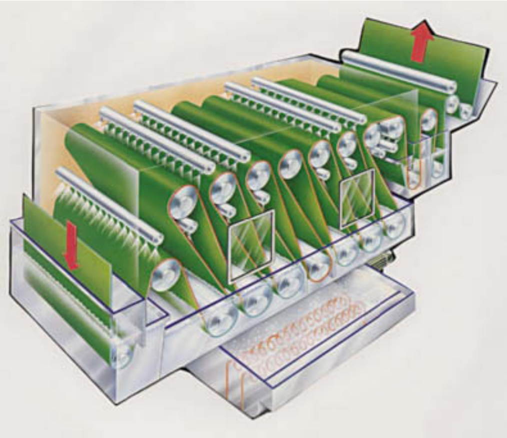

Fig. 6: Technoplus open-width washing machine (MAT).

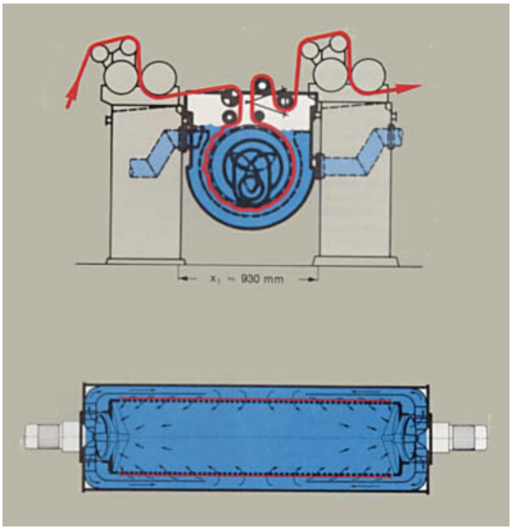

Fig. 8: Particular case of the perforated drum washing machine: suction drum (Babcock).

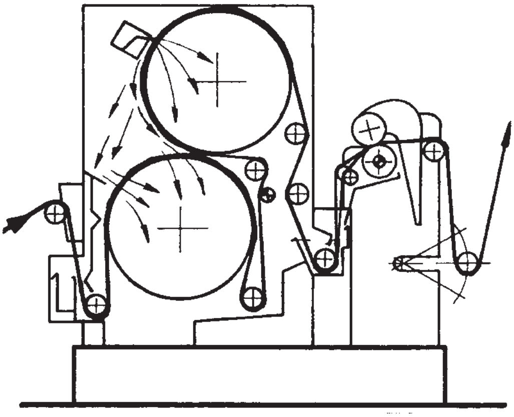

Fig. 9: Rotojet drum-type open-width washing machine (Küsters).

relative to the liquor level in the trough (outside), so that the liquor flows through the goods under gravity through the perforated drum. In contrast to perforated drum open-width washing ranges, in which the flow through the goods is effected by sucking the liquor out of the drum interior, in the fourth group of open-width washing ranges, (Fig. 9), the liquor is sprayed onto special drums around which the goods run. A special feature here is the grooved drum, since with this the liquor which is sprayed onto it runs through the fabric into the grooves, and then flows downwards and then through natural gradient, once again runs through the goods which have been conveyed by the drum. In today's washing units, the rules of liquor separation and substance exchange processes are realised consistently, i.e. liquor throughput with low-ballast liquor, early setting of washing equilibrium, washing temperatures close to boiling point of water, machine action deformation of the fabric fibre bulk, etc. A step in this direction is represented by the concept of an open-width washing unit in which the washing liquor is applied via a special liquor application device (bath-free), in which the liquor is separated and led away in the squeezer nip, and in which liquor throughputs of 5 l/kg are under discussion.

Open width wet pretreatment machines In the design and construction of washing machines, the trend has become established of ensuring as great a throughflow of liquor as possiblewith intensive substance exchange. Turbulence must be achieved on the one hand by the cloth itself, and on the other hand by mechanical devices. And not least, this task is performed automatically by the deflecting roller. Squeezing units and consistent use of the contraflow principle represent the state of the art. From these design concepts in machine technology, essentially four typical systems have developed: → Roller vat with horizontal passage of goods, perforated drum, cloth batch, and roller vat with vertical guidance of materials. Due to the number of large-sized baths, the result is, in part, relatively high in consumption of chemicals, corresponding high energy costs, and – under certain circumstances – a greater staffing requirement than for smaller compact plants; also considerable space requirement, since continuous washing ranges require space which is often not available. Open width wet pretreatment machines for open-width goods, in principle: pieces are wound onto a perforated tube, treatment liquor or rinsing water is introduced centrally whilst the roll rotates. In an ideal case, impregnation, dwelling, rinsing and spinning take place on the tube. In other cases, impregnation takes place on a padder, followed by winding onto the tube, dwelling and rinsing out. The fabric can also be sprayed with liquor whilst being wound on, and after winding on it can be pressed through the roll by means of a pump.

Operating costs (running costs) Pure, mostly fixed costs which result from those portions of the production costs accounted for by machinery and energy.

Operating point In a system (e.g. a pump) the actual operating status results from the intersection point of all the characteristic curves involved (e.g. in the pump diagram, see Fig.).

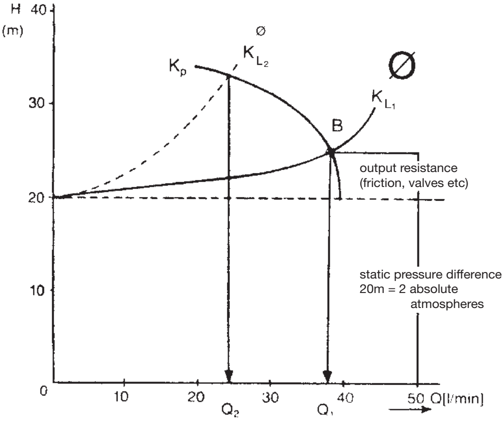

Fig.: Pump characteristic curve with operating point B with large pipe cross-section (K_{L1}) in comparison with pipe characteristic curve (K_{L2}) with small pipe cross-section.

Operating time Individual procedure within the → Processing sequence as a whole, time available to the worker for performance of the task within the period under observation. Divided into activity time and rest time (determined by the work sequence, interruptions, break times, other unavoidable activities).

Operational data logging In order to construct a realistic cost accounting system, operational data from meaningfully subdivided departments are necessary.

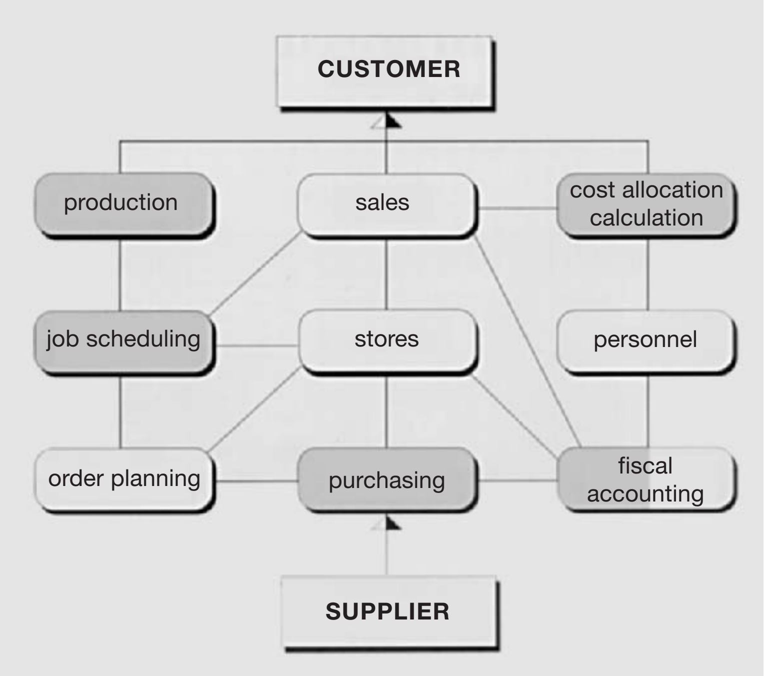

Fig.: Diagram showing the organisation of various operating spheres via an operational data logging system.

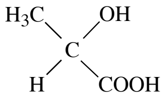
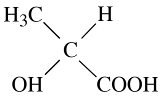
The firm (see Fig.) can be divided up according to technical considerations (organizational chart); for the purpose of operational data logging, the firm can also be divided up according to business management aspects. Here, production is a significant cost centre. Other costs centres include purchasing, distribution, operations planning and work preparation or warehousing.

Operational planning Predetermined sequence of individual processes or envisaged operations (→ Processing sequence in textile finishing). → Machine utilisation planning.

Optical Activity Characteristic feature of predominantly organic molecule bonds with spatial asymmetry. They match as the left hand and the right hand (mirror image isomerism), behave analogously in chemical and physical terms, have the same energy content, and yet are not identical, for → Polarised light in one case effects a laevo-gyration (l- or L- form, Latin: laevus = left), referred to as a negative rotation (–), and in another case a dextro-gyration (d- or D-form, Latin: dexter = right), here designated as a positive rotation (+). Such a pair of counter-rotating "optically active isomers", with the same structure otherwise, is called an antipodal pair. L and D forms of a molecule bond thus have optical activity. By contrast, a mixture of the same parts of both forms (D, L form) is optically inactive, since the L and D forms balance each other out (so-called racemic compound or racemate). Example: four different atoms or radicals adhering to the C atom, which take up different volumes, thus yield in space an irregularly distorted tetrahedron and thus lead one to expect optical isomerism, as e.g. lactic acid with asymmetrical C atoms can be laevo-gyratory (L-lactic acid) and dextro-gyratory (D-lactic acid):

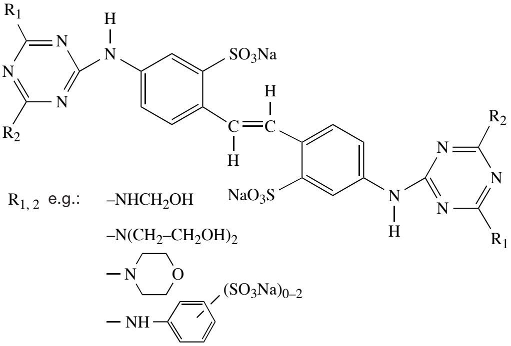




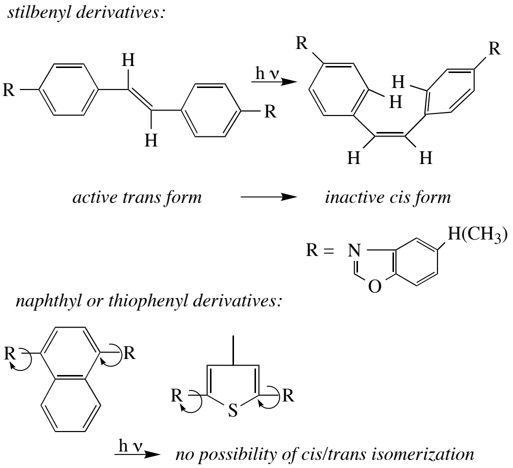
or non-rotating, optically inactive in the racemic mixture (D, L-lactic acid), as with commercially available fermentation lactic acid. Countless organic compounds exist in similar isomerism forms, such as optically active amyl alcohol, tartaric acid, glucose, fructose, sorbitol etc. Also included here are all proteins; they consist exclusively of L-amino acids, and are thus in their natural state only laevo-gyratory, i.e. optically active.

Optical brighteners (→ Fluorescent brightening agents). "Colour substances" which absorb light in the ultra-violet range and emit it again in the visible range. They therefore bring about an optical illusion on textiles, in that they raise the level of whiteness of the goods. This characteristic is associated with their chemical structure, as follows:

Cellulose fibre brighteners are derivatives of diamino stilbene di-sulfonic acid. What is effective here is only the trans-configuration, since only this form has a planar π-electron system enabling mesomerism in the excited state:



Above all in solution, stilbene derivatives suffer a light-induced de-activation of the optical brightener into the polymer matrix of the textile goods, but on the other hand there is a stabilization of the trans-stilbene form. Stabilisation of the trans-form of the optical brightener can also take place chemically, in that this configuration is sterically fixed, as in the naphthyl- or thiophenyl benzoxaolyl derivative:



Optical brightening agents → Fluorescent brightening agents.

Optical fibre Cladded core fibre made of inorganic or organic glass, whose core (diameter 5–100 μm) has a higher refractive index than the sheath. Through total reflection, light which enters at one end of the fibre and emerges at the other end transferred with as little loss as possible. Used for information transfer, lighting engineering, etc.

Optical Isomerism → Optical Activity.

Optics → Light wavelengths.

Optimization The organisation of technical and economic systems or processes in order to achieve a given aim in the best possible way, taking into account all secondary conditions. The optimization of finishing processes must be the aim in every firm. → Process control through measuring and control equipment represents the means for this. Many opportunities for reducing finishing costs remain unused, although the behaviour of most finishing products can be precisely described. Optimized process recommendations have been developed for, e.g., many classes of dyes or fibres. However, for the practical person it is often too costly to implement the knowledge available. Thus with changing finishing conditions (e.g. changes in the liquor ratio) or when transferring dyeing formulae from the laboratory and putting them into practise, it is frequently necessary to settle for wholesale corrections. Process recommendations are much simplified so that they can be applied easily and safely. Finally, in the selection of the most economical formulae, the process costs and the ecological effects are often ignored. With the current state of computer technology, computers and process controls can be successfully deployed in order to facilitate the selection of the most economical and ecologically optimized formulae, as well as to design the finishing process so that it is safer and simpler. In recent years, computers and process control systems have become considerably more powerful and cheaper. The question of their use for optimizing formulae and processes is therefore particularly topical. This is illustrated by two optimizations from the field of finishing:

1. Polyamide fibres take dye at relatively low temperatures. For this reason, energy-saving low temperature processes (e.g. at 55–75°C) have been proposed. However, to optimize, the low energy costs must set against the higher time costs, since in the case of polyester, a temperature which has been reduced by 10°C means that the necessary dyeing time is approximately doubled. The optimum maximum temperature, at which the overall costs (steam and time) are minimal, depends on the ratio of steam costs to time costs, as well as on the formula (rate of dyeing), the fibres (staining speed) and the heating rate (Fig. 1). The necessary dwell time in the case of this optimum maximum temperature is, by contrast, almost independent of the formula and fibres, and is essentially given by the cost ratio of steam/time. If the quality of the goods permits, it is consequently more economical to dye different formulae at different maximum temperatures but the same dwell time than (as has been more common to date) to dye for different lengths of time at the same temperature.

2. Some of the parameters which are characteristic for the quality of resin-finished textiles (e.g. crease

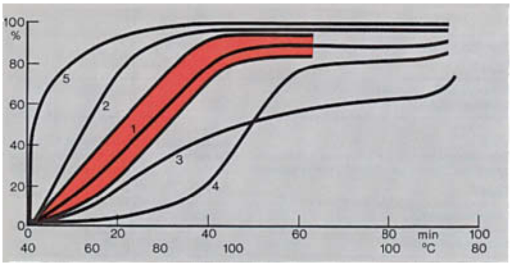


Fig. 1: Absorption curves for various dyestuffs applied to polyamide, whereby Curve 1 is approximately optimum. Curves 5 and 2 represent a rapid dyeing process with the accompanying risk of unevenness. Curves 3 and 4 guarantee even dyeing but require expensively long dyeing times. Curve 1 is the optimum compromise.

recovery ability and tear strength) change in opposite directions relative to one another, so that optimizing them simultaneously can be realised only by way of a compromise. The optimization process must be on the basis of process parameters which are typical for the crease-proof finishing of cotton fabric. In all three cases, the monomer is DMDHEU; the processes differ from one another in relation to the catalysts used and the condensation conditions. As an initial step in optimization, the mathematical relations which are characteristic for the individual processes were determined by means of test programming. The optimization parameters were dry and wet crease angles, decrease in tear strength, and releasable formaldehyde content. 20 tests were required to build up one database in each case. Of the so-called multi-purpose optimization methods, the method of loss reduction was used. It was thus possible to determine the compromise optimum values, with the aid of the loss reduction method. On the basis of all this, it was possible to work out a computer-controlled optimization program (Fig. 2). The program is constructed in the modular system, with one module corresponding to one finish in each case. The results obtained on the basis of test programming form the databases of the finishing technologies which are to be optimized. The databases can be compiled for each finishing agent which is used in practice within the firm, for each catalyst and its permitted concentration range. The databases and the system-description functions can be stored on diskette, so that the modules can be expanded, exchanged or put together in accordance with the finisher's requirements and capabilities. After selection of the databases for the finishing processes to be used, the characteristic data for the fabric to be finished, and also the requirements made of optimization parameters and optimization direction (minimum or maximum) must be fed in.

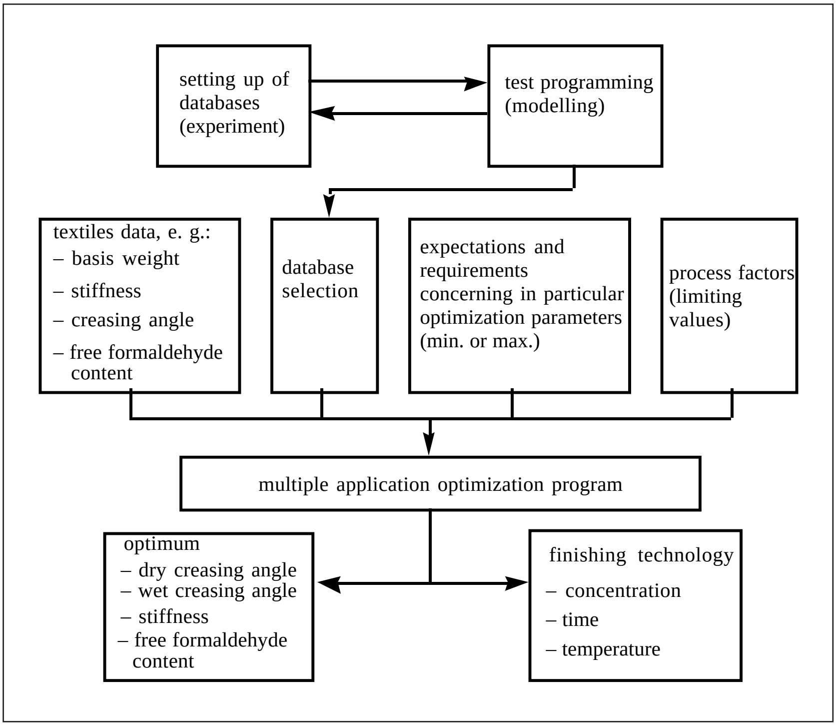

Fig. 2: Diagram showing computerized optimization.

According to the requirements, the following options can be selected: achievement of optimum crease recovery ability with

a) permitted max. tear strength reduction,
b) permitted max. amount of releasable formaldehyde content,
c) simultaneous permitted max. values for tear strength reduction and the releasable formaldehyde content.

(Source: Csanyi).

Optimum processing conditions

Optimum processing conditions Textile finishing methods which are associated with chemical processes often have optimum processing conditions, within the scope of which, they are applied (example: see Fig.).

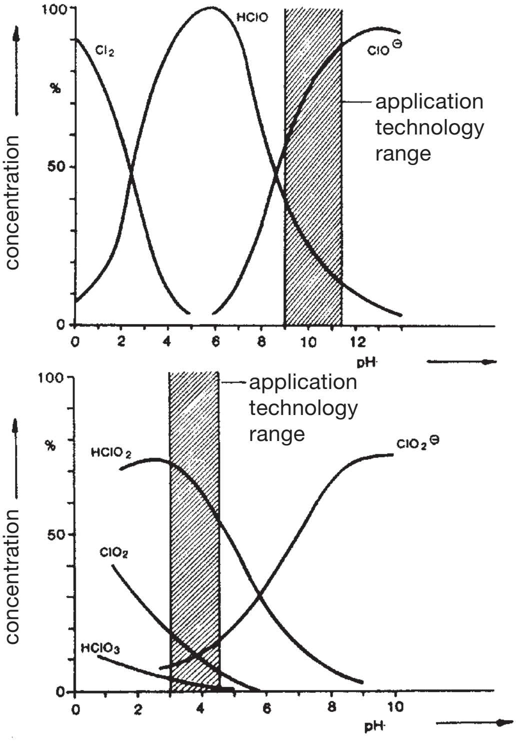

Fig.: Application technology range of activity with regard to the pH of the bleaching liquors of a hypochlorite bleach (top) and a chlorite bleach (bottom).

Optoelectronics For the transmission of information by optical wave guides through fibre-glass cables, using laser technology, the following principle applies: the shorter the wavelength, the more units of information can be transmitted. Since light has a considerably shorter wavelength than, e.g., radio waves, it can be used to convey considerably more information. A prerequisite for this, however, are the techniques and materials which can create and transmit the light signals, and where necessary amplify them, process them, store them, and appropriately decode and output them. Here, it is primarily the task of chemistry to smooth out new paths. By way of analogy to electronics, the technology based on light waves is called "optoelectronics" or "photonics" (see Fig.): tasks which were hitherto taken on by electrons are taken over by photons. When photonics was conceived in the late 1950s, the materials with which it could be achieved were not yet available.

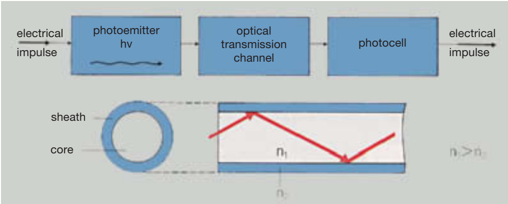

Fig.: The transmission of information by means of an optical waveguide (optical fibre).

The most obvious suitable material was undoubtedly glass. However, first of all the technical pre-conditions had to be created in order to produce glass which was as pure as possible. Although high quality optical glass was already very transparent around 1960, the residual absorption was still so great that it was not suitable as a light conductor for information transmission systems.

Due to the demands of the telecommunications industry, in 25 years the optical losses in glass have been reduced to one ten-thousandth of the 1960 value. A pane of the best optical waveguide glass which can be produced today, 3 km thick, would allow more light through than a conventional pane 3 mm thick. However, this does not exhaust the possibilities for optimizing materials suitable for optoelectronics by a long way. New perspectives are being opened up with polymer optical wave guides in particular. In optical waveguide technology, it is mostly quartz glass fibres which dominate. The transition from multi-mode to mono-mode fibres with a higher transition capacity has been achieved. Although initially the German post office preferred copper coaxial cables for extending the cable TV network, increased use of glass fibre cables in the extension and modernisation of the telephone and telecommunications network is becoming apparent.

Non-oxide optical waveguides are however already undergoing trials as alternatives to quartz glass. The high optical transparency of the non-oxide glasses predestines the fibres extracted from them for use in telecommunications. They should enable signal amplification ranges of up to 10 000 km. However, practical utilisation of these capabilities is countered by considerable implementation costs, which cast doubt on their economic viability. For applications in the close range area, interest is focused on optical waveguides made of organic polymers. Currently these are produced mostly from polymethylmethacrylate (PMMA) or polystyrene as the core material, and from fluorocarbon polymers as the sheath material. The purification stages (distillation, filtration, etc.) are carried out under clean room conditions at the monomer stage. Through melt spinning, a so-called step index fibre with a core/sheath structure is produced. Through the very low refractive index of the sheathing material, rays which impinge on this boundary surface at a flat angle are reflected back into the core, and are thus passed on. (Source: Hoechst).

Oral poison Pesticide for combating textile pests (→: Insecticide; Mothproofing) which is ingested with food. Potency is usually stated in mg/100 g (x mg have a fatal effect on living textile pests).

Orange peel effect Local shrinkages in two-layered fabrics such as e.g. synthetic leather; occurs particularly when non-woven fabrics are used as carriers. The cause is likely to be an uneven fibre distribution in the non-woven fabric.

Orbis printing (Tschekonin method). Patterning by means of a semi-solid coloured (mosaically composed) gelatine mass which has been applied to a metal roller, and which is produced beforehand and cut out in accordance with the pattern. Printing takes place with this, until the printing mass has been used up (i.e. similar to → Offset printing). A new roller can then be produced in the same way. Strong prints are produced by this method.

Orbitals (Latin: orbis = circuit, orbit). A term from quantum chemistry to describe the region around the nucleus of an atom, or around several nuclei in the case of a molecule, in which an electron is most likely to be found. In modern wave mechanics, atomic model for three-dimensional states of an electron, we have orbitals as so-called wave functions, in place of electron paths. This wave function of an electron is called the orbital wave function. We say that the electron has an orbital, not a path. The idea that when atoms and molecules are united, the bonding electrons come together and form chemical bonds, is expressed in the language of the molecule-orbital theory as follows: from the atomic orbitals (AO), the molecule orbitals (MO) follow, through linear combination. After that, a distinction is made between bonding, non-bonding and anti-bonding orbitals.

The term “orbita” originates from quantum theory. In 1925, the physicist W. Pauli showed that within an atom, two electrons can never have the same spin at the same time (Pauli’s exclusion principle). This rule allows the configuration of atoms to be determined, and the logic of the periodic system to be explained.

The shell configuration corresponds to definable energy states (Fig. 1):

Energy state	s	p	d	f
Max. no. of electrons	2	6	10	14

The energy states of atoms can be described thus:

Hydrogen: $Z = 1$ H: $1\,s^1$

Oxygen: $Z = 8$ O: $1\,s^2$, $2\,s^2$, $2\,p^4$

The orbital is a mathematical function whose spatial limits attempt to circumscribe the body within which the electrons of an atom move (Fig. 2). The square of this function gives the probability of the presence of the electron in the space. One cannot simultaneously determine the speed and position of the electron in the orbital. Moving from the atom to the molecule, the orbital is described as the linear combination of the atomic orbitals.

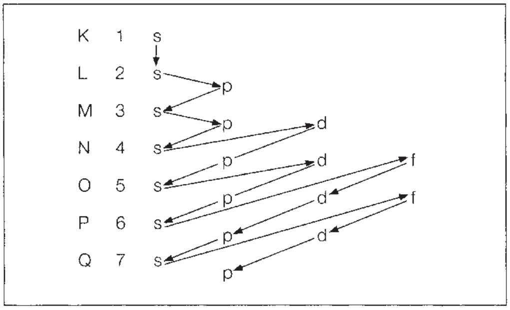

Fig. 1: Energy states according to shells, groups and sub-shells.

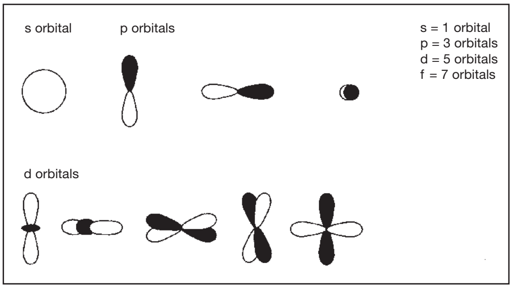

Fig. 2: Sketches of orbitals.

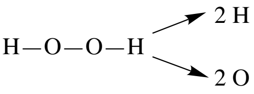
In peroxide bleach, the connection between orbitals and a stabiliser is shown. Hydrogen peroxide consists of a symmetrical molecule:



$$\mathrm{H{-}O{-}O{-}H}\ \begin{matrix}\nearrow 2\,\mathrm{H}\\ \searrow 2\,\mathrm{O}\end{matrix}$$

It is oxygen which is responsible for the bleaching effect. The oxygen atom OS^{16}_{8} belongs to the atoms with the neutron numbers 2, 8, 20, 50, 82, 126. Their nuclei are very stable, since they have the same number of protons and neutrons. The molecule structure of the stabiliser connects with the peroxide orbitals: synergy with an optical brightener. In the atom, as a rule the electrons are at the lowest energy level (Fig. 3). The UV radiation of the light excites the atoms and the electrons are brought to a higher energy level; since this higher energy level is unstable, the electrons change back to the lower level and in doing so, emit photons in the range of visible light. This also explains why, instead of 100% of the visible light falling on an optically brightened

Order planning

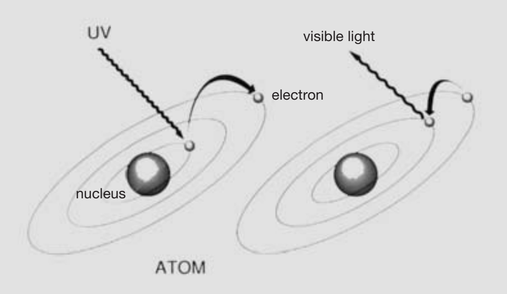


Fig. 3: Excitation states of an electron in an atom due to the absorption of electromagnetic energy.

substrate, there is a remission of 140%, thus giving rise to the impression of a high-white.

Order planning One application option for production control using computers is operations planning or order planning, and production tracking. Unfortunately, the arrangement of "Order planning – Planning" in spinning, weaving, finishing and garment manufacturing shops is variable. However, when the target is clear in

- the determination of the data for the start and end of manufacture of an order,
- the evaluation of machine utilisation over a unit of time,
- the checking of possible circumstances in connection with the delivery date for an order,

the restrictions in manufacture influence the method of order planning. To take an example from the mill: in view of the inertia of this type of manufacture and the existing difficulties in a change of article (tying, setting, etc.), continuous manufacture is out of the question (over-booking of the department for warp preparation, non-productive times, etc.). In the case of a finishing works, the waiting times between certain machines are associated with the maximum or minimum dwell times which have to be observed in order to prevent damage to the goods (through chemical reaction, wet goods, etc.). For this reason, planning which is suggested by an order planning software program, should be regarded as a representation of the operations which are to be carried out, in order of sequence. The solution must be permissible in respect of planning, and must be adapted to suit the technology. If one uses software for tracking production, the field surrounding production must be divided up into two large data groups: a) the machinery available within the firm; b) definition of the manufacturing sequence for each article. Machines equipped with the same features are grouped into operations planning points. This grouping allows e.g., one batch to be relocated if a machine is occupied and the manufacturing sequence is the same. This takes place in a manner which is transparent to the user. For an article, one determines a manufacturing area, which is ordered within the sequence of the work stages. Here, precise details of the manufacturing conditions and data belonging to the work stages (such as speed, response time, operations planning point, etc.) are established. Each work stage can be assigned an instruction for the staff entrusted with operating the machine (special requirements, etc.).

In its assembly, each article is clearly defined via the linking together of individual work steps (operational sequence). This assembly is carried out once, and stored in the computer master file. When planning a manufacturing order, the product plan is copied from the master file into the file of the internal order admin-

TIME PLANE	MARKETING (MIS) PLANE		PRODUCTION (CIM) PLANE
PLANNING PLANE season planning approx 160 – 220 days	sales planning	↔	production planning → supply planning → investment planing
ORDER PLANNING PLANE released working stock approx 10 – 30 days	order planning	↔	production order planning → personnel utilisation planning → machine load planning → ordering system/material reservation
EXECUTION PLANE throughput time approx 1 – 5 days	order monitoring ↕ order logging allocation/delivery note release	↔	production control ↕ operational data logging

Tab.: Integration requirement between MIS and CIM.

istration. Changes or supplements which specifically relate to the order can be made in the copied product plans. In the master file, on the other hand, all data remain in their original form. When a copy is produced, an order number is automatically issued, under which the product plan is stored in the system. This way, it is possible to check at any time how an order has passed through the works, even if modifications or supplements have been made in the master file in the same article, or if individual work steps have been deleted.

The algorithm is based on utilising each of the envisaged machines in accordance with the time required for the manufacture in question. This utilisation takes place based on several criteria, according to the level of intelligence of the software.

- Priority of calculation of the critical value: N = J/O; where J = number of days until the due date, and O = number of remaining work stages.
- Economic allocation, in order to increase the number of machines utilised at one operations planning point, with the aim of reducing the delay times during manufacture.
- Economic overlapping, which consists of starting a manufacturing process as soon as the material is available and before the current work cycle is concluded.

The planning which is thus achieved (see Table) can be altered manually if necessary, if certain regulations associated with the work cycle are to be taken into account. The modifications are made visible on graphic representations of the machine utilisation. At this stage of processing of the software programs, the user has at his disposal several printouts in the form of tables and lists. Usually these are manufacturing lists, monitoring lists, work tickets or operation lists. Confirmation that the work has been carried out is obtained via the recording of the data of the work sheet (length passed through, pass time). The system is then in a position to determine the dislocation in manufacture (orders not on time, room for play, etc.), and to supply the lists or screens with all the tasks necessary for the user (delays, etc.).

Order processing time (T). According to REFA, the association for time and motion studies, the time required by the worker from taking on the order to delivery of the finished goods. Dependent on the → Setting-up time and → Execution time.

Ordinates Vertical line in a system of co-ordinates. Horizontal: → Abscissa.

Organdy Fabric of cotton, viscose spun fibre and viscose filament woven fabric in taffeta weave construction, similar to → Mull or → Voile, with medium-strength finish, also figured and printed, transparent. Used for fine summer clothing materials; sometimes with stiffening finish.

Organdy finish → Transparent and opal finishes.

Organic chemistry Classification of chemical compounds of → Carbon, with the exception of carbon monoxide and carbonic acid, which for practical reasons belong to → Inorganic chemistry. Further sub-division of organic compounds into aliphatic and aromatic, which can often also be mixed (aliphatic-aromatic). Important organic compounds include, e.g. alcohols, esters, aldehydes, ketones, amines, carbohydrates, fatty acids, etc.

Organic glass By analogy to the term → Phosphate “glass”, this denotes colourless synthetics which are transparent like glass (e.g. aminoplasts, PVC, polyacrylics, melamine resins, the prototype → Plexiglas, etc.).

Organizational chart, organigram The classical textile finishing firm is divided into auxiliary establishments (e.g. laboratory), technical divisions (boiler house, repair departments, etc.) and production areas, as expressed in the organization chart (see Fig.).

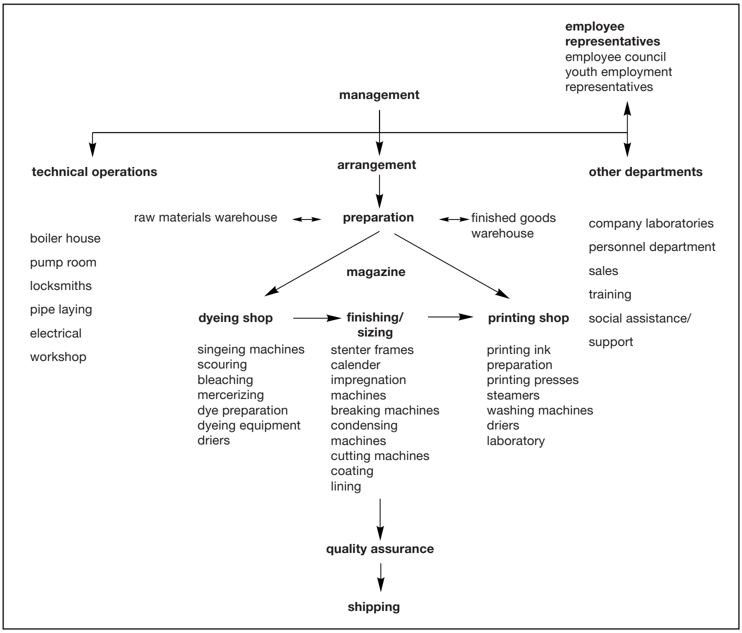

Fig.: Organigram of a finishing company.

Organizational structures in textile finishing

Organizational structures in textile finishing In textile finishing, as a rule a distinction is made between three different organizational structures (Fig. 1), which can be termed as follows:

- works finishing,
- integrated finishing,
- commission finishing.

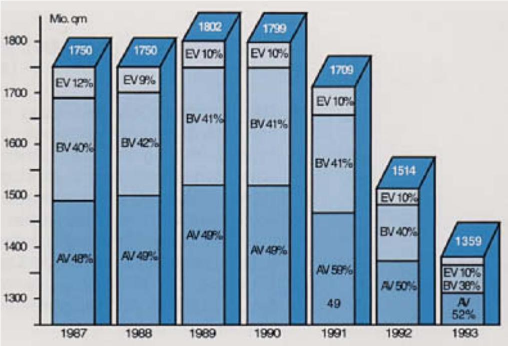

Fig. 1: Commercial finishing in the Länder of the original German Federal Republic according to the Central Association of the Textile Finishing Industry: contract finishing (AV), in-house finishing (BV), independent finishing (EV).

To clarify the different organizational structures, the relations between the mill, finishing shop and garment manufacture will be explained on the basis of structure models.

1. By works finishing, we mean finishing of raw goods produced in one's own works, on one's own account. Structure model 1 shows the classic vertical company. Finishing is a constituent part of the overall manufacture. This structure can provide ideal conditions of mutual communication. In vertical companies, efforts similar to those for other organizational structures are necessary for bringing the individual works, which are often set up relatively independently along the principle of divisions, to work together (Fig. 2).

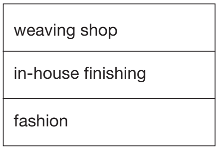

Fig. 2: Structural model no. 1 of in-house finishing.

Model 2 shows partial verticalisation, a common form which is a variant of model 1. The garment manufacturing shop is the customer, and the works' performance ends with the manufacture and sale of the run of fabric ready for making up (Fig. 3).

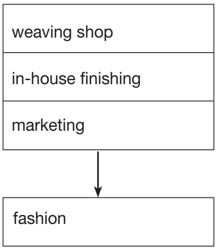

Fig. 3: Structural model no. 2 of in-house finishing.

2. By integrated finishing, we mean finishing of raw goods which one has bought in oneself, on one's own account. In this case, the finisher is one stage on the market, and is autonomous. The raw goods are bought, finished, and passed on at one's own risk. This possible organisational form is illustrated in Fig. 4.

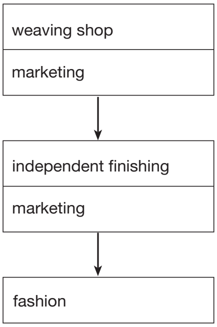

Fig. 4: Structural model no. 3 of independent finishing.

3. By commission finishing, we mean the finishing of outside raw material for the account of others. The finishing shop is practically turned into a service company, which exclusively offers its services for sale. The weaver is able to turn his entire attention to creativity and opening up markets, and to leave the extraneous finishing, which, due to its high requirements for energy, steam and water alone, also involves special environmental considerations and risks, to be dealt with by specialists.

The vertical "one-stop shop" type of firm with its own works finishing resorts to commission finishing if, due to good economic trends, it cannot cover certain production peaks, if its machines cannot deliver the required finishing effects, or if an article is particularly difficult and the finishing risks within one's own works are deemed to be too high.

The customer for the finishing cannot be either the weaver or the maker-up, but the textile intermediary, the manipulator. Experience shows that from this constellation, interesting tasks for textile finishing can result, but that partnership in the technical works is practically missing, which can have serious consequences. The manufacturing process of the fabric runs, the fibre material used, the texturing type in the case of filament yarns, and similar important details are mostly lost in the obscurity of the trade channels, so that often extensive checks on raw goods are necessary before corresponding batches can be worked on.

Organogens Those elements such as →: Carbon; Nitrogen; Sulphur which are predominantly involved in the construction of organic compounds.

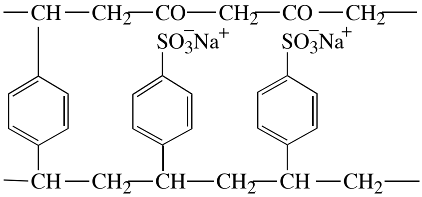
Organoleptic From the Greek, relating to perception by the senses. Organoleptic testing relates to the evaluation of appearance, handle, odour and taste; e.g. a purely visual assessment of a cleaning effect.

Organoliths Organic → Ion exchanger, subdivided into:

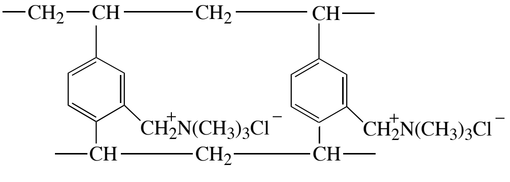
I. Artificial organoliths (carbon exchangers): sulphonated high molecular humus coals (brown coal, peat, wood), as acid-resistant ion exchangers.

II. Synthetic organoliths (exchanger resins, synthetic resin exchangers, resin exchangers): porous condensation and polymerisation synthetic resins with a large inner surface, with numerous reaction-capable, ion-forming acid or basic groups.

a) Cation exchangers are, e.g. condensation products of aromatic basic bodies of an acid nature, such as mono-valent or poly-valent phenols, aromatic and aliphatic sulphonic or carboxylic acids, with aldehydes, sulphonated phenol resin, sulphonated styrene, carboxylic acid resin, oxysulphonic acid resin, etc.; e.g. (in 3-dimensional terms):



b) Anionic exchangers are, e.g., condensation products of aromatic and aliphatic amines with aldehydes and related compounds of quaternary polyamines, etc.; e.g. (in 3-dimensional terms):



Organopolysiloxanes Organic silicon compounds of an oily or resin-like condition. Used for water-impermeable finishes.

Organosiloxanes (organopolysiloxanes) → Silicones.

Organosol Colloid solution in organic solvent.

Organosol process Hand dyeing process with dyes dissolved in solvents, for painting scarves, shawls, ladies' clothing fabrics and goods sold by the metre. Execution of partial plain dyeing, as well as all types of patterns. The latter is carried out with a cotton wool wad or brush, dipped in dye solution, onto the surface of the taut fabric.

Organotropic compounds,

I. These auxiliary solvents are organotropic compounds or polar, hydrophobic substances.

II. The solubility of strongly polar compounds in organic solvents is sometimes too low. The addition of organotropic compounds can increase solubility in that the hydrophobic proportion of micelles is increased in comparison with the hydrophilic ones (displacement of their → HLB value in favour of solubility in the organic non-polar medium). This requirement is fulfilled by polar hydrophobic substances. → Lyobipolarity.

Organotropy The capacity, especially of surfactants, to dissolve in organic media those compounds which are not soluble in solvents (→ Lyobipolarity).

Organzine Organzine (for warp ends, bolting cloth, etc.), twisted from 2–3 grège threads, given a corresponding preliminary twist, and twisted together counter-wise.

Oriental carpets Genuine, tightly-woven plush carpets, originating from the Orient: usually hand-knotted (typical → Knot density), always knotted through (each individual knot and each pattern discernable on the reverse), irregular pattern, often not quite uniform colour (slightly stripey in the background), fringed edge formed of warp threads. Main groups: →: Smyrna carpets; Persian carpets; Nomad carpet. Dyeing: previously with vegetable dye (usually good fastness to light, frequently not sufficiently fast to water and washing); European imitations of Oriental carpets are more resistant to washing and cleaning.

Orientation → Texture; Fibre texture.

Orientation forces → Secondary valency forces.

Original cost (prime cost) → Service life of textile plant and equipment.

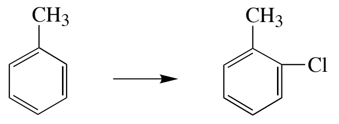
Orleans Smooth or patterned woven fabric (half-wool) in plain weave, twill weave and fancy weave (with figuring weft); also termed → Alpaca.

Orpiment Arsenic trisulphide, AsS_4. One of the oldest chemical reducing agents for indigo (orpiment vat). In the 18th century, generally known in Europe as "blue applied by brush onto calico" (orpiment brush blue), also known as orpiment English blue. Now found only in India (cottage industry).

Ortho- (Gk.),

I. Prefix for inorganic compounds which contain molecular linked water.

II. In the case of compounds of aromatic nuclei, term for the isomer (1,2-) position of substitution products, e.g.:



toluene *orthochlorotoluene*

Ortho acid → Acid anhydrides.

Orthocortex → Wool structure.

Orthokinetic coagulation Imperfection in the degree of dispersion of dispersion dyes in the dye bath, through strong mechanical influence, e.g. in pumps, conduits, etc. of circulation dyeing machines.

Orthophosphates Older term for → Monophosphates.

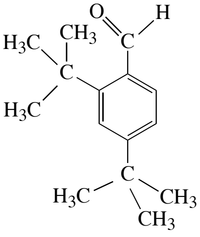
Os Symbol for the element Osmium (76).

Oscillation, oscillating (Lat.). Regular swinging to and fro.

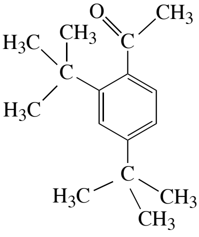
Oscilloscope → Stroboscope.

Osmometer Device for determining molecular weight.

Osmophore (odoriphore, Gk.: osme = odour, phorein = carry). Triggering sensations of smell. Relates to typical characteristics of so-called osmophoric chemical groups (such as carbonyl, hydroxyl, ether, nitro groups, or other groups containing nitrogen, sulphur or halogen, and unsaturated carbon compounds), which lend the odorous substance molecule a certain polarity and thus initiate the first step towards response contact with the specific receptor points of the olfactory nerves. They form an orientation factor, with the chemical condition generally having only a slight influence on the odour quality, for in many cases these groups are even interchangeable. For example, in the following molecule pair, exchanging the hydrogen in the carbonyl group for a CH$_3$ group alone is sufficient to change a strongly odorous substance into an odourless one:

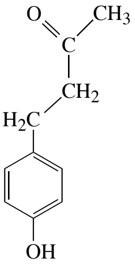


strong-smelling

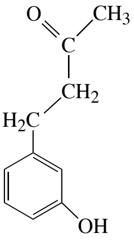


odourless

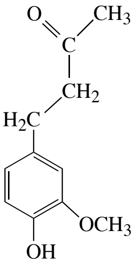
A strong shielding of the osmophore >C=O can prevent the interaction with the receptor system (olfactory nerves). On the other hand, the position of the osmophores also plays an important role, as the examples illustrate:



H = odour substance



odourless



odourless

Even the most minimal structural changes can alter the impression of odour completely: H is the olfactory principle of raspberries [so-called raspberry ketone (1-(p-hydroxyphenyl)-3-butanon)], with the osmophore -OH in para-position. By merely displacing the hydroxyl group into the meta-position, the molecule becomes odourless, likewise where the methoxyl groups (-OCH$_3$) are added in the m-position to the H-figuration. These examples show the complicated relation between chemical structure and → Odour, with osmophores only deciding together with their molecular environment whether an impression of odour arises, and in what differentiation. → Odour nuisance.

Osmosis (Greek: osmós = jolt, push) → Osmotic pressure.

Osmotic pressure Pressure exerted by dissolved molecules in their solvents, under → Brownian movement, to compensate density or concentration through → Diffusion (principle of tendency towards dilution). On the solution side of a semi-permeable membrane or dividing wall (→ Diaphragm), this pressure effects a drawing in of the solvent molecules, as a result of the higher mass concentration and thus the van der Waals attraction forces which have a stronger effect, until pressure equilibrium between the solution and the solvent is reached. Single-sided diffusion is called osmosis. The ability to diffuse through membranes fundamentally depends on the size of the molecule. Thus, for example, dissolved colloid-disperse Prussian blue cannot diffuse through a parchment membrane with water on one side (but water from outside inwards for the purpose of “dilution” of the concentration = osmotic pressure), whilst through this same membrane, in the case of dissolved molecular-disperse methylene blue, colour diffusion also takes place to the water side, through which a concentration dilution is effected on the one membrane side, and on the other side a concentration increase (→ Substantivity). Suitable membranes can thus also serve for separation (dialysis) of the two dispersivity systems. Associated with the osmotic pressure is the vapour pressure of solutions, which is small in comparison with the pure solvent medium, and which in turn, e.g. in relation to water is the cause of the aqueous solution boiling at a higher temperature (saturated sodium chloride solution at 108.7°C) and solidifying at a lower temperature (sea water only freezes at –2.6°C). Osmotic pressure is fundamentally involved in numerous textile finishing processes, particularly in all types of diffusion processes and swelling reactions.

Ossein, collagen A so-called scleroprotein or albuminoid, glue-providing substance with approx. 4% nitrogen, contained in bone cartilage. As a raw material, it is used for the production of animal protein chemical fibres (Ossein fibres), amongst other things.

Ostwald colorimetric measure → Colorimetric measures.

Ostwald colours → Colour circle.

Ostwald colour triangle → Chromaticity diagram.

Ostwald hue number The number allocated to each of the 24 hues in the → Chromatic circle.

Otting process Multicolour process for colouring carpets, with the work being done without thickening.

Ottoman cloth Light to heavy, stiff cloth with transverse ribbing, where the ribs are distinct and can be of even or different sizes (approx. 3–5 per cm). Worsted yarns are practically the only suitable type to use as warp yarn, and the weft can either be worsted yarn or carded yarn. Bonding: smooth or patterned ribs. If the weft yarn used is thick enough, cloth bonding can be used as well. These fabrics are either shorn or singed, to ensure that the threads are clearly defined. Use depends on the fabric and its weight. Woollen ottoman cloth is primarily used for ladies' suits and coats, upholstery and soft furnishings. Fabrics used for suits and coats are often raised on the reverse side to provide better heat insulation. Usually they are piece-dyed goods. Finely ribbed ottoman cloth in particular falls into the épinglé category, and is primarily used for covering upholstered furniture.

Outage time Interval of time between the point at which outage occurs (when one unit cannot be operated), until the system becomes functional again.

Outdoor textiles,

I. Textiles designed for open air use, such as synthetic lawns, sunshade fabric, marquees, etc.

II. Collective term for tarpaulins, tents, marquees and garden furniture with textile components. High-strength synthetic fibres, outstanding colour fastness, rot resistance, as well as a variety of designs are all essential qualities for outdoor textiles.

Outer drum Forms a large outer shell that encloses the → Inner drum and the "free liquor area" in → Double drum machine. The outer drum contains the necessary installed components and valve fittings, such as water supply and drainage, steam heating, condensate drain, chemical feed tanks, liquid level glass, remote thermometer, lid safety device for outer/inner drum, etc.

Outerwear Garments such as shirts, blouses, trousers, skirts, jackets, coats, as opposed to underwear. → DOB; HaKa; KOB.

Outline Thin, sketchy lines drawn around (print) patterns; contour, bordering. In print designing: Fine line printing. Clarity is mainly dependent on the thickeners used.

Outline printing with rotary screens Clear, fine outlines can be produced if the print paste channels are deepened: a) The nickel screen can be etched using iron (III) chloride solution after the lacquer layer has been cauterized (channel depth 0.04 mm); b) A thicker layer of lacquer can be applied using a special squeegee device (channel depth 0.08 mm).

Outward contract processing The German clothing industry is having more and more tailored fabric panels sewn ("finished") abroad, and the exported items are subsequently re-imported as finished garments (see Fig.). Typical countries that participate in outward contract processing (i.e. without any profit-sharing arrangement) are countries such as Greece, Portugal, Tunisia, Turkey and Morocco, where there is a backwards trend, causing the industry to turn to Eastern European countries like Russia, Poland, Hungary, the Czech Republic, Slovakia, Rumania and Bulgaria.

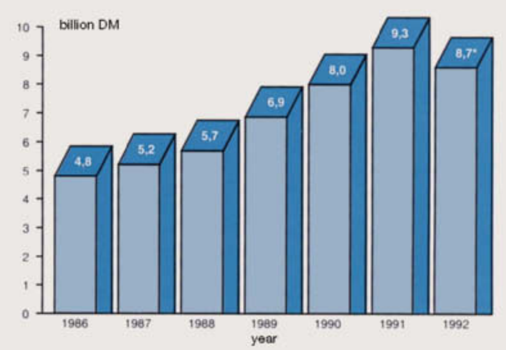


Fig.: Imports in the form of outward contract processing.

Oval winch → Winch beck.

Overall bonding Process for bonding nonwovens by means of coating with padding liquor containing binders, and using thermal induction to crosslink the binders (→ Print bonding).

Overboiling This can occur in situations such as boiling or protracted dyeing of cotton, wool or wool union goods. Causes: in cotton fabrics there are pectins present in the cellulose, which if they are not sufficiently removed before dyeing, will exert a dye reducing effect. In wool or wool union goods there are wool decomposition products that are produced as a result of a protracted dyeing process (possibly with a pH increase). Another cause of decomposition products is large quantities of sodium sulphate in the dye liquor (loss of molecular sulphur and nitrogen due to solubilization), which also exert a dye reducing effect. Effect: the dye is broken down or altered, causing incorrect shades, inconsistent surface appearance, difficult colour matching, extended dyeing period, and possibly a negative influence on fastness. Solution: do not use reduction-sensitive dyes and avoid addition of oxidants or salts that release acid when dyeing wool in a neutral dye liquor.

Overboiling inhibitor Auxiliary to help prevent → Overboiling of dyes and colourings. Lessens the reducing effect of alien substances on direct and wool union dyes, thereby reducing dye breakdown. The product is usually based on ammonium sulphate, urea, and possibly anionic active surfactants.

Overcoat (top coat) Dark, self-shaded or conservatively patterned (mottled) carded yarn cloths (e.g. Marengos); high-quality fabric in almost all types of finish. The fabric is used for smart, timeless coats of the same name.

Overdrying Excessive drying of fibre material, so that the capillary water content is removed. Heat and overdrying are damaging to a greater or lesser degree for any textile fibres, if allowed to take effect under uncontrolled conditions as opposed to controlled heating. It can result in thermal splitting of polymer chains. (→ Drying).

Overfeed devices Device particularly on pin stenters, to allow lengthways shrinkage during fabric tensioning (see Fig). Overfeed devices consist of two pairs of powered rollers located above the clip chains, which feed the fabric to the chains at a higher speed than the chains are capable of. This means that the fabric edges are fed onto pins while they are in a crimped position. Clip stenters have specially constructed clips with slits.

Overfeed system Fabric advancing devices for compression and crimping, e.g. on pin stenters, sanforizing machines, etc.

Overflow Dyeing Machines This rope dyeing machine system for woven cloth and knitgoods, is particularly suitable for delicate fabric types, and was designed on the basis of the overflow principle, which is easily manageable.

In Germany the “Liloc-Overflow”, an elongated, horizontal machine distributed by Jagri, can claim to have achieved success in 1971 as a non-winch beck rope dyeing machine for woven fabric (Fig. 1).

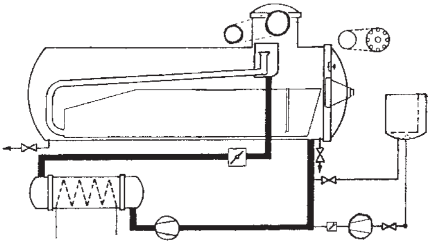

Fig. 1: Overflow principle (Liloc by Jagri).

Frauchinger launched a similar type of machine, the “Fastral”, in 1969 as a stationary version, which was developed into the “Fastex” in 1973. This type of machine, i.e. a system where the liquor contained within the sealed liquor exchange zone does not move much faster than the fabric (Figs. 2 + 3), has so little mechanical contact with the fabric that easily-creased fabrics can be dyed effectively in flat chambers without the need for tubular dyeing. The other advantage of horizontal dyeing machines is that they have two dwell chambers with a total capacity of approx. 300 kg of fabric, which means that two runs of fabric can be sewn together, resulting in shorter finishing times.

However, with thick cloth, a run-up time is required after feeding into the machine, which is stiff at first and thus must be monitored by the machine operators.

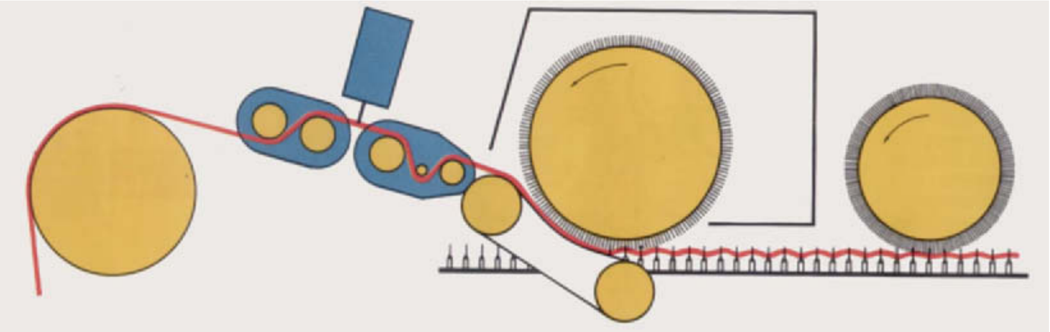

Fig.: Producing overfeed in a shrinking unit (Monforts).

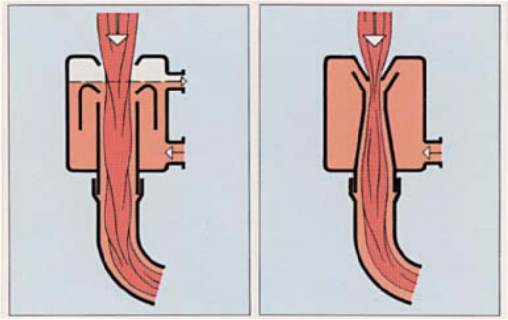

Fig. 2: Nozzle system (right) compared to the overflow principle (left).

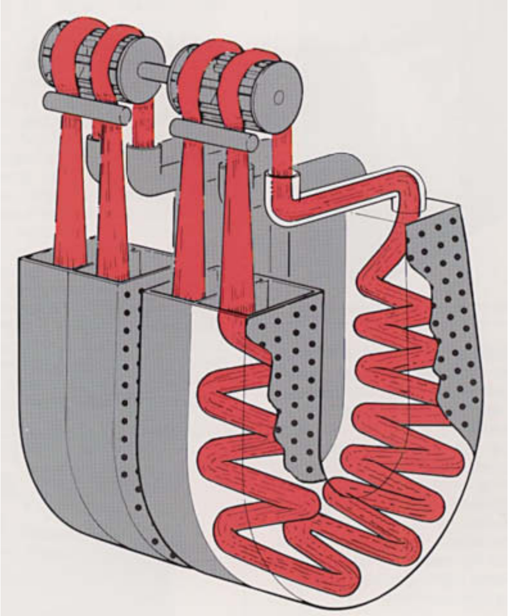

Fig. 6: Longclose with 125 kg chamber.

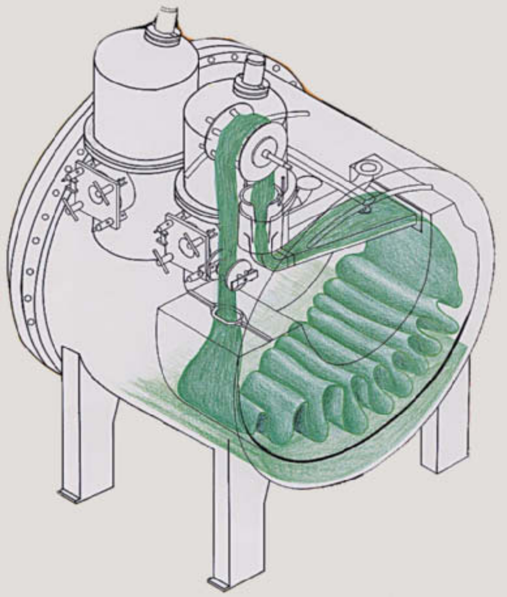

Fig. 7: MCS with 150 kg chamber.

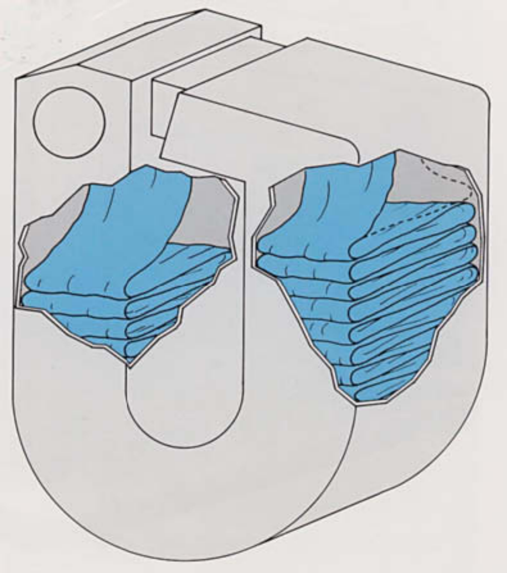

Fig. 8: Fong's with 200 kg chamber.

One definite disadvantage of semi-flooded overflow machines, which have become the standard type, is the liquor-to-goods ratio, which is still too high for practical use (Fig. 4).

Different overflow types offer different batch capacities depending on the fabric being dyed (Figs. 5–9).

→: Jet dyeing machines; Jet dyeing, development of.

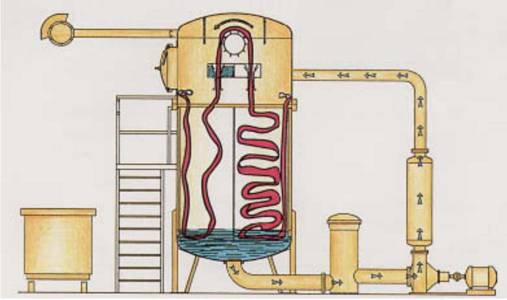

Fig. 9: Pandora (MCS) for 300 kg (type PA 300 HT).

Overflow system → Overflow Dyeing Machines.

Over maxing It is found (by using the → Waxing method) that the → Friction coefficient of jersey yarn reduces very rapidly as more lubricant is applied, in comparison with the friction coefficient for untreated fabric, until it reaches a minimum value known as the optimum friction coefficient. This optimum friction coefficient is usually half the value of the friction coefficient for untreated fabric. Based on this optimum state, if even more lubricant is applied, the friction coefficient will rise again. This phenomenon is referred to as over maxing, and is dependent on the lubricant used.

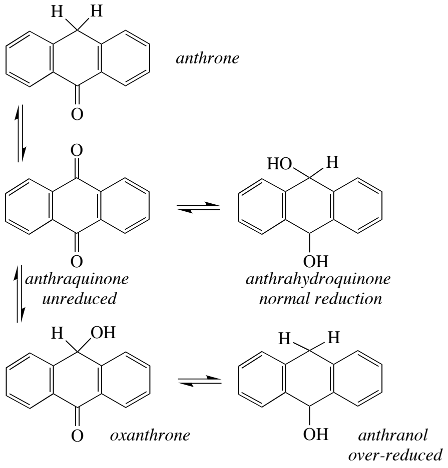
Overpressure → Air pressure.

Overprint In dyeing, a direct print covering lighter colour shades, not affecting the dye underneath.

Overprinted compound shades →: Half-tone resists; Half-tone screen; Half-tone printing on textiles.

Overprinted resists → Resist printing.

Over-reduction Undesirable characteristic of certain vat dyes, caused by factors such as an excessively high dyeing temperature, excessive levels of sodium dithionite in the dye liquor, extended dyeing periods, or a combination of these factors. Blue indanthren-type dyes are particularly sensitive to over-reduction:



Over-reduction leads to a loss in strength, significant dulling of colour shades, and sometimes causes reduced fastness to chlorine.

O/W Abbreviation for → Aqueous emulsion, i.e. an oil-in-water system.

Ox- Used as a prefix or suffix, or in the middle of a word; denotes the presence of oxygen in the molecule.

Oxacarbonic acids → Carboxylic acids with ether-type bonded oxygen atoms –C-O-C- in a continuous chain.

Oxalates Salts of dibasic → Oxalic acid; in the form of acidic, neutral, or double/complex salts. Alkaline salts are water-soluble, the rest are easily soluble in strong acids.

Oxalic acid (saccharic acid), $(COOH)_2$ or $C_2H_2O_4 \cdot 2H_2O$. Molecular weight 126.058; density 1.653; salts → Oxalates. Colourless crystals that are slowly eroded when exposed to air, mid-strength acid (one of the strongest organic acids), soluble in water, alcohol and ether. Strongly acidic solution (attacks cellulose fibres when in vapour form); toxic; powerful reducing properties; oxalic acid breaks down mineral-acidic alkaline salts. Potassium permanganate oxidizes oxalic acid to CO_2. Uses: reduction agent for dichromatic mordants (wool dyeing); discharge printing (indigo); bleaching agents (straw, etc.); detaching agents (for fruit, rust, ink stains); also used as a bleaching agent for leather.

Oxazine dyes Individual cationic, direct, acidic and benzidine dyes, deriving from phenoxazine.

Oxford Bi/multi-coloured woven cotton shirt fabric with a “sturdy” appearance; usually calico weave; occasionally also available as Panama or cotton twill weaves. Due to its soft, voluminous effect, it is also known as “non-raised flannel”. 2-thread warp and coarser weft, causing the Panama effect.

Ox gall → Gall extract.

Oxidation (oxidization), bonding of oxygen or release of hydrogen or electrons as a negative charge in chemical compounds. Typical example: Zinc + Oxygen = Zinc oxide ($Zn + O \rightarrow ZnO$). Opposite of → Reduction.

Oxidation bleach → Bleaching of man-made fibres using oxidizing agents, usually in an aqueous solution. This causes the natural dyes in the fibres to be broken down by means of oxidation and removed during subsequent rinsing, etc. There are different categories of product in common use:

I. Chlorine bleaching process (→: Sodium hypochlorite; Sodium chlorite).

II. Oxygen bleaching process (→ Hydrogen peroxide, less frequently →: Sodium peroxide; Peracetic acid; Potassium permanganate; Ozone).

Oxidation discharges → Discharging agents in printing resulting from oxidation.

Oxidation of metallic threads Tarnishing or colour change resulting from the action of oxygen in the air.

Oxidation of oils Dependent on the presence of one or several unsaturated fatty acids:

$$R-HC=CH-R-COOH$$

The principle behind oxidation of oils is that the double bond(s) break, and at the same time the free valency is saturated with oxygen. Double bonds, oxidation and drying properties are all directly proportional to one another. Examples of unsaturated fatty acids: oleic acid (1 double bond), linolic acid (2 double bonds), linolenic acid (3 double bonds).

Oxidation surge Term for rapid, immediate release of oxygen in large quantities, for example, if iron is present (as a catalyst) during peroxide bleaching of cellulose fibres. This reaction occurs primarily at high temperatures in an alkaline liquor at the iron/fabric interface, causing oxycellulose formation. It is assumed that continuous interaction is taking place as follows: iron with a valency of 3 is partially reduced by hydrogen peroxide ($Fe^{3+} + H_2O_2 \rightarrow Fe^{2+} + H_2O + {}^1/_2O_2\uparrow$) to valency 2 iron; however there are other possibilities currently under discussion.

Oxidative bleaching processes Oxidation bleaches for cellulose fibres (particularly viscose and viscose mixes) and protein fibres (wool, silk). Ammonium persulphate, potassium persulphate, sodium perborate, sodium percarbonate, sodium perpyrophosphate, sodium persulphate, sodium peroxide, hydrogen peroxide and potassium permanganate are the chemicals used most frequently for this type of bleaching process. Process is also known as → Peroxide bleach process. Neutral or non-dissociated hydrogen peroxide has no significant bleaching effect (minimal bleaching action at pH 7) but a strong danger of damage (maximum fibre damage at pH 7). Because of this, an alkaline additive is necessary as well as the oxygen carrier, to activate the bleaching energy and also to act as a cleaner. In excess of min. 20°d waterglass acts as a stabilizer, minimizing the damage factor. If the liquor is too alkaline (in excess of pH 12) and in hot concentrated baths, stabilizers no longer provide sufficient protection, preferably in the absence of extreme soiling. For this reason the two-bath process is frequently used: Pre-bleaching is carried out in a highly alkaline environment, and after-bleaching with a lower level of alkali (→ Bleaching of …). Uses: a level of pure white that is resistant to storage can be achieved, with a process that has a very mild effect on the fibre and excludes kier-boiling and chlorine; cleaning and bleaching is combined into a single process (→ Alkali scour-chlorine-peroxide), even suitable for raw cotton as a pure white single-bath bleaching process, for delicate textile mixes, dyed and printed fabric; also suitable for pre/after-bleaching using the standard chlorine-free two-bath process for fast, easy bleaching of cotton and viscose to pure white (also suitable for light wovens, jersey knits, coloured fabrics, etc.).

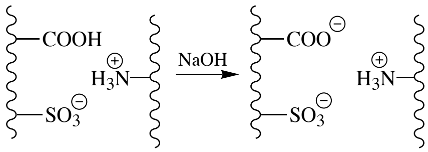
Oxidative bleaching with peroxide Oxidative bleaching process used mostly for natural fibres (wool, cotton, silk). The principal product used in this process is → Hydrogen peroxide. Alternative products of less importance are sodium peroxide, potassium permanganate, sodium perborate (only in detergents), peracetic acid. Of no significance: sodium percarbonate, ammonium and potassium persulphate, sodium perpyrophosphate. Neutral, non-dissociated hydrogen peroxide has no bleaching properties. It is only effective in an alkaline bath, at an ideal pH of approx. 11, achieved by adding sodium silicate (water glass), which also has stabilizing properties. Other stabilizers: sodium pyrophosphate, protein breakdown products, fatty alcohol sulphonate derivatives. → Bleaching of …; Peroxide bleach.

Oxidative washing agents This type of washing agent can consist of soap, alkali (sodium carbonate, phosphates, etc.), stabilizers (magnesium silicate) and a source of oxygen (sodium perborate, percarbonate, perpyrophosphate). Oxygen salts ensure that the alkali level is not too high and will therefore cause no damage. Modern oxidative washing agents contain appropriate synthetic surface active detergents instead of, or in addition to, soap (→ Syndets).

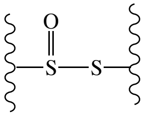
Oxides Oxygen combines with the elements. In situations where polyvalency arises, the valency is written in Roman numerals between the element and the oxide; for example the oxide of iron with valency 2: Iron (II) oxide (FeO); and of iron with valency 3 (also iron oxide) = Iron (III) oxide (Fe_2O_3).

Oxidimetrie → Titration.

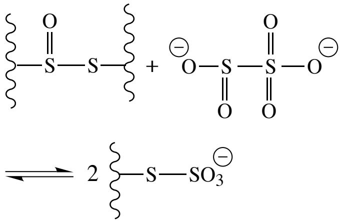
Oxidized wool In antifelt finishing processes on a subtractive basis, as well as during wool bleaching, the wool cystine is oxidized (a desirable effect for attacking scale, but unwanted when decolourizing melanin pigments). Oxidized wool is mechanically stable because wool keratin is electrostatically neutral in a model situation and therefore stable. In contrast to this, oxidized wool exhibits a high level of alkaline solubility because of osmotic pressure at pH 10, for example.



The complete oxidation of the cystine into cysteic acid occurs via various different oxides that are not immediately bonded when the crosslinking breaks down. If peroxomonosulphuric acid is used to oxidize wool, cysteic acid is not the primary product formed, as is the case with chlorination. The following structure shows the type of compound that is likely to form:



The process which is actually degenerative, but is essential for antifelting finishes, does not occur until subsequent sulphitolysis is carried out in a neutralization bath:



(The examples of wool used in these structures, by Zenko Stary, are highly simplified.)

Oxidize, to → Oxidation.

Oxidizing agent Either causes accumulation of oxygen or extraction of hydrogen. Oxidizing agents have practical uses, such as:

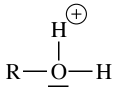
1. In oxidation bleach (chlorine products: calcium and sodium hypochlorite; products giving off oxygen: per compounds; sodium chlorite).
2. As oxidative products for unlocking starch.
3. For oxidizing/resoaping fast dyes (vat dyes, sulphur dyes and naphthol dyes) before setting (greater level of rub fastness, better general fastness, brighter colours).
4. → Stripping of dyeings.

Oxiranes Saturated three-section heterocyclical compounds with one oxygen atom, of the type ethylene oxide (C_2H_4O). Complicated and condensed ring systems of this type are → Epoxides.

Oxo acids (oxy-acids) Oxygen/hydrogen compounds with non-metals (e.g. chlorine, phosphor, nitrogen, sulphur) and metals with a valency higher than 2 (e.g. chrome, manganese, iron). Where there are polyvalent compound possibilities, the acidity level rises in proportion to the atomic number of oxygen (e.g. sulphurous acid H_2SO_3 and sulphuric acid H_2SO_4, etc.). Terminology of the salts: acids that are low in oxygen, or dithionic, hydro or hypo acids, have salt names ending in "ite" (→ Sodium sulphite, Sodium hypochlorite); salts from high-oxygen acids or → Per acids have the suffix "ate" (→ Sodium sulphate, Sodium perborate).

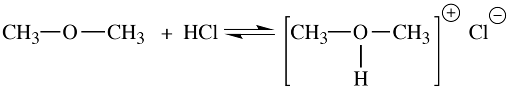
Oxo alcohols → Synthesis alcohols.

Oxonium compounds Chemical compounds with positively charged oxygen, e.g. in ethers with a weak basic character. They have oxygen-accumulating properties, analogous to ammoniac formation:



$R-\overset{H^{\oplus}}{\underline{O}}-H$

oxonium ion



$CH_3-O-CH_3 + HCl \rightleftharpoons \left[CH_3-\underset{H}{O}-CH_3\right]^{\oplus} Cl^{\ominus}$

Oxycarbonic acids Contain the hydroxy group (OH); e.g. (in castor oil in the form of) ricinoleic acid $C_{17}H_{32}OH\text{-}COOH$. → Fatty acids.

Oxycellulose → Cellulose damaged during oxidation (more or less broken down by oxidizing acids, bleaching agents, kier-boiling, etc.). The properties are analogous with those of photocellulose and → Hydrocellulose. Test: oxycellulose on its own →: Gold purple reaction; Nessler's reagent; Phloroglucinol reaction. In addition, as with hydrocellulose, with →: Prussian blue reaction; Fehling's solution; Methylene blue test; Vatting test, Turnbull's blue reaction.

Oxydiphenyls → Phenylphenols.

Oxyethylated cellulose (glycol cellulose, polyethylated cellulose),

$Cell\text{-}O\text{-}C_2H_4OH \rightarrow Cell\text{-}O(C_2H_4O)_x - C_2H_4OH$.

I. Cellulose ethers: produced as a result of ethylene oxide and a small amount of alkali acting on cellulose. In this way, fabric can be immediately oxyethylated, providing it with a stiff handle, transparent appearance and immunization. Synthetic fibres, monofilaments, films, etc. can also be produced from oxyethylated cellulose (synthetic fibres have almost as much wet strength as viscose filament yarns). Other uses are for glues, sizes, chemical finishing, etc., for which a degree of alkylation is of significance, i.e. the ratio of oxyethyl to glucose anhydride. If the alkylation level is between 0.2 and 0.9, there will be solubility in alkali and at min. 1.4 it will be water-soluble.

II. Methyloxyethylated cellulose: $Cell\text{-}OCH_3\text{-}OC_2H_4OH$. Produced from the action of ethylene oxide and dichloromethane on alkali cellulose, where there is usually approx. $^1/_4$ oxyethyl residue $O\text{-}C_2H_4OH$ and $^1/_4$ methoxyl residue $O\text{-}CH_3$ for each glucose residue. This type of product is used for sizes, chemical finishing, thickening agents, etc.

→ Cellulose derivatives.

Oxyethylation (ethoxylation, polyethoxylation, oxyalkylation), conversion of aliphatic, aromatic or aliphatic-aromatic compounds containing one or several reactive H atoms, using ethylene oxide, generating polyglycol ethers as a result. Oxyethylation can be explained as condensing polymerization, by means of the following equation:

$R\text{-}H + n\ C_2H_4O \rightarrow R\text{-}(C_2H_4O)_n\ H$.

The level of oxyethylation corresponds with the number n of oxyethyl groups. An increasing level of oxyethylation up to approx. n = 20 results in a constant increase in water solubility, lime soap dispersing properties and levelling effect (also in foaming properties up to n = 6). However surface activity is lowered, where the optimum value for fatty oils is in excess of n = 9, and for mineral oils the optimum value is as low as n = 5. For detergents the optimum is usually n = 5 – 12, but detergents acting on pigment soiling have a higher level of oxyethylation. Levelling agents for vat dyeing also have a group number of about n = 20.

Oxygen (O), atomic weight 16. Categorized under → Non-metals, gas, colourless, odourless and tasteless, non-flammable (but supports the combustion of other substances), liquefies (at approx. 100 bar) into a bluish substance, forms compounds with almost all elements (→ Oxidation). Extremely reactive. Combination of 3 oxygen atoms: → Ozone (O_3). Oxygen is water-soluble. Oxygen compounds: water, hydrogen peroxide (salts: peroxides), → Oxides (metallic oxides are alkaline, non-metallic oxides are acidic).

Oxygen carrier for bleaching → Bleaching catalysts.

Oxygen demand (waste water), The usual methods of analyzing waste water pollution are the → Chemical oxygen demand (COD), measured by the amount of potassium dichromate ($K_2Cr_2O_7$) used, or the → Biochemical oxygen demand (BOD).

Oxygen depletion Bacteria are responsible for the depletion of most organic impurities, consuming oxygen at the same time. It is essential that the micro-organism/waste water interface provides water-soluble conditions, and that the molecular weight is low, to ensure that penetration into the bacteria cell is possible. The bacteria cells do not absorb polymers.

$$\text{Organic substance} + O_2 \rightarrow CO_2 + H_2O + \text{new bacteria (biomass)}$$

Problems can occur with oxygen depletion if there is a low oxygen solubility level in the aqueous medium in which transfer into the cells takes place. To simplify, this is what happens during oxygen transfer: in anaerated nutrient solution containing micro-organisms, the micro-organisms absorb the dissolved oxygen, the concentration of dissolved oxygen becomes lower, and further oxygen diffuses from the air into the water. As the number of cells increases, both speeds become equal, at which point the dissolved oxygen content almost reaches its limit value. This is the point at which optimum

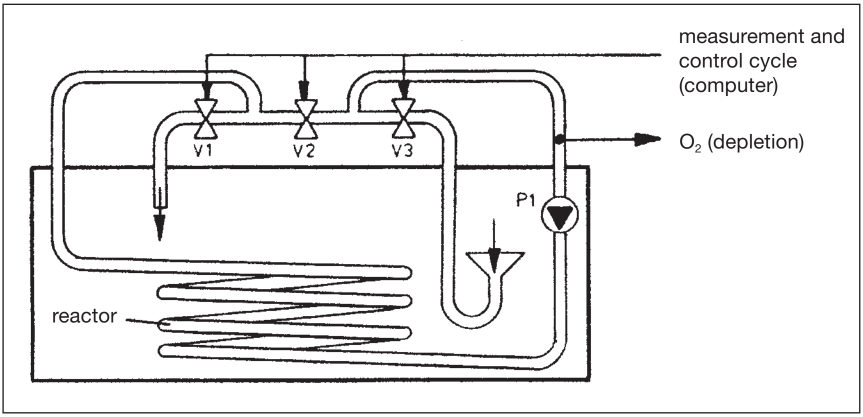


Fig.: Design and function of a depletion measuring device for determining the degree of oxygen depletion.

conditions are present for the process as a whole. Therefore there must always be sufficient oxygen diffusion occurring to meet the oxygen requirements of the cells.

BOD_5 specifications do not provide measurement values until five days have elapsed. For this reason, BOD_5 is just as unsuitable for running a biological purification plant as the COD or TOC specifications, because the specified values only apply to the level of impurities comparatively precisely in situations where the external conditions are constant. It seems more practical to measure depletion in relation to the level of impurities. The advantage of this method is that the measured values are available within 10 min, and the gauges, which are relatively easy to use (see Fig.), can be installed directly into the activation tank or the return sludge line. If the valve V2 is closed (V1,3 being open), the medium to be measured is transported from the tank in which it is immersed to the reactor. After only a few circuits V2 is opened (V1,3 closed). The medium is circulated through the reactor, where depletion measurement begins.

Oxygen fading → Ozone fading.

Oxygen-Index → LOI.

Oxygen measurement in steamers When dyes are set in a steamer, the steam needs to fulfil several functional requirements:

- It must supply heat and moisture.
- It must extract exothermic heat.
- It must extract reaction products.
- It must ensure that a constant level of fabric moisture is maintained.
- It must prevent oxygen in the air from causing redox reactions.

The influence exerted by oxygen in the air is of particular significance:

- setting vat prints or vat discharge prints,
- setting reduction-sensitive dyes (e.g. reactive dyes).

For the setting of vat discharge prints the oxygen content in the air must not exceed 0.06% by vol. O_2 (i.e. 0.3% by vol. air). However complete protection against oxygen in the air can lead to significant shade deviation during setting of reduction-sensitive reactive dyes. This is particularly apparent if sodium alginate thickeners are used in an alkaline environment, for instance.

It must be possible to measure and control the oxygen level in the steamer. Until now the state of the art method of measuring air/oxygen content was to extract the steam/air mix into a bottle filled with cold water, which provided qualitative and quantitative information. A direct analysis of the O_2 content is not possible using this method. In contrast, an oxygen measurement gauge measures the oxygen content directly in the textile steamer. The device consists of an oxygen sensor in direct connection with a pre-amplifier, and electronics for the purpose of analysis. The sensor is made from zirconium dioxide and has two electrodes. One of the electrodes is exposed to the air within the process, and the other is exposed to the external air in the room. Depending on the concentration difference between the two air sources, the sensor emits a certain voltage signal, which is processed in the electronic pre-amplifier. The analysis electronics compute the oxygen content in vol. % from the pre-amp signals, with the assistance of a microcomputer. The microcomputer has additional important tasks: It controls the function of the sensor and also calibrates it.

Oxy-sulphuric acid → Sulphur oxyacids.

Ozone (O_3), oxygen molecule with three atoms. Individual free oxygen atoms (known as “oxygen in status nascendi”, which have an extremely high level of oxidation energy → Ozone bleach) accumulate around O_2 molecules and combine with them to form ozone.

Ozone, action on fibres Ozone can react with aliphatic and aromatic bonds. For this reason it is possible to use ozone gas for antifelt finishing of wool, without the treatment becoming economically significant. Polyester is more easily damaged by ozone than polyamide, because polyester's aromatic ring system can be easily oxidized and destroyed by the ozone. The aromatic ring can be regarded as a double bonding system. When the dipolar ozone molecule attacks it, an epoxide is formed, in a defined rapid reaction sequence. Shortly afterwards the epoxide is broken down by the ozone, which at a higher temperature results in glyoxylic acid derivatives. As an example, the reaction for benzene is briefly sketched out in the Fig. below.

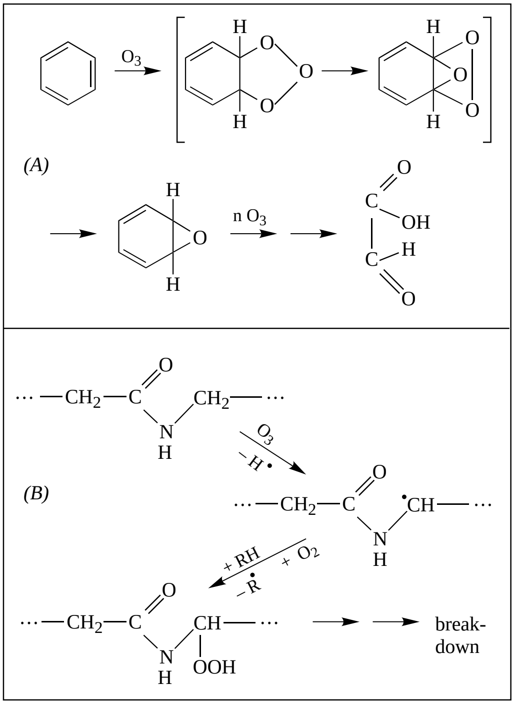

Fig.: Reaction pathway in the breakdown of aromatics and amides by ozone.

Aliphatic C-H bonds are much less readily attacked by ozone. This is why there is a lower level of damage in polyamide. It is only the CH_2 group adjacent to the nitrogen amide which is so unstable that it can be attacked. A radical is formed as a result of radical ozone reaction with this type of group (H abstraction), which reacts with the oxygen in ozone to form hydroperoxides. This reaction sequence is essentially the same as polyamide breakdown, which is influenced by atmospheric conditions (or xenon test conditions). The ozone treatment causes both materials to become more intense in colour, which is explained by the removal of a diffusion barrier. In the actual fibre structure, crystalline areas are bonded together by tie molecules (molecule chains that link one crystalline area to another, passing through the imperfect zones). Tie molecules of this type are under considerable tension, and are chemically more vulnerable to attack. For this reason, the oxidative breakdown process will remove these chains first. When the molecule chains are broken down, there is less resistance to prevent the diffusion of dye molecules into the imperfect areas of the fibre, so that the fibre can take up more dye during the dyeing process (Schollmeyer).

Ozone bleach Industrial development of an old type of bleach known as grass bleach, designed specifically for linen, less suitable for cotton. It has not been implemented on a large scale, both for cost reasons and also because it has no particular advantages over other bleaching processes.

Ozone fading (oxygen fading), the appearance of oxidative bleaching of blue, red and yellow dispersion dyes caused by the effect of atmospheric ozone, which is similar in appearance to gas fume fading. This effect is most common in acetate, triacetate and polyester dyes. Heat treatment of triacetate and polyester improves fastness to ozone fading. Penetration dyeing seems to be a significant factor (polyester dyes with a carrier are more resistant than those without). A maximum level of protection can be achieved by using an inhibitor and heat setting. Ozone fading can be prevented, by using anti-oxidation agents such as diphenylethylenediamine (also used as a gas fading inhibitor) and para-octylphenol (which has no gas fading inhibition properties), which means that using the methods detailed here, both gas and ozone fading can be prevented at the same time.

Ozone fastness Common in the USA, meaning the resistance of textile colour to the effects of atmospheric ozone in the following conditions: a) Air humidity below 65% at normal temperature; b) High air humidity of at least 80% at a raised temperature (40°C). Samples, and also control samples, are subjected to the effects of ozone in special chambers under the above conditions. The colour change is evaluated by means of a grey scale after a certain number of cycles.

Ozone layer depletion In the stratosphere there is a layer rich in ozone, which acts as a filter to block out UV rays (Fig. 1). At the Earth's poles (especially at the South Pole), a significant concentration of chlorofluorocarbons (CFC) has accumulated, generated by aerosol propellant chemicals, the production of synthetics, and refrigerator coolant.

UV radiation in the stratosphere causes chlorine atoms to break away from the CFCs, which react spontaneously with ozone (Fig. 2).

Ozone oxidation-drying process

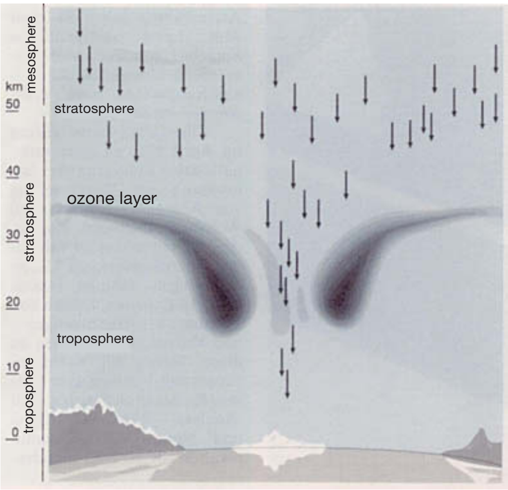

Fig. 1: Without the protective filter of the ozone layer damaging UV radiation passes unhindered through the atmosphere.

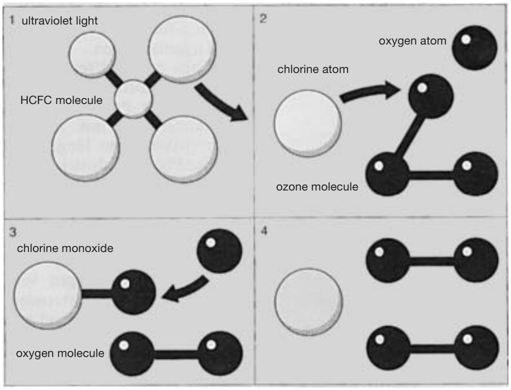

Fig. 2: Reaction of hydrochlorofluorocarbons with ozone.

The ozone is converted into oxygen, which has no UV light filtration properties. Excessive UV light radiation on the skin can cause pathological changes (skin cancer).

Ozone oxidation-drying process Drying process for → Oil size, in particular the gamma process (emulsion oil sizes) by ozonizing during the drying process, reducing the standard long drying times, which are sometimes in excess of 48 h, down to approx. 2 h.

Ozone treatment of waste water Treatment of waste water from dyeing with ozone can cause the dye molecules to break down (particularly in reactive dyes) into small fragments, causing the waste water to become decolourized (see Fig.).

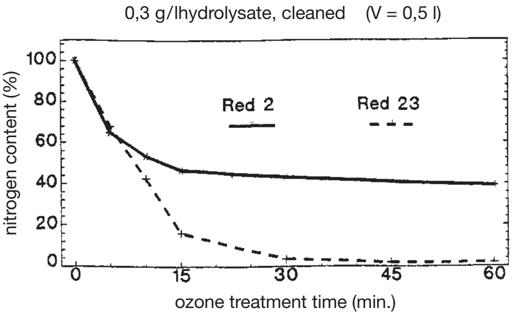

Fig.: The breakdown kinetics of two reactive dyestuffs (red C.1.2 and red C.1.23) during the ozone treatment of waste water from a dye works.

P

P,

I. Element symbol for phosphorus (15).

II. Textile care symbol for dry cleaning with tetrachloroethylene (perchloroethylene).

p → Para-.

PA → Polyamide fibres, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

Pa,

I. Unit symbol for → Pascal.

II. Element symbol for protactinium (91).

PAC → Polyacrylonitrile fibres, → Textile fibre symbols, according to DIN 60 001 until 1988, from 1991 → PAN.

Package Wound package, consisting of a tube and winding, e.g. →: Pirn; Crosswound yarn package; Flanged bobbin; Hollow cop.

Package density Information in g/volume. Uniformity of package density is important. Based upon a liquor related flow equation, which is supplemented by taking into account the radial package density differences, the following equation is used for the determination of the yarn package flow resistance Δp_L [mbar]:

$$\Delta p_L = \rho_F/2 \cdot \upsilon \cdot \upsilon_{20^\circ} \cdot \frac{6{,}14 \cdot \rho_{TL}{}^{1{,}5} \cdot h_L \cdot 0{,}01}{d_S{}^3 \cdot \sqrt{\rho_S} \cdot (0{,}952 \cdot \sqrt{\rho_S/e_H} - \sqrt{\rho_{TL}})^2}$$
$$\left[\left(1 + \frac{Q_M}{F_L} \cdot \frac{d_S}{2{,}25 \cdot \upsilon_{20^\circ}}\right)^2 - 1\right] \text{ [mbar]}$$

Δp_L [mbar] = flow differential pressure of the yarn package,
$\rho_F/2$ [kg/m^3] = density of (ambient air) flow medium (0.60),
ν [m^2/s] = temperature dependent viscosity (at 20°C = $15.2 \cdot 10^{-6}$),
ν_{20° [m^2/s] = 20°C viscosity ($15.2 \cdot 10^{-6}$),
F_L [m^2] = (average) yarn package flow area,
h_L [m] = package height of the yarn package,
ρ_{TL} [kg/m^3] = (average) package density of the yarn package from G_T/V_T (G_T = textile weight; V_T = textile volume),
ρ_S [kg/m^3] = density of the textile substrate,
e_H [–] = (average) fibre form factor,
d_S [m] = (average) fibre diameter,
Q_M [m^3/s] = environmental air or liquor flow rate.

The representative characteristic values for 20°C ambient air and the yarn package textile meter are added in brackets after the formular symbols used in this equation..

For the arithmetic evaluation of environmental air flow experiments using the yarn package textile meter, the generally valid equation is rearranged so that the equation can be used to calculate the flow effective package density ρ_{TLX} of the yarn package through which flow occurs using the yarn package textile meter, whereby d_S is used in µm:

$$\frac{\rho_{TLX}{}^{1{,}5} \cdot h_L}{d_S{}^3 \cdot \sqrt{\rho_S} \cdot (0{,}952 \cdot \sqrt{\rho_S/e_H} - \sqrt{\rho_{TLX}})^2} = \frac{164\ 10^{-9}}{\left[\left(1 + \frac{0{,}051 \cdot 10^{-3}}{z_G \cdot F_L} \cdot d_S\right)^2 - 1\right]}$$

ρ_{TL} [kg/m^3] = flow effective package density,
z_G [s] = graduated time-calculated value of the textile meter, (graduated time display of the textile meter in 0.1 s).

(according to Kretschmer).

Package dislocation Deformation of crosswound yarn packages, yarn slides off the dyeing tube.

Package dyeing Advantages: Short liquor ratio, direct use of the yarn package for warping or warp yarns on the sizing machine. Disadvantages: Absolute evenness cannot be guaranteed in hard packages.

Package dyeing machines,

I. Yarn packages are packed and if necessary, compressed on material carriers (Fig. 1), which are transported by conveyors and craneways to the dyeing machine in question. In dyeing machines supplied with a centrifugal pump (Fig. 2) or an axial pump (Fig. 3) the dyeing liquor flows through the yarn package columns. → Dyeing machines, circulating liquor type.

II. → Dyeing machines for crosswound yarn packages, bottle package, combed top bobbins, card sliver and warp beams.

Package hardness testers The package hardness is an important criterion for faultless full penetration dyeing. A densiometer, which detects the → Shore hardness, is used for hardness testing.

Package hydro-extractor (package centrifuge) → Centrifuge hydro-extraction of yarn packages. These

Fig. 1: Crosswound yarn package dyehouse (Thies) with material transport by means of roller conveyer and craneway plus metering and automation units on each dyeing machine.

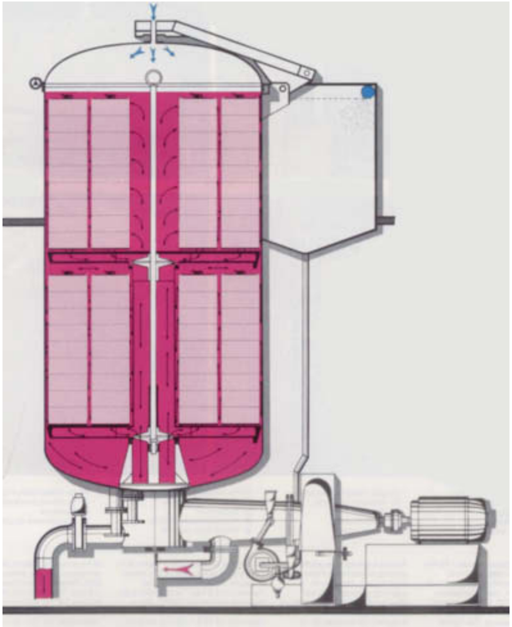

Fig. 2: High temperature crosswound yarn package dyeing machine (Krantz) with centrifugal pump and alternator.

are deformed in normal centrifugal baskets, which is why baskets with spool carriers or single spool centrifuges are used.

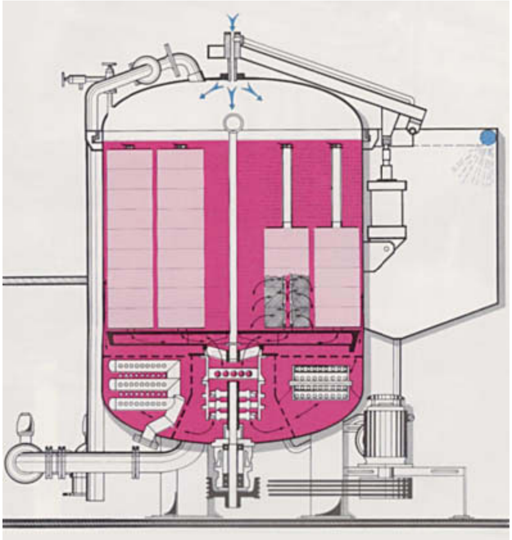

Fig. 3: High temperature crosswound yarn package dyeing machine (Krantz) with multi-stage axial pump and bypass unit.

Package width Width of the winding casing.

Package winding systems The winding of a → Package (→ Crosswound yarn package) determines its properties during further processing and thus the quality of the end product and the effectiveness of production. This has a critical influence on characteristics such as for example consistent package density or good run-off characteristics. Traditionally, there are two package winding systems: Random winding and precision winding (Fig. 1).

I. In random winding there is a fixed relationship between the package surface speed and the speed of traverse winding. This keeps the thread crossing constant, whereas the winding ratio, i.e. the number of package revolutions per cycle to-and-fro, falls with increasing diameter. The advantage of this winding system is that it creates solid packages, which have a uniform density. The disadvantage is that ribbon zones occur with this winding system, which lead to poor run-off characteristics and can cause irregularities after dyeing (→ Yarn packages in dyeing).

In random winding, the crosswound yarn package is driven by friction at its circumference (Fig. 2). The surface drive is mechanically linked with the thread changing device. Drive and thread changing devices are incorporated into one and the same machine element, namely the slotted drum. The surface speed of the yarn package has a fixed relationship to the thread lay. This ratio is expressed by the crossing angle of the threads on the package, which is constant, during the entire build up of the package regardless of the diame-

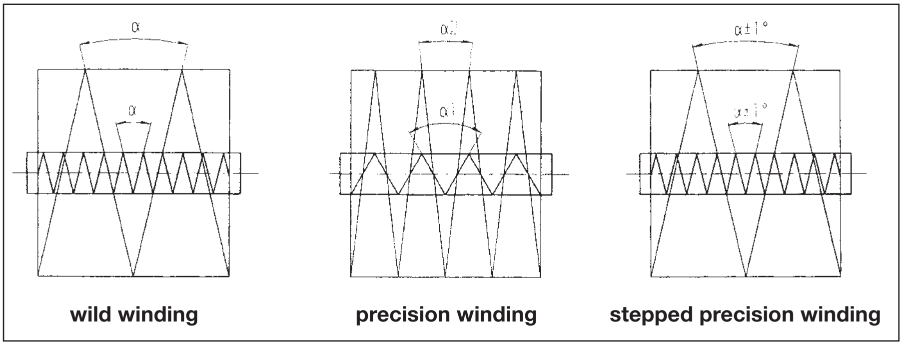

Fig. 1: Package winding systems.

ter of the package. This gives rise to a stable package construction with almost uniform density. The winding ratio, i.e. the number of package revolutions per cycle to-and-fro, alters in relation to the package diameter. For example it is 1 : 8.2 near to the dyeing tube and approx. 1 : 1.6 at a diameter of 280 mm.

If there is a whole numbered ratio of the diameter of the slotted drum and the diameter of the yarn package during winding, one thread is placed upon another, and ribbon winding occurs. Critical zones occur e.g. at 90 mm drum diameter and 90 or 180 mm package diameter. Ribbon winding is unfavourable for the run-off of the package in further processing. For this reason a ribbon breaker is used in yarn packages with random winding.

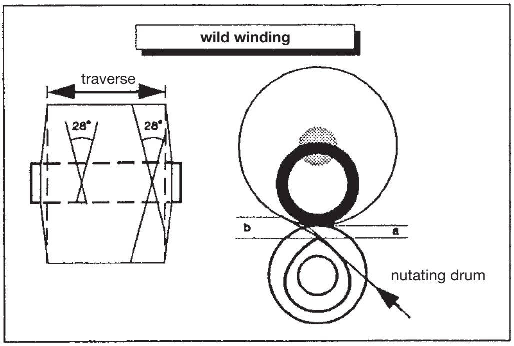

Fig. 2: Wild winding.

II. In precision winding the relationship between the package speed and the speed of the thread change is kept constant. Thus the winding ratio remains the same during the entire winding process. The thread crossing angle, however, decreases as the package diameter rises. No ribbon zones occur with this winding system. The package has good run-off characteristics, which means that high discharge speeds can be achieved. It also gives a high package density. The advantage: depending upon the yarn number up to 38% more running length for the same package volumes.

The stability of the yarn package is limited due to fact that the thread crossing angle decreases as the package diameter increases. The decreasing angle also causes an increase in package density towards the outside of the package, which can lead to inconsistent penetration by the dyeing liquor.

In precision winding (Fig. 3), the crosswound yarn package is usually axially driven. This drive is linked to the thread traverse mechanism. Therefore the crosswound yarn package always makes the same number of revolutions during one to-and-fro cycle of the thread guide. The winding ratio thus remains constant during the entire formation of the package and is independent of the package diameter.

If the speed of the crosswound yarn package is constant then the speed of the thread increases with the package diameter. However, constant package speed is a prerequisite for uniform package formation. Therefore, in order to keep the thread speed unchanged, it is necessary to control the package rotation speed. For this reason, precision traverse winding frames have a expensive adjustable drive.

Because the winding ratio remains constant, the thread crossing angle changes automatically as the di-

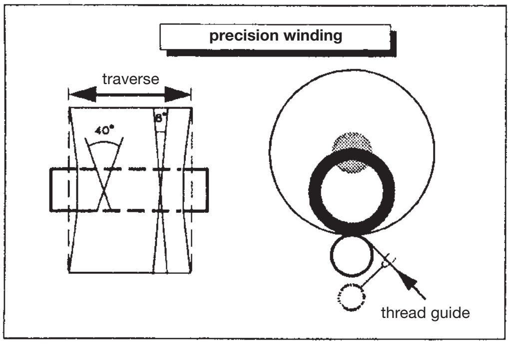

Fig. 3: Precision winding.

ameter of the crosswound package increases. So, for example at the start of winding, i.e. near to the tube, there is a crossing angle of 40°, whereas with a full package with a diameter of 280 mm only an angle of 8° remains. As a result of the varying thread crossing angle, the density of the crosswound package increases with its diameter.

III. Graduated precision winding: in order to combine the advantages of the two winding systems, and at the same time to eliminate their disadvantages, graduated precision winding was developed. This is a precision winding system in stages. After each stage the thread crossing angle is returned to the original number of degrees. The result is an almost constant angle, with the winding ratio being reduced in stages.

The benefits are clear. The almost constant thread crossing angle guarantees the stability of the yarn package and a uniform density. The defined thread distance of precision winding prevents ribbon zones and facilitates a high winding density. Because of this, the package has good run-off characteristics and running lengths are noticeably greater than those achieved with random winding.

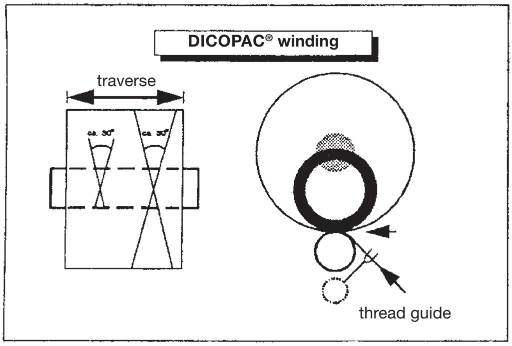

Fig. 4: Dicopac winding (Schlafhorst).

In the Dicopac system by Schlafhorst (Fig. 4) the placement of the thread is accomplished using a traverse mechanism. The crosswound package is driven on its surface by a driving cylinder. Because of the control of the thread guide movement, the winding ratio does not change continuously as in random winding, but in stages. This has the result that each thread layer is precisely wound.

Fig. 5 illustrates schematically the graduated change in the winding ratio with increasing diameter. The change is kept within narrow bounds due to continuous adjustment. Random winding with 20° crossing angle and precision winding are shown for comparison. This graduated adjustment results in the crossing angle remaining approximately equal on the package at all diameter ranges. This gives a uniformity of density similar to that of random winding, which cannot be achieved with precision winding.

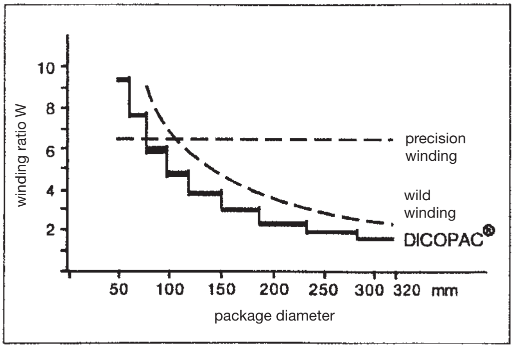

Fig. 5: Winding ratio related to package diameter.

Packaging For dyestuffs; should be practical, recyclable, standardized and environmentally friendly. Packaging cost/kg dye e.g. 45–55 g (see Fig.). A polyethylene bag can be loosely connected to the packing box, so that after complete emptying, separate disposal or full reuse is possible.

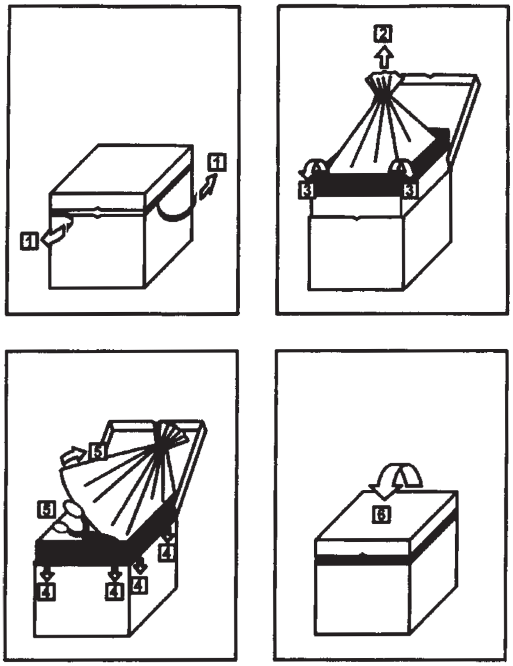

Fig.: Dyestuff packaging (source: Bezema, Gefatech and Mosburger AG): 1 = sealing strips; 2 = the PE inliner is provided with a gusseted base; 3 = holding tabs; 4 and 5 = opened around entire area of box; 6 = re-sealing.

Packaging of textile auxiliary chemicals In connection with the problem-free handling of dyestuffs and chemicals in the textile finishing industry, the packaging in which products are delivered to the textile company is particularly important. The criteria “efficient”, “customer friendly” and “easy to dispose of” are of primary importance in their development. Strict requirements are made of distribution, safety and protection of resources. There are still calls for a ban on non-reusable packaging. Self contained plastic packaging such as canisters and barrels could become less important. For every consignment (by rail, road, ship or air) the packaging must always fulfil the applicable safety requirements (UN legislation). It should also be noted that packaging (depending upon destination) will be subject to different storage conditions, which it must also conform to. Liquid and solid substances must be efficiently dispatched and stored. The following are used for this purpose:

a) less large barrels with 150–250 kg capacity, more packages with maximum 30–60 kg capacity;
b) packages for deliveries in palletised units, facilitating mechanized handling throughout the entire distribution chain,
c) large packaging of 500–750 kg in the form of returnable containers, which contain an easily disposable internal container,
d) bulk deliveries in tankers or silo vehicles.

Packing density Specification of textile goods in weight/volume (g/l).

Packing order (German legislation, VerpackVO, Verpackungsverordnung), a significant part of the packing order relates to the compulsory returning of sales packaging: As of 1.1.1993 industry is obliged to take back used sales packaging and reuse the material without public waste disposal. In § Section 3 VerpackVO the legislator permits a privately performed collection and sorting system for sales packaging, which frees the companies and all their suppliers from the obligation to take back material. By allowing an independent organisation to perform the collection and utilization of used sales packaging it strives to free companies from their obligation to take back packaging and charge a deposit. This system, which runs in parallel to the public waste disposal system is called the “dual system”. The dual system for sales packaging is run by a company called: “Duales System Deutschland GmbH (DSD)”, Bonn. DSD primarily performs monitoring and control functions in the dual system. The collection and sorting of valuable substances is performed by regional waste disposal companies under contract from DSD. Different collection systems are used to collect valuable substances, and after sorting and preparation these materials are transferred to the guarantors of material utilization as secondary raw materials so that they can be put back into the material cycle for utilization. The idea is that DSD will finance itself and the orders given to it by licensing the “Grüner Punkt” (green point). In order to participate in the dual system, the seller of sales packaging must purchase the “Grüner Punkt” for a licence fee. This “Grüner Punkt” signifies that licence payment has been made, which is used to finance the collection and sorting of the sales packaging. The “Grüner Punkt” also tells the consumer, that the packaging is a reusable material and he should return it to a collection system, which is also identified with the “Grüner Punkt”. The licence fee is calculated for each type of packaging, and differs depending upon the packaging volume. This flat rate classification was supplemented by a specific payment scale for flat and lightweight packaging.Recently, criticism of this type of reuse or recycling and of the DSD has increased.

Pack system dyeing Dyeing using the pack system (derived from package dyeing); pack dyeing of carpet yarns. The equipment in question must be carefully packed with the material to be dyed (loose stock, combed tops, yarn).

Pack system dyeing machines → Dyeing machines, circulating liquor type, in which the treatment liquor flows through the packed textile material. Circulation equipment without systematic liquor guidance, for universal application and for H_2O_2 bleach, made of special steel. Capacity 500–2000 kg.

Pad Impregnation on a padder. Differentiated according to procedure e.g. →: Pad-batch process; Pad-dry-process; Pad-jig-process; Pad-Roll-Process; Pad-Steam-Process.

Pad-batch process (→ Cold pad batch dyeing), performed on the padder (Fig.); high performance fabric opening and rolling machines guarantee crease-free material flow without edges rolling up from material entry to the nip. On the way from the nip to the rolling point the material is fed over additional rubberized rollers. The fixed material feed prevents the material from stretching lengthways and the edges from rolling up. This requirement to prevent rolling up on the batch roller is achieved by an adjustable hydraulic force on

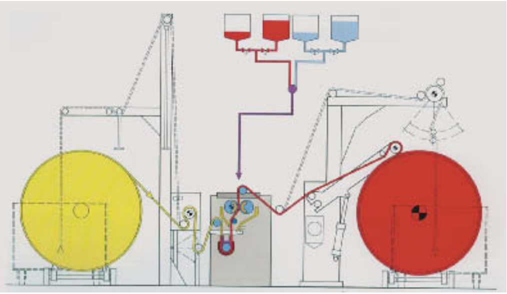

Fig.: Cold-batch-application (Küsters) with mini economy trough.

the last transfer roller. The material tension is modified to suit the process using a computer controlled centre roller. The following material qualities can be dyed economically, gently and with reproducible effects using the pad-batch process:

1. knitted fabrics: Single jersey, interlock, lining fabrics, nikki plusch,
2. woven fabrics: Mercerized and non-mercerized cotton fabric, inlet material, cord, terry fabric.

After the padding and cold dwelling the material must be washed in a suitable manner.

Pad-batch process control Padding the material with liquor in the padder, followed by a dwelling stage so that the applied liquor can be fixed or allowed to act. Padding can take place under controlled conditions (Fig.). The most important pad-batch-processes are:

→ Cold pad batch dyeing (CPB),
→ Cold pad batch dyeing with reactive dyes,
→ Pad-batch process,
→ Pad-Roll-Process.

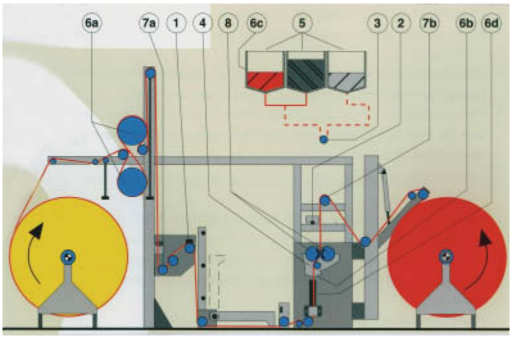

Fig.: Dyeing centre with new technology designed to control processes and to minimize defects and the volume of waste liquor in the cold pad-batch process.

Pad-batch processes → Pad-batch process control.

Padder Open-width dyeing machine, padding machine for open-width treatment, padding, impregnating, (padder) delustring etc. of piece goods (loose material on special padders.) The task of the padder is to remove the excess liquor absorbed in the dyeing trough by uniform squeezing across the entire width of the fabric. Not every padder is suitable for this. We can differentiate between two types:

1. Relatively small, long trough with 1–3 guide rollers and 2–4 squeezing rollers mounted above and an elevated preparation vessel for the dyeing liquor, which is connected via a pipe with the trough to be continuously filled during dyeing. The 2 roller padder is selected specifically for absorbent material, the 3 roller padder is commonly used when frequent submerging is necessary for materials that are more difficult to wet, whilst the 4 roller padder is recommended for material that is easily stretched between submersions. The dry material passes through the roller system once or twice, whereby the dyeing liquor per pass is adjusted for the desired shade.
2. Colour box free high-performance padders are becoming ever more important, specifically for continuous dyeing techniques. There is a short padding liquor in the nip (therefore particular care should be taken, that the dye has actually dissolved, for dark dyes) between the 3–5 rollers, which both squeeze and move the material. Some typical examples are shown in Figs. 1–3 and 5–7.

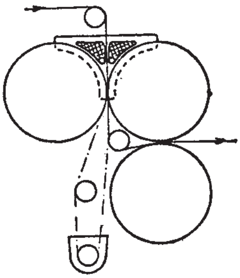

Fig. 1: Peter Econom with dividers (top at fabric entry).

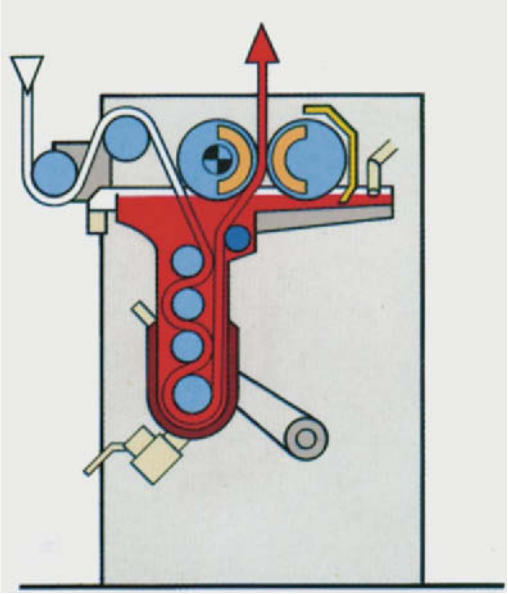

Fig. 6: Special "lapping-up" trough permitting squeezing rollers to dip into the liquor. Economic trough with pneumatic lifting device and 4 soft rubber covered rolls for underliquor squeezing serving simultaneously as displacer, indirect jacket heating, curved expander roller for woven fabrics (Küsters).

in order to firstly save dye, chemicals, assistants (Fig. 4), and secondly to reduce the problem of dye migration in the subsequent drying stage and to minimize the amount of water to be evaporated. The application of wet-on-wet application (Fig. 8) is an option that has recently become available. Pad-steam plants are used for the treatment of batches of virtually unlimited size, usually as continuous lines (padder, steamer, washing box). For knitted fabrics, continuous processes with in-

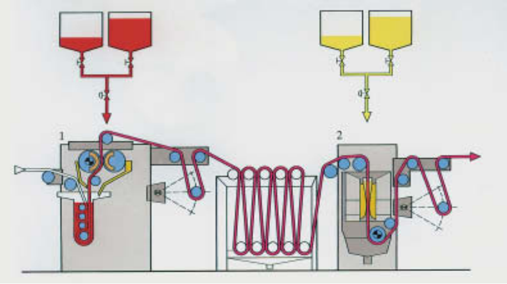

Fig. 8: Wet-on-wet application technique: dye padder (1) with Küsters' Flexnip (2).

termediate dryers give rise to particular difficulties, because the two layer tubular form causes dye migration problems that have yet to be solved.

Padder-jig Combination → Padder with → Jig dyeing, whereby the upper padder roller functions as a jigging roller. Used for discontinuous dyeing (→ Pad-jig-process) with vat, vat leuco ester, reactive dyes, etc.).

Pad-Develop-Thermosol-Process Pad-dyeing technique for polyester/cotton using vat leuco ester and disperse dyes.

Padding,

I. According to Rüttiger, the entire padding function can be divided into elementary functions:

1. Submersion of the textile material in the liquor for mixing.
2. Squeezing the loaded textile material for proportioning.
3. Transport of the reaction mixture (textile material with defined product application).

The elementary functions can be further subdivided into basic functions:

1. Basic functions during submersion:
   a) wetting,
   b) penetration of the liquor into the gaps in the textile material,
   c) removal of air from the textile material,
   d) diffusion of water into the fibre material,
   e) swelling of the fibre material,
   f) diffusing of the dye or finishing agent into the fibre material.
2. Basic functions during the squeezing process:
   a) compression of the textile material in the nip,
   b) liquor backflow as it flows through the textile material,
   c) capillary transport in the direction of the material movement,
   d) adhering liquor is returned to the rollers,
   e) squeezed out liquor flows back.
3. Basic functions during transport (similar to those during submersion):
   a) diffusion of the water into the fibre material,
   b) diffusion of the dye or finishing agent into the fibre material,
   c) evaporation of the water.

When considering the influence of the individual elementary functions during padding it is useful to consider extreme cases. So, for example, if wetting is merely adequate, squeezing is solely for proportioning, otherwise, depending upon the specific roller design and suitable padding conditions, air must be removed despite adequate wetting. If wetting is inadequate air is removed during the squeezing process by cross-flow and the inside of the material is wetted. Wetting is thus repeated by a mechanical effect in the nip (flow through the material). Therefore the squeezing process always becomes the dominant elementary function if there is inadequate wetting during submersion. The overall function of a system cannot be obtained by knowledge of the basic functions alone, because these are generally defined, i.e. without specifying the inputs and outputs of the system in question. Moreover, it is not just these basic functions that are decisive for the overall function, but also (and much more importantly) their interaction. In order to develop a padding procedure, the dominant relationships need to be found, rather than merely investigating them as individual functions. Options on offer are performing operational and laboratory experiments. Despite this fact, knowledge of the basic functions is of great value, because this knowledge can be applied to make predictions regarding the dominant influence variables of the system, particularly in certain extreme cases. In the case of padding, wetting, flowing through and compressing, these can be viewed as the dominant basic functions (according to Heidemann).

II. i.e. impregnation of piece material on the padder with dye or textile assistants. → Pad process.

Padding auxiliary (solvent), must fulfil the following requirements when used in the → Padding of woven fabrics and hosiery goods:

- increasing the wetting and penetration capacity as well as improving flow in the pigmenting process,
- little or no effect on the degree of distribution of pigments,
- prevention of pigment migration in the intermediate drying of pigmented material,
- low foaming in the padding liquor,
- adequate electrolyte or alkali resistance.

We differentiate between two padding auxiliary groups:

I. Padding auxiliary to increase the dye affinity of the fibre, preventing dye migration during intermediate drying or pigment separation. These padding auxiliaries are anionic surfactants.

II. Padding auxiliary to increase the padding liquor viscosity, increasing dye migration without influencing the degree of distribution of the dye. These padding auxiliaries are usually thickeners based upon alginate, carboxymethylcellulose, acrylates, etc.

Padding index Comparative dyeings are produced using absorption curves without adding salt. The depth of dyeing achieved after 10 min is set at 100, and the padding index is established as the depth of dyeing after 2 min. On this basis, direct dyes applied without using salt with high and steeply rising curve are particularly suitable for pad dyeing.

Padding machine → Padder.

Padding material Plain weave fabric made of linen and linen union, as roller covering material for finishing machines, for covering ironing presses, etc. with fabric.

Padding, stuffing (material). Inner material of outer clothing. Used for elastic shaping and shape retention.

Paddle machine Large, oval tub made from wood or stainless steel (vessel capacity up to several cubic metres), with the “island” in its centre containing the drive mechanism for the paddle, which consists of a paddle immersed in the liquor from the side, which can be rotated from top to bottom, ensuring continuous circulation of the liquor and material during operation. Application: Preferably with a high liquor ratio (approximately 1 : 150) for large batches (clothes dyeing), particularly for woollens for felt free finishing (see Fig.).

Paddles → Fallers.

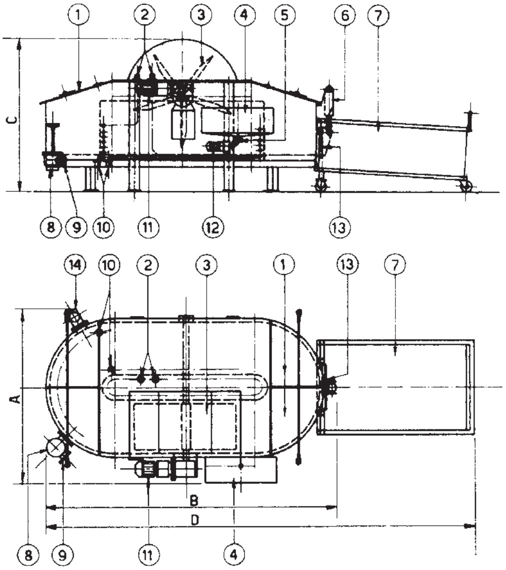

Fig.: Flainox paddle dyeing machine for finished items.
1 = lid; 2 = cooling; 3 = paddle; 4 = additives tank;

12 = liquor circulating pump; 13 = liquor quick drain.

Pad-dry-process,

I. Variant of the heat setting process for reactive dyes (→ Reactive dyeing). Dye fixation on the fibre takes place after padding, during the drying process.

II. For antifelting finish of woollen piece goods and garment panels with a prepolymer made of polyether with reactive groups.

Pad-dyeing The → Pad process is replacing discontinuous dyeing methods for woven fabrics to an ever greater degree. Function mode of padder with swimming rolls (Figs. 1 and 2).

Pad-Fix-Process Pad-dyeing process for polyester spun tow. The tow, which is padded with the dye dispersion, is either packed into a packing cylinder or wound onto a perforated cylinder and dyed in the liquor in the HT circulation machine.

Pad-jig-process Garment panels are padded with dye solutions and developed or fixed on the jigger. The process is of particular practical interest in the dyeing of cotton and linen woven fabrics using vat dyes and also direct dyes to a lesser extent. Advantage: Better penetration and dyeing of larger batches. Disadvantage: The discontinuous vatting can sometimes cause lack of end-to-end uniformity in the full bath of the jigger, because some of the dye is transferred into the blank vat. These faults can be rectified by the addition of padding liquor to the bath at the start and end of the first passage.

Pad-jig-process for reactive dyes Discontinuous

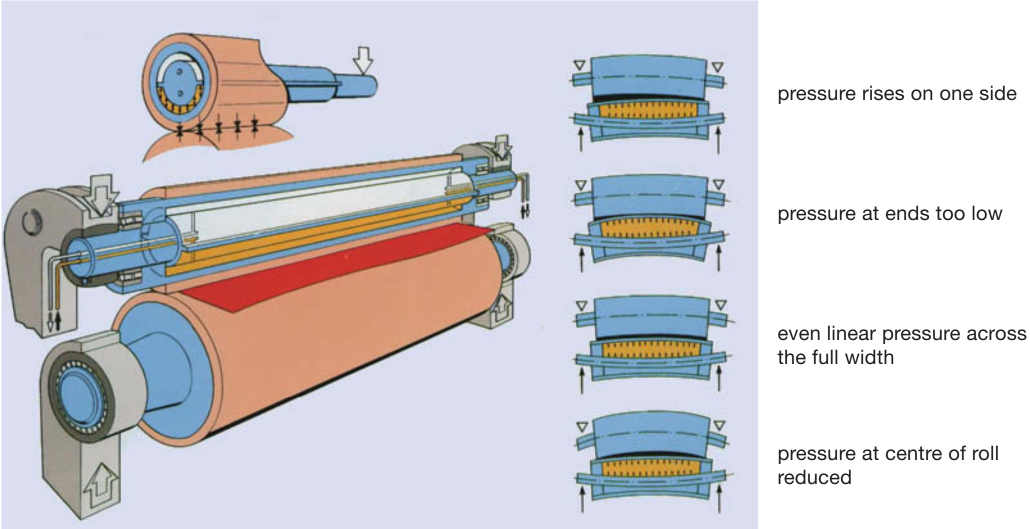

Fig. 1: Function mode of a padder with 1 swimming roll: controlled even and uneven linear pressure across the full width.

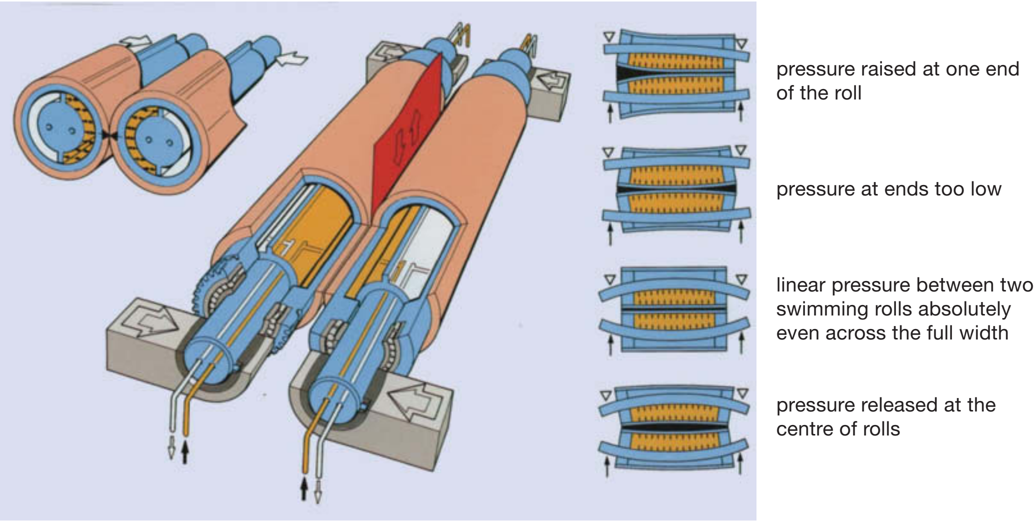

Fig. 2: Uses with a wider range of adjustment: function examples of a padder with 2 swimming rolls: controlled even and uneven linear pressure (Küsters).

principle: Padding with neutral dye solution, drying and treating on the jigger in a saline alkali solution.

Pador gum Lowest quality class of → Senegal gum.

Pad printing Complete printing of a material with the →: Kiss roll; Thousand-point roller or hatching roller.

Pad process Used for padding (→ Padding). The material is impregnated with liquor containing the dye or chemical on the padder, whereby the substantivity of the application product is almost eliminated due to shorter submersion time and shorter liquor ratio. Unlike the exhaustion processes, material flow is continuous, as the first work stage, if necessary followed by a second wet treatment (wet-on-wet-padding (Fig.).

Pad-rapid dry process Single bath continuous

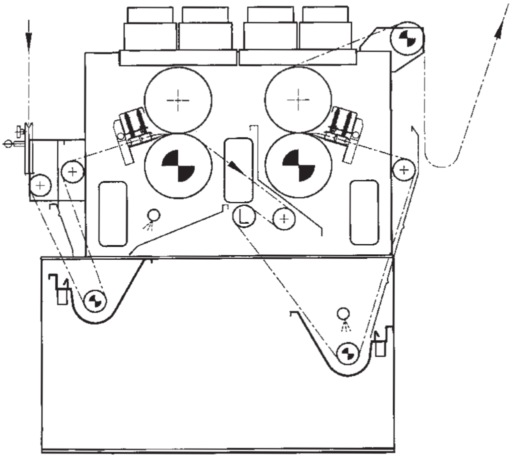

Fig.: Wet-on-wet-padding of knitwear (Küsters).

process for vinyl sulphone dyes using the caustic soda liquor/salt quantity required for the normal CPB process and a dosing pump. Machine requirement: Padder with economy trough and hotflue. Drying temperature 100–120°C. Urea generally not necessary. Yield as for the CPB process.

Pad-roll bleach Semi-continuous process for cotton, cotton/polyester mixes, reclaimed cellulose. Material is impregnated with bleaching liquor and batch rotated and dwelled in a heated chamber.

Pad-Roll-Process Discontinuous pad-dyeing process for dyeing cellulose fabrics with direct dyes, in batches of up to 5000 m. The woven fabric impregnated with the dye is heated up to approximately 100°C in a pre-chamber by IR emitters and wound in an adjoining travelling and heatable chamber. When winding is complete the chamber is connected to a steam line (direct and indirect), whilst the skein slowly turns (“roll”). Dwell time is dependent upon the colour depth. A plant always consists of several chambers. In principle, this process corresponds with dyeing using a 1 : 1 liquor ratio. Temperature and moisture variations in the chamber give rise to certain difficulties due to seam impressions and listing or ending. Reactive dyes can be successfully used in the pad-roll process. The plant is also suitable for desizing, scouring and bleaching according to the pad process.

Pad-Steam-Process With the exception of the jigger, the padder is the most important open-width dyeing machine for the application of liquor (pad). It is used in connection with a fixing facility (steam). Particularly strict requirements must be imposed on the dyeing padder: Each irregularity shows up as uneven dyeing. The quantity of dye applied to the fabric by the padder depends upon the dye concentration of the liquor, the liquid quantity absorbed (pick-up) and the ratio of “absorbed dye to absorbed liquid”. This ratio can vary during dyeing (lack of end-to-end uniformity), for example in exhaust dyeing using substantive dyes: The batch ends become lighter; or in vat pigmenting, by preferential take up of water: The batch ends become darker. A constant material speed is important, and the submersion path should be as long and constant as possible with as small a liquor volume as possible. It is better to work in a manner that allows fresh liquor to constantly flow into the trough during dyeing, than to allow the liquor to circulate continuously between trough and preparation vessel. For heavy or tightly woven fabrics it is beneficial to repeat the submersion and squeezing processes.

The material speed during padding is generally 40–50 m/min. As the speed increases the uniformity of the fabric appearance diminishes. The refinement of the padding design has now made it possible to pad not only woven fabrics, but also hosiery goods (including tubular tricot). These qualities pass through a fabric opening machine before entering the nip. However, good quality dyeing depends upon the tension along the fabric as well as across it. Irregular liquor application or turned over edges result in edge-to-edge unevenness. Shade inequalities across the width of he material can also be attributed to minor differences in the material structure. This can be detected by measuring air permeability. Dark edges occur due to drying out if the standing period before fixation is too long. Lack of end-to-end uniformity is the result if the material takes up a disproportionately large amount of dye from the liquor (tailing effect), or too much water, with the result that the dye concentration in the bath decreases (reversed tailing effect). The same can also occur with insoluble dyes (vat pigments). Non-uniform moisture content before padding can also result in inconsistencies in dyeing. If consistent padding is to be achieved it is important that the fabric swells completely. In cotton fabrics this requires 1–2 s submersion time, for fabrics made of regenerated cellulose fibres, 3–4 s. Therefore, very good pre-treatment of the material, with consequent absorbency, is important.

In the pad-dyeing process with intermediate drying, migration occurs if there is inconsistent air circulation; the points that dry first take dye from the surrounding fabric areas, thereby becoming darker (duplex dyeing). Excessively rapid drying at high temperatures causes dye migration from the inside of the fabric to the outside. The fabric then appears to be poorly penetrated. Migration is strongly dependent upon the fabric and its moisture content. Below around 30% moisture content, there is no migration. Additives that increase the viscosity of the liquor, agglomerating products and agents with “reversed” solubility, i.e. substances in which the solubility falls with increasing temperature, hinder migration.

Pad-Steam-Process

Critical factors for faultless pad dyeing can be summarized as follows:

Factors relating to the fabric:
- uniform width of the fabric batch,
- rolled up without creases,
- no curled selvedges,
- uniform absorbency,
- uniform temperature,
- uniform moisture content.

Factors relating to the padder:
- faultless roller covering,
- uniform roller pressure across the entire width of the material,
- uniform liquor temperature,
- uniform liquor feed,
- uniform liquor level in the colour box.

There are two alternative methods for the pad-steam process. During the steaming process attention should be paid to uniformity of the temperature throughout the whole of the steamer. If side-to-side deviations occur the material temperature should be checked to eliminate this fault. In saturated steam steamers temperature differences occur less often than is the case with superheated steam.

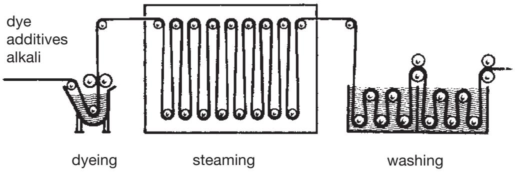

Fig. 1: Principle of the Pad-Steam-Process without intermediate drying (saturated steam process).

The pad-steam plant is a universal continuous dyeing plant (Fig. 1) for all dye groups and is the preferred equipment for vat dyeing. In order to be able to exploit the dyeing advantages of the process for small batches, various companies build so-called compact plants with smaller steamers (Fig. 2). Laboratory pad-steam equipment is available for patterning and experiments. The so-called “Williams unit” is used in some companies instead of the development (vat) padder. This is an open-width treatment dyeing vat with guide rollers at top and bottom. The area between the rise and fall of the material lengths is reduced to a minimum by inserted walls, so that it is possible to make do with a small liquor quantity, at the same time achieving a high bath turbulence. Bath and material feed is by the counter current method.

Soaping is a problem with all continuous dyeing plants for vat dyes. In order to achieve a sufficiently long soaping period, soaping must be performed in several compartments, depending upon the material speed. Kleinewefers KTM has found a solution by designing a “soap steamer”. The soaping effect is accelerated by steaming. The area above the soap tub is closed and fitted with direct steam feed pipes.

A large-scale pad-steam plant (Fig. 3) consists of a dyeing padder (2 or 3 rollers), hotflue, chemical padder (for sodium dithionite and lye), a small steamer (material capacity 40–50 m) and an open-width washing machine, if possible with several roller vats for oxidation, rinsing, soaping. For light shades the intermediate drying stage may be dispensed with (wet-on-wet, pad-wet process). The plant is also suitable for dyeing using reactive, vat, vat leuco ester, sulphur, naphthol and direct dyes.

All continuous dyeing processes for cotton fabrics

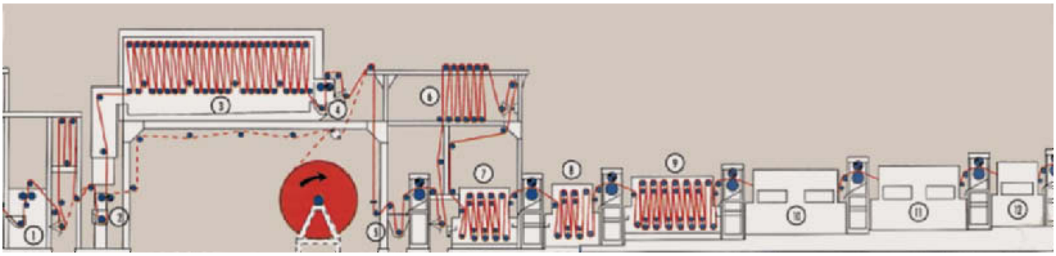

Fig. 3: Pad-steam facility by Kleinewefers KTM (material width 1800 mm, throughput 60–80 m/min, material weight up to 250 g/m^2, also for pile and cord fabrics). Key in Fig. 4.

(Fig. 4) have the following procedural stages in common:

1. Dye application: If the material to be dyed is a pure cellulose fabric the dye application always takes place in a single bath (for mixed fabrics made of cellulose and polyester fibres for example the dye can be applied in single or dual baths).
2. Fixation process: May differ for the different continuous dyeing processes. Options range from dry heat to wet steam fixation. It is the dye fixation stage that most clearly characterizes the individual process.
3. Aftertreatment: Dye and chemicals that have not been fixed are removed from the material. This

washing out process can be carried out in the same way for all processes, e.g. in continuous washing lines on successive roller vats.

A significant procedural difference in continuous dyeing is in the application of chemicals: One option is to combine the chemicals and the dye in a pad liquor and apply them together. This is a single stage process. The other option is to put chemicals and dye in separate pad liquors and to pad them separately. This is called a two-bath process with liquor stabilization, which has the advantage that hydrolysis-sensitive residual liquor is stable for longer and is sometimes reusable.

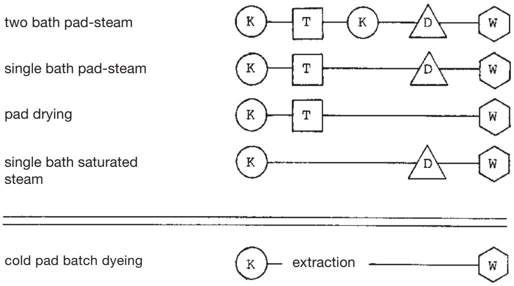

Fig. 5: Diagram comparing continuous dye processes using reactive dyes.
K = padding; T = drying; D = steaming; W = washing.

The pad-steam-processes include the two-bath pad-steam-process and the single-bath wet steam process. As can be seen from Fig. 5, padding takes place twice in the two-bath pad-steam-process; first the dye is applied and then the chemicals are applied after drying. The damp material then travels into the steamer, where the reactions between the dye/cellulose and dye/water (hydrolyzate) take place. Then the hydrolyzate and the chemicals are removed by washing. This process is also called the pad-steam-process with intermediate drying. The single-bath wet steam process (pad-steam-process without intermediate drying) only includes one padding process, in which both the dye and the chemicals are applied. The intermediate drying is dispensed with, which means that the damp material is steamed immediately after the first padding process. The washing off stage has the same purpose as in the other process.

Which of the two pad-steam-processes is preferred depends upon the material quality and quantity, the dye characteristics and the options open to the individual company. In general the pad-steam process with intermediate drying is recommended for companies with a complete continuous line and high production. The wet-steam process is of interest, due to the saving in drying costs, its high flexibility and high production. However, the process is only recommended for light to medium shades, because the build-up behaviour of dyes should be limited compared to the process with intermediate drying.

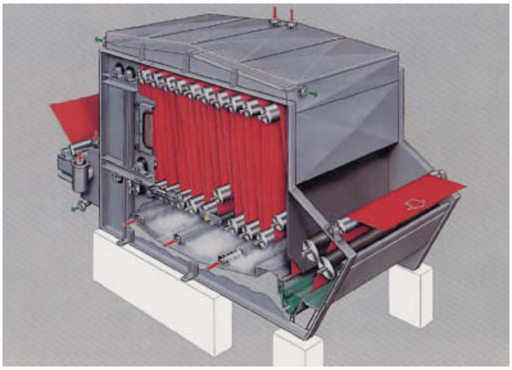

Fig. 6: Dye steamer for all pad-steam dye processes.

Steaming plays a decisive role in the fixation of dyes. The material is heated up rapidly in the steamer (Fig. 6) and wetted by the condensate. The dye migrates from the liquor into the fibre and is fixed. This process is an exhaust dyeing process with a short liquor ratio (1 : 0.7–1 : 1). Steam, an ideal heat conductor, supplies moisture and high temperature to the material soaked in liquor and thus takes on the function of the dyeing liquor. The main differences between saturated and superheated steam are as follows: If water is heated to its boiling point, steam is generated. Saturated steam can have a temperature of 101–103°C. If saturated steam is heated further, with the pressure remaining constant, then its volume increases; it is superheated. The steam condensation temperature is virtually the same as the fabric temperature. Because the steam will always condense where the textile fibre surface is “colder” than the steam condensation temperature, the fabric temperature is not influenced by differences in fabric weight or liquor application. The textile-dependent heating up time of approx. 3–10 s increases only slightly for damp padded material. The dye reactions during steaming are greatly accelerated; but it is not only the fixing of reactive dyes on the material that is improved, but also the hydrolysis reactions with the water. Moreover, the dye substantivity falls significantly as the temperature increases, which can result in yield losses depending upon the dye type. Because the steam condensate can increase the “liquor ratio”, i.e. the water quantity on the material, it is important to be able to calculate the amount of condensate. The damper the material when it enters the steamer, the greater the quantity of steam condensate. The condensate loading f_{TK} (kg condensate/kg textile) of the liquor-laden material, which is damp from padding, after heating is calculated using:

$$f_{TK} = \frac{C_T + e_F \cdot C_F}{C_D} \cdot (t_K - t_R) \quad [-]$$

C_T (kJ/kg °C) = specific heat of the textile,
C_F (kJ/kg °C) = specific heat of water,
C_D (kJ/kg) = specific heat of steam,
e_F (kg liquor/kg material) = liquor loading of the textile,
t_K (°C) = condensation temperature (= 100°C),
t_R (°C) = room and textile temperature (= 20°C).

For the entering material, damp from padding, with a liquor loading of $e_F = 0.70$ (= 70% by weight), then using the above values, we calculate a condensate loading of 0.148 = 14.8%. According to this worked example there is a condensate quantity of 14.8% on the material with 70% liquor loading, so that in total a moisture loading of 70% + 14.8% = 84.8% (by weight) is carried by the material during its passage through the saturated steam atmosphere. This example shows the increase of the liquor ratio. This results in a decrease in the yield for reactive dyes, which do not have a high enough substantivity to react with the material instead of hydrolyzing.

The hydrolyzate increases because the dye is too far away from the fibre due to the high moisture content and the excessively high substantivity. A better yield could be achieved when using reactive dyes with “poorer” substantivity, by selecting superheated steam for fixing instead of saturated steam, and possibly adjusting the steamer dwell times. The partial pressure of the steam is not altered by superheating; likewise the increase in the heat content of the condensate is so low that it can be disregarded. Therefore it is not possible to achieve an increase in the temperature of the material by the use of superheated steam. However, the dye yield can be improved by using superheated steam, because the increased energy content facilitates partial evaporation of the material moisture, so that dye concentration in the added liquor can again be increased. The same increase in effect due to partial evaporation can be realised if the steamer dwell times are increased. From the point of view of reproducibility, in this method a residual moisture meter must be installed after the steamer, so that the degree of partial evaporation can be measured.

The wet-warm dwell process represents an alternative to the wet steam process with regard to dye yield. The practical performance of this process is such that the wet, dye impregnated, material is heated by IR emitters as it enters the treatment chamber. In the chamber there is a steam/air mixture, in which the material dwells for approx. 40–60 s at a material temperature of 70–80°C. Because no further moisture can be added, as when fixing with saturated steam, a signficantly lower moisture content is achieved, thus obtaining a better yield when using less substantive dyes.

Pad-thermofix process General term for the pad-dyeing process using reactive and/or disperse dyes.

Pad transfer technique Low wet pick-up technique by transfer, e.g. → QS-process.

Pad-wet fixation process for reactive dyes (Hoechst), continuous process according to the principle: Padding with neutral dye solution, drying, passage through hot, saline, alkali solution.

Pad-Wet-Process Dyeing process, in which development or fixation of the dye after padding takes place without an intermediate drying stage.

Pad-Winch-Process (Pad-Winch beck), process for dyeing difficult to penetrate woven fabrics (above all those made of viscose staple fibres with direct dyes). Material is padded with the dye solution and then treated by boiling with a sodium sulphate or sodium chloride solution on the winch beck, whereby the dye is fixed.

Pailletine,

I. (Yarn) rice straw yarn for furnishing fabrics.

II. (material) Fine clothing material similar to → Paillette; 8 thread, reinforced satin.

Paillette,

I. Sequins, mica; thin perforated metal or glass plates for applying to clothes.

II. Light, shiny clothing, blouse or lining satin with a soft handle (Satin de Chine); 5 or 7 thread warp satin.

Palmer Open-width tensioning device on the felt calender for decatizing/drying open-width materials. Modern design → Pin wheel.

Palm fibres Vegetable fibres of numerous palm types belonging to the group of → Hard fibres, mainly in the form of so-called vegetable horse hair substitute, for brushes, braiding, upholstery material, etc. We differentiate between the dwarf palm fibre (Algeria, Morocco, Spain), the date palm fibre (similar to coir fibres) and further bassine, crin d’Afrique, kitul fibre, panama fibre, para fibres (the most important), piassava fibre, rafia bast, tecum fibre. They are all of regional importance only.

Palm wax → Carnauba wax.

PAM → Modacrylic fibres, → Textile fibre symbols, according to DIN 60 001 until 1988, from 1991 → MAC.

PAN → Polyacrylonitrile fibres, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

Panama (hopsack),

I. Variant of plain weave (→ Weave), whereby at least 2 warp and weft threads are in the same setting (natté or dice weave).

II. Clothing material (wool) with dice-like surface (similar to the Panama hat) in multi-thread plain weave. It has a softer handle than plain weave material.

Panama soap (Quillaya bark, soapbark, wood soap), pieces of bark (from Quillaja saponaria, South America) a tree-like, evergreen rose bush. Dirty white to yellow, different shapes and long, approx. 1 cm thick, up to 10 cm wide. Contains 5–10% → Saponin, which strongly foams like soap when dissolved in water (boiling). Washing effect approx. three times greater than soft soap; fibres and colouring are not corrosive. Application: washing agent for sensitive textiles, for wool degreasing.

Pancreas diastase → Diastases. The active enzyme degrades starches, up to glucose, and also protein substances into easily water soluble products. Derived from the animal pancreas, which is otherwise unusable. Application quantity 0.5–3 g/l. High acidity and high temperature destroy the enzyme. Existing alkali sensitivity is reduced in special products. Temperature sensitivity is reduced by hydrochloric acid, with effectiveness being increased at the same time. It should be noted that heavy metal salts and some surfactants reduce its effectiveness.

Pancreatin (pancreas enzyme), protein degrading, so-called typical or proteolytic enzyme from the pancreas.

Pannonia process Lustring process for sheep skins; most commonly practised in USA, England, France, Italy, etc. Sheep skins with the softest wool possible are moistened with aqueous solution (with the addition of alcohol, organic acids, formaldehyde etc.) and drawn over heated, rotating cylinders (ironing machines). This uncurls the wool hairs and makes them take on a marked shiny character of precious furs (beaver, sea-lion), called Moutonderé, Beaver lamb, Hudson seal.

Panthenol An alcohol derived from pantothenic acid (group of B vitamins), which releases the vitamin in the organism. Promotes functions and regeneration of epithelial tissues, is particularly important for the local treatment of wounds. Used against burns and causticizations.

Pantograph (micrograph), drawing instrument used in pantograph engraving (→ Engraving) for the manufacture of calender rollers. The pattern is transferred from zinc plate onto a calender roller, which is painted with acid resistant paint, by a heated diamond pantograph, and the engraving is enhanced by etching.

Papain Enzyme (→ Proteinases) in the form of the dried milk of the so-called papaya fruit (American Carica papaya; melon or mamong tree). Similar → Trypsin. Acts on high molecular proteins in the presence of certain activators (hydrocyanic acid or thiophene compounds such as → Cysteine or reduced glutathione), whereby the latter function by reducing the enzyme disulphide to SH groups. Papain was proposed for antifelting finish of wool, either alone or in combination with the previous chlorine treatment (chlorzyme process) or hydrogen peroxide (enzyme + hydrogen peroxide treatment). This enzyme is used for the gentle degumming of silk when boiling soap baths are out of the question, e.g. when acetate is present in mixed fabrics.

Paper chromatography Capillary analysis for testing dye uniformity, based upon the different migration speeds of dye in solvents.

A drop of dye solution is applied to a strip of filter paper approx. 5–6 cm from the lower edge, allowed to dry and the lower end of the paper hung 1–2 cm in a suitable solvent. The “chromatogram” is evaluated by the heights of the different coloured zones. Paper chromatography is also successfully used as a separation process for the detection of different sugars, amino acids, etc. In the latter case, the initially invisible chromatogram is subsequently “developed” by spraying with ninhydrin solution and warming (red-violet colouring) or with diluted alkaline fluorescein solution. → Chromatography.

Paper nonwoven (paper fabric) → Nonwoven, manufactured on paper machines using a wet process, reinforced with long cut fibres (e.g. 7% polyamide or high wet strength rayon staple fibre), also without reinforcement, then preferably with loose polyamide long fibres and cellulose. As in paper manufacture, fibres are suspended and the nonwoven formed in a sieve-drum. The rinsing fluid contains an adhesive, which sticks the fibres to the paper nonwoven in the subsequent drying/pressing stage. Weight approx. 50 g/m^2, finishing as required. Application: In particular, disposable underwear, tissues, medical textiles.

Paper taffeta Paperlike taffeta with a thin paint-like layer of synthetic resin (preferably soluble in amyl acetate) applied to the back, which at the same time generates a rustling handle.

Paper textiles Fabrics made of → Paper yarns or products of → Paper nonwoven. Both can be very strong and finished.

Paper yarns,

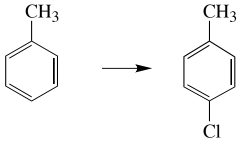
I. Made of cut narrow strips of spinning paper which (possibly after previous folding) are twisted together on a spinning machine in a moistened state (drilled). Sulphite paper or (tear resistant) sodium or sulphate paper or mixtures of these are used. Finenesses from 33–1000 tex, resistance to tearing from 4–7 cN/tex at 4.5–7% elongation at tear.

II. Wood pulp yarn is created by twisting together band shaped, wet strips of wood pulp, without previous processing into spinning paper. Finenesses from 33–2000 tex, resistance to tearing 7–9 cN/tex.

Application: For carpet underlays, carpet runners, wall coverings, bags, cord, hat braiding, etc.

PAR ISO abbreviation for → Polyaramides (aromatic polyamides).

Para- Prefix in compounds of aromatic cores as a term for isomer (1.4) position of substitution products, e.g. paratoluene derived from toluene (→: Meta-; Ortho-):



toluene *paratoluene*

Para-chloro-m-cresol Crystalline powder, white, cresol-like smell, slightly toxic. Virtually insoluble in water, easily soluble in alcohol, benzine, chloroform, soap solution. Application: Strong disinfectant and preservative for finishes, sizes, leather, woods, etc.

Paracortex → Wool structure.

Para-dichlorobenzene → Dichlorobenzenes.

Paraffin distillate Residue of petroleum and lignite distillation, from bituminous shale or synthetic products. Mixture of various aliphatic hydrocarbons. Solid at room temperature.

Paraffin lubrication → Wet paraffining.

Paraffin oil (vaseline oil), oily hydrocarbon mixture (mineral oil) made of liquid components of paraffin manufacture. Colourless, clear, density min. 0.88; does not rancidify or acidulate. Application: Fine lubricant for valuable machine parts; for lubricating wool (plus emulsifier) and in particular wool/viscose mixes.

Paraffins → Saturated hydrocarbons. Technically speaking, long chained, saturated → Hydrocarbons of waxy to solid consistency.

Paraffin test for dyeings on cellulose and protein fibres Used for → Dye class identification on fibres (on acetate, polyacrylonitrile, polyamide). Method: Soak some test threads with melted paraffin, place in glass tubes (2–4 mm long) which are hermetically closed at the bottom, heat carefully above a naked flame (without carbonizing), until paraffin melts and collects at the bottom. The colouring of this paraffin indicates the dye class: Vat leuco ester and vat dyes and naphthols.

Paraffin wax → Paraffin distillate.

Paraffin wax treatment → Wet paraffining.

Paraformaldehyde → Polyoxymethylenes.

Parallel ventilation in driers Takes place in parallel to material transport; e.g. as mixing component in jet ventilated stenters, because jet ventilation is arrested when it hits the material and reversed to form parallel ventilation.

Parallel winding Even or uneven, slightly helical thread winding, with threads lying side-by-side or one on top of each other. →: Yarn packages, preparation; Random winding.

Para-oxy-diphenylmethane Antifungal, antibacterial, sweat deodorizing and recommended for the permanent antifungal impregnation of hosiery; good material penetration, fibre preserving, relatively abrasion resistant, does not impair handle, darkens dye shades.

Parasite control in textiles →: Mothproofing; Antimicrobial finishes.

Parasites, textile → Textile parasites.

Paris blue, Prussian blue → Berlin blue.

Part by weight Mass relationship, weight of a part as a proportion of the entire weight.

Partially automatic Certain machine work stages are initiated manually but run automatically. Only part of the processes are automatic.

Partition chromatography → Chromatography.

Pascal (Pa), in the → SI system as derived unit for mechanical tension, strength and → Pressure. 1 Pa = 1 N/m^2 = 10^{-5} bar.

Passage application Squeezing process in water-impermeable finishing. Performed on an impregnating machine, jigger or squeezing padder, usually in 2–4 passes.

Passage counter So-called run time regulator, as reversing device (on jigger) for the control of forward and reverse, in connection with mechanical shutting down of the machine (after a predetermined number of passages). This device allows the drive motor for the jigger to be directly controlled or shut down.

Pass-Fail quality control Colorimetric Pass-Fail colour classification can be linked with the calculation of dye addition. This programme for colour quality control based upon objective colour tolerances determines whether a colour to be tested lies within or outside the tolerances set internally or agreed with the customer (Fig. 1). It determines whether a readjustment is too light or too dark, too clear or too cloudy, too red, too green, too yellow or too blue and immediately calculates the required addition, making the best possible use of the permissible colour tolerances (Fig. 2). Pass = can pass the colour check; Fail = fails the colour check.

Colorimetric matching is based upon the colour measurement of references and quality samples and the calculation of their colour differences (→ Colorimetry).

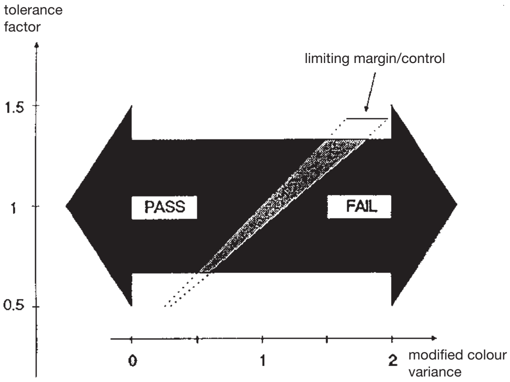


Fig. 1: Determining the size of tolerance margin using tolerance factors relating to the colour.

Pass-Fail quality control

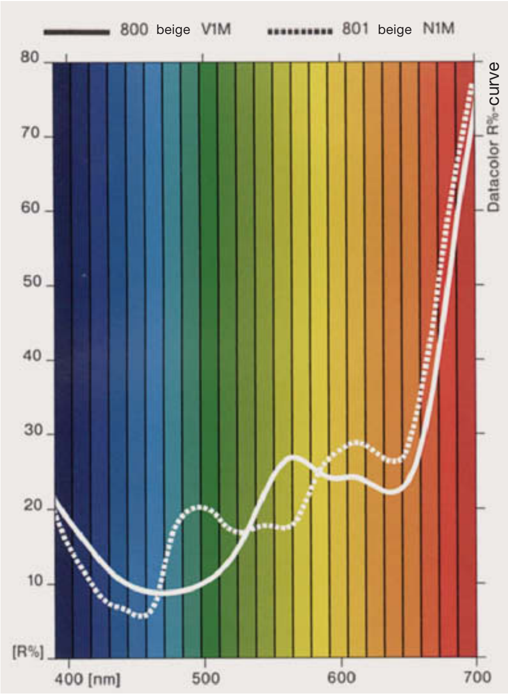

Fig. 2: Remission curves for two metamer dyeings whose standard colour values match for standard light type D_{65}.

Colorimetric detection and objectivication of the colour deviations between the two samples however is not in itself enough to permit colorimetric colour matching: For one thing the colour tolerances that must be satisfied are unknown. Determining these tolerances is hindered by the fact the CIELAB system, which forms the basis for the colour difference calculation, is not ideally sensitive according to the invention and tolerance limits. In CIELAB units take on different values depending upon the colour in question. The magnitude of the colour tolerance is therefore dependent upon the colour, i.e. the location of the colour in the CIELAB colour space. Secondly, the technical possibilities of the company must also be taken into account when determining colour tolerances.

Therefore, in the past empirical methods had to be used by the dyeing company to determine colour tolerances, e.g. for internal company use. As many repeat batches as possible were visually colour matched so that they could be accepted or rejected and the colour differences between reference and batch samples were determined by colorimetry. If we plot the colour differences of the known accepted and rejected sample on axes with the co-ordinates ΔC^*_{ab}, ΔH^*_{ab} and ΔL^* then the tolerance range is determined graphically based upon the boundary between accepted patterns. This process is illustrated based upon two examples (Figs. 3–4). The colours are defined according to DIN 6164.

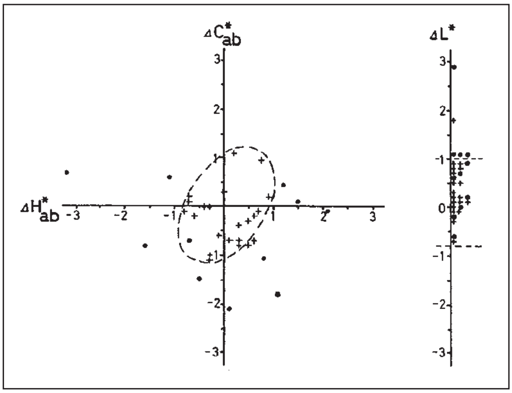

Fig. 3: Colour tolerances for the colour red 9 : 1 : 1.

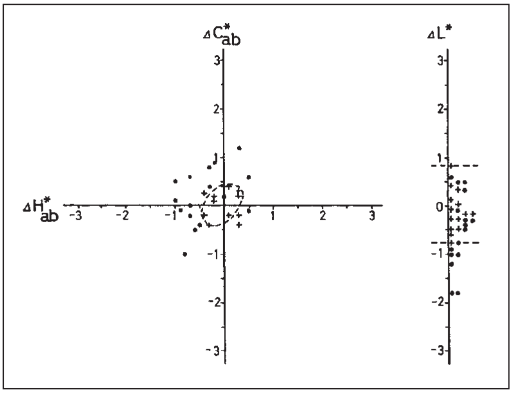

Fig. 4: Colour tolerances for the colour grey 1 : 1 : 7.

This process is expensive. However, there are programmes which can determine the tolerance limits automatically on the basis of the accepted sample. Secondly, a minimum number of samples from repeat batches are required for a certain colour, in order to achieve meaningful limits. This condition is however not fulfilled in many companies (e.g. in commission finishers). Therefore, colorimetric colour matching with the aid of pass-fail formulae represents a great step forward. These are colour difference formulae, which automatically account for the dependency of the tolerances on the colour by using factors for ΔL^*, ΔC^*_{ab} and ΔH^*_{ab}. They contain a mathematical transformation, which manages equidistance and weighting of the brightness, saturation and shade differences, so that a decision can be made whether to pass or fail a colour sample with just one number describing the colour tolerance (Fig. 5). This dispenses with the necessity of having a great many batch repeats available. Pass-Fail formulae are part of

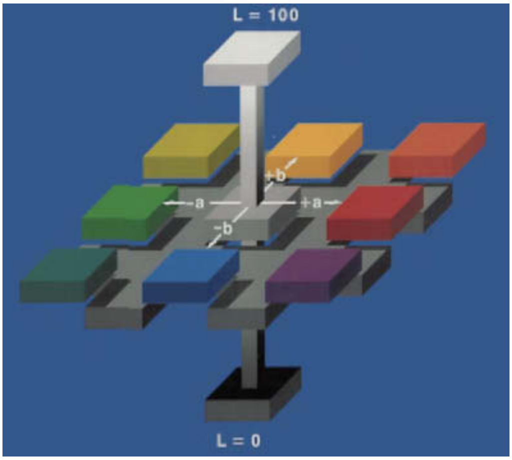

Fig. 5: Pass-Fail values for the colour specification and brightness of a sample to be matched.

the computer programme of some colorimetric systems (result e.g. as screen representation).

One problem is that depending upon the formula (DC; IPC; CMC; M & S) the same samples can lead to different Pass-Fail statements. This is understandable when we consider that the mathematics underlying the formulae is based upon colour matching with the following degrees of freedom:

- different distribution and different scope of the pattern in the colour space, as a result of the use of random and market determined batch samples;
- different make-up form (yarn or piece material) of the sample;
- different requirements of the personnel undertaking the evaluation;
- differences in the mathematics used for the description of the relationships.

Passive Transponder Can be used as a unit recognition system in fields of textile finishing, where pressing does not take place. Passive transponders can take the place of the barcode system, which is greatly limited due to the size of the bar code, the read distance, the read angle and the fact that it cannot be used in unfavourable environmental conditions and in many applications. The size of the passive transponder only needs to be a fraction of that of a single bar code stripe and can be read by a hand-held reader from distances of more than 20 cm (in some transponders more than 90 cm), regardless of read angle, light or environmental conditions. The system is based upon a hand-held reader or a stationary reader, which emits a low frequency magnetic field and activates the passive transponders within its range. The passive transponder does not have its own power source, because it draws the necessary power from the magnetic field of the reader. The transponder may be a unit encapsulated in plastic, which is available in different shapes and sizes. Each individual transponder is given a unique code during production. The code cannot thereafter be altered. The number of possible code combinations is approx. 500 billion and gives the user of the passive transponder system the possibility of identification.

Passive transponders function in liquids and can be read spherically (through most materials, with the exception of some metals) from every direction. The activated transponder sends its unique code to the reader. The code is then forwarded to a decoding logic where the code is analysed, simultaneously displayed on the LCD and stored in the memory of the reader for immediate or subsequent data processing. Hand-held readers, also called scanners, are a replacement for conventional keyboard data entry and other data collection methods. The main advantages of the use of a combination of hand-held readers and coded passive transponders are the reduction in the number of data capture errors, the reduction in work and administration costs involved in the processing of data, faster and more precise inventorisation and improved tracking and control of woven fabrics or knitted fabrics in finishing (according to Trovau).

Passive yarn → Immunization.

Paste resist printing Synonym of paste resists (→ Resist printing): Purely mechanical pre-printed resist made of many high solids thickeners, thickener containing a weighting agent (e.g. kaolin, zinc oxide, lead carbonate, etc.), preferably using indigo and vat dyeing.

Paste resists → Resist printing.

Paste transmission index Measure of print paste throughput in screen gauzes. The paste transmission index is determined by the stitch opening and the fabric thickness.

Paste up Term for the stirring of dyes, textile assistants, etc., usually with water, which precedes dissolving.

Pasting (chemical), transitions of fats into the state isotropic soap solution (→ soap paste), by → Saponification.

Patent application disclosure Patent disclosure of the patent application. Contains significant bibliographic data (name/address of the applicant, application date, priority, name of the innovation, etc.) in addition to the original application documents (description, claims, signatures). When access to the documents is granted (18 months after application or priority date), so that they can be viewed by anyone free of charge (in the patent office), even third parties have the option of conducting research or making an application for an examination. → Patent law.

Patent disclosure → Patent application disclosure.

Patent law The patent system is a subsector of the system for the protection of inventions. Every textile finisher (whether employee or company) should know his rights regarding the protection of his ideas. Possible commercial protective rights are:

- Patent law,
- Protection of inventions act,
- Trademark law,
- Design Patent law,
- Copyright,
- Utility model,
- Employee invention law,
- Peripheral subjects of the unfair competition act, cartel act, general contractual law, etc.

Prerequisites for applying employee invention law in Germany are:

1. There is a claim for a patentable invention;
2. which has been proven by the employee in the form of his invention.
3. It is significant whether the invention was solely part of the employee's duties or whether commercial experience was merely put into practice.

It is an employee invention if these three points apply. If none of the points apply, then it is a free invention. In the case of an employee invention the employer must first be immediately notified, who must make a written notification of his utilization of the invention within 4 months. He can make an unlimited claim for exclusive exploitation rights. Of course, the employer then has an obligation to make an appropriate remuneration to the inventor and employee. However, if the employer does not utilize the employee invention, his preferential claim lapses and the invention is free.

The rights of the inventor are regulated by the following acts depending upon the type of protective right:

– Patent:	ArbEG (Gesetz über Arbeitnehmererfindung – law relating to inventions of employees)
– Design:	ArbEG
– Protection of new plant varieties:	Compensation arrangement based upon ArbEG
– Copyright:	the artist
– Trademark:	–
– Design patent:	the employer or special contractual arrangement

For the granting of a patent the following must be made clear a) the objective of the inventor and b) his solution. The objects of this protective law for a patent are technical inventions, i.e. a guide to technical action, which consist of a task and solution. This covers patents for devices, procedures or applications.

The objects of other protective laws are:

Registered pattern: Implements of trade, artefacts, and parts thereof, that have a concrete physical form, e.g. sewing machines, rollers etc.

Trademark: Descriptions (word, picture, pictorial trademarks) of goods or services, e.g. Trevira®, crocodile pictorial trademark etc.

Design patent: Pattern and models with a certain aesthetic form or colour, whereby the shape or colour may not be exclusively technically determined.

Copyright: Artistic works, scientific works, musical works, etc.

The filing and patent application act is fullfilled by a patent attone.

The following protective conditions apply to the different protective laws:

Patent: Level of invention, commercially applicable: Registration at e.g. European Patent Office, test procedure.

Protection of inventions act: Innovation, invention progress, commercially applicable: Application at e.g. European Patent Office, official examination procedure.

Trademark: Differentiability, need to keep free, cannot be mistaken for other trademarks: Filing and application act at e.g. European Patent Office, testing procedure.

Design patent law: Innovation, ownership: Registration with e.g. European Patent Office.

Copyright: Artistic creation: No registration.

Protection of new plant varieties: Differentiability, homogeneity, stability, innovation, registrable type description: Registration at BSA (Bundessortenamt – Federal Office for protection of new plant varieties), testing procedure.

Protective scope and duration of protection differ depending upon the type of protective law.

Patent: Exclusive right to use the patented invention (use: manufacture, sale, trading, consumption, adoption, possession); 20 years from date of application in Germany.

Registered pattern: Exclusive right to use the object of the design 10 years.

Trademark: Exclusive right to identify goods and packaging: 10 years with the option of a 10 year extension each time.

Design patent: Imitation of the protected sample/model; 5 + 5 + 5 + 5 years (max. 20 years).

Copyright: Exclusive right to use the artistic work; 70 years after the death of the creator.

Patent letter → Description of the patent invention together with figures and drawings.

Paternoster batcher Batching device for the rapid changing of the yarn package. Consisting of axle drive to the winding spindle, by means of belts, and 2 changeover points at the sides for holding the yarn package while it is created.

Paternoster store For warp beams, roller printing rollers, dye packaging on moving chains; space saving (see Fig.).

Pathogenic bacteria Illness generating → Bacteria.

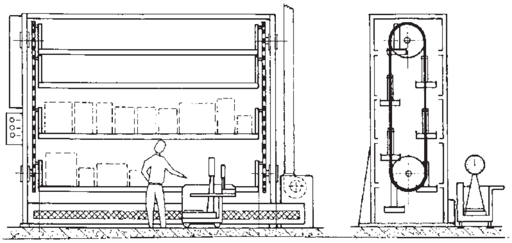

Fig.: Paternoster store for dye containers, with weighing facility.

Pattern brushing Patterns are brushed onto the surface of pile goods using a brush unit inside a round screen (Figs. 1 and 2) to brush the pile down.

Fig. 1: Circular brushes (not set) inside a circular screen for the pattern brushing of pile fabrics (Comet).

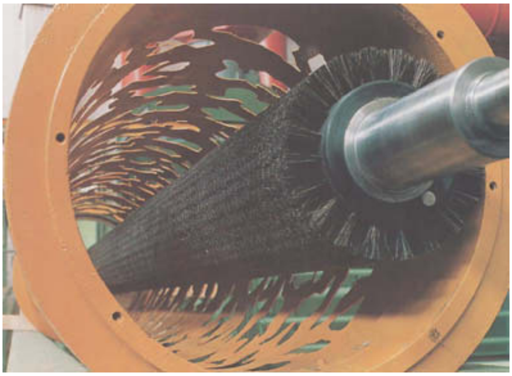

Fig. 2: A cylinder brush drum ready to brush a pile fabric article (Comet).

Pattern cards Patterned collections of coloured fabrics and dyeings relating to dyes or shades on offer in the form of standard depth dyeing, colour regulations, fastness data, etc.

Pattern cutting systems (making-up). Computer aided construction systems are used to graduate (Fig. 2) basic designs (Fig. 1) created using Computer Aided Design (CAD) and generate cutting patterns (Fig. 3)

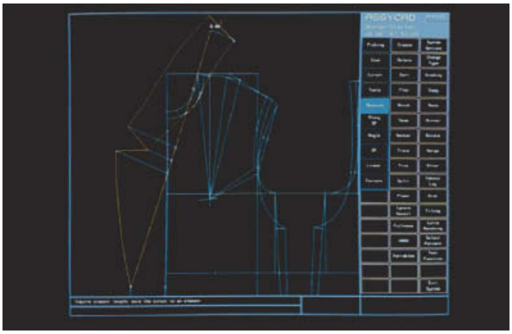

Fig. 1: Basic patterns using a pattern cutting system (assyst).

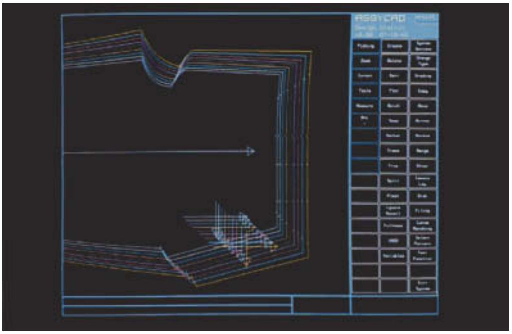

Fig. 2: Grading with the aid of a pattern cutting system (assyst).

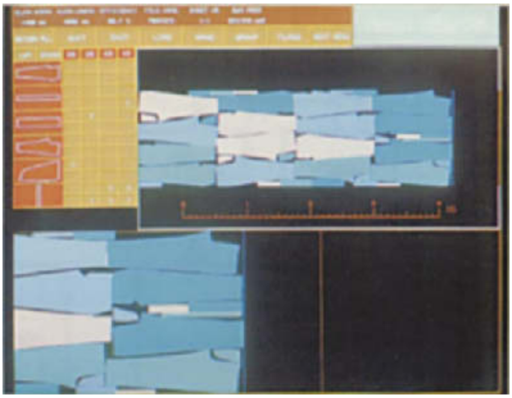

Fig. 3: Reference marker as pattern master (assyst).

which minimize material consumption. Using such a system, in order to minimize waste, it can be used to construct up to the material selvedges and thus keep tolerances for material widths below 1.5 m, equal to zero. If other EDP systems are available in a company (e.g. systems for production planning and control), the data from the pattern cutting system (dimensions, material consumption) can be transferred directly to these systems, and the systems thus linked together.

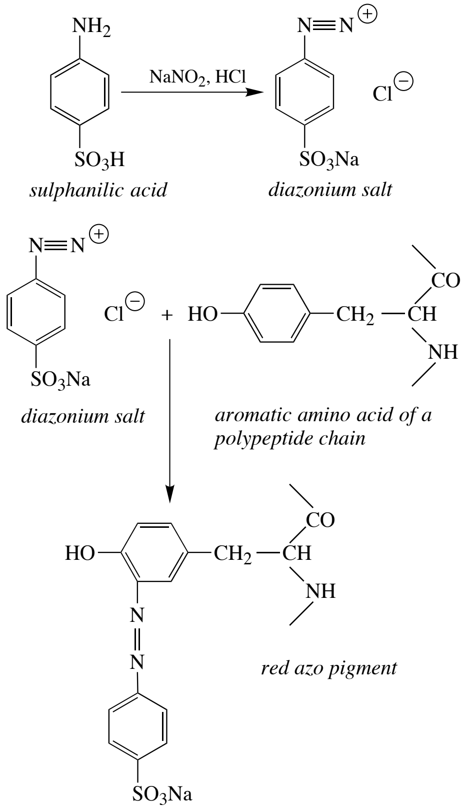
Pattern die Small roller with embossed “spur shaped” patterning. In practice the term pattern die is often mistakenly used instead of relief. In mill engraving (particularly for the creation of roller printing rollers), which is suitable for very small repeat and geometric designs, the design repeat is engraved in a small mild steel roller (→ Engraving). This takes place manually using graving tools or a stamping machine, or mechanically by an engraving machine. Photoengraving processes are also possible. The so-called parent pattern die or pattern die for short is created. Its patterning element is indented. The following usage applies: All manufacturing stages (in pattern die engraving) that generate indented patterning elements, fall under the term → Mill engraving. After hardening, the pattern die is rolled under high mechanical pressure on a wide mild steel roller, the relief pattern die, or relief for short. An impression of the pattern die is created in the relief. Its pattern elements are raised. All processes (in pattern die engraving) of this type, i.e. which generate raised patterning elements are called relief engraving.

Pattern flocking → Flock printing.

Patterning fault Faults in carpets (and textiles) made of multi-coloured (particularly space dye) yarns. Repeating pattern on the surface due to undesired regularities in the arrangement and size of the colour dots on yarn and loop sequence in carpets.

Patterning yarn trimming machine Long, floating weft threads (e.g. jacquard curtains) are mechanically cut and then sheared.

Pauly reagent (Pauly-Diazo reaction), has proved useful for detecting damaged wool. The reagent dyes damaged wool yellow, or orange to reddish brown depending upon the degree of damage; it being irrelevant whether the damage is chemical, biological or mechanical. The Pauly reagent is made of sulphanilic acid, which is diazotized. The diazobenzene sulfonic acid that forms is collected on a filter and dissolved by pouring 10% ice cold sodium carbonate solution over it. The fibre material, which has been thoroughly degreased by extraction with petroleum ether, is placed in the freshly dissolved, ice cold diazobenzene acid for 10–15 min. Then it is thoroughly rinsed with ice cold distilled water, the sample dried in air and the colouring evaluated. The Pauly reaction is based upon the fact that the amino acid building blocks with aromatic groups contained in the wool, form a red azo dye with the diazotised sulphanilic acid. The amino acid building blocks (with aromatic groups) are only found in the spindle-cell layer below the scale, i.e. colouring only occurs when the scale layer (cuticula) is attacked or destroyed. One such amino acid building block is tyrosine, for example, which has been detected both in wool and in silk. The dyeing reaction takes place according to the following diagram:



PB,

I. → Elastodiene fibres, → Standard abbrev. for textile fibres, according to DIN 60 001 until 1988, from 1991 → ED.

II. → Polyureas, symbol according to the → EDP key system.

Pb Element symbol for lead (82).

PBI fibres → Polybenzimidazole fibres.

PBTP → Polybuteneterephthalate.

PC,

I. → Polyacrylonitrile fibres, → Textile fibre symbols, according to the → EDP key system; → PAN.

II. Plastic abbrev. for → Polycarbonates.

III. Abbrev. for → Paper chromatography

PCB → Polychlorinated biphenyls.

PC Control In order to classify microelectronics projects according to their size, we differentiate between four device classes:

- Hardware replacement: The computer is "invisible".
- Small devices: They only contain one microcomputer.
- Large devices: They contain more than one microcomputer (this class includes PC).
- Systems: They contain several, different micro and minicomputers.

We talk of "hardware replacement" if the microelectronics system fulfils logical functions, which in principle could also be realised by conventional means (e.g. mechanical components, integrated circuits). The reason for the use of microelectronics is a reduction of space and power consumption. The microprocessor is not visible from outside. The user is usually not aware of its existence.

A system belongs to the class of "small devices" if a microprocessor is used because the desired function can only be realised by conventional means at excessive cost. A single processor usually suffices. However, it is more clearly visible than is the case of pure hardware replacement, i.e. the interested user is aware of its existence. Some small devices are fitted with several processors. Teleprinters for example have three processors: One is devoted to the keyboard and display, the second operates the printing equipment and the third takes care of communication with the remote station.

Small devices are limited, in that they have no loadable software, only permanently stored ROM software. External data carrying media (e.g. disk drives) are not involved.

The class of "large devices" includes all devices with loadable programmes or parameter lists. They often have several processors, of which one is usually evident to the user. There are often computers of different types. Examples: Word processing systems, checking machines, numerical controls for machine tools (NC control). The ability to load programmes is an important classification criterion for the following reason: The customer receives a device, the characteristics of which can change over the course of its useful life. This change can be made without modifications to the hardware. It is made by new software supplied at a later date or even by parameters that are changed by the customer himself. Parameter lists are often also called "programmes". The term "large" device should not be taken literally. Despite their small size, personal computers belong to exactly the same class of device as machine tools with numerical control.

If the product is assembled for each customer individually from elements (configured), then we talk of a system. The elements can be both hardware and software elements (programme components). Again, the individuality of each delivery is more decisive for classification than the physical size.

Simple temperature/time controllers for dyeing plants in companies and laboratories are based upon PCs with relatively low storage capacity (Fig. 1). Part machines for temperature/time regulation and control of partial processes such as filling finishes, rinsing, emptying, accessing storage containers require large PC storage capacities (Fig. 2). Interactive dialogue programming with a memory card to external programme storage and by interfaces for the connection of a central computer or controls again increases the required PC capacity.

Differentiated programming options and integrated dosing control (Fig. 3) are connected with comfortable PC storage.

→ Stored program control (SPC), which can control

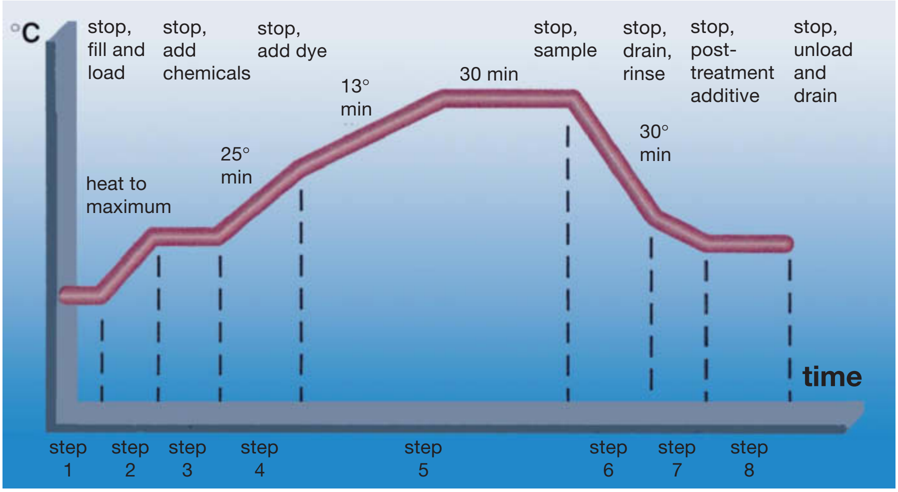


Fig. 1: Example of a program for a PC controlled dye process.

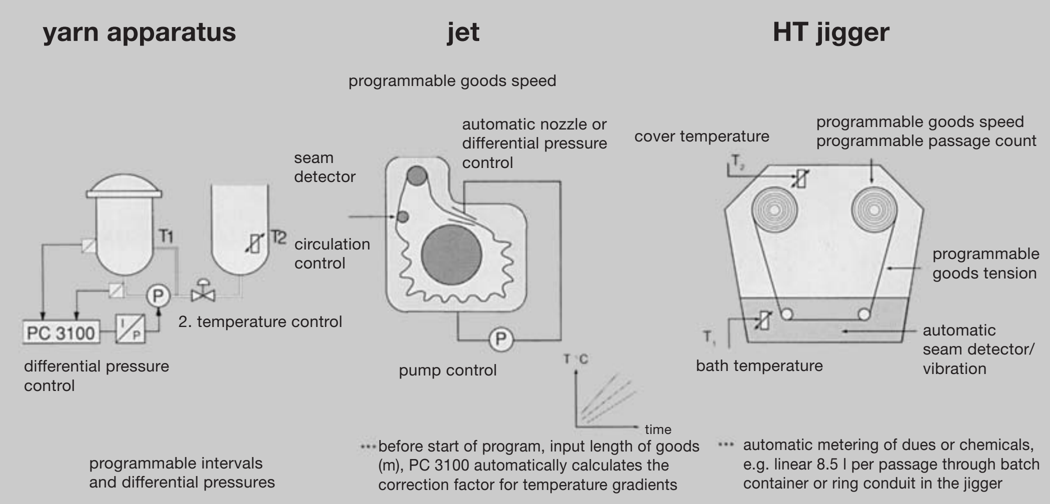

Fig. 2: Example of typical application for the PC based control of peripheral apparatus with suitably larger microprocessors (Barco-Sedo).

a large number of processes in dyeing equipment and in its periphery or provide a superior central control or fully automatic process control for "continuous plants", should be suitably large with regard to PC capacity used (partially according to Becker).

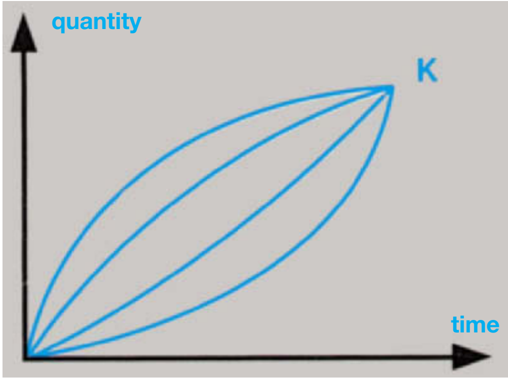

Fig. 3: Prescribed dosage curves for PC control systems.

PCL Abbrev. for protein contaminant layer, a layer surrounding the wool hair, which is dissolved during raw wool scouring.

pCl Concentration of Cl ions, similar to pH. Can be determined by → Potentiometric measurements using silver/silver chloride electrodes.

P Controller, Proportional action controller Continuous controller with proportional action. → Control equipment.

PCP → Pentachlorophenol.

Pd Element symbol for palladium (46).

PE → Polyethylene fibres, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

Peachskin → Apricot skin.

Pearl printing Performed on the hank (→ Yarn printing) using a suitable yarn printing machine, in the form of point single colour illuminating dye.

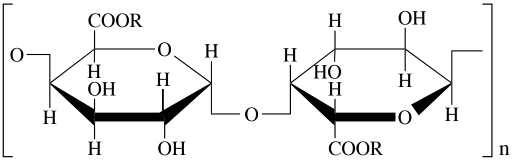
Pearl yarn (knitted yarn), pearl ply yarn made up of two different (heavily) twisted single threads (usually with opposing twist).

Peat fibres Peat contains residues of grass, swamp plants, mosses etc. that have decomposed in the absence of air. The dark brown or black strands it contains (approx. 15 cm long) consist of cellulose fibres, which provide a spinnable material. These fibres, which belong to the group of → Hard fibres, can be extracted mechanically or by boiling in lye with subsequent oily emulsion treatment (approx. 2%). The fibres are on average 30–40 mm long, the individual cells 1–3 mm long. Strength and elongation are low, absorbency on the other hand is high. They also have a certain antiseptic property. The fibres are similar to → Merino fibre.

Peat yarns Yarn made of → Peat fibres, either on their own or mixed with cotton or wool, etc., from which, covers, carpet runners, mats and carpets are manufactured.

Pectinases Specific → Enzymes (belonging to the hydrolases and carbohydrases), which gradually break down high molecular pectins (and hemicellulose) to single galacturonic acid. Pectinases play a decisive role in the biological retting of stalk bast fibres.

Pectins High molecular, carbohydrate-like vegetable substance, composed mainly of methylated polygalacturonic acid in a glucosidic bond:



R = $-CH_3$
$-H$

Pectin molecules are not stretched as tightly as cellulose molecules. It is thought that pectins represent a preliminary stage of vegetable lignin. Naturally occurring, dissolved in cell sap; as insoluble calcium pectates most commonly in the middle lamella of the cell wall of bast fibres; also insoluble, probably linked with cellulose, as proto-pectines in the primary cell membrane. Normal, soluble pectin is technically extracted from the latter by a type of hydrolysis (dry pectin by atomizing the solution or by reprecipitation with alcohol).

Pectins represent the majority of impurities in pure cotton. They absorb energetic dye and are split by kier boiling to form sodium and calcium pectate.

Peel adhesion Testing process for determining the adhesion of a matrix to the reinforcement material. The peel test is typically used for laminated or backed material, with the composite being pulled apart with a force x (with the two constituents of the compound at a defined angle). Alternatives are the shear test or a test in which the matrix is poured over a thread, and then a force x applied to try to separate the two (see Fig.).

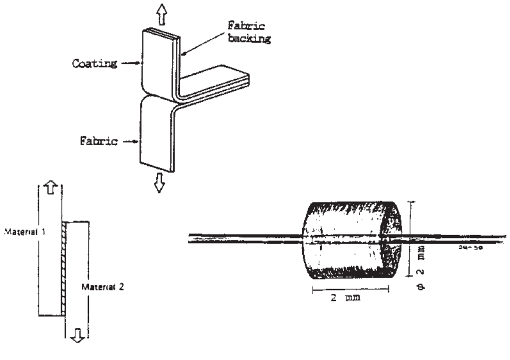


Fig.: Peel adhesion (centre) compared to other methods of testing (shear test left; micro-bonding test right), all with the same goal of determining the adhesion between matrix and hardener.

PEG → Polyethylene glycol.

Peg Small flakes falling through the grid during the → Opening of carbonized wool (waste).

Pelts Term for the hairy outer skin of smaller animals in particular, e.g. rabbits, goats, etc. →: Skins; Tanning.

Penetration,

I. Penetration of a fibrous mass with the applied liquor, which if possible must wet all surfaces if uniformity of product application is to be guaranteed before fixation. Good penetration can be worsened by subsequent migration as an overriding effect. If there is undesired print penetration through fabric or knitgoods, it can be rectified by the use of a suitable printing thickener. In padder pigment dyeing the penetration, as a time-dependent process, can be improved by air flow.

II. Characteristic feature of printed fabric (roughly comparable to full penetration dyeing), which is particularly dependent upon the type of fabric and thickener. A thick, dense fabric or a suitable filter paper is used to evaluate the penetration capacity of a thickener. Penetration percentages are best obtained by a comparatory whiteness measurement. Penetration is = 0% if the printing on a thick fabric remains invisible on the reverse side, i.e. the material still shows its original high, intrinsic degree of whiteness (for thinner fabrics 0% is never achievable, print with very high thickener concentrations is always visible on the reverse). Therefore: Penetration = 100%, the colouring is the same on the reverse and right sides. If the degree of whiteness of a the undyed fabric (W1), the printing (W2), and the penetration (W3) are measured, then the percentage penetration is calculated as follows:

$$\text{penetration} = \frac{W_1 - W_3}{W_1 - W_2} \cdot 100$$

Penta- (Gk.), determinative element for compounds, which means “five”, e.g. phosphorus pentachloride (containing five chloride atoms).

Pentachlorophenol (PCP), C_6Cl_5OH. Whitish to brownish needles, almost odourless (irritant to the mucus membrane), anhydrous, slightly acidic; almost insoluble in water. Soluble in lyes (salt formation) and organic solvents. Irritating to the skin (above 1% solution). Highly toxic to bacteria, fungi, yeasts, etc. Possesses high affinity to cellulose. Application: Preserves glue, casein, leather, wood, solvent impregnated textiles etc.; however, as a carcinogenic substance is not suitable for textile finishing. Usage and import ban.

Pentacholorophenol test Colorimetric procedure similar to → Hexachlorophene test.

Pentane C_5H_{12}, → Saturated hydrocarbons.

Pentanol (amyl alcohol), $C_5H_{11}OH$, → Alcohols.

Pentaoxane $(CH_2O)_5$; it is a → Polyoxymethylene. Applications include use as crosslinker in resin finishing.

Penta screens Second generation of → Rotary screens for screen printing with mesh values of 125–215. Finer designs can be achieved by using screens with higher mesh values (→ Mesh number). This is made possible by better mastery of the hole/web ratio by altering the cross-section of the engraving from the sawtooth type to drop-shape. Penta screens require a new special paint. Improved uniformity and higher printing speed and low doctor blade pressure at the same printing paste viscosity are further advantages.

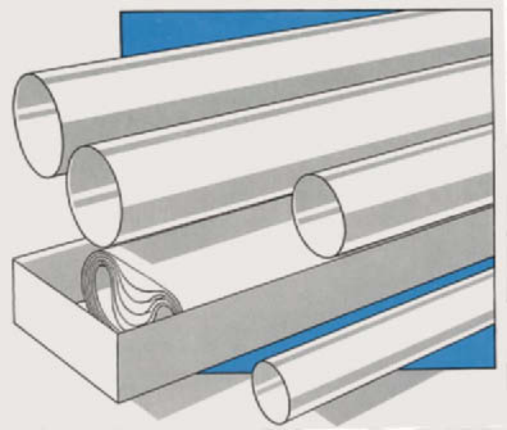

Fig. 1: Typical make-up of rotary serigraphy penta screens as delivered to the printer.

Standard screens have conical openings and a relatively high level of surface roughness. Penta screens have double cone openings and a much smoother surface, both on the inside and the outside (Figs. 1–2). This hole shape represents a significant improvement: The printing paste flows through the holes much more easily and the probability of blocking is reduced. Furthermore, the most important advantage is that penta screens have a much greater relative permeability, whereas a max. number of hole per cm^2 is achieved. For comparison: The most commonly used standard screen of 80 mesh has a permeability of 11% (Fig. 3); the finer penta screen of 125 mesh is 15% open (Fig. 4). There is also a difference in the number of holes: An 80 mesh standard screen has 1128 holes/cm^2, a 125 mesh penta screen has 2275 holes/cm^2. Fig. 5 shows possible differences in the patterning.

Fields of application of standard screens:

40 and 60 mesh: Suitable for blotch printing on heavy material qualities, excellently suited for penetration printing.

Fig. 2: Typical penta screen with end ring.

Fig. 3: Standard rotary screen by Stork.

80 mesh: For not too fine contours (up to 0.3 mm), blotch printing on normal material qualities, can also be used after penetration printing, 80 H specifically for half tone effects.

100 mesh: Surface printing, contours and details up to 0.25 mm.

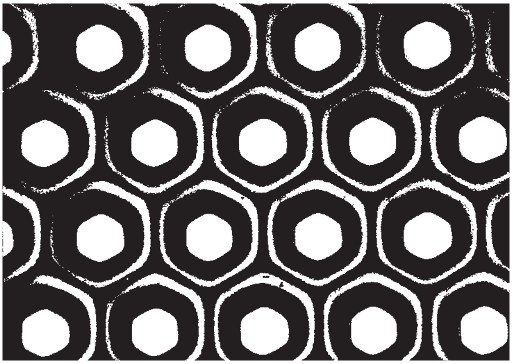

Fig. 4: Penta screen by Stork.

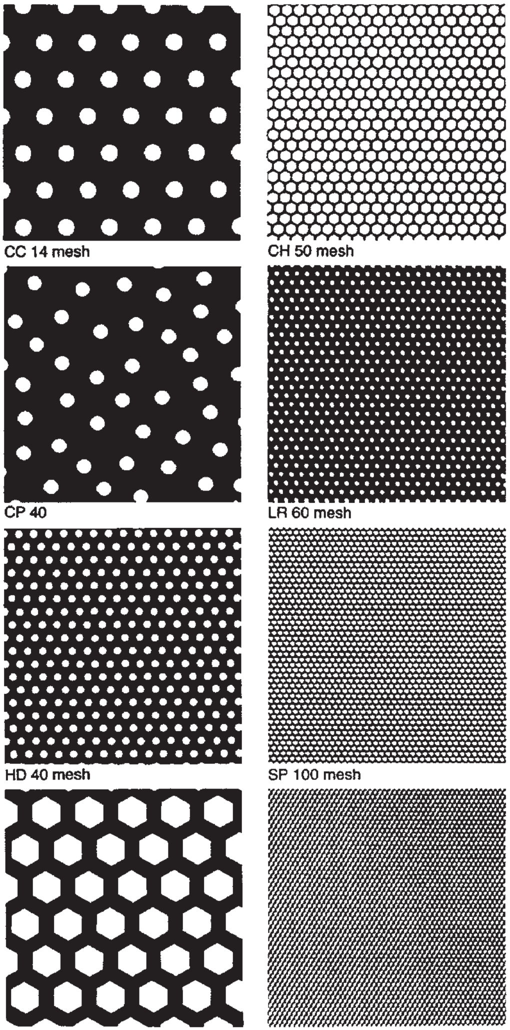


CC 14 mesh
CH 50 mesh
CP 40
LR 60 mesh
HD 40 mesh
SP 100 mesh
HX 14 mesh
LR 125 mesh

Fig. 5: Different rasters on Stork rotary screens.

Fields of application for penta screens.

Penta 125 mesh: Universally applicable, blotch printing is even more consistent, surface and penetration printing, contours and fine details up to 0.2 mm.

Penta 155 mesh: Suitable for blotch printing on light material qualities, contours up to 0.16 mm, half tone printing, discharge and resist printing, excellently suited for designs with horizontal and vertical lines, 155 DLH: Specifically for transfer printing and half tone printing with magenta pattern SCR 6480.

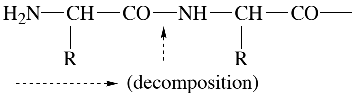
Penta 185 mesh: For extremely fine half-tone printing, contours up to 0.13 mm, designs with horizontal and vertical lines.

Penta 215 mesh: Half-tone printing with magenta pattern SCR 6480, contours up to 0.11 mm.

Pepper and salt Colour patterning effect, also known as thread by thread, in which a light thread alternates with a dark thread in warp and weft, giving rise to a diagonal stripe. Grey shades are typical, but beige-brown and other colour combinations are also possible. Weave primarily even-sided, 4-thread twill or panama 2/2. In German designs the so-called “staircase” in the finished material, runs from the top left to the bottom right (the twill ridge runs the other way); in English materials it is exactly the opposite. Finish generally bald. Application for ladies’ and gentlemen’s outerwear.

Peptidases Group of protein decomposing → Enzymes (belonging to the hydrolases and proteases), which however, only hydrolytically decompose (poly)peptides. In the polypeptidases one differentiates between:

I. Amino polypeptidase:

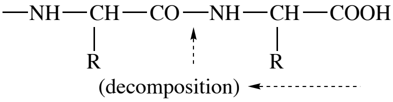


$$H_2N-\underset{\substack{|\\ R}}{CH}-CO\underset{\uparrow}{-}NH-\underset{\substack{|\\ R}}{CH}-CO-$$

$$\dashrightarrow \text{(decomposition)}$$

Decomposition in this case occurs from the side of the free amino groups.

II. Carboxy-polypeptidases, on the other hand, act from the free carboxyl groups.



$$-NH-\underset{\substack{|\\ R}}{CH}-CO\underset{\uparrow}{-}NH-\underset{\substack{|\\ R}}{CH}-COOH$$

$$\text{(decomposition)} \dashleftarrow$$

Peptide Condensation product made from → Amino acids, in which the amino group of one molecule links with the carboxyl group of another, discharging water:

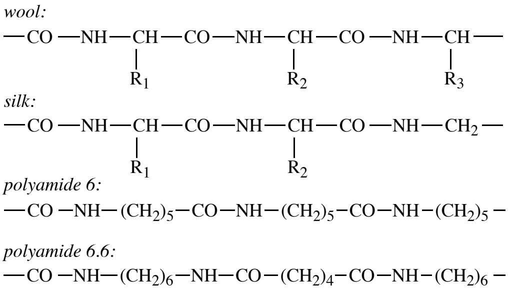
$$H_2N–CH_2–CO\boxed{OH + H}NH–CH_2–COOH$$

$$\downarrow$$

$$H_2N–CH_2–CO–NH–CH_2–COOH + H_2O$$

dipeptide

In the same way, any number of different amino acids can react with each other (polypeptides), whereby the acid amide group (COHN) represents the characteristic binding link (peptide bond). Wool and silk are chemical polypeptides made up of 12–20 different amino acids. The peptide bond determines the chemical properties and dyeing behaviour of the protein fibres (wool, silk) and also polyamide fibres:



wool:

$$—CO—NH—\underset{R_1}{CH}—CO—NH—\underset{R_2}{CH}—CO—NH—\underset{R_3}{CH}—$$

silk:

$$—CO—NH—\underset{R_1}{CH}—CO—NH—\underset{R_2}{CH}—CO—NH—CH_2—$$

polyamide 6:

$$—CO—NH—(CH_2)_5—CO—NH—(CH_2)_5—CO—NH—(CH_2)_5—$$

polyamide 6.6:

$$—CO—NH—(CH_2)_6—NH—CO—(CH_2)_4—CO—NH—(CH_2)_6—$$

Peptide bond → Peptide.

Peptization (eptize), formation of a stable dispersion of loose stock or aggregates, i.e. taking colloid particles (e.g. dirt) into a solution (as pepsin does with protein in the stomach), using small quantities of either acid or alkali (soap). Hereby H ions (acid) or OH ions (alkali) are strongly absorbed by colloid particles and the latter given a positive (acid) or negative (alkali) charge. Because particles with the same charge repel each other, → Colloidal solution (dirt-washing liquor) forms.

Peptones Protein-like, water soluble protein decomposition product, which is similar to high molecular synthetic → Polypeptide with regard to structure and molecular size. They form a transition stage between the latter and → Protein. No precipitation occurs as a result of ammonium sulphate (→ Albumoses). Peptones lack some typical protein reactions, such as coagulation when boiled or due to the action of diluted acids.

Per,

I. Abbrev. for → Tetrachloroethylene (perchloroethylene).

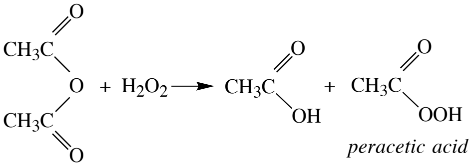
II. Prefix “over”, e.g. Permanganate, salt of permanganic acid $HMnO_4$.

Per acids Acids created by to the action of hydrogen peroxide (H_2O_2) on normal acids, which contain the –O–O–H group instead of –OH, e.g. caro’s acid H_2SO_5; Peroxy disulphuric acid $H_2S_2O_8$; peracetic acid CH_3COOOH; performic acid. Oxygen releasing principle:

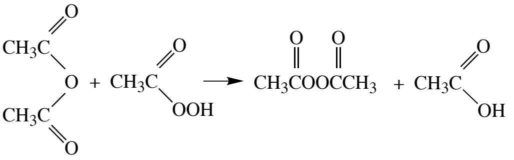
$$H_2SO_5 \rightarrow H_2SO_4 + {}^1/{}_2\, O_2$$

Peracetic acid Molecular weight 76. A 40% organic acid with 8.6% oxygen. Is classed as explosive; colourless; slightly ionized at pH 8.2. Commonly used as polyester and polyamide bleach, for the stripping of triacetate dyes and also as an oxidative bleaching and stripping agent for proteins and other alkali sensitive textiles, particularly for bright fabrics, for polyamide/cotton mixes (optimal 65–80°C; not damaging to fibres) and acetate materials (pH 6–8). Iron and copper vessels are unsuitable. No excessively unpleasant odours or noxious gases form in evaporated peracetic acid. Good ventilation is nevertheless recommended.

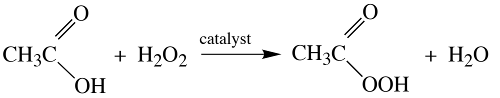
Peracetic acids can be manufactured from acetic anhydride or acetic acid with hydrogen peroxide. In the first method the acetic anhydride reacts with hydrogen peroxide to form one mole of peracetic acid and one mole of acetic acid.



It should be noted that a very dangerous sec. reaction may occur in the manufacture from acetic anhydride.



If excessive acetic anhydride is present, then it may react with the peracetic acid that has already been formed to create biacetyl peroxide and acetic acid. Biacetyl peroxide is a slightly soluble substance with a fixed point of 26.5°C. It is explosive upon impact or heating. By creating a chemical balance in a mixture of hydrogen peroxide, acetic acid and water, with the additional effect of catalysts and stabilizers, equilibrium peracetic acid is manufactured.



The sequence of processes for achieving the finishing objective is determined by a series of influencing factors:

- duration of bleaching,
- temperature,
- pH,
- oxygen concentration.

To fulfil this objective, the following recipe is used for a discontinuous peracetic acid bleaching:

quantity required: 1–3 ml/l peracetic acid (100%),
pH: 7–7.5,
temperature: 60°C,
duration: 30 min.

During the bleaching process acetic acid is released continuously. This must be captured by a suitable buffer, or balanced out by a pH control device with liquor dosing. The sequence in which bath components are added is also important. This sequence is water, peroxide, acetic anhydride, caustic-soda solution (for pH adjustment), and a buffer. When all chemicals are dosed via single, continuous, teflon coated dosing pumps the smell, which would otherwise increase in proportion to quantity, is completely inhibited. However stock pastes, like those used for other bleaching techniques, cannot be used due to their instability. Continuous processes including padding, dwelling on a dwelling belt, using a water lock before and after the dwelling to prevent odours, are possible. It is evident from the process conditions (pH and temperature) that the absorbency of the material and seed shell removal must be inferior to those of peroxide bleaching. However, this in no way rules out bleaching with peracetic acid, but rather predestines it for use as the 1st stage of a 2-stage combination bleaching process with subsequent peroxide treatment.

To greatly simplify, the bleaching effect of peracetic acid rests upon the breakdown of peracetic acid into atomic oxygen and acetic acid. The maximum bleaching effect is achieved at pH 8.2. This can be easily reproduced in laboratory experiments in catalyst-free systems. pH 8.2 corresponds with the pK_S value of peracetic acid and is the pH at which the same concentrations of peracetic acid and peracetateanion occur. As for every bleaching process, precise process conditions must be maintained to ensure that the reaction takes place in this manner. If the pH is too strongly alkaline (in this case pH > 9), then the peracetic acid breaks down at an incredibly high speed, resulting in an inadequate whitening effect and possible fibre damage. In the acid range, a balance between acetic acid and peroxide occurs that has almost no bleaching effect. Under practical conditions it has proved more expedient not to work in the range of maximum bleaching speed, which is 3–4 powers of ten faster than for hydrogen peroxide, but rather at pH 7–7.5.

Perborate → Sodium perborate.

Perborate activator → Bleach activators.

Percale Medium to fine threaded cotton or viscose material in linen weave, bleached or printed (stripes or small checker squares). Also called printed linen. The starting material is →: Cretonne, Chiffon or Renforcé. Fabric with thick ply threads at certain distances is called string percale. Application: For shirts, blouses, clothes and quilt covers.

Percarbonic acid → Carbon oxo-acids.

Percentage by weight (weight per cent), is a percentage mass relationship, i.e. grams in relation to 100 gram units, e.g. dye mass stated as a percentage of material weight. Where percentage figures are given in recipes, solvent concentrations etc., and no further information given, the percentage by weight is usually referred to, in solutions → Per cent by volume. Conversion:

$$\text{percentage by weight} = \frac{\text{per cent by volume}}{\text{density}}$$

Percentage set,

I. Proportion of orientated to non-orientated fibre components.

II. Proportion of actual to potential fibre stability.

A statement to the effect that following treatment a degree of setting of 90% has been achieved requires a reference quantity such that under defined conditions a measured surface shrinkage of, say, 20% of a textile to be treated has itself been reduced by 90% to 2%. With this definition the specifiable percentage set is as much dependent on the conditions of shrinkage measurement as the shrinkage of the original material itself. From this example it may clearly be seen that the set status is better defined independently of a standard reference sample, and that the best parameters are the thermal stability of the network formed on setting and the level of the strains frozen-in or locked-in at various temperatures. The terms effective temperature and effective tension as used here are determined by means of → Differential Thermal Analysis.

Per cent by volume (Vol.%), a certain quantity (e.g. mg, ml) of a substance is dissolved in a predetermined volume (e.g. 100 ml). In contrast to → Percentage by weight.

Perchloroethylene → Tetrachloroethylene.

Percolating filter Used in biological → Waste water treatment for enriching the waste water with air. → Biological filter media.

Perfluorocarbon compounds → Perfluoro compounds.

Perfluoro-carboxylic acids → Perfluoro compounds.

Perfluoro compounds Hydrogen fluoride serves as a fluorinating agent in manufacture. Many compounds, amines, ethers, esters, nitriles and fatty acids are suitable for fluorinating. Perfluoro carboxylic acids have a good wetting effect and excellent chemical stability. Perfluoro compounds have an oil-repellent effect and are used for → Oil-repellent finishing.

Perforated belt dryer Ventilation dryer (→ Conveyor drier), in which the perforated belt that serves as the transport mechanism (usually supported by rollers) has a low bending stability and is thus not suited to high loading, and is therefore only used for gentle drying at moderate air speeds. Dry air is sucked under the belt via a fan, transported via heaters, the jet housings of which are evenly spaced across the width, and thus passed over the material.

Perforated cage stenter Ventilation dryer consisting of sieve drum and revolving chain: Used for applications with defined end width, e.g. all fixation and curing processes and above all in the final drying of finished tufted carpets. Airflow (as for sieve-drum dryer) offers the most favourable conditions for the installation of a heat recovery plant, including preheating of outside air. The transport unit consists of the sieve drum inside the drying room and the transport chain which takes in material from outside and re-delivers it. – Manuf.: Fleissner.

Perforated disk beating process → Foam test methods.

Perforated nonwovens,

I. The often papery, non-textile handle of → Nonwovens can be improved by slit-like perforations. A hole-type perforation is also possible.

II. → Nonwovens with slits or incisions (e.g. perforations) to produce a softer handle (various different slit arrangements are possible). Amongst other things, this increases the permeability for gaseous and fluid media and creates better absorption characteristics. Have improved dimensional stability compared with un-slit non-wovens and lower strength depending on quality and slit arrangement.

Perforation Systematic perforation of materials in order to guarantee flow. For example, cheese centres (Fig. 1) or dyeing beams are perforated so that the dyeing liquor can achieve a good liquor exchange with the dyestuff. Nonwovens made of synthetic fibres (Fig. 2) are perforated with hot needles to guarantee air penetration or moisture exchange depending upon the field of application.

Performance, output Work performed, work yield.

Performance specification If a project is to be implemented, e.g. the purchase of a machine or an assembly line, a performance profile must be drawn up defining a list of priorities regarding the goals to be achieved. The performance specification created in this way must be continuously checked to establish whether the goals contained within it are being achieved.

Example: Development of a mercerizing machine.

Fig. 1: Perforated steel dyeing cores for the dyeing of cross-wound yarn packages (Fong's).

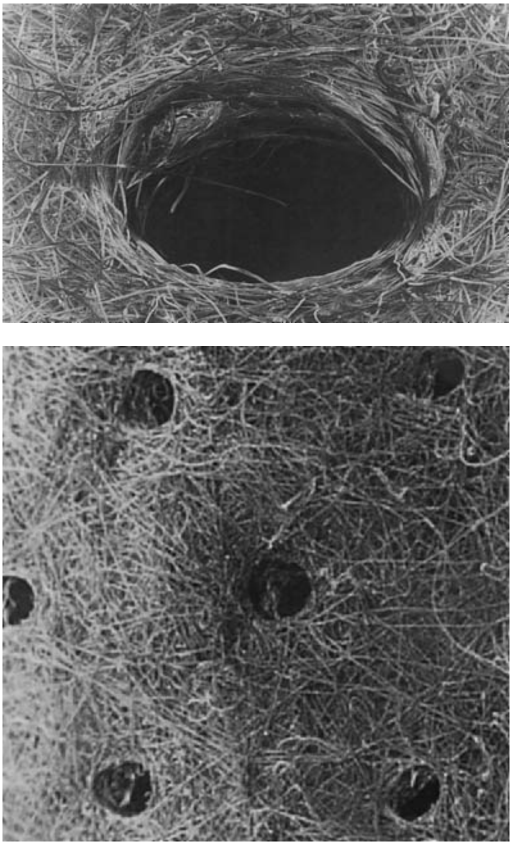


Fig. 2: Hot needle perforation of synthetic fibre mats (Kahnes).

The following performance specification was to be fulfilled:

1. Process technology:
   - intensive, complete and safe impregnation in a few seconds;
   - low liquor volume use;
   - automatic liquor management;
   - easy changing of the liquor concentration;
   - possibility of hot impregnation followed by cold mercerizing;
   - low liquor, water and steam consumption;
   - maintenance of preselected fabric length and width;
2. Textile material quality:
   - maximum dimensional stability in warp and weft;
   - optional, targeted influencing of the dimensional stability in warp and weft;
   - no edge-to-centre differences caused by the mercerizing;
   - quiet, even patterning in dyeing;
   - achievement of the normal mercerizing effects such as lustre, covering of dead cotton, increasing the dye affinity with good reproducibility.
3. Engineering:
   - set of modules for great flexibility with regard to customer’s wishes;
   - high degree of automation;
   - element construction method for short installation times;
   - use of rust and acid resistant material.

Performic acid CH_2O_3. A per compound of formic acids. Can be manufactured using special precautions (can be explosive) from formic acid, hydrogen peroxide (H_2O_2) and sulphuric acid (H_2SO_4). Colourless liquid and more volatile than formic acid. Decomposes readily when stored, forming H_2O_2, formic acid, carbon dioxide and oxygen. Is sometimes explosively decomposed by metals and metal oxides. Not available commercially due to its high instability. In finishing technology it serves as an oxidizing agent in the form of a reaction of formic acid and H_2O_2, whereby performic acid is created in an equilibrium reaction.

$$\text{H–CO–OH} + H_2O_2 \rightleftharpoons \text{H–CO–O–OH} + H_2O$$

Perfumes (scents). Precisely chemically defined natural or synthetic substances with → Osmophor groups, which, in combination with the molecular environment determine whether and in which differentiation an odour impression is created. → Odour nuisance.

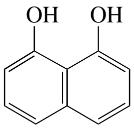
Perfume treatment of textiles Specifically of jersey knit goods, hosiery, etc. For removing, improving or covering the smell of oil, grease, dyes etc. Achieved using so-called → Fragrant finishes. Treatment stage in softening, rinsing, finishing, spray dampening, etc.

Perhydrates Addition compounds, which contain → Hydrogen peroxide (H_2O_2) in the form of crystal hydrogen peroxide (in addition to water of crystallization). Method of oxygen release: Slow decomposition of the H_2O_2 formed in the solution.

Periodic system Natural ordering system of → Elements in the order of their → Atomic weight, which permits inferences to be made by analogy regarding the behaviour of related element groups.

Periphery Environment of the actual work unit, i.e. control unit, power supply, electropneumatics, crane and other transport devices for the operation of the plant, EDP, recycling plants, exhaust and waste water disposal, waste collection. The periphery of a machine is usually at least as expensive as the work unit itself.

Peri-position In connection with chemical structure formulae. In the naphthalene nucleus this is the adjoining 1.8 or 4.5 position of certain substituents, e.g. mordant attracting groups in mordant dyeing:



Perkin, Sir William Henry (1838–1907), English chemist. In 1856, at the age of 18, discovered the first technically usable coal-tar dye (aniline purple or mauvine) when looking for a quinine synthesis. Founder of the dyestuffs industry.

Perlite Vulcanized stone with many small water voids (23% molecularly bound water). After fine milling and heating to over 1200°C perlite expands due to water vaporization to a swollen, feather light “foam stone” (approx. 20 times volume and more), which is used in the construction industry for temperature and sound insulation (rock wool). Repeated fine milling and subsequent separation treatment gives rise to a highly active filtration agent, which is excellently suited for application e.g. in chemical cleaning.

Permanent adhesive Water insoluble plasticized synthetic polymer used as a table adhesive for affixing material to be printed onto screen printing tables, sometimes also onto the back grey printing of screen printing machines.

Permanent emboss → Embossing.

Permanent finishing Applications or effects on textiles, which resist the stresses of use and care, e.g. washing, chemical cleaning.

Permanent hardness → Water hardness salts.

Permanent-press process Originally used exclusively as a collective term for → Resin finishing processes (dry cross-linking), in which the final fixing or stabilizing of the material takes place during garment manufacture. This produces items of clothing with excellent permanent dimensional stability, sharp ironing folds and pleats, nonshrink seams and particularly good smoothness after washing. Fixation is therefore not performed flat, but shaped. Also a common term for conventional resin finishing, however only for items with high-quality finishing effects.

Permanent-press process for wool Collective term for: → Antifelting finish and → Non-shrink finish.

Permanent white → Barium sulphate.

Permanganate → Potassium permanganate.

Permanganate number,

I. → Permangate number. For quantitative determination of fibre damage to cellulose. Oxycellulose and hydrocellulose are dissolved from the fibre by repeated boiling and detected using a potassium permanganate solution.

Permanganate number = number of millilitre 0.1 n $KMnO_4$ solution, consumed by 1 g fibre.

II. → Waste water permanganate consumption.

Permangate number (Kaufmann), → Permanganate number. Oxycellulose content of cotton bleached goods, which have not been alkaline-boiled before or after bleaching. Method: Boil 1 g material with NaOH and titrate dissolved organic products with 0.1n $KMnO_4$. $KMnO_4$ consumption up to 10 ml normal, 10–13 ml little damage, above this significant damage. When making the calculation, deduct the basic value for unbleached material. The permangate number can also be an important method of detecting cotton materials kier boiled in the presence of air.

Permeability (permeability to radiation, D), identical German term for → Transparency.

Permeability bag test Used for evaluating waterproof impregnation effects on textiles. Method: Fill clamped, sagging material trough with measured quantity of water (e.g. water level of 5, 7.5, 10, 15 cm, effect 24 h) and check the time it takes for water to start leaking through. Different water quantities are used depending upon the properties of the material. The permeability bag test usually does not accurately reflect the conditions in which the fabric is worn, but is still often used by finishing companies (particularly for tarpaulins, tent fabric, etc.).

Permeability determination In printing screens with a → Light transmission measuring instrument this permits the precise photometric determination of the open printing area.

Permeation Passage through a membrane. In membrane separation procedures this is a so-called pressure penetration. Permeation is the collective term for many different, yet fundamentally similar, and simply functioning membrane procedures: Micro, ultra and nano filtration as well as reverse osmosis (see Fig.). In all four procedures the waste water being treated flows turbulently across the filter element, the membrane,

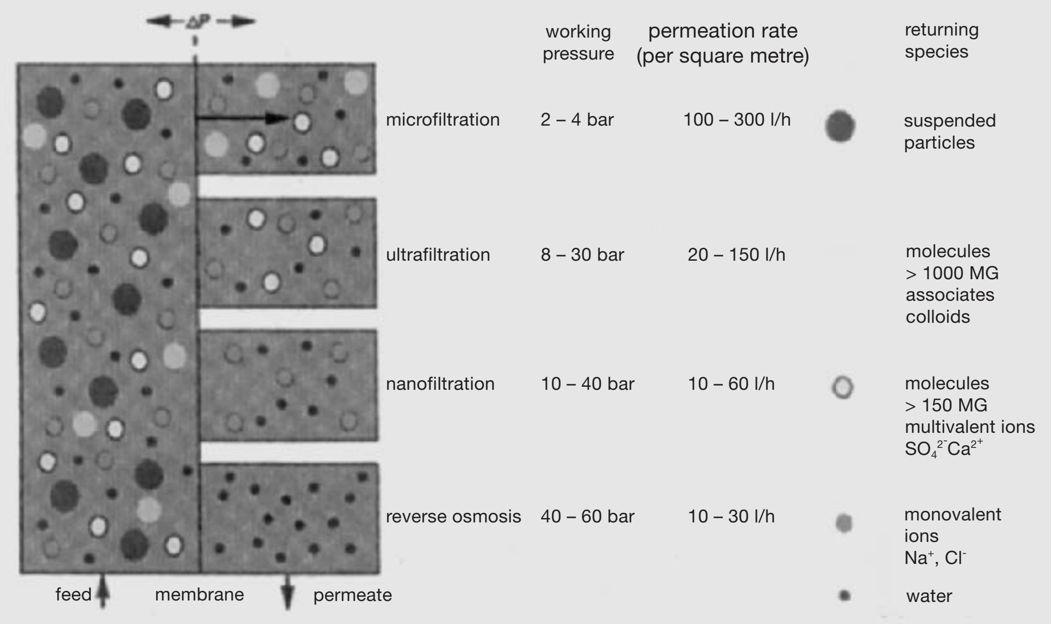


Fig.: Pressure permeation process (Bayer).

by the “cross-flow” technique. Under hydrostatic pressure a flow of water is forced through the semipermeable membrane at right angles to the direction of flow. Depending upon the membrane structure or the size of its pores, almost all the substances in the waste water, from large particles to small molecules and dissolved salts, can be concentrated.

Thus the pressure permeation process is nothing more than a filtration technique in the finely dispersed to molecular range, whereas the four individual processes differ according to the fineness at which the substance is separated out. Microfiltration membranes can only retain undissolved particles of a size of approx. 0.1 µm, whereas all dissolved substances flow through the pores of such a membrane. It is thus suitable, for example, for the clarification or prefiltration of solutions. The membranes used in → Ultrafiltration can retain larger organic molecules in dissolved form and separate these from small molecules and organic salts. As dyestuff molecules associate in aqueous systems and are thus not monomolecular, but are present as clusters, any dyestuff present in the solution will be almost completely (> 99%) retained by UF membranes with low separation limit. In this manner it is technically possible to largely decolorize waste water using ultrafiltration. However low molecular COD and AOX loads are not retained by this membrane or heavy metal salts, so that the permeate, although colourless, is only biologically capable to a limited degree. A nanofiltration membrane, on the other hand, has such fine pores that even small organic molecules with a molecular weight of > 300 g/mol and polyvalent ions are retained, although a sodium chloride solution, for example, would still pass through the membrane. The technical process of → Reverse osmosis is in principle, as the word appropriately describes it, the exact reverse of natural osmosis, which ensures a regulated balance of nutrients and fluids in every plant (Tegtmeyer).

Permutit Group of artificial → Ion exchanger. The strongly acidic permutit-cation exchanger in sodium form (insoluble in water → Sodium aluminosilicate) can absorb calcium and magnesium ions and release an equivalent quantity of sodium ions.

$$\text{permutit–Na}_2 + \text{CaCl}_2 \rightleftharpoons \text{permutit–Ca} + 2\,\text{NaCl}$$

$$\text{permutit–Na}_2 + \text{MgSO}_4 \rightleftharpoons \text{permutit–Mg} + \text{Na}_2\text{SO}_4$$

Permutoid,

I. Identical to →: Intracellular; Intramicellar.

II. Normally in the sense of “exchangeable”, e.g. ion exchanger property; so we talk of permutoid behaviour in textile fibres, permutoid conversion, etc.

Peroxide binding of fibres Fibres containing nitrogen (polypeptides) bind significant quantities (in mg/g fibre) even from 3% solution of H_2O_2 at 20°C (pH 8):

wool	9.8
polyamide 6.6	5.5
silk	4.5
cotton	0
glass fibres	0

Peroxide binding increases with concentration. In a reaction of 40% H_2O_2 solution a maximum of 2–3 mol peroxide/kg wool are bound. In the pH range 2.5–9 for wool (absorption falls below and above), and between pH 0–6 for silk and polyamide there is no dependency upon the hydrogen ion concentration. It is thought that peroxide binding is primarily determined by the amino groups (0.9 mol/kg wool, 0.1 mol/kg silk) and imimo groups (9 mol/kg wool, 12 mol/kg silk) present.

Peroxide bleach The oxidizing agent hydrogen peroxide (H_2O_2) has become prevalent in the pre-treatment of textiles made of cellulose fibres in the bleaching process. It is most convincing in the application technology and ecological field. Its competitors: → Sodium hypochlorite (NaOCl) and Sodium chlorite ($NaClO_2$), on the other hand, have significant ecological disadvantages; the ecological hazards consist of exhaust air pollution due to the formation of “poisonous” gases and waste water pollution (AOX).

Hydrogen peroxide dissociates only slightly in an aqueous medium.

$$H_2O_2 \rightleftharpoons H^+ + HO_2^-$$

If the hydrogen peroxide solution is activated with alkali, then the dissociation equilibrium is moved to the right and the concentration of perhydroxyanions is increased.

$$H_2O_2 + OH^- \rightleftharpoons H_2O + HO_2^-$$

The actual oxidation of the discolouring, i.e. the bleaching reaction probably occurs via a superoxide anion radical. In parallel to this a self-decay takes place in a secondary reaction that has no effect on the bleach. As the alkali concentration of the bleaching liquor increases the bleaching reaction and self-decay as a competing reaction decreases. Due to this fact, peroxide bleaching is usually carried out in the range of pH 10–12. Peroxide decay is accelerated by a number of substances or substance mixtures. The presence of such so-called catalysts in the bleaching liquor and/or in the textile material leads to a spontaneous breakdown of the bleaching agent. This is associated with fibre damage, which expresses itself by the oxidation of cellulose into familiar oxycellulose, and its subsequent depolymerization (→ Catalytic damage).

The permanganometric determination of the peroxide content takes place in a sulphuric acid solution by titration with potassium permanganate. Reaction process:

$$2\,KMnO_4 + 5\,H_2O_2 + 3\,H_2SO_4$$
$$\rightarrow H_2O_2 + 2\,MnSO_4 + 8\,H_2O + 5\,O_2$$

Titration takes place at 0.05 n $KMnO_4$. According to the equivalent ratios (34:2 = 17), this yields:

1 ml 0.1 n $KMnO_4$ = 1.70 mg H_2O_2
1 ml 0.05 n $KMnO_4$ = 0.85 mg H_2O_2

The quantity of peroxide (C_P) contained in the sample (5 ml) is found using the following equation:

$$C_P\ [mg] = \text{consumed ml } 0.05\ n\ KMnO_4 \cdot 0.85$$

If we relate this concentration at a volume of 1litre and use another conversion factor for the weight unit, then we find

$$C_P\ [g/l] = \frac{C_P\ [mg] \cdot 1\,000\ ml \cdot 10^{-3}}{5\ ml}$$

The peroxide breakdown can be calculated by the following equation:

$$\text{peroxide breakdown (\%)} =$$

$$\text{peroxide content} : \frac{\text{starting content}}{100} - 100$$

Determination of the max. titration error yields 0.1 ml 0.05 n potassium permanganate solution, so that the determination of the peroxide content with an absolute error of = 0.6% of the starting content: 2.9 g/l ± 0.1 H_2O_2 can be viewed as being sufficiently precise. However, a greater measuring error results if the sample is taken in deviation from the specified time (depending upon the decomposition speed of the bleach liquor). It is therefore vital that the specified time is adhered to. There is a functional dependency of the peroxide decay on the bleach breakdown. However, the bleaching result (i.e. the ratio of material quality to usability) is also influenced by other factors, which means that the reduction in peroxide content has no direct relationship with the bleaching result.

The catalysts contained in the impurities in the cotton in the form of compounds containing heavy metals can lead to fibre damage in the peroxide bleach, particularly where there are local concentrations in the yarn. The fibre damage can be attributed to the radical peroxide decay initiated by the catalysts. Radical decay should therefore be prevented under all circumstances. If possible, the heavy metal ions must also be removed in appropriate pre-treatment stages prior to bleaching, or the effectiveness of the catalysts must be repressed. Iron compounds make up the majority of potentially catalytically active escort substances in cotton. The point material damage (holes) depend partially upon the pre-treatment and bleaching conditions. The degree of fibre damage caused by catalysts is however, usually only recognisable in the subsequent treatment stages or during use, meaning that significant damage can occur. In an attempt to solve the problem of preventing catalytic damage, much effort has been expended to try to develop a procedure by which fibre damage is ruled out, despite the presence of catalytic compounds. The dissolution speed of the impurities containing heavy metal in the pre-treatment and bleaching liquor is a dominant influence factor for radical peroxide decay. Above all the dissolution speed of the iron hydroxide, i.e. the concentration of the dissolved iron ions in the bleach liquor, determines the catalysis of the peroxide decay.

Peroxide decay is, therefore, critically dependent upon the stabilisation of the system. Good stabilisation is characterised by a low H_2O_2 consumption, and the suppression of undesirable secondary reactions such as self-decay into water and oxygen and the formation of radicals. However, stabilisation using the classic regulator water glass is associated with disadvantages, which arise due to the deposits of only slightly soluble silicate on textiles and in the bleaching equipment. The suitability of most regulators can only be determined by practical stabilisation experiments. The determination of the H_2O_2 decay in empty baths should be sufficient for an evaluation of the stabilisation capacity. In this testing method the H_2O_2 content is titrated in the bleaching baths without the textile material and with the regulator being tested in relation to time. The decay curve obtained in this manner is compared with that of a known stabiliser, e.g. water glass.

Peroxide bleach fastness Resistance of dye to the effects of bleaching baths containing peroxide.

Peroxide bleach process Optimal stabilisation of the bleach bath consists of a balance between inorganic and organic stabilisation. Foaming and increasing liquor temperature (e.g. above 50°C) clearly indicate poor stabilisation of the bleach bath, and in parallel to this they also indicate a significant loss of peroxide. Addition liquors are often used in practice, if a modern dosing station for individual components is not available. The application conditions for the products used are strict. They require good alkali resistance and a good H_2O_2 stabilisation (e.g. 50–60 g/l NaOH and 200–250 ml/l H_2O_2 35%). When adding the liquor a very specific addition sequence must be adhered to:

1. water (stipulate maximum possible volumes),
2. magnesium salt,
3. organic stabiliser,

4. surfactant,
5. water glass (if required),
6. caustic soda liquor,
7. peroxide.

The addition of all products must take place slowly, whilst stirring. It should be borne in mind that the addition of the caustic soda liquor to water generates an exothermic reaction and warms the bath by 8–10°C prior to the addition of the peroxide. If the organic stabiliser is not effective enough or if it complexes the magnesium ions to an excessive degree, then sooner or later the liquor will destabilise, because the thermal reaction that is occurring can no longer be maintained. The increase in temperature occurs in parallel to the loss of peroxide. The liquor is controlled by titration with potassium permanganate. It is advantageous not to use too much liquor, but rather to renew the bath more often. If strengthened addition liquor is left to stand for too long then the peroxide concentration should be checked at predefined time periods from the start by titration.

The degree of whiteness and the waste of the polymerisation degree of the cellulose (s, according to Eisenhut) should be used to define a quality factor (Q) for the bleach. The damage factor of cellulose is based upon the difference between the polymerisation degree at the start and the end of the treatment. If the value s is less than 0.4 then the material is not considered to be damaged. The quality factor Q is defined as follows:

$$Q = f\,(W, s)$$

W = degree of whiteness,
s = damage factor of cellulose.

The Q value thus depends upon the material, the selected procedure, the selected recipe and the product selection of the bleach. Q values above 80 can be described as peak values (according to Fornelli).

Peroxide cold bleach Same process as →: Peroxide cold-pad-dwell process; Cold pad batch bleach; Cold dwell process. Very suitable as a pre-bleach. Only recommended for clean husk-free raw material.

Peroxide cold-pad-dwell process Bleaching process specifically for cotton circular goods. Method: a) Impregnate with bleaching and brightening solution on padder using expander for circular material; b) dwell in heat insulated vehicle; c) rinse on rope washing machine.

Peroxide decomposition kinetics During the bleaching process a decomposition process competes with the bleaching reaction, so that as the decomposition component increases the bleaching effect falls. Heavy metal compounds catalyse peroxide decomposition whilst forming radicals, whereby the latter statistically attack the cellulose, which leads to a reduction in the DP degree. It is also possible that the coloured accompanying material may be decomposed in the case of radical peroxide decomposition, so that an increase in the degree of whiteness is feasible. However, peroxide decomposition initiated by heavy metal compounds during bleaching is to be avoided due to the fact that this can be expected to minimize the DP degree. The peroxide decomposition in bleaching liquors can be described by a reaction of the 1st order in the case of the ionic mechanism. The reduction of the peroxide concentration at constant pH is proportional to the peroxide concentration itself.

$$-\frac{dc}{dt} = k \cdot c.$$

Integration between the limits c_0 and c_t according to the peroxide concentration at the beginning and at time t yields:

$$\ln \frac{c_0}{c_t} = k \cdot t.$$

Therefore plotting ln c_0/c_t against time t, yields straight lines, the gradients of which correspond with the speed constant k for peroxide decomposition. These conditions are illustrated in Fig. 1 for buffered systems.

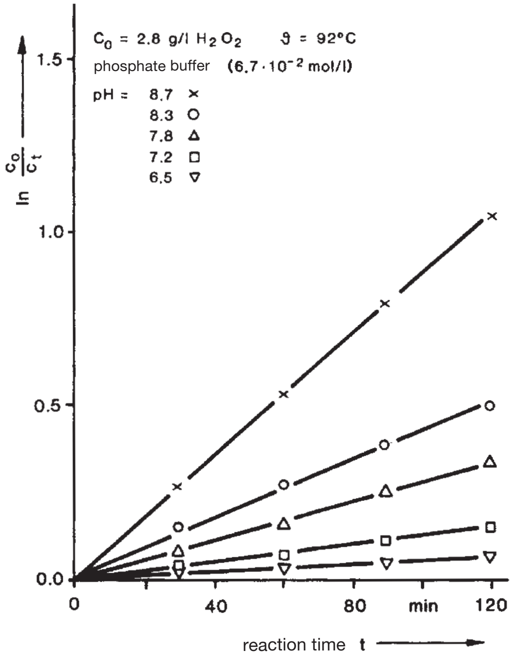

Fig. 1: Peroxide decomposition with changing pH in the absence of textile (according to Heidemann).

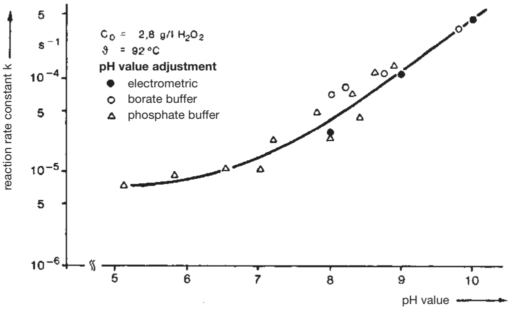

Fig. 2: Peroxide decomposition in the absence of textile (according to Heidemann).

Fig. 1 is based upon the marked dependency of peroxide decomposition on the pH of the medium. This fact is illustrated once again in Fig. 2, in which the speed constant of the peroxide decomposition is plotted against the pH of the liquor. Within the measuring accuracy, the decomposition constants are independent of the selected system, so that the interaction between the electrolytes used for adjustment and maintenance of the pH and the peroxide, e.g. in the sense of a stabilisation, are ruled out. The speed of the peroxide decomposition is, however, relatively high at a normal temperature even for bleaching processes in the weak alkaline range, which indicates the use of regulators (according to Heidemann).

Peroxide-hypochlorite-peroxide bleach Combination bleach for cotton and viscose items of all types, particularly for pure white without kier boiling on medium and heavy fabrics. In the case of mixed textiles or pure viscose items, high viscose losses can be expected, e.g. in the → Kier boil-chlorine bleach (losses approx. 3%) and → Alkali scour-chlorine-peroxide (losses approx. 7%). → Bleaching.

Peroxides (superoxide), compounds of type → Hydrogen peroxide H_2O_2, → Sodium peroxide Na_2O_2, magnesium peroxide Mg_2O_2. Principle of acid release:

$$H_2O_2 \rightarrow H_2O\ ^1/_2 + O_2$$

Peroxide wash, colour fastness to Washing in the presence of sodium perborate. Resistance of textile dyes, which are mechanically treated at high temperatures in washing liquors with bleaching agents that release oxygen. Guidelines particularly for cellulose fibres. Perfuse test piece plus two accompanying fabrics with 60°C warm washing solution (5 g/l soap; 2 g/l sodium carbonate calc.; 0.8 g/l sodium perborate ($NaBO_3 \cdot 4\,H_2O$); 0.15 g/l magnesium chloride ($MgCl_2 \cdot 6\,H_2O$); 1.2 g/l sodium silicate 35°Bé) in liquor ratio 1 : 50, then warm to 95°C within 10 min and treat at this temperature for 20 min. Rinse test piece, squeeze and dry open at max. 60°C. Evaluation according to colour change and bleeding with grey scale.

Per(oxy)carbonates (percarbonic acid sodium salt), salt of percarbonic acid (→ Carbon oxo-acids). Types: $Na_2CO_4 \cdot 1\,^1/_2\ H_2O$ and $Na_2C_2O_5$. Both decompose when dissolved in a) oxygen and sodium carbonate or in b) hydrogen peroxide and hydrogen carbonate:

$$Na_2C_2O_6 + 2\,H_2O \rightarrow H_2O_2 + 2\,NaHCO_3$$

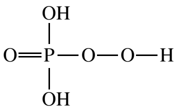
Peroxyformic acid → Performic acid.

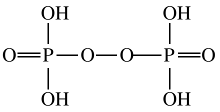
Peroxy group, –O–O group in peroxy compounds.

Peroxy-monosulphuric acid → Caro's acid.

Peroxysulphuric acid,
I. → Caro's acid.
II. → Sulphur oxyacids.

Perphosphates (peroxyphosphates), salts of genuine → Per acids, derived either from peroxymonophosphoric acid (H_3PO_5) or diphosphoric acid ($H_4P_2O_8$) (→ Phosphoric acids).





In the exchange of acid-hydrogen atoms by alkali metals (sodium, potassium) the salts in question are created as peroxymonophosphates or peroxydiphosphates (→ Perpyrophosphates).

Perpyrophosphates Salts of type $Me_4P_2O_7 \cdot 2\,H_2O_2$. Addition products of H_2O_2 on the carrier of → Pyrophosphates, thus not genuine → Per salts, like for example → Perphosphates. Perpyrophosphates are described in literature as those that have deposited approx. 20–50% H_2O_2. The sodium-perpyrophosphate, which is commonly used in practice, contains approx. 19.1% H_2O_2 and corresponds with approx. 9% active oxygen content. It decomposes into an aqueous solution in H_2O_2 and sodium pyrophosphate, has a low pH and excellent complex-forming characteristics. It dissolves hardness constituents and heavy metal salts or renders them inactive. The excellent stabilizing effect in comparison with bound oxygen also rests upon the latter characteristic. This useful combination of pyrophosphate and H_2O_2 is excellent for pre-bleaching in textile assistants and as an oxidizing agent or in the soaping aftertreatment of fast dyes.

Perrotine Printing machine named after its inventor, Perrot, which can be considered as the first stage in the mechanisation of block printing.

Per salts Genuine salts of → Per acids, such as for example ammonium persulphate or potassium persulphate. Principle of oxygen release:

$$K_2S_2O_8 + H_2O \rightarrow [K_2SO_4 + H_2SO_4 + {}^{1}/_{2}\ O_2]$$

Application: Oxidizing agent in dyeing and printing, kier boiling, desizing, bleaching agent; disinfectant.

Persian carpets → Oriental carpets of Persian origin. Usually dense knotting of 400 000 to 1 million knots per m^2 with fine patterning. Names such as →: Bakhtiari carpets; Bijar carpets; Hamadan carpets; Isfahan carpet; Kashan carpets; Shiraz carpets; Senneh carpets; Seraband carpets (Mir) describe the province of origin.

Persoz reagent Dissolves only silk from silk/wool mixes at 45°C. Consists of 10 g zinc chloride in 10 g water and 2 g zinc oxide.

Perspiration fastness Resistance of dyeing and printing to human sweat.

I. Determination according to DIN 54 020: one sample each is treated with an undyed accompanying fabric in an alkaline or acidic testing solution for 30 min (liquor ratio 1 : 50) at room temperature (slight mechanical action for better penetration). After the removal of excess testing solution the test pieces are individually exposed to a pressure of 12.5 kPa between two plates and are treated for 4 h in a warming cupboard at 37°C ± 2°C. After opening, the test pieces are hung to dry at max. 60°C. The change in colour and the bleeding are evaluated against the grey scale.

II. Perspiration fastness according to AATCC: a) Alkaline: 10 g/l sodium chloride, 4 g/l ammonium carbonate, 1 g/l disodium phosphate (Na_2HPO_4) and 0.25 g/l histidine monohydrochloride, pH of the solution = 8; b) acid: 10 g/l sodium chloride, 1 g/l lactic acid 85%, 1 g/l disodiumhydrogenphosphate and 0.25 g/l histidine monohydrochloride, pH of the solution = 3.5. Procedure: treat test piece for 15–30 minutes in the solutions a) and b) individually, squeeze (squeezing effect 250–300%) and load 10 kg for 6 h (or more) in perspirometer at 38°C.

Perspiration removal Thorough wet treatment, intensive steaming or stain removal by dry cleaning using → Deodorants.

Perspiration transport measurement Facilitates important test predictions regarding the serviceability value for items of clothing (→: Wesel triangle; Clothing physiology). Two adjacent drums are used with openings opposite each another, between which the material samples, which have been weighed, are clamped. In the first drum an air stream of 90% relative humidity circulates at 31°C, in the second drum air of 50% relative humidity circulates at 18°C. Under these conditions, with equal pressure in the two drums, the perspiration transport from drum one to drum two is measured with a hygrometer and the amount of condensation in the test piece is calculated by its increase in weight.

Perspirometer Am. device by AATCC for testing → Perspiration fastness. Sample is treated at a pressure of 4.5 kg between glass plates for at least 6 h at 38°C.

Persulphate desizing Procedures for the removal of starch sizes generally use enzymes because, unlike oxidizing agents, this rules out damage to the cotton. The latter are therefore only found in isolated cases, for example in cases where the size contains enzyme poisons. Persulphate desizing can be used both after the cold dwell process and after the steaming process. In order to avoid fibre damage, max. 0.5% sodium persulphate can be used in the cold dwell process, and no more than 0.2–0.35% (in relation to the material weight) in the steaming process. Application takes place in an alkaline medium. Without the alkali, complete desizing is impossible.

An oxidative desizing with persulphate destroys the carboxyl and fixed groups of polysaccharide into low molecular and water soluble size fragments (Fig. 1). Oxidative desizing is performed:

- If e.g. tapioca starch is present, which as a branched polysaccharide can only be broken down by enzymes with difficulty, depending upon the degree of ageing;
- If fungicides are used in the size recipe to prevent the formation of mildew (mould spots) (fungicides, which are mainly used in countries with high air humidity act as enzyme poison);
- For cost reasons, to save a separate work stage;
- If there is not enough space for the dwelling batch rolls.

Desizing with oxidizing agents involves a high risk of fibre damage. Unlike enzymes, persulphate does not differentiate between the chemically similar substances of cellulose and starch. If the starch is converted into a washable form by persulphate due to oxidative decomposition, then the cellulose will be damaged with possible remaining residual persulphate (recognisable by an excessive reduction in the DP value). The danger of oxidative damage can be minimized by using stabilised persulphate in place of pure persulphate (Fig. 2).

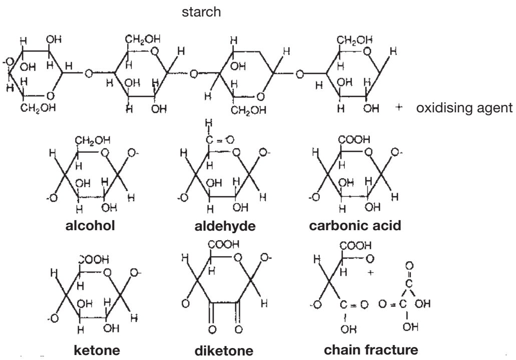


Fig. 1: Oxidative decomposition of starch by the action of persulphate or peroxide.

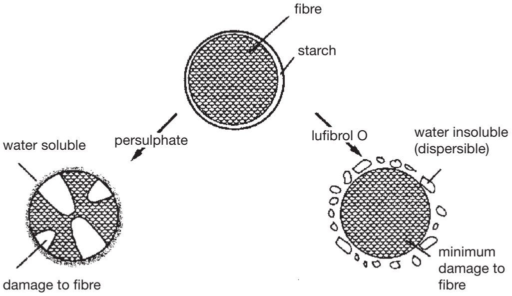

Fig. 2: Avoidance of oxidative damage.

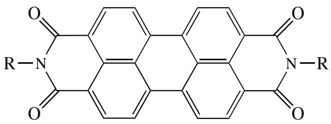
Persulphates (peroxysulphates, dioxysulphates) Salts of peroxysulphuric acids ($H_2S_2O_8$ → Sulphur oxyacids), such as the highly water soluble ammonium, potassium or sodium persulphates. Application: Bleaching and strong oxidizing agent for vat dyeing and printing; desizing agent; bleaching agent for wool, waxes, fats and oils.

Persulphuric acid This is usually used to mean Caro's acid H_2SO_5; correctly persulphuric acid is the so-called peroxysulphuric acid $H_2S_2O_8$.

Perylene ($C_{20}H_{12}$) → Cyclic hydrocarbons.

Perylene tetracarboxylic acid derivatives → Perylene.



Representatives are particularly red and blue vat dyes, e.g. Indanthren red, Indanthren scarlet.

PES → Polyester, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

Pesticides Means of pest control used in the cultivation of plants, e.g. in monocultures of cotton cultivation, to protect against weeds, fungi, bacteria and insects. Because of cultivation in the form of monocultures, the growing cultivation areas in half-dry areas generates a high pressure from pests, making it necessary to tackle this problem using pesticides (in cotton: approx. 20% herbicides; approx. 75% insecticides; approx. 5% fungicide) in order to increase harvest yields. The pest control strategy consists of spraying different types of pesticide (e.g. in three "windows", i.e. sections of the growth phase, each with different composition) intensively from aeroplanes. The use of substances such as DDT or Lindan is banned worldwide. It also appears, and this has been proven by analyses, that these persistent chlorinated hydrocarbons no longer play any role as a pesticide. Quantities used in plant feed fall well below the specified maximum quantities (1 ppm DDT; 0.5 ppm Lindan). Wool contains pesticides, if the sheep is driven through baths containing pesticides in order to fight parasites in the sheepskin.

Natural cotton ("green cotton"), which is not textile finished, brings its carrier into contact with the pesticides, the percentage of which can be 7–858 µg/kg cotton depending upon the cultivation area. Therefore efforts are made to bring "green cotton" onto the market from ecological cultivation without the use of pesticides.

Defoliants, which are sprayed over fields by aeroplanes before the mechanical cotton harvest, are particularly useful. They make their way into the cotton shrubs through the ground and cause the leaves to fall off, so that harvesting machines have easier access to the seed capsules.

PET Often used as an abbreviation for polyester in the Anglo-Saxon language area.

PETP → Polyethylene terephthalate, → Textile fibre symbols, according to DIN 60 001 until 1988.

Petroleum ether → Benzine.

Petroleum gas Wet → Natural gas.

Petroleum sulphonates → Mahogony sulphonates.

Petticoat finish In particular in polyamide and polyester items to achieve a permanent stiffening finish using aminoplasts and/or thermoplastic artificial resins.

Pfersee-testing instrument Simple test instrument for checking water-impermeable finishes on textiles in accordance with the American → Spray test. The stretched test piece is irrigated at an angle of 45° with 250 ml test water at 27°C by a funnel-shaped shower then, whilst still stretched, the table edge is struck to remove excess water in accordance with guidelines. Evaluation by comparison images (marks 0–100) : 100 = no clinging or wetting, 90 = slight, accidental clinging or wetting, 80 = wetting at irrigation points, 70 = partial wetting of the entire surface, 50 = complete wetting of the entire surface, 0 = complete wetting of the entire surface and back. Mild test method, which only shows up large differences. More precise evaluation by the → Water sprinkling apparatus Pfersee. – Manuf.: Erhardt & Leimer.

pH Describes the acidity or alkalinity of aqueous solutions. Water dissociates to a small degree according to

$$H_2O \rightleftharpoons H^+ + OH^-$$

According to the law of mass action the dissociation constants are found to be

$$K_{H_2O} = \frac{[H^+]\,[OH^-]}{[H_2O]}$$

A good approximation of the molar concentration of water is found by 1000 g (1 l water) divided by 18 (relative molar mass of water) as 55.6 mol/l, because water is virtually 100 % undissociated. Therefore we can consider $[H_2O]$ as a constant and rearrange the above equation as follows:

$$K_{H_2O} \cdot [H_2O] = [H^+] \cdot [OH^-]$$

We thus obtain a new constant, which is called the ionic product of water and the numeric value of which is determined as $1.00 \cdot 10^{-14}$ at 25°C.

$$H_2O_{dest} = 1.00 \cdot 10^{-14} \text{ mol/l} = \text{const. } 25°C.$$

Therefore, at 25°C in water $[H^+]$ and $[OH^-]$ each contribute 10^{-7} mol/l, which varies with temperature (Tab.). Because the H^+ and OH^- ionic concentration is clearly linked over the entire ionic product of 10^{-14} mol/l, it is sufficient to quote the concentration of one ion type, in order to be able to derive the concentration of the other.

$$[H^+] = \frac{10^{-14} \text{ mol/l}}{OH^- \text{ mol/l}}$$

or

$$[OH^-] = \frac{10^{-14} \text{ mol/l}}{H^+ \text{ mol/l}}$$

Therefore, if the H^+ ion concentration increases, the OH^- ion concentration falls and vice versa. For this purpose we quote the negative decimal logarithm of the molar H^+ ion concentration for the pH, i.e.

$$pH = -\log [H^+]$$

From this we find

$[H^+]$ mol/l	$[OH^-]$ mol/l	pH
10^{-0}	10^{-14}	0
10^{-1}	10^{-13}	1
10^{-2}	10^{-12}	2
10^{-3}	10^{-11}	3
10^{-4}	10^{-10}	4
10^{-5}	10^{-9}	5
10^{-6}	10^{-8}	6
10^{-7}	10^{-7}	7
10^{-8}	10^{-6}	8
10^{-9}	10^{-5}	9
10^{-10}	10^{-4}	10
10^{-11}	10^{-3}	11
10^{-12}	10^{-2}	12
10^{-13}	10^{-1}	13
10^{-14}	10^{-0}	14

A solution of pH 6 therefore contains 10 times more hydrogen ions than a solution of pH 7.

The pH plays a role not only in many chemical processes, which naturally include corrosion; biological processes too require an optimal pH, without which bacteria, for example, would not be capable of existence. This illustrates the importance of the pH for waste water and biological treatment plants. To measure pH a measuring electrode and a reference electrode are needed. If these electrodes are submerged in an aqueous solution, ions diffuse from or into the swelling layer, depending on whether the solution is acidic or alkaline. The inner wall of the electrode has a constant pH, so that a potential difference exists inside/outside, which is proportional to the hydrogen ion concentration. After calibration, the pH can be determined in this

temperature of distilled H_2O in °C	total ion production in $mol^2 \cdot l^{-2}$	H^+-ion production in $mol \cdot l^{-1}$	pH	conductivity in Ω^{-1}
0	$0{,}078 \cdot 10^{-14}$	$0{,}28 \cdot 10^{-7}$	7,55	$1{,}0 \cdot 10^{-8}$
18	$0{,}61 \cdot 10^{-14}$	$0{,}78 \cdot 10^{-7}$	7,11	$3{,}8 \cdot 10^{-8}$
25	$1{,}00 \cdot 10^{-14}$	$1{,}00 \cdot 10^{-7}$	7,00	$6{,}0 \cdot 10^{-8}$
35	$2{,}1 \cdot 10^{-14}$	$1{,}45 \cdot 10^{-7}$	6,84	$9{,}0 \cdot 10^{-8}$
50	$5{,}4 \cdot 10^{-14}$	$2{,}30 \cdot 10^{-7}$	6,64	$17{,}0 \cdot 10^{-8}$

Tab.: The influence of temperature on pH.

manner by a voltage measurement. The pH is a measured variable related to the concentration of hydrogen ions c_{H^+}. In normal notation this definition is

$$p_{cH} = -\log c_{H^+}$$

However, this relationship only holds as a first approximation, so a 10^{-2} normal hydrochloric acid with $c_{H^+} = 10^{-2}$ has a pH of around 2. Concentrations of alkaline solutions can also be estimated from the pH, because at room temperature the equation

$$c_{H^+} \cdot c_{OH^-} = 10^{-14}$$

is always true. It follows from this that a 10^{-3} normal alkaline solution with $c_{OH^-} = 10^{-3}$ and, according to this equation, $c_{H^+} = 10^{-11}$ has a pH of approx. 11. The pH is defined by a conventional pH scale with the aid of a range of precisely manufacturable buffer solutions. It is related more to the activity than the concentration of H^+ ions, but is normally an important indicator in various processes, including washing.

If the pH is measured during an acid/base titration (the simplest method uses a titration machine, which writes the titration curve), then a comparison of the titration of a strong and a weak acid, as shown in the Fig., shows a significant difference.

In a strong acid there is a precipitous change in the pH, and this is in the vicinity of the end of titration at pH 7. For a weak acid on the other hand this leap, which is still recognizable, is at a very different shaped 2nd area of the titration curve. The pH changes by only a relatively small amount with the addition of alkaline solution (or also opposing titration with acid). This means that in this area the solution is capable of collecting acid or alkaline additions, a relationship that is known as buffer characteristic. Depending upon the type of weak acid (its dissociation constant is decisive) the buffer area can be moved between pH 2 and 12 at will.

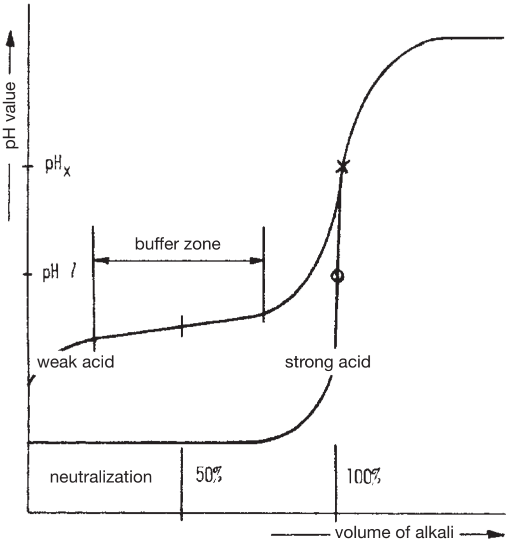


Fig.: Diagram comparing the titration curves of a strong and a weak acid.

It is significant that most washing agents are designed as buffered systems from their recipe. Thus they remain largely insensitive to pH changes, a reason why there is normally no need to make a → pH measurement for washing liquors.

Phase → Homogeneous material within a system which is separated from other components by physical boundaries. Each individual phase in a system encompasses all components with the same characteristics and the same composition. One example of a typical 3 phase system would be a closed tank, partially filled with water, in which ice is floating. Solid phase = ice, liquid phase = water, gaseous phase = air. According to the above definition, several pieces of ice do not represent several phases in this system, but rather just one, the ice phase.

Phase boundary → Interface.

Phase contrast microscopy Also known as microphase contrast. Makes finer structural details (thick/thin, high/low, convex/concave) of the micro-object and its environment more easily visible to the eye (photoplate) by phase differences in the illumination beam. In principle the zero order, i.e. the straight line beam, is changed by the addition of an annular phase plate (the condenser screen in the picture), which alters the phase of this zero bend (and only this one) by 90°. The micropicture created shows light differences in grey scale shades instead of the phase differences that are actually present (density and/or thickness differences). So the finest superpositions, textural changes, dispersions, cloudiness and layer thickness deviations can be recognised which are not picked up by bright field microscopy.

Phase diagrams of wash liquors The working mechanisms of surfactants are an important factor in the study of mass transfer in finishing processes. Surfactants act with water to form micelles, i.e. aggregates made up of a greater number of surfactant molecules or ions. However, these only form above a concentration limit called the → Critical micelle concentration. Nonionogenic surfactants make particularly good washing agents due to some advantages, such as:

– low critical micelle concentration, i.e. they produce a good washing effect at relatively low concentrations;
– high solubilization power for oils;
– low sensitivity to hardness;
– high adsorption power, even on negatively charged surfaces.

Binary mixtures of water and non-ionogenic surfactants pass through several phases in relation to temperature and concentration. In addition to these binary mixtures, ternary systems of the type “water/surfactant/oil” are also of interest (Fig. 1). They can form three-phase micro-emulsions, which offer advantages for washing practice. Microemulsions are optically isotropic, thermodynamically stable systems made up of water, oil and one or more amphiphilic surfactants.

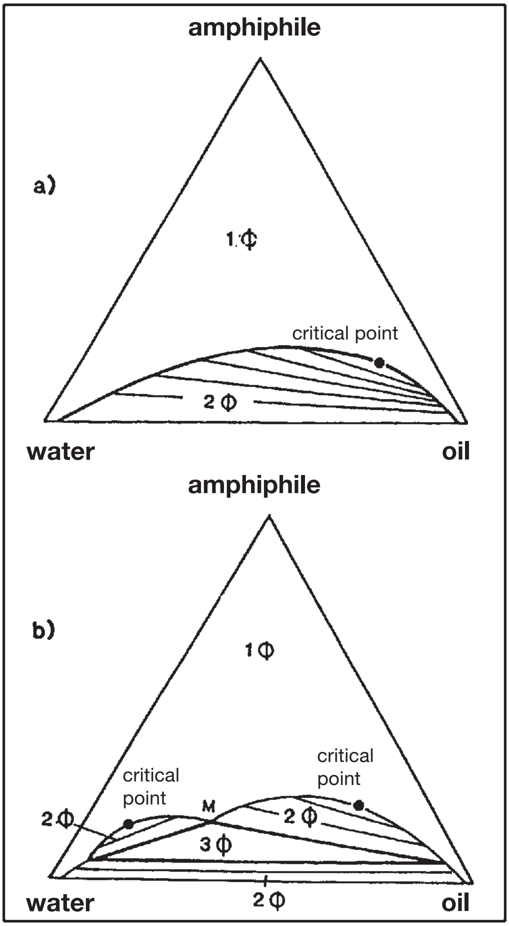

Fig. 1: Gibb’s phase triangle for a tenary system of water, oil and amphiphile (diagrammatic) (according to Kahlweit und Strey).

In a binary phase diagram of the Marlipal system 013/80/water (Fig. 2), the upper closed miscibility gap for surfactant concentrations lies between 0 and 30 percent by weight above 30°C. We can also see the area of the liquid crystalline phase above 45% surfactant by weight, which extends to temperatures equal to the upper closed miscibility gap. Liquid crystal phases however, lead to problems with regard to the kinetics of phase separation, because the surfactant-rich middle phase of such systems has a relatively high viscosity, which leads to a slow separation of the individual phases.

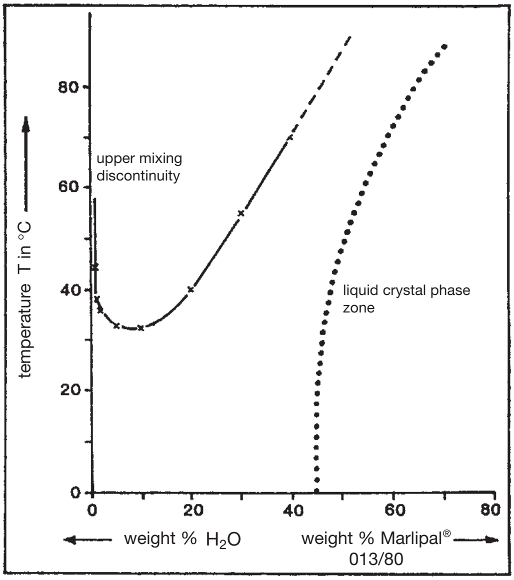

Fig. 2: Binary phase diagram (according to Schollmeyer and Knopf).

The characteristic sections through the Gibb’s phase triangle illustrated in Fig. 3 are worth studying for a suitable oil. These sections can lead to conclusions regarding the system being considered. The representation of the A section as a quasi binary system leads to a “fish-like” body. In the “tail” of this fish the three phase body deals with the surface of the central miscibility gap. The quasi binary representation of sections B and C supply predictions about the length of the coexistence point of the 3 phase area (B section) or about the areas of composition, in which the transition from an oil-in-water to a water-in-oil emulsion in the single phase area is possible. In practice, the temperature allocated to the washing process is an important parameter. The dependence of the superposition of oil on the temperature in the range between 50–80°C contains the transition from the two-phase area into the three-phase area and back into a two-phase area for the system being investigated. The best washing result under these conditions is to be found in the three-phase area. When a technical surfactant and a model oil (toluene) are used with such systems as a washing medium the best washing result is achieved in the single-phase area, if possible close to the transition to the three-phase area (according to Dierkes and also to Schollmeyer and Knopf).

Phase inversion temperature

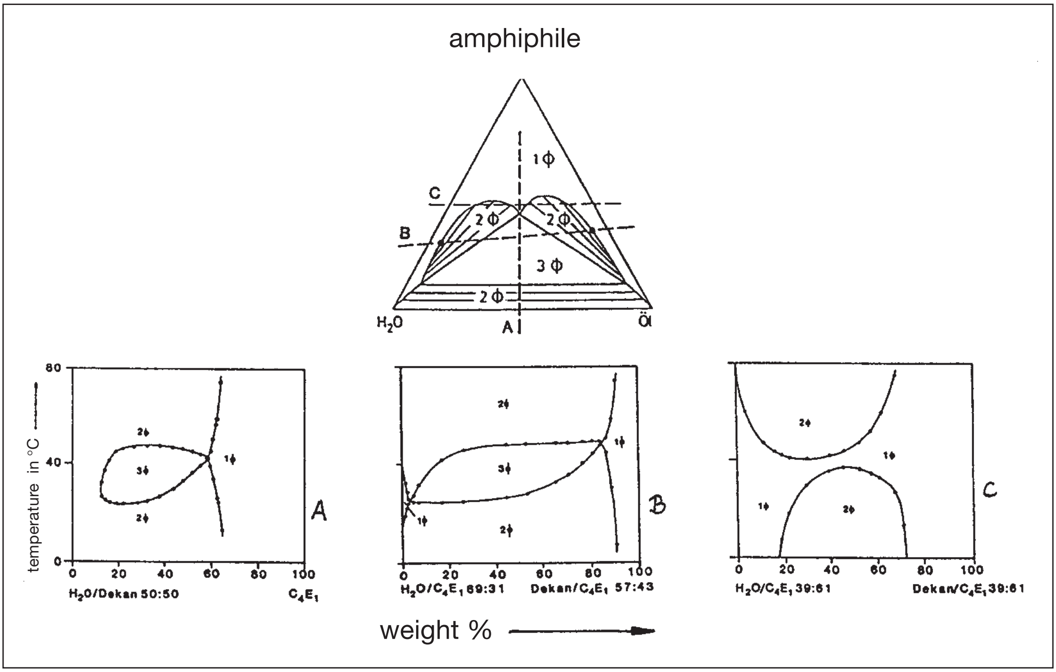

Fig. 3: Significant sections through the phase diagrams of tenary micro-emulsion systems (according to Kahlweit and Strey). n F = n-phase zone, C_iE_j ethoxylised linear alcohol of C-chain length i with j ethoxy units.

Phase inversion temperature (PIT). An emulsion can be made to change phase due to a temperature increase. The dispersed → Phase thus becomes the continuous phase, the continuous phase is dispersed. The Fig. showing the phase diagram of water/dodecane (as oil) with 20% pentaethylene glycol decyl ether by weight shows a micellar solution $M_{O/W}$ (oil is solubilized) at low temperatures and low concentration of oil-in-water. At constant emulsifier concentration, increasing the oil proportion brings us into the area of the O/W emulsion $E_{O/W}$. A great temperature increase and medium temperature brings us into the mesomorphic, liquid crystal phase FL, before a further temperature increase changes this into a W/O emulsion $E_{W/O}$. The FL phase (can be recognised visually by the clearing of the cloudy emulsion) is only stable within a narrow temperature range, because at a small reading below/above this temperature, oil or water coalesce quickly into large drops (the basis of the mechanism of de-emulsification due to temperature increase).

Because a phase reversal takes place in the transition through this temperature range, this critical temperature area is called the phase inversion temperature (PIT).

At the PIT (also known as the → HLB value) hydrophilic and lipophilic characteristics of the emulsifiers maintain the balance. PIT is thus a clear measured value for the emulsifier effect in a certain system. Within homologous rows the PIT increases with increasing hydrophilicity of the emulsifier. To generate stable

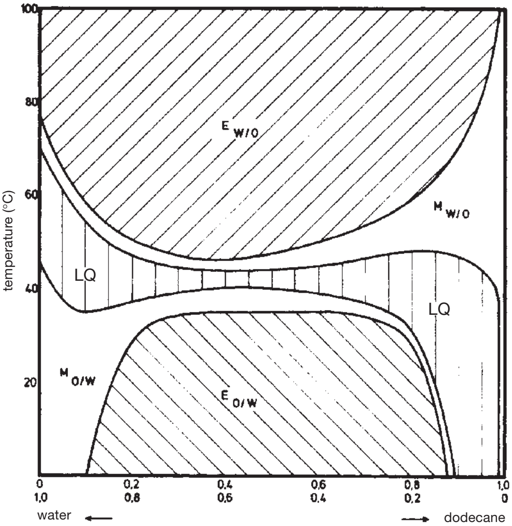

Fig.: Phase diagram of water and dodecane as oil with 20% pentaethylene glycol decyl ether by weight at various temperatures.

emulsions, emulsifiers are selected for which the PIT lies as far as possible from the temperature at which the emulsion is used. For O/W emulsions the PIT should be 20–65°C higher, for W/O emulsions it should be 10–40°C lower. It is recommended that non-ionogenic emulsions are manufactured at a temperature above the PIT and rapidly cooled.

Phase model for the structure of finishing processes One objective of process control technology is to describe and structure the information relating to production processes. The phase model of production is a tool in the structuring of the process and also of information. The results gained from the use of this semantic structuring tool have various applications, e.g. in quality assurance, safety and procedural analyses. The individual process elements can be viewed as operators, which transform the product characteristics from an input into an output state. This model facilitates, amongst other things, the representation of the information flows necessary to conduct the entire process so that the procedure is maintained in its current desired state. It also encourages consideration regarding the information that should be available in and after every individual process element for process control and quality assurance. In each process element monitoring, regulation and control tasks relating to certain product or process characteristics have to be performed.

A further characteristic of the phase model of production is the representation of a production process in varying depth. To achieve this the process is described hierarchically in several levels each with increasing level of detail. In this manner, detailed process information can be ascertained and incorporated into the structure of the phase model.

The application rules for the structuring of a process with the aid of a phase model of production are illustrated in the sample process “piece dyeing of cotton” in the Fig. The process, which is illustrated in three levels of detail, is structured so that it can be described with the aid of the process elements and the associated products which are allocated to the different levels.

The levels are defined by vertically structuring the processes into the levels “procedure”, “procedure step” (which is the specific term for “part process” in the case of a continuous production process) and “Procedure element”: The procedure supplies a textile with predetermined characteristics. Examples are desizing, dyeing, mercerizing etc. The procedure steps, which are part of the procedure, deliver a predetermined change of state in the textile in the sense of textile finishing. The procedure steps usually take place in a finishing group or are characterized by a certain recipe structure. Examples of procedure steps are impregnation, steaming and washing. A procedure element is the smallest indivisible

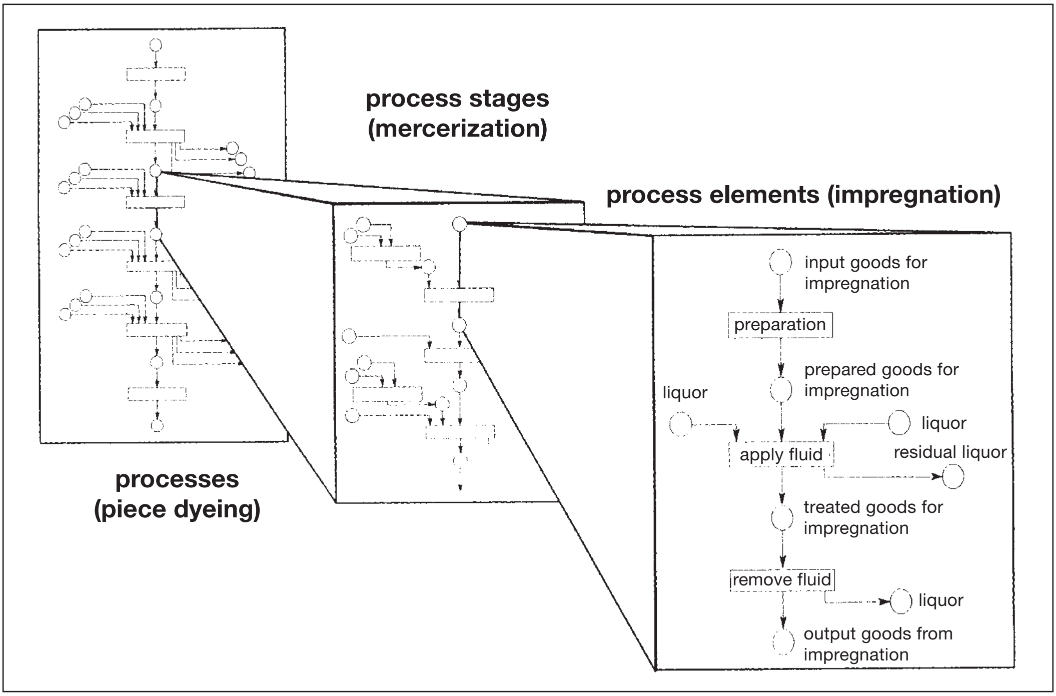

Fig.: Phase model of production in “processing of cotton piece goods” (according to Wulfhorst).

process in a procedure. It represents part of the treatment of a material that takes place in a single procedure element or a group of linked procedure elements, e.g. heating, cooling, extraction, squeezing, dipping, mechanical guidance of the material. The process elements of the first level are further detailed at the procedure step level, whereby the sample process is limited to the minimum possible number of procedure steps (washing, impregnation, reaction and drying). This incorporates products such as wetting agents, water and enzymes. At the procedure element level the procedure steps are described using standardized elements (preparation, application of liquor, liquor removal, dwelling, heating, cooling).

The process is structured in accordance with the classification of process and product characteristics. Process characteristics include state variables, process parameters, control variables, adjustment parameters and process indicators, and product characteristics include physical and chemical variables, technological characteristics and product indicators. In order to maintain an overview of the large amount of data, the characteristics are allocated to the following categories:
- organizational data,
- technological characteristics,
- physical characteristics,
- chemical characteristics.

The classification of the characteristics will become clear in the next step, the structuring and sorting of process and product characteristics in tabular form. This stage determines which characteristics can be measured "on-line". After the characteristics of the substances to be added or removed have been described, such as chemicals (type, quantity), water (quantity, hardness, purity) and exhaust (pollution, smell, temperature), the detailed procedure elements, such as dwelling, heating and cooling can be allocated specific characteristics, e.g.
- process form (continuous, discontinuous),
- type of material feed,
- voltage,
- temperature, etc.

If the sample process is structured using the phase model of production, then the results yielded can be interpreted with regard to a predetermined task formulation (according to Wulfhorst).

pH dependence of wool The relationships between the pH determined during manufacture and the change of the textile characteristics of the wool fibre was investigated by Elöd. He systematically deduced the relationships between pH (plus temperature) of a wet finishing bath and the chemical and physical characteristics of the wool keratin, and evaluated their implications for practical application. Wool can be finished at the → Isoelectric point in a manner that protects the fibres. The chemical and textile mechanical properties of the wool will be impaired in the event of deviation from this point (pH 4.6 at 90 °C) in both directions at boiling point. Dyeing takes place (except for 1 : 1 metal-complex or acidic levelling dyes) between pH 4 and 7.

In the wide range between pH 4 and 8 for wool neither acid nor base are bound (Fig.) and the charge remains zero (isoelectric zone). This is a result of the insolubility of wool and the formation of an electric double layer on the surface of the fibre. Hydrogen ions can only penetrate this with difficulty. The addition of salt reduces the electric double layer so that the wool behaves like a soluble protein and the curves for the acid and base absorption meet at the isoionic point.

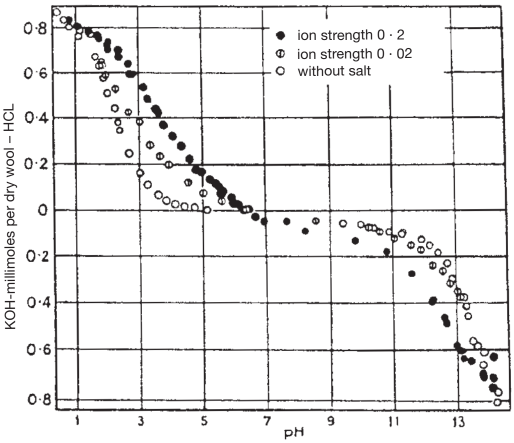

Fig.: Titration curve for wool (according to Steinhardt and Harris).

Phenol (carboxylic acids, C_6H_5OH), molecular weight 94.06; density 1.06; crystals or coarse crystalline mass, colourless to reddish, melting point 43°C, typical odour, (synthetic phenol up to 5% application odourless), water soluble (1 : 15), also soluble in alcohol, ether, benzene, chloroform etc.; aqueous solution slightly acidic, highly corrosive, toxic, volatile in combination with water vapour. Concentrated phenol solution dissolves acetate and polyamide fibres (fibre detection). Application: Antiseptic for chemical finishing (liquor ratios of 1 : 100 work reliably); solvent and saponification agent for acetate; good solvent for cationic dyestuffs (particularly for methyl blue); developer for substantive dyes; manufacture of synthetic resin, chemical finishing etc. Phenol and its derivatives are classed as → Co-carcinogen.

Phenolates Aromatic compounds originating from → Phenol in which the hydrogen atom of the hydroxyl group (OH) is replaced by metal.

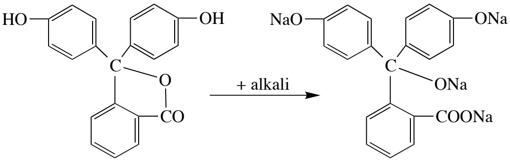
Phenol coefficient Comparative figure, comparing the effect of aromatic disinfectants and preservatives against bacteria with that of → Phenol, the effectiveness of which is equated to 1. The phenol coefficient varies considerably for different comparative products depending upon the chemical constitution, which is also almost always the case for the same product in relation to different bacteria cultures.

Phenol gential violet solution Micro colour reagency for → Gram stain made of 10 ml saturated alcohol solution of gential violet (mixture of methyl violet and crystal violet) + 1 ml phenol, topped up to 100 ml with distilled water.

Phenolic plastics → Synthetic resins made of phenol formaldehyde by polycondensation. A differentiation is normally made between a) non-hardenable (meltable) synthetic resins, soluble in solvents, e.g. as a shellac substitute, and b) hardenable synthetic resins of the bakelite type, temperature deviating and swellable in solvent or meltable and non-soluble in solvents. Latter are pure high grade synthetic resins (colourless, odourless, highly refractive, cannot be scratched with the fingernails, poor conductor of heat and electricity, temperature resistant up to 300°C, resistant to diluted acids and alkalis).

Phenolic resins → Phenolic plastics.

Phenolphthalein(paper) White powder, in solution of 1 g in 100 ml alcohol. Very sensitive indicator of alkali traces. Transition interval: pH 8.2–10. In the range pH 7–8.5 pink shade, above that crimson (recognisable at dilutions of 1 : 1 000 000). Even weak carbon dioxide acts on alkali reddened phenolphthalein paper.



Colourless in the form of free acids, sodium salt red coloured. Application (solution or paper): Alkali detection on wool, for wash liquor, vat dyeing, etc.

Phenols Aromatic compound with hydroxyl groups directly attached to cyclic hydrocarbon(s).

phenol

Differ from aliphatic → Alcohols due to their stronger acidic properties (are also weak acids). Dissolve in weak aqueous alkalis, form → Phenolates and produce a deeply coloured co-ordination compound with iron(III) salts. Most important derivatives:

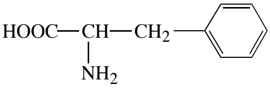
C_6H_5 OH	phenol (hydroxybenzene, phenylic acid)
C_6H_4 $(OH)_2$	resorcinol (meta-dioxybenzene)
C_6H_3 $(OH)_3$	phloroglucinol (1, 3, 5-tribenzene)
CH_3 C_6H_4 OH	cresol (methylphenol; o-, m-, p-isomers)
$(CH_3)_2$ C_6H_3 OH	xylenol (dimethylphenol, as disinfectant and mercerizing assistant)
CH_3 C_6H_3 Cl OH	para-chloro-m-cresol
C_6H_2 Cl_3 OH	trichlorophenol
C_6 Cl_5 OH	pentachlorophenol (hexachlorophene)
C_6 H_5 SH	thiophenol type (sulphur phenol)
	phenylphenol type
	naphthol type

Application: Phenoplasts, mercerizing assistant, disinfectant and preservative, carrier, developer for direct dyes, solvent for cationic dyes, acetate delustring, etc.

Phenothiazine → Heterocyclic compounds.

Phenoxazine → Heterocyclic compounds.

Phenylalanine A cyclic → Amino acid (monoamino monocarboxylic acid).



Contained in wool (3.75%) and silk (1.5%).

Phenylene group C_6H_4, bivalent radical, contains two hydrogen atoms less than → Benzene, from which it is derived.

Phenyl group C_6H_5, monovalent radical of the benzene residue, contains one hydrogen atom less than → Benzene.

Phenyl lithium test Unambiguous detection and differentiation of

1. Polyacrylonitrile and polymethacrylic acid ester. Based upon the conversion to lithium carbinols, from which free carbinols produce characteristic conversions and colour reactions.
2. Polyvinylchloride (also post-chlorinated), polyvinylether and polyvinylchloride co-polymerizate. Converted polyenes are used for the colour reaction.

Phenylphenols (oxydiphenyls, arylphenyls, hydroxydiphenyls) used as preservatives and carriers (swelling agent). No longer widely used in Europe for ecological reasons.

I. Ortho-phenylphenol: White, crystalline or scaly, melting point 58°C, boiling point 287°C. Usually used in the form of sodium salt. Application: Preservation of finishes, sizes, adhesives, textile assistants, textiles, leather; against rancidification of solid soaps and as the cheapest carrier in the dyeing of polyester and polyacrylonitrile.

II. Para-phenylphenol: Colourless, lustrous needles of flakes, melting point 164–165°C, very soluble in alcohol and ether or with caustic soda. Application: Antioxidant for greases and oils; wood preservative; carrier for polyamide, polyester (more difficult to wash out than I).

-philic (Gk.), loving, friendly, attractive, e.g. →: Amphiphilic; Hydrophilic; Lipophilic groups; Lyophilic. Opposite: → -phobic.

Phlobaphenes Anhydrides or oxidation products of → Tanning agents. Are particularly difficult to dissolve.

Phloem (Gk.), so-called “young soft bast”, e.g. in stalk bast fibres (→ Flax stem structure). Consists mainly of the still soft screen part (screen tube as conduction elements for the transport of sap), in which the forming cells of the young bast or phloem fibres are embedded.

Phloroglucinol (1,3,5 trioxybenzene), $C_6H_5(OH) \cdot 2\,H_2O$. White or yellowish crystals, soluble in water, easily soluble in alcohol and ether; reduced → Fehling’s solution in heat. Application: Detection of lignin and pentose (→ Phloroglucinol reaction).

Phloroglucinol method For the colorimetric formaldehyde detection of synthetic resin finished textiles with → Phloroglucinol according to Japanese specification (MITI test methods). The possibility of important secondary reactions must be taken into account.

Phloroglucinol reaction Solution of 10% → Phloroglucinol in alcohol and concentrated hydrochloric acid. Used for the detection of:

I. Wood pulp substances. The higher the lignin content, the stronger the colouring:

native protein substances	not coloured
regenerated protein fibres	not coloured
regenerated cellulose fibres	not coloured
cotton, flax	not coloured
ramie	not coloured
hemp	pink in places
jute	dark reddish violet

II. Protein viscose (reddish brown) next to wool or undyed silk.

III. Oxycellulose (red colouring) next to hydrocellulose (no red colouring).

pH measurement Used for determining the concentration of → Hydrogen ions (→ pH), using the following methods in particular:

I. Colorimetric measurement using pH indicators. When dissolved, the degree to which these indicators are present in a dissociated state depends upon the pH of the solution, and they therefore supply pH-specific colour changes. By arranging the indicators, which each represent 1.5–2 pH units by specific colour shade transitions, the entire pH scale can be detected colorimetrically. Due to certain temperature dependencies of the pH the reference temperature selected, unless stated otherwise, is 20°C.

Colorimetric measuring methods are usually cheap to use, simple and quick to perform, but are not all associated with maximum precision. They are however adequate for practical purposes. The method of application uses either a) indicator solution, in which individual indicators or a mixture in the form of so-called universal indicators are common (drop-by-drop application, comparative measurement with buffer solution of a known pH or more simply with artificial colour comparison standards, even for dark and dyed solutions. Error limit of pH ± 0.1); or b) pH paper, i.e. paper strips impregnated with an indicator, which is submerged for a few seconds and the shade that appears after 15–30 s compared with a colour scale to find the appropriate pH. Difficulties or inaccuracies are possible, particularly with high temperature bleaching liquors, dark coloured solutions, liquors with ionogenic textile assistant additives, protein compounds and colloids etc. Common as universal indicator paper (measuring range and accuracy vary depending upon origin), also as special indicator paper for greater accuracy. Measuring accuracy approx. pH ± 0.2; also suitable for coloured and cloudy solutions); or c) pH foil (similar to b), impregnated cellophane strips, commercially available as foil colorimeters, pH foils, etc. Application: Submerge for 1–2 min, possibly rinse briefly for coloured or cloudy solutions, accuracy approx. pH ± 0.1–0.2; colloidal dispersions and chloric and poorly buffered solutions between pH 5–8 cannot be measured.

II. Electrometric or potentiometric pH measurement is based upon the measurement of the voltage difference (potential difference) between two electrodes (so-called electrode chain) in mV, which serves as the measured variable for pH. The electrode chain consists of a reference electrode with a constant potential (usu-

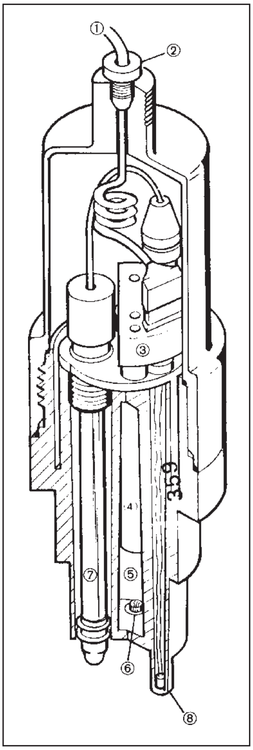


Fig.: Sketch showing the principle of the Type 381 pH/ ORP probe (Rosemount AG).
1 = connecting cable;
2 = cable holder;
3 = preamplifier or connecting plug;
4 = reference electrode;
5 = electrolyte chamber;
6 = diaphrams;
7 = glass electrode;
8 = temperature sensor.

ally in the form of a saturated potassium electrode) and a measuring electrode submerged in the solution being measured, the potential of which depends upon the current pH of the solution. The glass electrode (see Fig.) is the most important as a useful dip or flow measuring electrode. Universally applicable for pH 0–13, also for oxidation and reduction processes and for bleaching liquors of all types; however, it is attacked by caustic alkalines above pH 12 or, if the temperature is higher, at lower pH. Has a thin glass membrane diaphragm. The compensation potentiometer is used as a simpler instrument, and for higher demands, the high-ohmic tube potentiometer (almost unbreakable, accuracy around pH 0.1–0.01) is commonly used, which for operational purposes is also available with simplified operation, direct pH display, mains or battery operation, transportable, etc. In the so-called single rod measuring chain both electrodes are combined in a simple component (resistant to mechanical loads, always ready to measure, submersion length up to 1.2 m). Possibility of continuous monitoring, remote display, signalling, continuous registration, automatic control etc. There are also efficient devices for simple direct measurement on the surface of the wet textile material.

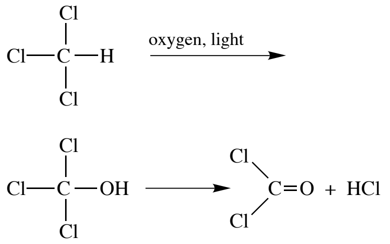
-phobic (Gk.), avoiding, hostile, fleeing, repellent; →: Hydrophobic; Lipophobe; Oil-repellent. Opposite: → -philic.

pH of fibre extracts Determination procedure: Fibre samples are leached for 60 min at room temperature in distilled water in a liquor ratio of 1 : 5, 1 : 10, 1 : 20 and 1 : 50 (in polyethylene bottles). The pH of the extracts is measured with a glass electrode and plotted against the associated liquor ratio in a co-ordinate system. The curve obtained is extended to intersect with the pH ordinate. This point is the pH (extrapolated) at a liquor ratio of 1 : 0 and corresponds with the pH of the fibre. It can be determined both graphically and by calculation and is applicable for all fibrous material (for wool only at pH < 3 or > 11).

Phormium fibre → New Zealand flax or → Hemp.

Phosgene (chlorocarbonic acid, carbonyl chloride), $COCl_2$, colourless, pungent smelling, highly toxic gas. In companies working with tetrachloroethylene it is, in some circumstances, a gas that occurs unchecked (by smoking or near a heating system) and is thus a “particularly dangerous substance” with a high inhalation toxicity (IT). Used e.g. for the synthesis of triphenylmethane dyes (→ Phosgene formation from chlorinated hydrocarbons). In order to protect against corrosion and damage to health, naked flames (e.g. from gas heated machines in the same room) and smoking should be avoided in working areas containing chemical cleaning plants or finishing operations that involve chlorinated hydrocarbon plants.

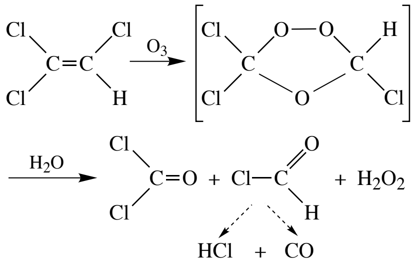
Phosgene formation from chlorinated hydrocarbons In chlorinated hydrocarbons from the methane series: In air and under the effect of sunlight, gradual oxidation occurs in chloroform accompanied by the formation of highly toxic phosgenes. The hydrogen in the triple chlorinated carbon atom can be compared with an oxidized carbon atom with regard to its sensitivity to oxidants. It is assumed that a hydroxylation takes place in the first stage.



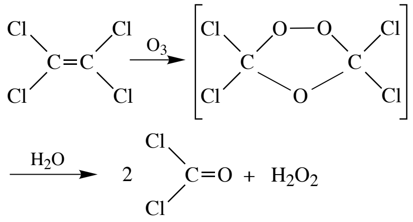
$$Cl_3C{-}H \xrightarrow{\text{oxygen, light}}$$

$$Cl_3C{-}OH \longrightarrow Cl_2C{=}O + HCl$$

In chlorinated hydrocarbons of the ethane series: If the chlorination production of ethylene is considered, even very pure trichloroethylene without a stabiliser is seen to be only resistant with the exclusion of light and air. Otherwise it decomposes, forming hydrogen chloride, carbon monoxide, phosgene and dichloroacetylene chloride after some time. After the addition of phenols, amines (most commonly triethylamine) or terpenes, it is stable in the presence of moisture. If the oxidation conditions are increased by ozonification, then the reaction may take place according to the following diagram:



This ozonification reaction is also feasible with tetrachloroethylene (perchloroethylene):



The ozone needed for the reaction can be created by static electricity, spark discharge onto hot iron and possibly by smoking in work areas.

Phosphatases → Esterases.

Phosphate, condensed (polymer phosphates), → Complex phosphates, are created by polycondensation of mono or dialkali monophosphates or their mixtures. Annular, chain-form and cross-linked products can be created. Basic types:

- diphosphates (pyrophosphates).
- triphosphates (tripolyphosphates).
- metaphosphates.

As the chain length increases the complex bonding capacity for water hardening salts increases, but the dispersing power decreases.

Properties include:

1. Buffering power: Due to metaphosphates = slightly acidic and neutral; due to polyphosphates = slightly alkaline; due to diphosphates = highly alkaline.
2. Complex bonding of alkaline earth and heavy metal ions. A differentiation must be made between stoichiometric and hypostoichiometric phosphate addition. Only in the first case does complex bonding of the multivalent metal ions occur. In the event of hypostoichiometric addition of condensed phosphates the precipiation of water hardening salts is prevented or delayed due to the physical effect of the added phosphate. Condensed phosphates in an aqueous solution are cation exchangers according to the equation

   $$n\ Alk^+(H_2O)_x(\text{phosphate})_n^-$$

   The alkali ions can be replaced by multivalent metal ions. If all the sodium ions are replaced by calcium, then water insoluble calcium polyphosphate is formed.
3. Suspending property and peptization property for pigment dirt.
4. Reduction of the titre of soap.
5. Supporting the washing effects of surfactants.
6. Adsorption suppressing effect, i.e. making it easier to rinse surfactants out of textiles.

Condensed phosphates tend to hydrolyse in neutral and alkaline solutions at temperatures above 60°C. Application: Softener for water, removal of iron, copper and manganese salts (rubber poison). Stabilizing effect for peroxide bleach, auxiliary in milling, degumming, washing, desizing, etc.

Phosphate “glass” Colourless, glass-like, non-crystalline → Polyphosphates. Phosphate “glass” is obtained under certain conditions by the heating of mixtures of mono and disodium monophosphate and the subsequent quenching of the melt. Such “glasses” are available commercially in the form of white powder and dissolve as a non-crystalline, glassy material. Depending upon their composition they possess good to excellent lime binding power, are much less temperature dependent and thus can be used equally well in the cold or at high temperatures.

Phosphate inoculum As the name suggests, phosphate inoculum is the water-soluble complex phosphate best suited for the phosphate inoculation process (→ Inoculation). Its specific protective mechanism is that it greatly reduces the precipitation of calcium carbonate and also, should calcium carbonate crystals in fact form, they are sufficiently modified in both size and physical shape that they are no longer capable of building a cohesive structure (scale).

Phosphate process for water softening and silicate removal The addition of → Trisodium phosphate (TSP) at temperatures above 50°C facilitates a quantitative reaction sequence without excess salt, quicker precipitation of hardness constituents, precipitation of silicates and colloids, easier filtration, simplified dosing and monitoring, reversal of elutriation losses, more uniform heat transfer, simplified boiler cleaning, etc. Principle: Conversion of hardness constituent to coarse flakes (completely insoluble) phosphates, with (sodium) sulphate, chloride, etc. remaining dissolved. Result: Virtually total softening and desilification.

Phosphates Derivative of → Phosphoric acid. To be differentiated between:

I. Inorganic phosphates in the form of salts of the tribasic monophosphoric acids H_3PO_4;

a) primary or monobasic type NaH_2PO_4 (monosodium monophosphate);

b) secondary or dibasic type Na_2HPO_4 (disodium monophosphate);

c) tertiary or tribasic type Na_3PO_4 (trisodium monophosphate).

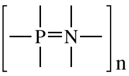
There are also condensed (polymer) phosphates; these include: metaphosphates (annular structure) and polyphosphates (chain structure), such as diphosphates, triphosphates, etc.; Graham's salt, and cross-linked phosphates (perphosphates, perpyrophosphates).

II. Organic phosphates in the form of esters of phosphoric acids.

Phosphate substitutes Relate to alternative efforts (since the start of the 1960s) to find substitutes for → Polyphosphates in order to achieve better ecological properties. Attempts aim to combine the positive washing agent properties of polyphosphates with toxicological and ecological harmlessness, plus faultless biological cleaning in sewerage plants. Well over 1000 substances have now been investigated, with the outcome that the performance of sodium triphosphate as a builder can be achieved by hardly any other phosphate substitute. Further phosphate substitutes are phosphoric acid derivatives, polyhydroxy compounds, polycarboxylic acid, hydroxy, oxo and oxacarboxylic acids, ester carboxylic acids, sulphor compounds and other compounds, including sodium-aluminium silicate.

Phosphating In the specific case of interface-active bodies this is a chemical reaction, in which phosphoric acid esters are created.

Phosphazenes Phosphor-nitrogen compounds of type

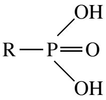


$$\left[-\overset{|}{\underset{|}{P}}=\overset{|}{\underset{|}{N}}- \right]_n$$

Spinning additive for the manufacture of flame retardant viscose fibres. Manufacture by esterification of a mainly trimeric chlorophosphazene (phosphorus chloronitrile). The best flame retardant finishes are achieved by alkyloxyphosphazene, chloralkyloxyphosphazene and alkylthiophosphazene compounds. Phosphane oligomers and polymers are also recommended. Approx. 20% should be spun in to achieve the desired effect. All these additives cause a certain reduction in the stability of the viscose.

Phosphines Similar to → Phosphonium compounds; alkyl substitution products of phosphorus hydride PH_3 of type R_2–PH or R_3–P; colourless bases, the basicity of which increases with the alkyl number.

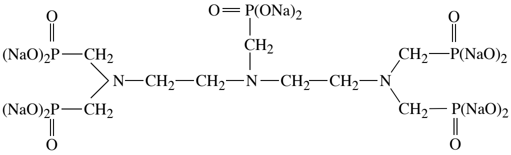
Phosphonates Types of the general formula



used for the stabilization of peroxide bleach, specifically

– amino phosphonates with nitrogen substituents;
– hydroxyphosponates;
– carboxyphosphonates.

The best results with regard to stabilisation are achieved with amino phosphonates that contain at least two phosphate groups. A phosphonate used as a stabiliser can be structured as follows:



This is a sodium salt of diethylene triamino pentamethylene phosphonic acid.

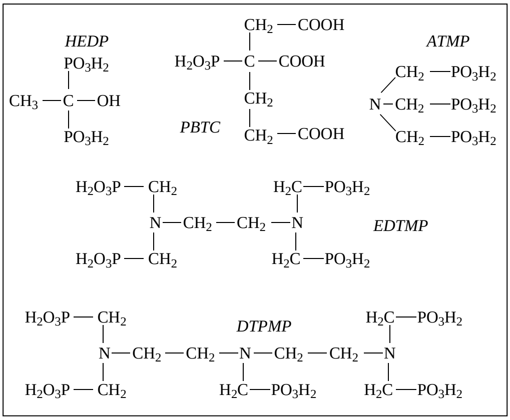


Fig.: Chemical structure of the important phosphonates.

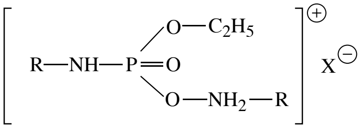
Phosphonates (see Fig.) in the quantities normally used in the finishing industry are assessed as follows:

– non-toxic to humans, animals and plants (at least not so far known);
– under aerobic conditions almost entirely non-biodegradable;
– degradable by photolysis;
– can be biologically eliminated by adsorption on different surfaces;

- chemical-physically eliminable by precipitation;
- low base mobility;
- its remobilisation power can be disregarded in relation to heavy metals.

Phosphonation Chemical reaction or reaction sequence, in which a molecule is introduced into one or more phosphoric acid groups with a direct phosphor/ carbon bond (→ Phosphonium compounds).

Phosphonium compounds Phosphor complexes of type (alkyl)$_4$P. Thus quaternary compounds, derived from co-ordinative pentavalent phosphorus and used as cationic-active products for improving fastness. However, the nitrogen-phosphor complex, also positively charged, is also of interest:



They represent cationic softeners and emulsifiers, which are oil-soluble and dispersible in water. Phosphonium compounds are important for flame-retardant finishes or as a mothproofing agent.

Phosphor bronze gauze → Screen mesh, screen gauze.

Phosphoramides → Phosphoric acid amides.

Phosphorescence Appearance of afterglow. A property possessed in particular by → Phosphors. The principle rests upon the retransmission of light energy accumulated (stored) previously during illumination. Procedure is thus not identical with the luminous phenomenon of phosphorus (→ Luminescence).

Phosphoric acid (monophosphoric acid), H_3PO_4, density 1.88. Salts → Phosphates. Rhombic, deliquescent crystals (melting point 41–42°C) or syrupy aqueous solution (70–89%, density 1.508–1.750), medium strength acids (less corrosive than sulphuric acid), tribasic (→ Phosphoric acids). Application: Dyeing of wool (with acid and chrome dyes); non-shrink finishing of wool; occasionally for silk softening; 89% phosphoric acid as cellulose solvent.

Phosphoric acid amides Compounds of phosphoric acid with amines or substituted amines for flame-retardant finishing. Nitrogen increases the flame retardant effect of organic phosphor compounds.

Phosphoric acid ester → Spinning preparations for friction texturizing.

Phosphoric acids,

$(HPO_3)_n$: Metaphosphoric acids, annular (n = 3 or 4); salts are genuine metaphosphates (e.g. sodium metaphosphate).

$(HPO_3)_n \cdot H_2O$: phosphoric acids; salt = polyphosphate (highly condensed, i.e. n is large).

H_3PO_2: hypophosphoric acid, monobasic; salt = hypophosphite (NaH_2PO_2), easily soluble in water, strong reducing agent.

$(H_2PO_3)_2$: corresponds with $H_4P_2O_6$.

H_3PO_3: phosphorous acid, dibasic; salt = phosphite (Na_2HOP_3 or NaH_2PO_3); more or less water soluble, weak reducing agent.

H_3PO_4: (mono) phosphoric acid, tribasic; salt = phosphate.

H_3PO_5: peroximonophosphoric acid; salt = peroximonophosphate.

$H_4P_2O_5$: diphosphorous acid.

$H_4P_2O_6$: per(di)phosphoric acid, strong acid, slightly reducing; salt = hypophosphate.

$H_4P_2O_7$: diphosphoric acid, tetrabasic; salt = diphosphates ($Na_4P_2O_7$), formation of phosphates in aqueous or particularly in acid solution.

$H_4P_2O_7 \cdot 2\,H_2O_2$: perpyrophosphoric acid; salt = perpyrophosphates.

$H_4P_2O_8$: peroxide phosphoric acid; salt = peroxide phosphate (polyphosphates)

Phosphoric acid trialkyl ester Used as → Wetting promotors.

Phosphors Light carriers, usually inorganic → Luminophores, which produce → Phosphorescence effects and consist of three different components depending upon the type of so-called Lenard phosphor:

1. light sensitive base substance (e.g. sulphide of cadmium, calcium, magnesium, strontium).
2. flux (e.g. sodium tetraborate, fluorite (calcium fluoride), sodium chloride, sodium phosphate).
3. traces of light generating heavy metal (e.g. copper, manganese, silver, thallium, bismuth).

In all cases daylight or artificial light previously accumulated in the phosphorus is re-emitted as a night-time illumination (8–24 h). This effect is easily recognized from several metres away.

Phosphorus (P). Chemical element, atomic mass 31; non-metal; crystalline mass (translucent rods), yellowy-white; waxy; smokes in air; slightly (self) ignitable (oxidation); glows in the dark (phosphorescent); very toxic; density 1.8; melting point 44.5°C; barely water soluble, but soluble in carbon disulphide, benzene, fatty oils. At 200°C red phosphorus is formed; insoluble in the above solvents, non-toxic. At 300°C black, metallic phosphorus. Compounds: Phosphorus hydride PH_3 (forms → Phosphines and → Phosphonium compounds), Phosphorus oxide (tri, tetra, pentoxide P_4O_6, P_2O_3, P_2O_4, P_2O_5). The latter and water yield → Phosphoric acids, halogen compounds, etc.

Phosphorus-containing polymers Whereas the flame-retardant effect of halogen compounds on fibres acts mainly in the gas phase and influences the burning mechanism by trapping radicals, the active mechanism in the pyrolysis of phosphorus compounds exists, but its function is unclear. Polymer phosphorus compounds

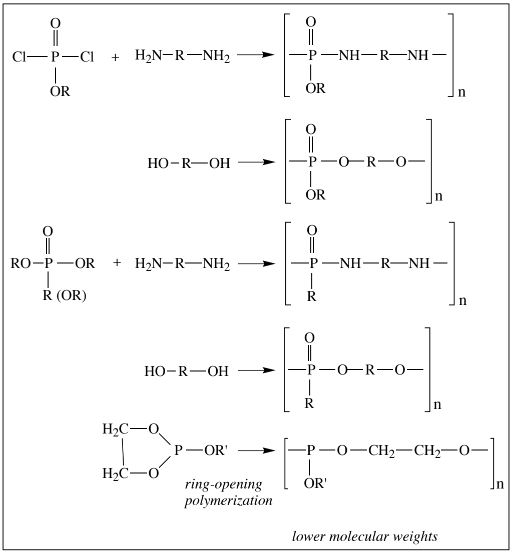


Fig. 1: Methods of representing macromolecular phosphorus compounds.

can be spun into polyacrylonitrile fibres if the phosphorus polymers are soluble in dimethyl formamide (DMF). The two polymers must be compatible with each other. The phosphorus can be anchored in the main chain or the side chain of the polymers. Cyclic phosphites can be converted into polyphosphites by ring-opening polymerization (Fig. 1).

Monomers with covalent bonds and phosphorus in the side chain can also be polymerized (Fig. 2).

Subsequent polymer-like attachment of the phosphorus to the side chain can also be realised (Figs. 3 and 4).

The washing fastness effects could be improved by the creation of copolymerisates from acrylonitrile and the phosphorus-containing acrylic acid esters. The spun phosphor-containing fibres show a surprisingly high degree of whiteness. The flame retardant effect is strongly dependent upon the chemical constitution of the phosphorus compounds. On the other hand, the same phosphorus content in the fibre leads to different flame retardant effects in different compounds (see Tab.). Copolyester also, which is obtained by the inclusion of phosphorus-containing comonomers in the polymer structure (Fig. 5), burns with difficulty. The comonomers are directly linked into the chain (according to Herlinger).

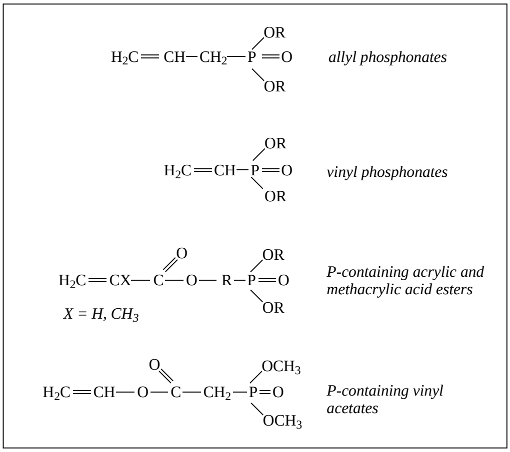

Fig. 2: Monomers in the production of polymer phosphorus compounds.

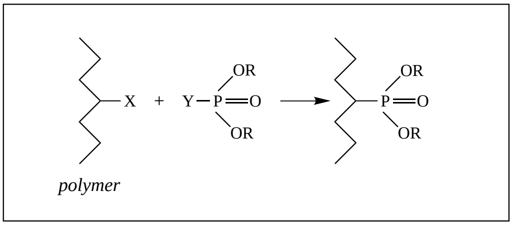

Fig. 3: Macromolecular phosphorus compounds by polymer-like conversion.

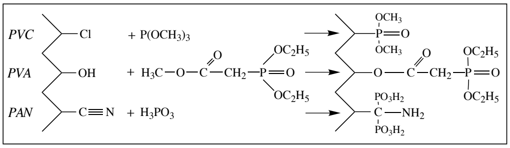

Fig. 4: Completed polymer-like conversions.

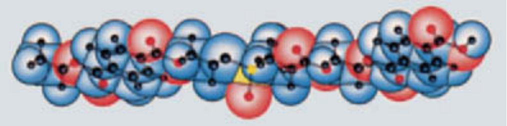

Fig. 5: Inclusion of a phosphorus-containing comonomer in the polymer structure of Trevira CS (Hoechst).

Phosphorus determination Determination according to DIN 38 405, Part 11; Phosphorus compounds are converted to o-phosphates by concentrated sulphuric acid and potassium peroxodisulphate ($K_2S_2O_8$) by boiling. The o-phosphate created in this manner is added to molybdate reagent, creating molybdenum blue. The intensity of the colour is determined photometrically and is proportional to the o-phosphate

compound type	formula	% P in polymer	% additive in PAC	% P in fibre	L O I	burning properties in vertical test

content of the sample. A calibration graph is necessary for evaluation.

Phosphorylase Ferment (magnesium adenylic acid protein), which splits starch into glucose (in test tube also artificial starch structure from glucose), whereby inorganic phosphate is inserted at the dissolved link point of the glucose molecule and splits glucose-I-phosphate.

Photoacoustic colour measurement Photometric spectroscopy encompasses numerous sensitive absorption spectroscopies, which are based upon the conversion of absorbed light energy into heat, whereby the induced temperature increase serves as the measured variable. A specific measuring arrangement is called photoacoustic spectroscopy and can be used for darker and more saturated dyes than colorimetry. A significant advantage of photoacoustic colour measurement, according to original theories, appeared to be its independence of the surface roughness of the sample. This would have meant that, unlike remission spectroscopy, no large databases need be stored to perform a colour analysis. However, investigations have shown a strong dependency on the fabric geometry. New theories indicate a relationship between the surface roughness or the porosity of the material and the photoacoustic signal. This means that appropriate corrections must also be made in photoacoustic colorimetry.

Photoacoustic spectroscopy Measuring procedures that facilitate on-line monitoring of dye concentration, or concentrations for mixed dyes and automatic after-dosing are desirable for a time-dependent monitoring of dye liquors. For current measuring procedures, for example, in transmitted light photometry, it is a great disadvantage, that in practice complex solutions exist, often with low transmission, which means that it is almost impossible to work with universal measuring cells, and drawn spectra are difficult to interpret or cannot be interpreted at all. Absorption spectroscopic measuring techniques, for example photoacoustic spectroscopy, have proved their worth as an effective procedure for determining material properties of solids. In such techniques the secondary effects (sample heating or expansion) of the energy absorbed is the origin of the measurement signal, so that unlike remission or transmission spectroscopy the absorption properties of the sample are determined directly.

For certain wavelength ranges the interaction of light with a coloured textile material leads to excited electronic states of the dye molecule. The deactivation of the applied light energy occurs partly without radiation (“internal conversion”) and is therefore converted into heat. Dyes undergo further competing processes such as fluorescence, phosphorescence and photochemical reactions, however it is assumed that the total light energy is converted into heat. These photo-physical excitation and relaxation processes are shown in a simplified manner in the Jablonski diagram in Fig. 1.

Photoacoustic spectroscopy is, in principle, a form of absorption spectroscopy. The sample is placed in a gas-tight cell of constant volume and is illuminated with an intensity-modulated Xe light (Fig. 2). The part of the absorbed light energy that is converted into heat

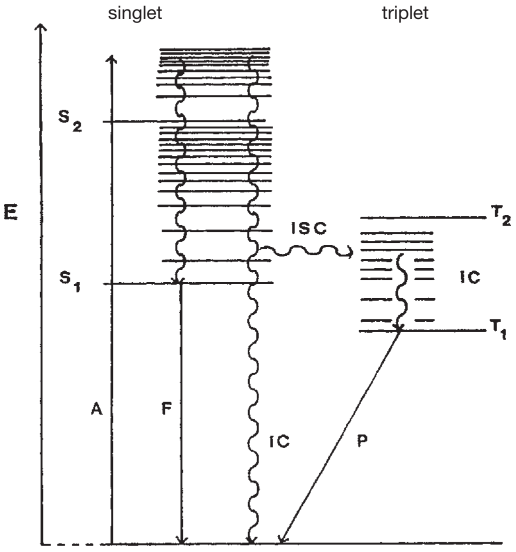

Fig. 1.: Jablonski diagram. Radiation emitting transfers involving the exchange of photons are indicated with straight arrows, non-emitting transfers with wavy arrows.
A = absorption; F = fluorescence; P = phosphorescence; ISC = inter-system conversion; IC = internal conversion.

causes pressure variations in the gas, which then dissipate as sound waves. The sound amplitude detected by the capacitor microphone is proportional to the light energy absorbed. Textiles differ according to their optical and thermal properties and are optically opaque and thermally dense solids. A sample is opaque if the optical penetration depth $l\beta$ is less than the investigated layer thickness l_p of the sample.

The optical penetration depth $l\beta$ is equal to the reciprocal of the absorption coefficient β:

$$l\beta = \frac{1}{\beta}$$

The thermal properties are defined using the thermal diffusion length μ:

$$\mu = \left(\frac{2\alpha}{\omega}\right)^{1/2}, \alpha = \frac{\kappa}{\rho\, C}$$

α = thermal diffusivity,
ω = modulation frequency ($\omega = 2\pi f$),
κ = heat conductivity,
ρ = density,
C = specific heat.

(according to Schollmeyer and Eickmeier).

Photocell, photoelement So-called photoelectric cell in the form of a → Photoelectric sensor. Basically consists of a light-sensitive layer acting as a cathode (e.g. grey selenium or alkali metal), which can be mirrored on the internal surface of a glass sphere that has been evacuated or filled with an inert gas and has inside it e.g. a platinum wire as an anode. When the photocell is illuminated, electrons migrate from the cathode to the anode. A so-called photocurrent occurs, which can be measured by a galvanometer (photometer) connected between the two. A number of photoelectric devices have been constructed according to this principle, which can be used for colorimetry, fluorometry, gloss testing, photometry, reflection measurement, spectrophotometry, turbidimetric measurement, whiteness measurement, etc. This also includes photoelectric operational control and monitoring. In more detail we differentiate between:

I. Photocells: Preferably made of alkali metal (alkali photocell) which, however, in the absence of a driving

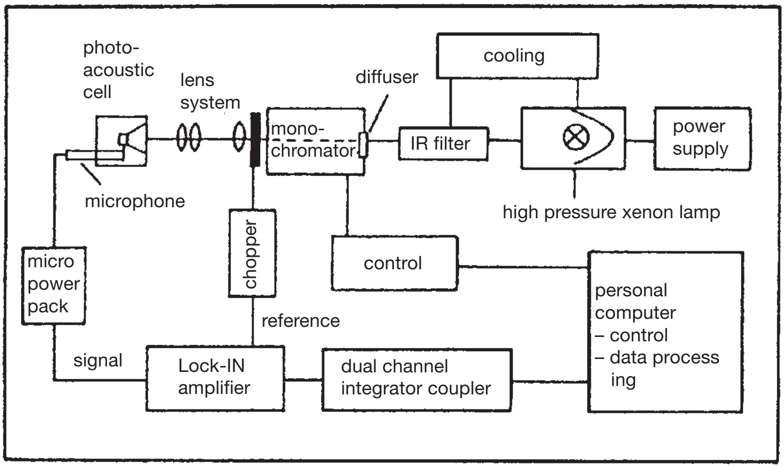

Fig. 2: Diagram of a photoacoustic spectrometer.

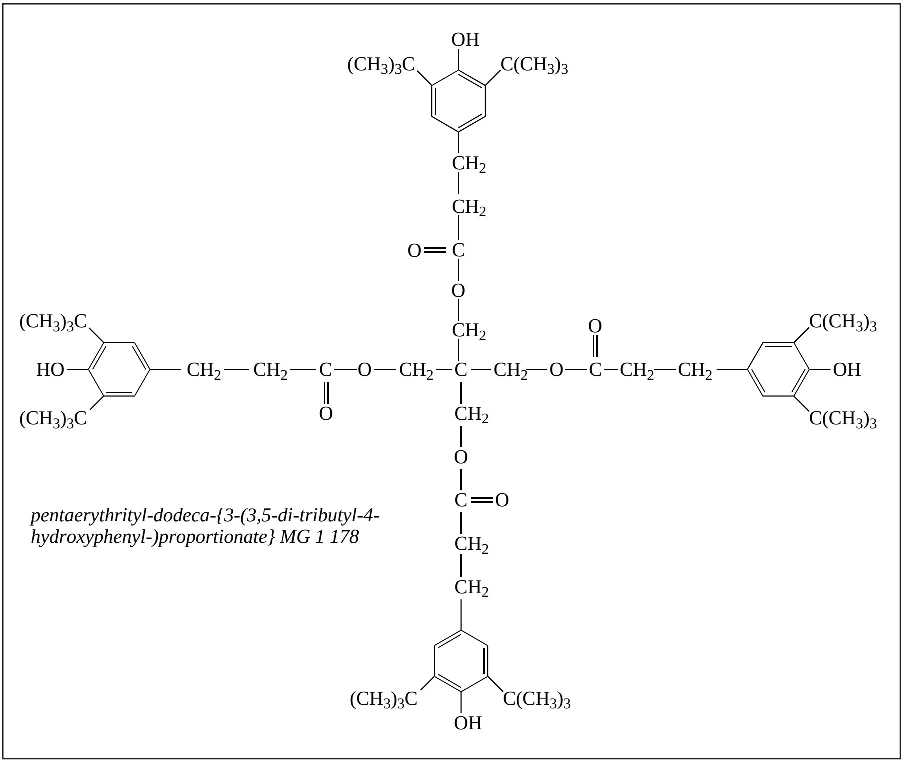
potential, only supply low photoelectric currents and therefore can only be used with an auxiliary voltage and then work in the same way as light sensitive resistors. So-called secondary electron multipliers are also used, in which auxiliary electrodes significantly increase the current generated in the photocell. Photocells are used, for example, for simple colorimetric measurements, where a significant increase in the photoelectric current is necessary. They are also used almost exclusively for → Spectroscopy due to their high light sensitivity over broad spectral ranges.

II. Photoelements: Consist of a so-called semiconductor layer between the metallic base area and the light permeable metallic front electrode. As soon as light falls on the latter, an electron movement over the front electrode and via an external conductive circuit to the base plate is triggered in the semiconductor. Unlike I., sufficiently strong measuring currents are created without an electric bias voltage. Selenium photoelements are used almost exclusively, e.g. for photocolorimetry. Germanium and silicon photoelements, which are used e.g. for the direct conversion of solar energy into electrical energy, are also worthy of mention.

Photochemical fibre degradation In nature, plant growth is based upon the principle of a photosensitive reaction, whereby carbon dioxide and water are converted into carbohydrates and oxygen by chlorophyll, also known as leaf green, as an activator. To protect the chlorophyll, β-carotene intervenes in the reaction mechanism and deactivates the singlet oxygen, which was created from the base-triplet-state by stimulation of the light by means of the activators, and which is reactive. If carotene production falls in the autumn, then chlorophyll is oxidatively broken down (also under the influence of hydrogen peroxide, which has been created by the reaction of the singlet oxygen with water), bringing about the characteristic autumn colouring of the leaves. This photolysis mechanism can be transferred to fibres and dyes.

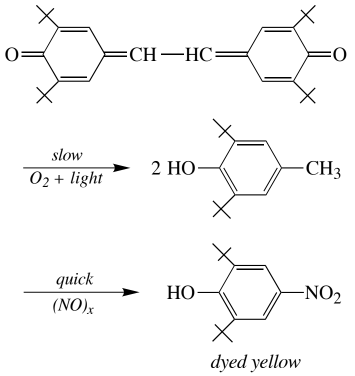
Pure fibres, above all polyacrylonitrile and cotton fibres, but also polyamide and polyester fibres that have not been delustred, are relatively stable against the effects of light. Wool needs a definite protection against photo yellowing (→ Light protective finishes for wool).

I. Polyester fibres: Dyes applied to carrier-free dyeable polyester fibres have poor light fastness due to the ether group content in modified polyester. Antioxidants in rubber, foam and other polymers (e.g. in coatings) react to the effects of light and also in the presence of nitrogen oxide and also in the presence of quat-based softeners:



pentaerythrityl-dodeca-{3-(3,5-di-tributyl-4-hydroxyphenyl-)proportionate} MG 1 178

Fig. 1: Antioxidant for polyester fibres.



There is an unmistakable chemical similarity between antioxidants for polyester fibres and substrate (Fig. 1).

II. Polyamide fibres: From the point of view of photochemistry, light falling onto material can be divided into two radiation strengths: Photoactivity in the ultraviolet range (280–400 nm) with an energy proportion of approx. 6% of all the radiation hitting the surface and heat radiation in the infra red range (720–2500 nm) with an energy proportion of approx. 52% (approx. 42% radiation strength in the visible range 400–720 nm). Accordingly, a differentiation is made regarding the effect of light on fibres (Fig. 2) between:

a) a physical mechanism of the interactions.
b) a chemical mechanism of the interactions.

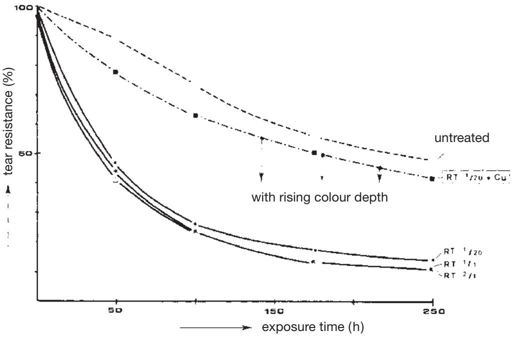


Fig. 2: Loss of tear resistance in dyeings of C. I. Acid Yellow 129 on polyamide filament yarn in relation to duration of exposure.
Exposure according to DIN 75202; copper content of the 1/20 RT-dye 83 mg Cu/g PA (RT = standard depth).

The kinetics of the photochemical decomposition of polyamide fibres (measured by the resistance to tearing) takes place in two phases: First chain decomposition, then stabilization (or slower decomposition) due to cross-linking reactions.

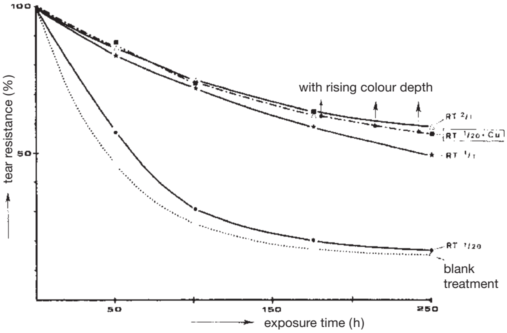

Fig. 3: Loss of tear resistance in dyeings of C. I. Acid Yellow 116 on polyamide filament yarn in relation to duration of exposure, with copper as optical protection.

In polyamide fibres, light stabilizers increase the resistance to tearing in relation to blank dyeing, e.g. C.I. Acid Yellow 116 (Fig. 3). Because the polyamide fibres are used as an additive in spinning, the absorption behaviour in sunlight changes erratically. Normal additives in polyamide fibres:

a) Delustring: 0.03–2.0% TiO_2 pigment, particle size 0.1–1 µm; preferred anastase modification; coated with aluminium oxide, silicon oxide, and manganese compounds to reduce photochemical activity.
b) Light stabilization: Up to 40 ppm manganese salts (phosphate, lactate, acetate) as an additive to the polymer, e.g. PA half-matt: 7–10 ppm; PA matt: 25–40 ppm manganese.

The titanium oxide delustring agent is the real cause of the light sensitivity of polyamide fibres.

Irradiation with short wave light causes an exciton (some electron holes) to form, which immediately reacts further with the surface hydroxyl groups, and Ti^{4+} ions. A hydroxyl radical splits, and the remaining Ti^{3+} ion gains an oxygen molecule, which is converted into O_2^- after the transition of an electron of Ti^{3+}. Finally a perhydroxyl radical HO forms with water (Fig. 4).

subreactions:

$$h\nu \xrightarrow{TiO_2} e' + p \text{ (exciton)}$$
$$HO^- + p \longrightarrow HO^\bullet$$
$$Ti^{4+} + e' \longrightarrow Ti^{3+}$$
$$Ti^{3+} + O_2 \longrightarrow [Ti^{4+}\,{}^\bullet O_2^- \text{ absorbed}]$$
$$[Ti^{4+}\,{}^\bullet O_2^-] + H_2O \longrightarrow Ti^{4+} + HO^- + HO_2^\bullet$$

overall reaction

$$H_2O + O_2 \xrightarrow[TiO_2]{h\nu} HO^\bullet + HO_2^\bullet$$

Fig. 4: Diagrammatic representation of the photochemical reaction at the surface of titanium oxide dye.

Photochemical fibre degradation

Type and quantity of polymer additives are in general not known; they vary according to provenance and can only be detected by costly analysis. Textile polyamide fibres always contain titanium oxide delustring agents (often coated with manganese salt) and/or manganese salt (increasing with a quantity of titanium oxide pigment). Copper salts are not contained in textile polyamide fibres. Limits are imposed on fibre manufacturers with regard to light stabilisation, the universal applicability of the fibres should be guaranteed. Material made of polyamide fibres can be exposed to aggressive processes during finishing, e.g. HT process, reductive and oxidative processes. Blind dyeing is problematic in relation to subsequent illumination, because under certain circumstances the manganese salt light protective finish dissolves out.

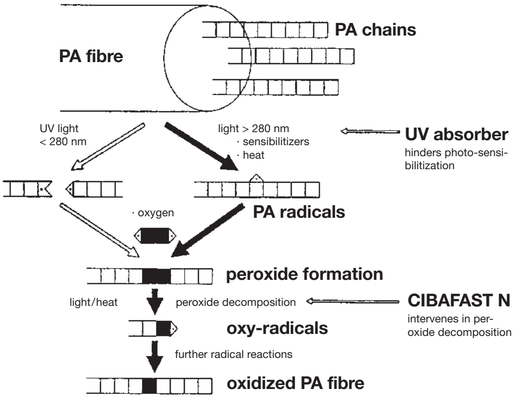

Fig. 5: Diagrammatic representation of the photochemical degredation of polyamide and the effect of UV absorbers and Cibafast N (Ciba Geigy).

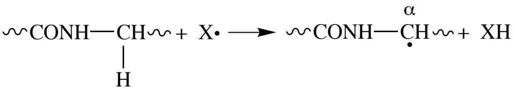
The photochemical degradation of polyamide is a complicated process and can only be explained by modelling the relationships (Fig. 5). The primary reaction in the presence of sensitisers appears to be an attack by radicals (e.g. hydroxyl, perhydroxyl radical), splitting hydrogen into the amino group causes α-carbon.

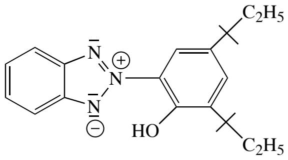


$$\sim\text{CONH}-\underset{\substack{|\\ \text{H}}}{\text{CH}}\sim + \text{X}\bullet \longrightarrow \sim\text{CONH}-\overset{\alpha}{\underset{\bullet}{\text{CH}}}\sim + \text{XH}$$

The main decomposition products of such reactions include aldehyde, carboxylic acids, peroxide, carbon monoxide, etc., in addition to chain fragments. Electromicrocopic pictures of non illuminated and illuminated fibre surfaces and cross-sections, which clearly show the fibre decomposition, show marked corrosion effects on their surfaces. There are cracks, channels, holes. Pictures of the fibre cross-section show cavities around the titanium dioxide pigment particles. These indicate on the one hand the photocatalytic action of the delustring and, on the other hand, the reason for the destruction of the fibre surface, caused by a pigment particle embedded in the fibre sheath. The obvious conclusion is therefore that the speed of photochemical fibre degradation depends to a significant degree upon the quantity (and quality) of the fibre pigmentation.

The formation of the radical along the polyamide chain is followed by the 2nd step of polyamide degradation: Atmospheric oxygen reacts with peroxides. Its decomposition due to further light and heat brings about a radical chain reaction. Oxidation products are the end product of broken down polyamide when the chain is broken due to traces of carboxylic acids, ketones, aldehydes or alcohols.

Light protective agents for polyamide fibres act firstly in the physical part of the mechanism; UV absorbers are used, which quickly convert light energy into heat. A differentiation is made here between a shielding effect (from 280–400 nm, a few sensitisers, such as, e.g., titanium dioxide can be excited) and the deactivation of the stimulated sensitiser molecules, by the transfer of energy, that has been taken in. Benzophenone and benzotriazole are UV absorbers, e.g.:



2-(2-hydroxy-3,5-di-tert.amylphenyl-) benzotriazole MG 351

Secondly, light protective agents are used to intervene in the chemical mechanism of photooxidation (Fig. 5) by destroying the peroxide and breaking up the radical reaction. Such stabilisers include copper salts (e.g. copper sulphate, an ecologically problematic substance) or copper complexes of a diazomethane derivative. Light protective agents should be applied in the dyehouse according to the profile of requirements for the final article (e.g. car upholstery, with hot illumination or carpets, with cold illumination) as a subsequent stabilisation process, and not non specifically exposed to the fibrous mass (with all the associated disadvantages).

III. Cellulose fibres: Cellulose fibres are also quite resistant to light; however, because cotton for example contains natural and artificial contaminants, these activators bring about light-related fibre damage by means of the following mechanisms (Fig. 6): The activator is stimulated by light; its reacts directly with the cellulose, which becomes a radical due to the removal of hydrogen. In the next step the cellulose radical forms a peroxide radical with atmospheric oxygen, which reacts with the original activator radical (AH) which has been created, whilst reforming the activator. The cellulose peroxide can also lead to decomposition products of the substrate. Unlike this hydrogen extraction mechanism, the attack on the cellulose due to the light stimulated activator can also occur directly (singlet oxygen theory). The energy of the stimulated activator is transferred to the air oxygen, whereby its triplet basic state is transformed into the stimulated, short-lived, reactive singlet state. Either the singlet oxygen extracts a hydrogen atom from the cellulose or hydrogen peroxide is formed.

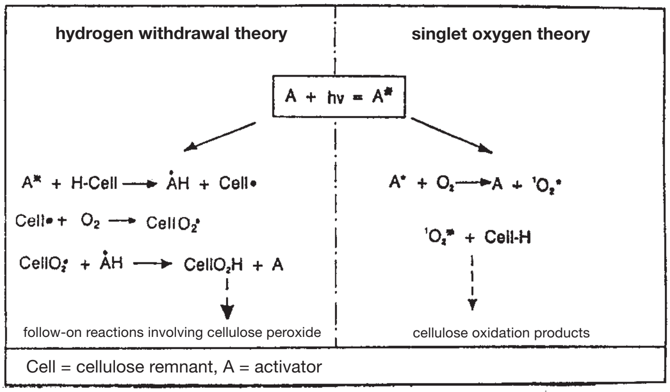


Fig. 6: Light damage to cellulose fibres in the presence of activators.

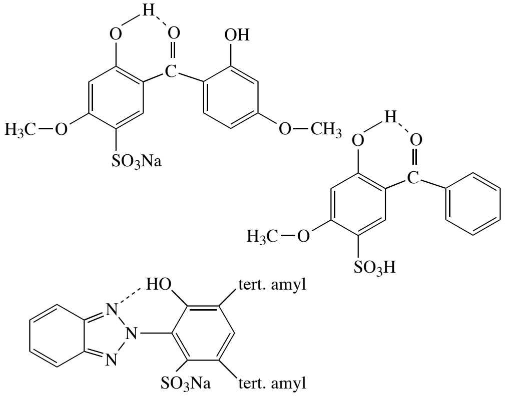
Fig. 7 shows possible cellulose degradation mechanisms with dyes as activators.

The primary step in the first mechanism is that a dye molecule D^* of cellulose stimulated by radiation extracts hydrogen (2). This creates free radicals. The degradation of the cellulose then proceeds by the destruction of cellulose peroxide. The accelerated effect of water occurs due to a 2nd reaction: The OH-radicals (6) created by the conversion of the stimulated dye with water extract further hydrogen atoms from the cellulose. This can also lead to the formation of hydrogen peroxide (7 and 8).

The mechanism illustrated in Fig. 8 is based upon the assumption that the triplet state of the dye D^* (2) stimulated by light will be deactivated by oxygen from the air. A stimulated oxygen molecule is created. It reacts with the substrate or with the water. The accelerating effect of moisture on fibre degradation is explained by the depicted hydrogen peroxide.

There are certain dyes, that not only cause no fibre damage when illuminated in the visible range (Fig. 9), but even have a significant protective effect (Fig. 10). This group includes e.g. vat green 3; vat blue 4, etc. It is possible to determine certain common features in the constitution of such dyes, which all possess an extremely high light fastness; they all contain NH functions, i.e. basic components, in the tetranuclear ring system.

IV. Wool: The main stabilisation mechanism of UV absorbers for the protection of wool (→ Yellowing of wool) is promoted by intramolecular hydrogen bridges. Three typical UV absorbers for wool:



The remaining polar molecular residues in the substrate influence the stability of these hydrogen bridges. The use of sulphonated UV absorbers on wool from aqueous liquor in the extraction process should there-

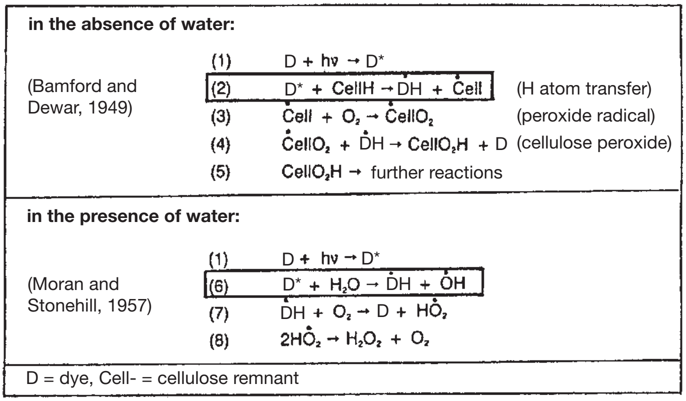


Fig. 7: Cellulose degradation (hydrogen withdrawal theory).

fore take place in a strongly acidic environment (pH 2) (60–80°C, 15–30 min). Although such UV absorbers for protection of wool against yellowing can actually at best dissipate the energy of light on the fibre surface, a ring "dyeing" is no better than a uniform distribution of the same amount of UV absorbers over the cross-section of the fibre. (according to Reinert, Schäfer, Baumgart and Wegerle, Krücker and Schmidt, Küster and Herlinger).

Photochemical reactions (photochemistry), chemical conversions triggered by the absorption of light (e.g. light damage to textiles and dyes, i.e. photodegradation, fading, light fading). Because the irradiated light wave consists of photons it can exert specific forces, and so-called electric fields, the strength of which increases with the intensity and frequency of the light. So, for example, in any absorbing molecule the increasing number of co-valent bonds effect an increase in the number of particularly mobile π electrons, and thus the molecule positions that can be excited by light energy, whereby the absorbed irradiated energy appears as a reaction triggering a burst of energy. According to Einstein the amount of energy is greater, the shorter the wavelength for each light quantum. The radiation energy is greatest in the entire UV range. The short wavelength UV range, at around 360 nm, alone suffices to split chemical bonds between fibre atoms and dye molecules, for example the splitting of cellulose C–C or C–O bonds with an energy of around 335 kJ/mol (photolysis). In the longer wavelength UV range, on the other hand, additional chemical energy (e.g. oxygen and easily splittable water) is

(1) $D + h\nu \longrightarrow D^*$

$\boxed{(2)\quad D^* + O_2 \longrightarrow D + O_2^*}$ (activated oxygen)

in water-free environment

(3) $O_2^* + \text{Cell-H} \rightarrow$ oxidation products

in moist environment

(4) $O_2^* + 2H_2O \rightarrow 2H_2O_2$

(5) $H_2O_2 + \text{Cell-H} \rightarrow$ oxidation products

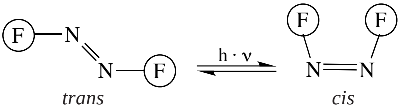
Fig. 10: Structural elements which have a protective effect on cellulose fibres.

required in addition to pure light energy for the splitting of chemical bonds (photooxidation). Therefore illumination using UV radiators brings about photolytic damage, whereas in sunlight, particularly behind window glass (wavelengths 320 nm with 35% penetration, 340 nm with 70% penetration and 360 nm with 90% penetration), we can expect photooxidation to be the main process. These photoreactions are the cause of → Light exposure damage.

Photochromism of dyes Also known as phototropism, however photochromism should be the preferred term. A time-limited colour change of coloured textiles under the influence of light. Determination: Sample is exposed to intensive illumination over a time period that is much too short to permanently change the shade. Evaluation takes place immediately after illumination and after 24 hour storage in darkness.

The effects of light on dyeings involving azo dyes on cellulose fibres can lead to reversible and irreversible changes to the dye molecules. Only in the first case do we talk of photochromism, i.e. of a shade change that is reversed in darkness. When illuminated in solution, azo dyes can change from the trans-form into the cis-form. The energy rich cis-form is unstable to some degree and returns to the stable trans-form in darkness. Because this effect is generally observed less often on cellulose fibres than on hydrophobic fibres, the phenomenon no longer represents a significant practical problem for the azo series.



Photochromism occurs in certain vat dyes and reactive anthraquinone dyes. In this the vat acid colour is observed. In vat yellow 1 (flavanthrone) on cellulose foil, it is caused by a reduction to the semiquinone radical (Fig.). Hydrogen is thereby extracted from the substrate. The semiquinone radical is coloured differently; the colour change is reversed in the dark because atmospheric oxygen oxidizes the reduction product to the initial dye. The intermediate radicals formed in the reduction of the dye by the cellulose can be detected with the aid of electron spin resonance methods. The dehydration of the cellulose is not associated with fibre damage.

Dyes also show the effect of photochromism in the presence of finishing agents, namely of the type N-methylol urea compounds. These agents take on the role of a hydrogen donor. This has the advantage that the effectiveness of these products on photochromism is in accordance with their tendency to form formaldehyde and free amino groups, which are easy to dehydrate. In addition, the reducibility of the dye is also important. The reduction of the dye could also come about due to an electron transition from the substrate. In addition to n-methylol compounds, hydrophobing agents, e.g. siloxane, also increase the tendency to photochromism; paraffin compounds, on the other hand, do not.

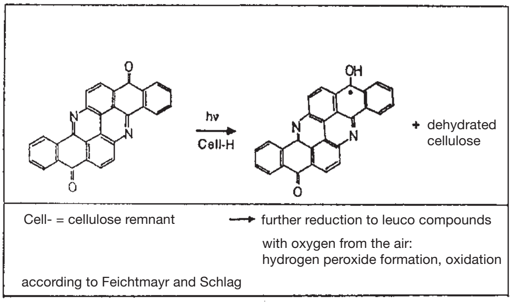


Fig.: Photochromism of C. I. vat yellow 1.

Whether photochromism occurs depends upon whether irreversible secondary reactions occur rapidly or slowly after the rapid primary step (the reduction of the dye). If they are very fast, then a poor light fastness is achieved, if they are slow then the possibility exists that in the presence of atmospheric oxygen the dye will be reformed in the dark, i.e. photochromism occurs. The greatest effect is observed naturally in the absence of oxygen, because a reversal reaction is not possible. In the presence of water the reversal reaction is accelerated due to the formation of hydrogen peroxide (according to Baumgarte and Wegerle).

Photodegradation Damage to dyeings caused by → Photochemical reactions.

Photoelectric sensors The optical techniques used in the textiles industry can be divided into three broad groups:

1. Monitoring
   a) of the textile material, its state during processing and after finishing: Photoelectric fuse fracture monitoring, lint monitors, thread cleaner, weft feeler, thread and seam monitor, error searching devices on stocking frames, pinhole detectors and devices for material presentation.
   b) of the processing machines, above all safety devices and photo-electric barriers on production lines, switching and control devices and needle monitoring on knitting machines, etc.
   c) of the treatment medium, i.e. flame monitor in gas heating of dryers, and indirectly also flue gas monitoring and turbidity meters.
2. Production using photoelectric output quantity indicator: Automatic weft aligning machines, synchronization control for the synchronisation of two machines; cutting devices; autolevellers with stored control parameters obtained by photoelectric meas-

urements of the belt thickness; material entry equipment.

3. Measuring and testing tasks that can be performed photoelectrically include all whiteness and colorimetric measurements, lustre measurements, liquor concentration measurements with the aid of the refraction index, extension measurements using a photoelectric transmitter, etc.

Photoelement → Photocell, photoelement.

Photographic colour separations Colour separations created using a reproduction camera from the pattern by the use of colour filters on panchromatic plates (for creating screens).

Photographic printing on textiles Phototype. It is possible to produce photographic pictures on textiles in rich patterns and all shades (→ Photone printing), e.g. washfast photographic printing with certain light sensitive vat leuco ester dyes. After illumination through a negative, clear, local prints on a prussian blue background are achieved. Locally reduced iron(III) salts and locally hardened points of chrome gelatine also serve for the local fixation of vat dyes under the influence of light. → Chrome photoprinting is based upon photochemical fixation of a chrome mordant with subsequent finish dyeing of the illuminated chromed pattern points with chrome mordant dye. Finally, coloured pattern prints can also be achieved by illuminating fabrics that have been impregnated with antidiazosulphonates, which thus rearrange to diazo compounds and link with phenols and napthols. Finally, there have also been proposals for multi-coloured prints, e.g. using three stage methods, the final effect of which represents a three-colour print produced by a mixture of vat, chrome mordant and insoluble azo dyes.

Photographic standards for fabric creasing Photographic fabric effect, which is creased by defined creasing methods and is used for the testing of resin finished textiles for their tendency to → Creasing (Monsanto crease photographs, random crease photographs). Evaluation uses a scale from 1 (very heavily creased) to 5 (no creasing).

Photoluminescence → Luminescence.

Photolysis of dyes The longer a molecule remains in the stimulated state, the greater the probability of it undergoing chemical changes. The reversible sec. reactions in dyes can take the form of intramolecular changes, e.g. in trans/cis conversions of azo dyes, or be caused by external influences, e.g. in the reductive attack on certain vat dyes and reoxidation due to atmospheric oxygen. In all cases a colour change occurs upon illumination, which reverses more or less slowly in the dark. This phenomenon is called → Photochromism of dyes. Irreversible secondary reactions express themselves by the bleaching of dyes or by shade changes, because colourless or coloured decomposition products can be created. There may also be damage to the substrate. Generally, the primary steps are oxidation or reduction reactions of the stimulated dye molecule with materials from the environment, whereby the latter may also have been previously transferred into the stimulated state.

Depending upon the substrate, there are dyes in the presence of hydrophilic or hydrophobic fibres. Water molecules and atmospheric oxygen are also present, and these can enter the fibres easily and quickly. Therefore, when illumination takes place, under certain circumstances an agent with a reducing action (cellulose) and an agent with an oxidating action (oxygen) are present in the system, in addition to the dye. In combination dyes, other dye molecules can also participate in the event. Many other influencing variables should also be taken into account, e.g. dye concentration, agglomeration, temperature, and the presence of other products, for example finishing agent. The complicated nature of the reaction mechanism should also be borne in mind.

In the photolysis of dyes that are present in the substrate, the following general rule applies: Dark dyes are more resistant to light than light colours. This is due to the state of the dye in the substrate. Dyes that are molecularly distributed are more quickly degraded by light than dyes are fixed in the fibre by aggregation (Fig. 1).

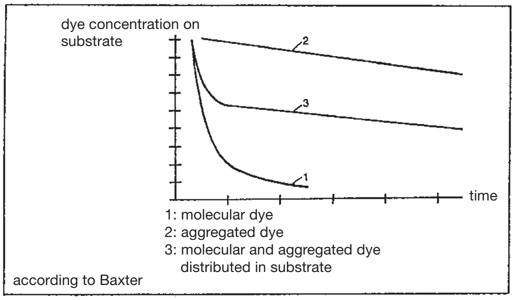

Fig. 1: Dye aggregation and kinetics of fading.

Not much is known about photo decomposition products of vat dyes. This is particularly true for the highly condensed aromatic ring systems. With regard to indigo, we know that although it is less light resistant on cellulose fibres than it is on wool, it is nevertheless amazingly stable. When illuminated, primarily the yellow oxidation product isatin is created, i.e. the dye becomes greener. If the article is washed, then the yellow product is removed and a colour is obtained that appears lighter, redder and more brilliant than the original dyeing.

It appears to be characteristic of indigo, that it is present in cellulose in the associated form, specifically in the trans form (Fig. 2). It is thought that the light stability of indigo is related to an intramolecular proton transition from nitrogen to oxygen in the stimulated

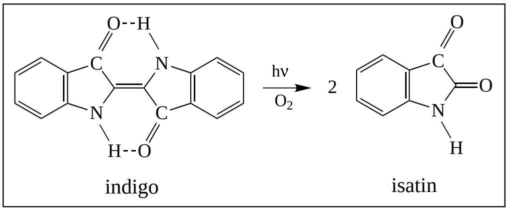

Fig. 2: Photodegradation of indigo.

singlet state. This stimulated state has only an extremely short lifespan, deactivation occurs without radiation.

Simple anthraquinone dyes are used for cellulose as reactive dyes and for cellulose acetate and polyester as disperse dyes. The photodegradation of 1 amino and 1.4 diaminoanthraquinone derivatives takes place in a polyester dyeing by oxidation processes with a number of degradation products.

If azo dyes are irradiated in solution and in the absence of oxygen, then reduction products are obtained. There are two reaction paths here (F = dye, RH = hydrogen donor, S = sensitiser):

direct reduction

$$F + h\nu \longrightarrow F^*$$
$$F^* + RH \longrightarrow \boxed{\dot{F}H} + \dot{R}$$

indirect reduction

$$S + h\nu \longrightarrow S^*$$
$$S^* + RH \longrightarrow \dot{S}H + \dot{R}$$
$$\dot{S}H + F \longrightarrow S + \boxed{\dot{F}H}$$

Unlike such model tests in the absence of oxygen, the photoreactions of dyes always take place in the presence of oxygen. For this reason it is not surprising that initial observations regarding the behaviour of azo dyes on cellulose fibres indicate oxidation reactions (Fig. 3). After illumination, oxidation products were detected. The dyes with a chemical bond between dye and fibre are more light resistant than the corresponding dye without a covalent bond. The “lightening conductor” theory is an attempt to explain this: Irradiated energy is taken from the dye to the substrate via the dye/fibre bond.

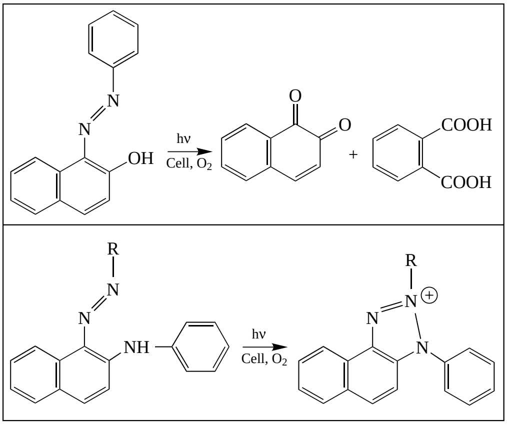

Fig. 3: Oxidation products following the exposure to light of cellulose dyeings with azo dyes.

Radical reactions are assumed to underlie the mechanism of photodegradation of reactive dyes. It is presumed that primarily the dye/fibre bond is split; only then is the molecularly distributed dye in the substrate destroyed. Particular problems can arise in certain reactive dyes after wet illumination (see Tab.). If a dyeing is illuminated in the xenotest device, and after 29 min it is sprayed with water for 1 min, then the fastness grades sometimes fall by up to 5 compared to dry illumination. Other dyes, on the other hand, show no significant effect. The type of reactive group plays no role.

C. I. reactive-	light fastness	
	dry	wet
yellow 2	6-7	5-6
yellow 6	6-7	5-6
yellow 22	6-7	5-6
yellow 35	6-7	5-6
yellow 14	6-7	4
yellow 1	6-7	1-2

according to Krallmann

Tab.: Wet and dry light fastness of reactive dyeings.

One attempt at an explanation assumes, that in dyes with poor wet light fastness the stimulated dye gives up an electron or splits a hydrogen atom particularly easily in an aqueous environment (Fig. 4). The radicals that

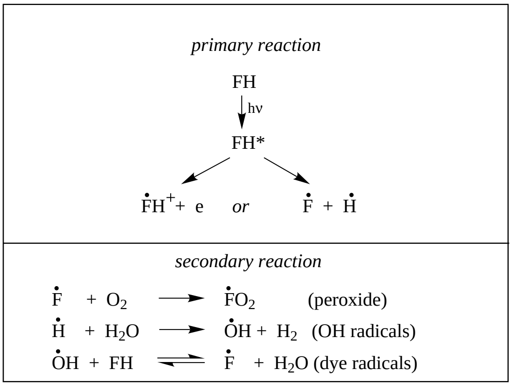

Fig. 4: Mechanism of the photolysis of reactive dyes in the presence of water.

are thus created suffer secondary reactions; the dye is destroyed. In dyes in which the wet light fastness is not reduced, fading occurs according to a different mechanism that is insensitive to water. Fibre plays no part in the reactions in these hypotheses.

Three reaction types have been found for the illumination of anthraquinone reactive dyes on cellulose foil or fibres and polyamide fibres (Fig. 5): A reversible photoreduction, a splitting of the bond between dye and cellulose and an irreversible dye degradation. Substrate and type of bond influence the kinetics and the mechanism of the photoconversion of the dye.

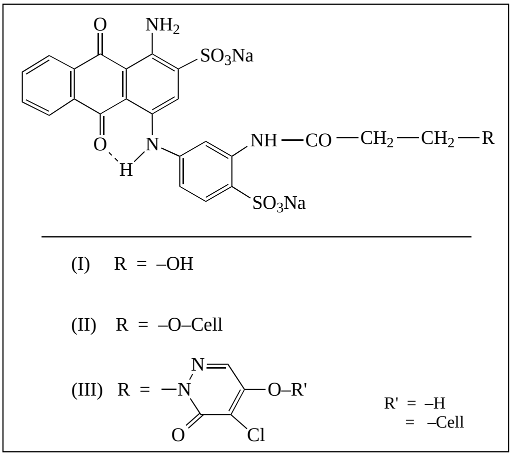

Fig. 5: Covalent bonding between dye and cellulose (anthraquinones).

Experiments with reactive 1.4 diaminoanthraquinone dyes showed that the fastness depends upon the type of illumination. Under artificial lighting, the fastness grades for the dye, regardless of whether the dye was covalently bonded in the substrate or not, were better than those for illumination in daylight. The fastness grades were better by 1–1.5 where there was a covalent bond between dye and substrate. As an alternative to the “lightening conductor” theory mentioned above, this could also be interpreted as meaning that where there is no covalent bond the dye agglomerates more in the substrate and is in closer contact to the cellulose molecules; in the chemically bonded state on the other hand the opposite is true: less aggregated and with poorer contact to the substrate (Baumgarte and Wegerle).

Photometer → Colour measuring instruments.

Photometer microscopy In a dyehouse, recipe variants are selected according to the criteria of price, metamerism and fastness. The dyeing behaviour of textiles is judged almost entirely by determining the exhaustion degree in the case of dyeing liquors (kinetic studies) and/or by the colorimetric evaluation of the substrate (CIELAB color standard values). On the other hand, a quantitative evaluation of dye distribution in fibre cross-sections is rarely performed due to experimental difficulties. The diffusion of dyes during a wool dyeing process initially takes place via the non-keratin between the wool scales, via the cell membrane complex and only then in the cortical areas of ortho, para and mesocortex, to varying degrees of intensity. One possibility for evaluating the quality of a dye is the degree of dye penetration; however there is no relationship between the visual impression of a dye, the standard dye values in inspection and the dye concentration profile in the fibre cross-section. The degree of dye penetration to which wool must be dyed to achieve the desired dye impression, on the one hand, and on the other hand to achieve an adequate fastness, is unknown.

When the photometer microscope was developed it became possible to determine the actual integral dye concentration taken up by means of transmission measurements across the cross-section of the fibre. The first measurements were made on polyamide fibres. There was a good correlation between the dye content determined by extraction and the integral dye concentration determined by photometer microscopy.

Using the λ-scan program (Zeiss), transmission spectra in the wavelength range 235–1050 nm can be taken from fibre cross-sections. In order to investigate the distribution of textile assistants in wool fibres, cross-sections must be prepared. Wool fibres are embedded in a shrinkable sleeve in a quick hardening two-component epoxy resin glue, whereby the wool fibres must be arranged so that they are as parallel as possible. After polymerization the tube is inserted into a wax block; cross sections are prepared with the aid of a hand microtome. Section thicknesses of 20–40 μm have proven themselves; the precise determination of the section thickness takes place by light-microscopy. Fibre cross-sections are scanned in a suitable embedding substance with the aid of the APAMOS program (Zeiss) in 2 μm steps (Fig. 1). At least 20 cross-sections of the average fibre diameter are analysed and this information is used to determine the transmission profile. The

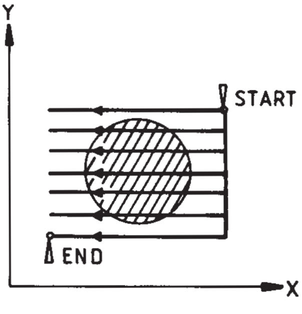

Fig. 1: APAMOS program for scanning fibre cross-sections (Zeiss).

migration of the textile finishing substance in the fibre is determined by evaluating the transmission profile.

The following method is used to determine the degree of dye penetration and the dye distribution over the fibre cross-section by photometer microscopy:

First, 40 µm thick fibre cross-sections are produced by using the traversing microtome on representative, dyed samples. The selection of the fibre cross-sections for analysis is made according to the unit distribution for the total sample, with a total of fifty fibres being measured. Then the transmission profiles are determined over the cross-section at the wavelengths λ_{max} red = 525 nm and λ_{max} blue = 630 nm.

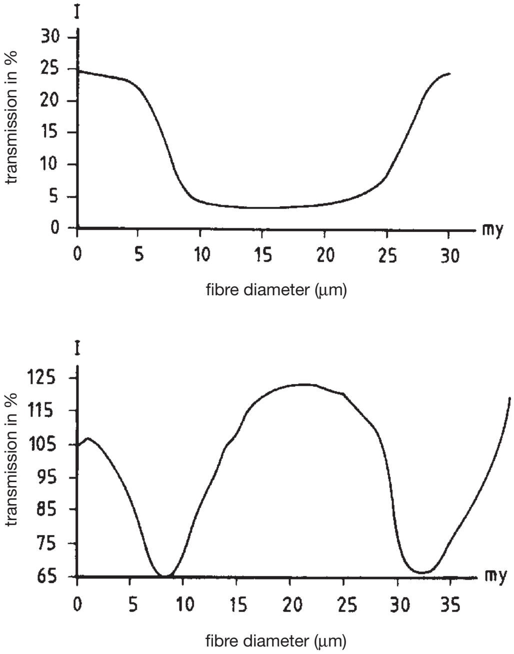

Fig. 2: Transmission profiles of woollen combed tops treated with UV absorber, measured at 350 nm (top = even dyeing; below = ring dyeing) (according to Blankenburg).

The transmission profile of a dyed wool fibre schematically represented in Fig. 2 is analysed according to the following aspects (whereby the definitions shown in Fig. 3 apply):

- the characteristic variable “relative dye penetration degree” is determined as a measure of the diffusion of the dye
- the characteristic variable “relative dye absorption” is determined as a measure of the dye concentration.

This procedure can be used for the evaluation of the photometric transmission measurement, because the absorption spectrum of the dye is known, the wavelength of the transmitted light and the thickness of the fibre cross-section (microtome section) are constant and thus diffusion and distribution of the dye can be determined (Blankenburg, Laugs and Souren, Schäfer).

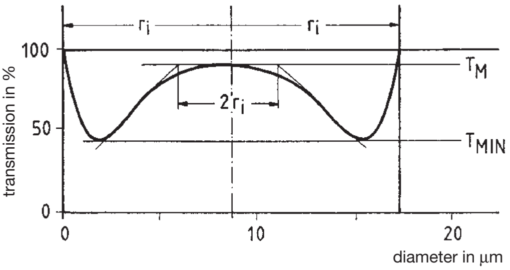

Fig. 3: Transmission profile of a dyed woollen fibre across its cross-section.

T_{min} = local minimum of the transmission value, preferably in the external area;
T_{max} = local maximum of the transmission value, preferably in the middle;
r = radius of the wool fibre;
r_F = radius of the transmission plateau in the range of T_{max};
A = transmission area of the undyed fibre = 2 · r · 100%;
A_F = loss of transmission area due to the dyeing =

$$A - \int_0^{2r} T \cdot dx$$

rel. dye penetration in %

$$= \left(\frac{\pi r^2 - \pi r_F^2}{\pi r^2}\right) \cdot 100\,\% = \left(1 - \frac{r_F^2}{r^2}\right) \cdot 100\,\%$$

rel. dye absorption in %

$$= \left(\frac{A_F}{A}\right) \cdot 100\,\%$$

Photometric measurements For the determination of the concentration c of a solution by determining the → Extinction E (Lambert-Beer law):

$$E = \log \frac{I_0}{I} = d \cdot \varepsilon \cdot c$$

I = light intensity behind the sample;
I_0 = light intensity in front of the sample;
d = layer thickness of the sample;
ε = extinction coefficient.

It is irrelevant whether the solution is an electrolyte or a non-electrolyte and whether it has natural colour or secondary colour (released by addition of certain rea-

gents). Technically particularly well suited for low concentrations or substance traces. Diverse applicability.

As can be seen from the Fig., the dispersed particles bring about a scattering of the irradiated light. For the intensity of the scattered light, the theory of Tyndall scattering applies for particles that are smaller than the wavelength α of the irradiated light, whereby the intensity of the diffused light is proportional to the intensity of the irradiated light, the concentration of the scattering particles and the sixth power of its diameter and inversely proportional to α^4. Furthermore, the diffused light intensity in relation to the particle size is also influenced by the scattering angle from the primary beam.

Photone printing A negative is first developed as normal from the photographed pattern to be used in printing, and from this negative a transparent positive is produced. This is placed upon a glass roller, which contains a mercury vapour lamp, around which the fabric, which has been impregnated with light sensitive dye (→ Photographic printing) is allowed to run. After fixation, rinsing and drying the fabric has the transferred pattern, which although it is in a single colour has all pattern details.

Photoreproduction on aluminium oxide layers According to the following principle: Impregnation with light-sensitive silver salts, copying, developing, fixating, toning, rinsing. Whereas the so-called Seofoto procedure is tied to the manufacturing location of the aluminium plates, in the so-called Al-phot process the silver salt is stored at the depth of the oxide layer and can be stored for any desired time before use. Light sensitivity is only created after dipping into a simple sensitizing solution. Further processing takes place as for normal photographic paper. This requires only a few tanks, developing tray and a copying device. Picture reproductions can be kept for an unlimited period, and are corrosion and fire resistant. Subsequent dyeing of the aluminium layer is also possible.

Photoscreens → Screen making.

Photosensitive coatings Photosensitive coatings are increasingly competing with chrome gelatine in the manufacture of screen printing screens. These coatings mainly use → Polyvinyl alcohol which has been sensitized using chromium salts. Such photosensitive coatings have better adherence, contain no water soluble components when illuminated and always have sharp, unchanging contours. The screens are coated cold, in daylight. It should be noted that these coatings require slightly longer illumination times.

Photosensitive lacquer Forms the basis for the creation of printing screens, because once illuminated it takes on lacquer-like solidity and resistance, i.e. after illumination no further reinforcement is necessary (→ Positive process for screen making).

Photosensitive layers Used for → Screen making.

Photosensitive screen coating Layer of photosensitive lacquer applied to the gauze during the manufacture of screen printing templates, which hardens due to the effect of light.

Photostable Light resistant.

Photosynthesis The Fig. shows the first stages of photosynthesis in the inside of a cell. Sunlight strikes the reaction centre and triggers the release of one electron (e^-) after the other. So an electron circuit is kept in motion, which “pumps” a proton (H^*) from one side of the membrane to the other for each revolution. A charge gap, similar to that in a battery, is created. The plant uses this to convert low-energy molecules into high-energy molecules. The power of the sun is stored.

Photothermic The process temperature represents an important parameter in the stages of textile processing. It is responsible, amongst other things, for the accessibility of the fibrous material to dyes and its thermomechanical behaviour. Structural conversions at the glass transition point T_G and the effective temperature T_{eff} are critical for the thermic behaviour of the fibrous material. Whereas T_{eff} is set during thermofixation, T_G depends upon the process, e.g. heating rates. One analysis method that is available is → Differential Thermal Analyis (DTA). This method is however limited to laboratory analysis and is not suitable for measurement in inaccessible areas or atmospheres. One possibility for analysing the parameters in the process is the use of photothermic radiometry (PTR), a process for the determination of thermal properties of materials. The measuring principle largely consists of the generation of a temperature gradient by the irradiation of energy, e.g. by the light from a laser. The temperature increase created in this manner, which is characteristic of the thermal and optical properties of the material, can be detected by means of an infrared sensor. The signal can be used to make predictions regarding the thermal properties of a material. The advantage of this procedure is the fundamental possibility of non-contact

Photostable Light resistant.

Photosynthesis The Fig. shows the first stages of photosynthesis in the inside of a cell. Sunlight strikes the reaction centre and triggers the release of one electron (e^-) after the other. So an electron circuit is kept in motion, which “pumps” a proton (H^*) from one side of the membrane to the other for each revolution. A charge gap, similar to that in a battery, is created. The plant uses this to convert low-energy molecules into high-energy molecules. The power of the sun is stored.

Photothermic The process temperature represents an important parameter in the stages of textile processing. It is responsible, amongst other things, for the accessibility of the fibrous material to dyes and its thermomechanical behaviour. Structural conversions at the glass transition point T_G and the effective temperature T_{eff} are critical for the thermic behaviour of the fibrous material. Whereas T_{eff} is set during thermofixation, T_G depends upon the process, e.g. heating rates. One analysis method that is available is → Differential Thermal Analyis (DTA). This method is however limited to laboratory analysis and is not suitable for measurement in inaccessible areas or atmospheres. One possibility for analysing the parameters in the process is the use of photothermic radiometry (PTR), a process for the determination of thermal properties of materials. The measuring principle largely consists of the generation of a temperature gradient by the irradiation of energy, e.g. by the light from a laser. The temperature increase created in this manner, which is characteristic of the thermal and optical properties of the material, can be detected by means of an infrared sensor. The signal can be used to make predictions regarding the thermal properties of a material. The advantage of this procedure is the fundamental possibility of non-contact

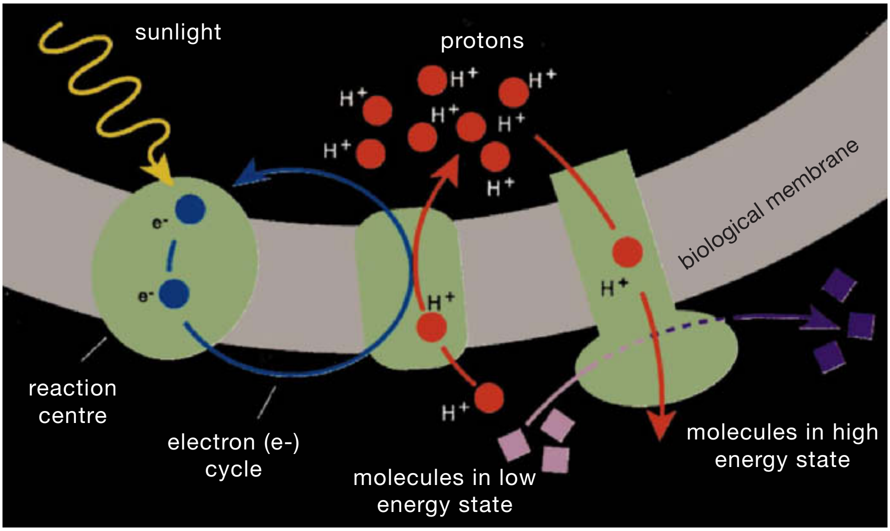

Fig.: Mechanism of photosynthesis within a cell.

and thus non-destructive measurement. In the use of the PTR in the textile industry, the influence of temperature on the expected measuring signal should be detected. Structural conversion points of macromolecules, such as glass transition points, premelting points (effective temperatures), are accompanied by a corresponding change in the thermal properties and therefore have a direct influence on the photothermic measuring signal (according to Schollmeyer).

Phototropism (Gk.), colour change due to UV light. Occurs if the dye reflects the UV part of daylight with longer wavelengths than that of visible light. This can be caused by after-treatments, such as anti-crease finishing, chintz finishing, etc. The normal shade generally only returns after long periods in the dark or when the material is irradiated with red light. → Photochromism.

pH paper Strips of indicator paper used for → pH measurement.

Phthalate resins (glycerol-phthalic acid resin, glyptal resins, glyceryl phthalate resins), group of → Alkyd resins, which are created by the esterification of → Phthalic acid and glycerol (therefore oil-free), are soluble in alcohol and are often used for the manufacture of paints; for water proof finishes, hat stiffeners, and in printing thickeners, coatings, etc. Also significant are so-called modified phthalate resins with condensed fatty acids, resin acids, etc., which also provide wash resistant fixation of colour pigments and at the same time give the material a full, not hardened handle.

Phthalates, phthalic acid ester Salts or esters of → Phthalic acid (exchange of carboxyl group hydrogen atoms by metals or radicals). Phthalic acid esters are used e.g. as plastification (softening) agent for paints, print thickeners (particularly based upon nitrate or acetate cellulose) in lacquer, bronze and pigment printing, and for coating, plastic finishing, etc. Compared to cellulose esters, phthalates act as a solvent and gelatinizing agent at the same time.

Phthaleins Derivatives of triphenylmethane-carboxylic acid (can also be understood as largely derived from xanthene, therefore → Xanthene dyes). Typical representatives are phenolphthalein, fluorescein, eosin, rhodamine.

Phthalic acid $C_6H_4(COOH)_2$, application: For the manufacture of → Phthalates, Phthaleins and modern surface active textile assistants (→ Sulphonated polycarboxyl acid esters and amides).

Phthalic acid ester → Phthalates, phathalic acid ester.

Phthalocyanine dyes possess extraordinarily clear, luminous colour shades with extremely good light fastness and usually excellent wear fastness. Constitution: → Metal-complex dyes.

I. Phthalocyanine metal complexes:

1. Soluble as direct dye type, made soluble by sulphonic groups. Individual, familiar, brilliant blue and green dyes have good light fastness and (with cationactive after-treatment) good wet, washing, sweat and ironing fastness; also good suitability for vulcanized items; for many purposes e.g. useful corrosiveness; however typically differentiated acid sensitivity. Application for natural and chemical fibres and for half-wool materials.
2. Primarily made soluble (vattable). a) Sulphur dye type, b) vat dye type in the form of “ansulphated” cobalt phtalocyanine with a clear blue shade, excellent light fastness and good washing fastness, but

only poor chlorine and peroxide bleaching fastness (not for bright bleaching items); easily vattable even with only a small amount of caustic soda liquor; particularly suitable as a dye for liquor dyeing of cellulose fibres with excellent dye penetration; c) cationic-active soluble type.

3. Insoluble copper phthalocyanine, sometimes strongly chlorinated, blue and green colour pigments with the clarity and brilliance of cationic dyes and the fastness of the best vat dyes for practically all fibre types, particularly for jet dyeing and pigment printing.

II. Metallizable phthalocyanine: A phthalocyanine, the solubility of which is brought about by acid groups, which subsequently form insoluble lacquers with chrome salts (phthalocyanine-chromium complex dyes). This lacquering occurs with exceptional speed and is controlled such that the reduction of the added chromates to trivalent chrome can occur at the moment the dye has penetrated into the fibre. Then the remaining bright blue pigment is fixed by steaming.

III. Metallizable phthalocyanine generated on the fibre: Synthetic generation of the dye/metal complex directly onto cellulose fibre by the pad dyeing process or direct printing; excellently reservable.

Phthalocyanine metal complexes → Phthalocyanine dyes.

Phycomycetes Aquatic fungi (→ Moulds).

Physical chemistry Science of mutual relationships between → Physics and chemistry and reaction research particularly of the fine structure of the atom (atomic theory, atomic energy), molecules, ions (colloid electrolytes), their behaviour in, and in relation to, other state forms and the regularity of chemical reactions, etc.

Physics (Lat./Gk.), science of conformity of regular and altered inorganic materials, energy and their transformation.

Physiological triangle → Wesel triangle.

Physiology (Gk.), study of the processes of life, in particular in humans, and their scientific relationships. →: Ergonomics; Clothing physiology.

PI,

I. Paper fibre (yarn), → Textile fibre symbols, according to the → EDP code.

II. Polyimides, → Textile fibre symbols, according to BISFA.

Piassava fibre → Palm fibres (Africa, Brazil) for mats, brushes, brooms, ropes, braiding, also stiff fabric. Light to dark coloured, containing silicic acid. Dyeing properties similar to coir.

Pick-and-pick bobbin changing (pic-à-pic), change of weft colour or weft thread after each weft insertion into the fabric.

Pickle (to) Treatment in special steel plants to limit corrosion due to chlorine dioxide during chlorite bleaching. This is achieved using concentrated solutions of H_2SO_4, HNO_3 and HCl.

Pick-up → Liquor pick-up as a percentage.

Pico- (Gk), standard unit for one trillionth = 10^{-12}, e.g. 1 pm = 10^{-12} m.

PID control (Proportional-Integral-Differential), generally valid temperature control principle that uses an additional measuring device to rule out variations in temperature control due to the delayed response of the control elements and guarantee an optimal constant temperature.

Piece-dyed goods Raw materials, which are dyed as a piece of fabric, in contrast to → Yarn dyeing or → Loose stock dyeing.

Piece dyeing machines (with fabric movement) The following general principle applies: the piece goods move, whilst the liquor remains stationary; for example → Winch beck, Jigger, Padder, Jet dyeing machines, Overflow dyeing machines. However, a clear demarcation of this type cannot be made. In jet dyeing machines, for example, both the material and the liquor are in motion.

Piece dyeing machines (with liquor movement) The following general principle applies: The liquor moves and the item to be dyed remains stationary; for example →: HT beam dyeing machines; Star frames. Only the discontinuous working mode is possible.

Piece dyeing plants Machinery, consisting of dye application equipment and associated fixing devices; sequence in semi-continuous or continuous processes (e.g. → Thermosol plants).

Piece glass (pick counter). A magnifying glass with horizontal and vertical measuring scales for determining the yarn count (woven fabrics) or stitch density (knitted fabrics).

Piece identification system If CIM (Computer Integrated Manufacturing) is to gain a foothold as a production control element in textile finishing, reliable piece identification systems are required. All such attempts have previously failed, because they were not universally applicable. Suitable piece recognition markings (e.g. using barcodes) must be resistant against

– mechanical effects (rope treatment such as milling, shearing, roughening, emerizing),
– against dyeing with disperse dyes,
– against shrinkage due to the effects of heat in order to remain readable.

Piece weight → Fabric weight.

Pie wool (pied wool), → Skin wool of hide pieces, obtained by bacterial decomposition.

Piezo- Relating to pressure, press. Piezo effect: electric charge caused by elastic deformation.

Piezo-electricity → Ultrasonics.

Piggyback process Term for a process used to prevent tangles in polyester fabrics in HT jet machines (caused by floating). A second piece is attached to the continuous rope.

Pigment The virtually insoluble, solid, finely dispersed colorant in binders, solvents or binder dispersants, which gives a coloured appearance when finely distributed. Application in the form of inorganic or organic pigment during delustring, in textile printing, in pigment dyeing, for paints, etc.

Plastics are dyed using soluble or insoluble, inorganic or organic dyes. Insoluble dyes are called pigments. Dyes and pigments are added to plastics in quantities of 0.001–5%. High demands are made in relation to heat resistance, dispersability, migration, light and weather fastness, physiological harmlessness, shades and price. Heat resistance is necessary due to the usually high processing temperatures. Light, weather and migration resistance and physiological harmlessness are tested by means of specific tests. The shade (shade, colour strength, colour purity) depends, in addition to the chemical constitution and the crystal modification, upon the particle size. Dyed plastics are transparent, if the pigment particles are smaller than half the wavelength of the light falling on the plastic. Pigments should have diameters between approx. 0.3–0.8 μm. Foils and threads up to a minimum thickness of 20 μm can be dyed using this type of pigment. For thinner foils or threads, so-called thread break occurs because the pigment particles are comparable in size to the foil thickness and the material breaks at the location of a pigment particle. Lighter shades can be obtained by grinding; however this also increases their swelling capacity. The coverage increases as the difference between the refractive indices of pigment and plastic increase.

Pigments can be inserted into the polymer by different methods. In soft polyvinylchloride they are usually mixed into the softener as a paste. In many cases a master batch (dye concentrate) is used or the pigment is mixed with a filler, to facilitate weighing. The surface of granulates are coated with pigment particles during mixing with pigments in granulate mixers due to the electrostatic charge; in this manner a total of up to 1% pigment can be inserted. Pigments used in lacquering and print pastes are often surrounded by so-called coating resins. So-called copolymers made of vinyl acetate and vinyl chloride, hydrated colophony or ethyl cellulose are used as coating resins.

Lumpiness of the pigments is determined by the inclusion of air; air is removed by the creation of a vacuum. Furthermore, pigments must be easily wettable. Improved wetting properties can, for example, be achieved by treatment with surface active agents. The totality of the pre-treatment processes for pigments is called conditioning.

The following inorganic pigments are most commonly used:

white: titanium dioxide (only rutile modification), ZnO, ZnS, lithopone ($ZnS + BaSO_4$).

yellow: CdS (acid sensitive), $Fe_2O_3 \cdot xH_2O$, $PbCrO_4$ (chrome yellow), benzidine yellow, flavanthrone yellow.

orange: pigments from the anthraquinone group.

red: CdSe, iron oxide red, molybdenum red and many organic substances.

bordeaux: CdSe, thioindigo, quinacridone.

violet: many organic pigments.

blue: ultramarine blue, cobalt blue, manganese blue ($Ba(MnO_4)/BaSO_4$), phthalocyanine blue.

green: chromium oxide, chlorinated copper phthalocyanine.

metal powder: aluminium.

pearly lustre pigments: leaf shaped lead carbonate.

(according to Elias).

Pigmentation processes for vat dyeing In a package dyeing machine, for example, these distribute the non-vatted dye first, in order to then make it soluble at the end of the exhaustion phase in the form of pigment adsorbed on the fibre surface. Normally the following procedure is followed for vat dyeing: Pre-vatting in the liquor (Fig. 1).

Benefits:

- preferred process for deep shades, including black;
- temperature stage variants (30–80°C) guarantee better levelling than other variants of the leuco procedure;
- result largely independent of the quality of the commercial form of the dye;
- suitable for all vat dyes.

Limitations:

- pre-vatting is labour intensive;
- preparation vessel is recommended;
- success depends upon levelling behaviour of the dye.

Vatting in long liquors is more widespread than the stock vat method, because handling is easier. This procedure can be used when the dye used has good levelling behaviour.

A time saving is achieved in the HT variant of the pigmenting process, as illustrated in Fig. 2.

Advantages:

- excellent levelling;
- virtually an “all-in” process.

Limitations:

- slightly limited dye selection;
- less suited for deep shades (rubbing fastness);
- special reducing agent necessary;
- reduction in degree of polymerisation possible;
- time consuming.

As a rule of thumb, the levelling capacity of a vat dye roughly doubles for each 10°C increase in the dyeing temperature. Due to the following advantages, the hot pigmenting process (Fig. 3) is widespread in practice:

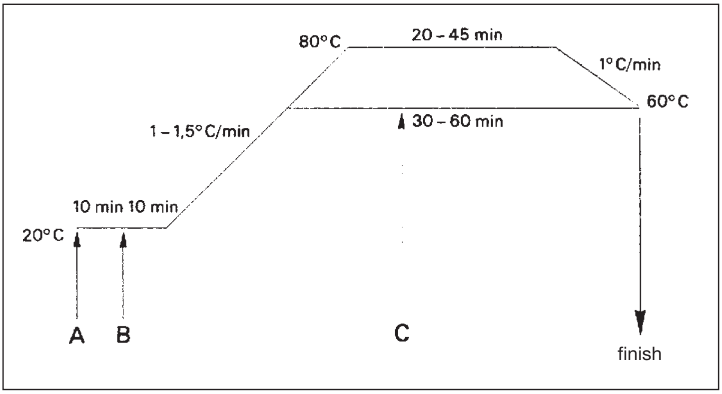

Fig. 1: Dyeing diagram for leuco processes (temperature level variants) with preliminary vatting. A = Albatex FFC (Ciba-Geigy), Irgasol CO (Ciba-Geigy) sequestering agent, dispersant additive, caustic soda, hydrogen sulphide (BASF), Albatex OR (Ciba-Geigy); B = stock vat; C = salt.

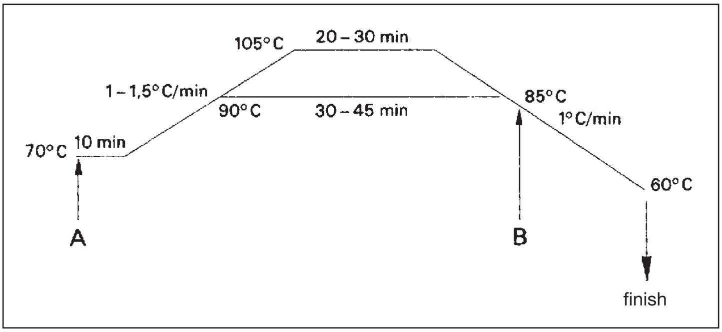

Fig. 2: Dyeing diagram for HT dyeing processes for pigmentation vat dyeing. A = Albatex FFC (Ciba-Geigy), Irgasol CO (Ciba-Geigy) sequestering agent, dispersant additive, dye, caustic soda, Rongal HT (BASF), Albatex OR (Ciba-Geigy); B = hydrogen sulphide (BASF).

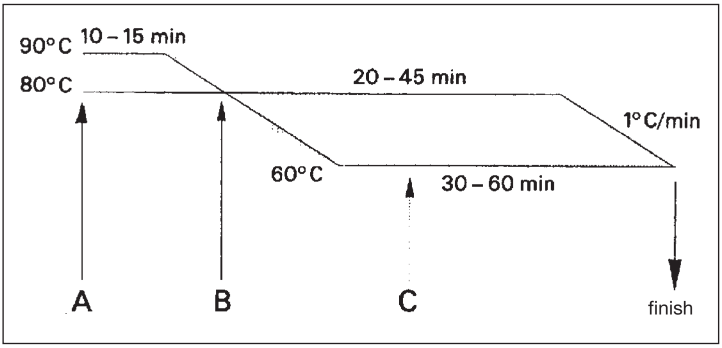

Fig. 3: Dyeing diagram for hot pigmentation processes. A = Albatex FFC (Ciba-Geigy), Irgasol CO (Ciba-Geigy) sequestering agent, dispersant additive, dye; B = caustic soda, hydrogen sulphide (BASF), Albatex OR (Ciba-Geigy); C = salt.

The greatest possible uniformity of pigment distribution on the material being dyed is striven for. A dispersing auxiliary is very useful. It is advisable to add caustic soda, reducing agent and levelling auxiliary together, because if caustic soda is added, agglomeration is only possible in the pigmenting phase.

Advantages:

- good penetration of the package at a high initial temperature in neutral medium;
- suitable for all shade depths (except black);
- problem free in difficult conditions, e.g. when using dyes belonging to different groups.

Limitations:

- not an “all in” procedure.

(according to Horn).

Pigment colorants Dyes with organic pigments, which are insoluble in water and only slightly soluble in organic solvents. Depending upon requirements, they can be applied as:

I. Metal free pigment dyes: Up to approx. 85% azo pigments (in particular red, yellow and orange shades). Further representatives of the carbonyl dyes are, for example, thioindigo derivatives, acrylamino anthraquinone, quinacridone, derivatives of naphthalene and perylene tetracarboxylic acid, indanthron and dioxazine.

II. Metal chelate complex pigment dye: Fastest blue and green pigments of insoluble phthalocyanine dye.

III. Colour lakes: The precipitation of water soluble dyes into slightly soluble salts. Earth alkalis, including bi and higher valent metal salts, are usually used as precipitating agents for anionic dyes, for cationic dyes hetero polyacids are used, amongst other things. Such colour lakes are manufactured from anthraquinone, azo, thiazine and triphenylmethane dyes.

Properties: Crystalline, particle size and dispersability represent critical preconditions for the application technology. They influence colour shade and colour intensity and are decisive for the resistance of usage options. Hardness and size of the pigment particles have a bearing upon the wear fastness of prints and are determined by the type of agglomerates precipitated during manufacture and drying. Excessively hard particles are difficult to reduce and disperse. Dispersability influences the stability of pigment distribution in the corresponding application media and can be improved by the addition of dispersants. The optimal particle size for pigments, depending upon application, is 0.05–0.5 μm.

Commercial form (so-called dispersal pigments, also formated pigments): Pastes, powder, platelets, flakes. Such preparations each contain additives suitable for the application. Pigment dyes for spin dyeing (spin pigments) must, as far as possible, guarantee a monodisperse pigment distribution in the spun substance, without the additive having a detrimental effect on the spinning process. Pigment dyes for printing and dyeing processes contain a binder that is necessary for anchoring to the substrate: Virtually all synthetic resins are soluble in water or solvents or are dispersible in water and also form a film that will bind sufficiently to the substrate. In pigment printing usually emulsion print pastes of W/O type (pigment dispersion in water) or O/W type (in organic solvent). Thickener and binder can be dissolved or dispersed in both the aqueous and the organic phase.

Pigment dyeing In the narrow sense it is an extension of the term → Pigment printing which is used to dye articles using pigments applied through the pad dyeing process. In terms of procedure it resembles the classic proofing process with pad-dye impregnating, drying and curing. The pigment dyeing process makes use of water-insoluble pigment dyes of either inorganic or organic nature which are fixed to the fibres with the aid of a fixing agent. Since no affinity between fibre and dyestuff is involved, dyeing can be carried out on all fibres and fibre blends. The following requirements for the fixing agent may be derived from the desired characteristics of the dyeing which results:

- bonds very effectively to pigment,
- a clear, colourless film,
- adheres well to the textile fibre,
- abrasion resistant, wash fast and can be dry-cleaned,
- minimal tackiness of film,
- very little or no hardening of the handle of the textile article,
- no yellowing, i.e. good light and aging resistance,
- resistant to mechanical and chemical agencies,
- compatible with other textile auxiliaries,
- smooth running characteristics,
- vessels, apparatus and machine parts can be cleaned easily and thoroughly.

These requirements can be met if the following conditions are applied:

- pigment dyeing without cross-linking agent, contains catalyst and anti-migration agent, fabrics have full handle.
- pigment dyeing with cross-linking agent, optimum fastness only in conjunction with cross-linking agent, fabrics have soft handle.
- pigment dyeing with and without cross-linking agent, fabrics have soft handle.
- pigment dyeing with and without cross-linking agent, particularly for dark shades with good fastness.

Even distribution of the dye pigment over the textile during dyeing is first and foremost a function of the machine technology. The pad rollers must apply pressure evenly. The dyebath must be agitated continuously to prevent settlement of the actual pigment. If possible air exposure should follow contact with the pad. Drying either in a hot flue or on stenter frames must proceed evenly and gently. Further, migration of the dye pigment must be avoided as far as is possible in the interests of even/level dyeing. It is penetration and migration which determine level dyeing (see Fig.). Penetration may be understood to mean the transport of pigment which begins with pad dyeing and must be concluded at least by the onset of drying. Penetration is favourably influenced by good preparation of fabrics and by a period of time (in air) between the pad dyeing

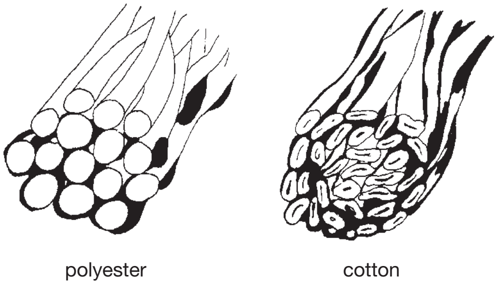

Fig.: Schematic representation of the distribution of fixed pigment on and within a thread made from polyester and from cotton; as a result of moderate penetration and/or of migration, the pigment is unevenly distributed (Bechter).

stage and the drying stage. In contrast to this, migration is a process which normally does not begin until drying takes place. Dyestuff migration may be minimized by the following means:

- reduced uptake of dye bath (greater squeeze pressure on the pad roller),
- adequate swelling time,
- gentle drying, i.e. reduction of fan speed and a maximum temperature of 120°C in the first two drying zones,
- anti-migration agent.

Ethylene/propylene block copolymer has proved effective as an anti-migration agent. At the onset of the drying phase the product physically absorbs the dye pigment and adheres it firmly to the surface of the fabric. At the same time it lends the textile both soft handle and good hydrophilic properties. Magnesium chloride or diammonium phosphate accentuate the anti-migration effect. The advantages of the pigment dyeing process are:

- Economy: one drying and curing stage instead of two production stages; large savings of water, chemicals and energy.
- Simplicity: pad dye impregnation, drying, curing; no post-treatment.
- Environmentally friendly: almost no pollution due to effluent or air except for formaldehyde given off by the fixing agent during curing.
- Fastness: wash fast in normal laundering and drycleaning, wear fast light colours and nowadays also dark colours; good to excellent light resistance.
- Universal application: all fabrics made from natural, synthetic and fibre blends can be dyed uniformly

(according to Haug).

Pigment dyeing process The simplest dyeing process which excludes affinity problems. The dye is padded, the material is dried and heat set. After-treatment is not necessary. Good fastness. Wash fastness depends upon the binder and not the dye. Suitable pretreatment necessary to create good absorbency, as are faultlessly functioning padder and drier (dye migration). Only light shades and possibly some medium shades are possible because the rubbing fastness is insufficient in darker shades. The pigment dyeing process is suitable for all natural and synthetic fibres and is used primarily for cheap qualities. If light pigment dyeings are combined with pigment printing, then the intermediately dried padding is printed and then dyeing and printing are fixed together.

Pigment dyeings/prints, test for The most reliable methods by microscopic testing of a fibre cross-section at 100–250 fold magnification. Evaluation by dye pigment distribution:

1. Evenly distributed over the total cross-section = spin dyeing.
2. Only surface layer with intercalation, attachment or depositing = pigment printing, pigment dyeing.

Pigmented wool bleaching i.e. bleaching of black hairs, that occur individually in wool fibre fleeces of white-yellow colour. The pigment dye of the pigmented wool is charged in a ferric salt mordant with iron ions, which bond to the carboxyl groups of the pigment melanin. After the excess iron has been rinsed out of the white wool, the whole fleece is treated in a peroxide bleach, which primarily relates to the pigmented hairs due to the presence of the iron catalyst.

Pigmenting process → Solvent technology in textile finishing.

Pigment printing Printing technique based upon a system of pigment and binder. Water insoluble white or coloured pigments with no fibre affinity are fixed to the textile material using synthetic resin binders. It differs from normal printing in that the dye is present in the form of insoluble bodies with no affinity to the substrate.

This type of printing gained importance with the development of suitable auxiliary substances (binders/thickeners/softeners), and is now the most important printing process in the world, representing 50% of all printing. Advantages of this system are:

- simplicity, good value for money (absence of all after-treatment processes),
- high light fastness (the diversity of pigments permits a strict selection),
- in theory applicable on all types of fibres.

Disadvantages:

- low fastness level (rubbing fastness, solvent fastness),
- negative influence on material handle if a suitable softener is not used.

The shortcomings listed are dependent upon the type of fibre and the fabric structure of the substrate to be printed.

The fields of application of pigment printing are to be found in the domestic textiles sector, in the fields of garden, camping and furniture material and in the outerwear sector. Pigments are insoluble or only very slightly soluble (solubility < 0.001 g/l), colorants, which as a further characteristic have no affinity to the fibre. They are fixed by means of a binder that creates a film, which surrounds the colour pigment and is responsible for fixing to the substrate. In addition to the textile sector (printing and dyeing of textiles), this class of dye is also used for the dyeing of paints, rubber and plastics and in paper printing. In the textile sector, pigment dyes should only be used in low and medium concentrations for reasons of cost, because at higher concentrations a poorer colour strength build up occurs due to the overlapping of pigments on the individual fibre.

Pigment dyes can be subdivided into inorganic and organic pigments. Fig. 1, which shows the different pigment groups with one or more typical representa-

carbon black	
metal powder	bronze, gold, silver
metal oxides	Fe, Ti, Cr, Zn, Mn
inorganic salts	$PbCrO_4$, CdS, ultramarine, Berlin blue, $BaSO_4$
natural dyes	buckthorn yellow, catechu
colour lakes	naphthol pigments	metal complexes	 *Cu-phthalocyanine*
vat dyes	
Fig. 1: Representation of pigment dyes.

tive, should serve to illustrate the different types of soft pigment.

Previously, the pigments were generated on the fibre itself in material printing; this working method includes, for example, chromium green, iron oxide, Prussian blue and colour lakes of natural dyes. The growth of organic pigments increased the selection of dyes available. From a chemical point of view, organic pigments can be considered superior to all other dye classes. They differ from soluble representatives of a dye class due to the lack of solubilizing groups. Vat dyes, which in their soluble (reduced) form are also used in classical printing procedures, can be taken as an example.

Binder properties are primarily drawn upon to explain the fastness of pigment printing or dyeing, however the fastness of the pigments also plays a certain role. A great advantage of this dye class is its high light fastness, due to the fact that pigments are crystals, which consist of a large number of dye molecules. In addition to the binder film, the rubbing fastness is dependent upon the particle form of the pigment, because sharp edged crystals will more readily scratch the binder film under rubbing loads than rounded off shapes with fewer edges. Furthermore, the pigments must demonstrate solvent resistance and thermal resistance, i.e. they may not melt, sublimate or be destroyed at the application temperature. They must also be resistant to the assistants that are also used in the dyeing or printing recipe.

The particle size of the pigments influences the dye yield, the brilliance, the dye quality and some fastnesses. Excessively large pigment particles only achieve low dye yield and brilliance. The reason for this is in the lower total surface area of larger particles compared to smaller particles of the same mass. Likewise, binder coating is made more difficult, as for the pigment shape, which again results in a detrimental effect on rubbing and wet fastness. Large pigment particles can lead to an excessively skittery colour quality, and where there is an excessively small particle size there is the danger of the pigment diffusing through the network of the binder when solvent treatments are used, which leads to lower fastness. Furthermore, secondary agglomerates can form, i.e. two particles do not give rise to a uniform crystal of double the size, but an agglomerate of the two joined parts, that still exist as such. The formation of secondary agglomerates can be prevented by coating the primary particles with dispersants.

For the textile sector the particle size should be around 0.2–1 µm, an optimal size is achieved at 0.2–0.5 µm. The dye finish generally consists of a milling or kneading of the pigment with dispersant and water. Ethoxylation products are usually used as dispersants. This process brings about a reduction of the dye agglomerate, whereas the dye aggregate (particles bound by areas) is barely influenced. The formation and size of the aggregate can only be influenced within the manufacturing period. The dispersions obtained in this manner contain 25–45% pigments.

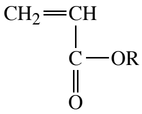
The binder serves as an adhesive between pigment particles and substrate. The properties of the binder determine the quality of the printed or dyed textile with regard to the quality of the handle and fastness properties. Due to the important role of the binder in the pigment process it is subject to a number of requirements:

– resistance against acids and lyes,
– wash resistance,
– swelling resistance,
– light fastness,
– resistant to ageing, weather and heat,
– dry and wet rubbing fastness,
– soft handle,
– physiological harmlessness,
– easy removal from machine components (e.g. rollers, screens, backcloths and rubber blankets,
– film formation.

The film formation properties represent the most important property of a binder. The film formed must be colourless, clear, of uniform thickness, neither too soft nor too hard, i.e. possessing elastic properties. Furthermore, it must coat and adhere to the pigment well and possess resistance to both mechanical and chemical loads. The listed requirements of the binder make it clear that the development of the pigment printing or pigment dyeing process followed the development of suitable binders.

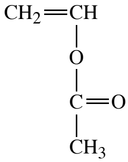
Modern binders are selected high molecular compounds, which are built up from single monomers by polymerisation, polycondensation or polyaddition. In textile printing, primarily weak dispersion binders are used, which are manufactured by emulsion polymerization. Common monomers are:

– different esters of acrylic acid (R = alkyl)



$CH_2{=}CH{-}C({=}O){-}OR$

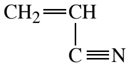
– vinylacetate



$CH_2{=}CH{-}O{-}C({=}O){-}CH_3$

– ethylene $CH_2{=}CH_2$

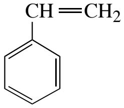
– acrylonitrile



$CH_2{=}CH{-}C{\equiv}N$

– butadiene $CH_2{=}CH{-}CH{=}CH_2$

– styrene



The homopolymers of the listed monomers cannot fulfil the diversity of required properties. For this reason, mixed polymers are used. These copolymers can be designed by targeted selection of the type and quantity of monomers according to the desired application. The glass transition temperature of the various homopolymers (see Tab.) represents a selection criterion. Because this has a direct relationship with the film hardness, predictions can be made regarding the handle quality. It is true from the Tab. that the film hardness increases with increasing glass transition temperature of the homopolymers. Thus certain monomers (those with high glass transition temperatures) do not come into consideration for the textile sector due to their excessive stiffening effect.

monomeres	glas temperature of polymer in °C
butadiene	–87
ethylene	–70 to –77
2-ethyl hexylacrylate	–85
n-butyl acrylate	–52 to –57
ethyl acrylate	–22 to –27
methyl acrylate	5 to 8
vinyl propionate	7 to 8
vinyl acetate	30 to 37
vinyl chloride	80
styrene	90 to 95
acrylnitrile (not fully crystalized)	100 to 106
acryl acid	166

Tab.: Glas temperatures of homopolymerisates.

Fig. 2 illustrates how a copolymer can be built up. If we conduct a polymerisation of two monomers of different hardness (butyl acrylate as the soft component and styrene as the hard component) then by varying the quantity ratios of the two individual components in relation to each other the softening range can be altered to suit the application. The softening range must be broad, because the temperatures, to which the pigment printed substrate is exposed, can be very varied (0–200°C). A quantity ratio of 60 parts by weight butyl acrylate to 40 parts by weight styrene yields a product that satisfies the main requirements. However, this copolymer also has disadvantages with regard to its resistance to higher temperatures and solvents. The latter can be achieved by the inclusion of a small proportion of a reactive compound, which brings about the cross-linking of the binder. If other monomer types are selected, the characteristics of this monomer give rise to corresponding relationships. So, if butadiene is used as the soft component a soft film is obtained with increasing butadiene content. This, however, has the disadvantage that the ageing resistance is greatly reduced due to the remaining covalent bond of the butadiene polymer.

In addition to variations due to monomer types and quantities, the degree of polymerization can be altered and thus influence exerted on the molecular weight and the chain length of the macromolecule generated. An important task of the binder is film creation. In order to make this possible the binder must be used in a suitable application form. It should be homogeneously distributed in the print paste and, if possible, uniformly separated. The aqueous solution and aqueous dispersion represent homogeneous distribution forms. The dispersion form is given preference due to the low viscosity, the high degree of water and wash fastness of the binder and the safeguarded procedure technique during manufacture.

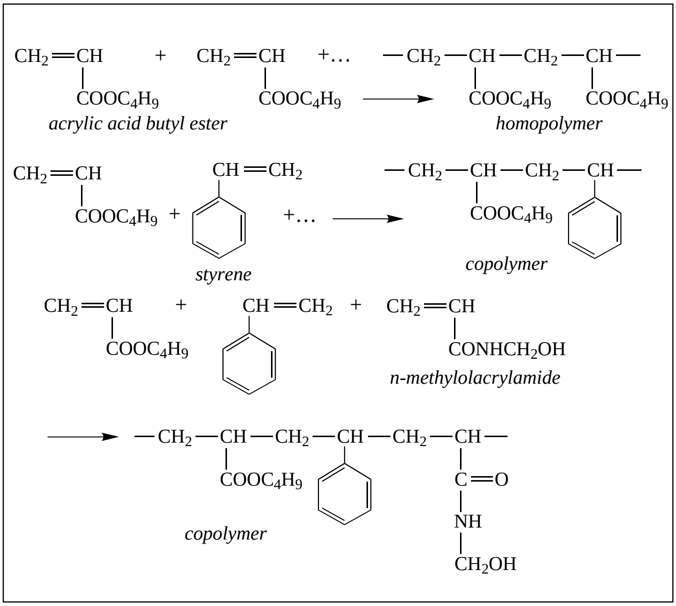


Fig. 2: Diagram representing a polymerization of butyl acrylate.

1. Self cross-linking: This type of cross-linking occurs if the chain molecules have reactive groupings such as N-methylol groups, which are capable of reacting with each other with the aid of a catalyst (acid or acid donor) at fixation temperature. Fig. 3 shows a schematic representation of this type of cross-linking, whereby N-methylolacrylamide has been selected as the reactive component. Both the condensation reactions described can occur.

2. Foreign cross-linking (cross-linking with additives): Multifunctional compounds in monomer or precondensed form, e.g. melamine resin or urea formaldehyde precondensate are added to the binder containing the functional groups. This type of cross-linking is necessary if the reactive group of the binder cannot react with itself (Fig. 4).

In addition to its influence on the viscoelastic properties, the cross-linking of the macromolecules also influences the swelling power of the binder film and thus the washing and solvent fastness (Fig. 5). By the formation of covalent bonds between the linear binder polymers, the rubber elasticity that exists to a small degree due to secondary bonds becomes more strongly marked. Rubber elasticity is the term used to describe the situation where exter-

Film formation takes place in two stages. First, water is extracted from the binder or print paste by vaporization and capillary action of the fibre and thus the stability of the emulsion removed. The disperse solids coagulate into a layer of thick spherical packings. In the second stage the coagulated particles coalesce under simultaneous deformation into a film surrounding the pigments. This has no elasticity and adheres only loosely to the textile, because the linear macromolecules can still move in relation to one another. It is only due to the cross-linking reaction that takes place during fixation that an elastic film is created.

We differentiate between two different types of cross-linking polymer binders:

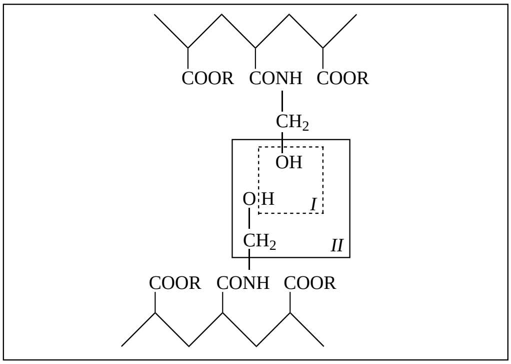

Fig. 3: Diagram representing spontaneous cross-linking.

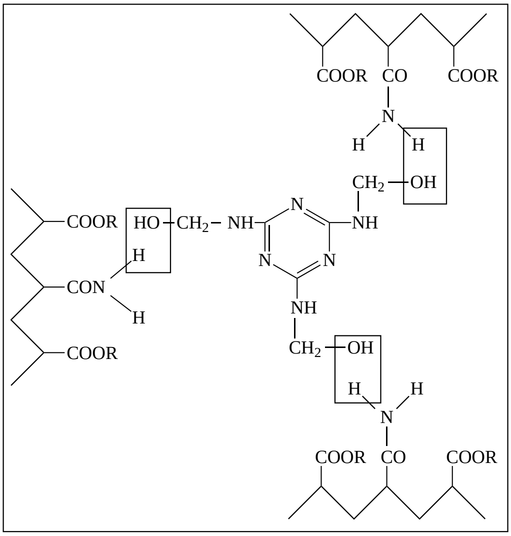

Fig. 4: Diagram of assisted cross-linking with acrylamide as the reactive component.

Pigment printing

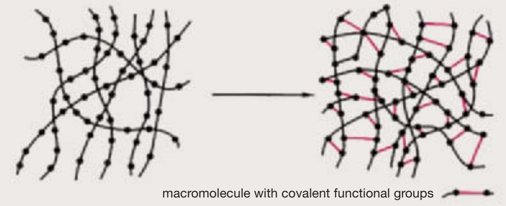

Fig. 5: Cross-linking of a binder film.

nally acting forces no longer impart lasting deformation; in the ideal case the deformed body can return to its initial position after the forces have been removed. As the degree of cross-linking increases, the swelling resistance improves, but the rubber elastic deformability falls; the film hardness is reduced. The objective of cross-linking is therefore to achieve the greatest possible swelling resistance with the lowest possible cross-linking.

The cross-linking takes place at the end of the whole process, because the binder for the pigment must remain accessible and able to be washed out of the substrate and devices for as long as possible.

The adhesion of the binder onto the dyed or printed textile determines the fastness to rubbing and washing of this substrate. We differentiate between three active components:

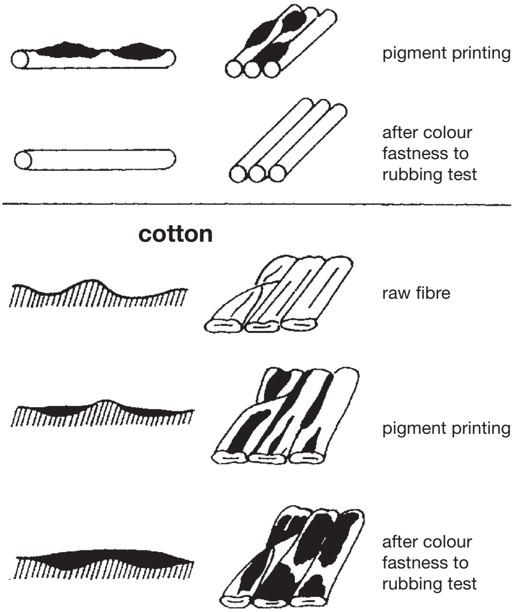

Fig. 6: Diagram representing the distribution of binder on polyester and cotton following shear loading (according to Bechter).

1. Physical bonding forces (adhesion forces) are dependent upon binder type and quantity of cross-linker. Fastness experiments have shown that for a given binder type the cross-linker concentration has no influence on the level of fastness of the substrate.
2. Chemical adhesion forces can only arise if both the binder polymer and the fibre material possess suitable (capable of reaction) functional groups. In the case of cellulose these bonding forces are so low that they can be disregarded.
3. Mechanical adhesion of the binder to the rough surface of the cotton fibre is the reason for the higher level of fastness of this type of fibre (Fig. 6).

A finished piece is expected to have a pleasant handle. Because a normal thickener, i.e. a water soluble high molecular bond, has a negative influence on the handle and wet fastness when inserted into the binder film, pigment printing was only able to achieve success after the development of emulsion thickeners. In these thickeners, benzine and water are used as the emulsion components, and they are known as oil in water or water in oil emulsions depending upon the distribution (Fig. 7).

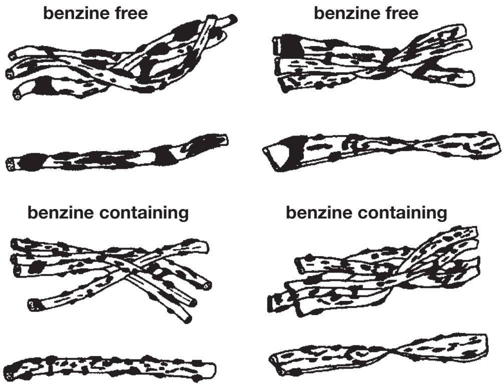

Fig. 7: Diagram contrasting binder deposition in the cases of benzine free and benzine containing pigment printing. Left: on polyester fibres; right: on cotton fibres.

A stock liquor (1000 g) contains the following approximate proportions:

150 g	water,
10 g	emulsifier,
50 g	low solids thickener (e.g. methylcellulose 7%),
30 g	ammonium sulphate 1 : 3 (as acid donor),
580 g	benzine (crystal oil),
180 g	resin binder.

The oil in water emulsion is formed from the water, emulsifier and benzine. The low solids thickener (methylcellulose) improves the printing properties of the print paste. The resin binder is the fixing medium, which is fixed by the acid donor (ammonium sulphate).

Naturally the benzine evaporates when the print dries, which is why the emulsion breaks down. The exhaust from the dryer must therefore be subjected to an expensive cleaning process using active carbon filters. Synthetic thickeners are better suited for pigment printing from an ecological point of view.

The following statement was taken as the starting point in the search for a thickening system with similar properties to the emulsion thickener: The product should be a high molecular, water soluble substance with high effectiveness, which is similar in structure to colloidal thickeners, but should show similar rheological behaviour to that of emulsions. Polymers were found in the homopolymers and copolymers of unsaturated acids such as acrylic acid (Fig. 8) and maleic acid (Fig. 9) that partially fulfilled the requirements.

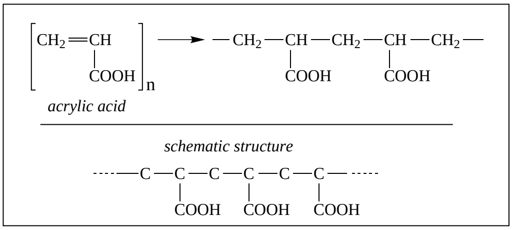

Fig. 8: Polymerization of acrylic acid.

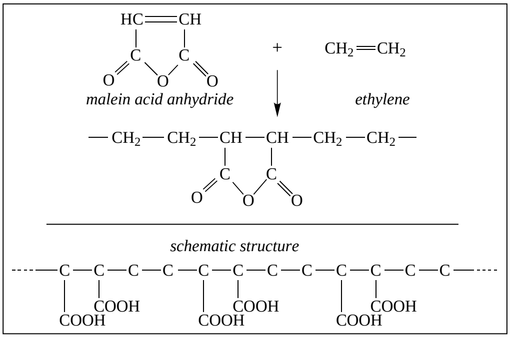

Fig. 9: Copolymerization of malein acid anhydride with ethylene.

The polymers are characterised by a multitude of carboxyl groups, which facilitate solubility in water. In aqueous solutions the macromolecules are present in the form of irregular balls. The viscosity of these solutions is in a functional relationship with the density of the balls, which is for its part dependent upon the molecular weight, the structure of the polymer chain, the solvation, the temperature and the degree of dissociation. If the acid groups are neutralised by the addition of alkali (e.g. ammonia) (if the acid groups go over from the non dissociated to the dissociated state), then a charge takes place along the chain, and the individual groups repel each other (Fig. 10). This causes an expansion of the molecule ball causing stretching.

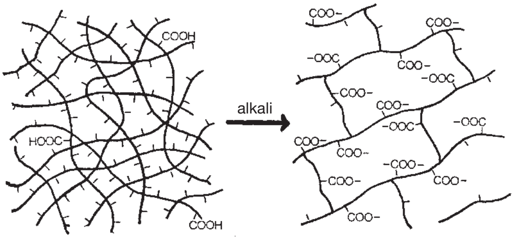

Fig. 10: Swelling of polymers caused by neutralization.

This increase in volume increases the viscosity, thus the effect of the thickener achieved. The viscosity increases until the balls have opened up to their maximum, which occurs before the neutralisation point. If further bases are now added, the dissociation is driven back (after a while quantitatively dissociated salts are formed), the balls shrink and the viscosity falls. This viscosity break down also occurs if ions are added in another form, e.g. as salts. For the printing company, this disadvantage of electrolyte sensitivity means that care must be taken that as little electrolyte is added to the print paste as possible. In the development stage described above, the thickener possessed good thickening properties but inadequate rheological properties. These could only be achieved by the addition of di or

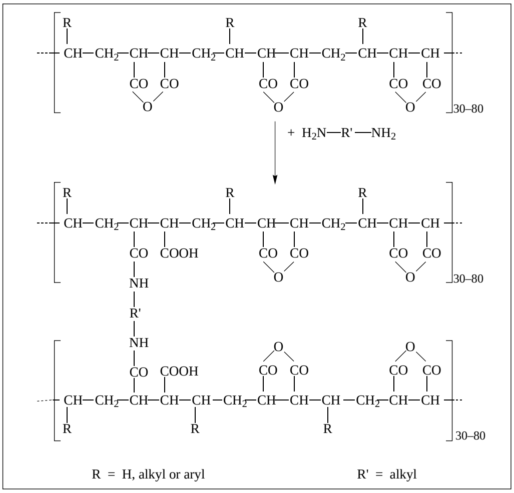

Fig. 11: Alternating copolymerisates of malein acid anhydride with olefines and subsequent cross-linking with polyamines.

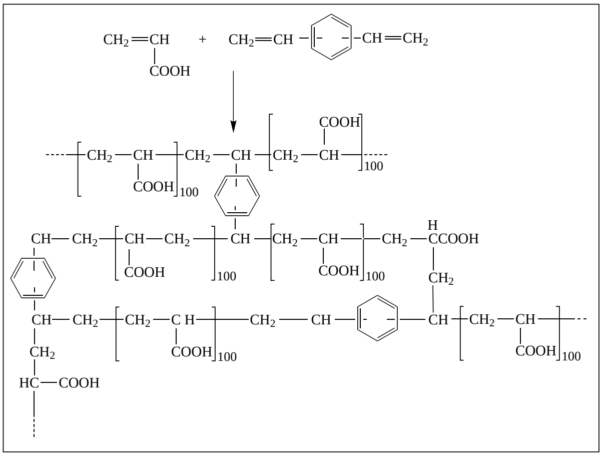

Fig. 12: Copolymerization of acrylic acid together with divinyl benzene.

trifunctional monomers into the polymer chain because they effect a cross-linking of macromolecules (as can be seen in Figs. 11 and 12).

By precise control of the polymerisation conditions it is possible to obtain polymers with a low particle size (1–10 µm) and targeted cross-linking. The cross-linked macromolecules are now no longer water soluble, but are still extremely swellable. The synthetic thickeners are low solids thickeners that can take on over 100 times their original volume in water. They are therefore particularly well suited for printing processes, in which a low solids content is desirable. Their rheological behaviour is characterised by a strongly falling structural viscosity with marked flow limits. This behaviour is caused by the deformability of the swelling bodies that occur in flow gaps. The polymer particles are aligned in the direction of flow and lose part of their solvate shell under the influence of shear forces, which leads to a rod-shaped deformation of the particles and can cause a loss of viscosity if the shear increases (Fig. 13). For pigment printing this viscosity behaviour facilitates the use of finer screen gauzes. Disadvantages of such thickeners are, in addition to the electrolyte sensitivity, the flushing sensitivity. This property can be improved by the addition of small amounts of colloidal thickeners or dilatant products such as polyglycolether derivatives. However, this results in a lower brilliance and colour depth of the prints.

Unlike pseudoplastic substances, these dilatant flowing substances show an increase in viscosity under shear stress (Fig. 14) (curve a). From a certain concentration the flowing resistance can become so high that the substances take on the consistency of a solid under certain circumstances. Depending upon the quantity of such products used in relation to the dispersion thickener (curve b) a viscosity curve is obtained with a correspondingly pushed out flow limit (curve c) and thus thickeners with altered printing properties.

The advantage of the pigment dyeing and printing process is that it can be used for many types of fibres

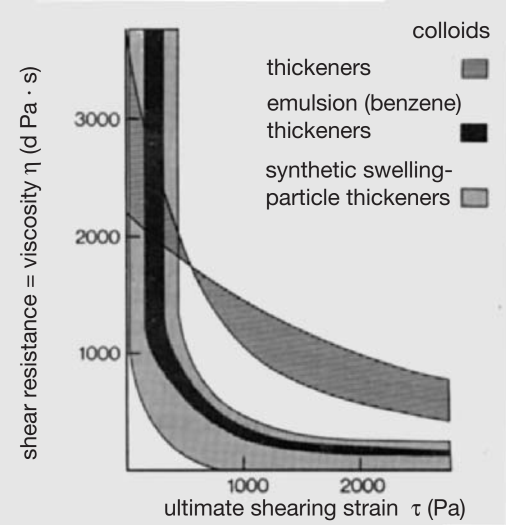

Fig. 13: Viscosity curves for different thickening systems (by Bayer).

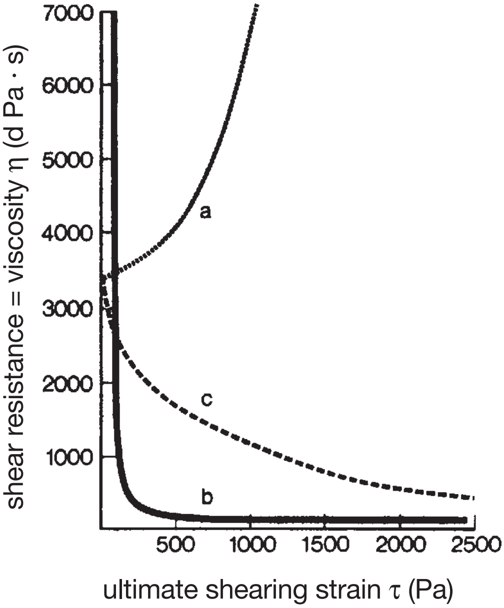

Fig. 14: Viscosity curves.

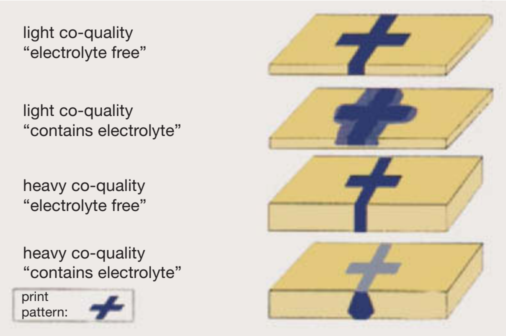

Fig. 15: Influence of the substrate on the outcome of pigment printing (by CHT).

and fibre mixes and is simple and economical to use, whilst at the same time yielding good fastness and general characteristics. A particular advantage of pigment printing is that it does not necessitate thickeners that need to be washed out after printing, as is the case with other printing processes. Originally emulsion thickeners with solvent naphtha were used for increasing the viscosity. Benzene free pigment printing is becoming increasingly common for ecological reasons.

In pigment printing every printer is familiar with the negative influence of excessive quantities of electrolyte on the material, but precise experimental regulations or even limit values for electrolyte concentration on the material are unheard of. The effects of material containing electrolyte on the printing quality in pigment printing are many. They extend from insufficient print stability, through colour shifts, to a worsening of the wear fastness of the textiles in question. It is common in practice for a pigment printer to have to print pretreated material from different finishers. Fig. 15 shows schematically the relationships in printing using pigment systems. If the printer has an ideally washed material available, then a good print stability and penetration would be achieved with both light and heavy material. However, if there is electrolyte on the material, the print on the light material quality will tend to bleed, because the print paste is not capable of distribution within the fabric. In heavy qualities, on the other hand, the print will penetrate too deeply, making the material appear significantly lighter (accordting to Becher, Wiggler, Burlesinger and Dorn).

Pigments for lustre and glitter prints The following pigments are used for special effects in pigment printing:

- metal pigments,
- pearly lustre pigments,
- glitter pigments.

The foil extraction process is also available for high lustre effects.

Procedures for the creation of laminar metal pigments use a highly pure copper cathode and a zinc electrolyte, because the pigments must be soft, ductile and extensible. The colour tones, the so-called natural colours, are determined by the zinc content, which can be 5–30%. The most important of the various alloys are:

- rich gold: Highest zinc content approx. 30%, colour yellowy green.
- rich pale gold: Medium zinc content approx. 20%, colour yellow.
- pale gold: Lowest zinc content approx. 10%, colour reddish.

The appropriate metal melt is poured onto horizontally rotating, water cooled disks and quickly solidifies to form palm sized disks of approx. 1 mm thickness. They are then reduced by cold working in ball mills in the dry (eddy mill) process or wet process (Hall process), with the addition of lubricants. During this process the surfaces of the freshly prepared metal pigments are covered with a lubricating film, thus preventing cold welding (secondary welding). Metal pigments of different sizes, shapes and properties are commercially available. Gold bronzes prompted textile printers to produce special lustre effects on textiles. They were put to use in ladies’ outerwear and decorative textiles. In addition to the so-called gold printing, silver printing using pure aluminium powder is also encountered. However, it has not achieved any great importance because it is associated with significant printing difficulties and fastness problems.

The fineness of pigments is of utmost importance for textile printers. Although the larger, predominantly laminar pigments provide the best lustre effect, they can block screen openings if the correct mesh number is not selected. Extremely fine, ball shaped pigments, on the other hand, allow problem-free printing; however the prints have a significantly reduced lustre effect. The size of the pigments for textile printing lies between 20–50 µm at a thickness of 0.3–0.5 µm.

Three main factors are of decisive importance for the quality of a gold bronze print:

- type of metal bronzes,
- selection of thickening system,
- selection of binder.

In the metal bronzes for textile printing we differentiate between single and coated types. Coating with a layer of silicium dioxide or a borate protects the metal against chemical influences and weathering. This also improves print paste stability and prevents premature “greening”. Gold prints using coating pigments have better perspiration and wash fastness (perborate-containing washing agents). No fine “void free” coating exists, and therefore it is not possible to provide complete and permanent protection against the above-mentioned influences.

The following thickening systems are available:

Pigments for lustre and glitter prints

Benzine emulsions, colloidal thickeners, dispersion thickeners. Print pastes based upon pure benzine emulsion have not proven themselves in practice, because they possess very poor running properties. Furthermore, the print pastes go green after a relatively short time; the keeping qualities of the print paste are very limited. Colloidal thickeners, on the other hand, have proven themselves, in particular polyvinyl alcohol and hydroxyethyl cellulose. In the first case, a high-solids thickener with high adhesiveness is available, which is particularly well suited for roller printing. Hydroxyethyl cellulose, on the other hand, (possibly in combination with polyvinyl alcohol) is better suited for flat and rotary screen printing because it is less detrimental to the handle of the prints, less than polyvinyl alcohol. Alginate thickeners are less favourable, because they do not react with the binders/cross-linking agents and thus achieve poorer fastness. When borate-containing bronze is used in conjunction with polyvinyl alcohol pastes a swelling of the print paste occurs in the alkaline range (above pH 7). This coagulation can be rectified by adjusting the bronze paste using diluted phosphoric acid at pH 7.

However, although bronze pastes used with synthetic thickeners provide prints of low hardness, the print pastes have a strong tendency to go green; their keeping quality is significantly poorer. The fastness level of the print also falls as pastes get older. This is due to the ammonium salt and the free ammonia in the print pastes because copper ions form, particularly under the effect of atmospheric oxygen (during the printing processes). These copper ions also damage dyeings using reactive dyes, because in the wet state (in washing during manufacture or domestic washing), depending upon the dwelling time, dye-metal complexes form that have a significantly altered colour shade. Only an intensive washing process using complexing agents may be capable of redissolving these complexes. Phosphate ions (diammonium phosphate) act against the greening of the pastes, because they precipitate the copper ions that are created. For these reasons, synthetic thickeners are not recommended for bronze print pastes.

Bronze pigments are fixed on the textile using both polyacrylate and polybutadiene binders. In specific cases, e.g. next to vat dyes in discharge printing, it may even be advantageous to use a polyurethane binder, because fixing is achieved by intensive drying of the prints above approx. 120°C.

Prints are often cold calendered on a calender at approx. 6 t pressure in order to improve the lustre, insofar as the printing material permits this. Printing with “silver bronze”, i.e. with aluminium powder, is not recommended because the print paste stability is not guaranteed. The pigments are coated with an hydroxide layer, accompanied by the formation of hydrogen, causing them to increase in size and block the print screens. The colour fastness to rubbing of such prints is poor, because the silver bronze has a strong tendency to “write” (determined by the softness of the metal).

Pearly lustre pigments (as suggested by their name) impart a pearly or mother-of-pearl type lustre. They are transparent, plate-like, thin, have smooth surfaces, high refractive indices and normally no intrinsic colour. Interference effects on and with suitable material are achieved by the precipitation of titanium oxide onto plate-like carriers, usually glitter. Printing with pearly lustre pigments is subject to the same condition as that described above for metal pigments: The diameter of the pigments is of significant importance for the lustre of the prints. The larger the plates, the greater the lustre effect, but the more problematic the printing process. The size of the pigments for printing is 10–50 µm. An opening of at least 3–4 times the plate size is necessary due to the so-called roof tile effect, whereby the pigments overlap like roof tiles, and can thus close screen openings. Because the pigments demonstrate indifferent chemical behaviour, print pastes with synthetic thickeners are the most favourable. It is important that the pearly lustre pigments are sufficiently well dispersed to be completely embedded in the binder system.

Glitter pigments impart a correspondingly high lustre due to their particle size. They are manufactured by the reduction of metallised foils made of polyester, polyepoxide or polyester/polyacrylate. They are gold, silver, mother-of-pearl in shade and can also be obtained in bright colours. Their high edge lengths (e.g. 0.2 × 0.2 × 0.01 mm) requires correspondingly large screen holes. In flat screen printing, gauzes with a maximum of 9 threads / cm should be used. In addition to possible clogging of the screens, there is also the danger of the print paste separating during printing. The specific light glitter forms a cream and floats on the surface of the print paste, but can be worked in again by intensive stirring. Therefore it is expedient to work from highly viscose, short print pastes, which hinder separation. The danger of flushing of prints during printing is particularly great with glitter, because these pigments remain on the surface of the textile due to the coarse nature of the pigments necessary for achieving the desired lustre effect. Multi-coloured prints using glitter pigments can only be achieved if there is an appropriate intermediate drying stage.

The foil stripping process for high-lustre effects takes place as follows: Metallically lustrous prints in gold or silver, but also bright and patterned (e.g. snake skin) can be created in melt-transfer. The textile is first printed with a suitable thermoplastic, colourless special adhesive. The drying temperature must not lie above the distortion temperature of the adhesive, so that the material does not stick together during plaiting down. Printed material and foil (with the matt foil side towards the printed material side) are combined on a transfer calender or a transfer press and, depending upon the type of adhesive, pressed together at 150–200°C under pressure. After the material has cooled the foil is removed. The points printed with binder appear as a pailletine effect. A closed, saturated binder film between textile and foil is necessary for good adhesion of the foil onto the textile. Such prints are effective, but unfortunately they are sensitive to alkali and ironing and furthermore often have insufficient washing fastness. In addition, the manufacture of such items is expensive, because the foil can only be used once (according to Wigger).

Pile,

I. Fine 2ply cellulose yarn, usually gas treated for weeds and mercerized.

II. Surface of velvet, plush and pile carpets in the sense of pile (III).

III. Right side material in carpets with marked three-dimensional character. According to DIN 6115: Material that forms the → Pile layer.

Pile brushing frame Used for the patterning of double ribbed fabric before → Moiring. The fabric ribs are scratched.

Pile carpets → Carpets with pile or → Pile layer (pile loops), in the form of knotted carpets, tufted carpets, or woven carpets; →: Axminster carpets; Bouclé carpets; Brussels carpets; Chenille, Plush carpet; Tapestry carpet; Tournay carpet; Velvet carpet.

Pile cutting machine Special form within the group of → Shearing machine. Whilst classical shearing machines always cut in several passes, new models make only a single shearing passage. Long pile items are cut to the desired pile height in a single stage. This makes it possible to economically reuse the cut off fibres.

Pile fabric Collective term for all plush, velvet, terry and carpet fabrics, whose decisive characteristic is vertical knops or loops, which are created by a certain pile warp. The loops may remain closed (frisé or bouclé) or are opened (coupé, e.g. velours). Cutting can take place directly on the power loom in single pile fabrics (Fig. 1) or on special cutting machines in the case of double fabrics (Fig. 2).

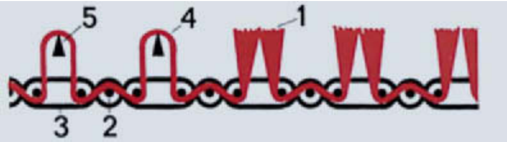

Fig. 1: Conventional process in which only a single woven fabric is produced.
1 = pile; 2 = weft; 3 = backing warp; 4 = pile warp; 5 = pile wire.

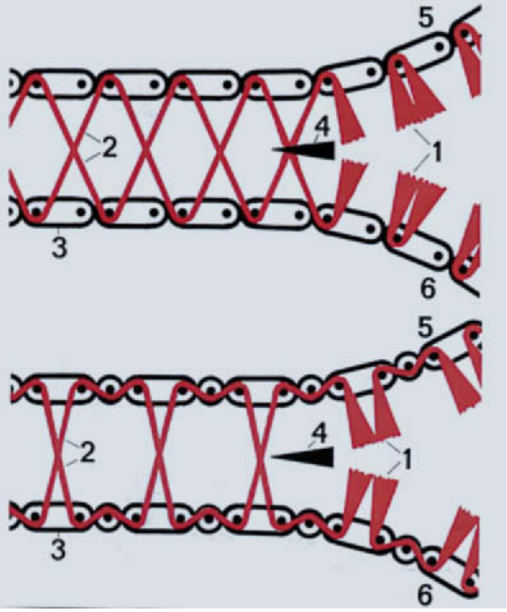

Fig. 2: More economical process for velour weaving; two woven fabrics are produced using a single pile warp.
1 = pile; 2 = pile warp; 3 = backing warp; 4 = band knife; 5 = upper weave; 6 = lower weave.

Pile firmness → Knops resistance.

Pile formation Undesired phenomenon in velour materials, particularly carpets. Pile fibres lie to one or other side in patches, giving rise to a blotchy appearance on the surface of the velour.

Pile goods Sheet goods, the third dimension of which in the form of thread or fibre ends (pile) is more strongly emphasized.

Pile height According to DIN 61151: Height of the pile layer above the carpet primary backing.

Pile-knitted fabrics Manufactured according to the type of → Plush cloth with pile surface, i.e. cut/shorn, pile quite short up to 14 cm long. Application for lining fabrics, outer cloth, imitation fur, blankets etc. Since the end of the 1950s particularly for imitation fur, for example, preferred base made of modacrylic fibres, also cotton, pile of polyamide fibres, or less commonly polyester and polyamide. The back is gummed, foam bonded, etc. if necessary. Sometimes such imitations are washable, but caution is advisable when dry cleaning, depending upon the material.

Pile layer Wear layer in carpet material (see Fig.) which contains an additional pile forming material above a special → Carpet primary backing.

Pile lifter Used in carpet shearing machines, for example, for aligning each pile row for shearing using a pile lifting roller fitted with special needles.

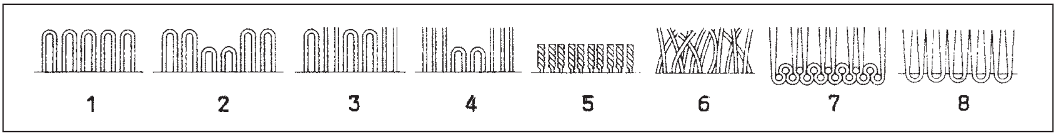

Fig.: Pile forms for carpets.
1 = level-loop pile; 2 = high-low pile; 3 = tip sheared pile (partially unsheared); 4 = cut-loop pile; 5 = Saxony; 6 = shag; 7 = woven tufting; 8 = tufting ware.

Pile-lifting machine Is used in the → Shearing of fabrics for the alignment of the pile or fibres to be sheared.

Pile loops,

I. In pile fabric systems that have closed or cut open yarn loops, typically for → Pile carpets.

II. Thread sections of the → Pile warp between the cutting/untying or bonding points. → Knops.

Pile opening With the aid of a pile opening machine (see Fig.) pile threads, which are usually made of twisted yarns, are gently opened in wool plush items, for example. The material is processed wet to minimize the material loss.

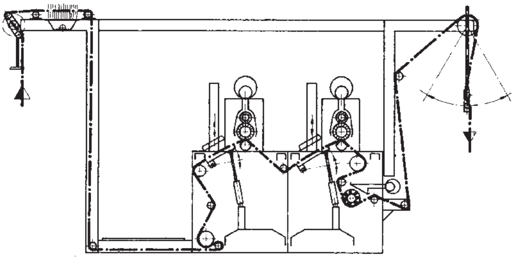

Fig.: Hergert PT II-D pile opening machine.

Pile patterning The surface of pile fabrics or pile knitted goods can be patterned using different methods:

- stencil brush (Fig. 1),
- whirling brush (Fig. 2),
- partitioned shearing tables, which are rotatable and driven (Fig. 3).

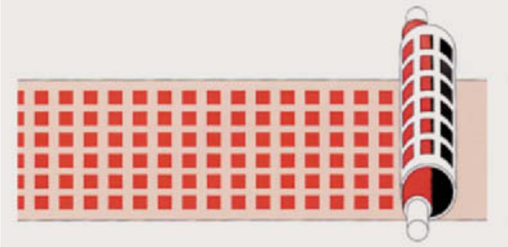

Fig. 1: Screen brushing.

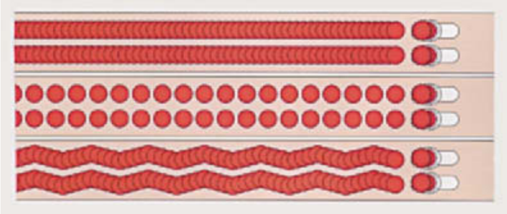

Fig. 2: Rotary brushing.

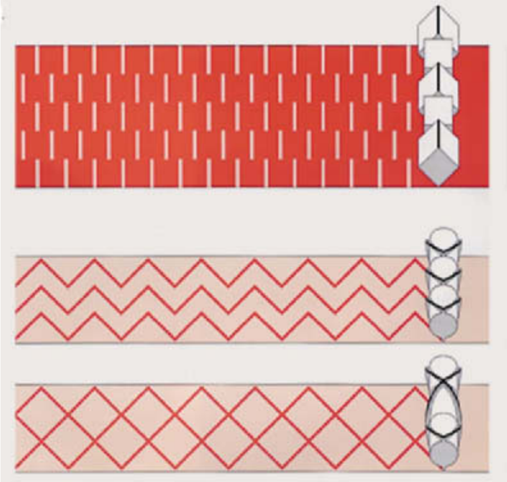

Fig. 3: Pattern cutting assembly with drive for geometric and floral designs.

Pile rotor → Glaze finishing machine (Fig. 1) for all pile and plush textiles with a working roller, the tem-

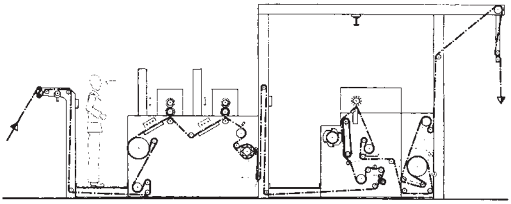

Fig. 1: Example of the final finishing of a acrylic velour by pile rotor treatment (right).

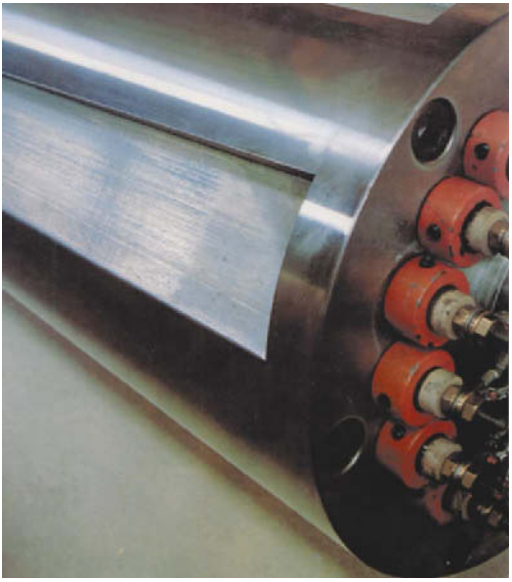

Fig. 2: Pile rotor with typical grooves and electric heating.

perature of which can be adjusted up to 500°C (Fig. 2). Roller rotation speed up to 1200 rpm. Material speed infinitely variable up to 15 m/min, working width up to 5000 mm. Lifts the pile of soft velours carpets and thus improves their lustre. Function see Fig. 3.

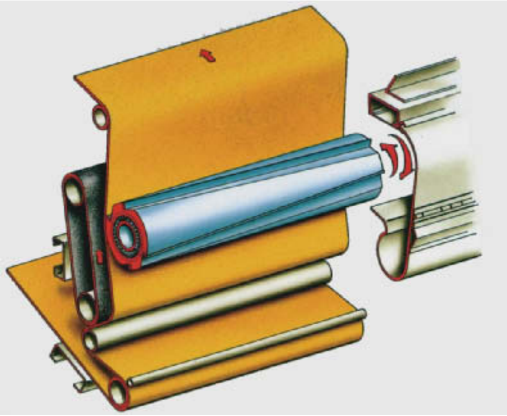

Fig. 3: Pile polishing unit (SMH).

Pile thermal treatment On thermally functioning → Raising machines for plush manufacture of synthetic fibres; can be used before and after dyeing. For final finishing of dyed material with shell damping, beaters and two infrared emitters and a cooling roller at the material exit, which prevents folding creases. When the material flow is interrupted the hot plate is pneumatically swung back from its work position, preventing the possibility of damage to the material.

Pile thread → Pile yarns.

Pile warp Warp ends for the creation of the → Pile layer and its bonding into the → Carpet primary backing.

Pile weight,

I. Weight in grams of the pile yarn processed per m^2 of carpet.

II. Weight in g/m^2 of the pile material protruding above the carpet base; determined by shearing (shaving) the pile.

Pile wires Thin metal rods used in weaving technology for pile fabrics. If the pile threads are to form drawn loops or pile loops, tension pile wires (with cutting blades on the end) are used.

Pile yarn → Pile.

Pile yarns Threads in → Velvet or → Plush, which form the characteristic pile. This occurs by threads being placed across thin metal rods (pile wires) during weaving, which are subsequently pulled out, creating loops over the base fabric, which can also be cut open. If the pile yarn is a warp thread this creates warp velvet; if it is a weft thread it creates weft velvet.

Pilgrim-step processing In order to increase the dwell time of material in a liquor, whilst keeping the material in motion with a short liquor ratio, a type of motion can be used that is reminiscent of the Echternacher spring procession: 3 forwards, 2 back.

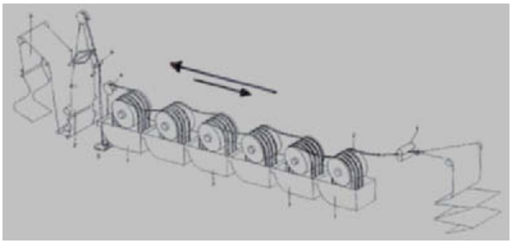

Fig.: The Rope-O-Matic principle.
1 = feed rollers; 2 = winch; 3 = washing vats; 4 = run-out winch; 5 = control panel; 6 = paired squeezing rollers; 7 = rope opener; 8 = plaiting down system.

The principle underlying the Stork Rope-O-Matic (see Fig.) is that at speeds of 30 m/min the bobbins carrying the fabric in rope form periodically change their direction of rotation, instead of having a continuously rotating movement. This pilgrim step movement of the bobbins vigourously moves the rope in the liquor, protectively, backwards and forwards, thus achieving a good washing effect. The forward speed is continuously variable. At speeds above 30 m/min the pilgrim step movement automatically switches off and reverts into continuous movement, which is adjustable up to 75 m/min (120 m/min in special cases).

Pillar stitch So-called single chain stitch seam, in which all stitches consist of one thread system and are easy to undo again, e.g. as decorative stitching and as piece goods sewing.

Pilling (pills, from the Lat. pila = hair balls), faulty, knop-like places that arise at points on clothing that are subject to particular wear due to the undesired rolling together of fibre ends on the surface of the fabric. It gives rise to a rough material surface (pilling effect) which is virtually impossible to dye uniformly. Most common on mixed fabrics and knitted goods made of wool with synthetics (polyamide, polyester or polyacrylonitrile fibres), also in pure synthetics.

Pilling is caused by rubbing and chafing. Textile surfaces made of staple fibres are affected. There are several factors responsible for this effect, for example, material, bonding, density, etc. Internationally, there are many different methods for evaluating the susceptibility of clothing materials to pilling, none of which are satisfactory for all applications: They are suitable for specific fabric or knitgood constructions or fibre types. In Great Britain, the British Standard (BS) is based upon the use of the ICI Pilling Box; in the USA, the ASTM is based upon the Atlas Random Tumble Pilling Tester (RTPT, Accelerotor), whereas in France the Balprest device is used when testing according to the ITF procedure.

The testing conditions to be applied for each individual testing procedure are carefully determined. The assessment and evaluation methods for the pilled sample surface are determined after comprehensive correlations with practical experiments and all test methods are in practical use.

The process of pill formation and development is rather complex and the speed of the creation of pills depends not only upon the fibre properties, the yarn structure and the construction of the pattern, but it is also determined by the surrounding conditions and the intensity of the loading. In the field of outerwear there are even significant differences, e.g. between pullovers for women's outerwear, men's outerwear or children's outerwear or between rompers for babies and jogging suits for adults. It is difficult to simulate such differences by a test method, although each of the standard test methods attempts to introduce certain differences in the severity of the stresses. In the case of the ICI Pilling Box and the Balprest Instrument these are achieved by varying the duration of the test; in the accelerotor the testing conditions are varied by exchanging the abrasive canvas or adding cotton linters. Consequently it is unavoidable that when testing a sample according to the same test procedure and using the same testing conditions, these test conditions are often totally unsuited to the intended field of use.

Low pilling polyester fibres exist, primarily in the form of fibres for wool spinning, the development of which is being particularly furthered in Europe. These fibres corresponded with the required soft, woolly handle and the demands of spinning and weaving. The pilling behaviour was also satisfactory in practice. The use of certain treatments within the finishing process, e.g. singeing, could be reduced for these fibres, which preserves and does not detract from a good handle. The development of the "rotor" and "Air-Jet" spinning techniques and the associated increases in the speed of carding, drawing and spinning itself was only possible after the development of a PES standard cotton type fibre. Due to their low mechanical resistance in comparison to standard fibres, low pilling fibres have forced spinners and weavers to reduce the speeds of cards, drawing and ring spinners and weaving machines and to avoid processing on rotor spinning machines altogether. For polyacrylonitrile fibres, the influence of the spinning type on the pilling behaviour has been proven (see Fig.).

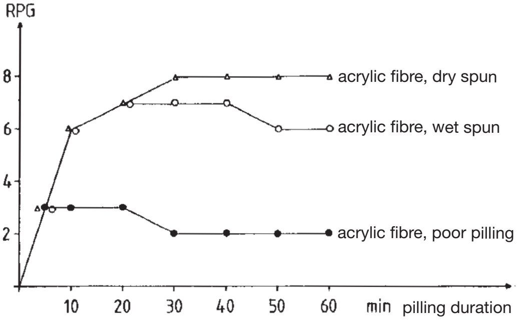

Fig.: Relationship between pill formation and the method of manufacture of the acrylic fibre; RPG (Reutlinger pill standard) = optical assessment grade.

The formation of pills may also be the result of inappropriate fabric construction. For example, pilling is promoted in mixed fabrics, particularly where there is a combination of a fibre of high abrasion resistance with a fibre of, at most, medium abrasion resistance. So, for example, there is some justification for thinking that softeners could promote this effect. Pill removal is dependent upon the material, and can be performed by shearing off or singeing but also by an → Antipilling finish.

Pilling behaviour, test methods Method: Fibre ends are extracted from the material by rubbing and balled by movement. Procedure and devices as for testing of → Abrasion resistance according to DIN 53 863, but with milder abrasive and lower stress.

Pilling effect, artificial Rarely used term meaning “pearl shaped” for the corresponding effects generated by → Friezing (pearl ratiné, perlé).

Pill in loop form → Pilling of texturized filament yarns in the form of twisted → Loop, which often also incorporates other fibre components. They appear mainly during processing as warp in loosely set elastic items, in which pill in loop is usually a result of increased surface wear perpendicular to the warp direction.

Pill test Method for testing the burning behaviour of carpets. A metheneamine pill is ignited upon the test piece and the combustion effects evaluated.

Pilot Dense, ribbed cotton fabric (a type of English leather or moleskin); usually dark coloured or black.

Pilot plant Semicommercial scale, in order to scale up experimental results from the laboratory scale, i.e. to reproduce them in the next largest scale.

Pin clips → Clips.

Pineapple cone → Biconical package, conical with spherical face. → Crosswound yarn package.

Pineapple fibre (pineapple leaf fibre) → Bromelia fibres.

Pineapple leaf fibre → Bromelia fibres.

Pine oil,

I. Product of destructive distillation (up to approx. 250°C) of resinous wood waste. Purified pine oil is extracted from raw pine oil, which produces a dark and unpleasant smelling oil, by the removal of acids, phenols, tar, etc.: Density 0.86, colourless to slightly yellowish, litmus neutral, with solvent properties and application similar to → Turpentine oils.

II. Wood turpentine, contains → Terpenes and considerable quantities of → Terpineol. Colourless to yellowish. Density 0.925–0.942. Soluble in most organic solvents. Application: Solvent, thinner, disinfectant, antifoaming agent, wetting agent, also for acetate delustring and as a swelling agent for polyvinylchloride dyeing.

Pink salt → Stannic chloride.

Pinning down In hand screen printing, fastening of the fabric onto the screen printing table, which is covered with felt and backcloth, or onto needle chains for linked fabric guidance.

Pin plates → Clips.

Pin wheel Derived from the → Palmer as a weft straightening device. The fabric runs on two inclined, non-driven (i.e. transported by the fabric) pinwheels (see Fig.). The wheels, which are each tilted forwards and outwards, create vectors in the warp direction, which accelerate the lagging weft side. When the pin wheels turn, their angle puts the weft threads under tension. This is therefore the setting device for positioning the two wheels in their angle in relation to one another. After a rotation angle of 180° between the in and out needling the weft thread position is once again at the right angle to the material warp.

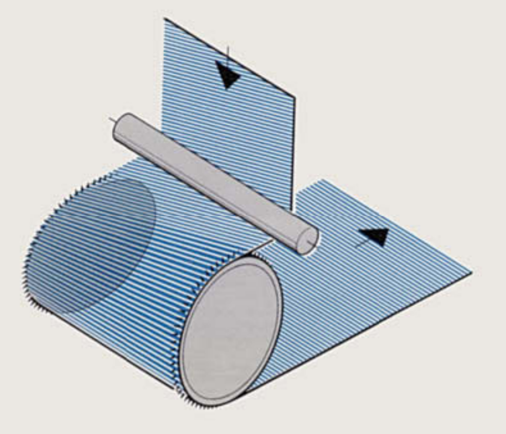

Fig.: Pin wheel device for aligning weft threads.

Pipette Narrow glass tube, with suction piece at the top, with a larger cylindrical area in the middle, pointed at the bottom; either with a calibrated ml filling mark (volumetric pipette) or graduated from top to bottom (scale pipette). Used for the removal of liquids during → Titration.

Pipework colour coding → Colour coding for pipework.

Piping Narrow border or strip of edging on seams, edges, collars and necklines.

Piping, cording Term for:

I. Yarn made of a large number of twisted individual threads.

II. Plaited threads, round cords.

III. Colored stripes or folds in clothes and uniforms.

Piqué (Fr: stepped), the characteristic stepped property is a result of the weave, sometimes also by an embossing treatment. Genuine piqué (fur piqué) consists of a fine plain weave top cloth and a coarse back cloth. The effect is created by filling and figuring wefts made of thick material and bound according to a pattern, which imprint onto the fine threaded surface to form the embossed pattern. In double piqué the material has two right sides. In press piqué, a non-genuine piqué, the figuring pattern is pressed into the smooth fabric by the embossing calender; often made durable by a special synthetic resin finish. These mechanically applied embossing effects are not always wash fast. Piqué matelassé, which has a relief-type jacquard pattern made up of 2 warp and 3 weft thread systems, is a piqué-like step fabric. A marked plastic effect is achieved by the internal filling weft. The plasticity can be increased still further by special finishing procedures due to a polyamide component in the material composition.

Pirn Short or long package, with or without cone, primarily for filling yarn.

Piston shaping unit Smoothly polished, perforated steaming and pressing piston, without a cover, for rapid special shaping of outer clothing. Different piston shapes, e.g. for upper section, shoulders and sleeves. Usually 2(–4) pistons per work table make up a so-called unit (set). Each piston has a steam supply, pedal operated, without or, more commonly, with suction. A pressing iron can also be connected to each piston (with a copper gauze filter insert to prevent water spots, or covered with sailcloth).

Piston steamer Piston steamer for the continuous dyeing of loose wool and polyamide flock. It consists of a long tube, which is steam heated by a double jacket and also has a connection for the direct entry of steam. Loose, impregnated fibres are inserted continuously into the steam pipes through a funnel, where pistons moving to and fro compress the fibres and propel them to the steamer outlet.

PIT → Phase inversion temperature.

Pita fibre → Mauritius hemp.

Pitch mark Several mm long indentation of approx. 1 mm diameter on the edge of the engraving of a printing roller for repeat setting.

Pitch pin Used for precise repeat setting of print rollers in the → Pitch mark.

Pitch pine Valuable American tropical wood type (pine), characterized by its special hardness and resistance cability. Used for bleaching and dyeing vats, which are also clad with porcelain or corrosion resistant metals.

Pitch tips Resin and pitch part of wool, characteristic of the sheep. Difficult to remove, they travel with the wool into the raw wool scouring, sometimes also to the milling stage, where they can be removed by appropriate fat-solubilising soap.

Pith straw → Straw.

Pitting corrosion (pitting), special case of → Corrosion, which appears in the form of point erosion and corrosion, in plates, equipment walls, etc. that are several millimetres thick, with undamaged areas between locally corroded points. Appearance after previous → Electrolytic corrosion mainly in solutions of halogens. Thus, special steels can also be rapidly locally corroded at points by solutions containing chloride ions (primarily at low pH and increased temperatures). Special steels containing molybdenum, on the other hand, are more resistant.

Pitting, selective corrosion,

I. In metals → Pitting corrosion.

II. In textiles: The → Alkali treatment of polyester with caustic soda liquor is not, as previously assumed, a weight reduction process in the sense of a transfer of the polymer mass in layers from the shell to the core. Rather, polymer degradation takes place in the form of point pitting corrosion (see Fig.).

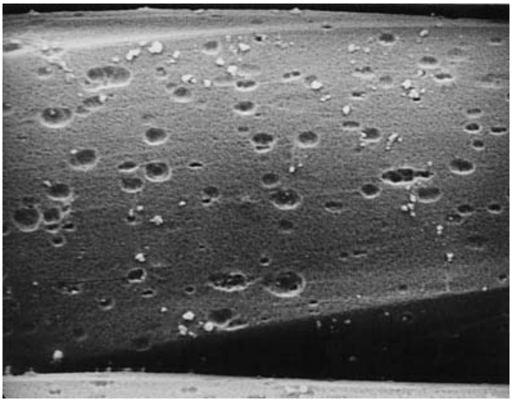

Fig.: Pitting on a polyester fibre exposed to alkali.

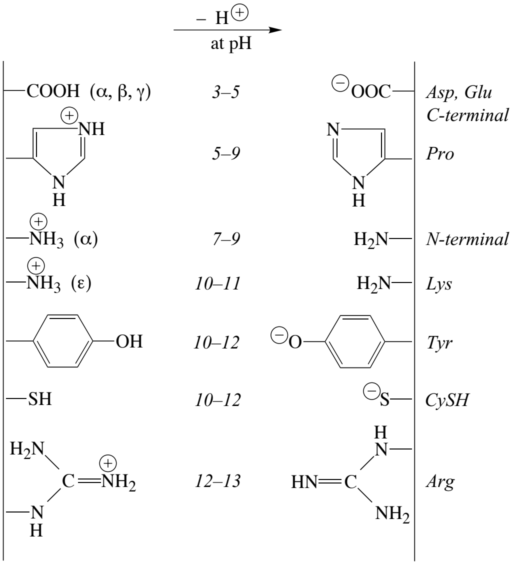
pK value Is the pH at which a compound splits off a proton by the addition of alkali or attaches a proton by the addition of acid. Plays a role in reactions of amino acid side chains of wool.



For example, if the pK_S value of peracetic acid lies at pH 8.2; at this pH there are the same concentrations of peracetic acids and peracetate anions.

PKN Polish standards association → Technical and professional organizations.

PKS bleach process (peroxide continuous fast process), the continuous immersion bleach process without a padder is suitable for the bleaching of all cotton, cotton mix and linen fabric as well as coloured fabric, particularly where relatively high demands are made of the material quality, such as good absorbency, absence of scale good handle, uniform degree of

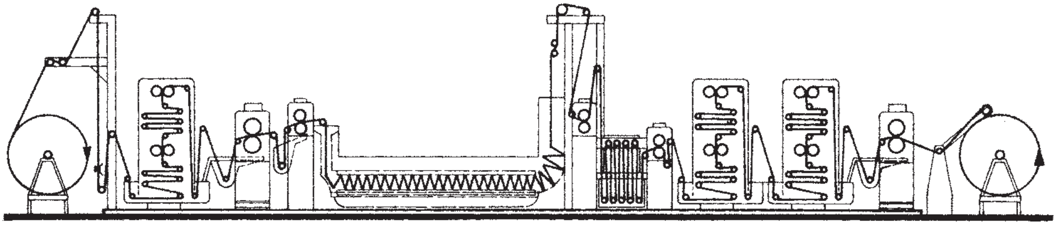


Fig. 1: PKS bleaching with immersion accumulator by Menzel.

bleaching, good material shrinkage, short bleaching time and low fibre damage. Bleaching takes place in strong, well stabilized peroxide liquor at 92–98°C with a dwell time of 8–20 min, chemical consumption approx. 20 ml/l hydrogen peroxide (35% by weight). The sectional drawing in Fig. 1 shows a continuous immersion open-width bleaching with tower washing units using the counter-current principle (economical water consumption 5–6 l/kg material).

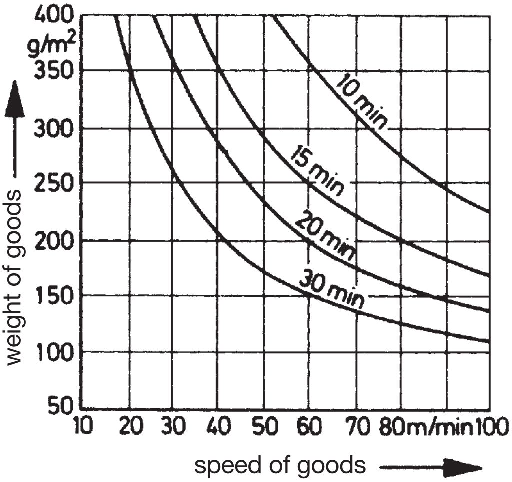

Fig. 2: Immersion time in the PKS bleaching immersion accumulator.

Fig. 2 shows material speed in relation to material weight and dwell time with an immersion accumulator (type 4000) with delivery lengths of 4 m.

PL → Polyester fibres, → Textile fibre symbols, in accordance with → EDP Code; → PES.

Place on the star frame, to Pinning piece material down onto the star frame of a star dyeing machine or star steamer.

Plaid Tartan fabrics; general patterning term for bright, checked fabric or cloth in wool, cotton, viscose, etc. The checked pattern is characteristic. Woollen plaids are woven from wool coloured carded yarns in a loose arrangement, usually milled and provided with a long nap. Application as travelling rugs and shawls.

Plain dyed fabric Single coloured, unpatterned.

Plain fabric Manufactured in plain weave, (usually) smooth material made of flax or cotton of different fineness, density and finish (the finest plain fabric = batiste).

Plain raschel fabric → Raschel-knitted fabrics, in which a guide bar forms the base and a further guide bar inserts a weft in accordance with the pattern, which achieves the side connection of the stitch wales (e.g. weft pattern).

Plain weave → Weave.

Plain weave cotton fabric Collective term for plain weave fabrics of different finenesses and thread densities made of single cotton yarn (nettle cloth, coarse cotton cambric), which are sometimes used raw, bleached, dyed or printed. The 3 basic qualities in increasing fineness of the fabric structure are a) → Cretonne; b) → Renforcé; c) → Calico.

Plaited goods wagon Means of internal transport for materials in stacked or rope form.

Plaiter Device for stacking material in folds.

Plaiting down Stacking of continuous fabric lengths (see Fig.) in a zigzag form. Takes up more space than batching.

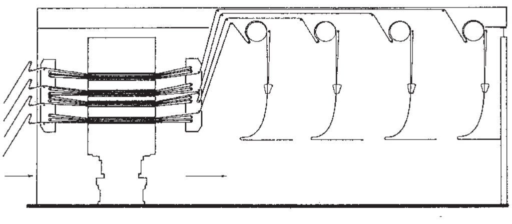

Fig.: Diagram of a Hattersley-Pickard intermittent operation boarding press (semi-continuous) and multiple plaiting down.

Planetary paddle mixer Mixing machine with two paddle mixers, which revolve around their axes and around each other.

Plangi (Malysian: bright, recessed spot), a resist technique that is still widespread in South East Asia and Africa (like the Japanese → Shibori technique) for the patterning of clothing materials. Before dyeing yarn package or binder resistance take place (→ Ikat), which appears as recessed pattern after dyeing. Stitch plangi is called → Tritik. In a wider sense the plangi technique is performed by folding, knotting or weaving, by screens, by resist application (sludge, paste, wax) and by negative resists using dye mordanting. Often several techniques are combined.

Planographic printing Mode of working in paper printing, whereby printing and non-printing positions on the printing block are adjacent in one plane and differ due to the application of a certain preparation which determines the acceptance or rejection of the print paste.

Plant comparison Comparison of the characteristics of different plants with the aim of selecting the most suitable plant for a given task. The following points are considered: a) Costs (plant and maintenance costs); b) Technology, operating safety, ease of combination; c) Performance parameters (cycle and operation characteristic figures); d) Delivery, guarantee and service.

Plasma Physics tells us that material is made up of atoms, which can themselves be subdivided into atomic nuclei and electrons. The decisive differences between the different states of matter is due to the compound make up of these particles. Plasma is the least organized collection of electrons and atomic nuclei, i.e. it is a mixture of these two components. The gaseous phase on the other hand, is characterized by the formation of atoms, the bonding of atomic nuclei and electrons. A further increase of order by the linking of atoms to form unordered, but dense bonds, allows the liquid phase to be created. The highest level of order is, however, in solid bodies such as crystals by the symmetrical organisation of atoms. The removal of the atomic bond between electrons and atomic nuclei, typical in plasmas, gives rise to the decisive difference between gases and plasmas. Whereas gases are electrically neutral, plasmas can conduct electric currents and can be manipulated by electromagnetic fields. Because this characteristic also occurs if the atomic bond is not completely ionized, and thus atoms have not given up all electrons, the term ionized gas and plasma are used synonymously.

Plasma is thus characterized by the following properties:

- contains an increased number of charge carriers (conductivity),
- quasineutrality (same number of positive and negative charges in a unit volume),
- increased energy and heat content,
- creation of equilibrium states (charge carrier formation and recombination is stationary),
- existence of speed and energy distribution functions (permit the characterization of the plasma by temperature).

Just as there are differences between individual solids or liquids, there are also different plasmas. An arc is fundamentally different from the discharge in a fluorescent tube. Primarily, the type of atoms and ions characterize the plasma. Further parameters that determine the properties of a plasma are energy content, pressure and expansion. Whereas in small plasmas, for example, those used in technical applications, the interaction of the plasma with its environment is of critical importance, this factor is of lesser importance for cosmic plasmas. Often it is just such boundary effects that are exploited for technical applications. So in arc welding, the interaction of plasma with a metal is exploited.

But the energy content is also an important factor for differentiating between plasmas, e.g. of the arc with a fluorescent tube. Whereas an arc possesses energy of a few kilowatts, the luminous discharge of a fluorescent tube only consumes a few watts. In addition to other parameters, pressure is critical in determining the properties of the plasma. Whereas arcs burn at atmospheric pressure (1000 mbar), the luminous discharge ignites in the region of 1 mbar.

Fig. 1 shows a classification of electrical discharges according to their current-voltage characteristic. After the application of a voltage to a gas line there is a region in which very low currents flow and this can be called the Townsend or non-self-maintained dark discharge. Adjoining this is a region called the corona discharge. It is characterized by a weak current discharge when a high voltage is applied (however an isolator hinders dielectric breakdown) in preferably bent elec-

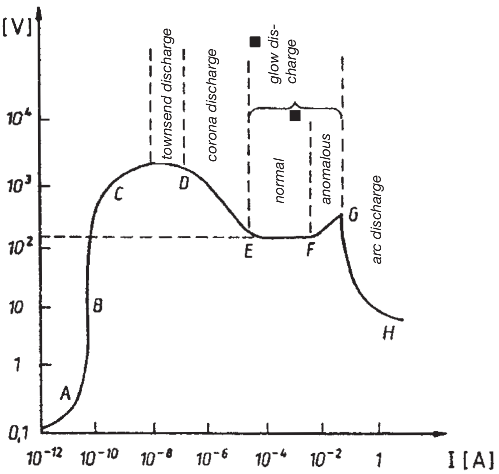

Fig. 1: The current-voltage characteristic of electrical gas discharges.

trodes accompanied by a weak glow. Luminous discharges occur at comparatively low pressures of approx. 10 mbar. In comparison to corona discharge, the luminous discharge can be performed at lower voltages and higher currents. Arc discharge represents the typical type of discharge at high pressures of 1 bar and above, in which very high currents occur.

Solid/liquid and liquid/gas phase transitions can be triggered by the addition of heat. At the same time we associate lightning, sparks and arcs with very high temperatures. The efforts to ignite a nuclear fusion plasma have also led to extraordinarily hot plasmas. Even though the temperature required for the self-sustaining ignition of a fusion plasma has not yet been attained, plasmas hotter than the sun have been attained. However, these high temperatures do not represent a necessary criterion for the existence of a plasma.

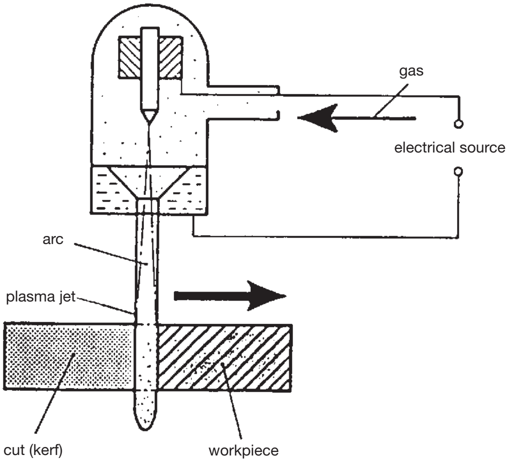

Fig. 2: Working principle of thermal separation with the aid of plasma.

In thermal cutting using plasma, the heat required at the work point is transferred to the workpiece by a gas in the plasma state (Fig. 2). Such plasma is an extremely hot gas with a temperature of 10 000–20 000°C, whereby all atoms split to create a mixture of ions and free electrons. The most common procedure for producing plasma is gas penetration through an electric field. This is achieved using a device commonly known as a “Plasma torch” and consists of a device that converts electrical energy into thermal energy and thus generates high-pressure plasma. When working according to the “not transferred” manner, the arc remains inside the torch. The high-temperature plasma jet is blown through the nozzle. Because the arc is formed inside, power consumption is limited by nozzle erosion. However, due to the precise construction of the internal torch geometry it is possible to maintain plasma jets with a small diameter and power densities of MW/cm^2. This torch type is suitable for cutting thin, non-conducting materials. The cutting process of the plasma jet consists of heat transfer from the jet to the cutting material by convection and the disposal of the material from the interface by mechanical means. The quality of cut performed by a plasma torch is influenced by a number of variables both inside and outside of the torch. New torch designs have reduced these to: arc power, gas pressure, nozzle diameter, distance (between nozzle and material), quality of the plasma gas. Cutting quality also depends on the cutting speed.

Torches are used for cutting textiles, from heavy polyamide belts to clothing materials. The latter field is of particular importance. Test cuts have been made on a number of clothing materials, such as smooth knitted wool, polyester, polyacrylonitrile, and cotton, with excellent results with regard to cutting quality and cutting speed. When cutting workpieces made of thermoplastic fibres the thermal procedure is superior to the conventional procedure when there is a small number of complicatedly shaped parts, for which even steel band cutters would not be economically viable. If there is a large number of different parts like this the need to keep stocks of tools is also dispensed with. However, the greatest advantage, particularly in the contactless thermal procedure, lies in the great flexibility in material and shape at low layer heights and in the possibility of integration into X-Y controlled plants with low tool mass at high path speeds. The development of cutting and separating techniques in textiles extends to complete plants including easily programmable controls and computers, in particular the guidance of crosswise and lengthways cutting and shape cutting are automated, giving rise to the need for light cutting heads.

In addition to this “hot” plasma, so-called “cold” plasma has increased in importance technologically. The word “cold” expresses the low energy content of these plasmas. Thermodynamically, temperature is defined by the movement energy of the particles. If we consider the kinetic energy of the two types of particle (electrons and ions), then we find that in low-pressure plasmas this energy is different for ions and electrons.

The electrical energy stored in the plasma is converted into the following energy forms:

– movement energy of the charged particles (electrons, ions),
– excitation energy of activated particles,
– electromagnetic radiation, which is emitted as visible UV and IR light and is a result of the recombination of the charged and activated particles.

The following elementary processes occur in plasma:

1. excitation: $A_2 + e^- \rightarrow A_2^{\bullet} + e^-$
2. dissociation: $A_2 + e^- \rightarrow 2\,A + e^-$
3. ionization: $A_2 + e^- \rightarrow A_2^{+} + 2\,e^-$

4. ionizing dissociation: $A_2 + e^- \rightarrow A + A^+ + 2e^-$
5. dissociation into radicals and ions: $AB + e^- \rightarrow A^\bullet + B^-$
6. electron capture: $A_2 + e^- \rightarrow A^- + A$
7. radical formation due to radiation.
8. formation of new molecules, atoms and radicals by neutralisation, recombination and structural reorganizations.

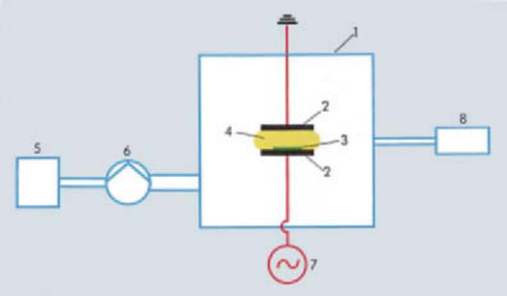

Fig. 3: Sketch diagram of a parallel plate reactor for plasma polymerization.
1 = vacuum chamber; 2 = electrodes; 3 = substrate;
4 = plasma; 5 = exhaust gas cleaner; 6 = vacuum pump;
7 = high frequency generator; 8 = gas supply (CH_4).

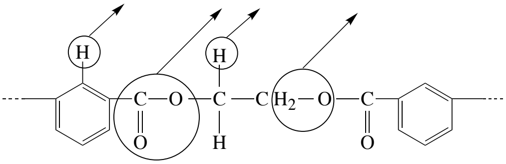
The high-frequency electromagnetic transmitter (Fig. 3), which is often used for the generation of a technical plasma, primarily give their energy up to the electrons, because these are significantly less inactive that the ions. This means that the electrons are "heated" and thus their average kinetic energy, i.e. their temperature, increases. Collisions between electrons and ions cause electrons to pass their energy on to the ions. Due to the great mass difference this energy transfer is only small. A number of collisions are necessary to achieve a balance between ion and electron temperatures. The number of collisions which a particle undergoes depends upon the pressure. At a high pressure the number of collisions is high, and there is a rapid equalization of the average energy of electrons and ions. In low density plasmas, on the other hand, this thermalisation between the particle types is not effective, and a system is created made up of hot electrons and cold ions.

In addition to thermal equalisation, collisions also play a role in the maintenance of the charge carriers. A mixture of electrons and ions will tend to form neutral atoms by the combination of the two particles. This process is known as recombination. This recombination leads to the two free charge carriers (electrons and ions) becoming a neutral atom, thus causing the plasma to lose some of its conductivity. Recombination is the process that converts an ionized gas into a "normal" gas. The stable burning of ignited plasma requires an equilibrium between the destruction and generation of charged particles. This source consists of the above-mentioned collisions between electrons and atoms or ions. If a hot electron hits an atom, it can knock out a captive electron (ionization). Whereas originally there was one free charge carrier, after the collision there are three. If equilibrium exists between recombination and ionization, then the plasma will burn in a stable manner.

However, the ionization of an atom is not the only process that can be triggered by an electron collision. In order for an electron to ionize an atom, it must transfer minimum energy to the atom during the impact, the ionization energy. If energy transfer due to the impact is less than the ionisation energy, then the struck atom is excited. The excited states are usually not stable, and such an atom returns to its original state, the basic state, radiating light as it does so. This is the cause of the illuminated appearance of plasmas.

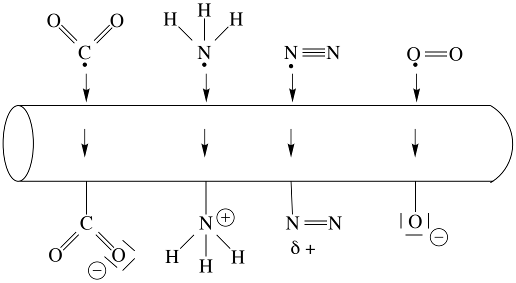
Plasma applications to fibres Low-pressure plasma can be used to chemically change the fibre surface in four areas:

I. Polymer etching: Oligomers are decomposed from the fibre surface in an inert gas plasma according to the following chemical mechanism (on polyester fibres).



In a longer treatment (1 min) and high power input (in watts) the etching is associated with a roughening of the fibre surface, increased refractive index and apparently darker colouring. Etching of wool fibre surfaces creates a sheen due to the partial removal of cuticle irregularities.

II. Functionalization: If, instead of a pure vacuum or inert gas atmosphere, "reactive" gases such as oxygen, air, nitrogen, carbon dioxide, ammonia are used, then the fibre surface is rendered hydrophilic and the immediate surface of the fibre is decrystallized.



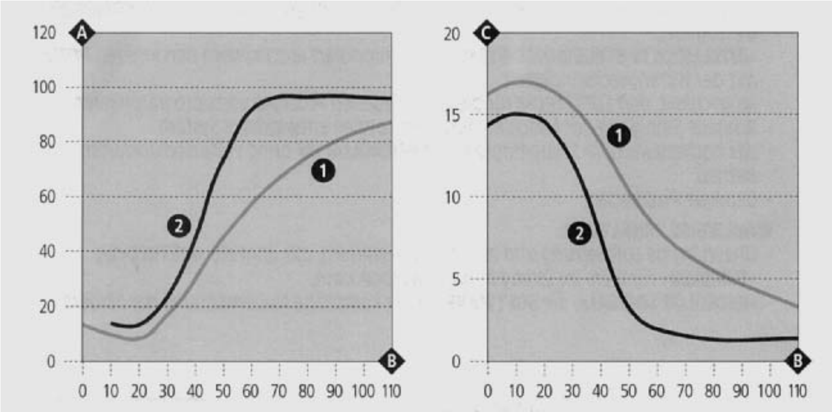


Fig.: Dye extraction by untreated and plasma treated wool when dyed with 3 % by weight of 1 : 2-metallic complex dye. A = dye extraction in %; B = treatment time in minutes; C = chromium content in mg/l; 1 = untreated; 2 = plasma treated (according to Höcker and Thomas).

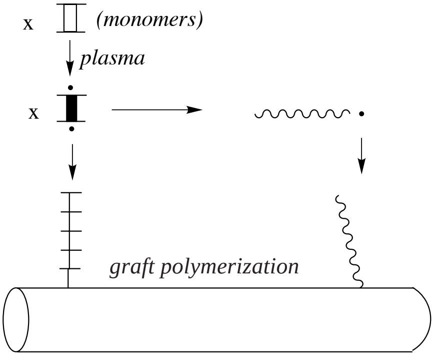
This effect can be demonstrated, for example, on polyester filaments. Filaments that have not been plasma treated normally hold only 10 µl water as drops from a fine dosing spray (with the filament in the horizontal position), whereas in this test a plasma treated filament will hold 30 µl water in the form of drops, before they fall off. If, for example, aramide fibres are treated with ammonia plasma, then due to the improved polymer compatibility the fibre can subsequently be embedded in epoxy resin, without delamination. In Japan, Yunica fabrics are discontinuously evacuated in a batch process (150 m) for 15 min and plasma treated for 1–3 min in order to render the fabric hydrophilic.

Treatment of wool with oxygen plasma increases the oxidized sulphur species in the cuticula, whilst undoing the disulphide bridges. However, this modification is limited to a few monolayers. Nevertheless, the fibre affinity increases, particularly in reactive dyes, but also in 1 : 2 metal-complex dyes (see Fig.).

This means that for a given shade, less dye is required to dye a plasma wool than is the case for the non pre-treated material. Because the bath exhaustion at the end of the dyeing process is also partially dependent upon the quantity of dye used, this provides (in addition to economic benefits) a further possibility for reducing the pollutant loads in the waste water of wool dying. Furthermore, wool can be pressure pretreated without the use of chlorine. If the above-mentioned reactive gases are replaced by the gas CF_4, then a polyester film can by rendered hydrophobic by such a plasma treatment (increase in contact angle from 75° to 180°).

III. Plasma polymerization: If gaseous, radical polymerizable gases (with double bonds in monomers) are allowed to flow into an evacuated plasma generating device, which contains synthetic fibres, and a plasma luminous discharge is generated, then plasma polymerization can be observed on the fibre surface by grafting:



More conductive fibres can be generated in this manner, for example by the grafting of organometallic polymers. Fire resistant textiles are created by the use of monomers containing phosphorus. Surface fluoridation is performed by first removing surface oligomers by argon etching, followed by impregnation with fluorocarbon monomers and finally grafting with CF_4 plasma gas.

IV. Sputtering: Aluminium can be steamed onto fibres with plasma.

(→ Low-temperature plasma).

Plasma treatment Excited neutral atoms or ions can be purposefully used for the creation of thin films. To achieve this, plasma is not ignited by an inert gas, as for example in the “neon” tube, but with a reactive gas, such as methane. In a methane molecule one carbon atom and four hydrogen atoms come together to form a particle. If a plasma is ignited with such a gas, then like the atomic inert gas plasmas, molecule ions and excited molecules form. In addition, however, molecule fragments are also formed if an electron strikes a molecule and in doing so splits a hydrogen atom, for example. Such a plasma then consists, in addition to electrons, of a number of molecule ions, excited molecules and fragments, which are sometimes the reactive radicals. If these radicals possess a great affinity to each other, then larger molecules are formed in and on the edge of plasma. If such a plasma is in contact with a solid surface then a thin film of these molecules can develop on the substrate. If this film is made from an organic compound, such as the monomer ethylene, then we talk of plasma polymers. The main differences between these and conventional polymers is due to the high number of reactive particles in the plasma. Whereas a polymer such as polyethylene is made up of a regular arrangement of one type of molecule, a plasma polymer can be composed of a large number of different molecules and thus have a highly cross-linked and irregular structure. In principle, the entire plasma polymer layer, which can have a thickness of up to a few microns, can be viewed as a single macromolecule.

The process of film formation consists of radicals from the plasma being deposited onto the substrate surface. The film begins to grow due to the subsequent diffusion of reactive particles from the plasma to the surface. The actual film formation mechanism depends greatly upon the parameters, with which the plasma is operated. So, for example, under certain conditions the radicals join together to form larger clusters in the gas phase, which are only deposited onto the substrate after this gaseous growth phase. Under different conditions the molecules adsorb on the surface, and only there are they met by electrons, excited and react with the substrate.

At low pressure, the number of collisions between particles is relatively low; accordingly the electrons can be accelerated to a high energy level between two collisions. Because of this the molecules become greatly fragmented and converted into many small fragments, e.g. H_2 molecules and CH radicals. Such a discharge is known as “hard” discharge. If the ions generated in the plasma are additionally accelerated by an electric field on the substrate, then films are formed with a high mechanical hardness, which are known as diamond-like films. They differ from polymers due to their structure and low hydrogen content. In contrast, the molecules in low energy discharge (known as soft discharge) are only fragmented to a small degree. This is due to the lower average movement energy of the electrons and ions in such a discharge. The film created is similar in composition to the initial compound used, e.g. styrene.

In addition to pure hydrocarbons, other compounds can also be used as a process gas. One example is silicon organic compounds. By varying the plasma parameters, films can be created with properties ranging from polymer-like to quartz-like. For coating plastics there is the possibility of going from a polymer-like structure to a quartz-like structure within the applied plasma film by continuously changing the plasma parameters during the discharge (according to Söder).

Plasma treatment allows plastic surfaces to clean themselves of adhering foreign bodies due to decomposition. High vacuum rolling plants for foils or for CD disk polymer lines are used in the sputtering process, in order to vapour-deposit surfaces with metal. “Hot” plasmas under normal pressure are important for the metal coating of, for example, resolution cylinders in spinning.

In plasma spraying, the surface being coated is sprayed with droplets in the same way as colour spraying. In contrast to colour spraying, the film material in plasma spraying is not liquid, and must first be melted by a high-energy heat source and then sprayed onto the cold surface of the fabric or three-dimensional body. When the droplets hit the surface they are flattened and cool off instantaneously due to heat transfer to the base material (substrate). The particles solidify and shrink. The films adhere primarily due to mechanical adhesion and locally due to chemical bonding forces of different types. In order to achieve a strong film adhesion, the cleaned surfaces are roughened by sandblasting. This gives good adhesion, because the particles penetrate into the surface roughness and shrink onto the peaks.

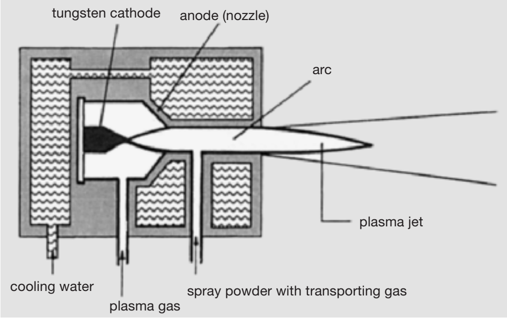


Fig. 1: Diagram of a plasma spray.

The heat source used in plasma spraying is an electric arc in a nozzle, which heats up a flow of gas (usually argon, nitrogen or helium) to very high temperatures (Fig. 1). Gas temperatures in excess of 20 000°C occur, which lead to the splitting of molecular gases and the partial ionization of atoms. As a result of the high temperatures a marked increase in the volume of the gas (plasma) takes place, which flows out of the nozzle at high speed. In plasma spraying plants the flow speed of the plasma jet reaches several times the speed of sound. The powdered film material is injected into this high-energy plasma jet with the aid of a carrier gas (Fig. 2). The particles themselves are melted and blasted onto the pretreated base material. The particle speed itself, how-

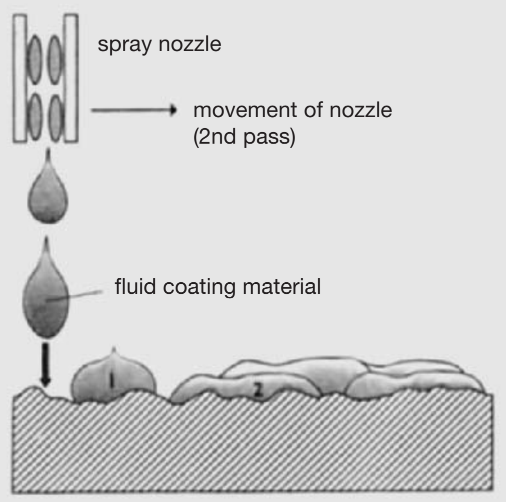

Fig. 2: Plasma spraying process.

ever, is below the speed of sound. Almost all materials which melt without decomposing and can be manufactured in a suitable grain size, can be processed into high quality coatings by plasma spraying. Normal plasma spray coatings are generally chromium oxide coatings or aluminium oxide coatings. However, tungsten carbide cobalt coatings and pure tungsten coatings can also be applied by plasma spraying (according to Schmolke).

Possible applications for low temperature plasma treatment in a vacuum in textile technology are currently envisaged in the following fields:

a) Antifelting finish of wool: The gas discharge “rounds off” the scales of the wool.
b) Improving the wetting properties and dyability of chemical fibres: In this process, hydrophobic chemical fibres are usually rendered hydrophilic.
c) Increasing the adhesion of composite textiles: There are interesting applications, for example in improving the adhesion of aramide or carbon fibres for composite materials.

The possible applications for the modification of fibre surfaces always compete with wet chemical procedures. Multi-layer printed circuit boards made of acrylate/polyimide have holes drilled while in continuous contact with copper plates. Previously, the only method of cleaning the hole walls in multi-layer circuits to remove grease from the drilled hole involved sulphuric or chromium acid, i.e. by wet chemical means. Over time, however, problems cropped up which could no longer be solved using this procedure and which made it necessary to look for other procedures. In 1983 the permanganate procedure was also introduced.

In addition to the wet chemical procedure a dry gas procedure, in the form of a low-pressure plasma technique, was developed. If rigid-flexible multi-layer plates based upon polyimide/acrylic adhesive were to be manufactured, the process of sulphuric acid or chromic acid cleaning, which was common at the time, encountered limitations. The acrylic adhesive, which easily smears as a result of drilling, could not be removed by wet-chemical means. Today, plasma desmearing and etch back plants are an integral part of the manufacturing process in multi-layer factories. All the problems of hole wall cleaning and etch back can be solved using this procedure. The hole wall cleaning process using oxygen-freon-plasma is fundamentally different from all wet-chemical procedures. This is a gas phase reaction, in which gases activated by high frequency react with the base material and oxidize it to CO_2 and H_2O. Because the reactions generally take place at above 100°C, the inclusion of any liquid is avoided. In contrast, a tempering occurs, which dries the printed boards. Because the plasma state can only be maintained whilst high-frequency is present, no “after-reaction” can take place, because at these temperatures the gases in normal (ba-

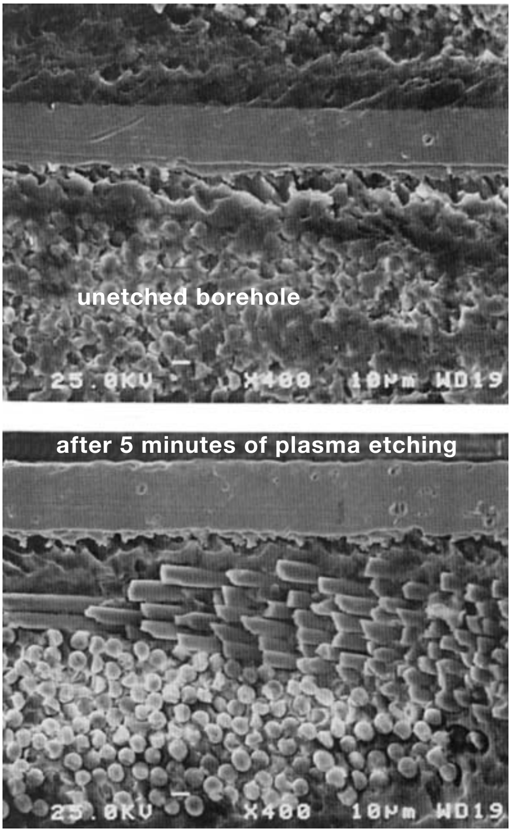

Fig. 3: Removal of borehole luting (top) on printed circuit boards (acrylate/polyimide bonding).

sic) state do not react. In the plasma procedure, oxygen/freon gases are continuously added and the reaction gases CO_2 and H_2O are continuously extracted.

The power of the plasma can be demonstrated by a few estimates. Approx. 1.6×10^{16} particles arise per second on the surface of a drilled hole with a typical diameter of 0.4 mm at a temperature of 400 K and a working pressure of 0.3 mbar. If we assume that the surface of the drilled hole is smooth, then these particles are opposed by approx. 1.8×10^{12} surface atoms. In reality the surface is of course roughened. But 1.6×10^{16} particles per second working on slightly more than 1.8×10^{12} atoms, illustrates the potential of plasma treatment. The particles themselves move at a thermal speed of above 400 m/s and have a typical dwell time of approx. 18 s. The smaller the holes to be cleaned, the more difficult is material exchange with viscose liquids; in hole diameters below 0.4 mm strong capillary forces are already noticeable. The viscosity of gases is at least a power of ten lower than that of liquids. Gases will penetrate the finest fissures and cracks (in the manufacture of semiconductors structures <0.5 μm can be etched). Small hole diameters are thus no obstacle to achieving uniform cleaning or etch back with gases (Fig. 3) (according to Tepla).

The advantages of plasma treatment also include the environmentally friendly nature of the process and the possibility of achieving effects, which rule out all analytical detection and are thus particularly “know-how intensive”. Plasma procedures are also non-contact and energy saving.

The problem of treating textile fabric lengths, which is dependent upon a costly procedure due to the necessary negative pressure, has not yet been satisfactorily solved. The increasing use of plasma procedures in the field of high-technology (semiconductor manufacture, magnetic tape manufacture, etc.) gives hope for new possibilities in textile applications (according to Kauter and Saiger).

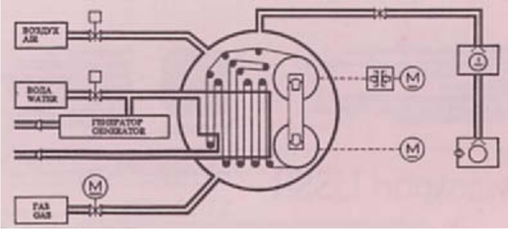

Fig. 4: Section of the Russian system for the non-continuous plasma treatment of fabric.

A first usable plasma treatment plant for textiles was presented at the ITMA in 1991 by Russian engineers (Figs. 4 and 5).

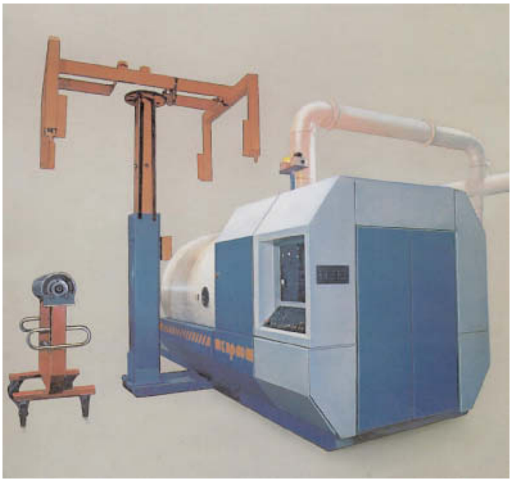

Fig. 5: External view of the Russian plasma treatment machine.

Plastic-coated textiles In its widest sense, this group also includes materials of various fibre composition with coatings, rubberizing and coating finishes. More specifically, it is used to describe products in which yarns, knitted goods from cellulose, natural or synthetic fibres are overall coated with synthetic polymers (during manufacture or as a subsequent permanent finish).

Plastic dye tube properties If single-use cross wound yarn package tubes (→ Dyeing tubes for yarn dyeing) are used in the pressing process, i.e. subject to axial deformation, their behaviour under pressure is influenced by three characteristics (see Fig.).

1. Intrinsic stiffness: The intrinsic stiffness of the tubes is such that they can be processed on all 6 inch spinning and winding components. Furthermore, it is also guaranteed that the tube can also be dyed in an unpressed state, with closed dyeing column and no spacer.
2. Pressability: When the yarn package is compressed by 1–30%, the tube deforms from the centre outwards; it is guaranteed that the two seams on the thread reserve and in the run-off head of the tube only deform at full pressure. The segmented deformation of the tube provides the option of completing the dyeing at 1–30%, depending upon the material and package thickness.
3. Distance trunnions: Because the behaviour described under 2 achieves a variable effect, the distance trunnions are also enlarged, in order to guarantee that the material always flows through. The largest distance trunnions are the ones on the two external seams (according to Giljam).

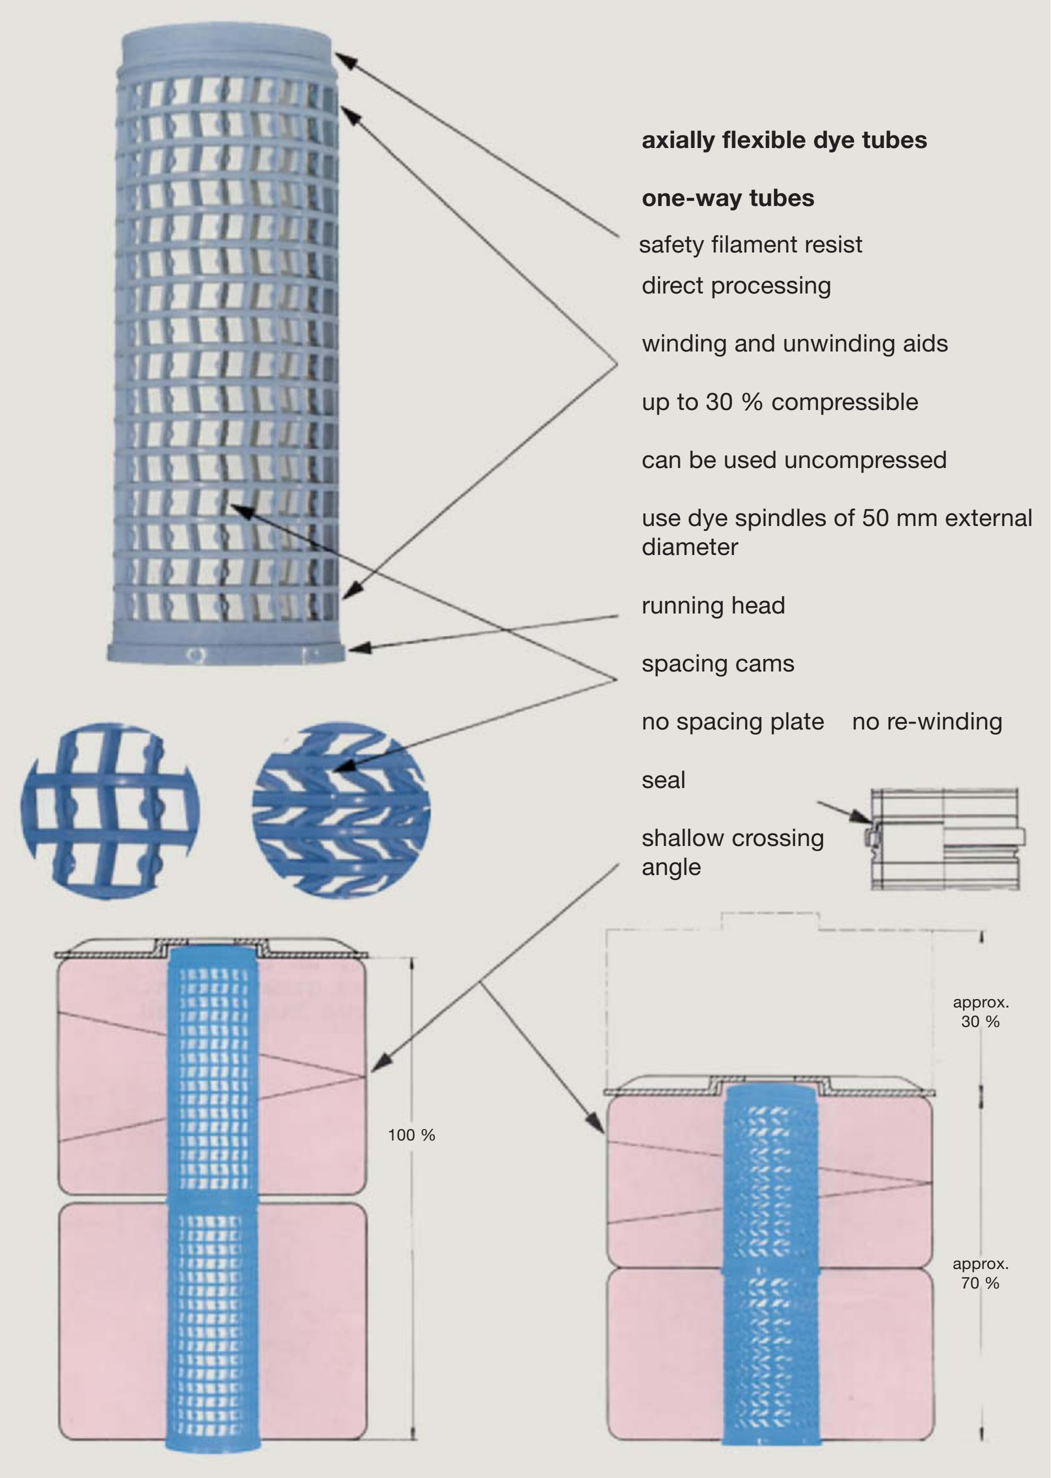

Fig.: Axially flexible dye tubes (Eisbär-Zimmermann).

Plastic foam (expanded plastics) → Expanded foam.

Plasticizers (softeners and gelatinizers), specific softeners used in the lacquer, rubber, synthetic resin and leather industries. They also play a role in textile lacquer, bronze and pigment printing, etc., because they have a favourable effect on the adhesiveness, suppleness and elasticity of such film-forming agents or printing thickeners, particularly those based upon nitrate and acetate cellulose. When added to a polymer, a plasticizer should improve the softness, suppleness, extensibility and workability of the former (effects include lowering the freezing point, modulus of elasticity, melting viscosity). For cellulose esters and resins plasticizers are practical, difficult to evaporate, organic solvents (phthalates, glycolethers, polyalcohols and synthesis alcohols) with boiling points between 250–350°C. Plasticizers differ significantly in their chemical structure from softeners used in actual textile finishing. They contain at least one polar group, whereby there is a dipolar bond with the basic molecules of high molecular film-forming agents. The latter differ from cellulose esters (nitrate, acetate cellulose).

1. Gelatinizing plasticizers (gelatinizing agents), which act like non-volatile solvents on nitrate cellulose, for example, to form a solid gel. Such films possess rubber-like elasticity; if too much is added or the temperature increases too much they may also become sticky.
2. Non-gelatinizing plasticizers, which are taken into the film compound without any solvent power and form more tough-limp films, which remain relatively hard even when a large amount is added.

Plasticizers in coating pastes The most frequently used coating paste is based upon the polymer, polyvinyl chloride. The polymers are sometimes obtained in the form of monomodal primary particles after synthesis, in which case the three-dimensional network structure gives rise to high ductility in coating preparations. The viscosity of bimodal pastes depends on the fact that small particles embed themselves between larger ones and act as ball bearings. When they exchange positions due to shear forces, the large particles need only overcome a low activation threshold to start flowing. Furthermore, in bimodal distribution, less space must be filled by plasticizers, if the coasting paste is used. The primary particles agglomerate on drying to form secondary particles. Plasticizers are used to convert these secondary particles in the pasty state into coating paste.

So-called hinge plasticizers (Fig. 1) have proved their value for the purpose of achieving a time limited plasticizing (swelling) of coating preparations. If greater quantities of plasticizers are used (over 20%), then the molecules act as a “hinge” between the dipole/dipole associates, making the molecule chains more mobile in relation to one another. This decreases the glass transition temperature (from around 70°C in plasticizer-free PVC to 0°C in PVC with 30% plasticizer), and a material which is more flexible and softer at room temperature is created.

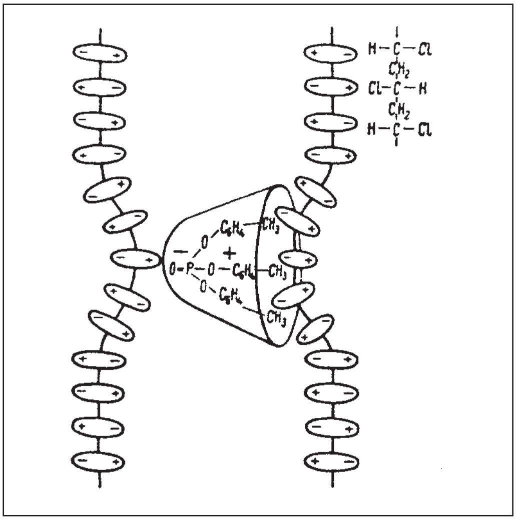

Fig. 1: Softening by means of an articulating plasticizer (coupling effect) – tricresyl phosphate molecule between two PVC chain molecules.

Permanent plasticizing is primarily achieved using phthalic acid ester by means of the shielding effect (Fig. 2). Phthalic acid esters make up around 90% of

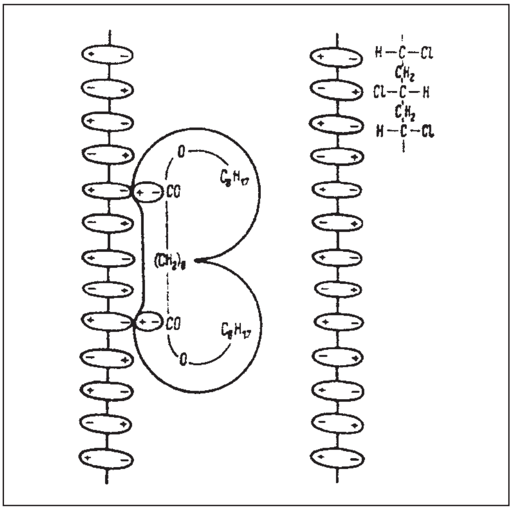

Fig. 2: Softening by means of a screening plasticizer (separation effect) – dioctyl sebacate molecule between two PVC chain molecules.

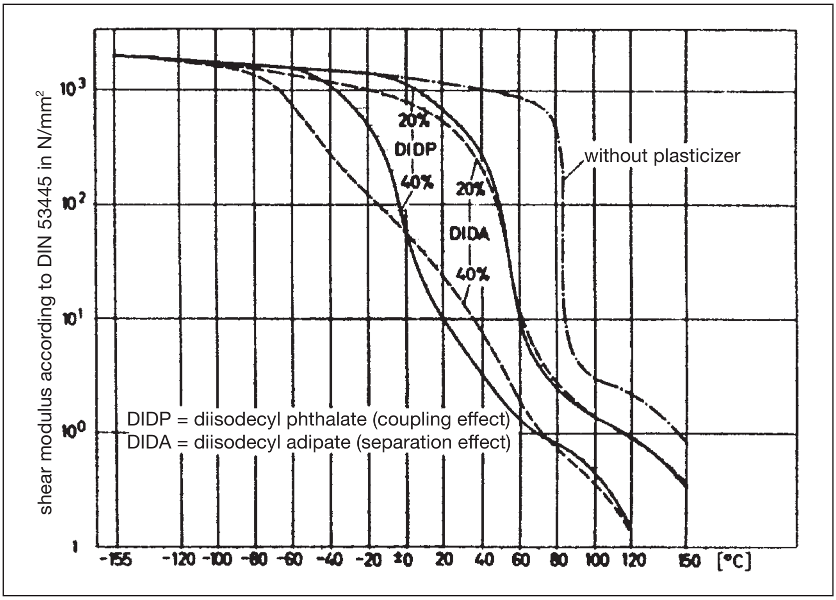

Fig. 3: Influence of various types of plasticizer on the shear modulus of suspension polyvinylchloride (S-PVC).

the market due to their economically favourable manufacturing capability combined with good technical properties. The low polarity of dioctylsebazate (DOS) is due to the low polarisability of the aliphatic CH_2 chain. They retain their nonpolar character and shield the dipole at the other end, so that the effect remains limited to one direction only.

The main difference between hinge and shielding plasticizers is that shielding plasticizers become brittle less quickly in the cold and soften less quickly in the heat, because the mobility of their molecules is less temperature dependent due to the double bond to the PVC molecule and the nonpolar groups. Fig. 3 shows the different effect of the two plasticizer types on the temperature dependency of the shear modulus, of suspension polyvinyl chloride (S-PVC). When an applied coating preparation is stirred, its viscosity may vary over time because the secondary cross-linking points are optimized between the softener molecules and polymer dipoles because the plasticizer molecules find the optimal dipolar interaction positions by diffusion.

The plasticizer thus has two tasks to perform: firstly it should give the finished coating the necessary degree of softness and secondly it should covert the PVC into a pasty state to facilitate processing. The change in viscosity over time can be explained in these highly viscose suspensions by the adsorption of the plasticizer by the primary particles and by its penetration into the particle. In this manner the more rheologically active plasticizers are removed from the suspension. The viscosity of a PVC plasticizer system depends largely upon the quantity of freely available plasticizer (Schollmeyer).

Plasticizing carriers The dying of polyester fibres using disperse dyes made it necessary to develop a whole range of carriers for the dying of polyester fibres. However, the chemical structure of such products did not always meet the requirements regarding toxicity and biodegradability. An alternative with regard to toxicity is represented by the o-phthalesters, whereby the application of some of them as components in textile assistants, i.e. carriers for the dying of polyesters, has been patented. There is a unified opinion about the mechanism of the accelerated action of carriers: They plastify the structure of the thermoplastic fibre and thus reduce the glass transition temperature. The dye diffusion through the polymer mass determines the speed, and the diffusion coefficient plays the role of a dyeing speed constant. The validity of the Williams-Landel-Ferry equation has been quantitatively demonstrated several times for a glass transition temperature (T_g) and dyeing temperature (T), whereby

$$\lg \frac{D_T}{D_{T_g}} = \frac{A\,(T - T_g)}{B + (T - T_g)}$$

This equation shows the degree of change of the dyeing speed under the influence of the plasticizer (the acceleration is greater, the greater the difference between the dyeing and glass transition temperature). On the other hand, the prognosis of the carrier effect of a substance requires a number of experimental data, not only in relation to the degree of change of the glass transition temperature, but also with regard to the interaction of the carrier with the fibre type in question, in order to bring about a plasticizing effect or a reduction of the glass transition temperature.

Plastic material lengths Collective term for synthetic foils, synthetic leather and other composite plastic and textile material lengths.

Plastics,

I. Very generally speaking, synthetically manufactured materials. More specifically, macromolecular organic compounds either thermosettable (→ Duroplastics) or thermal imaging (→ Thermoplastics) or elastic (→ Elastomers).

1. Regenerated natural substances, e.g. based upon cellulose (such as →: Cellulosic fibres, regenerated; Cellulose derivatives) or based upon casein-formaldehyde (such as → Casein plastics) or as vulcanized natural caoutchouc (such as rubber, hard rubber).
2. Synthetic plastics (→ Synthetic resins): Built up synthetically from low molecular basic substances, either a) → Polymerization products (such as polyvinyl products and butadiene), b) → Polycondensation products (such as aminoplasts, phenolic plastics, polyamides) or c) → Addition polymerization products (such as polyurethane, epoxy resin).

solvent \ plastic	polyethylene	polyamide	polyvinyl acetate	vinyl chloride acetate*	cellulose acetate	polyvinyl acetate	ethylene/vinyl acetate*

Fig.: Tensile strength, ductility and module of elasticity of plastics (1 kp/cm^2 = 9.81 · 10^4 N/m^2).

ble ductility and tensile strength oppose each other in homogeneous plastics. The ranges shown in the Fig. indicate the possible construction properties of homogeneous plastics. Many combinations of properties are possible within these ranges.

II. Term proposed according to DIN 7731 for plastic synthetic resin substances.

Plastic sheeting →: Foil; Simulated leather foil.

Plastic white scale →: Ciba-Geigy white standard; Whiteness scale.

Plastisol coating (paste coating), working method using → Plastisols, consisting of synthetic resin, softener, pigment, stabiliser, etc. in premixed form, which is spread upon the fabric or knitted goods, upon which the resin is hardened.

Plastisols Dispersions of plastic powder in → Plasticizers, which do not gelatinize the plastic powder when cold, e.g. vinyl resin dispersions plus softener or polyvinyl chloride paste made up of polyvinyl chloride plus softener.

Plastomers → Thermoplastics.

Plate cutting tool Application in pantograph engraving. Using an epidiascope a two to five-fold enlargement of the pattern is projected upon a whitened zinc plate, with subsidiary lines for repeating and pattern offset, and all contours traced by the draughtsman with a pencil. The plate cutting tool then engraves the contours of the pattern into the plate.

Plated steel Substitute material for solid metal sheets in equipment construction, for fittings, etc. Principle: Coated metal surface as the carrier of corrosion resistance. Manufactured by a sealed rolling process (in the absence of air). Non-ferrous metal coatings on steel sheets or special steels.

Plate felting machine For the manufacture of fabric felts, which are usually used as technical felts. In the plate felting machine the upper plate (50°C) describes a circular or elliptical path, whereas the lower plate (40°C) is fixed. The pressure is mechanically applied.

Plate heat exchanger Reclamation of heat energy by means of compression moulded plates, which are sealed at the edge. The two media involved in the heat exchange are alternately led through gaps. If there are large device dimensions and costly air channels, air inlet and exhaust air flows and external air and escaping air flows meet at the device separating walls (crossflow plate heat exchanger). The heat exchange takes place directly via the exchange surfaces (glass, metal, plastic). There is no exchange of moisture nor dirt transfer from the escaping air flow to the external air flow.

Free flow plate heat exchangers are particularly suitable for the heating or cooling of very dirty fluids containing fibre or solids and for energy reclamation from dyeing and washing liquors (see Fig.).

Plate spring in roller printing With plate springs a more elastic pressure can be applied to printing rollers than with → Roller printing. This conserves cloth, printing roller surface and fabric.

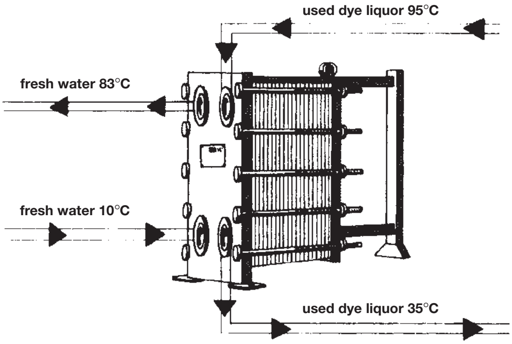

Fig.: Diagram showing heat exchange in a plate heat exchanger.

Platinum Abbreviation Pt; atomic weight 194.8; whitish grey, tough heavy metal; ductile, weldable; stable in air; density 21.4; melting point approx. 1764°C; soluble in chloronitrous acid (hydrochloric acid/nitric acid 3 : 1). Sensitive to sulphur alkalis and liquids containing chlorine. Marked tendency to form complex salts. Application: Laboratory devices (crucible, basin), electrodes, thermoelements, physical equipment; catalyst (oxidation accelerator), in x-ray technology, etc.

Pleated sheet structure (chain lattice), two-dimensional system consisting of chain molecules (keratin sheet structure in wool, lamella in cellulose, basic structure of silk fibroins), a skeleton-like primary valency bundle with side chains protruding from both sides. The three-dimensional system grows from layered, bundled, chain lattices in the form of →: Crystallites; Micelles.

Pleating Creation of very varied shapes and arrangements of folds on textiles using → Pleating machines. Permanent, wash-resistant pleating can be produced:

I. On cellulose fabrics and mixed fabrics with a high cellulose content: Padding with heat-hardenable synthetic resins, followed by pleating and hardening.

II. On wool: Padding or soaking with substances

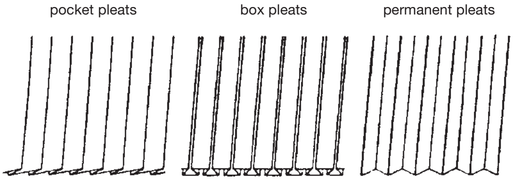

Fig. 1: Pleat forms.

suitable for wool fixing (thioglycolates) followed by pleating, steaming/ironing/pressing.

III. On synthetic fibres and mixed fabrics with a high synthetic fibre content: Pleating, thermofixing.

One differentiates between the following mechanically produced pleat types: knife pleats, squeezed pleats, box pleats and group, crystal, accordion, fancy, wave and harlequin pleats. Shaped pleats are parallel pleats such as sunray and special pleats (Fig. 1).

The term "pleat" comes from the French, and is used to describe material pressed into narrow folds. Pleating experienced an enormous boom due to the development of synthetic fibres. The fact that the thermoplastic properties of synthetic fibres make it possible to produce a permanent pleat using heat, has opened up fields to pleating, which were previously closed to it: Underwear, blouses, clothing, etc.; once formed, the pleats are permanent, moisture resistant and washable.

In principle, all fibres can be pleated, however, a permanent, i.e. water and wash resistant pleat, can only be generated in vegetable and animal fibres by the use of certain chemicals. A permanent pleat in woollen fabrics can be achieved by the use of the Siroset procedure. In this process the woollen material is evenly sprayed with thinned Siroset solution, until the weight has increased by up to around 40%, laid in the correct shape (preferably with intermediate layers of tulle) and then steamed. However this process has not become widespread, because unpleasant side-effects occurred due to the high degree of moisture. The pleat shapes had a significantly reduced lifespan, because the card became too wet. A further difficulty was presented by the condensate, possibly containing Siroset, which formed in the templates, causing spotting in the material. Due to the relatively high degree of moisture in the material, any relaxation shrinkage had a greater effect than is the case during steaming; this increases the tendency to bagginess in fabrics. Furthermore, the increased moistening of the material leads to possible decatizing losses, i.e. loss of sheen and handle. With the intermediate layer of tulle problems were encountered in the laying of the material on the template and due to imprints on the material, some of which could not be removed.

A material quality is said to be normally pleatable if pleating can take place without special precautions. Materials intended for pleating must have certain shrinking and dyeing fastness values, and these should be taken into account in the finishing.

In general, pleating permanence means that the pleats have a certain durability when worn, above all when sitting down, and after clothing care. Permanence also relates to the maintenance of the sharpness of the folds (including following a garment care treatment).

When pleating with pleating machines, steam cabinets and autoclaves and when pressing folds using special fixing presses, the first step is the crease formation. But at the same time attention must be paid to the smooth surface of the material between the fold lines. These material areas between the fold lines appear in the form of the visible fold width and underlay area (fold depth) and in the form of the outflow (smooth areas e.g. at the hips). We differentiate between economy and full folds. In economy the fold depth (underlay area) is less than the fold width (Fig. 2); in full folds the fold depth is the same as the fold width.

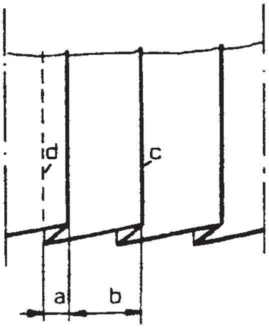

Fig. 2: Example of pleat folds.
a) pocket (fold depth); b) visible fold width; c) pleat fold; d) hidden pleat fold.

Although, in principle, there are only a few basic forms, there is an extraordinarily large number of possible pleat variants. We differentiate between (Fig. 3):

- sunray pleat based upon shaped template (circle or segment of circle),
- straight pleats with parallel folds based upon straight template,
- straight pleats with conical folds based upon straight template,
- special pleat (fancy pleat) with plastic patterns based upon straight or shaped template.

There are also the basic fold types:

- knife pleats (on one side),
- box pleats or squeezed (knife pleats lying to both sides),
- accordion pleats.

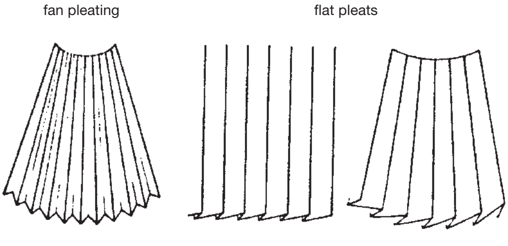

Fig. 3: Basic pleating forms.

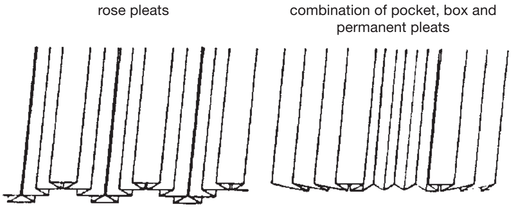

Fig. 4: Combination of pocket, box and permanent pleats.

These fold types can be used alone or in combination. A good example of combined arrangement of knife pleats and box pleats are the rose pleats. Fig. 4 shows a combination of knife, box and accordion pleats.

The fold depth (underlay area) and the outflow provide a wide range of possibilities for variation, as does the arrangement of pleats on top of each other and the fold height. Crystal, arch and gather pleats can be described as variants of accordion pleats, although they have no genuine fold. Sunray pleats and straight pleats with conical folds have special properties with regard to cutting and laying compared to straight pleats with parallel folds. Sunray pleats must always be cut in a circular shape.

We differentiate between hand pleating and machine pleating processes, which are not mutually exclusive, but complement each other. In hand pleating a so-called pleating template is used, in which the cut piece of material is placed by hand. The pleating templates are made of a special cardboard with a high number of folds and consists of two identical pieces of card in the shape of the desired pattern. These templates are for an upper and lower layer with the same pleat pattern.

Unlike the package for the steaming cabinet, the thin card laid in folds is placed in a steam forming press in a even condition. The steam is forced through the template and material under pressure and at the same time contact heat fed from the heated work surfaces of the press. The steam only needs to penetrate a single layer of card to act on the material; the inside of the folds are heated through more quickly due to the temperature at the top and bottom. With a treatment time of 1–2 min per pressing procedure this method requires only a fraction of the treatment time of approx. 20 min in the annealing cabinet. The programme for steam, action and cooling time is regulated via automatic switches and is fully automatic. Temperature and pressure are also adjustable, so that the pleating press can be set up according to the material quality.

Hand pleating is mainly significant for the manufacture of sunray pleats and conical pleats with a greater underlay area at the top, using special pleating templates. The disadvantage of hand pleating is that productivity is low and a great deal of working space and personnel are required.

Machine pleating has the advantage that high performance can be achieved with significantly less personnel. In principle, the folds are laid by rearranging the fabric over the entire width of the machine with the aid of a metal bar (knife). The fabric folds then run between a heated metal roller and a roller covered with felt (Fig. 5). The upper roller covered with felt presses the fold against the metal cylinder. It may be accompanied by an over and under paper or just an under paper. The paper thickness depends upon the material quality.

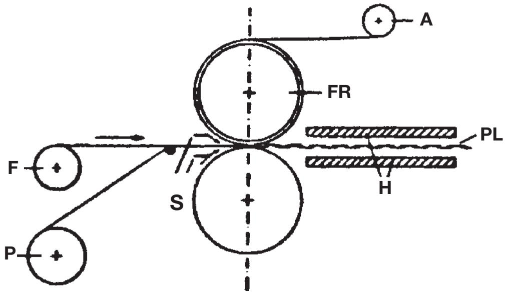

Fig. 5: Diagram of a pleating machine.
FR = felt roller; F = fabric reel; H = heating plates;
A = adhesive tape for edges; S = open shears; P = paper reel; PL = pleated fabric.

Pleating machines Used for → Pleating:

I. Knife, squeezing and group pleating machines for the generation of a wide range of different patterns (approx. 1 mm to several cm underlay area and fold width).

II. Crystal pleating machines for the generation of vertical folds (approx. 1–5 mm fold height).

III. Accordion pleating machines for upstanding folds (5–50 mm fold height). Such machines usually have straight, serrated or corrugated sets of blades for fold formation. The pleating is fixed on the material, which is usually accompanied by a special paper, passing through heated rollers, and subsequently travelling through a water cooling device to increase the fold permanence of synthetics. There may also be an electrically heated condensation heat table for the creation of permanent pleats on resin finished cellulose materials (cotton, viscose) as an add-on device. The material is not normally fully fixed, but pre-fixed (10–30°C below the optimal fixing temperature; with dry heat max. 140°C, with steam fixing max. 1.5 bar). The pleating temperature is always dependent upon the fibre type (thermofixation):

cellulose	150–200°C
fibre mixes	150–210°C
polyamide 6	180–194°C
polyamide 6.6	190–208°C
polyacrylonitrile	120–160°C
polyester	160–180°C

Care should be taken to ensure that there are no thermo-yellowing impurities (greases, softeners), and sublimation fast dyes are used. Material that has already been fixed can be provided with wash fast pleats if previously resin finished (cellulose).

Pleat resistance Of fabrics after complete moistening (like creasing). The remaining folds are determined in % = (fold height after the wetting : fold height before wetting) × 100.

Pleionomers (Gk.: Pleion = more; meros = smallest component/basic building block), homogeneous molecular homologous polymer with molecular weight above 1000, which unlike → Oligomers can no longer be sufficiently differentiated with regard to their physical properties to be separated into homologues. Pleionomers play a role in synthetic fibre-forming polymers.

Plexiglass Transparent, colourless plastic made of → Polymethacrylic acid ester (density 1.18; tensile strength 700–759 kg/cm^2; light permeability 90–99%) castable, polishable, cuttable, grindable, weldable, etc. Application as → Safety glass.

Plie Piece material laid in uniform widths; hanging in plie (e.g. when suspending silk goods), i.e. hung folded on the stick. The stick has three notches for suspension loops, onto which the piece ends can be attached.

Plissé Folded material, which can be achieved in different manners.

I. Woven plissé: Produced by an additional device on a power loom; 2 warp systems of different tension achieve drape. Folding can also be achieved by suitable bindings. In knitgoods folds are created by stitching.

II. Shrunk plissé is produced by the use of synthetic fibres with different shrinking properties.

III. Finishing plissé: The material is laid in folds, which are thermally fixed in so-called pleating machines.

Application for clothing materials, skirts, etc.

Plotter Peripheral device for electronic data processing plants. The plotter is a computer controlled output device for the graphic representation of curves, text, symbols, etc., it represents a further development of the XY writer used in measuring technology. We differentiate between flatbed plotters (moveable drawing pen, fixed drawing sheet) and drum plotters (drawing sheet on rotating drum, drawing pen only moves in the crosswise direction).

Ploughing up Damage to engraving and doctor blade during printing due to poorly distributed pigments in the print paste.

Plucker (opener, willow). Preparation machines in spinning. Classified as tearing, beating, striking, oil lubrication, mixing, carding plucker, etc. according to application.

Plucking out Term for pulling out dark hairs from white woollen materials. This manual work can be replaced by selective bleaching.

Plugging, repair of printing rollers Concerns the reworking of worn engravings, caused by frequent use of the printing rollers. Dabbing can be carried out on a grinder.

Plumbic acid → Lead.

Plung suction device Additional device in the debris trap in wide wool washing machines with which liquor is sucked in and released by means of a rubber suction cup. The purpose is to intensify the washing process and liquor exchange. Manuf.: Hemmer.

Plush,

I. Woven plush: high pile → Velvet.

II. Knitted plush: Plush-like appearance due to pile formation in tricot by a plush loop. → Plush cloth.

Plush carpet General term for carpets with cut open pile warp (thread pile); either shorter velour-like (velours carpet, → Tournay carpet) or longer pile (plush carpet). Named according to material and pattern: Hair yarn, linen, wool, knotted, striped plush carpet, etc. Manufactured in the form of → Wire carpets or as → Face-to-face carpets (face-to-face tournay carpet).

Plush cloth (plush fabric, knitted plush), 2–3 thread → Knitted fabrics usually made of ground thread and plush thread. The latter are formed into long loops and either closed, curled, frizzy (thermal underwear, jogging suits, lining material, etc.) or cut, shorn for velvet, pelt or fur like pile goods (lining material, outer material, fake fur, blankets). → Pile-knitted fabrics.

Plush trimming Trimming the pile loops of knitted plush fabrics by → Shearing.

Ply-yarn Thread made of two or more → Yarns twisted together. We talk of 2-ply, 3-ply, 4-ply yarn, etc. Soft ply-yarn made of numerous slightly twisted yarns is also called a wick.

Pm Element symbol for promethium (61).

PN Polska Norma, Polish standard.

pNa value Concentration of sodium ions. Can be measured using a sodium-sensitive measuring chain by potentiometric methods, in a similar way to measuring pH, e.g. concentrations of sodium chloride or sodium sulphate solutions.

Pneumatic (Gk), moved by air pressure (→ Compressors), e.g. → Pneumatic cylinder.

Pneumatic cylinder Pneumatics is the technical application of tools (cylinders, motors, valves) driven by air. Low pressure pneumatics include static switching elements, for example, membrane and piston valves, whilst air jet elements belong to the group of dynamic switching elements. Compacted air is called compressed air. It is the energy carrier of the pneumatic system. Compressed air exploits an important property of gases: Compressibility. Gases, unlike solids and liquids, are very compressible.

If the microprocessor in a control circuit sends an instruction for the elements in a process to carry out certain actions, then this often means the generation of movement or the performance of a service of one type or another (mechanical, electrical, thermal). The pneumatic cylinder is a tried and tested drive for the generation of linear movements. The pneumatic cylinder consists principally of a cylinder tube, a piston and connecting rod, a return spring, the compressed air connection and the exhaust connection (Fig. 1). If the cylinder chamber A admits compressed air, then a pressure acts upon the piston surface. If the force generated by the pressure (Force F = Pressure p × Piston area A) is greater than the opposing force of the spring, then the piston moves to the right with the connecting rod. This movement is called a forward stroke. The compressed air in the right-hand cylinder chamber B can escape via the exhaust connection. If the compressed air supply is interrupted the power of the spring is sufficient to allow the piston to move back to the left and allow the air to escape from the cylinder chamber A. This movement is called the return stroke. The term “single acting cylinder” refers to the fact that mechanical work can only be performed during the forward stroke. This work is greater, the greater the piston area and the air pressure in the cylinder chamber A. The stroke of this cylinder is around 100 mm.

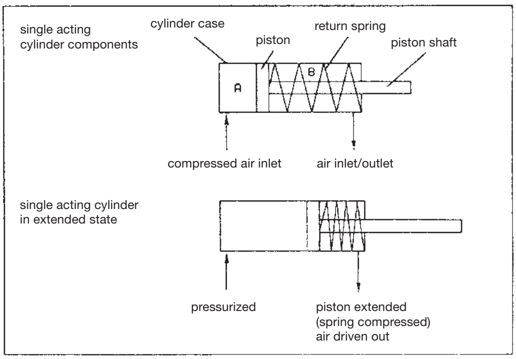

Fig. 1: The single acting pneumatic cylinder.

In addition to the piston cylinder another form of single acting cylinder is the membrane cylinder. In this, a stiff membrane is stretched between two halves of a cylinder. Compressed air impinges on the membrane and causes it to flex. The degree of flexing determines the cylinder stroke; the connecting rod is directly connected to the membrane. We differentiate between the single membrane cylinder and the roller membrane cylinder.

A 3/2 way valve has three connections and two switching positions (Fig. 2); the method by which it switches between one position and the other can vary. The example shows a valve, which is held in the rest position by a spring. In this position the compressed air is shut off from the valve. This is called a 3/2 way valve with blocked rest position. In situation 1 the valve is drawn in the rest position; there is a connection from the cylinder via the valve to the vent. The cylinder chamber A is ventilated and the piston retracted. The arrow F in situation 2 indicates the operation of the valve. There is only a connection from the valve compressed air connection to the cylinder, so that the cylinder chamber admits pressure and the piston extends.

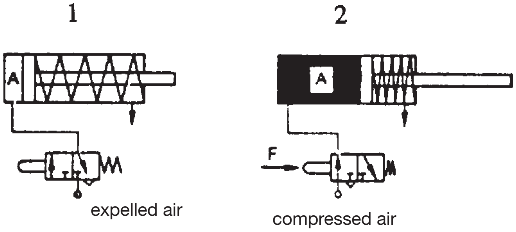

Fig. 2: Control of a single acting cylinder by means of a 3/2 way valve. F = auxiliary manual control moved into working position.

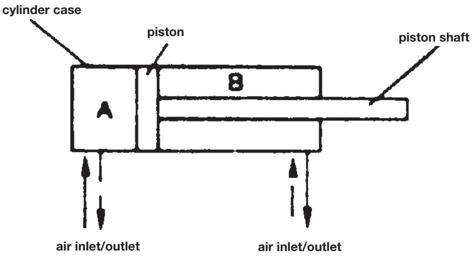

Fig. 3: The dual acting pneumatic cylinder.

The principal structure of the dual acting pneumatic cylinder is similar to that of the single acting cylinder (Fig. 3). However, there is no return spring, and each connection can be used either as an air inlet or an air outlet. If air enters the cylinder chamber A and is withdrawn from B then the forward stroke takes place. The return stroke takes place after air inlet to B and air outlet from A. This has the advantage that the cylinder

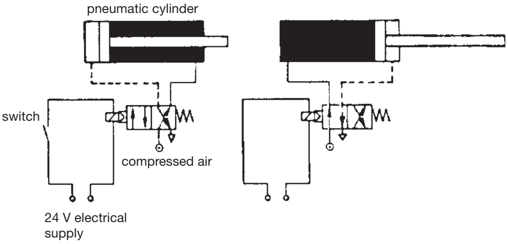

Fig. 4: Electro-pneumatic control.

can perform work in both directions of travel. If there is electro-pneumatic control an electric sensor triggers the movement of the pneumatic cylinder (Fig. 4).

Pneumatic guiders Expander and edge uncurling device. Works with 2 pneumatic blowers and photoelectric sensors; material is scanned and expanded using compressed air. Differs from mechanical guiders due to non-contact, low tension material guidance.

Pneumatic squeegee In this screen printing squeegee the squeegee rubber is held pneumatically and can be changed quickly and easily.

Pneumatic stretching frame Can stretch all screen sizes between 800 × 1100 and 1800 × 2850 mm (screen manufacture). The gauze is held, tensioned and, after pasting to the frame by hand, released by quick release clips. After the necessary tension has been achieved via a control panel, the gauze is lowered onto the frame without altering the tension and pasted onto it. Starting from the largest screens the device can be converted for smaller formats using extension tubes.

Po Element symbol for polonium (84).

POC (particulate organic carbon), describes the carbon content of suspended particles in biological waste water cleaning (→ TOC).

Pocket piping Pocket opening with → Piping.

Poil-grege (high twist grey pile yarn). Highly twisted → Grège threads with approx. 1000–2000 twists/m.

Point bonding Point welding of nonwovens. → Spot-bonded nonwovens.

Poise Outdated measure for dynamic → Viscosity. Replaced in the SI system by Pascal seconds (Pa · s): 1 P = 0.1 Pa · s.

Poison Substance which has a harmful (→: Corrosive poison; Toxicology) or lethal effect on living organisms even in small quantities, always a question of dose (→: Tolerance limits; Lethal index). Examples of inorganic poisons are ammonia, arsenic compounds, barium salts, lead compounds, bromium, chlorine gas, chromium compounds, etc. A further group relates to the poisons generated by the organism itself, known as metabolic poisons or toxins. Toxins are highly toxic, protein-based, natural substances with a specific effect. Most toxins are formed by bacteria: Endotoxins are constituents of them, exotoxins are discharged from them, e.g. the tetanus toxin. Most bacterial toxins act as antigens. The following classification of poisons was drawn up on the basis of the EC guidelines of 18.9.1979 (per kg body weight):

highly poisonous substances	≤ 5 mg,
very poisonous substances	5–25 mg,
poisonous substances	25–200 mg,
less poisonous substances	200–2000 mg.

for an LD-50 (→ LC-50 and LD-50 values) in a rat with oral intake. Skin irritation and inhalation criteria are determined in the same way. Furthermore, the EC guideline defines additional terms in relation to harmful substances: Irritating, environmentally hazardous, carcinogenic, teratogen, mutagenic.

Polar Terminal, working in opposite directions (→ Dipoles). For example, in textile auxiliary products the polar arrangement of the hydrophilic group in relation to the hydrophobic group. In the wetting process, water molecules are in a polar arrangement to the auxiliary at the boundary layer, if the latter aligns its hydrophilic (negatively charged) groups against the positively charged groups of the surrounding water.

Polar-apolar structure Relates to the presence of at least one → Polar group and a larger → Nonpolar group, which gives the molecule in question a hydrophilic and lipophilic character.

Polar bond → Ionic bond.

Polar group Functional group, the electron distribution of which gives the molecule a considerable → Dipole moment (→ Polar). It determines the affinity to markedly polar liquids (particularly to water) and the → Hydrophilic molecule character.

Polar interaction → Adhesion.

Polarity → Dipoles.

Polarization Eccentricity of centre of gravity of negative and positive electricity, whereby e.g. → Dipole molecules are created. If a molecule has a permanent dipole, then it is able by induction or influence to give a dipolar alignment to other nonpolar molecules, in which the centre of gravity of negative and positive charges coincide. This creates an “induced dipolar moment”, which brings about small additional intermolecular attraction forces, so-called induction forces (→ Secondary valency forces). This charge eccentricity is a displacement polarization, in which around 85% of electrons (electron polarisation) and around 15% of ions (ion polarization) are involved.

Polarized light Using a double slit crystal, “normal” light consisting of different amplitudes and different directions is split into two perpendicular radiation directions it is linear polarized (→ Birefringence). If one radiation direction is eliminated, pure linear polarized light is obtained, i.e. only light of one plane of polarization.

Polarography A special case of voltametry used for plotting current-voltage curves. Dripping mercury is often used as the collector due to its clean surface. The measuring currents can be easily smoothed electronically, or, by use of a highly damped recorder, ensure that only small pulsations caused by the growth of the drop remain. If a cell voltage and current change is recorded on the print out of an indicator recorder then a d.c. polarogram is obtained.

Polarography is rarely used for the detection of organic compounds. The substances in question must be easy to reduce. The detection limit is around 10^{-5} Mol/l. The main field of application is in the detection of metal ions. In special cases, such as differential pulse polarography (DPP), the detection limit lies in the picogram range.

Pole-change finishes “Pole-changing” is the term used to describe the change of contact potential (in the course of spinning processes), which a non-softened or prepared fibre shows compared with iron. The normal contact potential of the fibre compared with iron is negative in the unprepared fibre. After completed softening the contact potential has become positive: The polarity of the fibre has been changed. Often a reduction in the charge is sufficient.

Pole finding test paper Filter paper soaked in sodium chloride and phenolphthalein solution; used moist to determine the electrical negative pole (cathode = red colouring).

Polishing Mechanically increasing the lustre on yarns or fabric lengths (plush material, imitation fur, floor coverings, etc. on → Polishing machines; → Lustring.

Polishing bench for engraved printing rollers are used for grinding and polishing of damaged rollers: Device similar to a lathe, in which the printing roller spindle is mounted so that it can turn, and is rotated by engaging a clitch. The polishing bench also incorporates a water basin, in which the roller is submerged approximately 5–10 mm during the polishing process. Dabbing can also take place using the polishing bench.

Polishing machines,

I. One differentiates between polishing machines (II) according to their field of application:

1. For yarns (sewing machine yarns), in order to give them the most lustrous finish possible.
2. For fabrics, in order to give long-pile materials in particular a lustrous finish (Fig. 1).

II. Universal finishing machines for polishing (Fig. 2). Lengths of fabric are transported under tension on heated, rapidly rotating cylinders with beater bars, etc., also in combination with cutting cylinder (polishing-cutting machine) or other functions (e.g. face fibre finisher, pile rotor, super finish, etc.).

Polishing shearing machine → Polishing machines.

Pollution control in textile finishing Successful measures to date are as follows:

1. Reduction in water consumption:

– reduced water quantities due to short and ultra-short finishing baths (liquors),
– minimum application processes (e.g. spray, foam application),
– optimized rinsing processes,
– combination of procedure stages (e.g. dyeing and finishing),
– recovery and multiple use of water (→ Recycling).

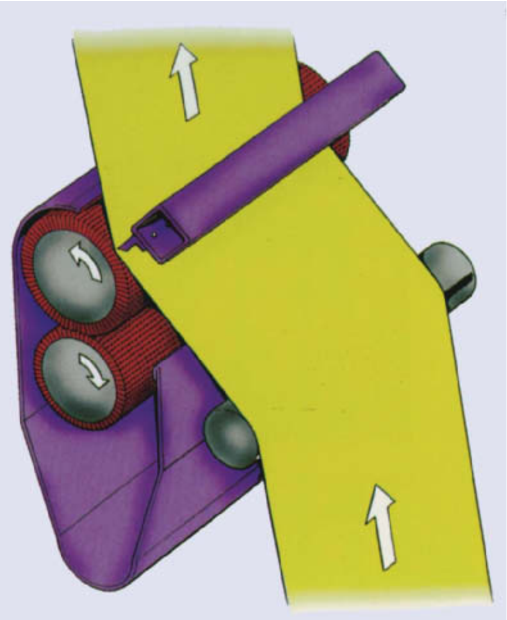

Fig. 1: Tigering unit.

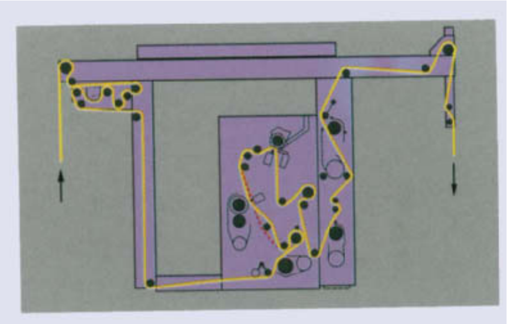

Fig. 2: Tigering machine OPTICUT GTS by Gematex.

2. Decolorization of waste water: dyes remain visible, even if there are just 3 parts dye in 10 million parts water. Reactive dyes with high washing fastness for fashionable materials, made of cellulose fibres in particular, are often noticeable for this reason. Although in these concentrations they are a long way from being able to cause damage, even this visual problem is undesirable. It can be combated by precipitation with specific flocculation and precipitation chemicals and adsorption by activated carbon or decolorizing with oxidizing or reducing agents. However, additional substances are introduced during decolorization, and polluted foam is generated during flocculation. There are still no satisfactory solutions to this problem. Therefore the search

goes on unabated for better methods. → Waste water treatment.

3. Avoidance of heavy metals: small quantities of heavy metals, e.g. chromium, copper, nickel or zinc, are contained in specific, usually, in particular, light and wash fast dyes, pigments or a few auxiliaries of textile finishing. The metal of the dye is largely combined in the form of a complex, i.e. a fixed component of the dye molecule. The proportion of free heavy metals, which may be contained as traces in some dyes, is being reduced further by improved manufacturing processes. In addition, heavy metal-containing compounds are increasingly being substituted in auxiliaries.

4. → APEO and → AOX: alkyphenolethoxylates (APEO) have excellent properties as washing and cleaning agents. However intermediate products can occur during their biological breakdown, which are harmful to fish above certain concentrations. The manufacturers of washing and wetting agents in Germany therefore switched to APEO free products. In other textile auxiliaries the use of APEO was stopped by 1992. AOXs, the adsorbable organically bound halogens, include above all highly volatile halogenated hydrocarbons and the chloraromates. As part of a voluntary agreement, German manufacturers are avoiding the use of LHKW in washing and cleaning agents. Chloraromates have been largely replaced in dyeing auxiliaries. Even during bleaching, attention is paid to low AOX values. Chlorine-containing bleaches are increasingly being replaced by peroxides.

5. Reduction of organic and inorganic pollution: the polluting of waste water and outfalls with organic substances is a central environmental problem. Private households are just as involved in this as agriculture or industry. A criterion for the pollution of water is the chemical oxygen demand of the introduced substances. Around 60–70% of the COD pollution, e.g. in dyeing waste water, stems from sizes and preparations. They were applied to threads and yarns in preceding work stages, in order to facilitate or ease further processing. Once their task of strengthening and smoothing threads and yarns is fulfilled, they must be removed again – and end up in the waste water. Traditionally, natural starch is used for sizing, which is very biodegradable. Due to the associated high oxygen demand, efforts are increasing to replace them with effective, and at the same time, regenerative synthetic sizing agents. However, procedural problems are associated with effective → Recycling, and intensive work is underway to overcome these problems. Chemicals based on phosphates, which can contribute to the overfertilization of waters, have already largely been replaced by other chemicals. In order to reduce the nitrogen pollution of waste water from textile finishing, attempts are underway to find a replacement for urea, which is necessary for some processes in the dyeing or printing of fabrics made of cellulose fibres.

6. Reduction of exhaust air emissions: Strict requirements are also imposed upon exhaust air quality of the textile finishing company (→ Exhaust air problems in textile finishing). These have the aim of preventing dust, smoke and harmful substances in the air and eliminating odour nuisance. Switching over to environtmentally friendly power is significant: natural gas already represents more than 60%. Dyeing at low temperatures, cold dwelling processes, etc. also contribute to low power consumption. The → TI-air, the technical regulations for maintaining clean air, sets high standards for production plants. By means of improved processes and environmentally friendly textile auxiliaries, it was possible to significantly reduce pollution. Progress in the technology of exhaust cleaning plants also brought about a significant improvement.

7. Safety in storage and transport: most chemicals used by textile finishers belong to water hazard class I (slightly hazardous to water). In all cases strict requirements are imposed on the labelling of substances, fire prevention and rinsing water recovery. Detailed safety data sheets provide the necessary information for transport, storage, handling and emergencies.

8. Avoiding waste, reclamation of materials: textile, paper, plastic and metal wastes are separated out to a large degree in companies within the textile finishing industry and recycling is carried out. Packaging is increasingly being limited to the degree necessary for transport and storage and designed in such a way that it can be refilled or the material recycled. Expensive techniques, such as automatic, computer controlled dosing, application with minimum quantities or computer controlled calculation of dye recipes, have led to a marked reduction in dye residual quantities. However, fibre, dye and chemical residues, which must be treated as special waste, have not been eliminated. Therefore the important task of finding safer disposal routes still remains. Ever stricter requirements force the textile finisher, like other industries, to take on more and more obligations, often of a voluntary nature.

Pollution control representative In order to ensure that companies have a comprehensive grasp of the current state of environmental protection and can recognize weak spots, regular environmental audits must be performed (similar to audits in the field of quality assurance). This information, in addition to the environmental protection guidelines and the organisational division of environmental protection, forms the basis for the creation of an environmental protection handbook. The obligations of a company to protect the environment are not limited to the generally known maintenance of emission limit values for pollutants and noise and the associated maintenance of existing plants. They cover:

- proper handling of hazardous substances,
- timely disposal of hazardous substances,

organization	task
Zentralstelle der Gesellschaft für Energie und Umweltschutz (central office of the society for energy and environmental protection)	– collecting, evaluating and communicating environmentally relevant regulations – advice – examination of projects – liaison with authorites/ministries – contribution to external expert groups
Werkstelle für Umweltschutz (office for environmental protection)	– introduction of new regulations – advising production units – inspecting operational facilities in respect of operation in accordance with regulations
Zentrales Umweltschutzlabor (central environmental protection laboratory)	– carrying out periodic emission checks – the handling of environmental protection problems – advice – drawing up specialist analyses – decisions on the classification of waste and refuse
Werkstellen für Giftverkehr (offices for the transportation of hazardous substances)	– advising production facilities on the handling and storage of hazardous substances – monitoring
Fire Brigade	– prevention and minimization of damage caused by accidental releases

Tab.: Organizational structure for assuring the carryng out of environmental responsibilities.

- planning of new plants in accordance with environmental requirements,
- accident prevention,
- handling special wastes according to regulations.

All environmental regulations and legislation must be noted, then read and understood, interpreted, applied to own conditions, introduced, implemented and monitored.

In large textile finishing companies the organizations listed in the Tab. ensure that all these requirements are fulfilled.

Smaller companies employ a pollution control representative, who should have the highest authority to issue directives, to assist the business management.

Pollution control responsibility Criticism of the supposed chemical and thus pollution loading of textile materials has aroused the general public. The textile industry has been burdened with a range of legislation by the authorities, which impose difficult tasks on textile manufacturers and finishers. This legislation includes:

- segregated flow treatment (disposal of waste water at the location of production, Textilabwasser-VwV [textile waste water administration regulations]),
- storage of water-hazardous substances (chemical and auxiliary storage in accordance with § 19 g Section 1 of the WHG [Wasserhaushaltsgesetz – Water Resources Law]),
- control of in-company waste water channels (self-checking of channel network),
- exhaust air treatment plants (for plants requiring a licence in accordance with BImSchG [Bundes-Immissionsschutzgesetz – Federal Immission Protection Law]),
- waste disposal (disposal of special wastes and residual substances subject to compulsory monitoring) and
- self-checking (Eigenkontrolleverordnung EKVO of Baden-Württemberg [self-checking act] with tightened requirements for indirect emissions).

The title of a draft act for pollution control responsibility act reads “Law Governing Responsibility for Environmental Pollution and changing the Water Resources Law and the Federal Immission Protection Law” (Gesetz über die Haftung für Umweltschäden und zur Änderung des Wasserhaushaltsgesetzes und des Bundes-Immissionsschutzgesetzes). An extension of the “polluter pays” principle is planned within this law, and thus extends the guilt-independent hazard responsibility from water protection to land and air.

The following new rules are planned as focal points:

- introduction of an absolute liability “for the protection of land and air” in addition to the existing absolute liability “ for the protection of water” in § 22 Water Resources Law (WHG). This absolute liability is like that in WHG, a liability that is independent of guilt.
- absolute liability for the operation of “environmentally hazardous plants” including normal operation and not just “accidents” as is the case in the WHG.
- lessening the burden of proof for the determination of causality of environmental effects not covered by the WHG.
- victims’ right to information from plant operators and licensing authorities, which the WHG does not provide.
- extension of the natural restriction, i.e. improvement of the options already in place in the BGB (Bürgerliches Gesetzbuch – Civil Code) for victims to “undo” damage to the natural condition of their property at the cost of the polluter.
- “compulsory insurance” for plants with “particularly high danger potential”.

The WHG covers not only the chemical industry, but also the “chemical producing and chemical using” textile industry, in particular, textile finishers. In the future it will cover all production plants, which represent a certain potential danger, thus not only the plants covered by the BImSchG. Where infringements of environmental legislation were already punishable according to the previously applicable environmental penalty law, the “new environmental penalty law” brings with it a marked tightening of liability and thus disciplinary action. The draft agreed on 14.2.1990 by the Federal Cabinet for a second law for combating environmental crime includes the following main new, proposed regulations:

- introduction of a statute against ground pollution (over and above § 326 STGB [Strafgesetzbuch – Criminal Code] – environmentally hazardous waste disposal);
- extension of the penal provision against air pollution (§ 325 STGB) by the introduction of an emission statute (§ 325 STGB was originally based upon imissions considerations);
- introduction of a general regulation concerning the irresponsible handling of hazardous substances (which also covers the particularly dangerous transport of hazardous goods);
- stronger safeguards to nature and water protection areas against harmful influences;
- penalties for the illegal export of hazardous waste;
- increased penalties, raising of financial penalties and introduction of custodial punishment;
- extension of the rules concerning voluntarily averting the effect of a wrongful act to encourage the timely averting of hazards;
- protection against contraventions in companies is improved; the penalty arrangements regarding the commercial contravention of supervisory duties (§ 130 OWeG) is made more practical, and the possibility of attaching financial penalties against legal persons (§ 30 OWeG) is made easier.

Particular importance is attributed to the law for the improvement of the previously patchy protection of soil against damaging influences. Furthermore, the law is intended to cover all infringements of regulations in the operation of plants causing air pollution and noise. The previous, gross, non obligatory infringement is replaced by “any culpable, negligent behaviour”. Furthermore, the gross, wilfull release of pollutants into the air is made a punishable offence, without the need to prove that damage has been done in the individual case. Furthermore, a general penal provision regarding the negligent handling of hazardous substances or materials and goods is introduced. Thus hazardous wastes termed as economic goods and so-called “illegal waste tourism” is also made a criminal offence.

The liability for breach of duty is extended to include all independent and responsibly acting supervisory persons in addition to the company owner or the company management (according to Hemmpel). → Legislation on environmental protection.

Pollution control sample archive Strategy of the German Federal Ministry for Environment, Nature Protection and Reactor Safety, under the scientific co-ordination of the German Federal Office for the Environment (UBA – Umweltbundesamt), Berlin, in the form of a systematically structured archive for the conservational storage of selected pollution control samples.

Main aims:

- retrospective identification of environmental chemicals; even those that were unknown at the time the sample was taken.
- retrospective repeat analysis of inorganic elements or organic compounds in samples that have already been analysed, which were stored under conservational conditions.
- checking the success of legislative environmental protection measures in the handling of chemicals that are viewed as being hazardous to man and the environment.

Authentic samples from various fields of the environment play an important role.

It was recognized at an early stage, that samples from biological collections do not permit reliable conclusions to be drawn regarding environmental pollution, because neither conservation nor storage methods are designed for retrospective investigations. This recognition gave rise to the demand for the creation of a collection, which can provide the environmental samples of today to future generations. Thus the evidence required to answer relevant questions will be available. Comparatory samples, which must be drawn upon for the determination of trends in the chemical pollution of the environment, can be optimally processed in accordance with the current state of technology. New findings regarding environmentally hazardous substances and improvements in analytical methods and the ability to draw upon authentic stored sample material facilitate the detection of long-term trends in the environment. Any need for action to implement preventative measures can be determined (according to Schwuger).

Pollution index (waste water), characteristic figure relating to waste water, derived from measured COD values (mg O_2/l), BOD values and water quantity in l/kg material; → Waste water evaluation.

Pollution index (effluent) Term from the waste water taxation act. According to this act a penalty is incurred for discharging waste water into an outfall, the level of which depends upon the hazard of the discharge. This hazard is expressed as a pollution index. It can be calculated on a flat rate basis for all textile finishers who do not discharge directly, possibly per m^3. The person liable to pay the levy must bear the cost of measuring the hazard themselves (→ Waste water evaluation). The following formula is proposed for the calculation of the pollution index from the analysis data (possibly regionally with other factors): for sewerage and pit water the following applies for determining the pollution number in the main pollution period:

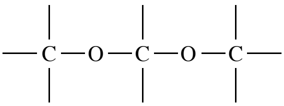
$$B = \frac{Q}{0,15}\left[0,04 + 0,25\,\frac{A - 0,3}{6,0 - 0,3} + 0,35\left(0,5\,\frac{BOD - 20}{250 - 20} + 0,5\,\frac{COD - 80}{500 - 80}\right)\right]$$

B = pollution number in resident values;
Q = discharged water quantity in m^3/day (without precipitation);
A = taxable substances in ml/l (without carbon component);
BOD = biochemical oxygen demand in mg/l of the taxed sample;
COD = chemical oxygen demand in mg/l of the taxed sample.

Polwarth wool Wool from New Zealand sheep. Cross-breed with smooth structure and shrinking property.

Poly- (Gk.), determinative element of compounds meaning “many, multiple representations”.

Polyacetals Formaldehyde and higher aldehyde homopolymer and copolymer. → Polyoxymethylenes.



$$-\overset{|}{\underset{|}{C}}-O-\overset{|}{\underset{|}{C}}-O-\overset{|}{\underset{|}{C}}-$$

Poly acids Anionic → Polyelectrolytes; can be described as high acid anhydrides, created from more than two acid molecules giving off water, e.g.:

$$3\,H_2SiO_3 \rightarrow H_2Si_3O_7 + (2\,H_2O)$$

From the same acid molecules iso-polyacids form from different hetero-poly acids. The following are well known (only in aqueous solutions or salt form):

I. Inorganic poly acids, for example → Polysilicic acids (salt type: water glass or sodium silicate Na_2SiO_3, $Na_2Si_2O_5$), → Polythionic acid, polyphosphoric acids (salt type: Polyphosphates).

II. Organic poly acids of type → Polyacrylic acid.

Polyacrylates,

I. →: Polyacrylic acid salts; Polyacrylic acid ester.

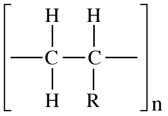
II. Polyacrylate products are for example used as finishing agents, coatings, binders for pigment printing, fibres, laminating agents, adhesives, sizes, thickeners, materials.

Polyacrylate size recycling The already high waste water loading in textile production (50–80% due to sizing agents) can be reduced by the co-application of polyacrylate sizes. Polyacrylate sizes in the filament field with low BOD_5 values have good biodegradability. The degree of polymerization appears to influence the degradation behaviour, so for example acrylic acid homopolymers with growing chain lengths are usually degraded slowly. High levels of short chain alkyl esters of acrylic acid are associated with satisfactory biodegrading of polyacrylate sizes. Such polymers can for example contain up to 20% by weight polymerized acrylonitrile, without biodegradability being noticeably inhibited. The earth alkali polyacrylate sizes promote low waste water loading due to their high reclamation rates, in addition to the fact that the residual polyacrylate size can be quantitatively precipitated out of the washing water by mineral acids.

Reclamation and reuse is the only option for the dramatic reduction of size costs for the sole use of high-value - but expensive, compared to starch products, synthetic sizing agents. One such option is a polyacrylate reclamation process called the Recupra process (BASF): In this the high swelling and dissolving speed of the polyacrylate sizes are exploited for selective swelling (by the application of sized raw fabric with minimal water content) and then the reusable reclaimed solution (4–8%) is separated from the fabric by high performance squeezing machines. The prerequisite for good weaving results and successful multiple recycling is sizing with pure polyacrylate, “dry” weaving environment, minimal use of auxiliaries (oil, wax). Due to its characteristic curve, size generation of thermostable earth alkali polyacrylates in particular offers a high reclamation rate and thus lower waste water loading. Therefore it is particularly important that raw thermofixable products (e.g. sodium/calcium salts, magnesium salts) can be manufactured as up to approx. 100% solid products and in this concentrated form facilitate higher reclamation rates. → Recycling.

Polyacrylate sizes possess great variation in molecular structure; numerous polyacrylate sizes are used in fibre yarns and filaments of almost all fibre types (→ Sizing agents). Modifications can be made by the copolymerisation of different types of monomers. Specific copolymers of acrylic acid with dominant homopolymer properties also facilitate the sizing of untwisted polyamide, even at high humidity. The degree of polymerisation and substituents determine important properties of polyacrylate sizes, such as film hardness, adhesive power, rubbing fastness, solubility and electrolyte compatibility. Polyacrylonitrile (and to a lesser degree polyacrylamide) increases the toughness and abrasion resistance of the size films. Esters promote elasticity and adhesiveness, particularly in filaments. In the ester, the length of the residual alcohol has a decisive influence upon the film hardness. The longer the carbon chain, the softer and stickier the polymer. Polymethacrylates yield harder films than the corresponding polyacrylates. Generally speaking, polyacrylate sizes of the same gross composition can differ greatly in their properties. The functional groups can be converted by chemical transformation. The carboxyl groups responsible for solubility and adhesiveness are capable, for example, of salt formation. Sodium salts are more soluble than ammonium salts, but more hygroscopic. At the same time, a higher proportion of carboxylate groups brings about marked adhesion to cellulose and polyester/cellulose mixed yarns and also improves washing off. Developmental differentiation of polyacrylate sizes according to the type of salt form:

I. Conventional polyacrylate sizes primarily in the form of sodium or ammonium poly salts:



$$\left[-\overset{\displaystyle H}{\underset{\displaystyle H}{C}}-\overset{\displaystyle H}{\underset{\displaystyle R}{C}}-\right]_n$$

R = $-COO^-NH_4^+(Na^+)$,
$-CN$, $-OH$, $-CONH_2$,
$-OOCCH_3$

Liquid products are becoming more and more prevalent (with the exception of powder products based upon polyacrylamide) so, for example, polyacrylate staple fibre sizes for cellulose and polyester cellulose in the form of usually aqueous ammonium salt solution (less tendency to stickiness than corresponding sodium derivatives), which are also far less hygroscopic, but have some drawbacks due to moisture sensitivity and thermoinstability. However, in mixtures with excess starch sizes, the hydrophilic nature of the polyacrylate sizes is positively influenced. These combinations (staple fibre sizes), which are almost exclusively prevalent for cost reasons, guarantee good weaving properties even at high humidity. On the other hand, the tendency of ammonium polyacrylate sizes to split ammonia under thermal stress leads to undefinable cross-linking in raw thermofixing and thus, sometimes to poor washing off properties, particularly in the presence of starch, whereby an alkali shock treatment sometimes helps to counter this effect. → Desizing with enzymes.

Polyacryate sizes of very different chemical composition in the form of “universal sizes” are an important class of size products for filament yarns in general. They produce good effects when used in water jet power looms, with a size film that is resistant to the influence of cold, neutral water. After weaving the polyacrylate sizes, present in acidic form, can be made water soluble again at an alkaline pH and washed out.

II. Earth alkali polyacrylate sizes: New generation moisture insensitive and thermostable sizes by partial or total substitution of ammonium or sodium in specific copolymers (acrylonotrile/acrylic acid) by earth alkalis (e.g. magnesium, sodium, calcium salts). Such Polyacrylate sizes can be completely washed off even after raw thermofixing because they are soluble in hot and cold water at high concentrations (up to approx. 25%). Furthermore, this substance class is electrolyte compatible, possesses high adhesiveness and offers high reclamation quotas, i.e. low waste water loading. In a mixture with starch sizes evening of viscosity variations (product safety), high thermal stability e.g. during machine down time or raw fixing, elimination or drastic reduction of starch degrading enzymes, particularly for native starch sizes, elimination of enzymatic desizing when suitable starch combinations are selected (“Sizes as a desizing agent”), accelerated desizing.

The functional principle is illustrated by the model of the structure of earth alkali salt bridge (see Fig.).

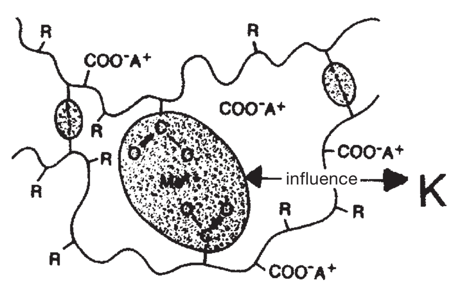


Fig.: Influence on the adhesion force K of two carboxylate groups on different polymers of polyacrylate size caused by the metal Me^{++} *(magnesium or calcium) acting as cross-linking agent between them.*

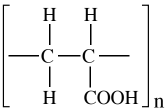
The polymer chain mobility is limited, the glass transition temperature of the polyacrylate is thus increased. Calcium is more active than magnesium. The reason for this is the lower water absorption of polymers containing calcium. With increasing earth alkali content the film hardness systematically increases, thus providing significantly better resistance against mechanical weaving stresses, as does thermostability. The ammonium ion acts as a monovalent cation in all products. After raw thermofixing, combinations including carboxymethylcellulose (CMC) can be easily and completely washed out after 50% neutralization with earth alkali. The functional principle also facilitates problem free, easily manageable, approx. 100% powder marks. In comparison to ammonium salts the earth alkali derivatives show significantly increased desizing speed when mixed with starches.

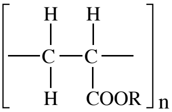
Polyacrylic acid Polymer of → Acrylic acid. Glass-like when solid; as solutions, emulsions and jellies; insoluble in water, soluble in alkali, gives sticky to hard films.



$$\left[-\overset{\displaystyle H}{\underset{\displaystyle H}{C}}-\overset{\displaystyle H}{\underset{\displaystyle COOH}{C}}-\right]_n$$

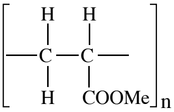
Application for sizes, finishes, adhesives, binders, etc. → Polyacrylic acid ester and → Polyacrylic acid salts are of greater importance.

Polyacrylic acid ester Polymer methyl, ethyl, propyl, butyl ester (mixtures) of → Acrylic acid.



$$\left[-\overset{\mathrm{H}}{\underset{\mathrm{H}}{\mathrm{C}}}-\overset{\mathrm{H}}{\underset{\mathrm{COOR}}{\mathrm{C}}}-\right]_n$$

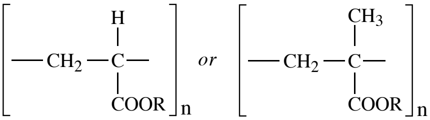
Polyacrylic acid salts Sodium and ammonium salts of → Polyacrylic acid.



$$\left[-\overset{\mathrm{H}}{\underset{\mathrm{H}}{\mathrm{C}}}-\overset{\mathrm{H}}{\underset{\mathrm{COOMe}}{\mathrm{C}}}-\right]_n$$

Water soluble, produce solid, elastic films with antistatic properties. Application: Sizing agents, finishing agents, thickeners for synthetic dispersions in coating finishes, coatings.

Polyacrylic compounds Polyacrylic acid and polymethacrylic acid, the salt esters and copolymers of which are used in a wide range of products in the form of acrylate polymers and polyacrylate for sizes and finishing agents. Polyacrylic acid base products and their salts are water soluble (e.g. for animal feeds and back finishes) and resistant to microorganisms. → Polyacrylic acid ester is water insoluble.

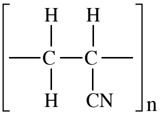


$$\left[-\mathrm{CH_2}-\overset{\mathrm{H}}{\underset{\mathrm{COOR}}{\mathrm{C}}}-\right]_n \quad \textit{or} \quad \left[-\mathrm{CH_2}-\overset{\mathrm{CH_3}}{\underset{\mathrm{COOR}}{\mathrm{C}}}-\right]_n$$

Aqueous dispersions of polyacrylic acid esters produce excellent water fast, transparent, light and water resistant films of high strength. Polyacrylates produce softer and stickier films the longer is the alcohol residue. Polymethacrylates are harder and less sticky than polyacrylates with the same alcohol residue. A linear alcohol residue leads to softer polymerisate, a branched alcohol residue gives a harder polymerisate. The solvent resistance falls with the length of the alcohol residue. Comonomers with acrylates or butadiene increase the solvent and oil resistance of the polymer. Polyacrylates are also suited for use in softeners (e.g. light rain coats), laminating, fibre/thread binding without the addition of a softener. Further application as weighting and stiffening finish, anti-slip finish, for fixing of calender effects (e.g. chintz, silk finish, embossing), increasing serviceability (abrasion resistance, breaking strength in bending, ladderproofing). In organic solvents (e.g. ketones, aromatic hydrocarbons, etc.) dissolved polyacrylic compounds are suitable for further water-fast special finishes (coatings, synthetic leather, hat stiffeners).

Polyacrylic ester →: Polyacrylic acid ester; Polymethacrylic acid ester.

Polyacrylonitrile (polyacrylic acid nitrile, polyvinyl cyanide), polymer of → Acrylonitrile.



$$\left[-\overset{\mathrm{H}}{\underset{\mathrm{H}}{\mathrm{C}}}-\overset{\mathrm{H}}{\underset{\mathrm{CN}}{\mathrm{C}}}-\right]_n$$

Used in emulsions or dispersions (particularly copolymers with butadiene, styrene, vinyl ether) primarily for wash fast finishes, for coating and laminating, as a material and for synthetic fibres (→: Polyacrylonitrile fibres; Modacrylic fibres). Acrylonitrile polymer emulsions with ammonium chloride as a catalyst can develop, when hardening, a toxic bi-chloromethylether (lung cancer hazard).

Polyacrylonitrile copolymer fibres → Modacrylic fibres.

Polyacrylonitrile fibres Group of synthetic polymeride fibres, the chain of which is made up of at least 85% → Acrylonitrile. The composition of the polyacrylonitrile fibres varies due to the polymer addition of affinity increasing foreign substances (monomers such as vinyl acetate, vinyl chloride, vinylidene chloride, vinyl pyridine, methacrylate, methacrylamide, etc.). “Pure” polyacrylonitrile fibres are subdivided into a) fibres consisting solely of polyacrylonitrile (non dyeable) and b) so-called modified polyacrylonitrile fibres(→ Modacrylic fibres) with up to 15% foreign substances (good dyeing properties), whereas if there is c) a high foreign substance content, we talk of polyacrylonitrile copolymer fibres. Polyacrylonitrile fibres are produced by dry or wet spinning and drawing (8–12 fold). Further processing from single titre 0.6 dtex upwards. The cross-section varies, usually dumbbell-like (dry spinning process) or kidney-shaped (wet spinning process).

Crystallite structure: The formation of crystalline areas in polyacrylonitrile fibres takes place due to the formation of laminar chain lattices by hydrogen bridges between the macromolecular chains (formation of → Lamella). Accessability and reactivity are of course reduced to the same degree as functional groups are attached due to intermolecular forces in the crystal lattice, which must be taken into account in the understanding of the dyeing process.

Properties (→ Synthetic fibres): Density low (< 1.13;

modified polyacrylonitrile fibres possibly higher: up to 1.37); full handle; absorbency below 0.5%; swelling value below 1%; highly resistant against microorganisms and insects including termites; physiologically harmless; excellent light and weather resistance; heat resistance relatively good (boiling fast, ironing fast up to 150°C), however shrinks at higher temperatures (approx. 4% with 100% hot air). Low hot-wet modulus gives rise to the danger of slight irreversible distortion or deformation particularly in knitted goods during hot-wet treatments above 60°C. Softening range 190–230°C (modified fibres possibly 150–160°C), becoming sticky at 300–320°C (does not melt, but decomposes). High breaking strength; lower abrasion resistance than polyamide and polyester. Crease reforming good (similar to polyester); breaking strength in bending high (similar to polyamide); elastic stretching and bulk elasticity good. Chemical resistance against acids, oxidants and solvents good; alkali sensitive. Washable and quick drying. Dye affinity varies (→ Dyeing of acrylic fibres). Can be electrostatically charged. Application: Sport and work clothing, swimming costumes, rainwear, imitation fur, clothing material, fleece, quilt fillings, curtains, decorative and furniture materials, tarpaulins, technical fabrics (acid protective clothing, filter cloths, leader and back grey cloths). Important as mixed fibre with wool, polyester, polyamide, viscose, copper and acetate fibres.

Polyacrylonitrile fibres in direct printing,

I. Cationic dyes: Brilliant and wet fast shades can be achieved with good light fastness. Print pastes contain the dye in dissolved or finely dispersed form. Powder dyes are dissolved by the addition of organic acids (acetic acid) and thiodiglycol and stirred into the thickener; then a non-volatile acid (e.g. tartaric acid) is added to the print paste, in order to maintain the acidic medium during fixation, because the dye is destroyed by alkalis. The addition of a carrier increases the colour depth, furthermore the fixation time can be reduced and the fixation temperature decreased. Cationic blue types based upon azo dyes are created by a reductive process; the reaction is accompanied by slight colour loss or shade change. The addition of an oxidant can help. When working with print pastes, in which the dye is present in finely dispersed form, they contain a slightly anionic dispersant in addition to the above-mentioned additives. It generates a finely dispersed, colloidal precipitation of the cationic dye in the print paste. This protects the dye in the paste against electrolytes and thus increases the stability of the paste. Furthermore, differences in the diffusion capacity of the individual products are equalised, which makes it possible to achieve more uniform and reproducible prints.

If the print paste contains a carrier, fixation takes place for 20–30 min in saturated steam, either discontinuously in the star steamer or continuously in the universal loop steamer. Print pastes with no carrier can only be discontinuously fixed with a low pressure of 0.3–0.5 bar. Then the material is thoroughly cold rinsed, soaped at 40–50°C or subjected to a reductive after-cleaning, rinsed again, dewatered and dried.

II. Disperse dyes are only used in certain cases, e.g. for large area patterns that are problematic from the point of view of evenness or for sharp contours. A further option exists if light beige or olive shades are required, which are difficult to achieve using cationic dyes due to reproducibility. The brilliance and wet-fastness of cationic dyes cannot be achieved with disperse dyes.

III. Dispersible 1 : 2 metal-complex dyes: subdued shades are achieved with good fastness.

The following dyes are used for mixed fabrics containing cellulose fibres:

a) Vat dyes are used according to the Rongalite-potash procedure.
b) Disperse/reactive dyes behave in a similar manner to when printing on polyester/cotton fabrics, however the selection of dyes is smaller; wet and light fastness is moderate.
c) Cationic/direct dyes: brilliant, shades are achieved with relatively good light and wet fastness.
d) Cationic/reactive dyes: brilliant shades with good light and wet fastness.

The following dyes are used for mixed fabric containing wool:

a) Disperse/acid dyes: brilliant shades with good light and wet fastness are achieved.
b) Selected metal-complex dyes: subdued shades with very good light and wet fastness.

Polyacrylonitrile fibre solubility Solvents for polyacrylonitrile fibres are sulphuric acid (96%) with a “Huggins constant” of kn = 0.32 and dimethyl formamide with kn = 0.24. The Huggins constant is found by measuring the viscosity of the solution.

Polyalcohols Alcohols with several OH groups, which includes glycols, glycerol $C_3H_5(OH)_3$ and sugar alcohol, but specifically high molecular alcohols such as polyglycol, polyglycerol, polyvinyl alcohol, cellulose (approx. 10 000 OH groups).

Polyamide blends, suitable dyes for,

I. Wool union/polyamide mixes are dyed with selected wool union dyes.

II. Wool/polyamide: selected acid, chrome (mordant), metal-complex dyes.

III. Cellulose/polyamide: selected direct dyes and mixtures with disperse dyes in single bath process. Disperse dyes including dyes that can be used for cellulose are applied in the two bath process.

IV. Acetate/polyamide: selected disperse dyes. Products are selected according to a) the tone-in-tone dyeing in self shades and b) the degree of soiling of the accompanying fibres in bicolour dyes.

Polyamide dyes Practical term for dyes for dyeing polyamide fibres. Selected dyes, specifically for dyeing polyamide, are disperse, acid and metal-complex dyes, which are usually classified into specific ranges. Developing, chrome and reactive dyes are also suitable. Pigment dyes can also be used for light shades.

Polyamide dyes, identification tests,

I. Agster: Staining reactions: Dissolve the dye from several fibre samples using certain solvents (→ Dye class identification on fibres), clean liquor and boil down. Put dye residue in hot water and neutralise with acetic acid or ammonia. Perform the dye test. Vat, vat leuco ester and naphthol dyes remain insoluble.

II. Bode: The dye is boiled sequentially with solvents for 6–8 min without intermediate rinsing.

III. Schumacher:

a) Boiling stripping with 5% formic acid. Disperse, water soluble disperse, cationic, chromium complex, chromium complex disperse and acid dyes are detected.

b) Boiling stripping with 5% ammonia. Chromium complex, acid, substantive and chrome dyes are detected.

c) Separation takes place at boiling point with 50 g/l zinc formaldehyde sulfoxylate conc. and 0.5 ml/l formic acid conc.

Vat dye = vatting usually in 10–20 s, colour shade re-oxidizable.

Leuco vat ester dye = vatting usually only after 2 min.

Naphthols = decolorizing in 1–2 min, the colour shade is not reoxidizable.

Pigment dyeing = no change, microscopic detection.

Polyamide fibre dyeing The neutral dyeing capacity defines the degree of bath exhaustion in percent at pH 6 and boiling temperature for a dye of double standard strength after a defined dyeing time. Dyes with low neutral dyeing capacity are strongly pH dependent and thus are only absorbed completely into the fibres in an acid bath. Dyes with high neutral dyeing capacity possess a high affinity to fibres and thus are completely absorbed by the fibres from a slightly alkaline or neutral bath.

The migration capacity is a measure for the migration of a dye from a dyed to an non dyed fibre in the dye bath. It is determined by boiling a 1/1 standard strength dyed fabric together with a non dyed sample at pH 6 in a colourless liquor for 60 min. A dye with a high migration capacity leaves the accompanying fabric colourless.

If the dyes are graphically represented in relation to the neutral dyeing and migration capacity, then the following positioning of the dye classes is found (see Fig.).

1. Reactive dyes show practically no migration at boiling temperature and have a medium to low neutral dyeing capacity.
2. Metal-complex dyes migrate slightly and possess a medium to high neutral dyeing capacity.

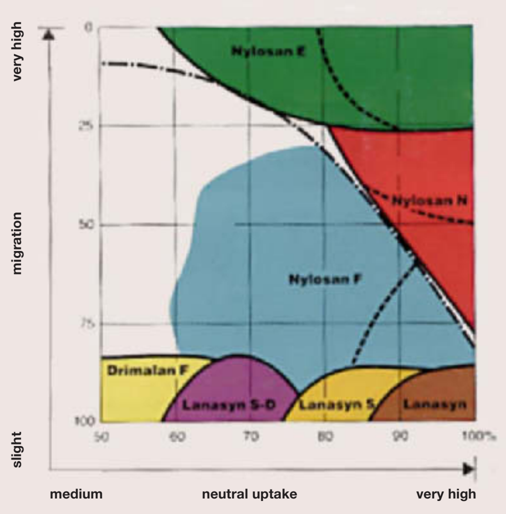


Fig.: The positioning of dyes for polyamide fibres according to their migration and neutral uptake (by Sandoz). (Drimalan F = reactive dyes; Lanasyn = metal-complex dyes; Nylosan = acid dyes.)

3. Acid dyes are spread over a wide range and their migration and neutral dyeing capacity vary greatly.

The representation conveys only a rough overview. In acid and metal-complex dyes a fine classification of dyes according to their dyeing behaviour and their fastness level has proved to be unreliable for experts. This classification permits a more precise selection of suitable products and their combinations, with the objective of increasing the operating safety and reproducibility of the dyes.

Acid dyes are, for example, divided into

- easily neutralized
- neutral dyeing types.

These two dye groups consist primarily of monosulphonated acid dyes. They can be combined well within their groups.

A further classification groups together wet-fast acid dye types. These dyes contain two sulphonic groups per molecule and are primarily used for self tints in double combination, specifically for brilliant shades. They also come into consideration as highlights for wet-fast metal-complex dyes.

The following groups of metal-complex dyes are of practical significance: 1 : 2 metal-complex dyes with

- “masked” sulphonic groups,
- one sulphonic group
- two sulphonic groups,

also some water insoluble, finely dispersed metal-complex dyes.

With the exception of metal-complex dyes with two sulphonic groups, metal-complex dyes can be combined well within the groups, because polyamide fibres have a good dye absorbency for such dyes. Under certain circumstances combinations of elements from neighbouring groups can also be used (according to Schwer).

Polyamide fibres Group of synthetic polycondensate fibres made of a chain of repeating functional amide groups (–NH–CO–). This group of synthetic fibres is important from a textile-technical and economic viewpoint. They are generally manufactured by spinning (see Fig.) from the melt (also as microfibres). The cross-section is round, profiled or smooth.

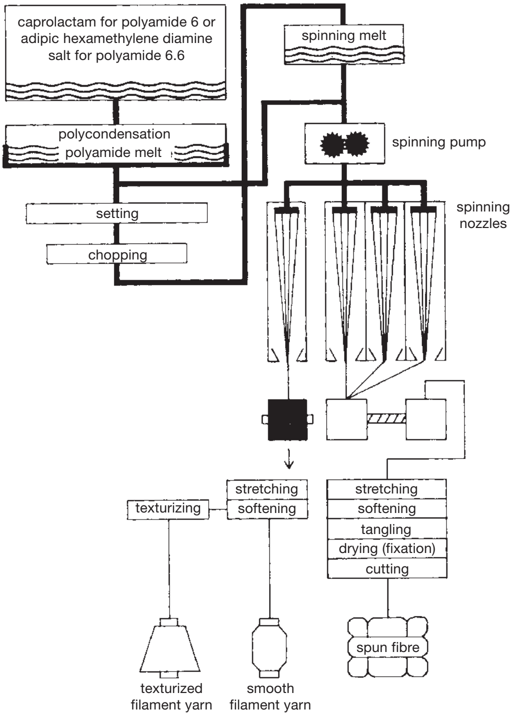

Fig.: The manufacturing process for polyamide fibres.

There are many options for polyamide production, depending upon the manufacturing process and the use of different basic materials. The figure next to the word “polyamide” (e.g. polyamide 6.6) gives the number of carbon atoms in the monomers which form the polyamide. The different number of CH_2 groups effects the properties of the finished fibre. Despite chemical similarity and sometimes a high level of similarity of the properties, there are differences. Physical constants of different polyamide fibre types are shown in the Tab.

Further properties: A certain acid sensitivity accompanied by good alkali resistance; soluble in phenols, conc. mineral acids and formic acids and glacial acetic acid at higher temperatures; sensitive to certain oxidizing agents, particularly peroxide; tendency to auto-oxidation, therefore not very light resistant (light sensitivity can be increased by the addition of light stabilisers during manufacture). The plasticity range, which is important for hot fixing, lies at 160–195°C for polyamide 6, for polyamide 6.6 this is 220–240°C. Polyamide fibres possess favourable strength characteristics (abrasion resistant), therefore used particularly where good wearing properties are required, e.g. carpets, but also widely for underwear, hosiery, outer clothing, fleece. Low swelling in aqueous media guarantees excellent dimensional stability when washed. Rot resistance and bacterial resistance (fishing equipment) are good. The low density and low absorbency mean that it is suitable for rainwear and swimwear.

Dyeing behaviour: → Dyeing of polyamide fibres. The dyeing behaviour of individual types of polyamide fibres, which is in itself very good, varies widely, and can be varied further by polymer additives in order to achieve differential dyeing polyamide fibre types.

Modification of polyamide fibre types:

1. Different (acid) dye take-up by changing the amino terminal group content. a) Low types: reduction of the amino terminal group content by coating with acrylic resin; b) Deep types: increasing the amino terminal group content by amidation of the carboxyl groups with basic groups.
2. Affinity to cationic dyes: blocking the amino terminal groups by a) addition of acid comonomers (e.g. metal salts); b) dispersing of sulphonated ethylene polymers (e.g. metal salts). Grafting of acrylamide (e.g. polymethacrylic acid).

Polyamide fibres in direct printing Acid and metal-complex dyes are most common. The print paste contains dye thickeners (e.g. locust bean flour derivatives, guar flour derivatives, crystal gum, starch ether), hygroscopic agents (e.g. thiourea, urea, thiodiethylene glycol), acid donors (e.g. ammonium tartrate, ammonium sulphate). Specifically in metal-complex dyes an acid donor can be dispensed with. Specific assistants are used to prevent a frosting in texturized polyamide. Alkylamine polyglycolether sulphate is used to eliminate unevenness, which occurs in particular on smooth fabrics with light shades. The addition of a swelling agent (e.g. phenol) sometimes darkens the colour shade considerably; application is problematic due to waste water pollution. Procedure: print, dry, steam with or without low pressure. Specifically in texturized polyamide there is a tendency to soil the white ground colour. This soiling is prevented by condensed phenolic bodies in the washing bath. The same substances are used as after-treatment agents for the improvement of the wet-fastnesses, as are tannin tartar emetic (potassium antimonyl tartrate).

PA types (*)	specific weight (g/cm³)	moisture uptake at 65 % relative humidity (%)	glass transition point (°C)	softening zone (°C)	melting point (°C)	specific heat (cal/g/°C)
polyamide 3	1.33	7.7			340	
polyamide 4	1.25	7.7			256	
polyamide 6	1.14	4.3	50	210	215	0.45
polyamide 7	1.10	3.0		220	225	
polyamide 8	1.09	2.9		180	200	
polyamide 9	1.09	2.5		190	210	
polyamide 11	1.04	1.2		175	190	
polyamide 12	1.01	0.9			180	
polyamide 6.6	1.14	3.8	45	236	255	0.40
polyamide 6.10	1.08	2.6			214	
alicyclic PA	1.04	2.5	135		275	
aromatic PA	1.38	4.5			decomposes at 370°	0.29

Tab.: The physical constants of various types of polyamide fibre.

Further dye application possibilities: The rarer disperse dyes are used in blotch printing in light to medium shades due to their good levelling capacity. With strong shades their wet-fastness is usually inadequate. Reactive disperse dyes are also hardly ever used. Reactive dyes (including wool reactive dyes) can, in principle, be fixed on polyamide, however only a certain dye proportion is chemically linked to the fibre; there is therefore inadequate reproducibility. The fixing degree is also highly dependent upon the fibre. Direct dyes are used if cheap items are to be printed without particular fastness requirements.

Polyamide fibres, solubility Polyamide fibres can be differentiated by their different solubility in ethylene glycol and propylene glycol at different temperatures (see Tab.).

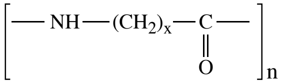
	ethylene glycol [˚C]	propylene glycol [˚C]
PA 6	135	129
PA 8	149	133
PA 11	insoluble	145
PA 6.6	153	153
PA 6.10	156,5	139,5
aromatic PA	insoluble	insoluble

Tab.: Differences in solubility of various polyamide fibres.

Polyamide gauze This has several advantages compared to metal gauze, such as greater elasticity, better dye paste penetration, alkali insensitivity, resistance to tearing. Disadvantages: Increase in elasticity when wet, the fabric must therefore be greatly stretched. Temperature variations also change the dimensional stability. → Screen making.

Polyamide imide → Aramidimide.

Polyamides Synthetic polycondensate, e.g. from diamine and dicarboxylic acids. The films are very scratch resistant, elastic, resistant to ageing, light, water (certain swelling property), alkali, oil and temperature (130–185°C and above), however poor acid resistance. Polyamides are also resistant to aliphatic hydrocarbons, esters and ketones.



$$\left[-NH-(CH_2)_x-\underset{\underset{O}{\|}}{C}- \right]_n$$

The functional groups are the acid amide groups –NHCO–. Polyamides (alcohol-aqueous solutions, emulsions, foils) are used as coatings, lacquer raw materials, materials for gears, etc. We differntiate between synthetic polyamides (polyamide fibres such as polyamide 6 and 6.6) and natural polyamide (wool, silk).

Synthetic polyamide fibres are named as follows according to the number of the carbon atom forming the monomer in question:

- polyamide 3, polyamide from β-lactam (β-alanine). Fibre raw material.
- polyamide 4, polyamide of γ-butyrolactam.

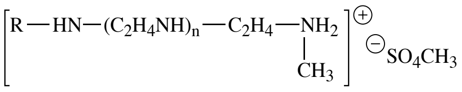
- polyamide 472, polyamide of diamino dicyclohexylmethane and decane dicarboxylic acid.
- polyamide 6, polyamide of ε-caprolactam. Important fibre raw material.
- polyamide 6.6, polyamide of 1.6-hexamethylene diamine and adipic acid. Important fibre raw material.
- polyamide 6.6/6, polyamide of → Adipic hexamethylene diamine salts and ε-caprolactam. Copolymer made up of polyamide 6 and 6.6.
- polyamide 6.9, of 1.6- hexamethylene diamine and nonadicarboxylic acid. Fibre raw material.
- polyamide 6.10, of 1.6-hexamethylene diamine and sebacic acid. The threads in moist state are stiffer than polyamide 6.6/6. Application specifically for wire and brushes.
- polyamide 6.12, polyamide of 1.6- diamino hexamethylene and dodecane carboxylic acid. Fibre raw material.
- polyamide 7 (polyheptanoic acid amide, polyoenanthic acid amide), of 7-amino-oenanthic acid (7-oenantholactam).
- polyamide 8, polyamide of 8-caprolactam.
- polyamide 9, of 9 amino-nonanoic acid.
- polyamide 9.1, polyamide of 1.9-nonamethenediamine and urea.
- polyamide 11 (polyundecanoic acid amide), polyamide of 11-amino undecanoic acid, which is extracted from castor oil. Fibre raw material.
- polyamide 12 (polylauryl lactam), polyamide of lauryl lactam (12-amino dodecanoic acid). In the form of homo and co-polyamides as fibre material, e.g. as monofilament and adhesive fibres.
- polyamide mP.I., aromatic polyamide of 1.3-phenylenediamine and isophthalic acid. → Aramide (fibres).

Polyamines, polyimines High molecular compounds with internal clustered imine groups NH, either uninterrupted with amino groups NH_2 (polyamines) or as follows with C_2H_4NH chains (polyimines):

alkyl polyimines: $R–NH(C_2H_4NH)_nH$

acryl polyimines: $R–COHN(C_2H_4NH)_nH$.

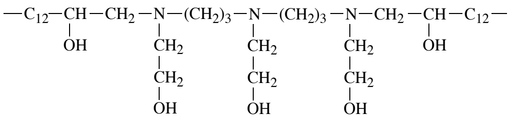
Due to the clustered NH bridges, products of this type have a cationic character. In particular, substituted polyimines with a high level of imine ethylation (C_2H_4NH), ethyleneimines, are markedly cationic. Familiar substituted polyimines, form e.g. cationic softeners such as: $R–CO(NHC_2H_4)_nNH_2$ or cationic fastness aftertreatment products for substantive dyes:



$$\left[R-HN-(C_2H_4NH)_n-C_2H_4-\underset{\substack{|\\ CH_3}}{NH_2}\right]^{\oplus}\ {}^{\ominus}SO_4CH_3$$

Polyamines are recommended to a greater or lesser degree as partly quarternisation scrooping active contents (fabric softeners) and also as flocculation agents in waste water cleaning. This group includes e.g. oxethylated bis(hydroxyalkyl)-dipropentriamine with three hydroxyethyl groups. With regard to softening power and manufacturing properties the product with two hydroxy-tetradecyl residues provides favourable conditions.

bis(-hydroxyalkyl)-dipropentriamine + 3 EO



$$-C_{12}-\underset{\substack{|\\ OH}}{CH}-CH_2-\underset{\substack{|\\ CH_2\\ |\\ CH_2\\ |\\ OH}}{N}-(CH_2)_3-\underset{\substack{|\\ CH_2\\ |\\ CH_2\\ |\\ OH}}{N}-(CH_2)_3-\underset{\substack{|\\ CH_2\\ |\\ CH_2\\ |\\ OH}}{N}-CH_2-\underset{\substack{|\\ OH}}{CH}-C_{12}-$$

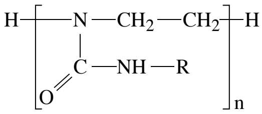
Polyamyloses Term related to soluble starches. → Amylose.

Polyaramide fibres → Aramide (fibres).

Polyaramides Aromatic long-chain polyamides, in which at least 85% of the amino groups are directly connected to two aromatic rings and whereby up to 60% of the amide groups can be substituted by aromatic imide groups. → Aramide (fibres).

Polyases Group of → Enzymes belonging to the hydrolases or carbohydrases, which split high molecular carbohydrates to some degree.

Polyaziridines have the formula



$$H\left[\underset{\substack{|\\ O=C-NH-R}}{N}-CH_2-CH_2\right]_n H$$

They can cross-link polyester polyurethane. They are applied, dried and fixed (cross-linked) as an aqueous dispersion of the two polymers e.g. by nip padding.

Polyazo dyes → Azo dyes.

Polybases Cationic → Polyelectrolytes.

Polybasic Term for acids with several active acid-hydrogen atoms, which can be ionized and replaced by metals, e.g. →: Dibasic; Tribasic, in contrast to monobasic.

Polybenzimidazole fibres (PBI fibres), were originally developed for space suits and parachutes. They have the same comfort properties as cotton, do not burn, do not give off toxic gases in a fire and possess similar processing properties to polyester.

Polyblends (polymer mixes, polymer blends), there are polyblends (Fig. 1) with:

- macroscopic phase boundaries in the form of composite materials;
- microscopic phase boundaries in the form of intermolecular mixtures (blends);

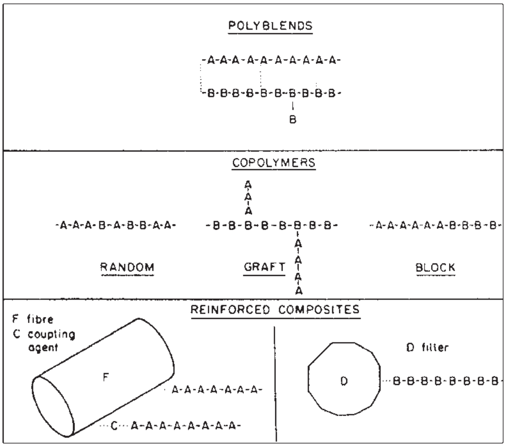


Fig. 1: Multiple component polymer systems (according to Platzer).

– quasi homogeneous intramolecular compounds in the form of graft copolymers and ionomers.

"Compounding" is the term used to describe the addition of a different hard-brittle polymer (e.g. styrene) to a tough-soft elastomer, so that a hard-tough thermoplastic is the result.

Cotton, wool and silk are examples of naturally mixed macromolecular systems in the form of biological composite materials. Synthetic polymers always represent mixtures, because the polymerization process leads to differing chain lengths, but a one hundred percent fractionation is not possible. Like the chain length distribution, the low molecular residues and other impurities remaining in the substance after the polymerization process can also lead to mixing effects. Mixtures also arise in the finishing of materials with softeners, stabilisers, dyes, etc. and during dissolving and swelling. Filled and reinforced materials and polyblends , if they are in inhibited equilibrium states, can be described by the thermodynamics of the mixtures. Block and graft copolymers with high sequence lengths, on the other hand, although they behave in a similar manner to mixtures, defy precise description by phenomenologic thermodynamics, because in this case mixing takes place on an intramolecular level. A differentiation can be made between homogeneous and heterogeneous mixtures. Homogeneous mixtures are characterized by a uniform, location-independent composition. Their properties are generally not additive, i.e. in addition to the contributions made by the individual components of the mixture to the properties of the system as a whole, the characteristic mix members also appear. It is possible to differentiate between different mixture types depending upon the type of these mix members. Heterogeneous mixtures consist of homogeneous subareas (phases) of different composition. Finally, the incompatibility of polymer mixtures in solution, which occurs in almost all polymers, should be mentioned. This is the phenomenon, whereby two polymers, when separately dissolved in the same solvent, form a homogeneous solution, but when these two solutions are combined a phase separation occurs. For example, if 10% solutions of polystyrene in benzene and polyvinyl acetate in benzene are mixed, then despite the use of the same solvent a phase separation occurs, which results first in a noticeable cloudiness and then leads to the formation of two separate phases. One phase contains more of polymer 1, the other more of polymer 2; however both phases always contain a certain proportion of the other polymer. This limited compatibility of polymer mixtures can be explained in terms of thermodynamics and depends upon various factors, such as the structure of the macromolecules, the molecular weight, the mix ratio of the two polymers, the overall polymer concentration and the temperature. Often small structural differences are sufficient to bring about an incompatibility of macromolecules. Sometimes compatible blends are desirable, in other cases incompatible blends are required. For example, natural rubber and poly(styrene-co-butadiene) give compatible elastomer blends; poly(styrene) with poly(2.6-dimethyl-phenylene-oxide) leads to a compatible thermoplastic blend. Impact resistant blends made of thermoplastics and elastomers, on the other hand, are incompatible; for example polystyrene is incompatible with poly-α-methylstyrene and polymethylacrylate is incompatible with polyethylacrylate. Copolymers from the same monomers often become incompatible even where there are only slight deviations in composition.

Marked morphologies may occur in polymer mixes depending upon external circumstances. For example, a polyacrylic ester-polystyrene-polyacrylonitrile product (ASA), which contains acrylic ester as an impact resist-

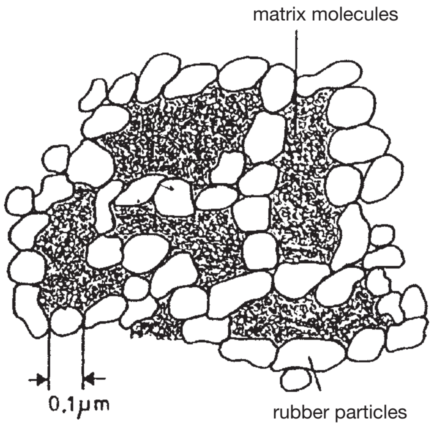

Fig. 2: The morphology within an ASA product (acrylic ester/ styrene-acrylonitrile copolymer) as a polyblend.

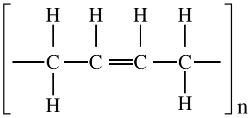
ant component in a styrene/acrylonitrile copolymer, has the structure illustrated in Fig. 2. The mobility of the matrix molecules within the cell is reduced, as long as the particles hold together. Under high stresses, however, the cell structure falls apart and thus the mobility of the matrix molecules increase, allowing flow processes.

Polybutadiene Polymer → Butadiene in the form of a substitute rubber material for rubberizing, coating, laminating, etc.

Polybutadiene fibre Synthetic polymeride monofilament made of butadiene, manufactured using the wet spinning (stretch) process. Water absorption 0.02%; dyeable only in spinning solution.



$$\left[\;-\underset{\mathrm{H}}{\overset{\mathrm{H}}{\mathrm{C}}}-\overset{\mathrm{H}}{\mathrm{C}}=\overset{\mathrm{H}}{\mathrm{C}}-\underset{\mathrm{H}}{\overset{\mathrm{H}}{\mathrm{C}}}-\;\right]_n$$

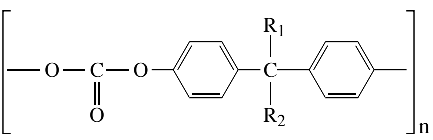
Polybuteneterephthalate (PBTP) → Polytetramethylene terephthalate fibre.

Polycaproamide fibres Rare term for → Polyamide fibres of type polyamide 6 or polyamide 6.6.

Polycaproamides Group of polyamide fibres of type polyamide 6 (base → Caprolactam).

Polycarbonate fibres Synthetic polycondensation fibres (polyester group) (formula principle → Polycarbonates). Manufactured from diphenylpropane and carbonic acid esters (easily accessible due to phenol and acetone). Properties: Density 1.2; water absorbency 0.6%; elongation at break 80–100%; highly heat resistant; high melting point; insoluble in benzine, diluted acids and lyes; soluble in acetone, ethyl acetate, benzene, dichloromethane, carbon tetrachloride.

Polycarbonates Thermoplastic, synthetic polycondensates in the form of polyester e.g. carbonic acid with divalent phenols.



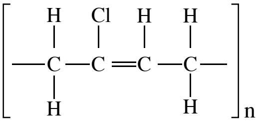
R_1, R_2 = e.g. $-CH_3$

Can be described as a “mirror image” of so-called polyester, also with similar properties: Colourless, transparent; resistant to water, weak alkalis, mineral acids, oils, hydrocarbons. Polycarbonate plastic is also light, rigid, hard, unbreakable, shock-resistant, (can be nailed, and can itself be used in the form of nails); has good electrical properties, is heat resistant up to approx. 137°C; odourless, physiologically harmless. Application: foils, fibres; materials for street lights, fluorescent tube mountings, bottles, transport containers.

Polycarboxylic acids → Carboxylic acids with several COOH groups, e.g. succinic, fumaric, maleic, malonic, oxalic, phthalic, tartaric, citric acid.

Polychlorinated biphenyls (PCB). Is a carcinogenic substance unsuitable for textile finishing.

Polychlorobutadiene Synthetic polymeride, in solutions and emulsions, for coatings and container linings.



$$\left[\;-\underset{\mathrm{H}}{\overset{\mathrm{H}}{\mathrm{C}}}-\overset{\mathrm{Cl}}{\mathrm{C}}=\overset{\mathrm{H}}{\mathrm{C}}-\underset{\mathrm{H}}{\overset{\mathrm{H}}{\mathrm{C}}}-\;\right]_n$$

Polychloroprene → Polychlorobutadiene.

Polychromatic Multi-coloured, bright. Opposite of → Monochromatic.

Polychromatic and monochromatic measuring arrangement In → Spectrophotometer. Optical path length for:

I. Polychromatic measuring arrangement: light source, monochromator, receiver.

II. Monochromatic measuring arrangement: light source, monochromator, sample, receiver.

Fluorescent samples can only be measured using polychromatic measuring arrangement. For non-fluorescent samples the measuring arrangement is unimportant. The results from correct and the incorrect measuring arrangements are shown in the curves in Fig.

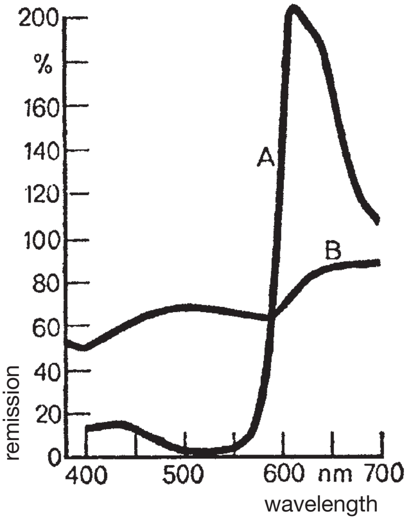


Fig.: Remission curves for a fluorescing red dye obtained using the right (A) and the wrong (B) measuring arrangement.

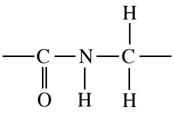
Polychromatic dyeing For fabrics and carpets. In principle this consists of aiming separate jets and dye solutions at continuously running lengths of material, before and whilst the material passes through squeeze rollers. The application device consists of a number of colour jets and is attached to two or more rods. The length of the rods is the same as the width of the application machine. The nozzles direct the jets of dye liquor at an inclined plate and from there onto the length of material (Dye Weave) or directly onto one of the two squeezing rollers (Flow Form). The nozzle rods can be moved backwards and forwards and in this manner form patterns and colour mixtures (→ Space dyeing).

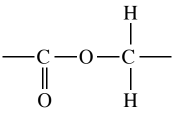
Polychromatic printing Multi-coloured printing with a printing roller. → Orbis printing.

Polycondensation → Condensation polimerisation.

Polycondensation fibres Currently the most important main group of → Synthetic fibres (natural fibres also belong to the group of polycondensation fibres), which are created by → Condensation polymerisation, i.e. by a condensation reaction between the different molecules (intermolecular condensation), whereby smaller molecules, such as water or alcohol, form due to splitting or as a secondary product. Unlike → Polymerization fibres, the main chain contains carbon and foreign atoms (usually nitrogen, sulphur, oxygen) or linking polar groups (–COONH–, COO–, etc.).



$$-\underset{\underset{O}{\|}}{C}-\underset{\underset{H}{|}}{N}-\overset{\overset{H}{|}}{\underset{\underset{H}{|}}{C}}-$$



$$-\underset{\underset{O}{\|}}{C}-O-\overset{\overset{H}{|}}{\underset{\underset{H}{|}}{C}}-$$

Polycondensation products (polycondensate, polycondensation resin, polycondensation plastic), products of → Condensation polymerisation, in the form of plastics or synthetic resins, such as →: Alkyd resins; Epoxy resins; Urea-formaldehyde compounds; Ketone resins; Melamine-formaldehyde compound; Phenolic plastics; Polyamides; Polycarbonates, Polycondensation fibres; Polysulphides.

Polycondensation resins → Polycondensation products with a synthetic resin character.

Polycotton Abbrev. for mixed fabric made of polyester and cotton.

The mix ratio varies depending upon area of origin. Typical values = 70 polyester : 30 cotton or 65 : 35 or 50 : 50. Pretreatment as pure cotton plus heat setting.

Polycyclic vat dyes Group of → Vat dyes with valuable properties. The molecules of many vat dyes can be enlarged by condensation reactions, without having a detrimental effect on the properties of the dye. Polyindigo, polythioindigo and polyindanthrene are produced in this manner and used to dye polyamide fibres. Polycyclic vat dyes can be dissolved in alkali and sodium dithionite, but are only slightly soluble, some are not soluble at all. Their poor adsorption by the fibre gives rise to a significantly higher wet fastness. Critical from an economic point of view is the freedom from sublimation in heat as a result of the increased size of the molecule, which no longer vaporizes. A further advantage is the protection of the fibre itself against thermal degradation. Whereas undyed polyamide 6.6 no longer has any solidity after 5 h at 200°C and indigo dyed polyamide 6.6 has only 8% of its initial solidity after 48 h, polyamide dyed with polyindigo retains 20% of its solidity. Polycyclic vat dyes therefore represent additional, valuable, heat resistant stabilisers against thermal degradation of fibres.

Polydialkylsiloxane (alkyl silicone) → Silicones.

Polydimethylsiloxane There are three generations of silicon emulsions:

1st generation: polydimethylsiloxane with terminal OH groups.

2nd generation: polydimethylsiloxane with amino groups in the side chains.

3rd generation: micro-emulsions.

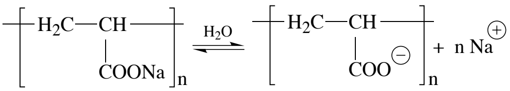
The 1st generation, which had been developed as early as 1972, relates to poydimethylsiloxane with terminally cross-linkable OH groups. The 2nd generation differs from the 1st due to the amino groups in the side chains. These are also called unitary elastomer systems. The 3rd and most modern generation is represented by the silicon micro-emulsions. Chemically these are amino functional polydimethylsiloxanes. Because these products have no terminal OH groups, they cannot be cross-linked like the above-mentioned emulsions. Despite this fact, there are advantages with regard to handle, effect level, mechanical and thermal stability and permanence due to the particle size and degree of distribution. → Silicones in finishing.

Polyelectrolytes High molecular → Electrolytes, natural (e.g. protein polysaccharide) or synthetic (e.g. krilium) macromolecules with incorporated ionic groups; their charge can be positive (cationic polyeletrolytes = polybases), negative (anionic → Poly acids, e.g. polyacrylic acid) or neutral (poly salts, e.g. salts of polyacrylic acid as polyacrylate sizes). Polyelectrolytes can be strong or weak electrolytes. Aqueous polyelectrolyte solutions conduct electric current, have higher osmotic pressure and higher viscosity than the same amount of non-ionic macromolecules. Polyelectrolytes are components e.g. of some boiler scale prevention agents, synthetic resin ion exchanger, sizes, thickeners, etc.

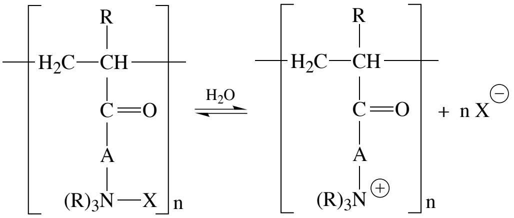
Monomer sodium acrylate dissociates in water into the polymerizable anion acrylate and the (cationic) counterion sodium.

$$H_2C{=}CH-COONa \xrightleftharpoons{H_2O} H_2C{=}CH-COO^{\ominus} + Na^{\oplus}$$

The polymerization of sodium acrylate leads to sodium polyacrylate. This dissociates into the polyanion polyacrylate in water, which is balanced by many sodium ions as counterions.



In the same way a cationic polyelectrolyte can be produced from a cationic polymerizable electrolyte, which dissociates into polycations and anions in an aqueous solution.



If the solution of an anionic polyelectrolyte is mixed with the solution of a cationic polyelectrolyte, then the polymer ions interlace in such a way that precipitation is the result. In copolymers, not all chain members must have an electrolytic character. It is perfectly possible for ionic monomers to be polymerized together with nonionic monomers. The greater the proportion of non-ionic monomers selected, the weaker is the ionic nature of the copolymer. Then, there are, for example, weak or strong cationic polyelectrolytes.

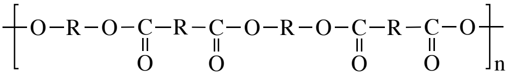
Polyenes Polymerized → Dienes.

Polyepoxides Polymer epoxy resin, → Epoxy resins.

Polyester,

I. Synthetic polycondensate made of e.g. multivalent alcohols and dicarboxylic acid, to higher and high molecular (ester) compounds such as phthalate resins (of glycerol and terephthalic acid). Polyester containing a hydroxyl group (e.g. glycol-adipic acid polyester) with 2–10% OH content are soft resins, oils or waxes, which organically soluble, can be additively cross-linked with di-isocyanates to form elastic-soft coatings (→ Polyurethanes).

II. Generic term for polyester fibres, according to an American proposal those of at least 85% by weight of an ester of a diol and terephthalic acid.



$$\left[-O-R-O-\underset{\displaystyle O}{\overset{}{\underset{\|}{C}}}-R-\underset{\displaystyle O}{\underset{\|}{C}}-O-R-O-\underset{\displaystyle O}{\underset{\|}{C}}-R-\underset{\displaystyle O}{\underset{\|}{C}}-O-\right]_n$$

Polyester amides Polyaddition product of type $-OOC-NH-R_1-NH-COOR_2-$; → Polyurethanes.

Polyester amines as demulsifiers The chemistry of demulsifiers is complex and has many variants. The base products are ethylene oxide/propylene oxide (EO/PO) block polymers with molecular weights of several thousand. These modules can be further cross-linked to increase the molecular weight and then have an improved effectiveness spectrum. Polyester amines (see Fig.) are frequently used to improve the quality of separated water. They have a slightly cationic character and are condensation products of one oxyethylated fatty amine, one dicarboxylic acid and one ethylene oxide/propylene oxide block polymer (Hoechst).

Polyester/cellulosic blends Sequence of pretreatment work stages: singeing, desizing, washing, scouring/bleaching, drying, fixing, mercerizing, drying. A continuous treatment process guarantees uniform treatment with the required chemicals, thus

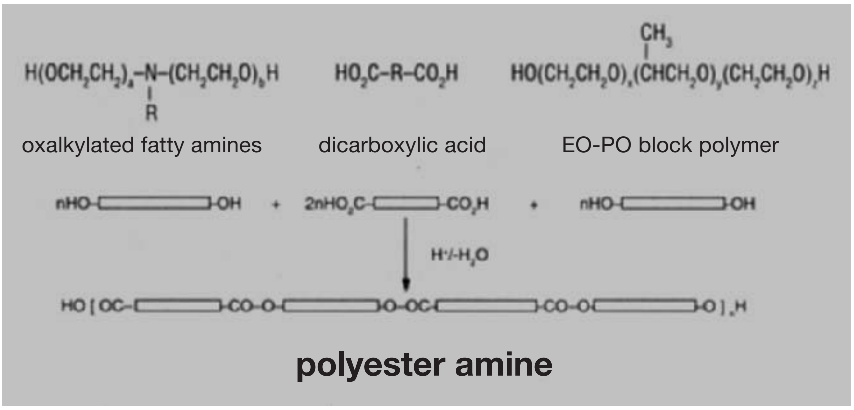


Fig.: The synthesis of polyester amine.

achieving good pretreatment effects with a high degree of reproducibility. Uneven dyeing will result if different swelling states exist between the centre and edges of the material. More intense local singeing of fabrics made of polyester/cellulosic mixed yarns can lead to thermal damage of the polyester fibre or the whole fibre composite and subsequently give rise to colour shade or nuance differences.

The ease with which sizing agents used in the manufacture of fabric can be removed varies. Removeability of sizing agents during pretreatment:

Easy to remove	**Difficult to remove**
I. sizes:	
polyacrylates	native starches of maize, rice and potatos
modified maize and potato starch	tapioca starch
CMC	glue containing sizes
polyvinyl alcohol*	
II. size auxiliaries:	
emulsified tallow	paraffin
PEO wax	non-emulsified tallow
PPO wax	silicon defoamer

* on condition that the pretreatment does not begin with an alkali stage

The use of water soluble sizes is becoming ever more prevalent, particularly in mixed fabrics made of polyester/cellulosic fibres. However, almost all of these products are not directly soluble in water, but only after swelling. Therefore, care must be taken that there is sufficient liquor take-up; furthermore the swelling process takes some time.

The fully continuous process with singeing, washing out of the water soluble sizes, scouring and bleaching requires the use of a device after the singeing stage, which allows the material soaked in wetting agent to dwell for several minutes before it is rinsed out. Such a device consists of two impregnation points with an air passage between them. The fact that particular importance is attributed to a good wetting agent with regard to the liquor take-up, is largely due to the material speed of up to 150 m/min when using a singeing machine. Surfactants with a good wetting power and a high emulsifying and dispersing capacity are preferred. Enzymatic desizing has the disadvantage that it cannot be combined with other processes. Therefore, oxidative desizing is preferred, which can be carried out in combination with the alkali stage and is therefore more economical.

Low tension pretreatment has become increasingly important for items previously assumed to be able to stand up to lengthways tension of any type during pretreatment without damage, or for which this was even considered necessary. The material quality and handle is influenced by completely tension-free scouring such that the final quality of material dyed according to a continuous thermosol pad steam process barely deviates from material dyed using an exhaustion process, e.g. by a jet.

Hot bleaching with hydrogen peroxide is the dominant continuous bleaching process. Catalytic damage hardly ever occurs as a result of bleaching processes such as NET processes or the PKS process. It is not necessary to bleach for coloured material. For light and, above all, brilliant colour shades, the cotton fibres are bleached with hydrogen peroxide. Chlorite bleach plays no role in continuous bleaching processes because it is less suitable for continuous pad-steam processes. Hypochlorite bleach is hardly ever used as a preliminary stage for a subsequent peroxide bleach due to environmental legislation (AOX). The demand for continuous pre-treatment is primarily a question of the quality of the material and the uniformity of the effects (according to von der Eltz).

Polyester cotton mixes are attributed great importance, because textiles manufactured from them possess good wearing properties and high wear resistance. Natural and synthetic fibres complement each other excellently. The mix ratio is usually polyester/cotton 67/33 or 50/50. The most important items are shirt and raincoat material. Tone-in-tone pastel shades can be achieved both in the exhaustion and the padding procedures using selected dispersion dyes alone. Finished dye mixes (mixed dyes) are in the ratio 67/33 and guarantee uniform shade dyeing of both fibres.

Polyester confirmation test Reaction to prove the presence of polyester. 0.5 g of hydrated oxide of iron (rouge) is moistened with a little methanol and then dissolved in 50 ml of m-cresol (hydroxytoluene). Short lengths of fibre are cut using blunt scissors and immersed in the reagent for five minutes at room temperature. The fibres are then thoroughly rinsed with methanol then briefly rinsed with acetone and finally washed with alcohol. The ends of any polyester fibres will appear coloured strongly red. The previously used phenol and oil red test reaction is no longer to be recommended because of the solubility of some forms of polyester in phenol.

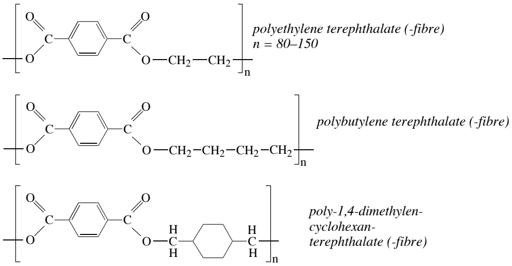
Polyester dyes Simplified practical term for dyes for → Dyeing of polyester fibres.

Polyester dyes, identification tests (according to Agster),

1. identification plan: procedure identical to that for → Acrylic dyeings, Identification of dye class.
2. dyeing reaction: procedure as for → Acrylic dyeings, identification of dye class. Azo and vat dyes remain insoluble (blank vat).

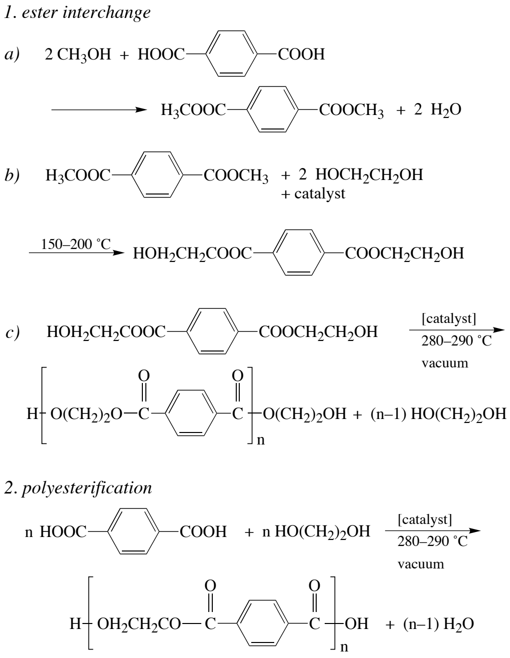
Polyester elastomers (polyester rubber), → Elastomers based upon polyester, which require no crosslinking. Some properties: unusual resistance against impact/bending cracks, good fabric adhesion; resistance against diluted acids good, against concentrated acids poor; against solvents excellent/good; against oxidation (ozone) excellent; against sunlight good; against ignition moderate to good.

Polyester fibres Group of synthetic polycondensate fibres made of terephthalic acid and ethylene glycol. The following polyester fibres, listed in order of decreasing importance, have proven their value in technical applications:



In the manufacture a differentiation is made between polycondensation, i.e. the synthesis of the polymer, and the melt-spinning process. The discontinuous process of “ester interchange” is used to produce special fibres in small quantities, whereas larger quantities (e.g. tyre cord) are produced in a continuous process combining synthesis and melt-spinning according to the process of “polyesterification”.

Whereas in the ester interchange process, the polyester fibre is produced in three stages:



- dimethylester production,
- ester interchange in the VK pipe (simplified continuous) with granule production (Fig. 1),
- melt-spin process,

in the polyesterification process polyester fibres are produced by the spinning process in a single step (Fig. 2).

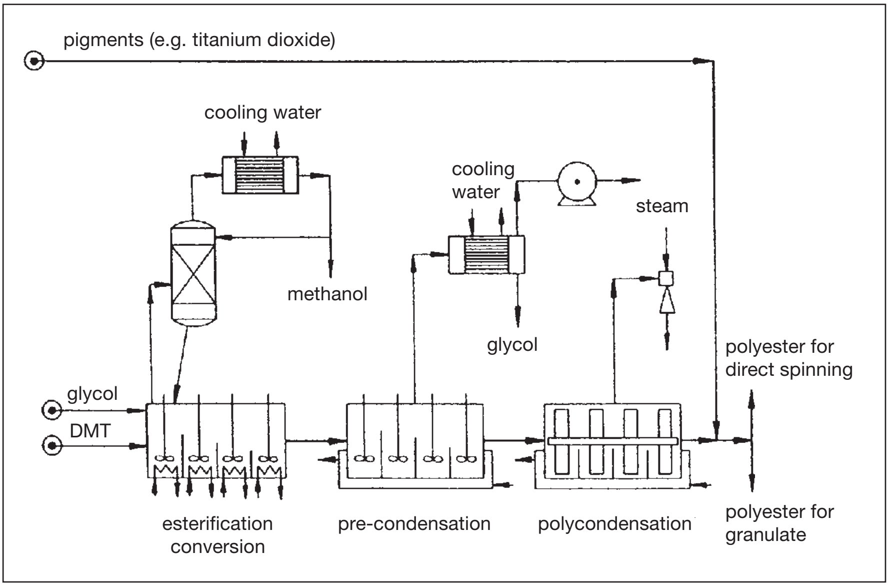


Fig. 1: The continuous production of polyester from dimethyl terephthalate (DMT) (according to Pelousek).

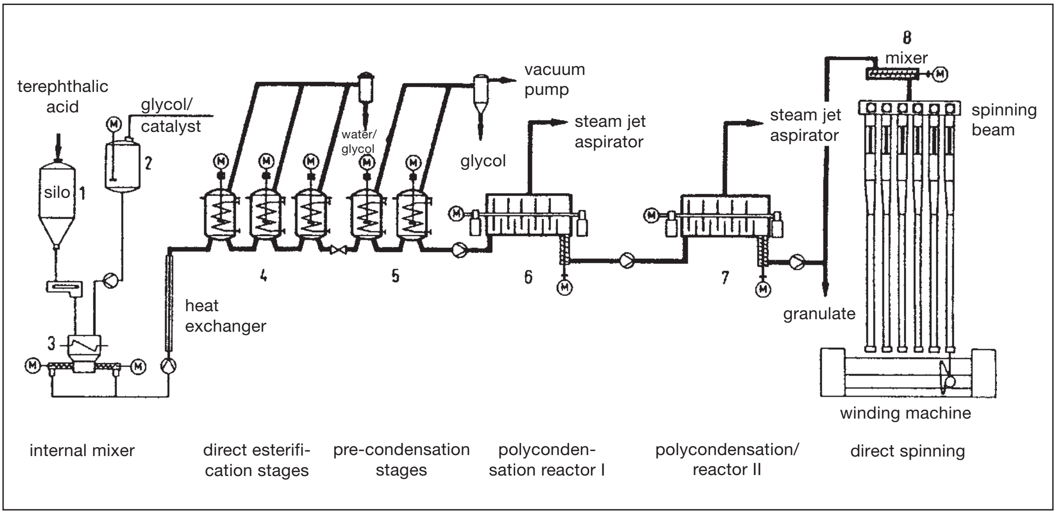

Fig. 2: Process diagram of a continuous polymerization facility with direct spinning for the manufacture of polyester cord, the starting point being terephthalic acid (according to Pelousek).

Depending upon the property profile one differentiates

a) in relation to the spinning speed (Figs. 3 + 4):

- 1000–2000 m/min LOY (low oriented yarn),
- 2000– 4000 m/min POY (pre-oriented yarn), amorphous, pre-elongation necessary;
- 4000–6000 m/min HOY (highly oriented yarn), part-crystalline, pre-oriented in a preferred direction;
- 6000–8000 m/min FOY (fully oriented yarn), fully elongated.

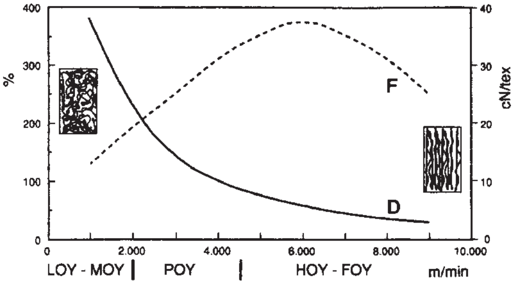

Fig. 3: Drawing speed (m/min) during the melt-spinning process together with the consequent expansion D (in %) and firmness F (in cN/tex).

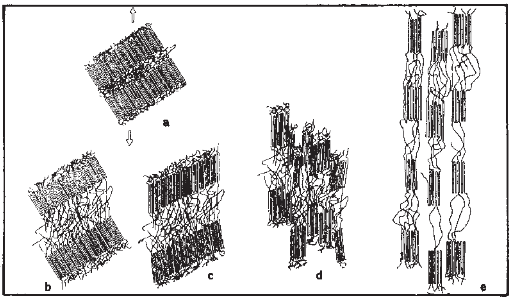

Fig. 4: Different degrees of drawing (a–e).

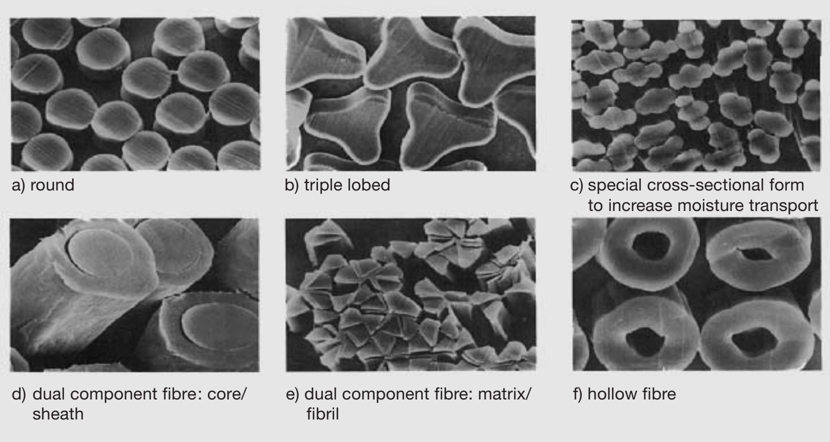
b) in relation to diverse influences:

- high-strength filaments with high degree of drawing for tyre cord and other technical textiles;
- low pill type due to reduction of the average degree of polymerization and thus low breaking strength in bending (pills break off);
- high-shrinkage fibres which shrink when boiled to achieve high-bulk during finishing;
- types that can be dyed without a carrier due to the inclusion of block polyethylene in the ester interchange process, thus reduced glass transition temperature;
- types that can be cationically dyed due to copolycondensation of terephthalic acid, isophthalic acid, sulphonicisophthalic acid, ethylene glycol or 1.4–methylcyclohexane.

c) in relation to the spinning profile (Fig. 5):

- microfibres between 1.0 dtex and 0.3 dtex;
- profile fibres such as triangular or pentagonal star in order to alter the lustre and handle; round, trilobal;
- bicomponent fibres (side-by-side type, S/S) with three dimensional ripples;



a) round

b) triple lobed

c) special cross-sectional form to increase moisture transport

d) dual component fibre: core/sheath

e) dual component fibre: matrix/fibril

f) hollow fibre

Fig. 5: Cross-sectional forms of polyester (according to Wulhorst, Tetzlaff and Dahmen).

- biconstituent fibres (bicomponent fibres of the matrix / fibril type, M/F) of polyamide with polyester as fibrils;
- hollow fibres.

d) According to the dyeing status:

- spin dyed (Fig. 6);
- white-delustred;
- flock, yarn, piece dyed;
- thermosol dyed.

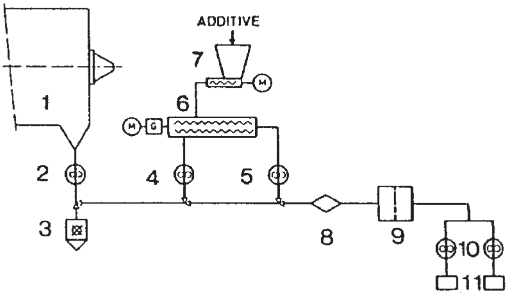


Fig. 6: Flow diagram of a facility for melt modification. 1 = final reactor; 2 = application pump; 3 = granulator; 4 = delivery pump; 5 = return pump; 6 = twin shaft extruder; 7 = additive dosing device; 8 = static mixer; 9 = melt filter; 10 = spinning pump; 11 = spinning heads.

e) according to the make-up type (Fig. 7);

- tow;
- staple fibres (broken or cut);
- smooth filament;
- Air entangled yarn (filament);
- texturized filament yarn.

Spinning process: after the first roll batching devices for higher speeds became available at the beginning of the 1970s the era of “high-speed spinning” had begun. This was not only an important step towards the improvement of product characteristics. Due to the change to product characteristics as a result of the higher speeds, there was a significant simplification of the process. The products became less sensitive towards external influences and new, more economical after-processing and further processing stages could be developed. Due to the feed speeds, which had increased to 2500–3500 m/min, and

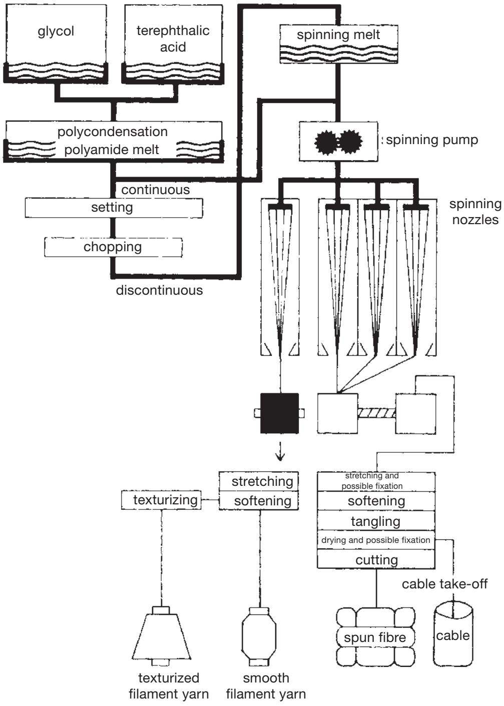

Fig. 7: The entire process of polyester fibre manufacture.

the resulting increased thread tensions the chain molecules were more aligned in the fibre longitudinal axis. The resulting yarn is therefore significantly more pre-oriented and is therefore called a pre-oriented yarn (POY). As Fig. 3 shows, this is associated with increased strength and lower elongation at tear.

However, the actual revolution triggered by these innovative yarn types lay in their stable and reproducible product characteristics. The yarns have excellent storage and despatch properties, which resulted in a previously unheard of flexibility in time and space. This high product stability is due to the presence of very small crystalline areas, which prevent the reorientation of the molecular structure at room temperature. However if the temperature is increased above the glass transition point T_g, then there is an increased reorientation of the amorphous (non-crystalline) oriented molecules towards their original disoriented position. This is associated with a shortening of the yarn, so-called “shrinkage”. The shrinkage value increases with increasing amorphous orientation. If the spinning speed is further increased, tension induced crystallisation occurs, i.e. amorphous areas are converted into energetically stable crystalline zones. This blocking increases the molecular reorientation of the amorphous phase, even at temperatures above T_g, and results in a drastic reduction of the shrinkage value. For the manufacture of smooth yarns, draw twisting is used as a subsequent process. Furthermore, the good and reliable product characteristics of the POY facilitated the development of the stretch warping process, in which a large bunch of POY reference yarn is stretched and at the same time, batched to warp beams for weaving. However, the development of POY is of greatest significance for the stretch texturizing process, which is used in the majority of POY production. As a result of the special molecular properties of POY, the temperature at which the heat induced crystallisation occurs is approx. 30°C lower than for LOY. This facilitates the single stage stretch texturizing process, in which the drawing and fixing of the applied yarn twist takes place on a heating element, without (as is the case for LOY) sticking to the hot plate. If we disregard the so-called highly oriented yarns (HOY), which must still be subsequently stretched or used where the higher yarn twist is acceptable, the next development stage is the FOY produced in a single stage process. The products created in this manner are exclusively flat yarns, which can be subjected to the air-jet texturizing process. There are different options for single stage manufacture from fully drawn yarn (FDY similar to FOY). They all have in common the fact that the drawing process is integrated and takes place between nozzle and batch rolling device (according to Zengel).

The dyeing properties depend upon the morphological structure of the fibre (Fig. 8), which is primarily influenced by the thermal and mechanical history of the fibre prior to the dyeing process. The dye absorbency increases with increasing thermofixing temperature, before increasing at above approx. 190°C.

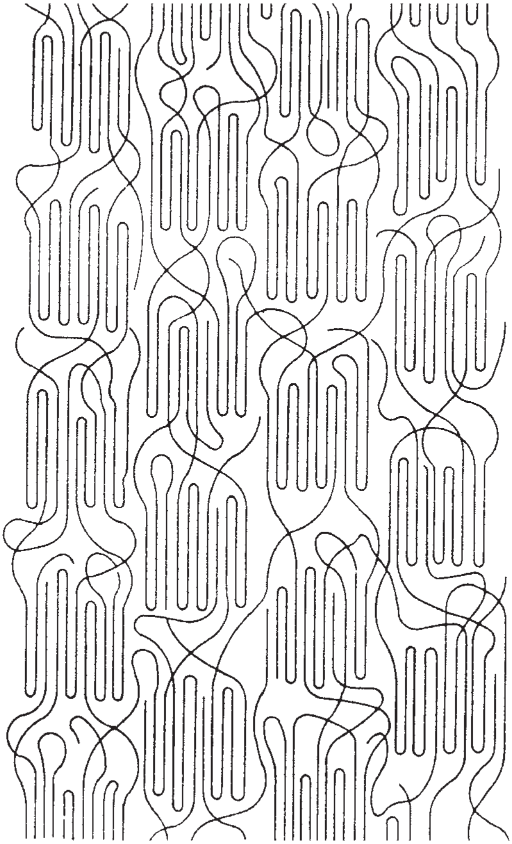

Fig. 8: Three-phase model of the structural make-up of polyester fibres, being composed of crystallized zones with chain folding and alternately adjacent amorphous zones together with interfibrillar voids.

Dyeing takes place

- using the exhaust dyeing process with a “carrier” [more correctly called a “plasticizing carrier” because the carrier (e.g. phthalate) predominates and the glass transition temperature falls, which improves the accessibility to disperse dyes after adsorption on the fibre surface];
- using the exhaust HT process at 130°C in accordance with the free volume model;
- using the thermosol process, in which at 200°C increased amorphous areas of sometimes, gaseous, sublimated dyes, are easily accessible, and show joint co-crystallization upon cooling.

Properties: Relatively flame resistant; resistant to micro-organisms and insects; physiologically inert; good

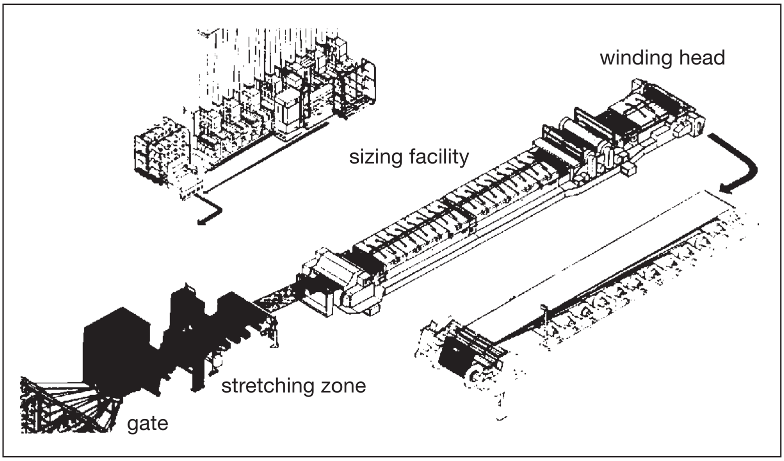

Fig. 9: Stretching and sizing facility for polyester fibres (Barmag-Tsudakoma system).

weather and light resistance (better than polyamide 6.6, lower than polyacrylonitrile); thermoplastic; softens at 230–250°C, melts at 256–292°C; elongated fibres shrink in boiling water (more than in air at 100°C) and hot air, therefore polyester textiles require thermofixation prior to heat treatments and to guarantee dimensional stability and freedom from creases (usually < 220°C; temperature increases cause temporary reduction in strength (at 180°C approx. 50% relative strength). The electrostatic chargeability can be managed by specific finishes (preparation, inclusion, fibre mixes). Breaking strength can be varied in broad bounds depending upon manufacturing conditions. Abrasion resistance good. Crease resistance excellent. Deformation resistant. The tendency towards pilling can be managed by certain polyester types and processing conditions. Chemical resistance: particularly excellent against cold acids, oxidizing agents and solvent. Easily washable, quick-drying. Low moisture absorbency. Some alkali sensitivity. Low dye affinity (→ Dyeing of polyester fibres).

Subsequent treatment processes such as drawing or sizing are sometimes linked; e.g. drawing in spinning or stretch-sizing (Fig. 9). In addition to the stretch sizing, size stretching and stretch sectional warping are also practised. In the former, drawing is done directly on the sizing machine, i.e. without a previous stretching zone. In stretch sectional warping, warp beams are manufactured in full thread density, which are used immediately prior to the weaving and knitting machines.

Application: men's and women's clothing material, non-wovens, blouses, sports shirts, knitted clothing, underwear, ties, raincoat material, swimming costumes, work clothing, sewing thread, net curtains, curtains, awnings; technical applications: gauze, filter material, drive belts, ropes, insulation material, tyre cord, etc. Great importance in fibre mixes (with wool, cotton, viscose spun fibres).

Polyester fibres in dyeing The use of dyes (→ Dyeing of polyester fibres) that form stable dispersions under dyeing conditions and neither agglomerate nor recrystallize is an important prerequisite for uniform jet, yarn or beam dyeing. However, even if this condition is met, uniform exhaust dyeing cannot be guaranteed. If the glass transition temperature is exceeded during the heating up phase, the substrate of the adjacent fluid layer begins to extract the dissolved dye. If the dye were to be supplied instantaneously by diffusion or by the dissolving of dispersed particles, then the concentration of dissolved dye would be the same at each point of the substrate surface and would be equal to the solubility of the dye. The sorption speed would be the same everywhere, and the result would be a completely uniform dyeing. This limit sorption speed is determined only by the diffusion process within the substrate. However, because the dye is supplied at a

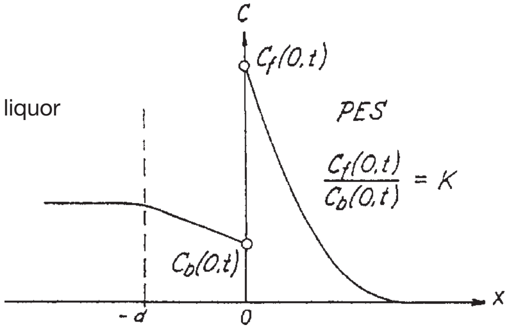

Fig.: Concentration profile at the boudary layer between liquor and substrate.

Next Page

limited speed, dissolved dye is depleted at the boundary layer (see Fig.). This depletion results firstly in a reduction of the sorption speed and at the same time an increase in the flow of dissolved dye to the boundary layer. The concentration C_b (0,t) of dissolved dye at the phase boundary liquor/substrate (x = 0) is always such that sorption speed and supply are equal. If the depletion at the boundary layer is low, because sufficient liquor exchange ensures a supply of disperse dye from the liquor, uniform dyeing can be expected. The supply of dissolved dye in this case is less dependent upon local flow conditions. If, on the other hand, depletion is high, then the supply is strongly dependent upon the thickness of the hydrodynamic boundary layer (according to Gerber and Griesser).

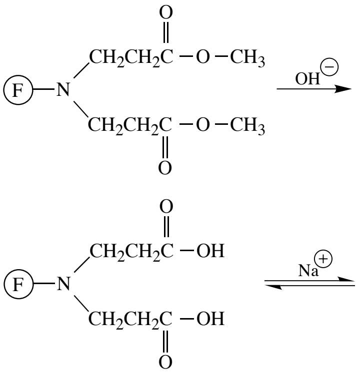
Polyester fibres in printing Disperse dyes are used for direct printing procedures. They can be classified on the basis of their fixing properties:

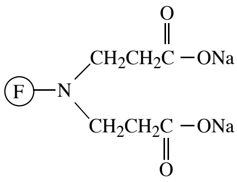
- fixation type and time,
- hot air 15–30 s,
- saturated steam 45–60 min,
- high pressure saturated steam 20–30 min,
- superheated steam 2–9 min.

When fixing in superheated steam, hot air or contact heat on hot cylinders fixation accelerators, e.g. based upon alkyl phenols, can be useful.

In order to be able to produce polyester prints with extremely fine lines, a naturally occurring inorganic polymer (bentonite) was mixed with conventional thickening agents to form a system with rheological behaviour suitable for fine prints. In etch printing, the light polyester fabric dyed using the exhaust dyeing process is printed during steaming with hydrolyzing auxiliaries (and possibly in coloured discharge printing with an alkali resistant disperse dye). If steaming takes place at 180°C for 7 min, the following reactions take place in the disperse dye due to its alkali sensitivity, while the alkali resistant printed disperse dye diffuses into the fibre.

alkali discharge:





In principle, when performing continuous background dyeing for etch printing, it is advisable to perform thermosol fixation only after printing, because then the disperse dye to be etched is still present, adsorbed on the fibre surface, and can be etched more easily than when it has migrated into the fibre and been fixed, i.e. is inaccessible to the etching paste.

Polyester fibres of modified dyeability The aim is to achieve easy dyeability without a carrier using the measures listed in the Tab.: polyester fibre modification.

There are deep dye polyester types, some of which can be dyed using cationic and disperse dyes. These polyester fibres can be satisfactorily dyed in a boiling bath with no carrier, and the dye take-up is greater than in normal polyester fibres. Although the dye take-up is roughly the same in all modified polyester fibres, penetration differs from fibre to fibre. So one fibre type may have a penetration of only 70% after a dwell time of 2 h in a boiling bath (or 15 min steaming), whilst other fibres are fully penetrated after 1 h boiling (or 10 min steaming) at normal pressure. Such differences are reflected in the thermofixation fastness. The dye migrates slightly from the fibre. The superior penetration in modified fibres in comparison to normal polyester results in higher dye yield and better rubbing fastness (therefore: reductive cleaning only with the deepest dyes). The lack of light fastness does not appear to be a problem with modified polyester.

All polyester fibre modifications are dyeable with disperse dyes. Reduced soiling rests in principle on the spinning in of (or subsequent finishing with) water soluble products, which promote the removal of dirt during washing; such substances may also influence the electrostatic behaviour of polyester. Polyester fibre modifications are also clearly less susceptible to pilling.

Polyester gauze The low moisture absorption, which results in good deformation resistance is particularly beneficial for → Screen making. Polyester gauze also possesses good light resistance and low elongation with good elasticity. Polyester gauze has to a large degree supplanted → Polyamide gauze, although dye paste penetration and abrasion resistance are somewhat lower.

Polyester hydrolysis In the finishing of materials made of polyester fibres, with the aim of improving the wear and hygiene properties of the end product, the surface hydrolysis of the fibres (“deweighting”) with a

Previous Page

limited speed, dissolved dye is depleted at the boundary layer (see Fig.). This depletion results firstly in a reduction of the sorption speed and at the same time an increase in the flow of dissolved dye to the boundary layer. The concentration C_b (0,t) of dissolved dye at the phase boundary liquor/substrate (x = 0) is always such that sorption speed and supply are equal. If the depletion at the boundary layer is low, because sufficient liquor exchange ensures a supply of disperse dye from the liquor, uniform dyeing can be expected. The supply of dissolved dye in this case is less dependent upon local flow conditions. If, on the other hand, depletion is high, then the supply is strongly dependent upon the thickness of the hydrodynamic boundary layer (according to Gerber and Griesser).

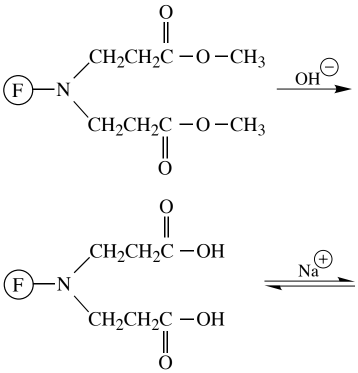
Polyester fibres in printing Disperse dyes are used for direct printing procedures. They can be classified on the basis of their fixing properties:

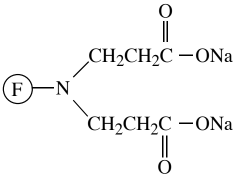
- fixation type and time,
- hot air 15–30 s,
- saturated steam 45–60 min,
- high pressure saturated steam 20–30 min,
- superheated steam 2–9 min.

When fixing in superheated steam, hot air or contact heat on hot cylinders fixation accelerators, e.g. based upon alkyl phenols, can be useful.

In order to be able to produce polyester prints with extremely fine lines, a naturally occurring inorganic polymer (bentonite) was mixed with conventional thickening agents to form a system with rheological behaviour suitable for fine prints. If steaming takes place at 180°C for 7 min, the following reactions take place in the disperse dye due to its alkali sensitivity, while the alkali resistant printed disperse dye diffuses into the fibre.

alkali discharge:





In principle, when performing continuous background dyeing for etch printing, it is advisable to perform thermosol fixation only after printing, because then the disperse dye to be etched is still present, adsorbed on the fibre surface, and can be etched more easily than when it has migrated into the fibre and been fixed, i.e. is inaccessible to the etching paste.

Polyester fibres of modified dyeability The aim is to achieve easy dyeability without a carrier using the measures listed in the Tab.: polyester fibre modification.

There are deep dye polyester types, some of which can be dyed using cationic and disperse dyes. These polyester fibres can be satisfactorily dyed in a boiling bath with no carrier, and the dye take-up is greater than in normal polyester fibres. Although the dye take-up is roughly the same in all modified polyester fibres, penetration differs from fibre to fibre. So one fibre type may have a penetration of only 70% after a dwell time of 2 h in a boiling bath (or 15 min steaming), whilst other fibres are fully penetrated after 1 h boiling (or 10 min steaming) at normal pressure. Such differences are reflected in the thermofixation fastness. The dye migrates slightly from the fibre. The superior penetration in modified fibres in comparison to normal polyester results in higher dye yield and better rubbing fastness (therefore: reductive cleaning only with the deepest dyes). The lack of light fastness does not appear to be a problem with modified polyester.

All polyester fibre modifications are dyeable with disperse dyes. Reduced soiling rests in principle on the spinning in of (or subsequent finishing with) water soluble products, which promote the removal of dirt during washing; such substances may also influence the electrostatic behaviour of polyester. Polyester fibre modifications are also clearly less susceptible to pilling.

Polyester gauze The low moisture absorption, which results in good deformation resistance is particularly beneficial for → Screen making. Polyester gauze also possesses good light resistance and low elongation with good elasticity. Polyester gauze has to a large degree supplanted → Polyamide gauze, although dye paste penetration and abrasion resistance are somewhat lower.

Polyester hydrolysis In the finishing of materials made of polyester fibres, with the aim of improving the wear and hygiene properties of the end product, the surface hydrolysis of the fibres (“deweighting”) with a

Polyester hydrolysis

target	modification	particulars
stronger dye take-up, so-called deep types	manufacture of copolymers by the addition of e.g. – dicarboxylic acids such as adipic acid, azelaic acid, sebacic acid, isophthalic acid – hydrocarboxylic acids – diolene	– lowering of glass transition temperature and melting point – evenness of dyeing
carrier-free dyeing with dispersion dyes	inclusion of – dicarboxylic acids – hydrocarboxylic acids – diolene manufacture of block polymers on the basis of polyethylene oxide	– lowering of glass transition temperature and melting point – risk of decomposition during manufacture – fixation not possible above 180°C – somewhat inferior high temperature and washing performance – caution with choice of dye (light fastness) – even dyeing – influence on mechanical and technological characteristics
	polyester on the basis of polytetramethylene terephthalate	– reduced melting point: 220-225°C – density 1.32
affinity with cationic dyes	– inclusion of acidic reacting groups in the molecular chain, e.g. isophthalic acid – addition of polymers with acidic reacting groups in the polymer melt	– influence on mechanical and technological characteristics
affinity with acidic dyes	inclusion of basic reacting groups, e.g. tertiary amines	– problems with fibre extraction – yellowing due to tertiary amines

Tab.: Polyester fibre modification.

mass loss of up to 10–25% is particularly important. Such a treatment improves the surface aspect and handle, yielding a similar effect to that of natural silk. The topochemical reaction of the hydrolysis of ester groups on the surface of polyethylene terephthalate fibres in a sodium hydroxide solution can be accelerated by additives that cause the fibres to swell or by amines and quaternary ammonium compounds (see Tab.). The addition of alkyl dimethyl benzyl ammonium chlorides, stearyl trimethyl ammonium chlorides and similar compounds, accelerates the saponification process and allows the alkali concentration in the solution to be reduced. Quaternary ammonia compounds are effective in the saponification of polyester fibres in solutions with a minimal NaOH content at temperatures higher than 100°C. Cationic polymers are of particular importance here. Fibre mass losses of 20–25% at 130°C in the presence of polydimethylaminoethylmethylacrylate derivatives are achieved in 30–45 min; in contrast, 6 h is needed without a catalyst.

In the case of heterogeneous hydrolysis of polyester fibres, the catalytic effect of the cationic polymers can only be seen at the phase boundary. Therefore the nature of the forces that hold the catalyst to the fibre surface, and its interaction with the reaction products, takes on particular importance in hydrolysis. This mainly relates to interactions of polycations with anions and polyanions. The catalytic activity of quaternary

compound	structural equation
1 tetraethyl ammonium bromide	$(C_2H_5)_4\,N^+\,Br^-$
2 triethylbenzyl ammonium chloride	$(C_2H_5)_3\,C_6H_5\,CH_2N^+\,Cl^-$
3 methyldiethyl aminomethyl polyglycol ester benzene sulphonate	$R-C_6H_4-O(CH_2-CH_2-O)_{10}-$ $-CH_2N^+(C_2H_5)_2CH_3C_6H_5SO_3^-$
4 polydimethyl diallyl ammonium chloride	 $(-CH_2-CH-CH-)_n$ $CH_2\quad CH_2$ $N^+\,Cl^-$ $CH_3\quad CH_3$
5 poly-4-vinylbenzyl trimethyl ammonium chloride	 $(-CH_2-CH-)_n$ $C_6H_4-CH_2-N^+(CH_3)_3Cl^-$

Tab.: Catalysts for the hydrolysis reaction involving polyester fibres.
(1 + 2 were used in solid form, 3–5 in aqueous solution.)

polymer ammonium compounds is greater than that of their low molecular counterparts. The catalytic effectiveness of the polymer catalysts depends upon their ability to enter into a hydrophobic interaction with the polyester fibre. In the NaOH solution there is a partial conversion of the quaternary ammonia salt groups of a polymer into base groups, followed by the adsorption of the polymer catalyst on the fibre surface and the hydrolysis reaction of the polyester ester groups with a subsequent transfer of the terephthalic acid anions, together with the polymer catalyst, from the fibre surface into the solution. Individually, the reactions are represented in the following systematic-parallel stages:

The formation of the quaternary ammonia base groups in the cationic polymer (1), its absorption at the fibre surface (2), splitting the ester bond into macromolecules of polyethylene terephthalate (3). There is the possibility of a reaction (3) of the complex cationic polymer / DNaPS, which decomposes in the next stage (4) under the effect of the NaOH solution. The polymer catalyst absorbed at the fibre surface is quantitatively regenerated (according to Jemaitaitiene).

$$1\quad (\mathrm{Poli\ Q^{+}})_{n}\,\mathrm{Cl}^{-}_{n} + m\,\mathrm{NaOH} \rightarrow (\mathrm{Poli\ Q^{+}})_{n}\,\mathrm{Cl}^{-}_{n-m}\,\mathrm{OH}^{-}_{m} + m\,\mathrm{NaCl}$$

$$2\quad (\mathrm{Poli\ Q^{+}})_{n}\,\mathrm{Cl}^{-}_{n-m}\,\mathrm{OH}^{-}_{m} + \mathrm{PES} \rightarrow \mathrm{PES}\,(\mathrm{Poli\ Q^{+}})_{n}\,\mathrm{Cl}^{-}_{n-m}\,\mathrm{OH}^{-}_{m}$$

$$\begin{aligned}3\quad & \mathrm{PES}\,(\mathrm{Poli\ Q^{+}})_{n}\,\mathrm{Cl}^{-}_{n-m}\,\mathrm{OH}^{-}_{m} + \mathrm{HO}\{\mathrm{OC{-}C_6H_4{-}COO{-}(CH_2)_2{-}O}\}_{m}\mathrm{H}\\ & \qquad\qquad \downarrow \mathrm{NaOH}\\ & \mathrm{PES}\,(\mathrm{Poli\ Q^{+}})_{n}\,\mathrm{Cl}^{-}_{n-m}\,(\mathrm{OOC{-}C_6H_4{-}COO^{-}})_{m} + m\,\mathrm{HO\,(CH_2)_2\,OH} + m\,\mathrm{H_2O}\end{aligned}$$

$$\begin{aligned}4\quad & \mathrm{PES}\,(\mathrm{Poli\ Q^{+}})_{n}\,\mathrm{Cl}^{-}_{n-m}\,(\mathrm{OOC{-}C_6H_4{-}COO^{-}})_{m} + m\,\mathrm{NaOH} \rightarrow\\ & \text{—}\,\mathrm{PES}\,(\mathrm{Poli\ Q^{+}})_{n}\,\mathrm{Cl}^{-}_{n-m}\,\mathrm{OH}^{-}_{m} + m\,\mathrm{NaOOH{-}C_6H_4{-}COONa} + m\,\mathrm{H_2O}\end{aligned}$$

Polyester-polyamide biconstituent fibres represent a two-phase system, composed of a polyester matrix containing evenly distributed polyamide fibrils. Acid and metal-complex dyes only dye the polyamide component. As the dyeing effect is only superficial it can be influenced by treating the biconstituent fibres in such a way as to bring about an increase in the polyamide content in the surface layers of the fibres and the formation of micropores, thus promoting the diffusion of the dye solution.

The main purpose of modifying the polyester fibres is to improve their dyeing properties. One process that is of interest is the joint spinning of polyester with polyamides, which have good dye affinity. When spinning melt dispersions of polyester with polycaproamide with a polycaproamide content of above 20%, the absorbency of the fibres for disperse dyes is greatly increased. Only at above 40% polycaproamide is dyeing with acid and metal-complex dyes possible. The spinning of melt dispersions could in principle be realised in the following two ways:

1. In the production of polyester-polyamide biconstituent fibres, polyamides must be selected that have a higher affinity to acid dyes than the traditional polyamide 6 and polyamide 6.6. This reduces the necessary quantity of polyamide, and the objective can be achieved with a mix ratio of the two polymer components that guarantees normal spinning and drawing.
2. Polyester-polyamide biconstituent fibres must be sought on the basis of polyethylene terephthalate and traditional polyamide 6 or polyamide 6.6, in ratios that guarantee the normal procedure of the technological processes of spinning and drawing and in which the subsequent effect upon the morphology of the fibres and the phase distribution bring about the desired dyeability by acid dyes (according to Georgiev et al).

Polyester resins High molecular cross-linking products made of unsaturated → Polyester and unsaturated polymerizable compounds (e.g. styrene). Of interest for lacquers, coatings and materials, because many polyester resins are available as more or less viscose fluids (so-called casting resins), which only harden after the addition of a catalyst (peroxy compounds) and accelerator, e.g. with excellent strength, proven on fibre glass materials as a binder.

Polyester rubber → Polyester elastomers.

Polyester sizes For example, type of a dispersion of isophthalic acid/diethylene glycolate with 5-Sulphonicisophthalic acid units formed by condensation.

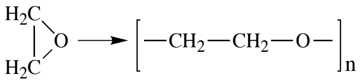
Water solubility of polyester sizes is achieved by the continuous side incorporation of salt functions (primarily sulphonate groups) via diol or dicarboxylic acid components of polycondensate. Polyester sizes have proven particularly suitable for polyester warp yarns. Due to their chemical similarity they posses an extremely strong adherence to polyester fibres. Due to sulfonicisophthalic acid formed by condensation, polyester sizes disperse in water but are not soluble. They are sensitive to strong electrolytes and high concentrations of weak electrolytes. There are possible variations in the polymer arrangement due to the use of other aromatic or aliphatic dicarboxylic acids and longer chain polyethylene glycol as building blocks. Sometimes polyester sizes are also used in the form of → Polyurethanes. Polyester sizes posses some important disadvantages compared to → Polyacrylate sizes:

- sometimes poor storage stability in disperse products (recrystallization, precipitation, hydrolytic splitting);
- impossibility of sizing polyester filaments on conventional sizing machines;
- narrow optimal effective range (“blocking”);
- electrolyte and alkali incompatibility (problematic desizing);
- poor biodegradability.

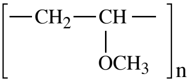
Stain washing off properties: the greatest problems are caused by polyester size stains, because they cannot be removed using normal washing recipes and conditions.

Even dwelling processes with increased lye quantities are not always successful. The most effective method is solvent treatment using dichloromethane. Other common chlorinated hydrocarbons are not suitable. In the absence of a cleaning plant using dichloromethane, polyester size stains can be removed by alkali treatment. This is performed at low temperatures and low caustic soda concentrations to avoid high polyester weight reduction.

Polyethers By the polymerization of ethylene oxide we obtain the simplest type of aliphatic polyethers, polyethylene oxides (→: Polyglycol ethers; Polyethylene glycol),



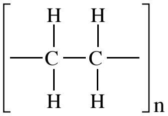
which also includes, for example, polyvinyl ethers.



$$\left[-CH_2-\underset{OCH_3}{CH}-\right]_n$$

Aromatic polyethers usually contain built-in benzene cores. Linear aliphatic and aromatic polyether with a melting point of approx. 130–150°C possess the ability to form synthetic fibres.

Polyethylene Polymer → Ethene.



$$\left[-\overset{H}{\underset{H}{C}}-\overset{H}{\underset{H}{C}}-\right]_n$$

Either in the form of high pressure polyethylene (softening point approx. 115°C) or low pressure polyethylene (Z-polyethylene after the inventor Ziegler), manufactured at low pressure and a temperature up to 70°C, with a higher softening point up to approx. 145°C, resistance to boiling, high resistance to tearing and abrasion. Applied films are translucent, flexible, with a waxy handle, non-yellowing due to light or heat, extremely resistant to chemicals and solvents, moderately resistant to oils, greases, aliphatic hydrocarbons, insoluble at room temperature in all solvents. Polyethylene is attacked by free halogens and dissolved by chlorinated hydrocarbon at above 70°C. The lightest plastic: Density 0.92–0.94. Commercial forms: pearls, powder, foils, monofilaments, fibres. Solutions are not normally manufacturable. Used in the form of a dispersion in organic solvents or water. Application particularly as material (pipes), packaging foil, container linings, chemical resistant containers, for acid protection fabrics, for coating ("hot sealing" or bonding of nonwovens, collar lining materials, etc.) and laminating (also laminated as a hot foil using rollers). → Polyethylene fibres.

Polyethylene fibres Synthetic polymerizate fibres of the group → Polyolefin fibres made of polyethylene, either in the form of branched high-pressure polyethylene fibres (used for special applications) or the more important low-pressure modified polyethylene fibres. Most common in the form of stretched coarse monofilaments (0.1–0.5 mm). The cross-section is normally round with a smooth delimitation (see Tab.).

	high pressure polyethylene (branched) [modified]	low pressure polyethylene (linear)
reaction type (according to Koch)	soluble in boiling carbon tetrachloride	soluble in hot decalin (■)
specific gravity	0.92 – 0.94 {0.94}	0.95 – 0.96
shrinkage	40°C onset 90°C approx. 40 % (less if tempered!)	loss of stretch effect for stretched polyethylene at 90°C
	may be stabilised up to approx. 60°C at 75°C approx. 5 % shrinkage	
folding	avoid during finishing (otherwise folds may well be fixed!)	
softens at	90 – 104°C {120°C}	105 – 120°C
melts at	105 – 120°C {130°C}	125 – 135°C
moisture absorption normal	practically 0	practically 0
tear resistance dry/wet	0.9 – 2.1 p/dtex {3.0}	5.0 – 7.2 p/dtex
elongation at break (necking) dry/wet	20 – 60 % {20}	14 – 40 %

(■ = this specific solubility allows the viscosity of the solution to be determined).

Tab.: Comparison of the characteristics of high pressure and low pressure polyethylene fibres (p/dtex = cN/dtex).

Further properties of the linear fibres in particular are waxy smooth and soft handle, high elasticity, excellent electrical insulating properties, resistance to mildew, bacteria and insects. Polyethylene fibres are completely waterproof and burn slowly. They have chemical resistance to acids and alkalis. They are insoluble in solvents at room temperature, but have a tendency to dissolve at higher temperatures. Difficult to dye, usually in spin dyeing. Application primarily for technical purposes such as electrical insulation, filter cloths, protective clothing, reference materials, awnings, car cover materials, cables, ropes, nonwovens, etc.

Polyethylene glycol (PEG) → Polyethylene glycols.

Polyethylene glycol esters → Polyglycol ethers.

Polyethylene glycols (polyethylene glycol, polyethylene oxides), type $HO–C_2H_4–O–(C_2H_4O)_n–C_2H_4–OH$. Polymers of (ethylene) glycol with molecular weight of up to 10 000, whereby its external state ranges from fluid (200–500) via vaseline-like (500–900) to similar to soft and hard wax (over 1000). As a result of the heaped oxethyl groups all members, even the highest, which are like hard wax, are completely water soluble. They represent colourless and odourless products; soluble in water, alcohol, ketones, esters, aromatic hydrocarbons; insoluble in benzine; hygroscopic to some degree, neutral, usually resistant to hardness agents, acids, alkalis, salts and boiling. Polyethylene glycols are superficially similar to oil substances, have a flash point far above 210°C, have a marked lubricating property and are therefore used as a popular machine lubricant that can be washed out, preparations for synthetic fibres, additives to sizes, finishing agents, printing additives, etc. From a chemical point of view, polyethylene glycols are polyalcohols due to the presence of two reactive OH groups. Of these, one terminal OH group can be substituted by etherification, esterification or other conversions. Because the majority of these compounds have properties more like ether than alcohol, one talks of “substituted → Polyglycol ethers”.

I. Liquid and semi-solid polyethylene glycols are excellent dye solvents, high quality glycerol substitutes in sizes, finishes, prints.

II. Solid polyethylene glycols (synthetic waxes): the hard wax character, setting point, density and viscosity increase with the molecular weight, whereas the hygroscopicity decreases fully. Particularly useful as high-quality components for lubricants, starch sizes (increase starch solubility, decrease viscosity, promote penetration, smoothness, adhesion, can be washed out without residue) and finishes (improve lustre).

Polyethylene oxides →: Polyethylene glycols; Polyglycol ether emulsifiers.

Polyethylene terephthalate (PET, PETP) → Polyester fibres.

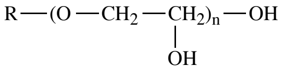
Polyethylene waxes Synthetic waxes, based upon polyethylene. They are either produced at high pressure and increased temperature in the presence of radical formers (high-pressure polyethylene waxes) or according to the Ziegler low pressure process with organometallic catalysts (low-pressure polyethylene waxes). Polyethylene waxes or polyethylene hard paraffin (correct term) can be further processed into oxidants or partially saponified products. Using suitable emulsifiers, these can be dispersed in water or “emulsified”.

Polyfluoroethylene fibres Type $(CF_2–CF_2)_x$, $(CF_2–CHF)_x$ or $(CF_2–CFCl)_x$; synthetic polymerizate filaments and fibres based upon tetra and trifluorethylene. Manufactured from fluorinated ethylene (starting base chloroform and hydrofluoric acid) by polymerization, spinning by jets under high pressure.

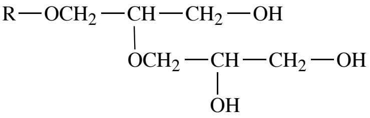
Polyformaldehyde fibre Synthetic fibres based upon thermostabilized → Polyoxymethylenes, in the form of homopolymers or copolymers of formaldehyde or meta-formaldehyde with polyacetal structure. As melt fibres with round cross-section, 200–500% extendible, density 1.38–1.42; slightly hygroscopic (0.2% at 65% relative humidity), thermo resistant from –60 to +130°C; high mechanical properties (1200–1400 N/mm^2 at 8–10% elongation); chemically relatively resistant; can be dyed using the normal processes.

Polyfunctional Multiple actions, e.g. a chemical compound with several → Functional groups, or a multi-purpose machine.

Polyglycerol Similar to diglycol or triglycol, for example, etherification product of several glycerol molecules in linear structure or in the form of complex polymers, e.g.:



$$R-(O-CH_2-\underset{\underset{OH}{|}}{CH_2})_n-OH$$



$$R-OCH_2-\underset{\underset{OCH_2-\underset{\underset{OH}{|}}{CH}-CH_2-OH}{|}}{CH}-CH_2-OH$$

Also mixed glycol-glycerol ethers, which become more similar to higher → Polyethylene glycols with increasing oxyethylation. Like → Glycerol, proposed for dyeing and printing purposes.

Polyglycol ether emulsifiers Non-ionogenic emulsifiers, based upon polyethylene glycol, are water soluble (at least up to the cloud point).

In pigment printing, selected non-ionogenic emulsifiers based upon ethylene oxide addition compounds are used on selected alkylphenols. These products, which were specially developed for pigment printing, have the advantage of better print fastness compared to anionic emulsifiers. Furthermore, they are effective in an acid and alkaline environment and have a lower foaming effect. As detergents, they have the task of reducing the interfacial tension between water and disperse phase in disperse systems. In pigment print pastes, they guarantee the maintenance of dispersion stability of the pigment, binder, softener and if necessary also heavy benzines.

The solubility of emulsifiers is determined by the length of the polyether glycol chains. Hydrophilicity increases with the ethylene oxide content, therefore highly ethoxylated products are only soluble in water and polar solvents. Whereas in the water free state the polyether glycol chain has a zig-zag structure, in aqueous solution a “meander” form is created. The creation of this meander form, in which the hydrophilic oxygen atom is pushed outwards (while the hydrophobic methylene group is protected in the interior), is the real cause of the water solubility of a polyethylene glycol chain. Polymethylene glycol, on the other hand, which should be even more hydrophobic due to its high oxygen/methylene ratio, is insoluble in water, because no corresponding structural conversion is possible. The favourable position of the “meander” oxygen atoms in the polyethylene glycol chain facilitates first the association of water molecules. Initially a primary hydrate layer forms, onto which further water molecules are deposited (secondary hydrate shell), giving rise to water solubility. The technical application properties of an emulsifier are classified according to its HLB value (hydrophile-lipophile balance), a ratio between 0 and 20. The HLB value for pigment print emulsifiers lies in the range between 13.8 and 15.5.

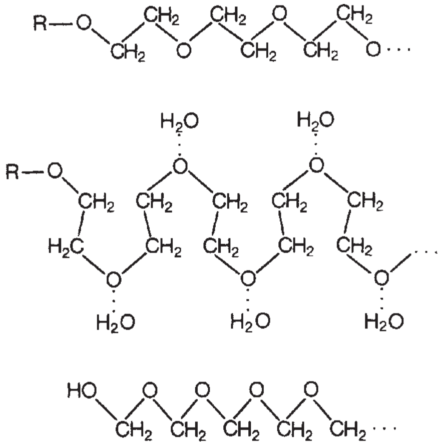


Fig.: The structures of polyethylene chains in both water-free state and in aqueous solution compared with a polymethylene glycol chain.

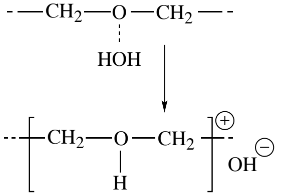
When using non-ionogenic surfactants based upon polyglycol ether emulsifiers, care should be taken that the washing temperature is always below the cloud point (e.g. 60–70°C). At higher temperatures the hydrogen bridges between the ether-oxygen of the chain and the water molecules are broken (see Fig.), the surfactant precipitates causing clouding, but goes back into solution as the temperature falls.

Polyglycol ethers Polyoxyether (polyoxyester) of type $R–O(C_2H_4O)_nH[R–COO(C_2H_4O)_n–H]$ (n = degree of ethoxylation). Addition products of ethylene oxide (ethylene oxide addition products) to fatty alcohols, fatty acids, amines, alkyl phenols, alkyl naphthols, etc. Polyglycol ethers form the group of non-ionogenic surfactants. A cationic character is also possible, because the water molecules, in aqueous solution with the residual valency of its O atoms, attach to the residual valencies of the ether oxygen atoms. This additive compound then stabilizes to form co-ordination compounds:



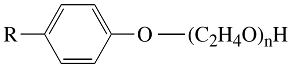
Polyglycol ethers are textile auxiliaries and due to their chemical resistance are often used as wetting, dispersing, levelling, stripping and, above all, washing agents, as well as emulsifiers and scrooping agents.

Polyglycol ether groups:

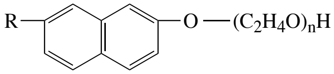
I. Alkyl polyglycol ethers are addition products of ethylene oxide to fatty alcohols. Depending upon the degree of ethoxylation they provide emulsifiers, washing agents or levelling agents.

$$R—CH_2—O—(C_2H_4O)_nH$$

II. Alkylphenol polyglycol ethers arise due to the addition of ethylene oxide to alkylphenols (preferably nonylphenolpolyglycol ether). Water solubility increases with increasing ethoxylation. The majority of these products are used as washing and wetting agents.



III. Alkylnaphthol-polyglycol ethers are addition products of ethylene oxide on alkyl naphthols. Are suitable for use as washing agents.



IV. Acyl-polyglycol ethers arise due to the addition of ethylene oxide on fatty acids. They form high-quality emulsifiers and softeners (for scrooping handle).

$$R—CO—O—(C_2H_4O)_nH$$

V. Ethoxylated alkanol amides are suitable for use as emulsifiers, washing agents and softeners.

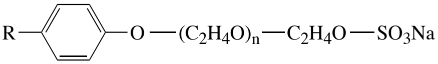
$$R—CO—NH—(C_2H_4O)_nH$$

VI. Ethoxylated fatty amines are proven levelling agents.

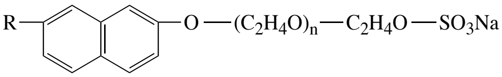
$$R—NH—(C_2H_4O)_nH$$

In acid solution these compounds have a slightly cationic reaction.

Polyglycol ether sulphates Sulphated → Polyglycol ether emulsifiers of an anionic nature, with increased solubility and foaming power, specific washing agent, which is derived either from alkyphenols:



or from alkylnaphthols:



Polyhedron Object with many surfaces; body limited by polygons (e.g. foam).

Polyhedron foams are represented by compounds of polyhedron shaped bubbles, which have lost their independence. The bubble compound of a polyhedron foam can only be formed of lamella bubbles and not of single bubbles. The polyhedron foam can be viewed as dewatered ball foam (→ Foam structures). It is metastable.

Metastable foams are characterized by the fact that the interlamellar fluid between the foam lamellae does not continue to flow until the foam is destroyed, but stops at some point. A metastable state occurs, which depends upon the stability of the lamellae, or upon the stability of the surfactant boundary layer films. The resistance of these films is influenced by a number of factors: firstly by the surface viscosity, i.e. the viscosity of the boundary film to the interlamellar fluid; secondly by the sufficiently high concentration of surfactants to form a closed film.

If two bubbles approach each other until contact is made, then a marked deformation is possible before the bubbles join. When the bubbles join together at the point of contact, part of the two outer films disappears, but the inner films remain. Both bubbles are surrounded by a common outer film and are subject to the same capillary tension. The same applies to the formation of bubble compounds. In polyhedron foam formation with spatial extension, polyhedron shaped forms (see Fig.) are created with a marked channel system. Due to the polyhedron type arrangement, triangular channels form at the polyhedron corners, where polyhedron edges are arranged in the form of tetrahedrons. At the edges of the polyhedrons, where three bubbles join together, crack-shaped channels are formed, which are smaller than the triangular channels. Both channel systems are connected together and play an important role in dewatering: The foam falls apart from the top down and the interlamellar fluid flows away through the channel system of the foam below, without destroying the foam. The foam below is thus irrigated with interlamellar fluid, which assists stabilization.

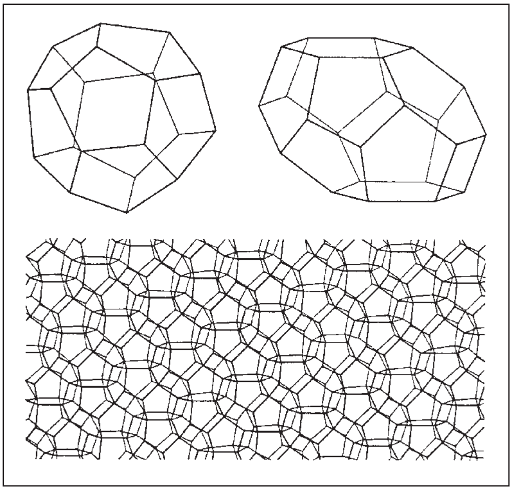


Fig.: Polyhedral shaped gas bubbles in a foam. Top left: pentagonal dodecahedron; top right: beta tetrakaidecahedron.

In the mathematical model of a polyhedron foam, identical polyhedrons, the surfaces of which meet at an angle of 120°, must be joined together if possible in such a way that the space is filled. Of the regular polyhedrons (those in which all surfaces are made up of the same regular polygon) this can be best achieved with the pentagonal dodecahedron. However, hollow cavities still exist. Furthermore, the lamellae of a genuine foam do not just form pentagons. A more realistic approximation is provided by an irregular polyhedron, the beta-tetrahedron. Although none of the models that currently exist, properly reflect all geometric properties of a genuine foam, the relationships between fluid content, bubble size, film thickness and foam geometries can at least be approximately calculated on the basis of such models.

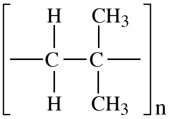
Polyhexamethylene sulphone fibres → Polymethylene sulphone fibres.

Polyhydroxyl fibres Fibres, which have hydroxyl groups as prosthetic groups, above all cellulose and cellulose regenerate fibres, also appropriately modified synthetic fibres.

Polyimides → Aromatic polyimide fibres

Polyimines → Polyamines, polyimines.

Polyisobutene (polyisobutylene). Synthetic polymer (obtained from isobutene or from isobutanol by water splitting) (also as copolymer with styrene, butadiene, etc.).

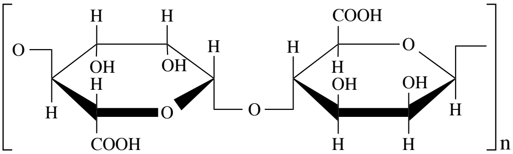


Depending upon the degree of polymerization viscous-oily, semi liquid-viscous, tough-sticky, extensible-elastic like soft rubber, flexible. Cannot be vulcanized, not cross-linkable (not dimensionally stable under load, therefore of no interest as fibre raw material), density 0.93; thermoplastic above 100°C; resistant against many acids, alkalis, alcohols, esters, ketones; soluble in benzine, benzene, chlorinated hydrocarbon; processing in solution and dispersion. Application: particularly for adhesives, coatings (raincoats, car cover material, carpet back coating), foils and container linings (for temperatures up to 85°C), etc.

Polyisocyanates Addition polymerization products of → Isocyanates or (preferably because more reactive) aromatic → Diisocyanates. Application: as adhesive, cross-linking component for coatings, lacquers, strong compounds, etc.

Polyisoprene → Natural rubber.

Polymannuronic fibre Alginate fibre type, so-called because → Alginic acid represents a polymer d-mannuronic acid (with pyranose structure):



Polymer dispersions are used for the bonding of technical textiles, for coating and in finishing. As a pigment binder and flock glue they must (as in finishing) give the finished textile material a good handle after application. The field of application is strongly oriented towards the physical properties of the film on the fibre. Therefore, polymer dispersions can be classified according to the hardness of the film formed (Tab. 1).

The following factors are critical

- minimum film formation temperature
- glass transition temperature.

The interaction of these factors, in relation to the profile of requirements for the textile material to be finished, determines the combination of the monomers used for emulsion polymerization (Tab. 2).

Vinyl acetate-ethylene dispersions are used for the stabilization of non-woven items, whereby ethylene is the copolymerized softener in the copolymer.

Some examples of application of aqueous dispersions should illustrate the importance of the polymer dispersion building block in the creation of a technical textile:

- *Polyester-spun-bond lining for roofing material:* hard, thermostable film former, styrene-containing copolymer
- *Textile glass fabric for roofing materials:* hard film former based upon vinyl acetate or styrene
- *Webbing:* soft film former based upon vinyl acetate-ethylene or acrylate-styrene
- *Car carpets for subsequent polyethylene powder coating and shaping:* medium-hard to soft film former based upon vinyl acetate-ethylene
- *Bonding:* depending on hardness, vinyl acetate-homopolymers, vinyl acetate-copolymers with ethylene or acrylic esters
- *Bonding emulsions:* vinylacetate-ethylene or acrylate-copolymers with low glass transition temperature
- *Technical flock items:* soft film former based upon acrylic ester, additive of melamine resin
- *Textile glass wallpaper:* viscoplastic film former based upon vinyl acetate-ethylene-vinyl chloride
- *Textile glass-construction fence:* medium-hard film former based upon vinyl acetate-ethylene or styrene-acrylate
- *Milk filter:* soft film former based upon vinyl acetate ethylene or acrylic ester
- *Hard coatings of technical fabrics:* styrene-acrylic ester copolymers
- *Nonwoven waddings:* hard film former, also medium-hard, no surface stickiness, based upon acrylic-methacrylic ester and vinyl acetate-acrylic ester or vinyl acetate-ethylene
- *Nonwovens for cleaning purposes:* soft film formers based upon vinyl acetate-ethylene or acrylic ester
- *Needle punched felt, mouldable for cars:* hard film formers based upon styrene-acrylic ester
- *Technical knitted fabrics:* soft film formers based upon vinyl acetate-ethylene
- *Back coating of technical knitted plush:* soft film former based upon vinyl acetate-ethylene, vinyl acetate acrylic ester, acrylic ester-styrene, acrylic ester
- *Filters:* soft film formers with surface stickiness based upon vinyl acetate-ethylene, acrylic ester
- *Sails:* combination of hard acrylate binder with melamine resin.

The use of polymer dispersions in finishing also orientates itself towards the glass transition temperature resulting from the copolymerization of vinyl acetate and vinyl acrylate (+ 33°C to – 40°C) (Tab. 3).

hard film-forming agents glass transition temperature zone > + 25°C	less hard, soft film-forming agents glass transition temperature zone -10 to +25°C	soft to very soft film-forming agents glass transition temperature -10 to -30°C	very soft, strongly adhesive film-forming agents glass transition temperature < -30°C
strong starch, interlinings nonwoven wadding fastening filter felts needle punched felt fastening tufting under-coat woven carpet backing starch glazed textiles light screening laminates edge fastening formable textiles	starch for inlet material, lining material, matress drill finishing of glazed textiles woven carpet backing starch textile coating roller blind coating milk filter	nonwovens starching of warp-knitted fabric coating of warp-knitted plush adhesive films pigment binder flock adhesive	bonding adhesive

Tab. 3: Polymers from vinyl acetate and acrylic ester.

In the resin finishing of cotton fabrics, dispersions are used not only to improve handle, but primarily because of their positive effect on strength; of course they must not have a detrimental effect on the crease angle.

Fig. 1 shows how dispersions and crosslinkers complement each other on a cotton fabric. The crease angle dry (lower curve) and wet (upper curve) are plotted as ordinates as the sum of warp and weft, the application quantities of crosslinkers and dispersion are plotted in g/l on the abscissae.

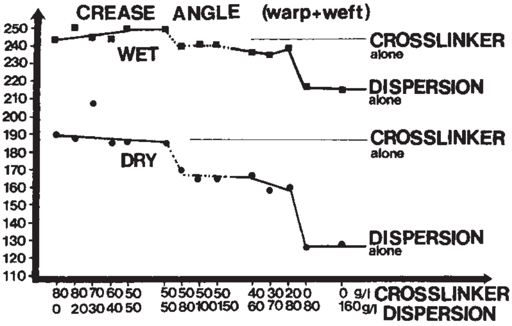

Fig. 1: Crosslinker and polymer dispersion very weak; crease angle dry and wet.

The recipes are:
80–0 g/l crosslinker (etherified, low formaldehyde),
16–20 g/l catalyst (heavy metal free),
0–160 g/l dispersion.

The curves begin on the left with the values for finishing with crosslinker and catalyst only, without dispersion (80 parts crosslinker). At the second point, 20 parts polymer dispersion have been added to the 80 parts crosslinker. The crease angle barely changes. In this recipe the dispersion acts as an additive and improves the resistance to tearing and abrasion. Thereafter, instead of the ratio 80 parts crosslinker/20 parts dispersion, the quantity of crosslinker was reduced in increments of ten and the quantity of dispersion similarly increased, thus less cross-linker and more dispersion was used. Up to a 50/50 ratio of cross-linker/dispersion, the crease angle remains the same. If more than 50 parts dispersion are added to the 50 parts (80, 100, 150 parts), then a lower crease angle is obtained. This is represented by the central part of the curve, which is dotted. Because the dispersion only increases the crease angle slightly (visible in the two points at the right on the curve), if there is a further reduction of the quantity of crosslinker to 40, 30, 20 parts with 60, 70, 80 parts dispersion, the crease angle also falls (according to Fischer).

Dispersions of polymers are produced by the emulsion copolymerization of the corresponding monomers (Fig. 2). If water insoluble monomers are mixed with an aqueous solution containing an emulsifier (whereby the ratio of aqueous phase to monomer phase is 2 : 1 to 1 : 1) we get an emulsion with a milky appearance. If a water soluble initiator is now added to this emulsion, then a lively polymerization begins in the absence of oxygen at 40–70°C. The milky character remains during polymerization, and after the reaction has run its course a polymer dispersion similar to natural rubber is obtained. The particle size is 0.05–0.15 µm. The advantages of this type of polymerization are, on the one hand, the ease with which the reaction heat is dissipated and, on the other hand, the low viscosity of the formed lattice (even at high concentrations up to 60%) in comparison to corresponding solutions. Mainly anionic (e.g. alkali salts of fatty acids, sodium salts of sulphonic acids with 10–16 carbon atoms) and non-ionogenic emulsifiers are used. Primarily hydrogen peroxide, potassium peroxodisulphate, combinations of water insoluble hydroperoxides and water soluble reducing agents, for example cumene hydroperoxide amine, come into consideration as initiators.

The reaction begins in the aqueous phase and initially takes place in the emulsifier micelles and later in the latex particles that have been created. The emulsifiers form micelles in aqueous solutions from a certain concentration, which are imagined as being arranged in parallel or radially, whereby the hydrophilic parts form the outer boundary. Monomers can be stored between the lamellae of the micelle (where the hydrophobic re-

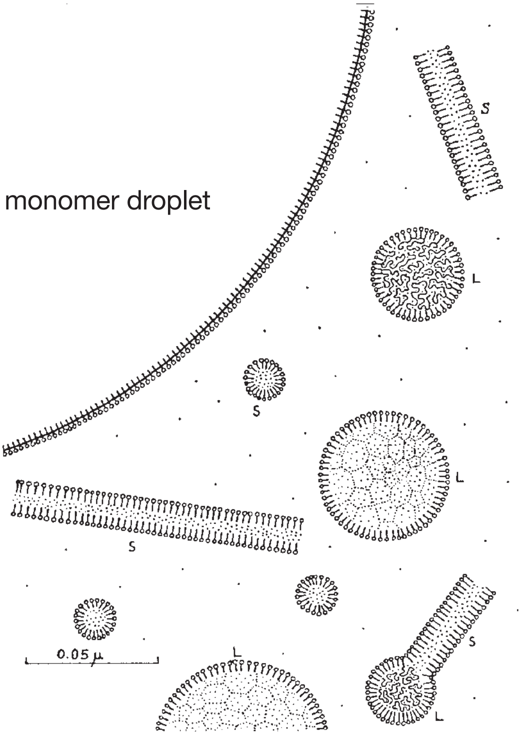

Fig. 2: Diagram representing relative sizes of emulsion polymers.
S = soap micelle; L = latex particle; ⚲ = monomer molecule in the aqueous phase; special symbol required = surfactant molecule.

mains collide). It is assumed that due to the high monomer concentration in the emulsifier micelle, the beginning of the chain starts by the absorption of a radical formed in the aqueous phase within the micelle. Although the chain can also start outside the micelle, it is assumed that the nucleii formed in this manner in the presence of emulsifiers are also absorbed by micelle.

The polymer finds the monomers required for the growth in the emulsifier micelle. If the monomer concentration is reduced in this due to polymerization, then the monomers are supplied from monomer drops via the aqueous phase. The saturation value of the monomer concentration in the water phase remains constant as long as monomer drops are still present. Due to the growing polymer chain, the emulsifier micelles are expanded and destroyed, so that a polymer particle surrounded by the individual molecules of the micelle is created. The surrounding of the polymer particle prevents coagulation with other polymer particles or with the monomer drops, which are also surrounded by emulsifier molecules.

The further chain growth now takes place in these polymer particles. Growth within the emulsifier micelle or of a polymer particle surrounded by an emulsifier layer is interrupted by the absorption of a second initiator radical. So in the course of polymerization the system shifts: Emulsified monomer particles become emulsified latex particles via the aqueous phase. The polymer dispersion formed in this manner consists of a large number of macromolecules (depending upon the latex particle size and molecular weight of the polymers between 50 and 500). It is used as a binder immediately without prior coagulation.

Polymer doping In 1977 a phenomenon was discovered, which led to an almost turbulent development of polymers, which possessed an intrinsic conductivity, i.e. without the addition of electrical conductors. It was found that polyacetylene manufactured according to the so-called Shirakawa process acquires a high electrical conductivity if it is brought into close contact with an oxidizing agent (in this case iodine) (see Fig.). This process is now called doping, in an analogy to semiconductor physics. Conductivity rose by a billionfold compared to undoped polyacetylene.

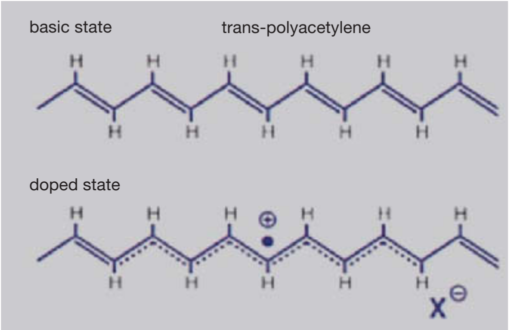

Fig.: The functional principle of intrinsically electrically conducting polymers.

Subsequently a number of polymers were discovered, in which intrinsic conductivity could be produced by doping. This was achieved not only with polyacetylene, which has a relatively simple structure, but also in polymers with a ring structure or in heterocyclical polymers. All polymers that can be brought into a conductive state, have an alternating sequence of chemical single and double bonds. In the basic state they are fixed in time and space so that electrical charge carriers cannot initially move along the polymer chain. Only in the doped state, e.g. by oxidation, are parts of these double bonds dissolved. They are now no longer localised and charge carriers possess a certain degree of mobility along the chain structure. So the polymer takes on new electronic states, which are termed solitones, polarones and bi-polarones. In the case of polyacetylene, specific electrical conductivities of up to 400 000 S/cm can be achieved. These are, at least as much as for copper and thus such a plastic can be termed a “synthetic metal”. The other “intrinsic” (from within) electrically conductive polymers (for example polyparaphenylene, polyaniline, polypyrrol, polythiophene) have values of a few hundred S/cm. They thus fall within the range of semi-conductor materials (e.g. doped silicon).

The almost revolutionary discovery of the intrinsic conductivity of certain plastics originally led to expectations of the turbulent development of this class of substances in industrial applications. There are various reasons for the fact that this has not been the case. The main reason is that it has become apparent that the stability of the electrically conductive state is usually very low. So, in the case of polyacetylene, conductivity falls by several powers of ten within a few weeks. A further significant disadvantage is that the above-mentioned polymers are insoluble and unmeltable in their conductive, doped form, which means industrial processing is impractical (Hoechst).

Polymer fibre specific gravities If polymers are spun into fibres the main difference between them is their density. The most important natural fibres can be classified in an appropriate tabular listing (see Fig.).

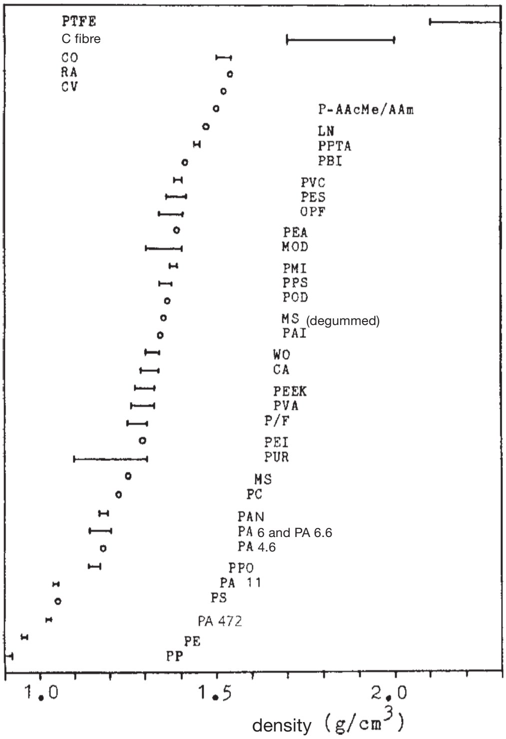

Fig.: Densities of natural fibres and synthetic fibres (for codes see: DIN 60001).

Polymer homologues → Macromolecules made up of the same basic building blocks (→ Monomer), but with a different → Degree of polymerization.

Polymer hydrophily relates only to properties of the polymer/water boundary layer and characterizes the structure forming influence of the polymer on the H_2O layer near the boundary layer. It is not possible to predict the → Hydrophilic property of polymers. However, rough estimates of the H_2O content can be made, based upon the H_2O binding capacity of the functional group of the monomers. Instead of a real measured number, however, variables such as sorption, swelling value, wetting angle, water permeability, mobility of the adsorbed H_2O, and H bridge bonding coefficient correlate with the hydrophily of the system.

Polymer implants Fibres are modified by chemical and physical processes (plasma treatment), in order to increase their mechanical or chemical (hydrolysis) stability or to develop a biologically active polymer surface. In the latter case, the aim is to produce a biocompatible or haemo- compatible material, which has a recognition sequence (pentapeptide of the fibro-nectine) for vascular inner skin cells (see Fig.). By the exchange of the carrier polymer, the polymer surface finished in this manner can be used for various medical implant purposes.

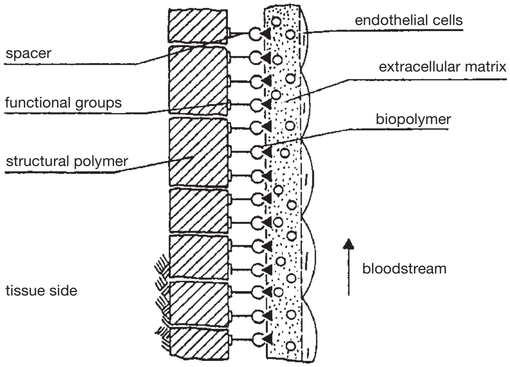

Fig.: Structure of a modified polymer surface for colonization by endothelial cells (according to Höcker).

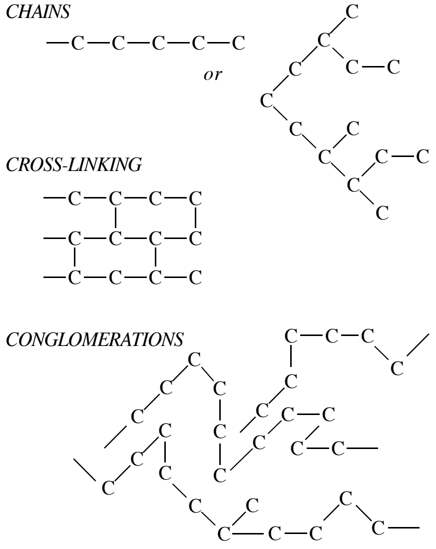
Polymerization Chemical linking of the same (isopolymerization) or different (copolymerization) monomers to polymers without the splitting of secondary products. One of the most important chemical addition reactions in nature and synthetic chemistry. All unsaturated compounds with double or multiple bonds are polymerizable.

$$-\underset{|}{C}=\underset{|}{C}- \qquad -C\equiv C- \qquad =C=C=$$

$$=C=NH \qquad -C\equiv N$$

They possess the ability to join together to form large molecules (growth of molecules) and to combine many thousands of individual molecules (→ Macromolecules). This occurs by the saturation of free valencies, by the shifting of unstable ring systems or by hydrogen migration. This creates either unbranched or branched chains, cross-linking or conglomerations:

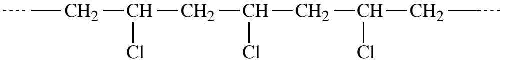


Either long extended (so-called chain or thread molecules) or round macromolecules (so-called ball molecules) form.

According to the chemistry of polymerization, e.g. polyvinyl and polyacrylic products are synthesized from acetylene (HC = CH), these may be polyvinyl alcohol ($(H_2C = CHOH)_x$), polyvinyl chloride, polyvinyl ester, etc.; similarly also polyacrylic acid, its esters and other derived compounds. A polymerization product therefore has the same percentage composition as the starting substance, but a fraction of its molecular weight. In general, a progressive change takes place to the chemical-physical properties of the starting substance as the → Degree of polymerization increases: Increase in density, increase in the melting and boiling points, increase in viscosity, loss of solubility and increase of the coherency (solidity).

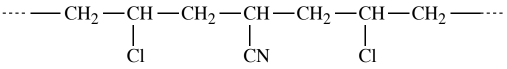
Classification:

I. Iso-polymerization: Built up from a single, chemically unified substance (rubber, polyphosphate, polyacrylic acid ester, polyvinyl chloride, etc.); e.g. polyvinyl chloride:



$$\cdots-CH_2-\underset{\substack{|\\ Cl}}{CH}-CH_2-\underset{\substack{|\\ Cl}}{CH}-CH_2-\underset{\substack{|\\ Cl}}{CH}-CH_2-\cdots$$

II. → Copolymerization: Built up from several (usually two), chemically different basic molecules. The latter may have the same polymerizability, which usually creates chain molecules with often innovative or modified properties (e.g. better dyeability, high water absorbency, lower thermoplasticity, etc.); → Copolymer fibres, e.g. polyvinyl chloride acrylonitrile copolymer:



$$\cdots-CH_2-\underset{\substack{|\\ Cl}}{CH}-CH_2-\underset{\substack{|\\ CN}}{CH}-CH_2-\underset{\substack{|\\ Cl}}{CH}-CH_2-\cdots$$

When the individual components have different polymerizability we talk of hetero-polymerization, which occurs, for example, in copolymers of polyvinyl or polystyrene and maleic acid. → Polymerization reaction for fibre-forming macromolecules.

Polymerization cross-linker Reactive compounds, which are capable of polymer formation and cellulose cross-linking, e.g. N-methylolacrylamide, N-methylolmethacrylamide, N-methylolpolyethylene urea. They yield a favourable ratio of resistance to tearing and abrasion in → Resin finishing.

Polymerization fibres Extensive main group of synthetic fibres, the macromolecule of which contains the same or different continuous long carbon chains, formed by → Polymerization, which is unique to all polymerization fibres (unlike → Polycondensation fibres), and which differ from each other due to side chains containing other foreign atoms (chlorine, fluorine, cyanogen, etc.) or groups ($-CH_3$, $-OH$, $-CONH_2$). This group includes e.g. polyacrylonitrile fibres, polybutadiene fibres, polyolefin fibres, polystyrene fibres, polytetrafluorethylene fibres, polyvinyl alcohol fibres, polyvinylacetate fibres, polyvinylchloride fibres, polyvinyl fluoride fibres, polyvinylidene cyanide fibres, polyvinyl copolymerization fibres.

Polymerization products (polymerizate, polymerized synthetic resins, polymerization plastics), products of → Polymerization, either in the form of → Plastics or → Synthetic resins, e.g. →: Polyacrylic acid; Polyacrylic acid ester; polyacrylates; Polyacrylonitrile; Polybutadiene; Polychlorobutadiene; Polyethylene; Polyisobutene; Polymerization fibres; Polymethacrylic acid ester; Polystyrene; Polytetrafluorethylene; polyvinyl alcohol; Polyvinyl ethers; Polyvinyl acetals; Polyvinyl chloride; Polyvinyliden chloride; Polyvinylpyrrolidone.

Polymerization reaction for fibre-forming macromolecules “Polymerization reaction” is the name given to all syntheses, which lead from low molecular (monomer) to high molecular (polymer) compounds. Polymerization reactions only occur if the appropriate chemical, thermodynamic and mechanistic conditions are fulfilled.

1. From a chemical point of view, polymerization reactions are only possible if the monomers are at

least bifunctional. However, functionality is not a constant for a compound being considered, but rather depends upon the reaction partner.

2. From a thermodynamic point of view, the free enthalpy ΔG_p of the polymerization reaction must be negative. In polymerization reactions, monomers M are either attached to or incorporated into a growing chain M_n^*, e.g.

$$M_n^* + M \rightleftharpoons M_{n+1}^*$$

or already formed chains $M_n + M_p$ (possibly with different building blocks M) are linked together.

$$M_n + M_p \rightleftharpoons M_j + M_k$$

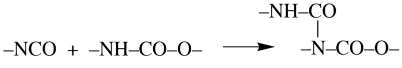
both reaction types are basically reversible.

3. Mechanistically two conditions must be fulfilled. First the molecules to be linked must be easy enough to activate. Furthermore, the speed of the linking reaction must be much higher than the sum of the speeds of all reactions which block the functional positions.

Chain molecules are formed when the functionality of the monomers is equal to 2. An isocyanate group –NCO is, for example, monofunctional compared to a hydroxyl group if both groups are present in roughly the same molar ratios. To form polyurethanes with the urethane group –NH–CO–O– therefore, di-isocyanate must react with diols:

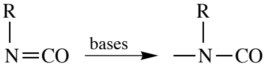
$$n\ \mathrm{OCN{-}R{-}NCO} + n\ \mathrm{HO{-}R_1{-}OH} \longrightarrow (\mathrm{-CO{-}NH{-}R{-}NH{-}CO{-}O{-}R_1{-}O-})_n$$

However, the urethane groups can convert to allophanates with excess isocyanate groups:



$$\mathrm{-NCO} + \mathrm{-NH{-}CO{-}O-} \longrightarrow \mathrm{-\overset{\overset{\displaystyle -NH{-}CO}{|}}{N}{-}CO{-}O-}$$

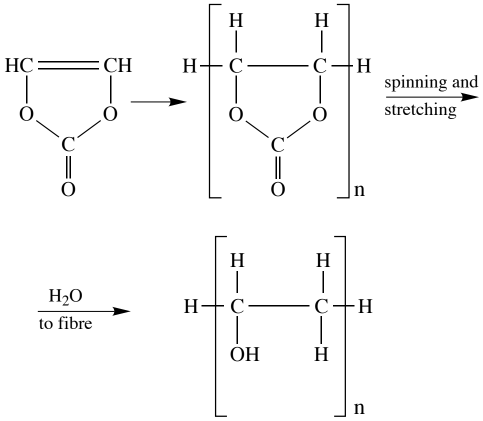
For the formation of allophanates, two isocyanate groups react with one hydroxyl group. The isocyanate group is always bifunctional in relation to the polymerization initiators



$$\overset{\overset{\displaystyle R}{|}}{N}{=}CO \xrightarrow{\text{bases}} -\overset{\overset{\displaystyle R}{|}}{N}-CO$$

Functionality is thus not an absolute property of a group, but should always be considered as relative to the reaction partner.

If we want to manufacture fibres from macromolecular substances, the fibre forming polymers must have a linear structure. The appropriate spinning process takes place from the solution or the melt; it is not possible with cross-linked molecules because this would make the orientation of the macromolecules more difficult. The chain length of the molecules, the type of covalent bond between the monomers of a chain and the possible interaction forces between the polymer molecules (dipolar forces, hydrogen bridges, crystal lattice forces) determine the fibre formation. Although polyvinyl alcohol, for example, is soluble, stretched polyvinyl alcohol fibres are insoluble in water.



PVA-fibre

The molecule type, molecular weight and molecule arrangement are determined by the chemical molecule type and the manufacturing process. All these variables determine the solid state, which is characterized by the “secondary bonds” and “crystallite formation”. The term “properties” used in this context refers to the mechanical and thermal properties, swelling and solution properties, density, stiffness and hardness and the dyeing properties.

By the → Polymerization of vinyl compounds, linear macromolecules are manufactured by the mechanism of radical, ionic or coordinative complex chain reactions. There are also secondary reactions in the chain reactions. Polypropylene is only slightly polymerized in the radical manner, so Ziegler-Natta catalysts are used. Due to lack of interaction between the chains, particularly in polypropylenes, high molecular weights are necessary for fibre formation.

Ring opening polymerization of cyclical polymers produce linear macromolecules, which are able to form fibres, if we use:

a) cyclic ether (3.3 bischloromethyloxethane),
b) cyclic ester (β-lactone and lactide),
c) cyclic amide (lactane, e.g. ε-aminocaprolactam).

By → Condensation polymerization as a chain reaction or as a stage reaction, thread forming macromolecules with a linear structure can be manufactured in the form of

a) polyester made of dicarboxylic acid and diols (e.g. of terephthalic acid dimethyl ester and ethylene glycol by re-esterification),
b) polyester made of hydroxycarboxylic acids,
c) polyamide made of dicarboxylic acids and bisprimary amines.

→ Addition polymerization is used in combination with condensation polymerization for prepolymers for the manufacture of linear macromolecules for elastic fibres based upon polyurethane (according to Elias).

Polymerized linseed oil Thickened or pre-oxidized, manufactured by heating in the absence of air or at reduced pressure with water vapour treatment. Yarns sized using polymerized linseed oil have a lower strength loss compared to untreated → Linseed oil. → Oil size.

Polmerized synthetic resins → Polymerization products with → Synthetic resin.

Polymer-like reaction The systematic alteration of functional groups of polymers is called chemical modification. If all basic building blocks react in the same way in a chemical reaction on a macromolecular material, without chain splitting or noticeable secondary reactions occurring, then the molecular weight will change, but not the degree of polymerization, i.e. the average number of linked basic building blocks, depending upon the macromolecule. Such conversions, which occur along the chain without the chain breaking, in which the macromolecule is retained during the chemical modification, are called polymer-like conversions. The chemical conversion at the macromolecule is often associated with a certain degree of chain degradation, particularly if there are ester, amide or acetal bonds, for example, between the monomers rather than a continuous carbon chain, because these bonds are easily split by the H^+ or OH^- ions that are necessary for many conversions (Fig. 1).

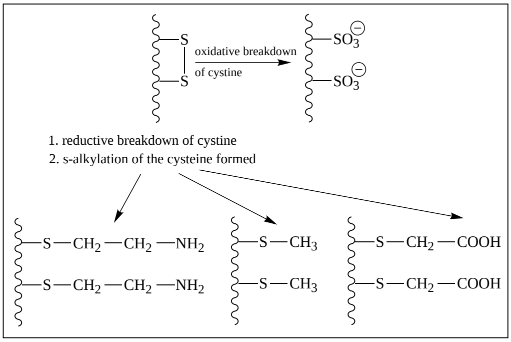


Fig. 1: Diagrammatic representation of chemical modifications of the cystine bridges in the scale protein of wool fibre, being a typical polymer-like reaction within a heterogenous system.

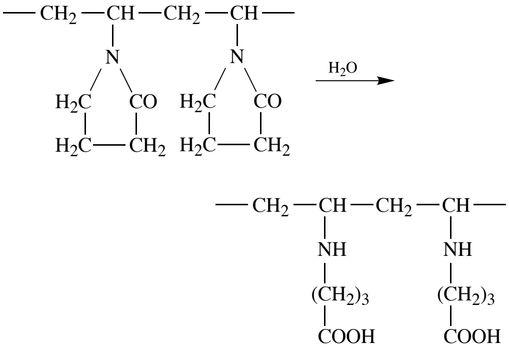
The degree of polymerization can be increased by the subsequent graft copolymerization or cocondensation and by cross-linking, by the conversion of two different reaction points in a chain with a reagent that is at least bifunctional. On an industrial production scale the cross-linking of natural and synthetic rubber is performed by the addition of a few percent sulphur to hard or soft rubber by "vulcanization".

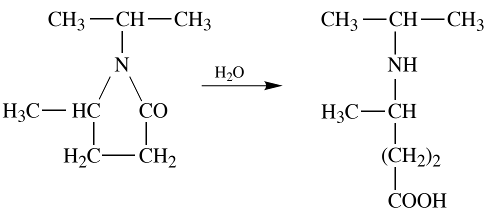
If macromolecules are converted using bifunctional reagents, then the cross-linking reaction may be not only intramolecular, but also intermolecular. In the latter case the reaction products become insoluble and usually unmeltable. Various cellulose reactions are amongst the important chemical conversions of macromolecular materials. The three hydroxyl groups per basic building block can be partially or fully esterified or etherified. One differentiates, for example, between cellulose triacetate, cellulose $2^1/_2$ acetate and others, depending upon the number of acetylized hydroxyl groups, for example, per basic building block. A further technically important conversion of cellulose is the transition into dithiocarboxylic acid ester (xanthate). Aqueous solutions of sodium salts are known as "viscose"; they are spun into threads and when precipitated in acids, accompanied by the regeneration of cellulose, supply the viscose fibres.

The group of polymer-like conversions also includes those that only affect the terminal groups, whilst retaining the chain structure (chain-like conversion). Examples include the reactions of terminal hydroxyl groups of polyesters with phthalic acid anhydride, terminal carboxyl groups with diazomethane or reactive dyes of polyamide fibres.

In polymer-like conversions, the reactivity of the functional groups is independent of the molecular weight of the polymer. So, for example, the alkaline hydrolysis (breaking of the ring) of polyvinylpyrrolidone

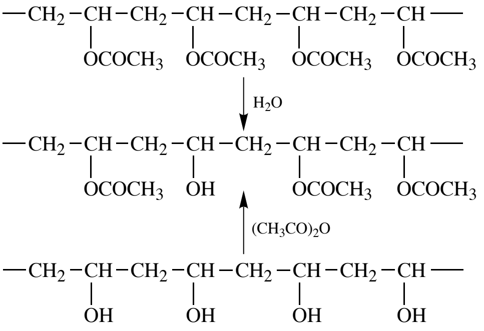


and N-isopropyl-γ-valerolactam



take place at virtually the same reaction speed and with the same activation energy.

If the chemical conversion of a polymer takes place in different directions, or if, when the conversion takes place in a uniform direction, no complete conversion is achieved, then the high molecular compounds obtained represent copolymers of the initial and final products or the initial, final and intermediate products. For example, a copolymer of vinyl acetate and vinyl alcohol is always the result of the incomplete saponification of polyvinyl acetate. A copolymer also forms as a result of the partial acetylization of polyvinyl alcohol:



$$-CH_2-\underset{OCOCH_3}{CH}-CH_2-\underset{OCOCH_3}{CH}-CH_2-\underset{OCOCH_3}{CH}-CH_2-\underset{OCOCH_3}{CH}-$$

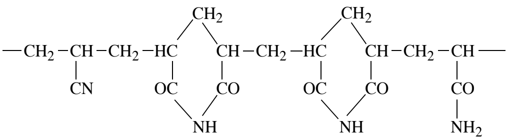
$$\downarrow H_2O$$

$$-CH_2-\underset{OCOCH_3}{CH}-CH_2-\underset{OH}{CH}-CH_2-\underset{OCOCH_3}{CH}-CH_2-\underset{OCOCH_3}{CH}-$$

$$\uparrow (CH_3CO)_2O$$

$$-CH_2-\underset{OH}{CH}-CH_2-\underset{OH}{CH}-CH_2-\underset{OH}{CH}-CH_2-\underset{OH}{CH}-$$

The product of the acid hydrolysis of polyacrylonitrile is a complicated copolymer of acrylamide and cyclical α-methylglutarimide:



The speed of the chemical conversion of high molecular compounds and the uniformity of the product obtained largely depends upon the physical state of the polymers, because the majority of high polymers are only soluble in a limited number of solvents and in most cases the reactions take place in a heterogeneous medium. Most polymers are non-uniform. Crystalline polymers are two-phase; they contain crystalline and amorphous areas. The molecules of individual sections of single phase, amorphous polymers can have different degrees of arrangement and different packing densities. The diffusion speeds of the reacting substances, and therefore the bonding speed of corresponding polymer derivatives, are different in the crystalline and amorphous areas and in the areas with more or less arrangement. It is therefore necessary for a uniform reaction sequence that the polymers dissolve and swell in the reaction medium.

In solid polymers the degree of conversion that can be achieved under given conditions is often limited by the complete accessibility of the polymers to the chemical reaction. Because even arrangement and accessibility are themselves often changed by the reaction sequence (swelling processes), neither the regularities of the homogeneous nor the heterogeneous chemical equilibrium can be unambiguously applied, and the kinetics of such conversions are often very complicated due to the interaction of chemical conversion and diffusion or swelling processes. When the conversion of polyacrylic acid derivatives with fatty chemical partners (alcohols, amines) takes place as a polymer-like reaction, products with different consistencies are yielded (Fig. 2).

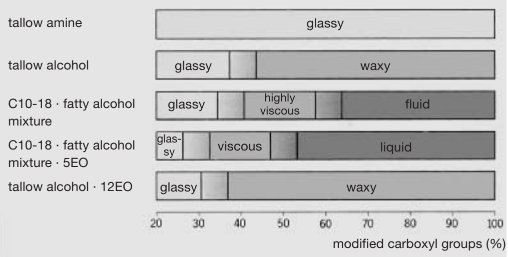


Fig. 2: The modification of polyacrylic acids with various alcohols.

The hydrophilicity or hydrophobicity of the fatty chemically modified polymers can also be adjusted within broad limits by the above-mentioned variables. The range extends from hydrophobic polymers with a high content of (non-ethoxylated) fatty side chains to products that are water soluble or self-dispersing in water. The latter are obtained by reaction with ethoxylated fatty products and/or only partial conversion of the carboxyl groups of the polymer. Further variations exist because in addition to fatty chemical residues, additional side groups can be introduced into the polymers. E.g. polymers with tertiary amino groups in the side chain become accessible due to the reaction of polyacrylic acid with a mixture of fatty alcohol and amino alcohol.

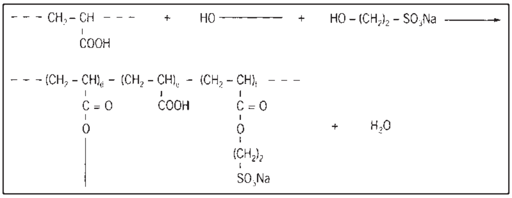

Fig. 3: Additional sulphonation when using sodium hydroxyethane sulphonate during the modification of polyacrylic acid with a fatty alcohol.

For applications, in which for example the dispersions of fat chemically modified polymers require good acid and salt resistance, the additional inclusion of sulphonate groups with the aid of hydroxyethanesulphonic acid is advisable (Fig. 3).

Polymer mixtures → Polyblends, suitable dyes for.

Polymer physics of fibres is concerned with the relationship between the structure and properties of fibre forming macromolecules. Attempts are made by modelling to theorize about what happens in the individual stages of fibre manufacture regarding the arrangement of the macromolecules in the fibre. If it is imagined that molecules take on a ball-shape in the melt prior to the spinning nozzle, then they are partially aligned within the spinning nozzle due to the high shear force, i.e. the chain molecules take on a preferred orientation (Fig. 1). If the fluid threads leave the nozzle at normal pressure, the orientation process is largely reversed due to thread expansion. Due to the influence of gravity and shear forces and due to further forces acting upon the thread discharge a contraction of the thread occurs, causing a new preferential orientation of the chain molecules. Depending upon the polymers in question a partial crystallization of the macromolecule or just a preferential orientation takes place. It is therefore known that polyamide fibres crystallize (Fig. 2) even in spun fibres, whereas polyethylene terephthalate fibres remain strongly amorphous with a preferential alignment.

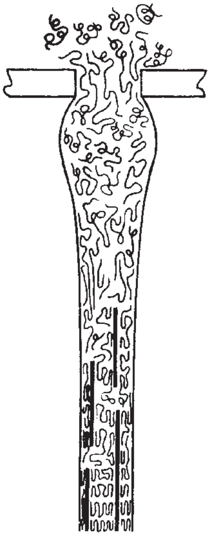

Fig. 1: Change to molecular conformation during spinning (model according to Katayama et al.).

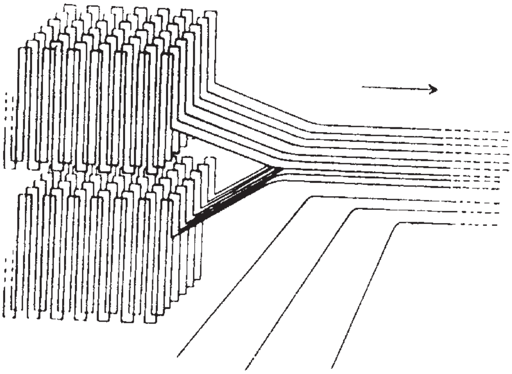

Fig. 2: Molecular model of drawing (according to Kobayashi).

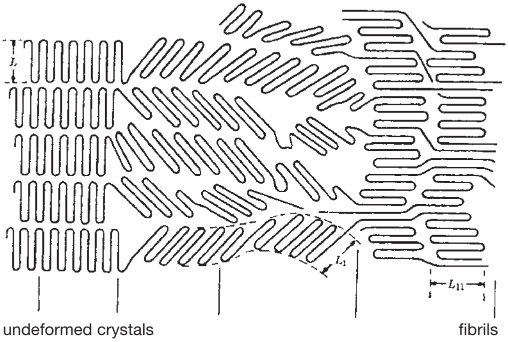

Fig. 3: Molecualr model of drawing (according to Peterlin).

The orientation processes during drawing (Fig. 3) occur both in the crystalline areas and in the non-crystalline intermediate layers. The following equation

$$f_m = \alpha\, f_c + (1-\alpha)\, f_{am}$$

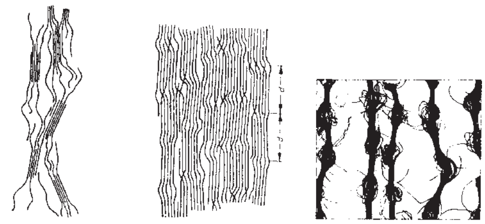
where

$f = (3\cos\Theta - 1)/2$,

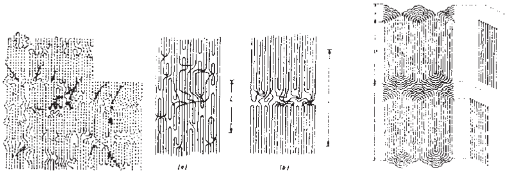
α = degree of crystallization.

shows the link between average molecular orientation f_m, orientation of the crystalline areas f_c and orientation of the molecules in the non-crystalline areas f_{am}.

All models of the fine structure of drawn, part-crystalline high polymers have in common the fact that they differentiate between phases (Fig. 4) of greater arrangement (crystalline areas) and lesser arrangement (amorphous areas).



strands and micelles model Hess-Kiessig model Statton model



Bonart-Hosemann model Fischer model (a = untempered; b = tempered) Pechhold model (meander)

Fig. 4: Two phase model of partially crystalline drawn polymers.

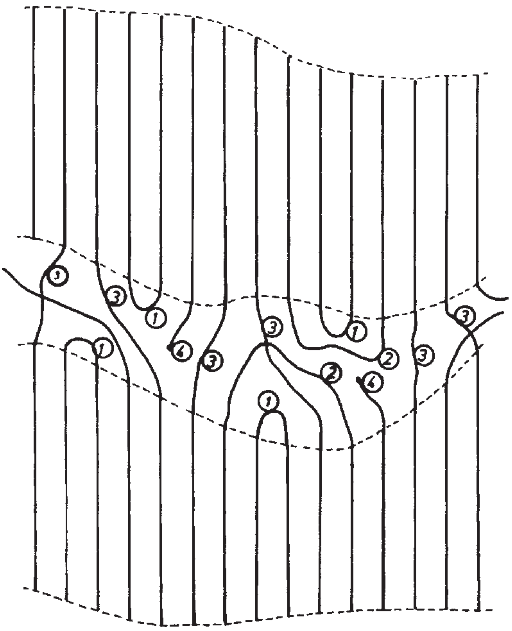


Fig. 5: The arrangement of molecules within the non-crystalline intermediate zone of drawn and partially crystallized high polymers.
1 = acute fold; 2 = loop; 3 = chain sequence under tension; 4 = chain end.

Model considerations have shown that the condition of the non-crystalline areas plays a decisive role in the physical behaviour of the drawn high polymers. The following molecular information is in the non-crystalline intermediate layers (Fig. 5):

- sharp chain folds (1),
- long chain loops (2),
- crystallite binding chain segments, which can be more or less distorted (3),
- chain ends (4).

In addition, there may also be crystalline bridges between the individual crystallites. Furthermore, chain segments, which bind together individual adjacent fibrils, should also be taken into account (Fig. 6).

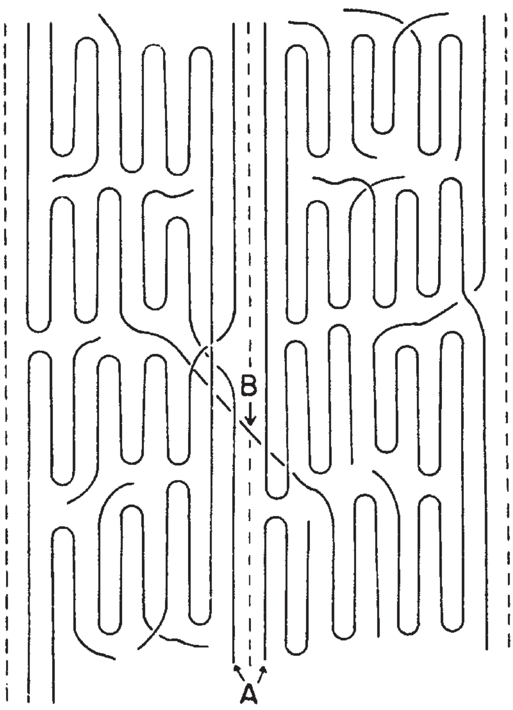

Fig. 6: Fibril model with interfibrillar linking molecules (according to Peterlin).
A = boundary of a fibril; B = interfibrillar zone.

The strength and elasticity modulus of a fibre is influenced by (Fig. 7):

- the number of chain segments binding the crystallite,
- the length distribution of the intercrystalline segments,
- the orientation due to drawing.

The degree of crystallisation has a lesser influence on strength, extension and modulus of elasticity than the

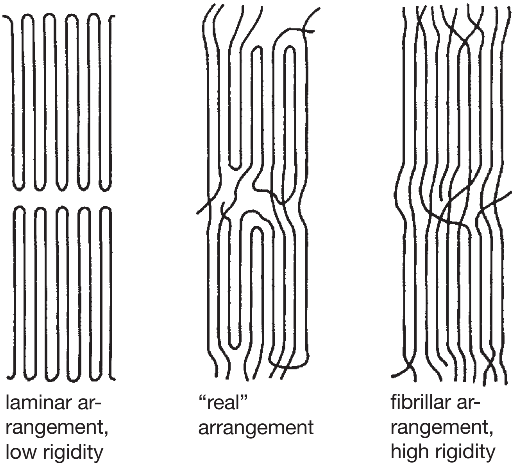

Fig. 7: Laminate and fibril arrangements.

layout of the crystallite. For example, in the crystalline areas of polyamide 6 there is the formation of so-called lattice planes, i.e. molecule planes, in which all the hydrogen bridges are arranged (Fig. 8).

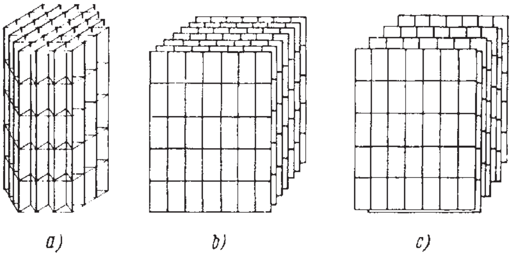

Fig. 8: Polyamide 6 crystal structures with lattice planes (according to Reichle and Prietzschk).
a) = hexagonal form; b) monocline β-form; c) monocline α-form.

There are no hydrogen bridges, or only a reduced number, between these lattice planes so that the lattice planes can slide over each other like sheets of paper when a voltage is applied. The sliding of molecules or molecular compounds is co-decisive for the level of the breaking strength and breaking elongation. The arrangement of crystalline and non-crystalline areas (Fig. 9) plays a decisive role in determining the stress/strain behaviour of oriented high polymers.

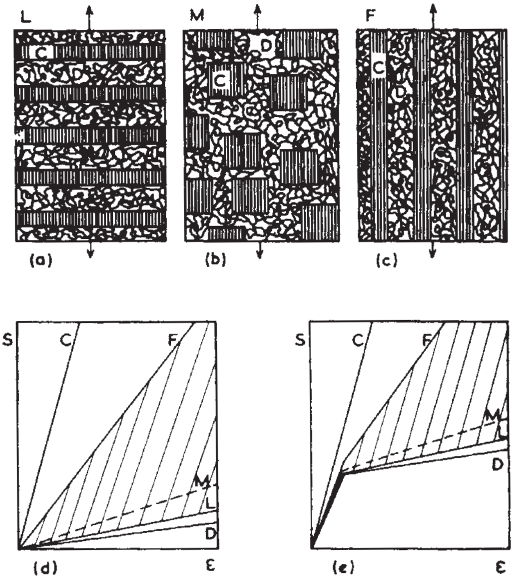

Fig. 9: The tension/extension behaviour of various superlattice structural arrangements (according to Hearle).
a = laminar system (L); b = micellar system (M);
c = fibrillar system (F); d = force/extension profiles without yield point; e = force/extension profiles with yield point.

If we consider extension in the direction of the molecular axis, then in the lamellar arrangement, the amorphous area, i.e. the area with the lower modulus of elasticity, is loaded first; in the event of higher elongation the crystalline area is loaded. The opposite is true for the fibrillar arrangement: When there is a slight elongation the crystalline area, which normally has the higher modulus of elasticity, is loaded. Only after a partial destruction of the crystallite, are the molecules in the amorphous areas involved in the extension process to a significant degree. The micellar arrangement, which corresponds best with the relationships in practice, represents an arrangement that lies somewhere between the fibrillar and lamellar structures. The stress/strain diagrams depend upon the arrangement in question (according to Hinrichsen).

Polymer recycling through depolymerization

Whilst the energetic recycling of polymers (burning) in many cases represents a suitable method, albeit one which has limited public acceptability, the pyrolitic and hydrogenating recycling of plastics generally leads to a multitude of low molecular products, which can only be converted back into suitable monomers by cracking. In contrast, “thermodynamic recycling” represents a method that, in the ideal case, provides polymerization-free monomers. In the presence of suitable catalysts, the thermodynamic equilibrium is shifted from the polymers to the monomer(s), which can be separated by distillation and then once again added to the polymerization. This process can be used on all polymers that can be degraded to polymerizable 5 or 6 link heterocycles. This includes polytetrahydrofuran, polycarbonates of polysiloxane, and many others. The particular advantage of the method is that mixtures of the above polymers can undergo this process just as block copolymers (according to Höcker).

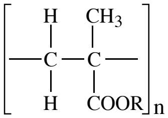
Polymers (high polymers), → Macromolecules created by → Polymerization, → Condensation polymerization or → Addition polymerization (natural, artificial or synthetic). The cellulose chain molecule of cotton forms a typical natural polymer (→ Degree of polymerization) made up of approx. 2000 cross-linked glucose residues.

Polymers are organic chemical compounds, which have different molecular weights together with the same qualitative and quantitative composition, e.g.:

glucose (residue):	$C_6H_{10}O_5$
hydrocellulose:	approx. $(C_6H_{10}O_5)_{100–300}$
cotton:	$(C_6H_{10}O_5)_{2600}$

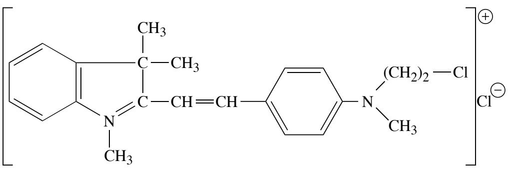
Polymethacrylates Identical to → Polymethacrylic acid ester.

Polymethacrylic acid ester (polymethacrylate), similar to → Polyacrylic acid ester, but significantly harder (butyl, ethyl, methyl ester with softening points of +18°C, +50°C, +100°C), sometimes very brittle. In the form of solutions and emulsions.



$$\left[-\overset{\displaystyle H}{\underset{\displaystyle H}{C}} - \overset{\displaystyle CH_3}{\underset{\displaystyle COOR}{C}} - \right]_n$$

Polymethine dyes (cyanine dyes), contain several linked methine groups (–CH =), which form a system of conjugated double bonds, e.g. a chain with trivalent and quadrivalent nitrogen at the "ends". Such symmetrically structured polymethine dyes are extraordinarily non-lightfast. Polymethine dyes of this type are used as sensitisors in the manufacture of panchromatic films. In contrast, certain asymmetric polymethine dyes have medium to good light fastness, a fact exploited by acetate printing with specific dyes and polyacrylonitrile dyeing.



Polymethylene chains Methylene groups arranged in a chain-like sequence [$–CH_2–CH_2–CH_2–$] in high molecular compounds (e.g. in textile accessory materials).

Polymethylene sulphone fibres (polyhexamethylene sulphone fibres), $[–(CH_2)_6–SO_2–]_x$ synthetic polycondensation fibre type. Manufactured e.g. from polythioether by oxidation with peroxide, spinning as a fused mass and cold drawing. Cross-sectional shape is round. Properties: density 1.2; normal moisture 2.2%; breaking strength 27.5–37.3 cN/tex, 95% moist; elongation at break 10–18%; soluble in most inorganic and organic solvents; dyeable with disperse dyes.

Polymolecular Property of → Macromolecules; their construction from different molecular sizes due to e.g. non-uniformity, i.e. varying length of the → Chain molecules. The results include varying → Degree of polymerization, strength differences in fibres, etc.

Poly-(m-)phenylene isophthalamide Flame retardant fibre material, which has the same mechanical properties as polyamide except for greatly increased temperature resistance.

Polynosic Derived from the French "polymère non synthéthique" (non-synthetic polymer). Since 1961 the trade name, protected by trademark law, has been "Association Internationale Polynosic" - members for → Polynosic fibres. The scope of protection is controversial, because countries with a fibre declaration of "polynosic" do not recognize it as a generic term.

Polynosic fibres Modified viscose fibres, subgroup of the cotton-like → Modal fibres. Differ from → High wet modulus fibres due to their good alkali resistance (mercerizability). They possess a characteristic uniform structure of fine fibrils in a rather homogeneous arrangement distributed over the entire round cross-section. Therefore, they have good penetration and reactivity at low swelling (approx. 60%) compared to finishing resins. They have good dimensional stability due to the high wet modulus. Cross-section round; DP 450–600. Application: 100% polynosic fibres for domestic textiles, coating base fabrics; in mixtures with cotton (40–50%); with wool for outer clothing; with polyacrylonitrile for clothes, skirts, sport and winter clothing and for nonwovens. As filament yarn for dimensionally stable high pressure hoses.

Polyolefin fibres (olefin), polymerization fibres of min. 85% ethylene, propylene or other olefins (→: Polyethylene fibres; Polypropylene fibres). Manufactured by polymerization as the polyethylene type, either under high pressure, branched structure (plays hardly any role as a fibrous material) or under low pressure with linear structure (for fibre manufacture), further as polypropylene type (as monofilament and multifilament) with isotactic structure of the side groups ($–CH_3$, $–CH_2–CH_3$, etc.). When drawn, such polyolefin fibres achieve significant strengths along with an increased melting range (see Tab.).

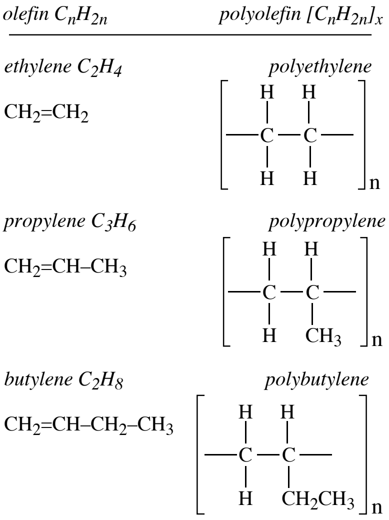
Polyolefin fibres are sometimes relatively coarse, but are also spun in fine titres in pure form or with cotton, wool and synthetics. Properties: bacteria and insect resistant, density < 1, water absorbency virtually 0, thermostabilizable (which makes them up to 170°C resistant without decomposition or yellowing), electric

	density [g/cm³]	melting zone [°C]	rigidity [cN/dtex]
polyethylene			
branched (HP)	0.92–0.94	105–120	1–3
linear (LP)	0.95–0.96	125–135	3.5–7
polypropylene			
isotactic	0.90–0.92	160–175	2.5–6

Tab.: Characteristics of polyolefins.

insulator, slow burning (fine polyolefin fibres melt first; increased flame resistant polyolefin fibres by spin-melt coatings). Chemical resistance good, insoluble in all concentrated alkalis and acids (exception conc. hot nitric acid and oxidizing agent at higher temperature). Aromatic solvents (benzene, toluene, etc.) and chlorinated hydrocarbons have a swelling effect at room temperature, and a solvent effect at higher temperatures (70°C). Mineral and vegetable oils are easily absorbed and have a swelling effect, increasingly so at higher temperatures. Subsequent dyeing difficult (only modified fibres) (mainly spin-dyeing).

Polyolefins (poly-α-olefins), polymer of α-olefin. Polyolefin designation, although there are no longer any double bonds (thus → Paraffins); Examples:



Polyols Multivalent → Alcohols, i.e. containing several OH groups, such as diols (e.g. glycols), tertiary alcohols (e.g. glycerol), etc.

Polyoses High molecular → Carbohydrates, made of hexose molecules, e.g. (from glucose) starch and cellulose.

Polyoxy compounds →: Oxyethylation; Polyethylene glycols; Polyglycol ethers (and polyglycol esters), etc.

Polyoxyether Type of → Polyglycol ethers.

Polyoxyethylation → Oxyethylation.

Polyoxyethylene thioether Surfactant of polyoxyethylated thioether type.

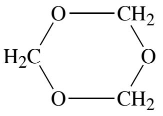
Polyoxymethylenes $(CH_2O)_x$, manufactured from gaseous → Formaldehyde, is easily polymerized to a low solubility mixture of different polyoxymethylenes in the presence of H or OH ions (water), usually in the form of a crystalline white substance, which can be depolymerized again and brought into solution by acids or alkalis. The reaction of formaldehyde in its hydrate form as methylene glycol $HO{-}CH_2{-}OH$ whilst giving off water (polycondensation) to dimethylene glycol, which is ethylated with a further mol of methylene glycol to give trimethylene glycol and high molecular polyoxymethylene:

$$HO{-}CH_2{-}O\boxed{H\ +\ HO}CH_2{-}O\boxed{H}+\ldots$$

$$\longrightarrow\ {-}O{-}CH_2{-}O{-}CH_2{-}O{-}\ +\ H_2O$$

This process is similar to the production of → Polyethylene oxides and → Polyglycol ethers. The different polyoxymethylenes are characterized by molecular size, degree of polymerization (determines physical constants such as melting point, solubility, etc.) and terminal molecule groups (determine the chemical behaviour). Examples:

1. paraformaldehyde: mixture of different polyoxymethylene-dihydrates, DP 3–100, approx. 95% formaldehyde content, develops gaseous formaldehyde from 100°C (space disinfection).
2. α-polyoxymethylene: $HO{-}CH_2{-}O{-}(CH_2{-}O)_x{-}CH_2{-}OH$, a polyoxymethylene-dihydrate with DP = 2 to above 100, reductive action, is split by sodium sulphite.
3. γ-polyoxymethylene: $H_3C{-}O{-}CH_2{-}O{-}(CH_2{-}O)_x{-}CH_2{-}O{-}CH_3$, a polyoxymethylene-dimethylether, DP = 2 to above 100, no longer has reductive action, no splitting by sodium sulphite.
4. trioxane (meta-formaldehyde): trimere cyclic form $(CH_2O)_3$



very soluble in water and organic solvents (unlike paraformaldehyde), very stable; for example as stabiliser for trichloroethylene.
5. tetroxane: tetramere cyclic form $(CH_2O)_4$.

Polypeptide High molecular linked → Peptide.

Polyphenylene sulphide $(–C_6H_4–S–)_n$, thermoplastic polycondensate, highly temperature resistant up to 160°C (as coatings up to 350°C), resistant against many solvents, self-extinguishing properties. Application: shaped parts, coatings for glass and metals, electrical insulator, special fibres.

Polyphosphates Phosphates with varying degrees of condensation and a chain-shaped molecular structure. Diphosphate (= pyrophosphate = two chain), triphosphate (= tripolyphosphate = three chain), tetraphosphate (= tetrapolyphosphate = four-chain), etc. up to high molecular polyphosphates = Graham's salt $(25\,Na_3PO_4)$. When dissolved in water, polyphosphates show the typical behaviour of complex formers. They dissociate max. at 30%. In water softening (i.e. bonding e.g. of calcium ions) initially non-dissociated sodium atoms (or H atoms in polyphosphoric acids) are continuously exchanged. The solubility of the complex salts decrease with increasing calcium content. If there are excess calcium ions, dissociated sodium ions are also replaced by calcium and water insoluble calcium polyphosphates. It follows from this that polyphosphates must always be dosed in a certain stoichiometric excess, in order to obtain soluble calcium (or other metal) complexes. Application: for masking water hardness and heavy metal ions, in washing, bleaching, dyeing, printing, resin finishing, as a component of domestic and industrial washing agents.

name	di-(pyro)phosphates e.g. sodium pyrophosphate	triphosphates e.g. sodium triphosphate	polyphosphates e.g. Graham salt

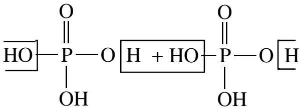
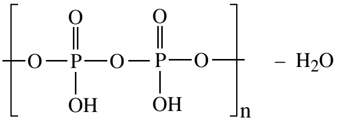
Tab.: Overview of the most important polyphosphates together with their properties.

We talk of polyphosphates when there are substances with more than one PO unit, which are arranged sequentially in a chain-like formation (see Tab.). They are formed due to condensation of orthophosphates according to the following diagram:

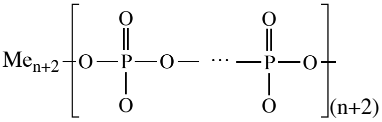


o-phosphoric acid (H_3PO_4)

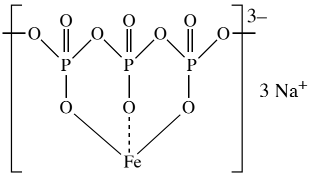


polyphosphoric acid ($H_{n+2}P_nO_{3n+1}$)

Therefore the following general structural formula applies for polyphosphates:



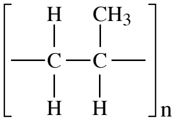
The stabilizing effect of polyphosphates on the H_2O_2 bleach liquor is often attributed to its capability of complex forming and its buffering ability. Furthermore, the polyphosphates are able to mask catalysts by binding them into a chelate complex:



The properties of the polyphosphate often vary with the chain length. Pyrophosphate is the shortest with two $NaPO_3$ units and Graham's salt is the longest chain-shaped polyphosphate with an average of 25 $NaPO_3$ units.

Their disadvantage is their hygroscopicity, which gives rise to the danger of agglomeration, making dosing difficult. A further disadvantage is their poor biodegradability. If polyphosphates find their way into waste water, they can lead to the eutropification of bodies of water. When used in textile finishing, therefore, quantities must be checked. Furthermore, when used in H_2O_2 bleach the bleaching conditions must be thoroughly checked, to see whether the danger of hydrolysis exists for the polyphosphates under certain circumstances (high temperatures, strongly alkaline range).

Polypropylene (PP). Synthetic polymer (→ Polyolefins), which has been manufactured since 1957, with an isotactic structure (low-pressure polymer of propylene and stereospecific catalysts).



$$\left[-\overset{\displaystyle H}{\underset{\displaystyle H}{C}}-\overset{\displaystyle CH_3}{\underset{\displaystyle H}{C}}- \right]_n$$

It is significantly softer and more flexible than low-pressure polyethylene. Particularly suited for the manufacture of foils and fibres and also for hot water pipes (tolerated up to 130°C).

Polypropylene bicomponent fibres Fibres of matrix/fibril type, which are fundamentally different to the earlier polypropylene standard fibres used in the carpet industry. The greatest difference is in their dyeability. In addition to spin-dyed polypropylene fibres these fibres can also be dyed during textile production at atmospheric pressure and boiling temperature using disperse dyes without a carrier. The fibres are available as semi-matt, lustrous or highly lustrous. Furthermore, there is the option of piece or padder dyeing for tufted goods. They can also be processed for pile yarns using semi-worsted yarn or carded yarn spinning processes. The surface structure which has been developed for the fibre imitates that of wool, which contributes to the natural handle of this fibre.

Polypropylene fibres (PP). Isotactic → Polyolefin fibres made of → Polypropylene, manufactured according to the melt-spin process and drawn. Production began in 1959. They are important as monofilaments and multifilaments. Properties: breaking strength 2.5–6 cN/dtex, 100% moist; elongation at tear 15–30%, 100% moist; softening range (unloaded) 149–160°C, melting range 163–170°C. Application: polypropylene fibres are becoming increasingly important in the textile industry in the form of filaments and fibres. Due to the improvement of their water absorbency and dyeability, the original fields of application (technical textiles, geotextiles, carpet primary backing fabrics, nonwovens) has been expanded, and now, for example, furnishing and decorative materials or swimming costumes and knitgoods are manufactured from texturized polypropylene. Microfine fibres are processed into insulating lining fabrics.

Polypropylene fibres, dyeing With the increasing use of propylene fibres in the fashion industry the question of subsequent dyeing has come further to the forefront. It is a well-known fact that polypropylene fibres are difficult to dye; large items are therefore spin-dyed. This has the disadvantage that rapid adaptation to ever-changing, diverse fashionable shades is not possible. Numerous attempts have been made to improve dyeability. Dye penetration can be increased by the use of dyeing auxiliaries, such as non-polar swelling agent for the fibres, however the washing fastness and solvent fastness are inadequate. The dyeing behaviour of the fibre can also be influenced by chemical modification. This is mainly performed by grafting reactions, with mainly acrylic acid, acrylic ester, vinyl acetate, vinyl pyridine and vinyl pyrrolidone being grafted. Partial oxidation of the methyl groups, conversions with chlorine, bromide and fluoride, with chlorosulphuric acid and hypochlorite give rise to the possibility of dyeing with cationic dyes, however these dyeings have a low light-fastness. The spinning in of dye affinity additives, in particular of nickel compounds, has been thoroughly investigated. Polypropylene fibres can also be spun-dyed with pigments.

The dyeing of spun polypropylene fibres however is associated with significant difficulties. Up until now no satisfactory process has been found for dyeing polypropylene fibres after the completion of fibre manufacture. The poor dyeability of a fibre can have many fundamental reasons. A prerequisite for dye uptake is the spatial accessibility of the fibre to dye molecules. Dyeing processes only take place in the amorphous areas of the fibre. Crystallite is not accessible to dye molecules. Fibres with a high degree of crystallization are therefore difficult to dye, as is the case with the aramides, for example. The degree of crystallization of polypropylene fibres is about 60%, which means that there should be enough amorphous areas for dye uptake. But even the amorphous areas have a limited degree of accessibility to the dye. Only if the chain segments in these areas are mobile is there a free volume, which facilitates dye uptake. This means that in the amorphous areas dye uptake is only possible at above the glass transition point T_g. If the glass transition point is high, as is the case in polyester fibres, for example, then only when using auxiliaries which lower the T_g is dye uptake possible at normal dyeing temperatures of 100°C. In polypropylene fibres the glass transition point should not present any dyeing difficulties, because it is very low, being only 35°C. Even if the steric relationships are favourable for dye uptake, it is still possible for no dye to be drawn into the fibre. Only if interactive forces are generated between fibre molecule and dye molecule, and if there is an affinity of the dye to the fibre, can dye take-up by the substrate occur according to the exhaust dyeing method. Fibres with ionic or polar groups are generally able to create such interaction forces. However, polypropylene does not possess polar or ionic groups, so that only van-der-Waals forces come into consideration for the generation of intermolecular forces, which at 4.2 kJ/Mol are very weak.

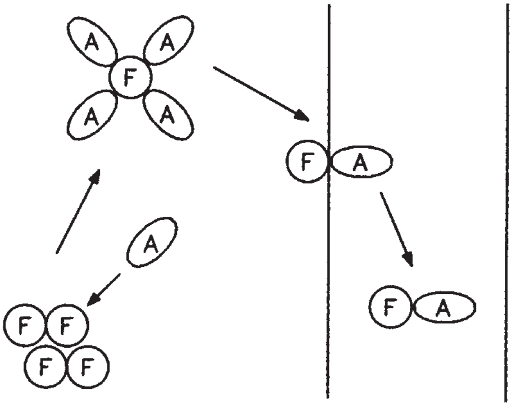


Fig. 1: The dyeing process during emulsion dyeing with affinity meditors (A) and dyestuff (F), represented diagrammatically (according to Herlinger).

Auxiliaries are substances, which can form interaction forces to the dye, but at the same time show an affinity to polypropylene. Such substances can be called affinity providers. Their possible working method is shown in Fig. 1. The auxiliary substances form interaction forces both to the dye molecules and the fibre molecules and in this manner ensure an affinity bridge between fibre and dye.

The affinity of a dye to polypropylene can be assessed using a lipophile parameter, which is easily accessible due to the “reversed” chromatography of the dye. Fat and oil soluble dyes, which have a few long or several short alkyl groups are best suited for dyeing polypropylene. Monoazo dyes have an inadequate degree of fastness, even though an improvement can be achieved by increasing the methyl group number in the dye. Significantly better results can be achieved with biazo dyes. The transition from unsubstituted parent substance Solvent Red 23 to Solvent Red 27 substituted with four methyl groups brings about an extremely large increase in the dye take-up. The washing fastness of this dye is at 60°C at mark 5. The overall fastness level is satisfactory.

1.4-bis-alkylaminoanthraquinone with different substituents of increasing chain length at C_{18} and the unsubstituted 1.4 diaminoanthraquinone and Disperse Red 60 are used as anthraquinone dyes. The dyeing properties range from very poor to very good with the transition from unsubstituted 1.4 diaminoanthraquinone to 1.4 bis-octadecylaminoanthraquinone. The quality of the dyes can be improved further by the addition of 10 g/l toluene to the colour baths. The mechanical-technological properties of the fibre are not impaired by the toluene treatment. The inclusion of longer alkyl residues or several shorter alkyl groups in dyes represents a possibility of manufacturing polypropylene affinity dyes with a built in affinity provider, giving satisfactory fastness.

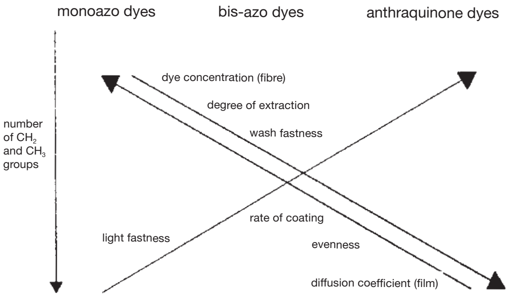

Fig. 2: The influence of dye constitution on the dyeing properties of polypropylene fibres (values increase in direction of arrows) (according to Herlinger).

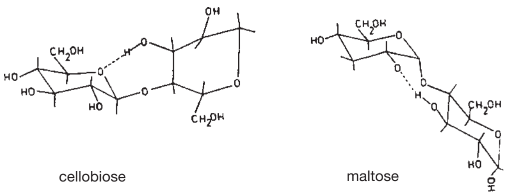
Phenomena dependent upon diffusion, such as levelling capacity and exhaustion speed, become poorer with increasing alkyl chain length and number, whereby monoazo dyes are better than biazo dyes, and these appear to be better than anthraquinone dyes. The washing fastness depends upon the ease with which a dye can be diffused out of the fabric. For this reason they improve in reverse order. Exhaustion degree and dye concentrations on the fibre improve with increasing alkyl chain length and number. For the investigated dyes the best suited monoazo dyes were poorer than the biazo dyes and these were poorer than the high affinity anthraquinone dyes. The exhaustion degree and dye concentrations on the fibre can be increased further by the inclusion of even longer chains in monoazo and biazo dyes. The light fastness behaves differently. So the anthraquinone dyes are more light fast than biazo dyes and these are clearly more light fast than monoazo dyes. Increasing the number of alkyl chains has a negative influence upon the light fastness (Fig. 2). (according to Herlinger).

Polypropylene glycol Synthesis product, colourless, non-volatile, does not corrode metals, highly to slightly soluble in water, cold resistant. Application: for lubricants, solvents, non-ionogenic cleaning products, synthetic resins, softeners, etc.

Polysaccharides The most important polysaccharides for textile finishers are the related substances of cellulose and starch. As polyols they have the ability to strongly interact with water and form hydrogen bridges. Whilst cellulose, being a structural polysaccharide, forms hydrogen bridge bonds intramolecularly but above all intermolecularly and as native fibre (cellulose I), crystallizes even without water, water represents an integral component of starch. Completely dry starches show an amorphous x-ray diffraction diagram. This shows that even at the dimers: β-cellobiose crystallizes without water, β-maltose only as monohydrate.



cellobiose

maltose

Fig.: The conformation of cellobiose and maltose.

We can see from the basic pattern of the dimers that the equatorial-equatorial β(1.4) glycosidic bond imitates the extended zigzag chain of cellulose, which determines the parallel arrangement of the chain, intermolecular hydrogen bridges and low solubility; the axial-equatorial α(1.4)-glycosidic bond promotes a helical or more ball-shaped structure of the amylose, and thus comparably better solubility (according to Pfannmüller).

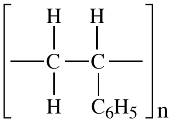
Poly salts → Polyelectrolytes.

Poly-Set-Process Two-stage → Permanent-press process: Stage I cross-linking in the presence of weak catalysts such as zircon acetate. Stage II after manufacture using strong catalysts such as zinc nitrate.

Polysilicic acids Higher → Silicon oxo acid e.g. of the type $(H_2SIO_3)_n$, the most well-known salt of which is water glass or → Sodium silicate.

Polysiloxanes → Silicones.

Polystyrene (PS, polyvinyl benzene), polymer → Styrene.

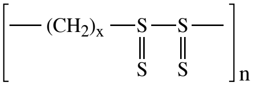


$$\left[-\overset{\overset{H}{|}}{\underset{\underset{H}{|}}{C}}-\overset{\overset{H}{|}}{\underset{\underset{C_6H_5}{|}}{C}}- \right]_n$$

Industrial form: grains, powder, organic solutions, emulsions. Applied films are colourless, transparent, non-yellowing (due to light or heat), hard, brittle. Resistant to water, alkalis, acids; not to hydrocarbons, chlorinated hydrocarbons. Application: lacquers, foils, materials, finishes and acetate sizes (particularly acrylic, butadiene, vinyl copolymers), → Polystyrene fibres.

Polystyrene fibres Synthetic polymer monofilaments. → Polystyrene spun from the melt, then drawn. Coarse, colourless monofilaments (synthetic horse hair), hard, brittle. Properties: burnable; density 1.04–1.06; softening point 70–80°C, depolymerization from approx. 190°C; normal moisture take-up 0% (in water 0.3–0.5%); no water swelling; strength dry/wet 6–7 cN/tex; elongation dry/wet 20–40%; resistant to acids and alkalis; soluble (varies according to degree of polymerization) in benzene, benzine, ether, esters, ketones, chlorinated hydrocarbons. Application: only for technical purposes, e.g. due to good solubility in a range of solvents as support fibres, which are later dissolved. Also as bristles or monofilaments for brushes.

Polysulphides Usually contain 2–5 sulphur atoms. Occur in the form of inorganic alkali polysulphides and compounds with the alkyl polysulphide group of the type

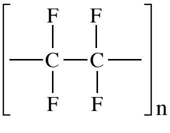


$$\left[-(CH_2)_x-\underset{\underset{S}{\|}}{S}-\underset{\underset{S}{\|}}{S}- \right]_n$$

Used for stabilizing sulphur alkaline dyeing liquors against atmospheric oxygen in the jigger, in the winch beck or in the jet.

Polysulphonated dyes → Acid dyes.

Polytetrafluoroethylene (PTFE, fluorocarbon plastics), synthetic plastic polymer of tetrafluoroethylene (manufactured under extreme conditions from chloroform, antimony fluoride and hydrofluoric acid).



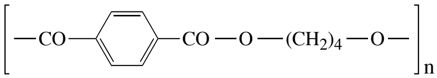
$$\left[-\overset{\overset{F}{|}}{\underset{\underset{F}{|}}{C}}-\overset{\overset{F}{|}}{\underset{\underset{F}{|}}{C}}- \right]_n$$

Translucent, beige-brown, soft-waxy. Until now uniquely inert. Resistant against all chemicals and solvents. Application: material (insulation material, seals, linings, chemical containers), technical fibres (→ Polytetrafluoroethylene fibres).

Polytetrafluoroethylene fibres Synthetic polymer fibres made of polytetrafluoroethylene chains. They possess extraordinary chemical and physical stability. Produced by the melt-spin process, extremely fine threads can be spun and cold drawn. Appearance: beige-brown (bleaching with boiling aqua regia, without damage), soft slippery, cross-section round. Properties: density 2.3; normal moisture absorbency 0.02%

(unwettable); virtually non-flammable (glows in flame); softening point approx. 327°C; at 225°C, 15% fall in tear resistance; at 310°C no strength; difficult fabric fixing, at 315°C, it takes 1 min to extract the decomposition gases (toxic); melting range from approx. 400°C (simultaneous decomposition); strength dry/wet 16–27 cN/tex; elongation dry/wet 13–15%; dermatalogically harmless; resistant to mildew, bacteria, insects, weather resistant; almost totally resistant to acids, alkalis, organic solvents; difficult to dye (disperse dyes; spin dyeing). Application: for technical purposes (filter cloth, packing material, protective clothing, dye bags, screen printing gauze, etc.), also for non-wovens.

Polytetramethylene terephthalate fibre Polyester modification, which can be dyed without a carrier, e.g. for domestic textiles. Density 1.31; melting point up to 224°C; glass transition temperature 40°C.

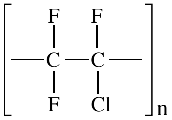


Polythioethers Synthetic polymers with → Thioethers (alkylpolysulphide), e.g. of type $[-CH_2CH_2S-]_x$. They form the basis for synthetic rubber-like products and as synthetic fibre formers (→ Polymethylene sulphone fibres).

Polythionic acid Higher → Sulphur oxyacids of the type $H_2S_{3(-6)}O_6$ which only occurs in salt form or aqueous solution. In alkaline solution decomposition to thiosulphate and sulphite.

Polythioureas → Polyureas.

Polytrifluorochloroethylene (polytrifluoromonochloroethylene), synthetic plastic polymer of trifluorochloroethylene (of hexachloroethane and hydrofluoric acid). Similar to → Polytetrafluoroethylene, but easier to process.



$$\left[-\underset{F}{\overset{F}{C}}-\underset{Cl}{\overset{F}{C}}-\right]_n$$

Density 2.1–2.2; colourless; translucent, hard and strong (not brittle); softening point approx. 230°C; unburnable; resistant up to above 100°C against almost all acids, lyes and solvents (highly-halogenated hydrocarbons and some aromatic compounds have a swelling effect). Commercial form: flakes, rods, tubes, 60% organic solvent dispersions pure or mixed. Application: packing, membranes, pipes, equipment parts, containers, etc.

Polyurea fibres Further development within the group → Polyurethane fibres made of spun → Polyureas. The properties of the polyurea fibres largely correspond with those of polyurethanes, having the following advantages compared to the latter: Low density of 1.07 and significantly higher melting point of 237°C.

Polyureas Organic conversion products of di-isocyanates and diamines, e.g.:

$$2\,H_2N-(CH_2)_6-NH_2 + OCN-(CH_2)_n-NCO \quad \textit{(Monomer)}$$

$$H_2N-(CH_2)_6-\underbrace{NH-CO-NH-}_{\textit{urea residue}}(CH_2)_n-\underbrace{NH-CO-NH-}_{\textit{urea residue}}(CH_2)_n-NH-$$

$$\underbrace{\left[-HN-(CH_2)_n-NH-CO-NH-(CH_2)_6-\right]_m}_{\textit{polyurea}}$$

While useable foils and threads can be manufactured according to this principle, threads produced in a similar manner from polythiourea have no useful properties due to their marked thermoplasticity, thus the latter are attributed no technical importance. Application: adhesives, cements; animalization; hydrophobing; fibre material (→ Polyurea fibres); moulded plastics; synthetic leather, etc.

Polyurethane carpet backing → Backcoating of carpets with polyurethanes is fundamentally different to other coating methods, because the rubber-like polyurethane polymer is formed on the back of the carpet by the spontaneous reaction of a hydroxyl group of (polyester or polyethylene) with (toluylene or diphenylmethane) di-isocyanate to form → Polyurethanes according to the diagram:

$$R-NCO + R-OH \longrightarrow R-NH-CO-O-R \ \text{(+ heat)}$$

Application now takes place either by air/gas impact (Dow process) or with a blowing agent, or the reaction described above is supplemented by the reaction of di-isocyanate and water to urea groups, whereby carbon dioxide serves as the gas component for foaming:

$$\begin{tikzcd}
R-NCO + H_2O \arrow[r] & R-NH-COOH \arrow[d] \\
 & R-NH_2 + CO_2 \arrow[d] \\
 & R-NH-CO-NH-R \ \text{(+ heat)}
\end{tikzcd}$$

Classification as follows depending upon the foam application:

I. transfer process.

II. spray coating: direct, single stage chemical foaming (ICI process).

III. knife-coating process: Mechanical foaming; reaction to the formation of polymer after a delay, coating substance is applied directly to the back of the carpet with a doctor blade (process according to BP Union-Carbide); in the Dow process foam generation is by the mechanical impact of air/gases.

The advantages of the polyurethane carpet backing compared to natural latex foaming are many: Smooth cut edges, high elasticity and better recovery power, high temperature and ageing resistance, high wheelchair and knops resistance, good sound-absorbency, good wet fastness and dimensional stability, as is also shown by the table comparing physical properties (polyurethane foam and non-gelled latex foam). The flame resistance is judged to be better than that of polyacrylo-butadiene and styrene-butadiene coating. The formation of hydrocyanic acid during burning should not represent a danger.

	polyurethane	latex
backing weight		
pre-coating	-	~ 800 g/cm^2
foam	~ 1250 g/m^2	~ 600-1000 g/m^2

pile fastening strength (loop on tape fabric)	~ 5 kg	~ 4 kg

Tab.: Comparison of the properties of polyurethane and latex (1 kp/cm^2 = 9.81 N/cm$^{2)}$.

Polyurethane coating Coating with solvent-free systems, e.g. laminating with foils or coating with aqueous dispersions or foams (see Fig.). An important criterion of polyurethane coating is its resistance to ageing. Under the influence of UV rays discoloration and decomposition of the coating takes place. The addition of light stabilisers greatly delays light damage.

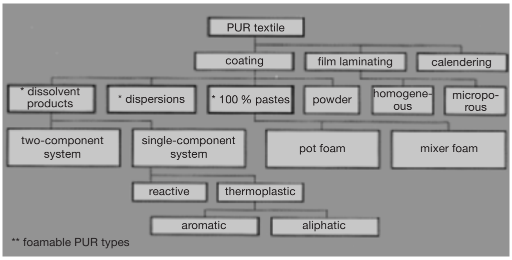

Fig.: The possible applications of polyurethane to textiles. The foamable types of polyurethane are bordered with heavier lines. PUR = polyurethane.

Polyurethane elastomer fibres According to DIN DIN 60 001, elastomer fibres made of high polymers, which consist primarily of segmented → Polyurethanes. The elastomer behaviour owes its elastic stretchability to amorphous soft segments (60–80% by weight), and to crystalline hard segments (40–20% by weight) for chain coherency (elastane fibres). Polyurethane elastomer fibres have rubber-like high elasticity. Compared to → Rubber fibres, finer, lighter, more stretchable, more tear resistant, retain elastic strength longer, are smoother, good dyeing properties, resistant to sweat, chemicals, oils, oxidation resistant, light resistant, resistant against “rubber poisons” and chlorinated hydrocarbons. Further properties: handle sticky-fishy, approximately white in colour, density 1–1.2, tear resistance dry/wet 5–8 cN/tex, elongation at break 500–700%, moisture absorbency 0.3–1%, melting point approx. 230–250°C, softening point 170–180°C (also higher), sometimes more heat sensitive, relatively good resistance against cold diluted acids and alkalis (at higher temperature, tendency to discolour and decompose; H_2SO_4, pH 2, boiling/90 min good compatibility), sensitive to chlorine bleaches and exhaust gas. Dyeable even in pastel shades using most dyes, specifically acid, metal-complex, disperse dyes. Soluble in boiling dimethylformamide and boiling cyclohexanon. Application: usually spun into → Core-spun yarns for foundation garments, hosiery, sports clothing, stretch fabrics of various types.

Elastane polyurethane fibres are manufactured in a two-stage process (Figs. 1–2). First the prepolymer is

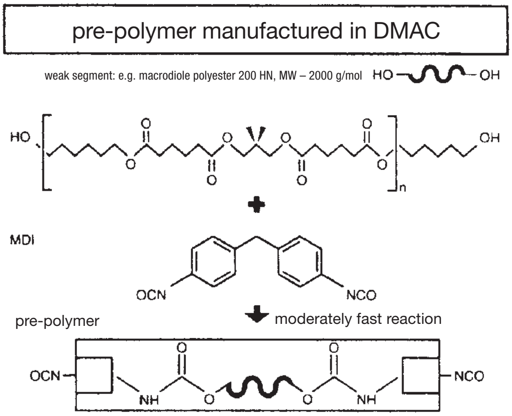

Fig. 1: The manufacture of an elastomer spinning solution; 1st stage.

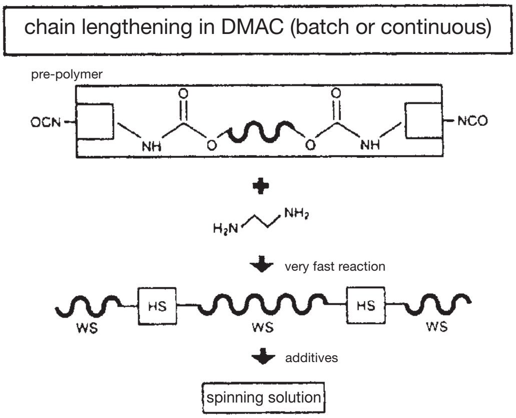

Fig. 2: Chain lengthening.
WS = weak segment; HS = hard segment.

produced. The moderately fast reaction occurs both in solution and solvent-free in selected conditions. The NCO terminated prepolymers are now “chain-extended” in a separate stage, i.e. they are built up by addition polymerization with diamines to form polyurethane ureas or with short chain diols, e.g. butandiol 1.4 to form high molecular polyurethane. Whereas the diol extension, as a reaction, can also be carried out in the melt (in principle thermoplastic polyurethane is also manufactured), diamin addition to polyurethane urea must be carried out as an extremely rapid reaction in a suitable solvent (usually dimethylacetamide). This synthesis step is particularly important for the quality of the elastane yarn and requires (carried out as batch or continuous process) a clean fine-tuning, in particular regarding the chain controller that is also used for the limitation of the molecular mass. After the addition of the necessary or desired additives, which must fulfil a specific task either in processing or in the finished part, we now have the finished spinning solution. This can in principle now be spun into elastane filament yarns in the wet or dry spinning process.

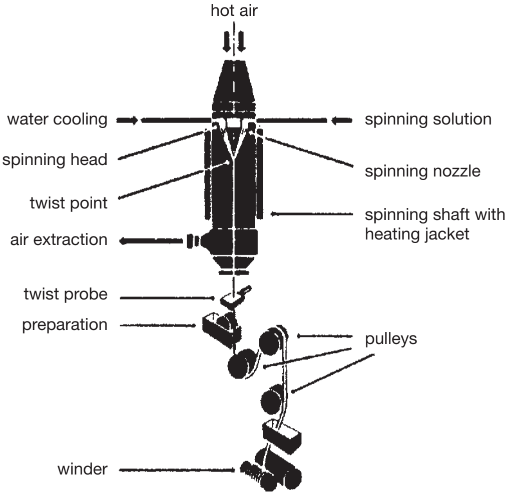

Fig. 3: Dry spinning process.

World-wide, the dry spinning process shown in Fig. 3 has largely gained acceptance. In the dry spinning process the heated, highly viscose spinning solution is fed to the heated spinning shaft and pressed through multi-hole nozzles, whereby the solvent is quickly vaporized by hot spinning air. The spinning conditions (in particular the discharge velocity, spinning temperature and twist) have, depending upon the type of elastane and the concentration of the spinning solutions, a significant influence, above all, on the mechanical properties of the filament yarn. The finished filaments are bundled to form a yarn in the spinning shaft, depending upon the desired titre, and stuck together to form a quasi-monofilament thread by a twisting device, prepared and wound onto packages.

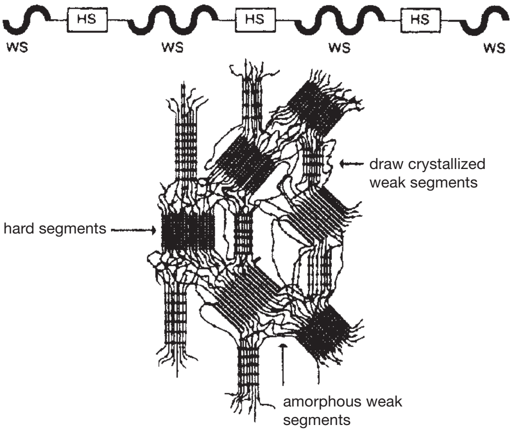

Fig. 4: Model of domains in segmented polyurethane (according to Bonart and Rinke).

We can see from Fig. 4 that the substances manufactured according to the di-isocyanate addition polymerization process are block copolymers, in which long, soft, mobile segments alternate with relatively short, hard segments in a continuous sequence. In finished threads, the soft segments form a cohesive, fluid matrix, in which the crystalline hard segments, which are associated with hard domains, are incorporated and thus physically cross-link the entire system. The principal structure of the elastanes follows the classical theory of rubber elasticity. Long chain molecules with freely mobile segments, with only weak interaction between them (as in a liquid), are cross-linked at defined points to form a three-dimensional network. Whereas rubber is known to be a chemically cross-linked polydiene, in which, in addition to the -diene component, the cross-linking density is determined primarily by wear properties. In elastane cross-linking takes place via crystallized hard segments in the hard segment domains. The shorter hard segments, in a regular, crystalline arrangement, cross-link the soft segment matrix, which in the extended state can be part crystalline, like rubber. Unlike rubber, the cross-linking points have spatial expansion and thus have the effect of a filling material. This is important for the strength of the elastane. In contrast to the chemical cross-linking in rubber, the physical cross-linking has a certain mobility. Thus thermal deformation is possible, and tension peaks can be smoothed out to a certain degree. The matrix of soft segments is present in the form of a melt at normal temperature, whereas the hard segments are glass hard or part-crystalline. Fig. 5 summarizes possible soft segments and shows their principle suitability for elastanes as building blocks.

type (molecular weight 1000-3000)		principle suitability
● polyeser made from		
– butane diole		−
– hexane diole	plus adipic acid	±
– butane diole/hexane diole		+
– hexane diole/NPG		++
– E-caprolacton		±
– butane diole/E-caprolacton/adipic acid		+
● polyether		
– EO, PO, EO/PO		−
– poly-tetrahydrofurfuryl		++

Fig. 5: Polymer dioles as weak segments.

Of the almost indefinitely large selection of polymers only those whose glass transition temperature lies below room temperature are suitable, in particular copolyester made of hexandiol and neopentylglycol with adipic acid. Polyethers based on ethylene oxide and/or propylene oxide are less suitable due to inadequate constancy of functionality and their susceptibility to hydrolysis in elastanes. Polytetrahydrofuranes have established themselves as the dominant soft segments world-wide. Below the congealing temperature of the soft segments, i.e. below the glass transition temperature or, in crystallizing soft segments, below the melting temperature, the rubber-elastic elongation disappears, leaving the elastane threads hard and brittle (according to Haug, Spilgies and Meyer).

Polyurethane fibres Synthetic fibres with the repeating urethane group –NH–COO–. They are spun as fibres, threads, monofilaments and bristles, predominantly as solution in a precipitation bath or according to the dry spinning process. Of the many manufacturing possibilities, addition polymers of di-isocyanate and glycols (formula → Polyurethanes) are of particular interest, which, spun directly from the melt and cold drawn (approx. 400%) are harder and stiffer than, e.g. polyamide 6.6. Cross-section round. Physiologically faultless. Properties: density 1.19–1.32 (oriented), moisture content 1–1.5%, strength 28–37 cN/tex (approx. 90% moisture) and elongation dry/wet 18–24%, softening point 170°C, melting point 183–184°C, slow decomposition above 220°C, chemical resistance, good against acids (conc. mineral acids dissolve, not conc. HCl), relatively good against alkalis, similar to polyamide against organic solvents (soluble in phenols, cresols), dyeable with disperse, selected acid (< pH 2), direct, vat dyes; increased affinity after steaming at 2–2.5 bar; polyurethane fibre fabrics are easy to stabilise by shrinkage process in hot water at 90°C. Application: synthetic horse hair, bristles, brushes, sieve fabric.

Polyurethane fine coating Mainly polyurethane, in the form of solutions or aqueous dispersions, is used for coatings. Polyurethane solutions are divided into two groups, which can each be further subdivided (see Fig.).

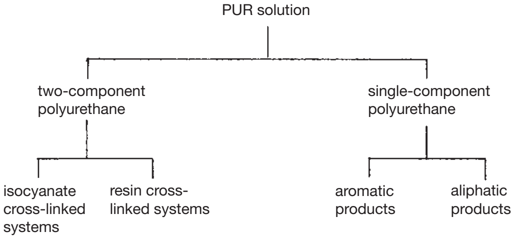

Fig.: Subdivision of fine coatings using polyurethane (PUR).

Two-component polyurethanes are systems of a solution of high molecular reactive polyester in a suitable solvent (ester, ketone), which has not yet been cross-linked, and a cross-linker, which is initially separated, and generally a reaction accelerator. It should be noted that the reactivity of the mixture means it has a limited useful life. After the volatilizing of the solvent, the formation of urethane or a final cross-linking of the polyurethane takes place in the drying channel. Because these films consist of cross-linked macromolecules, an increased level of fastness is achieved. Polyurethanes are resistant against solvents, but are no longer thermoplastic.

In the isocyanate cross-linkable systems (usually trifunctional isocyanate), the cross-linking, which occurs at a relatively low temperature, takes place at room temperature over a period of four to six days. The resin cross-linkable systems require a higher temperature, which guarantees a complete cross-linking in the vapour phase. Single component polyurethanes are fully reacted linear polyurethanes, which require no additional cross-linking. According to their molecular structure they are thermoplastic and are characterized by their resistance to benzine, mineral oils, greases and tetrachoroethylene. Depending upon the selected isocyanate, the cheaper aromatic single component polyurethanes are obtained, which are only soluble in strong polar solvents, or the aliphatic products, which are soluble in weaker polar solvents and have excellent light fastness.

Dispersions can be created by the inclusion of hydrophilic groups in the polyurethane molecule or the use of external emulsifiers, whereby, however, the self-dispersability of the molecule generates a stable product. The use of dispersions is generally environmentally friendly if only water is vaporized, so less safety precautions are necessary. The extraordinarily high fastness created result from strong physical bonds between the macromolecules. Most polyurethane dispersions are aliphatic and therefore possess high light fastness. A further advantage is the high solids content at low viscosity, the thermoplastic behaviour and the relatively good miscibility with other plastics. The dispersants, emulsifiers, and thickener remaining in the plastic film can have a detrimental effect upon water susceptibility. The high energy consumption and frost sensitivity of most products, which result in limited stability during storage, should also be mentioned. Undesired high swelling or redispersing during film formation can be avoided by careful structuring of the product.

Polyurethane preparation plants Plants are used in → Polyurethane carpet backing for storage, conveying, dosing, mixing and intermediate storage of the individual components of the mixture and the finished compound. The so-called chemical stations are completely piped up and programme controlled. In the spread coating process the plant consists of silos and tanks for calcium carbonate, aluminium hydroxide as an infill material, (because of its flame retardent property), polyol, isocyanate and additive for dosing in the weighing and mixing containers in accordance with the recipe.

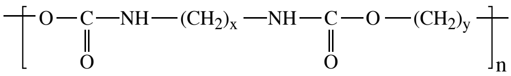
I. For procedures according to BP Union Carbide, compound (calcium carbonate, polyol, additive) and isocyanate are circulated by pump to separate process plant and containers, from there fed to the foam mixer and transported to the application. Weighing, mixing and mechanical equipment (which is water cooled). Polyol, isocyanate and compound are stored in dry air.

II. For processes according to Dow Chemical, the compound is stored in intermediate containers; isocyanate, polyol and compound containers have a protective gas atmosphere. Compound and isocyanate are pumped into separate machine pre-containers and the controlled pumping station conveys them, along with the catalyst, to the foam mixer and then to the application.

III. For procedures according to ICI (spray coating): chemical station of calcium carbonate silos and tanks for polyol, isocyanate, for surface reagents and catalyst. Program controlled chemical feed and dosing to the mixing head. In parallel to the chemical pipes there is a cleaning pipe for solvent to the spraying heads, where the spray application takes place.

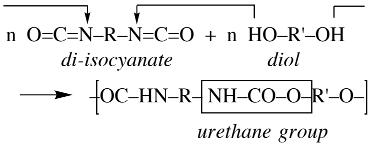
Polyurethane rubber (urethane rubber), synthetic rubber based upon → Polyurethane elastomer fibres.

Polyurethanes (polyester amides), addition polymerization products of high polymer → Urethanes:



$$\left[-O-\underset{\underset{O}{\|}}{C}-NH-(CH_2)_x-NH-\underset{\underset{O}{\|}}{C}-O-(CH_2)_y- \right]_n$$

The fundamental principles of polyurethane chemistry, which have been used to produce polyurethane (PUR) since 1940, were developed by O. Bayer and his colleagues in Leverkusen in 1937. Polyurethane is created by addition polymerization, i.e. the linking of different types of monomers, of multivalent isocyanates with multivalent alcohols. The H atom of the alcohol group migrates to the N atom of the isocyanate, at the same time splitting the N = C covalent bond. This principle is illustrated based upon the example of the addition polymerization of di-isocyanate and a diol to form a linear polyurethane.



$$n\ \underset{\textit{di-isocyanate}}{O{=}C{=}N{-}R{-}N{=}C{=}O} + n\ \underset{\textit{diol}}{HO{-}R'{-}OH} \longrightarrow \left[OC{-}HN{-}R{-}\underset{\textit{urethane group}}{\boxed{NH{-}CO{-}O}}{-}R'{-}O{-} \right]$$

However, medium to high molecular polyester or polyethylene with terminal OH groups are generally used rather than low molecular diols. Polyurethanes are actually polyester or polyethylene with an intermediate polyurethane group.

Polyols are the reactants of the second main component of polyurethane, and isocyanates, and this reactant is attached to any type of “active” hydrogen. Linear high molecular addition polymers are created with numerous polar urethane groupings. These thermoplastic polyurethanes are only soluble in strongly polar solvents. The use of multivalent starting materials permits the generation of three-dimensionally cross-linked addition polymers, which allows polyurethane to be manufactured in the form of thermoplastics, elastomers and duroplastics as required. The combination of different diol and isocyanate components, their quantity ratios and synthesis methods permit many variations in the properties of the material. The application spectrum is further extended by the individual customization of additives to suit the intended application. Important additives are: accelerators, reaction inhibitors, cross-linkers and/or chain extenders, surface active additives, foam stabilisers (ageing protection agent). The broad application spectrum shows that there is no uniform set of properties, therefore polyurethanes are subdivided into product classes.

The chemical structure and molecular size of polyol significantly influences the properties of the polyurethanes manufactured from them. The polyol is responsible for

- resistance to cold or heat,
- hydrolysis stability,
- swelling behaviour in solvents.

Polyester and polyethylene polyols fulfil the demand for technically and commercially useable materials. The molecular weight of polyols lies between 400 and 6000. Polyester for the manufacture of polyurethane achieves a molecular weight of 2000 and contains a typical ester grouping,

e.g. polyester alcohol (n = 2–20):

$$HO–R–[O–CO–R–CO–O–R]_n–OH$$

Polyethylene polyols have a molecular weight of 300–8000 and include the typical ethylene grouping, e.g. polyethylene alcohol (n = 5–80):

$$HO–[CH_2–CH_2–O]_n–CH_2OH$$

Because of this subdivision, two polyurethane groups are created with characteristic properties, which are listed in the Tab.

	polyesterurethane	polyetherurethane
mechanical properties	+ e.g. wear resistance, good firmness, high degree of softness without stretching	- high degree of elasticity, good low temperature flexibility
resistance to hydrolysis and to weathering	-	+ however, sensitive in comparison with polyesterurethane to light and to oxygen
colour stability	–	+
resistance to solvents	+	– e.g. shows strong swelling in solvents
resistance to oil	+	-

Tab.: Comparison of polyesterurethane with polyetherurethane.

Isocyanates are low molecular substances, which are produced in pure form. This occurs for example by the conversion between amines and phosgene:

$$COCl_2 + H_2N(CH_2)_6NH_2 + Cl_2CO \rightarrow OCN(CH_2)_6NCO + 4\ HCl$$

These highly reactive compounds require careful handling, because they also react with the cellular protein of human tissue. The isocyanates determine the hardness, strength, thermoplasticity and light fastness. The selection of isocyanates to be used permits a further subdivision into a) aromatic and b) aliphatic polyurethanes. The aliphatic polyurethanes are characterized particularly by their light fastness, but also by their higher price.

The physical structure in the macromolecular composition makes a significant contribution to the differentiation of the mechanical properties. The construction has a segmentation, in which the diverse urethane segmented groups, as hard segments, alternate with the relatively long-chained polyester or polyethylene chains, the soft segments, which have the cubic, elastic structures (see Fig.).

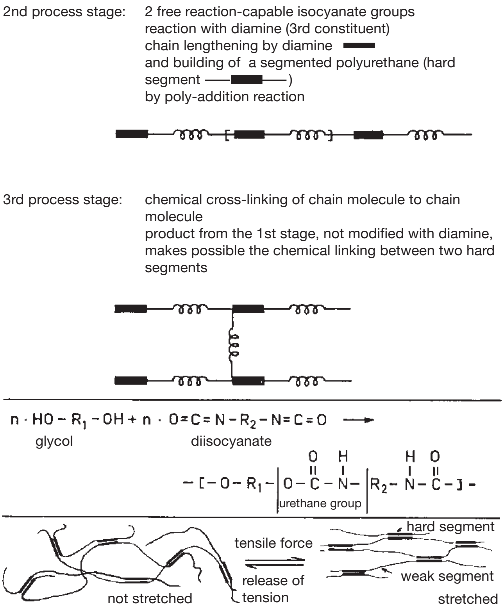


Fig.: The segmentation of polyurethane molecules.

Hydrogen bridges form in the hard segments, which are broken by mechanical loading and can then be immediately reformed. Thus any forces occurring are uniformly distributed and lead to excellent values of elongation at break, resistance to tear propagation, breaking strength and permanent deformation. The proportion of hard or soft segments is determined by the combination of starting products. Polyurethanes with a linear structure represent the normal commercial thermoplastic polyurethane fibres, whilst three dimensionally cross-linked polyurethanes are used for finishing purposes and are prepared directly onto the material from organic solvents.

Properties (adjustable within certain bounds): excellent adhesive properties (even on smooth synthetic fibres and glass fabrics); hard to elastically soft (even without the addition of a softener): high abrasion resistance and bending strength, resistant to ageing (but yellows in light); cold and heat stability between approx. – 60 to +170°C; highly water resistant (even at higher temperatures); resistant to chemical cleaning and oil/grease; good adhesion; good pigment binding (own weight on pigments, bronzes, etc.). Application: finishes, coatings, adhesives for laminates and flocking, adhesives, lacquer, material, foam plastic, fibre material.

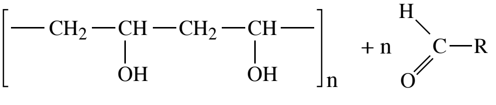
Aqueous polyurethanes for ionic coagulation: for the creation of fibrous porous surface effects by the aqueous ionic dispersion of a polyurethane with covalently bonded, solubilizing ionized groups, whereby the polyurethane coagulates in the length of material. Such dispersions consist of fully reacted polyurethanes, which have no free N=C=O groups, but have ionic groups in covalent bonds with the polymer. These groups have the advantage of making the product self-dispersing, i.e. the dispersion consists only of the polymer (up to 30–40%) and water; this is in contrast to other aqueous polyurethane dispersions, which require further solvents or dispersants. The stable dispersion can be immediately destabilized by the removal of the ionic group or its conversion into non-ionic forms; sudden coagulation occurs: textile impregnation with the aqueous dispersion followed by coagulation due to the effect of 2% acetic acid, then washing out and drying. The process is performed on normal textile finishing machines (no polyurethane migration during drying; no air pollution, no problems with machine soiling/cleaning). In contrast to comparable closed film coating obtained by the dry process a poromeric, water vapour permeable structure is obtained.

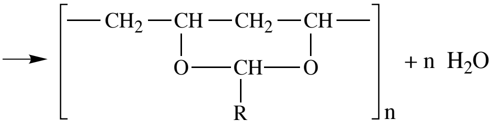
Polyvalent Active in many different ways, with several functions.

Polyvinyl Generic term according to DIN 60 001 for fibres made of high polymers, created by straight chain polymerization of vinyl compounds.

Polyvinyl acetal fibres Fibres of → Polyvinyl acetals; → Vinylal fibres.

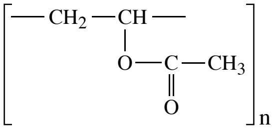
Polyvinyl acetals are created by the conversion of → Polyvinyl alcohol, polyvinylacetate or copolymers of other vinyl esters with aldehydes according to the following principle:





Due to the possibility of partial acetylation, polyvinyl acetals can be produced with a defined content of acetate, ester and hydroxyl groups, whereby variation products with different solubility and differentiated properties can be produced. In general, thermoplastics prove to be brittle to tough-elastic with high softening point and excellent breaking and tensile strengths. Application: for difficult adhesions (metal to metal, etc.), synthetic leather production, rubber substitute, raincoats, lacquer raw material, coatings (with softener), laminating, etc.

Polyvinyl acetate Thermoplastic synthetic polymer of vinyl acetate (produced from acetylene and acetic acid). Also as copolymer.

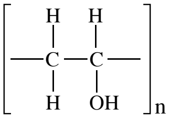


Chunks, pearls, powder, organic solvents, for textile purposes usually aqueous dispersions; solutions and dispersions of different viscosity (thick flowing dispersions; dilute slowly whilst stirring, otherwise clumps will form). The dispersions are frost sensitive. The applied films are clear, colourless, stiff, non-slip, elastic, somewhat hard (high polymers), and softer. As softener: phthalic acid ester (if too much: stickiness). Softening point 30–100 °C (depending upon degree of polymerization); insoluble in water (but swellable), soluble in ketones, esters, chlorinated hydrocarbons. Application: particularly for finishes (weighting stiffening effects, hat stiffeners, ladderproof finishes, cheap coatings (synthetic leather, nitrate cellulose line end), laminating, pigment print pastes (production shortly before processing due to rapid hardening), lacquer raw material, adhesive, seam free floor covering.

Polyvinyl acetate fibres Vinyl acetate is represented in copolymers with polyvinyl chloride and polyacrylonitrile fibres as a modification component. Polyvinylacetate fibres can be dissolved.

Polyvinyl acetate sizes → Polyvinyl acetate, as waterproof sizes for polyester chains for use on water jet weaving machines. Properties: good water solubility and adhesiveness. Variable properties with regard to degree of polymerization and saponification, whereby the solubility decreases with increasing hydrolysis. Fully saponified polyvinyl alcohol swells only in cold water, only goes into solution above 75°C. Polyvinylacetate dispersions containing carboxyl can be brought into solution by neutralization with ammonia.

Polyvinyl alcohol (PVA, PVOH). Synthetic polymer, produced by the saponification of → Polyvinyl acetate.



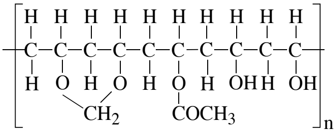
$$\left[\begin{array}{ccccc} & H & & H & \\ & | & & | & \\ - & C & - & C & - \\ & | & & | & \\ & H & & OH & \end{array}\right]_n$$

White, amorphous substance, granular, powder, solutions (jellies), emulsions. Slightly soluble in water (quick dissolving powder: Wetting with methanol, elutriation in water whilst stirring). The solutions are to some degree viscous, depending upon the degree of polymerization (addition of methanol, boric acid, sodium tetraborate, etc. also increases viscosity until gelling and precipitation). Polyvinylalcohol emulsions can be non-ionogenic, anionic or cationic. The applied (water soluble) films are clear, solid and stretchable (both increasing with increasing degree of polymerization). Glycerol, ethylene glycol, and polyethylene glycols act as softeners. The water solubility of polyvinylalcohol dispersions, etc. is significantly decreased by heat treatment above 120°C. Application: particularly for sizes (also polyvinyl alcohol copolymers), finishes (dry-cleaning resistant), printing thickeners, as emulsion protective colloid and stabilizer), for screen printing screens (sizing agent) adhesive, washing additive, foils; → Polyvinyl alcohol fibres.

Polyvinyl alcohol, dye ranges Selected individual dyes of different dye groups:

- direct dyes and
- 1 : 2 metal-complex dyes for light to medium subdued shades;
- vat and vat leuco ester dyes for light and wash fast dyes;
- disperse and
- acid dyes are only used in exceptional cases.

Polyvinyl alcohol fibres



Synthetic polymer fibres of min. 85% vinyl alcohol. Usually produced by wet spinning from → Polyvinyl alcohol (always with certain proportion of non-saponified polyvinylacetate) and subsequent hardening, usually with formaldehyde. Polyvinyl alcohol fibres are similar to cellulose fibres due to their OH group structure, whereby variations are usually gradual (polyvinyl alcohol fibres have less OH groups). Special polyvinyl alcohol fibres also contain e.g. acetyl sulphide (this makes them more heat stable), chloroacetaldehyde (water and chemical resistant), higher aliphatic aldehydes (more elastic), chloracetaldehyde and amines (more elastic, water resistant and good acid dye affinity). The cross-sectional is bean-shaped.

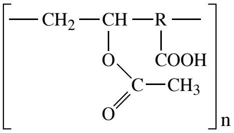
Properties: density 1.26–1.30; normal moisture absorbency 4.5–5.5%; softening temperature wet 110°C, dry 220–210°C (iron with care, similar to polyamide 6 and acetate fibres); melting point 210–238°C; swelling water absorbency at 20°C approx. 30%; shrinkage in boiling water 2–3% (fixing at 90–98°C); greater shrinkage above 110°C (steam); strength 22–36 cN/tex (65–85% moisture); elongation 16–30% (20–40% moisture) abrasion resistance dry and bending strength very high, but low crease resistance (crease-resist finishing normally impossible). According to Japanese experience significantly higher abrasion resistance and durability in fabrics than wool, 3–5 times longer lifetime than cotton hosiery, longer than wool hosiery; tearing strength of ropes 30–50% higher than that of manila hemp ropes. Electrostatic charge low; resistant to fungi, bacteria, insects; good boiling stability, but not particularly resistant to hot water (at 100°C relative fastness 70%); good resistance against acids (better than polyamide 6.6), good resistance against alkalis, salts and organic solvents (at above 60°C swelling and dissolving in formic acid, phenol, cresol).

Dyeability: normally only light and medium shades can be produced (deep shades and black are difficult); selected disperse dyes (colour depth similar to acetate fibres) are suitable, possibly acid and direct dyes (+ magnesium chloride also deep shades) and light fast and wash fast metal-complex dyes, vat and leuco vat dyes. Significance: relatively low, great efforts particularly in Japan (one of the cheapest synthetic fibres, cheaper than Japanese polyamide 6.6, more expensive than cotton), also attempts in England, USA and Germany (surgical sewing threads). Application: for industrial purposes (filter screens), sail cloth, fishing nets. Mixtures for underwear, socks, work clothing, cheap outer clothing, lining material, covers, curtains, carpets. Unhardened polyvinyl alcohol fibres (= water soluble) as substitute for alginate fibres for burn out lace (embroidery background), (soluble) washing bag cords, etc.

Polyvinyl alcohol sizes → Sizing selection criteria.

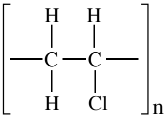
Polyvinyl benzene → Polystyrene.

Polyvinyl carboxylic acid Thermoplastic synthetic polymer in powder and solution for sizes and finishes.



Polyvinyl chloride

Polyvinyl chloride (PVC). Thermoplastic synthetic polymer of vinylchloride, produced e.g. by attaching hydrogen chloride to acetylene.



$$\left[-\overset{\displaystyle H}{\underset{\displaystyle H}{C}}-\overset{\displaystyle H}{\underset{\displaystyle Cl}{C}}- \right]_n$$

Polyvinyl chloride, which is an important coating polymer, is produced as follows: caustic soda liquor and chlorine are produced from sodium chloride (NaCl) in chlor-alkali electrolysis by the consumption of energy. Sales of these two different chemicals vary greatly depending upon the current market situation. Since 1936, excess quantities of chlorine have been combined with ethylene from natural gas, or petroleum, or acetylene from coal, to form the intermediate product, gaseous vinyl chloride (VC). Because of the ability of the VC molecule to bind itself into long, chain-shaped macromolecules in a polymerization reaction, the powder polyvinyl chloride (PVC) is created. By means of various technical conversion processes the polyvinyl chloride base material is manufactured by the plastics industry, which is a part of the chemical industry. The subsequent mixing is performed either by the polyvinyl chloride manufacturer or the polyvinyl chloride processor. The semi-finished and finished products are then produced by the plastic processing industry. The addition of specific, different additives greatly alters the properties of the polyvinyl chloride. These additives influence the durability and resistance to a number of different stresses in specific fields of application and the lifetime of the polyvinyl chloride plastic product. Of the 7.8 million tonnes of plastic produced in the Federal Republic of Germany in 1986, approx. 1.3 million t were polyvinyl chloride. Polyvinyl chloride, which makes up approx. 15% of total plastic production is subsequently processed into soft polyvinyl chloride (32%) and hard polyvinyl chloride (68%) (Fig. 1). The polyvinyl chloride products produced from this break down as follows: Over 55% in the construction sector, 2% in the electrical sector, 4% in the vehicle manufacturing sector, 16% in packaging and 23% in other fields such as medicine, agriculture, environmental protection and the grocery industry.

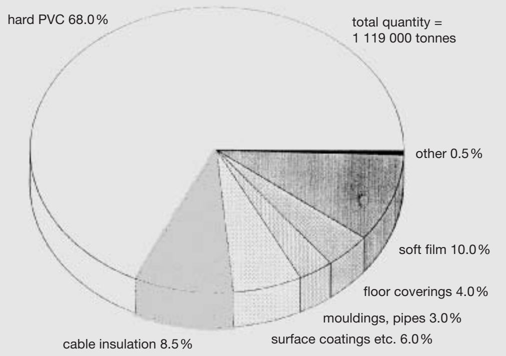


Fig. 1: Uses of polyvilnyl chloride (PVC) in the FRG.

The basic materials of polyvinyl chloride are hydrogen (H), carbon (C) and chlorine (Cl). The chlorine content of 57% in polyvinyl chloride decreases in polyvinyl chloride products due to additives such as stabilizers and possibly pigments, extenders and softeners. In hard polyvinyl chloride products it is between 52–57% and in soft polyvinyl chloride products it is, on average, 40%. The stabilizers used (critical for processability, lifetime and ageing resistance of the polyvinyl chloride products) are calcium, zinc, magnesium, barium and cadmium soaps; tin acetyl compounds, basic lead compounds, calcium zinc, epoxidized soya bean oil, pentaerythritol ester and sorbitol. Cadmium soap, which is now only used as a stabilizer in long life hard polyvinyl chloride products such as window frames and roller shutters (Fig. 2), must be classified as a particularly critical product. Cadmium is a very problematic heavy metal in water, both in the air and in the ground. Because the polyvinyl chloride industry is aware of these environmental problems associated with cadmium, attempts are underway to largely replace cadmium with stabilizers consisting of organic metal compounds of tin, lead, calcium/zinc and barium/zinc.

The pigments used such as titanium oxide (white), carbon black (black), cobalt (blue), iron oxide (yellow/

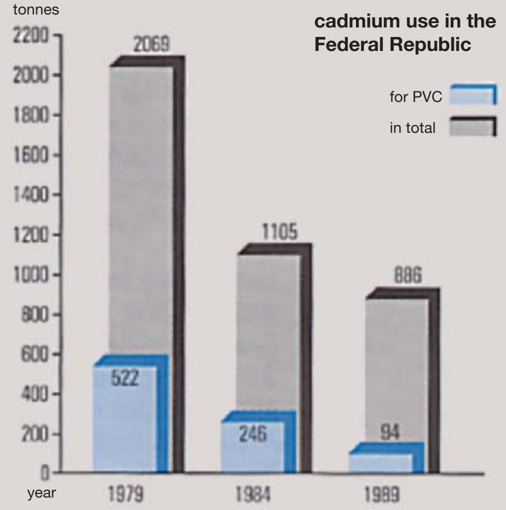

Fig. 2: Use of cadmium, a stabilizer for polyvinyl chloride, in the FRG.

black/brown/red) and other organic products do not give rise to problems in the treatment and disposal of used polyvinyl chloride. The lubricants added in the form of soaps and waxes such as metal soaps, montan and paraffin wax, waxy polyethylene types, fatty alcohols and esters, silicon and glycerol esters are not problematic. Softeners increase flexibility at different temperatures and consist, amongst other things, of phthalate types, phosphate types, epoxidized fatty acid esters, alkyl sulphonate acid ester, adipic acid ester, azelaic acid ester and sebacic acid ester, trimellitic acid ester. Di-(2-ethylhexyl)phthalate DEHP (previous term DOP), used as a softener e.g. for floors or cable sheathing, is only harmful to health in extremely high concentrations. The possibility of a carconogenic effect on organisms can be ruled out within the range of normal concentrations in plastic. The softeners used in the production and use of polyvinyl chloride are naturally degradable by photochemical and microbial means. They therefore do not represent a burden on the environment (Fig. 3).

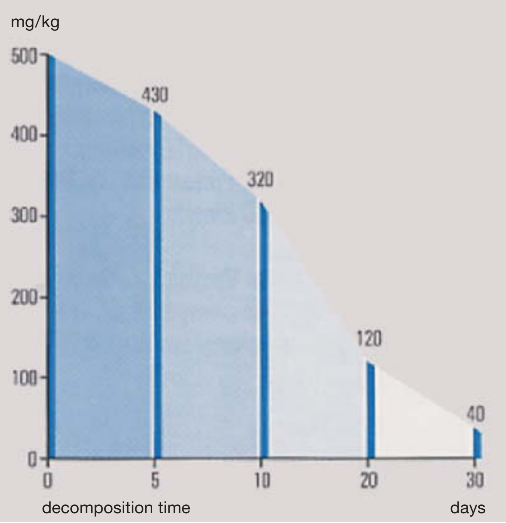

Fig. 3: The residual soil concentration of DEHP, a softener for polyvinyl chloride.

Flame retardants reduce ignitability, flame formation and burning. These are mainly aluminium-magnesium oxide hydrate, phosphoric acid derivatives and antimony trioxide. Antimony is classified as a class III heavy metal according to TI-air, highly volatile at high temperatures, but it can be non critically condensed in filter dust. Extenders improve the physical usage properties of polyvinyl chloride. The addition of extenders is mostly limited to soft polyvinyl chloride products, whereby extenders such as chalk, mica, talcum, limestone, marble, gypsum, quartz powder, kaolin and magnesium oxide do not lead to disposal hazards.

Commercial forms: white powder, aqueous dispersions, emulsions ("polyvinyl chloride pastes"), fillable and dyeable dispersions in plasticizer (without solvent). The normal commercial types of polyvinyl chloride may or may not contain sodium carbonate (heat stabilized against HCl splitting). Polyvinyl chloride is soluble in cyclohexanon, tetrahydrofuran. As plasticizer: e.g. dibutylphthalate (for coating pastes approx. 30–50% plasticizer; pastes with high K value + 20–30% plasticizer + 5–10% organic solvent such as benzine, for better coatability). The polyvinyl chloride films are translucent, rubber-like or leathery hard, softening above approx. 70°C, non-flammable, resistant. Film forming, e.g. after coating, by brief heating to 160–180°C. If embossing is desired this must take place after heat treatment whilst the polyvinyl chloride layer is still hot. Pure polyvinyl chloride is not stable, i.e. particularly under the intensive effects of heat and sunlight it tends towards hydrochloric acid splitting, which can have an autocatalytic accelerating effect, forming polyenes (metal corrosion, discoloration from yellow to black, brittleness).

It has been known since the 1970s that monomer vinyl chloride is toxic and has a carcinogenic effect. The question was soon posed, whether polyvinyl chloride depolymerizes to form vinyl chloride when welded, thus posing a hazard in the workplace. Thermal decomposition was therefore thoroughly investigated. Even at temperatures of 100–120°C polyvinyl chloride shows clear decomposition effects. If it is heated in air, at between 250–300°C it splits the majority of the chlorine in the form of hydrochloric acid. In addition, carbon dioxide, carbon monoxide and benzene are emitted as further main components.

Welding takes place within the temperature range of 180–230°C. No depolymerization occurs at this degree of thermal loading, however any residual monomers from production may be converted into the gaseous phase. Whereas prior to 1974 raw polyvinyl chloride contained residual monomer proportions of 1000–10 000 µg/g, now usually less than 10 µg/g is detected. In animal experiments pyrolysis gases of polyvinyl chloride containing a plasticizer have proved to be more toxic than products without a plasticizer.

As part of preventative health measures, toxicologically relevant substances, which can occur during the welding of polyvinyl chloride coated fabrics, have been detected within the breathing range of those carrying out the welding. In addition to vinyl chloride, hydrogen chloride and benzene, the associated plasticizer diethylhexylphthalate was also detected analytically. The measured pollutant concentrations were below the relevant TLV values for both hot air welding and heated wedge pressure welding. In heated wedge pressure welding, however, due to the pyrolysis of polyvinyl chloride residues on the hot metal wedge, at a temperature of approx. 400°C, significantly increased pollutant concentrations occurred. Although these were outside the direct breathing area, in unfavourable air conditions the TLV values could be temporarily exceeded. Therefore, heated wedge pressure welding plants should be ventilated in the pyrolysis area.

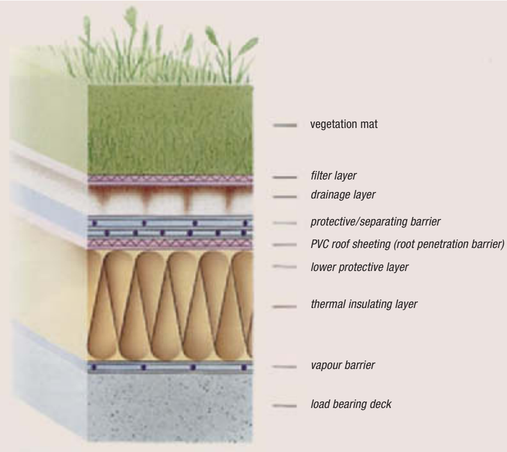

Fig. 4: The construction of a grassed roof sealed using polyvinyl chloride sheeting.

Polyvinyl chloride is one of the most versatile raw materials for the coating of textile and other carriers. Its most outstanding property is the pasteability of types manufactured according to the emulsion polymerization process. With the aid of plasticizers, e.g. dioctylphthalate, the polyvinyl chloride grain is converted into an easily spreadable plastisol, which can be gelled into an elastic film after application. Technical polyester fabrics coated with plastisols are used widely in the form of awning materials for various fields of application. Noteworthy examples are lorry tarpaulins and materials for air-inflated structures and also use in geotextiles (Fig. 4).

The breakthrough in the fashionable, leather-look field, owes its existence to both the foamability of polyvinyl chloride and the diverse thermoplastic shaping options, which are due to the wide softening range. The result is synthetic leather, which consists of a compact, e.g. leather-like formed covering film, a volume-providing, chemically inserted foaming layer and a textile carrier.

PVC can also be applied to textile bases in organic solvents, in the form of aqueous dispersions and in particular as thermoplastic masses. The properties of the so-called dry blend can be varied in widely by compounding. However, the group of polyvinyl chloride coated textiles still includes fields, upon which requirements with regard to physiological behaviour must be imposed. In general, this applies to cushion, shoe and clothing materials. Although there has been no shortage of attempts to make these coatings "breathable", it must be said that the sitting and wearing comfort of coated products is unsatisfactory. The same also applies to the various rubber types (according to Brocks, also Schefer et al.).

Polyvinyl chloride copolymer fibres Vinyl chloride copolymers, group of modified polyvinyl chloride types in the form of multipolymer fibres. Application: technical fabrics, protective clothing; also heat-pressure welded with other fibres, however usually mixed due to low strength and high expansion (cotton, wool, viscose staple).

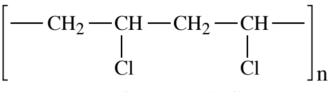
Polyvinyl chloride dyeings, identification tests,

I. Similarly to → Acrylic dyeings, identification of dye class, for the detection of disperse dyes the fibre sample is boiled with the following solvents one after the other: water (= no colouring or only a trace); alcohol (clear colouring); glacial acetic acid (strong colouring); concentrated ammonia (no colouring or trace); benzene test.

II. Disperse dyes under consideration are detected as follows: boil sample in test tube for 4–5 min with 5–8 ml of the following in succession: 1. Water; the solution is not coloured; 2. Denatured alcohol; the solution is slightly coloured. Or place the sample in a mixture of alcohol and acetic acid ester 1 : 1 for approx. 10 min at room temperature. Disperse dyes go completely or mainly into solution. The latter is now vaporized, absorbed in water and used to dye acetate fibres experimentally at 70–75°C with the addition of soap. If colouring takes place then disperse dyes are present.

Polyvinyl chloride fibre modification In addition to → Polyvinyl chloride copolymer fibres the varied tacticity in the polyvinylchloride macromolecule structure has found practical application, which has an effect on important fibre constants, as shown in the Tab.

Polyvinyl chloride fibres Group of synthetic polymer fibres (the first commercially available synthetic fibres) made of at least 85% → Polyvinyl chloride (if lesser proportion: → Polyvinyl chloride copolymer fibres), which can also be post-chlorinated, whereby two polyvinyl chloride fibre types can be differentiated:



$$\left[-CH_2-\underset{\displaystyle Cl}{\underset{|}{CH}}-CH_2-\underset{\displaystyle Cl}{\underset{|}{CH}}- \right]_n$$

PVC (55–57 % Cl)

	normal PVC	syndiotactic PVC

$$\left[-CH_2-\underset{\underset{Cl}{\vert}}{CH}-\underset{\underset{Cl}{\vert}}{CH}-\underset{\underset{Cl}{\vert}}{CH}- \right]_n$$

PVC+ (60–64 % Cl)

Manufacture according to dry or wet spinning process (drawn 3–8-fold). Properties (basic physical and chemical properties → Synthetic fibres), to the extent that they are approximately comparable: external fibre shape similar to cotton (preferably milky-cloudy, not delustred); difficult to burn, difficult to ignite; normal moisture content virtually zero, therefore does not absorb sweat; water immune (no swelling); same mechanical properties dry and wet; easy to wash, quick drying and highly crease resistant; heat retention capacity good; excellent electrical insulator; electrostatic charge has a specific anti-rheumatic effect; good light and weather resistance (exceeds that of polyester). Excellent resistance to micro-organisms and pests; physiologically harmless; heat sensitive, i.e. heat resistant < 60°C (not ironing fast); high shrinkage > 70 °C. Within certain limits thermofixable up to 100°C (hot water 30 min or dry steam 3–10 s, e.g. stenters). Chemical resistance: excellent against alkalis and oxidizing agents, excellent against acids, variable against organic solvents. Trichloroethylene brings about high shrinking, swelling and hardening. Dye affinity is normally not particularly good (→ Dyeing of polyvinylchloride fibres). The addition of a swelling agent is advisable. Application: mainly for technical purposes such as work clothing, filter cloths, screen fabrics, brushes and awning cloth, blankets, decorative material, cushion covers, quilt fillings; (in fibre mixes) for non-wovens, rheumatism underwear, underwear, knitgoods, pullovers, swimming costumes, filling material for cold weather clothing, shrunk for imitation suede (sports clothing, gloves), etc.

Polyvinyl chloride fibres in printing Polyvinyl chloride can be printed using cationic dyes precipitated with anionic auxiliaries. The high plasticity of the fibres, e.g. during fixing, and the often moderate light fastness should be borne in mind.

Polyvinyl chloride recycling For years, production residues from polyvinyl chloride have been collected and re-used. This type of recycling contributes towards optimizing production and reducing costs. From a technical point of view, the re-use of waste is no longer a problem, because polyvinyl chloride can be recycled with other plastics and also on its own. Therefore numerous projects have come into being, particularly in the field of construction, for returning used polyvinyl chloride products. New floors are made from old. The first European recycling plant for polyvinyl chloride floor coverings in Grossefehn in East Friesland commenced production as early as 1990. This plant produces a high-value powder from old floor coverings, which is used by floor covering manufacturers in the production of new floors. The recycled material can also be used in other fields of application. At the same time a pilot project, initially in three areas in Lower Saxony, North Rhine Westfalia and Rhineland-Palatinate, was initiated to collect used floor coverings. The working group Polyvinyl Chloride Floor Covering Recycling (AgPR – Arbeitsgemeinschaft Polyvinylchlorid-Bodenbelag Recycling), a union of 20 polyvinyl chloride raw material and floor covering manufacturers from Germany and other European countries, initiated and financed this large project (Fig. 1). In large consumers, such as public institutions or industrial companies, the person laying floor covering collects

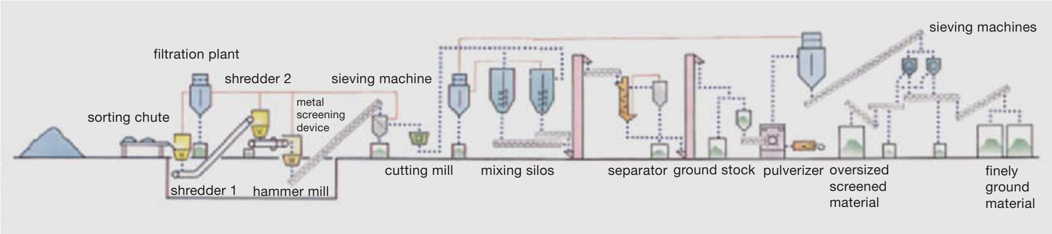

Fig. 1: The Großefehn facility for recycling PVC floor covering material. On delivery the disposed flooring is sorted and coarsely shredded before passing to the actual recycling process. The end result of the process is a finely ground PVC powder which can be used again in the manufacture of PVC floor coverings.

the old floor covering and delivers it to Grossefehn for processing. There are containers in large shops and DIY supermarkets for the free depositing of old material. The AgPR believes that in the medium-term it will be possible to collect approx. 30 000 t old floor coverings annually. This represents around one third of total production. The plant in Grossefehn is commercially viable, if only approx. 6000 t old material is delivered annually. Six to eight plants would be necessary for the reprocessing of all old floor coverings in Germany in the long term.

As there is only a small market for the material reprocessing of the proportion of polyvinyl chloride and polyvinyl chloride mix products contained in domestic waste and because polyvinyl chloride is a high-value fuel, the waste heat utilization of this product currently seems justified. If modern exhaust gas cleaning processes are used in accordance with the anticipated exhaust gas cleaning conditions there is no need to fear critical environmental pollution from the constituents of polyvinyl chloride, either in the form of chlorine or heavy metal emissions or in increased dioxin and furane emissions. Even now, reusable residual substances such as sodium chloride, calcium chloride and hydrochloric acid can be generated from the chlorine of the polyvinyl chloride, and these products are taken back by the chemical industry. Thermal utilization of the medium and long-life polyvinyl chloride products, possibly containing cadmium, which do not belong in domestic waste, should be ruled out due to the necessary purity of the wastes and the possible feed back into the material cycle. The use of pyrolysis, hydrolysis or hydration as thermal processes for these polyvinyl chloride products does not count as thermal waste reprocessing, but as a thermal “decomposition” process for the reprocessing of the polyvinyl chloride constituents. When waste is burnt, organic pollutants in waste gas are the only pollutants, which are partially recreated after thermal decomposition of the charging material. All other pollutants, heavy metals, salts, etc. come

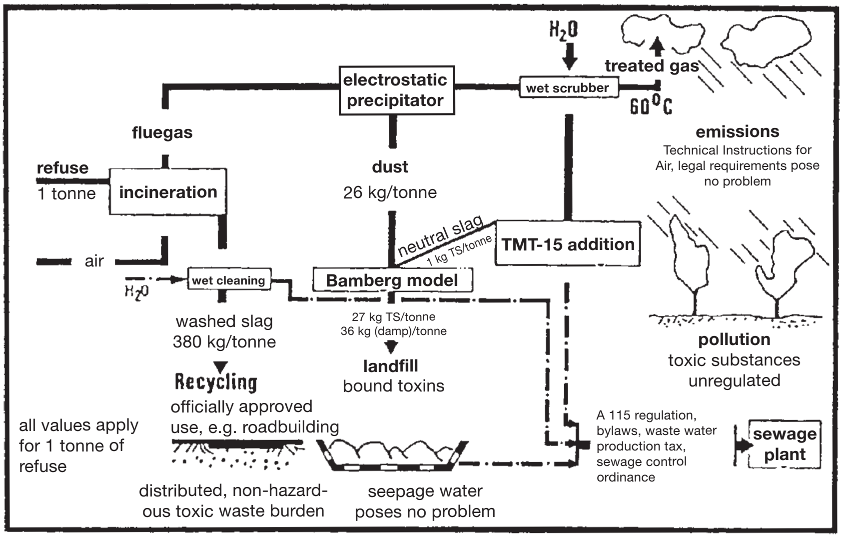

Fig. 2: Waste incineration process technology.

from the waste charging product itself. Many investigations have provided evidence showing that organic pollutants are released in almost all thermal processes. At temperatures > 800 °C if cold draught is avoided in the combustion area the creation of organic pollutants can generally be avoided. Prerequisites for the formation of dioxins and furanes are favourable temperatures of 300–400°C, the presence of chlorides, carbons, fly ash, oxygen and metal constituents with a catalytic action, and a sufficiently long reaction time. The chloride present in domestic waste, even without polyvinyl chloride, is in itself sufficient for the formation of dioxin. The above-mentioned conditions are normally in place during the flue gas cooling phase from the boiler until the first stage of gas cleaning. The creation of dioxins and furanes can be reduced, e.g. by improved cleaning of the boiler tubes, by constructional improvements in the boilers and by low flue gas temperatures after the boiler or before dust collection.

The use of inhibitors in the raw gas at a temperature of approx. 400°C or the use of activated carbon for adsorptive retention of emissions and organic pollutants, or an oxidation stage by ceramic catalysts may prove to be a trend for the extensive reduction of polychlorinated and polybrominated hydrocarbons, including dioxins and furanes. Using these methods it should be possible to maintain the extremely low emission limit required by the new 17th BImSchG (Bundes-Immissionsschutzgesetz – German Federal Immission Protection Law) for dioxin/furane of 0.1 ng TE/m^3. In waste combustion it is known that dioxins are not created with optimal combustion management and if possible complete burning at high temperatures is important in the combustion zone (Fig. 2).

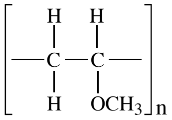
Polyvinyl cyanide → Polyacrylonitrile.

Polyvinyl derivatives Plastics or synthetic resins as polymerization products of vinyl derivatives, which have in common the vinyl group $CH_2=CH–$ (polyvinyl group: $–CH_2CH–$).

Important vinyl derivatives:

$CH_2=CH–CH=CH_2$	divinyl (butadiene)
$CH_2=CH–C\equiv CH$	vinyl acetylene
$CH_2=CH_2$	ethylene
$CH_2=CH–HCO$	acrolein
$CH_2=CH–Cl$	vinyl chloride
$CH_2=CH–F$	vinyl fluoride
$CH_2=CH–OH$	vinyl alcohol (unstable)
$CH_2=CH–OCOCH_3$	vinyl acetate
$CH_2=CH–OCH_3$	vinyl methyl ether
$CH_2=C(CH_3)_2$	isobutylene
$CH_2=CH–C_6H_5$	styrene (vinyl benzene)
$CH_2=CH–CN$	acrylonitrile (vinyl cyanide)
$CH_2=CHCOOH$	acrylic acid
$CH_2=CH–COOCH_3$	methacrylic acid ester
$CH_2=C–CH_3COOH$	methacrylic acid
$CH_2=C–CH_3COOCH_3$	methacrylic acid methyl ester
$CH_2=CCl_2$	vinylidene chloride
$CH_2=C(CN)_2$	vinylidene cyanide

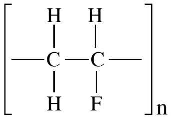
Polyvinyl ethers Synthetic polymer of → Vinyl ether. Particularly polyvinyl methyl ether.



$$\left[-\overset{\displaystyle H}{\underset{\displaystyle H}{\overset{|}{\underset{|}{C}}}}-\overset{\displaystyle H}{\underset{\displaystyle OCH_3}{\overset{|}{\underset{|}{C}}}}- \right]_n$$

Soluble in water and organic solvents. Resistant to saponification. Reversible coagulation point at 30°C in aqueous solution. Generates full soft handle. Application: sizing agent, finishing agent, printing thickeners (organically soluble); adhesive; lacquer raw material; softener for nitrate cellulose.

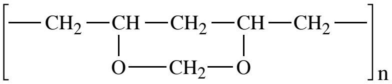
Polyvinyl fluoride Polymerized vinyl fluoride, produced from acetylene and hydrogen fluoride (polymerization at 810 bar).



$$\left[-\overset{\displaystyle H}{\underset{\displaystyle H}{\overset{|}{\underset{|}{C}}}}-\overset{\displaystyle H}{\underset{\displaystyle F}{\overset{|}{\underset{|}{C}}}}- \right]_n$$

Polyvinyl fluoride fibres are produced in the melt-spin process and drawn (100%). Properties: melting point 175–200°C; softening point 130°C; temperature resistance and shrinkage are superior to those of polyvinyl chloride fibres, as is their resistance to light and chemicals; insoluble in xylene; very difficult to dye (thus spin-dyeing). Dyed polyvinyl fluoride is used as a heat resistant fibre glass application.

Polyvinyl formal Conversion product of → Polyvinyl alcohol and formaldehyde (→ Polyvinyl acetals).

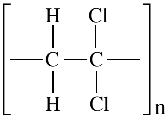


$$\left[\begin{array}{ccccc} -CH_2- & CH & -CH_2- & CH & -CH_2- \\ & | & & | & \\ & O & -CH_2- & O & \end{array}\right]_n$$

Softening point approx. 190°C; specifically soluble in chlorinated hydrocarbons (such as dichloromethane, chloroform), ketones, aromatic hydrocarbons (toluene, xylene), aromatic alcohols (such as benzylalcohol) and such mixtures. Application: lacquer raw material (plus softener, chlorinated aromatics), compatible only with nitrate cellulose and phenoplasts. Polyvinyl formal fibres of this type have not yet gained any importance in the textile field, in contrast to → Polyvinyl alcohol fibres, which are subsequently formalized under other conditions (only approx. 35–40% of the OH groups; thus not pure polyvinyl formal) and are thus completely insoluble and also resistant against most organic solvents.

Polyvinyl formal fibres → Polyvinyl alcohol fibres that are subsequently hardened with formaldehyde (degree of formalization approx. 35–45% of the OH groups) are also termed polyvinyl formal fibres.

Polyvinylidene chloride Synthetic polymer; of asymmetric dichloroethylene, produced by, e.g. chlorinated vinyl chloride and HCl splitting.



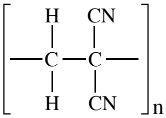
$$\left[-\overset{\mathrm{H}}{\underset{\mathrm{H}}{\mathrm{C}}}-\overset{\mathrm{Cl}}{\underset{\mathrm{Cl}}{\mathrm{C}}}-\right]_n$$

Application: emulsion for lacquer, adhesive, for coating; (acrylonitrile copolymer:) acid resistant pipe and container lining, also tank linings for benzine and petroleum products → Polyvinylidene chloride fibres.

Polyvinylidene chloride fibres Synthetic polymer fibres of min. 80% vinylidene chloride. When spun and drawn, such polyvinylidene chloride fibres mainly form horsehair-like monofilaments (for wear-resistant cushion and grille cloths, filter cloths, sieve fabrics, conveyor belts, ropes, bristles, decorative materials) and also for continuous filament yarn and smooth and curly fibres (for nonwovens, technical felts, upholstery and grille cloth, blankets, carpets, etc.). Cross-section round or oval. Properties (largely similar to polyvinyl chloride fibres, superior, e.g. against solvents, more recent polyvinylidene chloride fibres also in thermal behaviour): Density 1.65–1.75; normal moisture 0–0.1%; strength dry/wet 13–21 cN/tex; elongation, dry/wet 20–30%; difficult to burn, dirt repellent, resistant against mildew and bacteria, good resistance against cold acids (except H_2SO_4 conc.), alkalis (except concentrated) and most organic solvents including acetone (if they contain oxygen, e.g. dioxane, there is a swelling or softening effect); heat resistance differs depending upon origin: shrinks even at 60–75°C (softens at 90–135°C), sometimes boiling resistant, softens at 115–140°C, shrinking range starts at 145–155°C and melting point 150–175°C. Chlorine resistance poor; dyeable (usually jet dyeing) with disperse dyes. Detection → Morpholine test.

Polyvinylidene cyanide → Polyvinylidene dinitrile.

Polyvinylidene dinitrile (polyvinylidene cyanide, ethylidene dicyanide, 1.1 dicyanoethene), synthetic polymer of vinylidene cyanide. Used as copolymer (vinylidene cyanide/vinyl acetate 1 : 1) for the production of → Polyvinylidene dinitrile fibres.



$$\left[-\overset{\mathrm{H}}{\underset{\mathrm{H}}{\mathrm{C}}}-\overset{\mathrm{CN}}{\underset{\mathrm{CN}}{\mathrm{C}}}-\right]_n$$

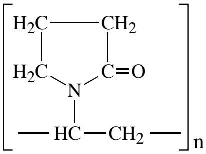
Polyvinylidene dinitrile fibres (dinitrile fibres), copolymer fibres of type → Polyvinylidene dinitrile, 50–230% drawn, cashmere-like character. Properties: cross-section kidney shaped, density 1.18; normal moisture take-up 2–3%; softening point 171–176°C; melting point 175°C; breaking strength 20–40 cN/tex (wet 15 cN/tex); elongation at break dry/wet 30–35%; burnable similar to cotton; good weather resistance; good resistance against mildew, rotting, insects; low shrinkage even after repeated boiling wash (max. 1%); very good continuous heat resistance (e.g. 195 days at 149°C: 100% breaking strength); insoluble in diluted acids; soluble in dioxan, dimethylformamide; sensitive against strong alkaline baths, dry temperature above 160°C, wet temperature above 120°C. Bleach with acid hypochlorite or sodium chlorite. Dyeing: particularly disperse dyes and naphthols, dark shades with carrier (methylsalicylate); polyvinylidene dinitrile fibres are more difficult to dye than polyacrylonitrile fibres, despite loosened "packing density" due to copolymerization. Application: pure or mixed (wool, cotton), particularly for knitgoods, high quality pile fabrics (e.g. imitation fur coat materials, downy soft, elegant fall, no pilling), for nonwovens, etc.

Polyvinylidene group ($–CH_2–CR_2–$); for R = Cl → Polyvinylidene chloride; for R = CN → Polyvinylidene dinitrile.

Polyvinyl methyl ether → Polyvinyl ethers.

Polyvinyl products → Polyvinyl derivatives.

Polyvinylpyrrolidone (PVP). Synthetic polymer of type



Polyvinylpyrrolidones can be produced in any desired chain length by polymerization, are soluble in water and many organic solvents; possess a certain structural similarity to protein substances, and this gives rise to very varied applications. Low viscosity polyvinylpyrrolidones form a high-quality blood replacement fluid with unlimited lasting qualities, whereas more viscose polyvinylpyrrolidone has adhesive properties (colloids), which are suitable for use as thickeners and finishing agents in aqueous solutions or emulsions. Particularly interesting property: even relatively low quantities of polyvinylpyrrolidones bind many dyes in solution and make removal impossible.

Polyzymes → Amylases, belonging to the class of bacterial enzymes, however not so heat resistant; effectiveness from 40°C; high liquefaction power, low saccharification power for starches. Bred from cultures of aspergillus orzyae on wheat germ.

POM → Polyoxymethylenes.

POM derivatives As POM dimethylether, less as diacetate, application in resin finishing as a cross-linker (formaldehyde donor) for dry cross-linking processes with, e.g. magnesium chloride as catalyst; usually together with reactive resins, particularly DMEU with buffering → Methoxymethylmelamines; wash and wear finishes with particularly good wet crease resistance.

Pond No longer permissible unit of force. SI unit is → Newton. Conversion: 1 p = 9.80665 mN; 1 kp = 9.80665 N.

Pongee Thin Chinese silk taffeta (warp: grège; weft: grège or schappe) for lining and clothing materials.

Poplin Plain weave fabric with very tightly set warp (1.5–3 times more than the weft) made of cotton, viscose, wool or silk, often in mixtures. Particular characteristic is a marked cross ribbed quality, which arises due to the somewhat loosely set weft. Ply-poplin: warp ply, weft single yarn. Full poplin: warp and weft ply; the material quality is somewhat more lustrous on the right side. Imitation poplin: ratio of warp and weft 1 : 1, ribbing is achieved by an appropriately thick weft. Only fine yarn numbers of certain, particularly fine cotton are used in the manufacture of good cotton poplin. The material is dyed and printed. It is also sanforized and impregnated for different applications. Application: men's shirts, pyjamas, ladies' dresses and blouses, rain and dust coats, camping equipment, etc.

Population equivalence (PE). Measure of the amount of organic pollutants (→ Waste water pollutant load), which is transported with waste water. A population equivalence corresponds with the pollutant load which an inhabitant produces per day on average, namely 60 g BOD_5 per day. Calculation from → BOD_5 of the waste water A (mg/1) and discharge Q (m^3/day) according to:

$$\mathbf{PE} = \frac{A \cdot Q}{60}$$

Populations Whole, collective, the quantity underlying the → Statistical analysis of all units or events. Finite populations only incorporate a certain, finite number of units. In an infinitely large population the number of units is indeterminate (e.g. quantity of all possible measurements under similar conditions).

Porcelain printing In hand printing with zinc plate screens small white, plastic dot patterns applied to dark coloured, usually black, silk.

Porcupine creel Carrier for a cross-wound package dyer in which packages are mounted individually on spindles which radiate horizontally from a hollow cylinder; no longer commonly used for cotton.

Pore size of fibres Of primary interest from the point of view of finishing technology are the intermicellar gaps (crystallite) of the → Pore volume of textiles. The so-called pore width of cellulose fibres is approximately 0.6 nm in dry state (with a few larger gaps and hollows of around 5–13 nm diameter and approx. 100 nm length), in aqueous swollen state 4–6 nm. These areas are initially only reached by water molecules and only after widening by swelling by dissolved substances. In swollen cellulose acetate we can only expect pore widths of 5–6 nm. The ratio of pore widths in dry and swollen wool is around 0.6 : 4 nm. The significantly more compact synthetic fibres with their low water take-up or water swellability only achieve pore sizes up to around 0.8–1 nm even in aqueous wetted state, which in combination with the lack of hydrophilic groups explains some dyeing difficulties, so that preswelling with suitable substances (carrier) should be given increased practical importance for the widening of the inner pore volume. Generally it is of dubious value to compare the pore sizes of water swollen fibres with the dimensions of dye molecules, because the intermicellar areas actually have poorly defined shapes, no clear demarcations and probably varying sizes. Furthermore, thermal energies (diffusion speed) and other fibre specific factors also play a decisive role.

Adsorption methods (nitrogen adsorption, mercury porosimetry) or x-ray small angle dispersion (crystallinity changes) are possible investigative techniques that lend themselves to the quantitative description of pores for solids and textile materials. The transferability of the results achieved with a dry fibre sample to behaviour in aqueous systems is dubious, particularly for cellulose, because the water present in the cellulose fibre, bound in different structural states, plays a significant role in determining the accessibility of the gaps in the swollen fibres. However, almost all textile pretreatment and finishing takes place in aqueous treatment liquors, in which one must logically assume a water swollen state. For this reason, the method of determining the pore structure using so-called "feeler molecules" of different sizes can be used, in which the penetration depth into the cellulosic substrate can be determined on the basis of the dilution of an aqueous solution of precisely known content. Large molecules cannot, or can only partially, penetrate small pores, i.e. they are "excluded" from the uniform distribution in the pore system. This approach takes its name from this effect, namely size-exclusion (SE) method (Fig. 1). These measurements permit a characterization of the water filled pore proportion, which is accessible to the molecules of a size typical of dyeing and finishing chemicals. However, a number of multiple measurements must be taken in order to plot a so-called size-

Pore size of fibres

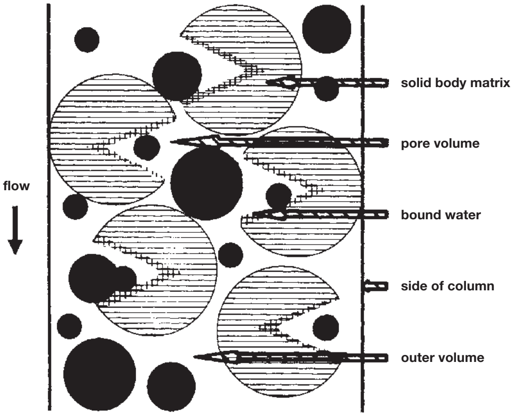


Fig. 1: The principle of exclusion chromatography in cellulose material. The matrix of cellulose solid bodies (dry weight m) possesses both bound water (not accessible) and water-filled (accessible) pores (volume V_p). Large molecules become distributed within the "outer volume" V_o, while medium and small sized molecules have available appropriately sized pores as their distribution volume.

exclusion curve for the molecular size range that is of interest; furthermore the investigation conditions (temperature, sample concentration) should be precisely checked, because otherwise significant disruptive possibilities can strongly scatter the measured data. As an alternative, the size-exclusion chromatography technique (SEC or gel permeation chromatography GPC) first used for milled cotton can be used for measurements on mercerized cellulose.

In all size exclusion chromatography methods, a chromatographic column made of glass or special steel is filled ("packed") with the textile material (the so-called "stationary phase") in a defined manner and swollen with water. The hollows thus created, or expanded, are more easily accessible to small molecules than large ones, so that different dwell times (chromatographic retention times) occur in the columns depending upon their size. Under the condition that no interactions occur between the molecules and the gel-like swollen textile material (usually cotton), the available internal volume can be calculated from the measured retention time. Therefore, an image of the gap distribution can be obtained by the use of differently sized molecules. Evaluation takes place using the so-called elution volume V_{el} (ml), which is calculated from the retention time t_R (min) of the sample molecules and the constant throughflow of elution agent (water) u (ml/min):

$$V_{el} = t_R \cdot u$$

This value is plotted on a diagram against the logarithm (base 10) of the molecular weight (log MW) of the compound in question, because the molecular weight can span several powers of ten. In the ideal case an S-shaped curve is obtained (Fig. 2), the path of which can be explained as follows: for substances with a high molecular weight, the elution volume is virtually independent of the size of the molecules, because they only move in the "external water" in the direction of flow and cannot penetrate into the pore system. As the size falls, V_{el} begins to increase, because from a certain molecular size the pores become accessible and thus the volume that is available for distribution amongst the molecules is increased. In small molecules, size differences are again meaningless for the elution volumes, because they penetrate fully into the hollows. Based upon the intersection point and axis projections drawn in Fig. 2 the "distribution or separation range" and the accessible total pore volume V_p and the "external volume" (size-exclusion volume V_o) can be read off from the curve. The elution data for individual columns soon differ from one another due to different values for the external volume V_o and the dry mass of the column packing m, determined by the column geometry and the packing process, so the curves must be "normalized". A tried and tested method is moving to the left of the value V_o and division by m, from which a "relative elution volume" is obtained:

$$V_{rel} = (V_{el} - V_o) \cdot m^{-1} \text{ (ml/g)}$$

This value represents the available inner volume per unit mass of the textile substrate for a molecule.

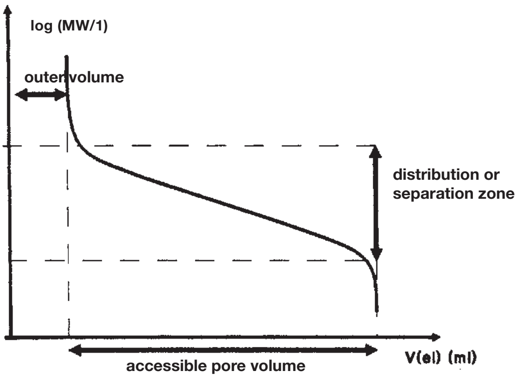

Fig. 2: Evaluating data from exclusion chromatography: determination of the "outer volume" V_o, the total accessible pore volume V_p, and the distribution or separation zone.

In the selection of the "feeler molecule", the approximately spherical molecules of dextran-fractions (polysaccharide) and the oligosaccharides and monosaccharides are usually used; or also the long chained poly(ethyleneglycol) molecules, which have the same molecular weight as dextranes and because of their long form can penetrate less far into the pore system. These two types of molecules can be viewed as limiting examples for a particularly marked form; most dyeing and finishing chemicals, because of their shape, lie between these two extremes (according to Bobleter).

Pore volume of textiles Porosity is made up of three elements:

1. porosity within the fibres, so-called intrafibrillary porosity.
2. porosity between the individual fibres, so-called interfibrillary porosity.
3. the gaps between the yarn threads, so-called yarn porosity.

The part of this total porosity that is accessible to fluids is called effective porosity and is composed primarily of 2 and 3. The current fabric porosity (also → Air permeability) is subject to great differences. The pore volume of textile fabrics is calculated as follows:

$$\frac{\text{density} - \text{volumetric weight}}{\text{density}} \cdot 100\ \%$$

Pores Small holes, fine openings; → Porosity.

Porosimetry The properties of fibres are determined to a large degree by the topographic condition of their surface. However, meso and micropores (< 50 nm) can be generated by redox or acid treatments, which can have a strong influence upon swelling behaviour and dyeing properties. Meso and microporosity bring about a significantly increased specific fibre surface. Macropores, on the other hand, are only transport routes, and make a much lower contribution to the specific surface. The porosity of the fibre can be determined either by gas sorption or mercury penetration measurements. Using a fully automatic gas sorption device for the volumetric determination of complete adsorption and desorption isotherms and with the aid of the microstructure data station, problem-oriented evaluation is possible in accordance with the Brunauer-Emmet-Teller method and according to Dubinin. Information is obtained about the specific surface, the pore diameter and the pore volume, which provides data about manufacturing process or topographic modification as a result of finishing processes. The mercury porosimeter is computer controlled equipment for determining the porosity in the range of 0–4000 bar according to the mercury penetration method. Pores with radii between 2 nm and 600 μm are detected. The method can be used to make predictions about the size of the specific surface and the specific pore volume, density, porosity and distribution of pore radii and particle sizes.

Porosity We need to make a differentiation here between fabric porosity, thread porosity and fibre porosity. If we describe a fabric as a porous plate and assume that threads and fibres are massive, then the proportion of empty space in the fabric is characterised by the fabric porosity ε_g (Fig. 1). This porosity plays an important role in the hydrodynamics of a liquid soaking into the fabric and in the transport of substances by conveyance in a film of liquid.

Fig. 1: Fabric porosity: the fabric is a porous plate, while the threads are solid.

If, however, the threads are assumed to be porous and the fibres are assumed to be massive, then we are dealing with so-called thread porosity ε_f, to determine the proportion of empty space in the threads (Fig. 2).

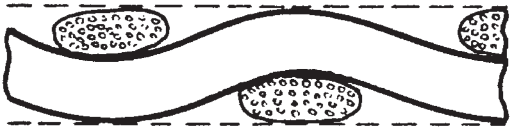

Fig 2: Thread porosity: the threads are porous, while their fibres are solid.

The overall material porosity ε_o is found by the definition formula:

$$1 - \varepsilon_o = \frac{\rho'}{\rho_s\, d}$$

ρ' = material mass per unit area
ρ_s = true material density
d = material thickness

and is made up of the two porosities ε_g and ε_f according to the material balance:

$$1 - \varepsilon_o = (1 - \varepsilon_g) \cdot (1 - \varepsilon_f)$$

The theories of dyeing kinetics are concerned with the nature of dye diffusion in polymer solids. They are primarily based upon two important, fundamentally different model assumptions of dye diffusion in fibres, namely the pore diffusion model and the free volume or segment movement model (Fig. 3). The pore mode represents the fibre as a solid with a network of interlinked channels or pores, which are filled with the dye-

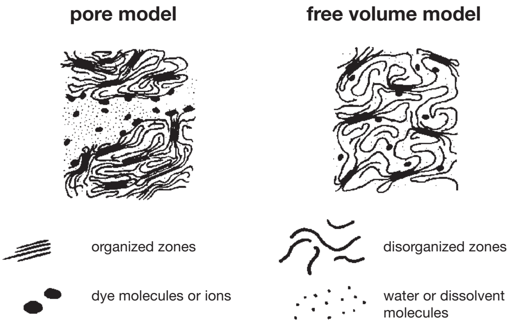

Fig. 3: The diffusion of dye within fibres: compare the pore model with the free volume model (according to Meyer, Rohner and Zollinger).

ing liquid, normally water. The dissolved dye diffuses through these pores, at the same time being adsorbed into the pore wall. The porosity P, i.e. the pore proportion of the entire volume of the fibre and the adsorption equilibrium are the main factors in making quantitative predictions regarding the diffusion speed.

The free volume model, on the other hand, describes the dyeing process as the diffusion of dye through disordered ("amorphous") parts of the polymer matrix. The diffusion speed is thus determined by the segment mobility of the polymer chains.

The most important evidence supporting this theory is the observation that the temperature dependency of the dyeing speed of a fibre type lies above a certain temperature. This means that the resistance of the fibre's solid structure against the penetration of the dye is much less above this temperature. This is called the glass transition temperature (T_g) of the fibre in question, more precisely as the glass transition temperature under dyeing conditions or the dyeing transition temperature (T_D), because the classical glass transition temperature is a value measured in the dry state. Both values T_g and T_D correspond with the temperatures at which (from a microscopic point of view) the non-ordered part of the polymer goes over from a glass-like to a visco-elastic state or (on a molecular basis) at which the disordered segments of the macromolecules become mobile in relation to one another, i.e. to a certain degree become "micro-fluids".

Whether pore or free volume diffusion dominates depends upon the physical structure of the fibres and the reaction conditions. At low temperatures, for example on highly porous polyacrylonitrile fibres, pore diffusion can be detected. Above the dyeing transition temperature the pore diffusion will be an equilibrium of the subsequent diffusion in the solid body according to the free volume model (according to Wassing and Zollinger et al).

Porous coatings A meltable polymer (polyamide/

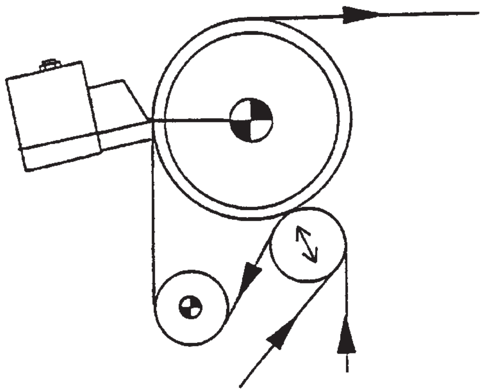

Fig. 1: The application of a porous coating against the coating roller in order to achieve good penetration (Nordson).

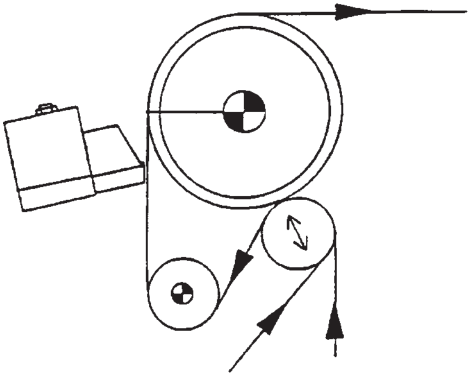

Fig. 2: The application of a porous coating onto the free fabric for the purpose of surface coating (Nordson).

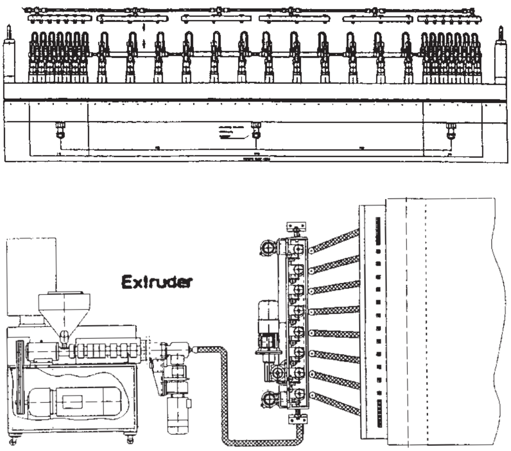

Fig. 3: A typical porous coating facility with extruder and application nozzles (Nordson).

polyethylene or polyurethane) is pressed from extruders mounted on a bar across the width of the material, and applied directly to the material. This gives rise to deep penetration if the extrusion takes place on material running around a roller, whereas extrusion on a free running material gives rise to a surface coating only (Figs. 1–3).

Portal steamer Continuous steamer for single or two-phase printing, combined underfloor/elevated machine type with oil heated steamer cover. Spiral-shaped roller arrangement in narrow arch or channel shape, without deflecting bar. Guaranteed freedom from drips, air and folds. For pile and stretch fabrics; material guidance usually from inside to outside; water stabilization gates for slow cooling off of polyacrylonitrile pile, also warm air gates. All rollers are driven. The spiral-shaped material flow has proved particularly beneficial when used on a continuous production line, e.g. for printing after-treatment or pile fabric dyeing, thus in continuous dyeing. Material content single track 45–170 m, multitrack correspondingly greater content.

Positioning of screen register crosses The automatic repeating of round screens in rotation printing requires a fixed optic for each screen and a fixed point on the screen (register cross). The register cross on the screen can then be detected (e.g. by means of a laser beam). The position of the carrier peg for the screen can also be located in the screen hole of the printing group, which also occurs optically by means of suitable sensors. This relies on there being an end ring glueing device. By means of a simple optical sensor the position of the register cross in relation to the end ring and thus also in relation to the point of application of the carrier peg on the screen opening of the printing machine can be set precisely and reproducibly (see Fig.). Precise cutting of the screen stocking and the control of thermal problems when glueing are further requirements, so that less corrections are necessary in the repeating of the screen in the printing machine.

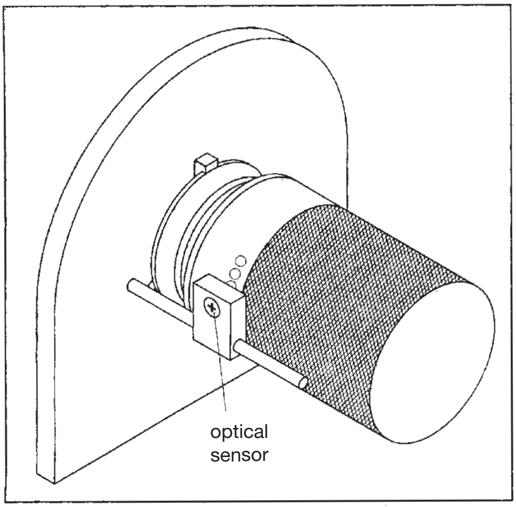

Fig.: An end ring glueing machine with an optical sensor for positioning the screen register cross.

Positive process for screen making The pattern is copied onto the gauze by placing a positive between lamp and photochemical layer and then illuminating. The positive can be produced either photographically or by placing a light-impermeable colour layer over a transparent foil. Whatever the method used, the pattern parts must be impermeable to light. The positive process differs according to working method or type of photosensitive layer:

I. Intensifier process: the illuminated and hardened gelatine layer applied to the gauze should be protected against chemical and mechanical influences during the printing process by a lacquer coating. Initially the gelatine layer (may also be polyvinyl alcohol, etc.) is applied, illuminated through the positive, and hardened thoroughly. This layer is reinforced by coating the inside of the screen uniformly with a film of lacquer. Before the lacquer is dry after coating, the still wet lacquer is rubbed out of the drawing sections on the back with a soft cloth. The gelatine layer, which is not soluble, ensures that the applied lacquer can only be rubbed out of the open areas, which are free of gelatine. Finally, the remaining lacquer film is removed by solvent without leaving a residue. Even greater durability of the screens is achieved if the gelatine layer is also reinforced on the back in the manner described. Another possibility is removal of the lacquer coating from the pattern points by direct suction.

II. Pre-lacquering process: in this method, the gauze is uniformly coated with screen lacquer before the screen is painted with the light sensitive coating. After drying, the light-sensitive coating is uniformly applied to the underside of the screen. It is then illuminated and developed in the normal manner. The lacquer coating on the points covered by the drawing, and thus not illuminated, can now be removed using solvent from the side of the gelatine coating and wiped away. After completion, the gelatine layer can be dissolved thus obtaining a screen printing screen with an extremely durable covering layer.

III. Photolacquer process: this process involves photo lacquers, which have good durability after illumination and washing without additional reinforcement. Particular importance is attributed to this process in the manufacture of screens with half-tone drawings, because the highest possible requirements apply for the drawing fineness to be achieved.

Postboarding Process (Am.) postforming in hosiery fixing, → Boarding.

Post-Cure → Permanent-press process.

Post-curing Variously called delayed and deferred curing: → Permanent-press process.

Post-dyed-bonded-Fabrics American term for laminated fabric or knitgoods, which are dyed after lamination. The binder (polyacrylic or polyurethane base) must endure the entire dyeing process.

Post-mercerization The abrasion resistance of linen cloth with an anti-crease finish can be significantly improved by mercerization after the hardening of the synthetic resin.

Post print washing → After-print-washing.

Potash alum → Aluminium potassium sulphate.

Potassium (K), atomic weight 39.15. Silver-white metal, melting point 62.5°C, cuts easily, lighter than water (specific gravity approximately 0.86). Further properties → Alkali metals. The positive potassium ion forms colourless salts with colourless acid anions, usually with good water solubility, with the exception of potassium bitartrate (cream of tartar).

Potassium bitartrate (cream of tartar, potassium tartaric acid, double potassium tartaric acid), $C_4H_5O_6K$, molecular weight 188. Slightly soluble in cold water, better in hot water. Application: No longer used.

Potassium carbonate (carbonate of potassium, potash), $K_2CO_3 \cdot 2\,H_2O$. Molecular weight 174. White (anhydrous) granular powder or crystalline mass, both hygroscopic, deliquescent, water soluble, solution strongly alkaline. Application: Milder alkali than sodium carbonate, particularly for wool treatment, in printing, as soap component, etc.

Potassium chlorate (chlorate of potassium), $KClO_3$, molecular weight 122.5. Transparent, monoclinic plates, water soluble. Application: As oxidizing agent, particularly for textile printing and aniline black dyeing.

Potassium chloroplatinate → Potassium hexachloroplatinate.

Potassium chromate (potassium chromic acid, potassium mono chromate), K_2CrO_4, molecular weight 194.5. Rhombic prisms, made of potassium dichromate and potassium hydroxide or carbonate, water soluble. Application → Potassium dichromate.

Potassium dichloroisocyanurate → Chloroisocyanuric acids.

Potassium dichromate (bi-chromate of potash, red bi-chromate of potash; double bi-chromate of potassium, potassium bichromate), $K_2Cr_2O_7$, molecular weight 294.5; density 2.7. Large crystals, anhydrous and dry, stable in air, orange-red, toxic, water soluble, solution weakly acidic, possesses oxidation property. Application: aftertreatment of chrome development dyes to improve fastness; dye mordant for wool; component of metachrome mordant; oxidizing agent for the development of fast dyeing and printing; vigorous decolorizer for wool. The applicable discharge limits should be observed.

Potassium ferricyanide → Potassium hexacyanoferrat III.

Potassium ferrocyanide → Potassium hexacyanoferrat II.

Potassium fluorozirconate → Potassium hexafluorozirconate.

Potassium hexachloroplatinate (potassium chloroplatinate). K_2PtCl_6, molecular weight 486.16; density 3.5. Small yellow crystals. Decomposition at 250°C. Soluble in water 1:100, concentrated hydrochloric acid; insoluble in alcohol, ethers. Application: determining the Hazen colour number, etc.

Potassium hexacyanoferrat II (yellow prussiate of potash, yellow potassium prussiate), $K_4[Fe(CN)_6] \cdot 3\,H_2O$. Light yellow crystals, stable in air, water soluble, insoluble in alcohol and ether. Application: Iron indicator.

Potassium hexacyanoferrat III (red prussiate of potash, red potassium prussiate), $K_3[Fe(CN)_6] \cdot H_2O$. Red crystals; break down in sunlight, gradually decomposing to potassium hexacyanoferrat(II) (yellow prussiate of potash) due to the separation of iron(III) hydroxide; strong oxidizing agent. Application: discharge printing, in analytic chemistry as an iron indicator.

Potassium hexafluorozirconate (potassium fluorozirconate). K_2ZrF_6. White crystals, soluble in hot water. Application: IWS flame retardant finish for wool.

Potassium hydroxide (caustic potash, potash lye), KOH. Molecular weight 56, density 2.04. White, highly caustic crystal mass (K_2O) or pieces, fragments, plates, powder; highly hygroscopic (eagerly attracts water and carbon dioxide, therefore store in sealed container); readily deliquescent, readily water soluble when warmed, also in alcohol; or viscous lye, strongly alkaline, strongest dissociated base. Application: similar to → Sodium hydroxide, soap component, etc.

Potassium iodide starch paper Filter paper, which is soaked in boiled starch paste and 3–5 g/l potassium iodide before drying. Application:

I. Detection of traces of free chlorine (in bleaches, etc.) = wetted material is dark blue.

II. Detection of acid traces on cellulose goods = dark blue colouring.

III. Testing of diazotization baths (detection of free nitrous acids), if no blue colouring occurs then there is no nitrite or acids. Principle: released iodide determines the formation of blue iodide starch.

Potassium percarbonate $K_2C_2O_6$, molecular weight 198.3. Bleaching agent and component of oxidative washing agents.

Potassium permanganate (permanganate of potash), $KMnO_4$, molecular weight 158; density 2.7. Dark violet crystals with metallic lustre, stable in air, water soluble; solution dark violet (store in brown bottles), strong oxidizing agent in a) acidic, b) alkaline and c) neutral solutions. In case a) release of 5, in case b) and

c) of 3 oxidation equivalents and manganese dioxide deposits, soluble with disulphite, sodium dithionite, oxalic acid, sulphurous acids or hydrogen peroxide, perborate and acetic acid aftertreatment. Application: Bleaching agent (for wool, silk, cellulose fibres); bleaching spotting agent; antidote for hydrogen cyanide poisoning (drink approximately 0.5 g potassium permanganate in a glass of water), etc.

Potassium persulphate (potassium sulphate peroxide), $K_2S_2O_8$, molecular weight 270. White, crystalline salt, 98–99%; contains 5.7–5.9% active oxygen, water soluble. Bleaching and oxidizing agent for greases, oils, silk, wool, dyes; starch degradent (desizing); for mordanting, browning, cleaning.

Potassium phosphates More readily soluble than → Sodium phosphate and less volatile in water vapour, therefore much more active. It is possible to differentiate between:

1. Primary potassium phosphate = mono potassium phosphates (sour potassium phosphate, potassium di-hydrogen phosphate), KH_2PO_4; density 2.338, molecular weight 136. White salt, somewhat hygroscopic, readily soluble. Reaction weakly acid, 1% solution pH 4.53. Application: water treatment for boiler feed water (steam purity). Detergent builder.
2. Secondary potassium phosphate = dipotassium phosphate (dipotassium hydrogen phosphate). K_2HPO_4; density 2.34, molecular weight 174.18. White salt, decomposes in air. Very readily soluble. Application: Occasionally for corrective final softening of boiler feed water after cation exchange, specifically for high pressure boilers (low steam solids as with disodium phosphate).
3. Tertiary potassium phosphate = tripotassium orthophosphate, K_3PO_4, density 2.56. White, granular powder, deliquescent in air; readily soluble. Application: Cation exchange.

Potassium polymetaphosphate Metal-complex phosphates, → Metaphosphates of potassium. Metal-complex parent substance (KPO_3) is pure, highly condensed potassium polyphosphate (previously erroneously known as potassium metaphosphate or “Kurrol Salt”). With a condensation level between approx. 1000 and sometimes well above 1 000 000, this compound represents the final member in the series of → Polyphosphates. The high and extremely high viscosity types have a fibre structure similar to asbestos or cotton wad. Sodium chloride, sodium sulphate, but preferably sodium pyrophosphate or sodium hexametaphosphate (Graham’s salt) are used as an organotropic compound. By selecting a suitable organotropic compound it is possible to firstly influence the pH of the aqueous solution created, and also to a certain degree the viscosity. The ratio of potassium polyphosphate : organotropic compound is usually 1 : 2–4. The application quantity of potassium polyphosphate varies; sometimes the effects can be achieved with just 0.1%, sometimes the final concentration is increased to 2–3%. In so-called “low viscosity” types, aqueous solutions have viscosities of 1–2 mPa · s. One talks of “high viscosity” types if values of around 6 mPa · s are obtained. Viscosities decrease over time, but are clearly detectable weeks later. The reduction in viscosity is accelerated by increasing the temperature, particularly above 50°C, disappearing completely when boiled, without decomposition of the potassium polyphosphate occurring due to normal hydrolysis.

Some metal-complexes that can be made soluble possess an intrinsic cleaning, washing and soil suspending capability, and facilitate particularly gentle washing, milling, etc. and their handle becomes fuller, softer and has improved elasticity and brighter colours. Water hardening salts, iron and manganese salts are kept in solution or, if insoluble (lime soap), redissolved. Metal-complex solutions themselves do not foam, but increase the foaming power of wash-active substances considerably, as well as the washing effect.

Potassium polyphosphate → Potassium polymetaphosphate.

Potassium tetroxalate (sal acetosella, “sorrel salt”, aceto oxy aceto of potash), KOOC–COOH + HOOC–COOH + 2 H_2O. Molecular weight 254. White crystals or fine crystal powder, toxic, water soluble, insoluble in alcohol, solution acidic. Soluble double salts are formed with iron. Application: substitute for potassium bitartrate (tartar) in dyeing; lightening of straw hats, etc., spotting agent for rust and ink spots.

Potassium thiocyanate (potassium rhodanide), KCNS, molecular weight 97; density 1.9. Colourless crystals, transparent, deliquescent, hygroscopic, water soluble (in cold solution), also soluble in alcohol. Application: for increasing the dye affinity of wool, analytic (iron indicator = blood red dye).

Potato starch Powder, pure white; Handle crunchy, floury, cool; usually pure; water content 19–21%. Properties: insoluble in water. If heated from slurry at 46.25°C swelling takes place, at 58.75°C gelatinization begins, at 62.5°C gelatization ends. Paste: jelly-like, slimy, sticky, slightly grey translucent, not very stable, has the lowest stiffening and adhesive power of all starches. Gradual liquefaction if continuously boiled. Boiling with oxidation product (e.g. sodium perborate) leads to (water)soluble starch; degradation by enzymes. Acids lead to dextrose. Alkalis (depending upon concentration) increase the viscosity at normal temperature (great adhesive power), boiling gives rise to very tough, creamy solution (without particular adhesive power). Similar also tannin, salts, paraffin, oils, etc. Finishing handle: mild, soft, supple, full. Application → Starch.

Potential difference The transmission of energy and matter generally occurs due to potential differences, e.g. current “flows” in a conductor due to a voltage difference. For the movement of liquids or gases in a closed system a potential "pressure difference" is necessary. Heat "flows" in solid bodies due to the presence of a temperature difference. So, in general, the following applies for stationary states: heat and matter transport are proportional to the applied potential difference. In → Thermodynamics it has become normal to denote the proportionality factor for heat transmission or transition as α and that for the transmission of gases as β.

Potential hydrogen-ion concentration affects the current → pH. → Normal solutions.

Potentials →: Standard electrode potential; Thermodynamics.

Potentiometer Electrical device for → pH measurement with hydrogen, quinhydrone, antimony or glass electrodes. The prevailing pH is read directly off a scale.

Potentiometric measurements For determining the ion concentration by measuring the potential E of measuring networks, which each consist of a measuring electrode (indicator electrode, such as, e.g. glass, antimony, silver/silver chloride electrodes, etc.) and a reference electrode. E is the difference between the two individual potentials ε_m and the reference electrode ε_b:

$$E = \varepsilon_m - \varepsilon_b$$

The potential of all reference electrodes is independent of the composition of the solution. The value of ε_m, on the other hand, depends upon the concentration c_i of a certain ion (→ Nernst's distribution law):

$$\varepsilon_m = \varepsilon_0 + 58.2 \cdot \log c_i \cdot f_i \text{ (mV)}$$

For diluted solutions the activity coefficient $f_i = 1$. If the concentration changes by a factor of 10, then the potential changes by 58.2 mV. A particular measuring electrode must be selected for each type of ion (for pH e.g. the glass electrode; → pH measurement).

Potentiometric recorder Recording device, in the form of a point or line recorder, which functions according to the potentiometer method or using an automatically adjusted bridge circuit.

Potting → Wet decatizing.

Potting fastness Resistance to the effect of boiling water (wet decatizing). Guideline applies for wool and possibly in mixture with other fibres. Roll test piece around a glass rod, treat for 1 h in boiling distilled water with backflow. Dry in air at ≤ 60°C. Evaluation: change of shade, bleeding of white adjacent fabric (wool or cotton) with grey scale.

Pour point, setting point Lowest temperature, at which an oil becomes stiff and ceases to "flow". Plays an important role, for example, in mineral oil lubricants, lubricating oils, heating oils, etc.

Powder coating plant Used for sprinkling thermoplastic powder on two or more surfaces in order to stiffen or stick them together.

The powder can be sprinkled in dot form or superficially (see Fig.).

Powder dispersal sinter process is particularly suitable for heavy materials, for example, shoulder pads. Thermoplastic powder is sprinkled superficially on the cold length of material and then melted and sintered (Fig. 1). In order to distribute the powder uniformly over the entire area, in contrast to point coating, powder is scattered from special needle rollers from an

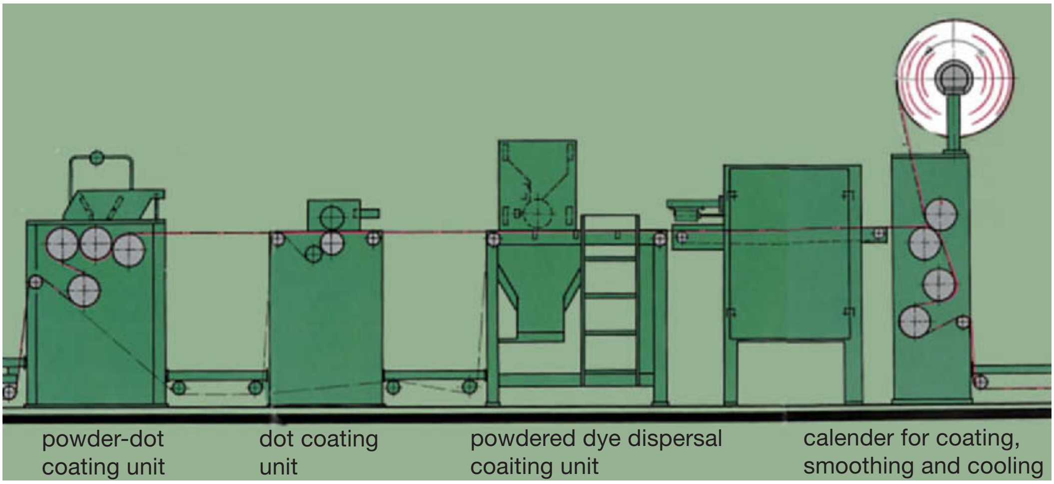

Fig.: A coating facility (Santex) allowing the choice between powdered-dot coating, dot coating or powdered dye dispersal coating, with dry and gel channels and with a calender for coating and smoothing.

oscillating hopper and brushes (Fig. 2), which distribute it on the material.

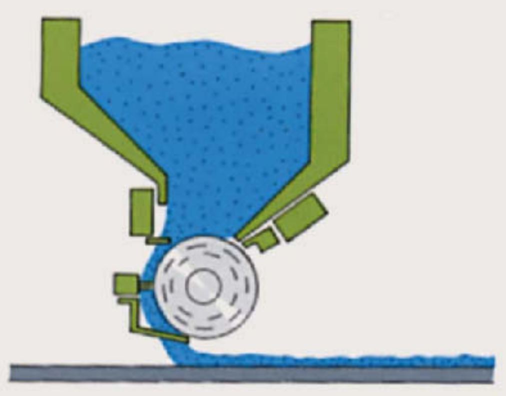

Fig. 1: Powder dispersal sinter process.

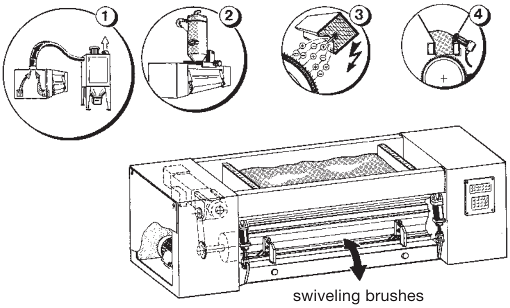

Fig. 2: The Villars powder dispersal unit with traversing dispersal funnel (2), special needle roller (4) whose electrostatic charge is compensated (3), and suction removal of excess powder (1).

Powder dissolving station For the use of dyes, chemicals, etc. Powder dyes require costly dissolving stations, which consist of stainless steel dissolving and storage containers. A smaller dissolving tank of 250–1000 l capacity with a connected storage tank is usually adequate for dissolving. The dissolving tank should be fitted with a stirrer and be heated directly by steam. The dissolved dye is further diluted by continuous stirring with cold water, before it is discharged into the storage tank via a fine-meshed sieve. The minimum capacity is determined by the production quantity, depth of colour and the solubility of the dye used. The storage tank should also be fitted with a stirrer to prevent undesired settling out or creaming. The dissolving of powder brands to form a parent solution is very energy-intensive especially for dyes with limited solubility. Considerable quantities of water and heating steam are necessary. Care must also be taken that the cold solubility is not exceeded. This applies even for short term storage. Un-dissolved or precipitated dye particles may re-dissolve into the substance (although quite often they do not). They then not only block the dosing system by blocking pipes and valves, but also represent a financial loss. Furthermore, it makes it difficult to precisely calculate the quantity needed for the parent solution in advance: residual amounts may no longer be discharged into waste water, missing quantities must be reclaimed under time pressure.

Powder-dot coating For light outer clothing materials to fine ladies' blouses, the powder dot coating process is used for coating the front fixing material. The indentations of a heated engraved roller are filled with thermoplastic powder which is then slightly agglomerated (Fig. 1). The material is heated to above the melting point of the coating powder on a heated roller. The hot fabric is pressed against the powder filled hollows, the powder melts and adheres to the fabric in the form of droplets. In the subsequent sintering zone the droplets are melted to form hemispherical pearls, which sit cleanly upon the surface of the fabric (Fig. 2). In contrast to the → Powder dispersal sinter process, patterns are generated.

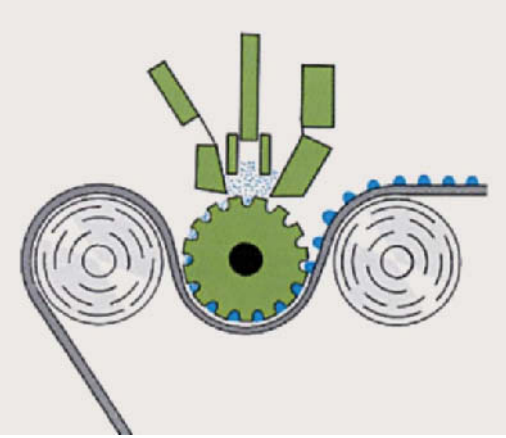

Fig. 1: The powder-dot process (Caratsch).

For the dot-like adhesion of material layers by powdered thermoplastics of different composition, e.g. for air permeable front fixing. Thermoplastic powders (such as high and low pressure polyethylene, polyvinyl chloride, polyolefins, vinyl acetate, polyamide and compounds of different types), which (partially) add desired characteristics of different basic components are used. Development is moving towards the creation of boiling, washing and dry cleaning resistant powder

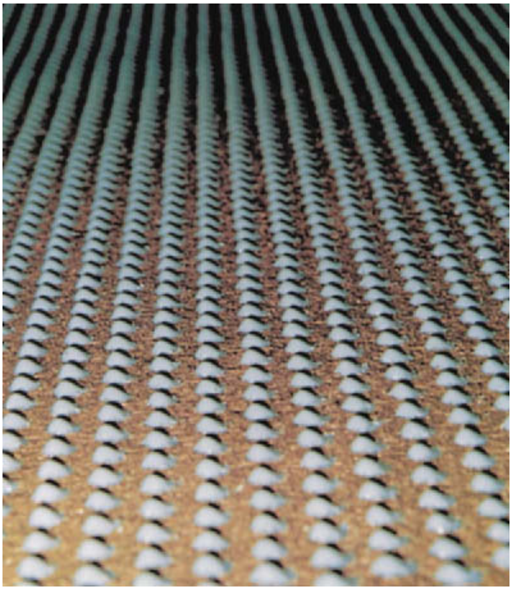

Fig. 2: Powder-dot application (according to Knobel).

qualities combined with optimal adhesion during the thermo process.

Powdered dye dispersal process Dyes or chemicals are sprinkled on the material in powder form, shaken up (shaker process) and, depending upon the nature of the material (dry, wet, dyed, undyed, not desized, etc.), provide dye, flow or resist effects. In accordance with another process, powdered dyes are sprinkled on the material together with water and crystallised salts. In the subsequent contact heat treatment the crystallised water is evaporated from the salts, dissolves the dye, and this is absorbed into the fibre and immediately fixed.

Powder point process → Powder-dot coating.

Powder-scatter coloration technique A technique for the production of coloristic effects which involves the application of dyes, together with salts containing water of crystallization, to textile materials by means of a powder-scatter machine (→ Powder dye dispersal process). After application, the fabric is passed over hot metal rollers in order to fix the dye/s. A notable feature of this coloration process is the fact that the water required to bind the dye to the fibre is provided by water of crystallization only.

Power As physical variable: → Work done per unit time, SI unit is Watt (W) = J/s.

POX Pergable (can be blown out) organic halogen; in addition to AOX (adsorbable) and POX we also differentiate EOX (extractable) as values for chlorinated hydrocarbons, which cause problems for the environment.

POY (Pre-oriented yarn) → Polyester fibres.

PP → Polypropylene fibres, → Textile fibre symbols, in accordance with DIN 60 001 T4/08.91.

ppb (parts per billion), billionths = 10^{-9}.

ppm (parts per million), millionth = 10^{-6}.

PR → Protein fibres, → Textile fibre symbols, according to the → EDP key system.

P.R. (Pressley-Ratio) → Pressley-Index.

Pr Element symbol for praseodymium (59).

Prato wool Italian cloth export from Prato, previously made primarily of → Reclaimed wool, which after the Second World War achieved world-wide importance due to its low price (around 50% of production for export was for the Orient, West Germany, England, etc.).

PRAVDA Product Recycling Altfahrzeug Verwertung Deutsche Automobilindustrie (Product recycling of used vehicles in the German automotive industry); interest group made up of seven German car manufacturers for the development of strategies for car reclamation and the extraction of valuable materials for recycling. Support of development work for similar types of plastics and fibres for trim.

Prayer mats Small, easily transportable oriental carpets for praying outside the mosque, on journeys, etc. The prayer niche is a rectangular, tapered internal panel.

Precipitation,

I. Formation of a solid deposit in a solution due to the addition of another solution.

II. Insoluble sediment. Arises as a reaction product of two dissolved substances in one another (also gas in liquid). Often becomes soluble again.

Precipitation and flocculation Related terms used in waste water cleaning. The waste water is partially cleaned by the coupling of precipitation and flocculation processes. The use of biological processes is ruled out for the cleaning of industrial waste water, or they can only be used as a third stage treatment. In this case, precipitation and flocculation methods are often used as the preliminary cleaning process. Basically, it is worth including a precipitation/flocculation stage if heavy metals, difficult to degrade → COD, mineral oils and precipitates or colloids need to be separated out in large quantities. Phosphates, which encourage eutrophication, and foul-smelling hydrogen sulphide can also be eliminated by precipitation and flocculation. It is also a commonly used method for decolorizing waste water. In the procedural technique used for waste water cleaning it is difficult to separate the two basic operations. Because of the complexity of waste water, it contains impurities with very different properties, which must be separated out using different reaction mechanisms. In addition, both processes interact and support each other. Chemicals used to promote precipitation and flocculation are metal salts or alkaline earth metal compounds, which form hydroxide floc or difficult to dissolve compounds in the waste water. The commonly used metal salts are chlorides and sulphates of iron and aluminium (aluminium sulphate $Al_2(SO_4)_3$, Iron(II) sulphate $FeSO_4$; Iron(III)chloride $FeCl_3$ or Iron-III-chloride sulphate $FeClSO_4$). One commonly used metal salt is iron(II)-sulphate, which is preferred due to its low price, plus it has proved to be a much more effective decolorizer than for example the more expensive iron(III) sulphate. Calcium, which is frequently used, deserves a mention as a representative of the alkaline earth metal compounds. Metals salts have been known to be used in combination with calcium.

The basic operation of precipitation allows various dissolved substances in waste water to be converted into non-soluble form. This makes it possible to precipitate hydrogen sulphide (H_2S) using iron (II) sulphate (odour prevention). The hydrogen sulphide reacts with iron sulphate according to the following reaction diagram to form water-insoluble, black and odour inactive iron sulphide FeS:

$$FeSO_4 + H_2S \longrightarrow FeS + H_2SO_4$$

In textile waste water, we can expect to find hydrogen sulphide if cellulosic substrates are dyed using sulphur dyes, using sodium disulphide as a reducing agent. Heavy metals are eliminated by precipitation with calcium hydroxide $Ca(OH)_2$, whereby the metals are precipitated as metal hydroxides according to the following reaction equation:

$$ZnSO_4 + Ca(OH)_2 \longrightarrow Zn(OH)_2 + CaSO_4$$

In order to precipitate a sufficient quantity of the metal ions as hydroxides, the pH must lie within the range of the solubility minimum of the metal hydroxide in question, because outside this range the metal ions cannot be precipitated in a sufficient quantity, or will dissolve again. In the textile finishing industry heavy metal traces may enter waste water due to stripping agents, dyes and catalysts. After inorganic carbon, phosphorus is one of the most important elements for the growth of algae and can be viewed primarily as a cause of eutrophication in bodies of water. To avoid excessive eutrophication, which may result in the “biological collapse” of a body of water, phosphates (ortho phosphates, pyrophosphates, tripolyphosphates, etc.) should be removed from the waste water. The easiest way of removing o-phosphates (PO_4^{3-}) from the waste water is by chemical precipitation in the form of poorly soluble iron, aluminium or calcium salts.

a) Aluminium phosphate precipitation:

$$Al_2(SO_4)_3 \cdot 18\,H_2O + 2\,PO_4^{3-} \longrightarrow 2\,AlPO_4 + 3\,SO_4^{2-} + 18\,H_2O$$

b) Iron-phosphate precipitation:

$$FeCl_3 \cdot 6\,H_2O + PO_4^{3-} \longrightarrow FePO_4 + 3\,Cl^- + 6\,H_2O$$

c) Lime-phosphate precipitation:
The individual stages of the process of lime phosphate precipitation are not yet fully understood. The phosphate ion is precipitated in the form of hydroxyl apatite, which may have different compositions, by adding lime and at the same time increasing the pH. Calcium hydrogen phosphate $CaHPO_4 \cdot 2\,H_2O$ is probably formed first, which then is converted over time into the more stable apatite $Ca_5(PO_4)_3(OH)$. The chemical reactions can be described in more detail as the following approximation:

$$2\,Ca(OH)_2 \longrightarrow 2\,Ca^{2+} + 4\,OH^-$$

$$2\,Ca^{+} + HPO_4^{2-} + 4\,OH^- \longrightarrow Ca_2HPO_4(OH)_2 + 2\,OH^-$$

$$4\,Ca_2HPO_4(OH)_2 + 2\,Ca^{2+} + 2\,HPO_4^{2-} \longrightarrow Ca_{10}(PO_4)_6(OH)_2 + 6\,H_2O$$

In the event that solid particles are not able to sediment sufficiently well, the separation of the precipitation must take place by flocculation using flocculation colloids (→ Flocculation).

Precipitation chromatography → Chromatography.

Precision regulator Used for the adjustment and automatic control, e.g. of set temperature values (temperature controller), relative air humidity (air conditioning units), etc. In principle contains a so-called impulse device, a bimetallic strip, a highly sensitive fluid temperature controller or pressurised fluid or compressed air (pressure regulator), an electrical resistance thermometer or hair hygrometer. The generated impulse is transferred (possibly electrically) to control device (membrane lever, valves, etc.).

Precision-wound packages Always a regular winding at all diameters (see Fig.). The rewinding tube is positively driven and has an adjustable, constant ratio to the movement of the thread guide at all times. The thread distance can also be selected. The number of windings per winding stroke remains constant from the starting diameter to the full batch diameter. The most advantageous winding can be adapted at will to the yarn material and field of application. (→ Crosswound yarn package).

Pre-coating of screen In order to facilitate possible painting of screens by hand, the screen is pre-coated e.g. with an auxiliary layer of gelatine or sodium alginate.

Pre-Cure → Permanent-press process.

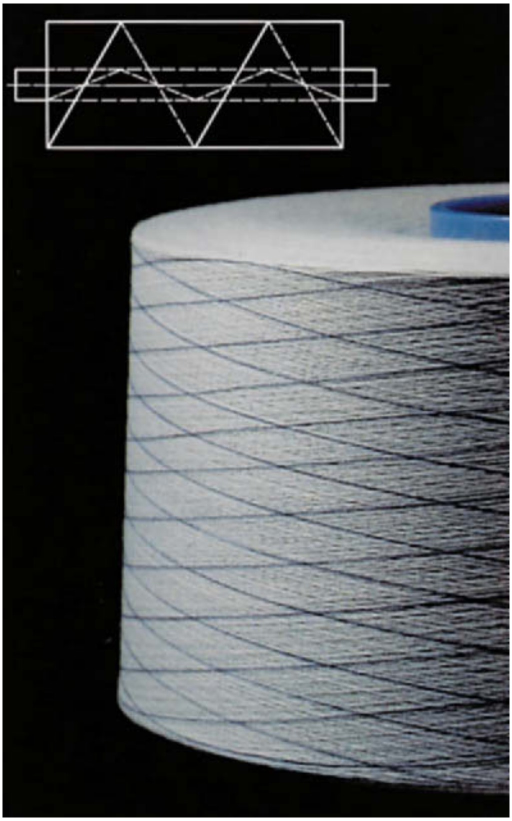

Fig.: A crosswound yarn package with precision winding (Schweitzer).

Precutting in mill engraving After the drawing has been transferred onto the molette, the predrawn lines are precut with a suitable graving tool.

Pre-dip Pretreatment of yarn or fabric with an auxiliary that promotes the adhesion of the subsequent impregnation.

Predrier Should prevent migration in the main dryer due to the mild nature of drying.

In fibreglass wallpaper impregnation with high product application (liquor application by impregnation in the horizontal two-bowl padder run “split”, in the order of magnitude of 150–200%) should achieve contactless drying in the IR duct with residual moisture of around 25–30%, before it is “pressed” on a subsequent cylinder drier.

Predriers can be:

- air supported jet driers,
- predrier with support sieve,
- hotflue with trough injector (Fig. 1),
- mostly, however, infrared driers with gas or electric operation (Fig. 2).

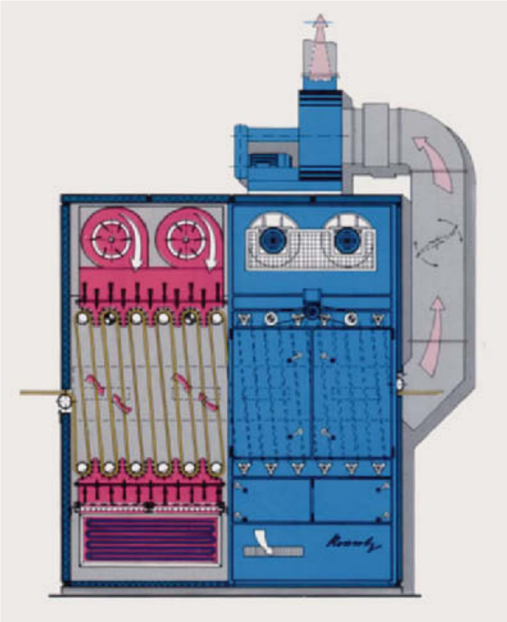

Fig. 1: Hotflue predrier with trough nozzles (Krantz).

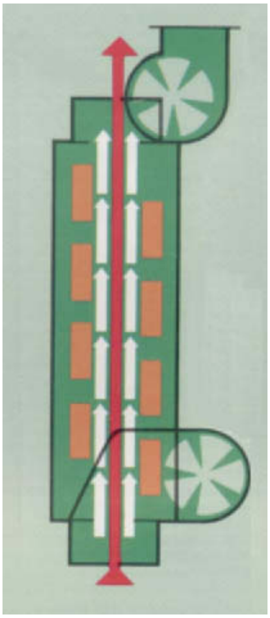

Fig. 2: IR predrier (Monforts).

Pre-drying → Water extraction.

Prefelting machine Prefelting of folded fur hats by means of rotating rollers or rollers with strong rope wound around them (ropemill).

Preference (Lat.: praeferre = prefer), preference, priority; e.g. in → Whiteness formulae as white preference (“white taste” of the observer), blue green preference, shade preference.

Preferential orientation of silicones on hydrophilic fibre surface to their water repellent finishing (see Fig.). The hydrophilic part of the silicon polymers align themselves to the fibre surface, whereas the hydrophobic parts point outwards.

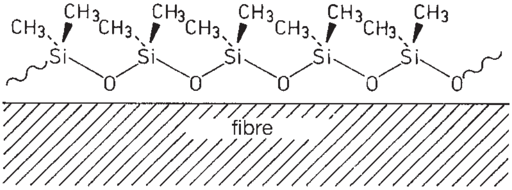

Fig.: Preferential orientation of silicones on hydrophilic fibre surface.

Prefix (Latin: praefixum = prefixed). In chemical compounds prefixes are a term or syllable placed before the root word for the differentiation of the word stem in question. Examples: Beta, cis, cyclo, di, meta, methyl, mono, para, poly, tri, etc. Opposite → Suffix.

Pre-keratin Preliminary stage of → Keratin formation in the hair root. The lower part, the hair papilla, contains soft protein liquid, which contains water and has almost circular cell nuclei, so-called ball or ring proteins. Then follows the so-called protein zone, in which the stretching process takes place. In the pre-keratin zone the partially hardened hair begins to grow from the previously closely enclosed, diffused hair root, fully cross-linking via disulphide bridges in the keratin zone. It now grows past the junctions of the follicular glands and emerges visibly through the outer skin.

Pre-lacquering → Positive process for screen making.

Preliminary finishing Pretreatment of textiles in wet finishing. → Wet processing.

Premetallized dyes → Metal-complex dyes.

Pre-milling Practical term for → Milling. It is used in the finishing of woollen fabrics to describe a slight felting of the fabric surface. Milling machines have a suitable setting (see Fig.).

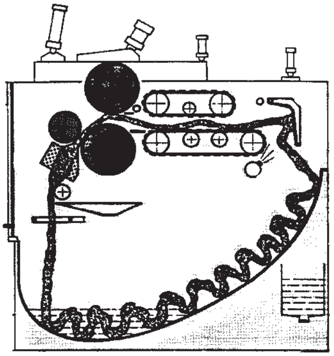

Fig.: Pre-milling.

Pre-mordanting → Chroming.

Preparation (formulation). Mixtures and solutions made of two or more substances.

Preparation vessel In textile finishing machines the treatment liquor is often prepared in a separate container (see Fig.), which is then supplied to the machine by a pump.

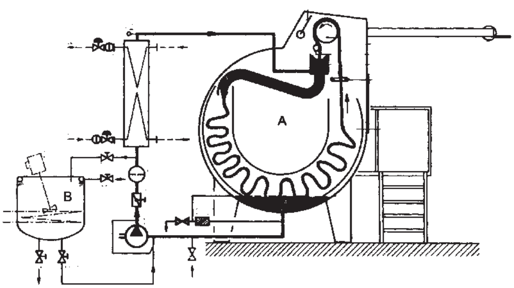

Fig.: Subtilo (Scholl AG).
B = separate preparation vessel; A = dyeing machine.

Preparing Pretreatment operation:
1. In dyeing with naphthols.
2. For turkey red dyeing.

Preparing salt → Sodium stannate.

Prepigmentation Unvatted vat dyes are padded onto fabric as a dispersion and deposit themselves onto the fibres as pigments during drying. Subsequent padding of chemicals (reducing agents and alkali) vats the dye to a solution, which diffuses into the fibre in the subsequent steaming process (see Fig.).

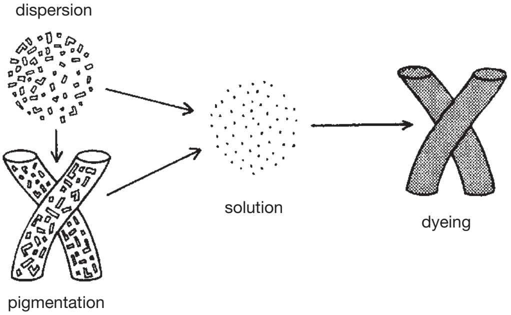

Fig.: Prepigmentation: the process of dyeing with either a dispersion dye or a vat dye.

Prepreg A fibrous mat impregnated with a heat hardening matrix material, which can be further proc-

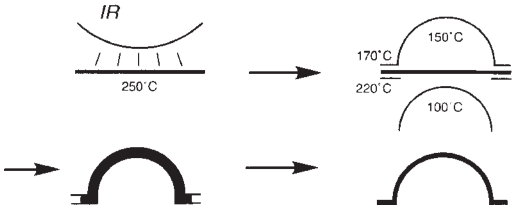

Fig. 1: The processing of a prepreg in a deep drawing process.

essed by heat pressing. Prepregs are not free-flowing, and therefore cannot change shape independently (Fig. 1). Prepregs consist of thermoplastic fibres (PA 6.6) or non-meltable fibres (in the field of prepreg forming), such as glass fibres, carbon fibres or para-aramide fibres; this selection is based upon the profile of requirements of the fibre-reinforced plastic component to be produced, above all on the requirement for drapability of the prepreg. By their use, a high fibre volume proportion of above 50% can be achieved. The use of this material promises to considerably reduce the cycle time compared to duroplastic materials. The shaping processes that come into consideration are similar to the deep drawing process common in sheet processing. Processing for laminate manufacture using a cold forming press is also possible (Fig. 2), above all with PA 12 as the matrix polymer.

One differentiates between stiff and bendable prepregs. The fibres should be embedded into the matrix as homogeneously as possible so that a high fibre/matrix adhesion is achieved, without the inclusion of air bubbles. The strength of the prepreg naturally increases with an increasing fibre proportion. The limits are determined, on the one hand by the geometry of the fibres, i.e. by their maximum achievable packing density, and on the other hand by the adhesive power of the matrix. A certain layer thickness of matrix material is necessary, which depends upon the thickness of the matrix polymer. The corresponding values are thus defined depending upon the material. Based purely upon arithmetic considerations, on the assumption of a round fibre cross-section and a max. packing density, the fibre volume proportion in a circular prepreg cross-section with seven threads is 78% (Fig. 3); in a rectangular cross-section, with e.g. eight threads, this proportion is 76% (Fig. 4). In this calculation, however, one assumes that the circular fibres rest upon the surface.

The stiffness of prepregs is determined by the fibre volume proportion, the number of threads used, the total diameter of the prepreg and the fibre and matrix type. Elastic matrix materials in combination with non-rigid fibre hanks, give a prepreg that can be processed as a normal textile fibre. If the fibre volume proportion is high or if stiff thread materials are used or a matrix material with a high Shore hardness is used, the prepreg has a high stiffness and is comparable to a monofilament with regard to processability. Such prepregs can be used for example for pultrusion.

The following processes as well as starting materials can be used in the manufacture of thermoplastic fibre composite materials:

- thermoplastic foils in combination with pure textile areas;
- solvent coated fibre hanks;
- hybrid yarns, consisting of reinforcing fibres and thermoplastic matrix fibres;
- powder coated fibres;
- melt impregnated prepregs.

For environmental reasons, the processing of solvents in the impregnation of fibre hanks should be viewed particularly critically, because toxic solvents are necessary for most thermoplastics. Furthermore, often only amorphous thermoplastics can be processed in this manner. In hybrid yarns both fibre components lie parallel to the fibre hank, whereby a certain mixing of the fibre components arises through air turbulence. However, fibre mixing can also be achieved by spinning or winding processes, although these processes do not achieve a homogeneous mixing of the fibres. In powder coated fibres the matrix material is mainly only applied

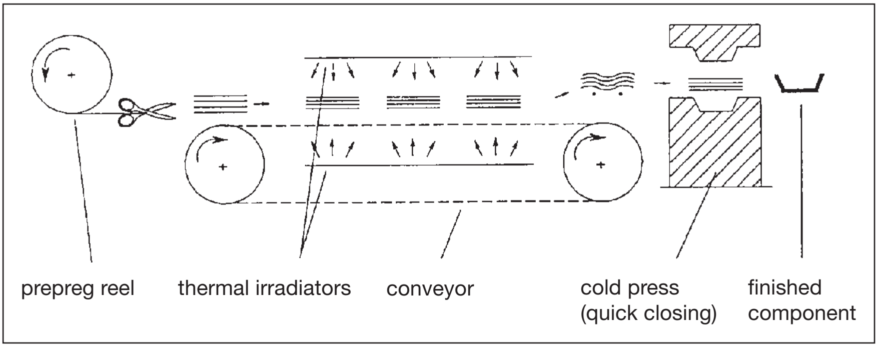

Fig. 2: The manufacture of components using VESTOPREG and a cold forming press (Hüls).

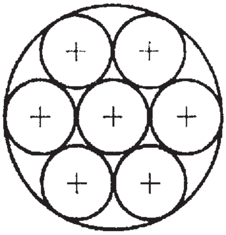
fibre volume ratio
theory (maximum packing density, obtained by calculation)
round cross-section:

7 threads: diameter d, radius r
Prepreg: diameter D = 3 d; radius R = 3 r



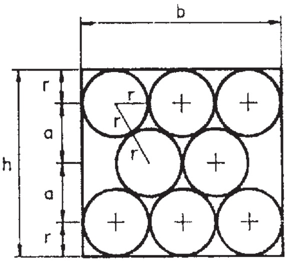
$$\text{fibre volume ratio } V_F = \frac{\text{area threads}}{\text{area prepreg}}$$

$$V_F = \frac{7\pi r^2}{\pi R^2}$$

$$= \frac{7\pi r^2}{9\pi r^2} = 0{,}78 \dashrightarrow 78\ \%$$

Fig. 3: The fibre volume ratio of a round cross-section (Planck).

rectangular cross-section:
8 threads: diameter d, radius r
prepreg area: $F_P = b \times h$
whereby $b = 3D = 6r$
$h = 2r + 2a$
$a^2 = 4r^2 - r^2 = 3r^2$
$a = r\sqrt{3}$
$h = 2r + 2r\sqrt{3} = 2r(1 + \sqrt{3})$
$= 5{,}46\ r$
$F_P = 6r \times 5.46\ r = 32.8\ r^2$



$$V_F = \frac{F_F}{F_P} = \frac{8\pi r^2}{32.8\ r^2} = 0.76 \dashrightarrow 76\ \%$$

in practice: limitation: adequate matrix/thread adhesion
--> adequate matrix thickness

empirical limit for adequate matrix / fibre adhesion: max. approx. 65 %

Fig. 4: The fibre volume ratio of a rectangular cross-section (Planck).

to the exterior surface of the reinforcing fibre hanks. When the textile is pressed in the component mould under pressure and heat, the thermoplastic component melts and in the ideal case penetrates into the reinforcing fibres. The reinforcing fibres are however compacted by the applied pressure. This brings the individual filaments together, so that, based upon the filter effect, only a low penetration of the matrix into the reinforcing hank is possible. This can only be improved slightly by the use of a vacuum (according to Planck).

Pre-printed resist →: Half-tone resists; Resist printing.

Prescouring agent (prewashing agent). System washing agent for prewashing in the two bath process. Should wet, swell, increase dirt viscosity and dissolve dirt. Prewashing agents contain less wash-active substances compared to the subsequently used → Fabric clean washing agent, more or less alkali and no bleaching additive.

Preservative Used to protect textiles and finishing substances (sizes, printing thickeners) against decomposition due to micro-organisms. Common preservatives in textile finishing are fungicides and bacterial poisons, often typical → Disinfectants, which should be used with care. In the preservation of textiles one differentiates between active and passive finishes. Active procedures are based upon the use of preservatives. Passive protection against the rotting of textiles is achieved by acetylization and the application of e.g. melamine formaldehyde condensates. Requirements of preservatives: safe action, fibre preserving, not aggressive to the materials of the treatment vessels, skin compatibility, low toxicity, easy application (in water) and washing fastness for the final finishing of textiles. In addition to formaldehyde, the following preservatives can be used for finishes and rot-proof finishing of textiles: salicylic acid, organic copper salts (copper soaps, copper-naphthenate, etc.). Chlorinated phenol (pentachlorophenol, lauryl pentachlorophenol, dihydroxydichlorodiphenylmethane), salicylanilide and bromine derivatives of salicylanilide, organic tin compounds (bis tributyl tin oxide), organic mercury compounds (phenylmercuric acetate) and also quaternary ammonium compounds. From an ecological point of view all the preservatives mentioned are problematic.

Presetter Used for the presetting of unsewn hosiery blanks, for fixing hosiery or socks made of polyamide (→ Hosiery setting) and for the relaxing of tufted carpets (→ Carpet pre-steamer). Working method for hosiery in saturated steam process with or without vacuum plant.

Pre-setting → Heat setting at temperatures that lie below the softening range of synthetic fibres, so that they are protected against creasing and folding in subsequent finishing operations, specifically wet processes.

Pre-shrink Steam or hot water pre-treatment for textured yarn for the development of texture.

Preshrunk Quality term for material that has been relaxed to the degree that under the effect of a normal ironing the length and width of the sample decrease by no more than ± 1% (→: Shrinkage; Sanforize). Such a material may still have a press lustre, for example, (final treatment on the flat press) which is not itself fast to hot pressing or spotting.

Pressboard Special cardboard, which is used as glazed millboard in → Flat press and is placed between the layers of material.

Pressboard press → Flat press.

Pressing Finishing character work. Relief printing treatment for the refinement of appearance and handle, particularly on wool, silk, viscose fabrics, etc. that are sensitive to roller printing. Usually performed prior to decatizing and before cutting and also immediately before completion. The → Flat press, one of the oldest devices in the cloth industry, is usually used for wool and wool mix fabrics, which are folded edge to edge with intermediate layers of polished pressboard inserted; electrically heated boards are inserted between each pack, and every 3–5 cm this is replaced by an electrically heated pressboard. The entire pack, consisting of different pieces, one on top of the other, is enclosed at the top and bottom by two thick sheets of cardboard (fire-resistant cover) and is usually left overnight in a hydraulic press at a pressure of 100–600 bar. The most common procedure is re-cutting with the break points of the first pressing in the middle of the pack, and then pressing again. Achieving the particular pressing effect by a flat press is labour intensive, and thus costly, so the flat press is rarely used.

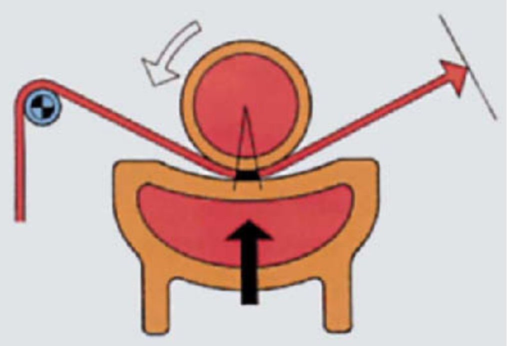


Fig. 1: Diagram of a rotary cloth press.

The rotary cloth press or cylinder press works quicker, is cheaper to run and guarantees fold-free material. However, the effect is not always as good and as permanent and, furthermore, slight loss of width and longitudinal stretch can occur. The machine (Fig. 1) consists of a rotating, heated cylinder, the underside of which travels on a semicircular, also heated, finely polished adjustable basin. Numerous rotary cloth presses have brush rollers and a steaming device at the material entry point. The material passes between cylinder and basin, this is necessary in order to exclude unwanted sheen, with an endless felt backcloth between the material and basin or cylinder. In the felt press, which, in principle, corresponds with the rotary cloth press, there is felt either around the cylinder or in the basin to prevent any sheen effect. The felt press is therefore used

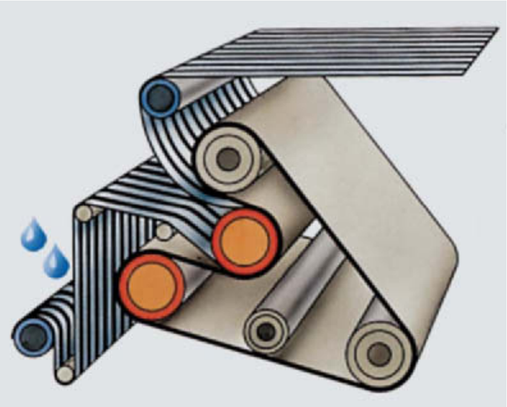

Fig. 2: Diagram of a contipress machine by Menscher.

for matt finishes and in finished pressing. The danger of width losses and longitudinal stretching associated with the rotary cloth press is almost ruled out in the felt press, which means it is also suitable for shrinkproof material and material that is ready for making-up.

In the conventional rotary cloth press, the friction between the stationary basin and the rotating pressure roller stretches the material by up to 6%. The contipress process guarantees stretch-free pressing because there is no relative movement during pressing (Fig. 2). In the contipress (Menschner) all rollers run synchronously. The material is thus not pulled through the machine. A special pressure band presses the material against an effect roller with controllable surface pressure (Fig. 3). Both elements are heated independently of each other. Moistened material is thereby placed under extreme surface pressure at a comparatively high temperature, with a marked sweating and fixing process being produced with pressure. Moisture, temperature and surface pressure (decisive factors for the fixing process) are available simultaneously. The pressure effect is achieved more intensively over an incomparably longer route. This has opened up new fields of application, not only for wool, but also for wool mix fabrics, cotton and cotton mix fabrics.

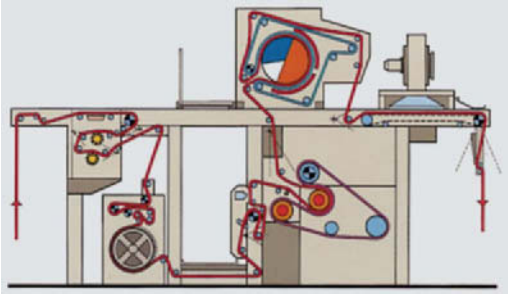

Fig. 3: Contipress machine by Menscher with pin-wheel take-up and with chilling unit at the run-out.

Pressing marks The accidental occurrence of “stripy”, curved or wavy folds or pleats as a result of unskilled ironing.

Pressley-Index (P.I.). Pressley ratio (P.R.), Pressley strength weight ratio. Describes the fibre bundle tensile strength (fibre strength) of cotton fibres. A parallelized fibre bundle is held in the Pressley tester by means of two clamps, the tensile force is achieved by a weight. The P.I. is calculated from the measured tensile force and the weight of the fibre bundle.

Press packing dye tubes →: Dyeing tubes for yarn dyeing; Plastic dye tube properties.

Pressure Mechanical tension. The derived SI unit is the Pascal (unit symbol: Pa).

$$1\ \text{Pa} = 1\ \frac{\text{N}}{\text{m}^2} = 10^{-4}\ \frac{\text{N}}{\text{cm}^2};\ 1\ \frac{\text{N}}{\text{cm}^2} = 10\ \text{kPa}$$

Special name for the tenth part of the mega pascal (MPa) is the Bar (unit symbol: bar):
1 bar = 0.1 Mpa = 100 kPa = 10^2 kPa = 10^5 Pa
1 bar = 1000 mbar
The previously used Torr, at., and kp/cm^2 units are no longer permitted:
1 mbar = 0.750 062 Torr

$$1\ \text{bar} = 1{,}019\ 716\ 21\ \frac{\text{kp}}{\text{cm}^2} = 1{,}019\ 716\ 21\ \text{at}$$

Pressure adhesion With hot melt foils for laminating fabric surfaces (see Fig.: pressure adhesion systems (Guttacoll)). Continuous roller pressure (calender) with IR preheating of the foil. Roller cloth pressure for gentler pressure. Discontinuous working method for small parts. Thermoform laminating, with the shaping pressure generated by vacuum, the shaping body is perforated and evacuated during the shaping process (heating from above).

Pressure boiler Autoclaves for the preparation of starch, rubber or tragacanth thickeners. The boiling time is reduced with temperatures above 100°C; thickeners are highly homogeneous.

Pressure difference in beam dyeing The most common way of checking the differential pressure or making a target-actual comparison during dyeing is as follows: Starting from no-load operation, i.e. with the bypass open or the butterfly valve almost closed and with the liquor temperature as high as possible, the beam dyer begins, during the next 2–5 minutes, to continuously close the bypass or open the butterfly valve. The differential pressure in which this results is then used for an actual comparison with a beam dyed batch of the same type which has already been dyed, which tells the dyer whether he can continue the dyeing process (if the target-actual difference is < 15%) or should interrupt the process, because at a higher differential pressure (> 15%) there is a high probability that another yarn package is present, that there are higher axial liquor losses, because the covering width is not correct or the covering collar has slipped, that the beam dyeing yarn package was wound on another machine or with different tension, etc. The foreman then uses his experience to decide whether to continue dyeing at this target differential, despite the high risk of false dyeing, whether to use additional dyeing auxiliaries or lower heating-up rate, or to interrupt dyeing and rectify the causes by rewinding, etc. It is therefore advisable to make an actual target comparison of differential pres-

Pressure difference in beam dyeing

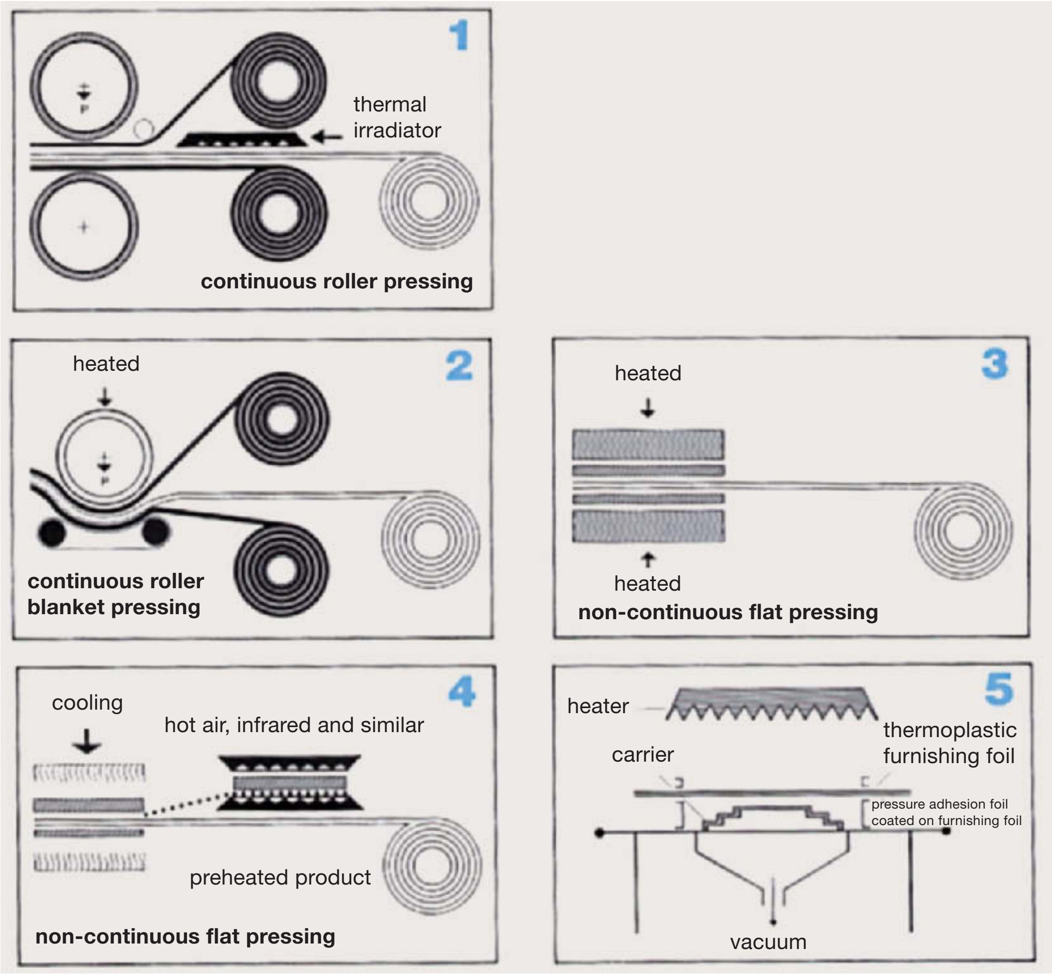

Fig.: Pressure adhesion systems (Guttacoll).

sure in critical batches before adding the dye, because dyeing time and the costs of false dyeing are saved.

The axial liquor content increases as the yarn package width falls, i.e. given the same beam package weight, the proportional axial liquor loss is greater for narrower yarn packages. This results in greater levelling or dyeing risks with narrower yarn packages (and the lower risk of oversized beam dyed yarn packages). Therefore it is advisable to reduce the yarn package height h_L of narrow yarn packages roughly in proportion to the yarn package width $\sqrt{b_T}$. For example, if a yarn package width of $b_T = 1.50$ m is dyed with a yarn package height of $h_L = 0.30$m then a narrow yarn package of the same item where $b_T = 1.00$ m should be dyed with a yarn package height of $h_L = \sqrt{1.00/1.50} \cdot 0.030 = 0.25$ m (Fig. 1).

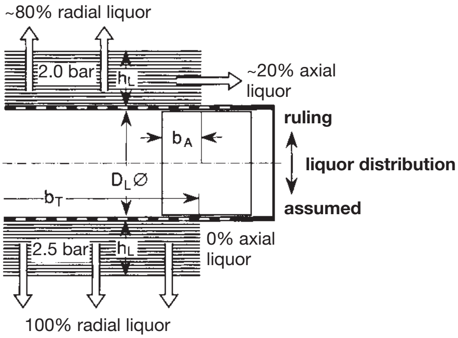

Fig. 1: Schematic example of radial and axial liquor distribution in a flooded beam dyed yarn package and covering cuff arrangement (Kretschmer).

Frictional forces as a function of viscosity are responsible for the pressure loss between inside and outside. Darcy's law applies here:

$$D_f = -\frac{k \cdot F}{\eta} \cdot \left(\frac{\Delta p}{\Delta x} + \rho \cdot g\right)$$

D_f = flow per unit time,
F = area,
η = dynamic viscosity,
Δp = pressure reduction,
Δx = distance over which pressure falls,
ρ = density of the liquid,
g = acceleration due to gravity,
k = constant, which depends only upon the properties of the porous material.

The constant k is described in the theory of permeability as a function of porosity ε and specific surface F_0:

$$k = c \cdot \frac{\varepsilon^3}{F_0(1-\varepsilon)^2}$$

$$\varepsilon = \frac{\text{solid matter volume}}{\text{total volume}}, \qquad F_0 = \frac{\text{solid matter surface}}{\text{solid matter volume}}$$

c = constant

The equation illustrates the strong influence of packing density upon the relationship of flow per unit time D_f/pressure reduction Δp.

At each flow speed a Reynolds number can be allocated according to the relationship:

$$Re = \frac{w \cdot d}{\nu}$$

w = flow velocity,
d = average pore diameter,
ν = kinematic viscosity.

If this falls below a so-called critical Reynolds number then inertial forces act in addition to frictional forces, which leads to the formation of a vortex. This value fluctuates from $Re_{crit.} = 0.1$ through $Re_{crit.} = 1$ to $Re_{crit.} = 75$. It is therefore not possible to quote a critical Reynolds number for all porous materials, above which Darcy's law, i.e. the linear relationship between flow quantity or velocity and pressure reduction, no longer applies. Furthermore, it is difficult to calculate the Reynolds number for flows in textile yarn packages because the average pore diameter (d) cannot be determined with sufficient accuracy. The reason for this difficulty is that the proportion of flow through the yarn filaments, compared to the proportion of flow through free volume, i.e. around the yarn, is dependent upon the packing density. For the practical case of a cotton cross-wound yarn package with a packing density of 0.23 g/cm^3, it has been calculated that only 6% of the total flow goes through the yarn. This percentage increases with higher packing densities. It should also be borne in mind that the flow rate in the yarn package is inversely proportional to the radius. Therefore, there may be areas within the yarn package, where the flow is laminar and Darcy's law applies, and areas where there is turbulence.

Above this critical flow rate the pressure reduction Δp over the flow distance Δx depends upon a quadratic component D_f^2 in addition to the linear proportion of the flow over time D_f. Where a and b are constants:

$$\frac{\Delta p}{\Delta x} = a \cdot D_f + b \cdot D_f^2$$

Pairs of hollow measuring needles are arranged in the yarn package to detect the pressure difference, and are connected to pressure differential detectors outside the dyeing equipment by heat resistant tubes and pipes fitted with a pressure tight seal into a flange (Fig. 2). In these differential pressure detectors an extended wire element is part of a Wheatstone bridge. Pressure changes are transmitted via a membrane on the extended wire element and effect a change in resistance and thus a shift of the bridge equilibrium. Bridge supply, output signal rectification and amplification are performed by a carrier frequency measuring amplifier. The output voltages are proportional to the differential pressures and are drawn by a multilinear recorder. Total pressure in the dyeing equipment and the liquor temperature can also be registered on this recorder (according to Kretschmer and Glander).

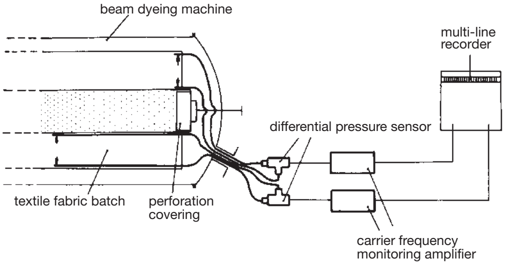

Fig. 2: Construction principle of a differential pressure measuring unit on a beam dyeing machine (Glander).

Pressure drier In this drier the system is completely closed and pressurised, up to 8 bar. The moisture is extracted from the circulating air via a cooler, heated up and fed back into the boiler; the water is removed by a separator. → Yarn dryer, air stream.

Pressure kier Wrought iron autoclaves for the kier boiling of loose stock, yarn, wound packages and piece material.

Pressure regulator Device based on the principle of fine control with a pressure sensor (impulse unit) and remote transmission (by compressed air, liquid or electric current), whereby the pressure in pipes (air, water, steam, gas) is automatically controlled by control equipment (motor-driven, reducing and shut-off valve). Application: For steam boiler operation; hydraulic and pneumatically operated components; as throttling controller, volume controller, circulation regulator, etc.

Pressure screws for printing rollers Steel spindles onto which the printing roller cylinder is screwed.

Pressure steamer Continuous steamer for steaming at temperatures above 100°C for developing pad dyeings and prints or HT bleaches. Discontinuous for combed tops (vigoureux) printing, loose material and piece goods. → HT pressure steamer.

Pressure steamer for hosiery For all types of forming processes for the preforming (preboarding) of undyed polyamide hosiery or socks, for forming dyed hosiery that has not yet been preformed (postboarding, recommended prior steaming of the unsewn hosiery blanks) and for subsequent forming (finish boarding).

Pressure steaming process Fixing, for example, of disperse dyes in the pressure steamer at 130°C with saturated steam. Application on polyester combed tops and spun tow. → Thermosol dyeing processes.

Pressure vessels All vessels or pipe layouts in which, when in use, there is a positive operating pressure greater than 0.1 bar or a negative operating pressure of under 0.2 bar. The directive regarding “Pressure vessels, pressurised gas vessels and filling plants” has been in existence since 1.7.1980 as the so-called Pressure Vessels Regulation ZH 1/400, available free of charge from the responsible textiles and clothing professional and technical associations. In the operation of HT dyeing machines it should be noted that material handling takes place under hydrostatic pressure at liquor temperatures well above boiling point. Due to these high liquor temperatures, even after the pressure inside the boiler or equipment has been reduced to atmospheric pressure (by opening the pressure valves and cocks, which are sometimes mechanically operated) so-called heat pockets may arise with temperatures above 100°C, which may once again bring the hot liquor to the boil. Due to sudden re-evaporation and the increase in pressure, the loosened, but not yet raised lid can be flung off and the contents explosively ejected, exposing the operating personnel to extreme danger. It is important to observe the following operating rules:

1. The boiler or device lid must never be opened immediately after the pressure has been released from the container.
2. Do not open the cover lock until you are certain that the temperature of the charge and the liquor has fallen to 80°C. It is then advisable, either to discharge the liquor prior to opening the vessel, or to pump it back into the preparation vessel (when charging with warp beams or crosswound yarn packages, etc.), or to rinse the vessel with cold water or cold liquor for a long period before opening (charging with loose material, flock, ropes, etc.).
3. The pressure pipes and valves should be checked on a regular basis for blockages due to clumps of fibres, etc.

Pressure Vessels Regulation HT equipment and vessels, in which gas can be formed (e.g. during bleaching with peroxide) are subject to this regulation. According to paragraph 3.1.2 of the “Technical Regulations Concerning Pressure Vessels TRB 403”, safety devices to prevent excess pressure must be designed such that when the permissible operating pressure has been exceeded by 10% the maximum mass flow can be discharged. According to section 3.1.3 of TRB 403, rupture disks should be used instead of safety valves, which cannot discharge the mass flows that occur, for example, due to the sudden formation of gas or steam. A further contribution can be made to increasing safety by designing pressure vessels for a higher maximum operating pressure.

Pretreatment All processes for the improvement of wetting capacity and absorption, dye take-up capacity, purity of the textile material, to increase the degree of whiteness and for better material development, i.e. for relaxing and structure development. At the same time tension (Figs. 1 and 2) and material non-uniformity (Fig. 3) arising from prior weaving and knitting processes should be removed.

In general, this finishing stage should take place in an intensive, but low tension process, in order to prevent relaxation and fabric compacting. Different processes and machines are required for the generation of the above-mentioned effects, depending upon material and requirements.

The raw material contains natural impurities such as grease, pigments or mineral substances and artificial or accidentally applied substances, e.g. sizes, mineral oil specks, caused during weaving, etc. All these impurities must be removed because they impair subsequent finishing. Precise analysis methods facilitate the detection of the different criteria of the pretreatment effects. Special machines, processes and products are necessary for removing the impurities without significant fibre damage.

Correct pretreatment is therefore dependent upon:

– the substrate (natural or synthetic fibres),

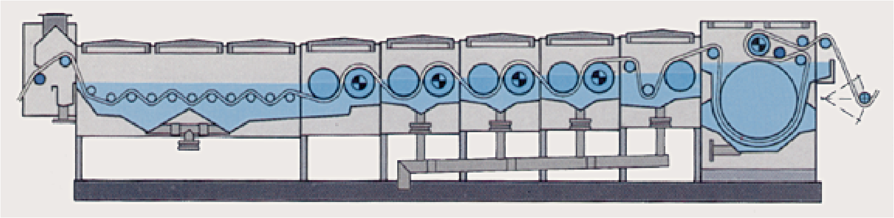

Fig. 1: "Flipper" (Küsters) for relaxation washing.

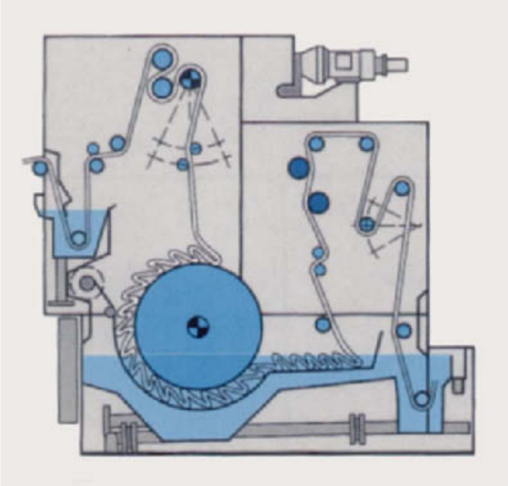

Fig. 2: Open-width rotary washing machine for low-tension washing (Küsters).

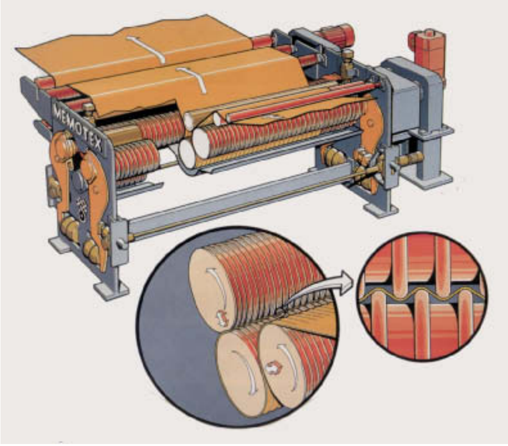

Fig. 3: Memotex woven fabric stretching machine for levelling out material irregularities (Küsters).

- making up form (fabric, knitted material, etc.),
- the procedure (desizing, scouring, alkali treatment, bleaching),
- the machines (continuous, discontinuous, semi-continuous),
- the chemicals (enzymes, wetting, washing, complexing, stabilizing, reducing, oxidizing, anti-foaming agents, etc.).

Numerous machines are available for pretreatment. The main continuous processes use pad-steam, J-box, U-box and immersion devices. The material flow speed is an important factor. Below 50 m/min counts as low speed and above 100 m/min high speed.

There are also discontinuous pretreatment devices, namely the winch beck, the jigger, the jet or autoclaves. The liquor ratio plays an important role. The individual process stages follow each other, whereby each step requires its own setting-up time.

In the semi-continuous process approx. 2000–5000 m of material are impregnated and treated for a dwelling time of 12–24 h at room temperature (pad batch) or 1–3 h using saturated steam feed (pad roll) (Fig. 4).

The following units are always needed in all pretreatment combination processes:

- impregnation unit (wetting trough, sieve drum, roller vat),
- dwelling section for time processes (under/over liquor, in steam environment).
- intensive washing units for the removal of impurities and chemicals,
- drying unit.

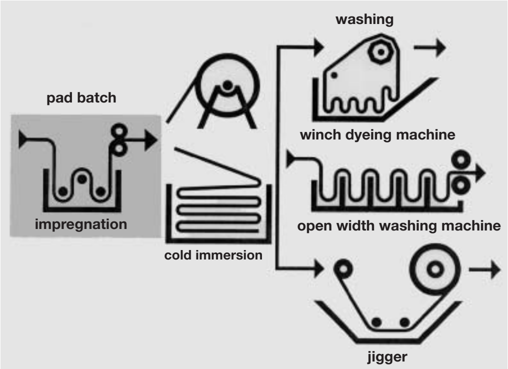

Fig. 4: A typical pad-batch situation in the pretreatment of cotton fabric.

Pretreatment for printing

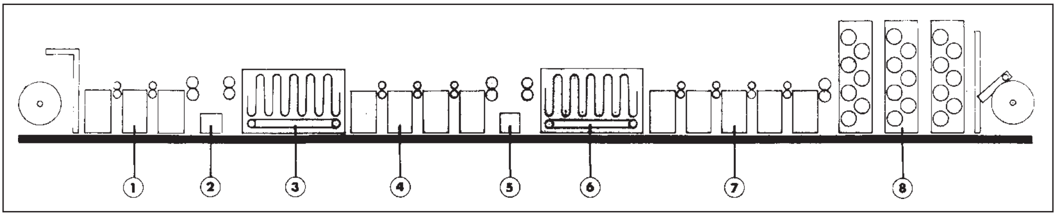

Fig. 5: A three-stage conventional pretreatment facility for desizing, scouring and bleaching cotton fabrics. 1 = washing out the degraded starch; 2 = impregnation with sodium hydroxide ready for the scouring stage; 3 = scouring stage steamer; 4 = roller vats for washing out the degraded products from the preceding stage; 5 = impregnation with hydrogen peroxide; 6 = peroxide steamer; 7 = washing following the bleaching stage; 8 = cylinder driers.

The following are amongst the pretreatment processes (Fig. 5):
- scouring,
- bleaching,
- desizing.

The Tab. illustrates the energy and water consumption in cotton pretreatment.

facility/plant components	final quantities consumed	
	water l/kg goods	steam without heat recovery kg/kg goods
conventional pretreatment		
1. pre-washing following desizing	4	0.6
2. impregnation with sodium hydroxide	1	–
3. immersion in combinination steamer box for scouring	–	0.5
4. washing following scouring	4	0.6
5. impregnation with hydrogen peroxide	1	–
6. immersion in combination steamer box for bleaching	–	0.5
7. washing following bleaching	6	0.9
8. cylinder drier	–	0.9
in total	16	4.0

Tab.: The requirements for energy and water consumption in cotton pretreatment (Kleinewefers KTM).

Pretreatment for printing The greatest proportion of these items are those made of 100% cotton. Specific requirements are imposed with regard to absorbency (wettability), dimensional stability and uniform whiteness with the greatest fibre protection. The quality of the print is dependent upon the absorbency of the material. The absorbency must be high if the print is to be visible on the reverse of the material. The dye consumption is thus correspondingly higher. If the print only needs to be faultless on the right side, then a deep effect is not necessary. Pretreatment therefore needs to be directed towards the demands of the printer. The classic process is 4-stage: desizing, mercerizing, alkali treatment and peroxide bleaching. Depending upon the quality of the fabric and the demands on the finished material, open-width treatment or treatment in rope form are possible for stages 1, 3 and 4. The trend is towards continuous treatment in open-width form.

Pretreatment jigger For desizing, bleaching, scouring and rinsing, also for impregnation during pad-roll bleaching.

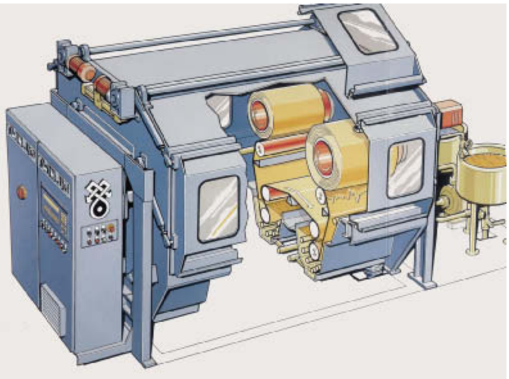

Fig.: Twin-Jig (Küsters) for dyeing and for batch-type pretreatment.

The pretreatment jigger counter-current water feed, (see Fig.) from the front to the rear basin is available for washing processes. An adjustable height spreading pipe between the basins improves liquor separation. Pressure rollers, which are pressed against the batching roller with adjustable pressure, ensure additional liquor exchange. Material feed problems, which occur with certain items due to liquor wrapping, are avoided with pressure rollers.

Pretreatment of cotton The raw cotton and the fabric produced from it contain non-cellulosic attendant substances and impurities. The impurities, such as seed shells, pectin, wax, etc. can have a detrimental effect upon the cotton finishing, because they are generally present in varying quantities and in a non-uniform distribution. The task of pretreatment is to use physical, chemical and biological processes, to largely and uniformly free the cotton from attendant substances in order to achieve a high and consistent dye take-up capacity and as high and uniform level of absorbency as possible. Furthermore, the cotton must be shell free and have a high DP value. The degree of whiteness is not always the most important quality feature, because the material is only lightened sufficiently to guarantee the colour shade and the brilliance of the dye or print. The quality of a dye or print depends upon the correct performance of the pretreatment (Fig. 1).

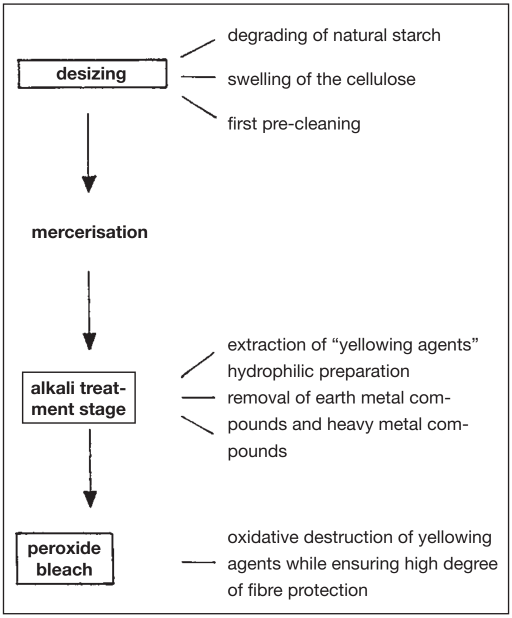

Fig. 1: The pretreatment of 100% cotton fabric for dyeing and printing.

The task of pretreatment is to remove substances from the raw material, which are brought into the cotton in the form of natural and process-related attendant substances by means of processes like singeing, desizing, alkali scouring, acid treatment and bleaching, with the associated passage of water (Tab. 1).

The attempt to reduce the aims of cotton pretreatment to a common denominator could be formulated as follows; preparation of a textile material, which as far as possible satisfies the demands of the subsequent finishing stages in dyeing, printing, and/or finishing.

naturally occuring	*arising through processing*
hemicellulose, pectins	size
proteins	fats
seed husks	oils
remnants of fruit capsules	waxes
pigmenting substances	metal filings
immature cotton	
salts	

Tab. 1: Contaminants in cotton.

Procedures and recipes, once worked out, should be reproducible without major modifications and loss of time at a low cost. Not only the interests of the dyeing and printing company must be taken into account, but also the mechanical and chemical final finishing: requirements, including those relating to crease resistance and dimensional stability, are becoming ever more demanding.

Pretreatment can make a critical contribution towards achieving the technological values, because important chemical properties are attained and mechanical damage such as the formation of folds, crease marks and uncontrolled stretching of the material are prevented (Tab. 2).

chemical technological	mechanical technology
rapid re-wetting high degree of absorption low ash content free of size level of whiteness shell-blemish free high dye take-up capability	evenness of styling effects (edge-centre-edge longitudinally and as a cross-section of the fibre and thread structure) dimensional stability freedom from folds and creases

Tab. 2: Requirements applying to the pretreatment processing of cotton piece goods.

In addition to these criteria, which can usually be clearly defined and the value of which can alter the application purpose of the material, managers are also interested in processes with:
- good safety,
- good reproducibility for different cotton provenances,
- applicability for all types of sizes,
- applicability on as many and varied items as possible,
- favourable cost/performance ratio.

Many faults can occur during pretreatment (Tab. 3).

Pretreatment can be performed as rope or in open-width form, in bound or free material feed (Fig. 2).

Pretreatment of cotton

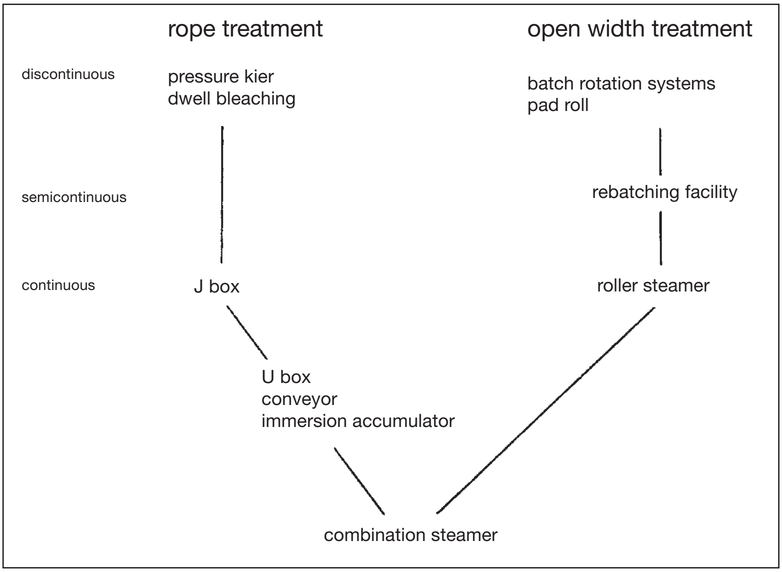

Fig. 2: The development of pretreatment facilities.

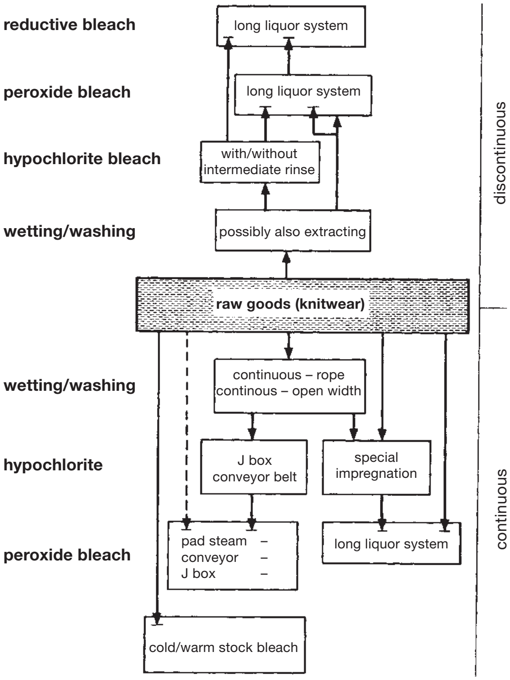
impurities	colouristic effects
coloured soils	lower degree of whiteness (mostly red-cast)
seed husks, leaf and stem residues, neps	restless fabric appearance
residual matter: – insecticides – growth regulating agents – defoliants	staining, resisting
metal traces	rust spots, bleaching damage, holes
foreign fibres, fibre fly	resisting, coloured ends
size and spin finish residues	unlevelness, resisting
lubricating oil and graphite residues	light/dark spots
soiling, e.g. dust	unlevelness, resisting

Tab. 3: Possible fault causes in pretreatment.

Fabrics (e.g. woven and knitted material) are pretreated (Figs. 3 and 4).

Pretreatment is carried out continuously or discontinuously depending upon the item and batch size (Tab. 4). Fig. 5 shows the classic operation sequence in pretreatment on a continuous line for cotton or mixed fabric. The mercerization (alkali treatment) may be dispensed with.

For environmental reasons, only bleaching with peroxide is recommended, because hypochlorite produces high AOX values in waste water. If only a single stage peroxide bleach is desired, it is recommended that normal moisture application (Fig. 6 and Tab. 5) wet-in-wet is dispensed with in favour of high moisture application (Fig. 7).



optional brightening agents may be added either during the peroxide bleach or during the reductive bleach stage

Tab. 5: Various normal humidity coating systems in classic cotton pretreatment (CRC by Sandoz).

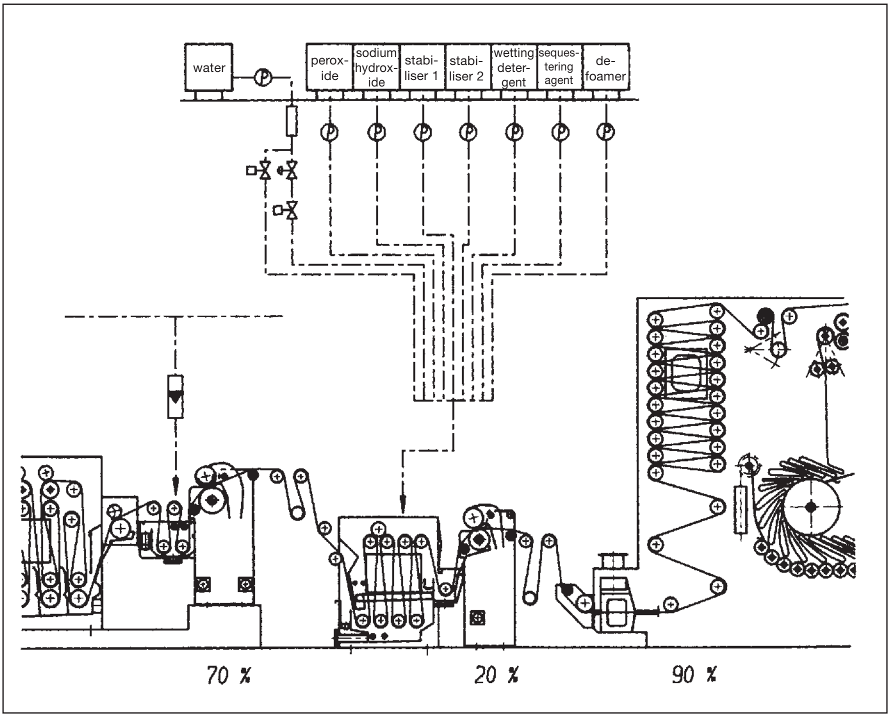

Fig. 6: Wet-in-wet liquor application including the impregnation stage.

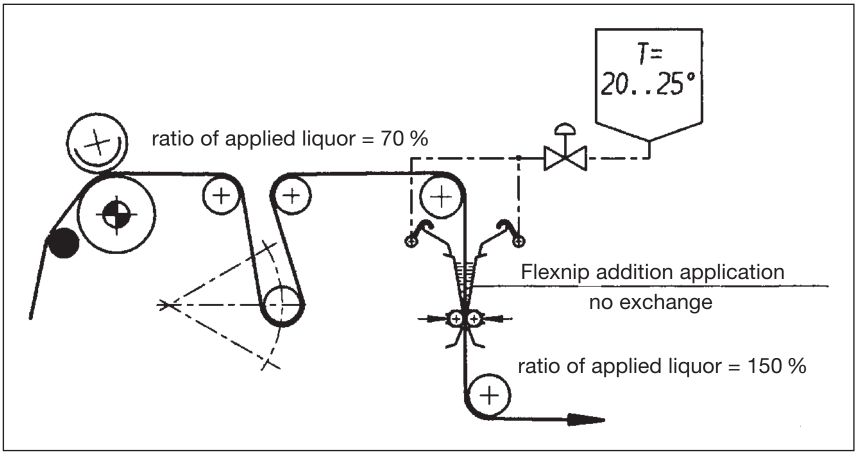

Fig. 7: Liquor addition application (Küsters Flexnip).

Higher degrees of whiteness are achieved using the pad-steam process with a longer liquor ratio. Using flexnip high moisture application, the material to be bleached is put into the steamer for peroxide bleaching with 150% liquor application (Figs. 7 and 11).

In order to make the pretreatment as reproducible as possible, it is recommended that the necessary chemicals are dosed according to consumption (Fig. 8).

High moisture application can also be achieved by the wet-in-wet process with two horizontal padders (1st horizontal two-bowl padder, 2nd padder “split”); this is achieved in the Optimax (Fig. 10). Maximum liquor application is desirable in textile pretreatment. New procedures facilitate, e.g. the combining of the scouring and bleaching processes into a single pretreatment stage following desizing. In the Optimax process total residual liquor values of approx. 150% of the dry weight of the material are measured in cotton twill material (Fig. 10). A section of the continuous pretreatment plant is shown in Fig. 9. After the washing out of the desized material on a tower open-width washing machine, the pretreatment liquor is applied in the subsequent application device. Because this is an addition application process, there is no dilution of the liquor. The continuous titration of the liquor can therefore be dispensed with. Then the material passes to a combination steamer of approx. 100 m with bound material feed and double stacking.

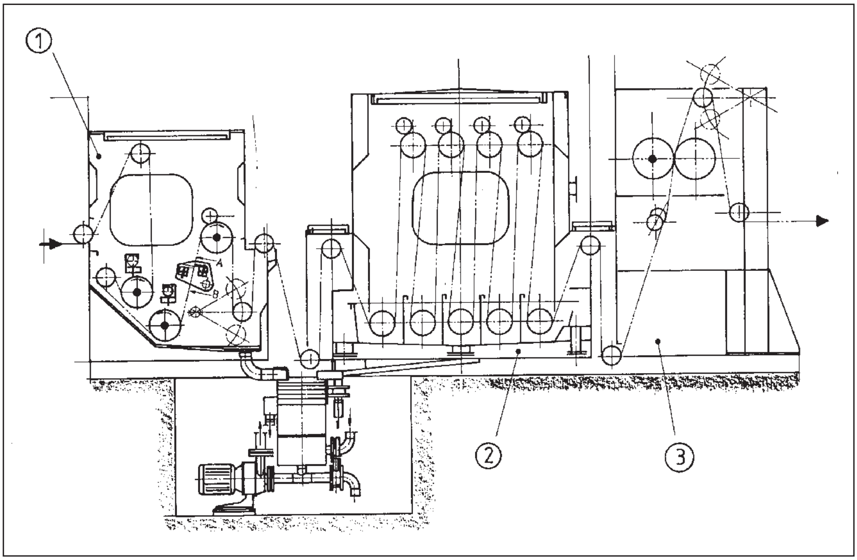

Fig. 8: Babcock Super-Sat laboratory machine for the Lower Rhine College of Technology. 1 = Super-Sat impregnating section with Polykomat dosing and recycling sump; 2 = Convitex: combined steam roller vat; 3 = squeeze traction unit.

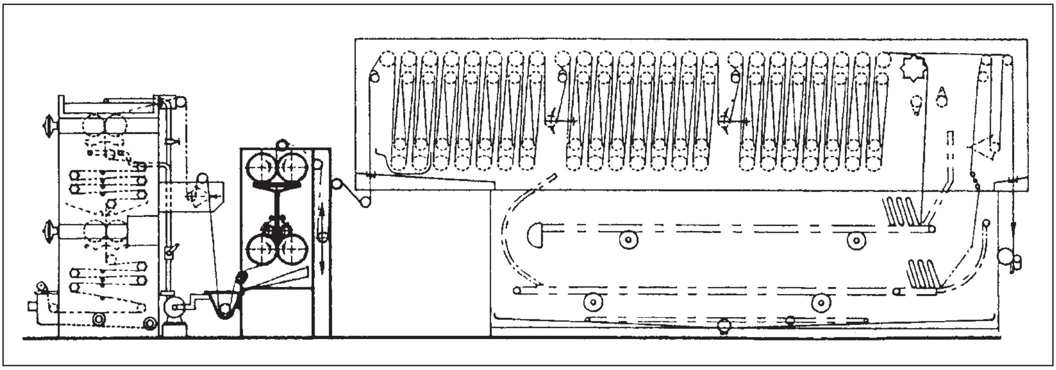

Fig. 9: Pretreatment line with Optimax applicator (Menzel).

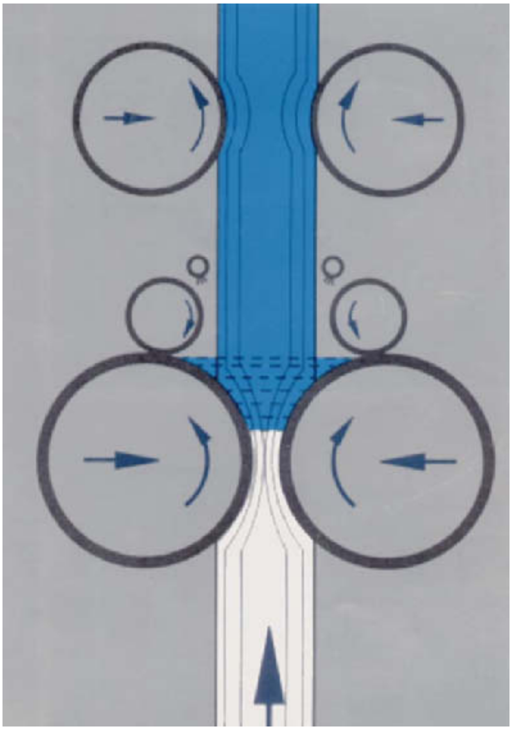

Fig. 10: Optimax high wet liquor application (Menzel).

If we compare single stage bleaching with the integrated scouring stage of the Flexnip system (Fig. 11) with the Raco-Yet process (Fig. 12), then we notice that after the hot impregnation in the Raco-Yet, shorter steaming times without free material feed (thus without dwell chambers) are possible (after the washing out of the water soluble size in a prewash) (according to Fornelli and Günther, Hager, Herlinger et al., Reineke, Rösch and Schlicht).

Pretreatment of knitgoods → Knitgoods, pretreatment.

Pretreatment of man-made fibres For the removal of preparations, softeners, sizes (see Fig.: Result of polyester fibre product pretreatment), the active surfactants are non-ionogenic products in an acid, neutral or alkaline medium depending upon the degree of soiling. In alkaline preparations synergetic mixtures of non-ionogenic/anionic components have proven themselves. There still appears to be no optimal recipe against oligomers in polyamide and polyester, with the exception of solvent-containing washing baths (e.g. tetrachloroethylene emulsions), also recommended for polyurethane fibres. In the case of polyamides, anionic surfactants can block basic groups (impairing subsequent dyeing with acid dyes). Polyacrylonitrile tends to yellow in alkaline liquors (i.e. wash acid or neutral). Polyester undergoes surface hydrolysing due to highly alkaline washing, whereas acetate fibres may not be

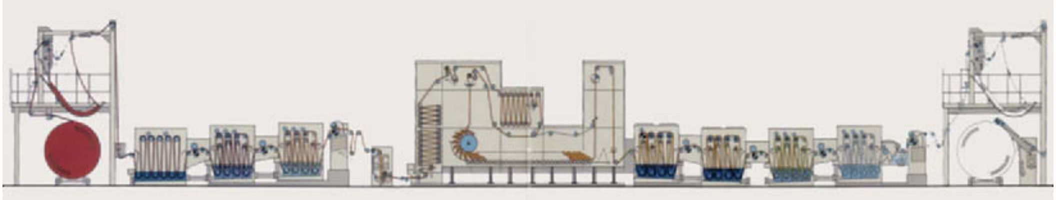

Fig. 11: Küsters cotton pretreatment with Flexnip addition application and with combi-steamer for longer steaming.

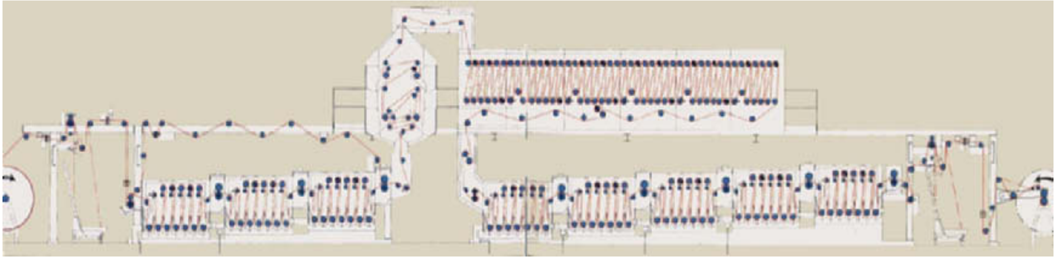

Fig. 12: Raco-Yet confined passage aerosol liquor application with short period steamer (Kleinewefers KTM).

treated at greater alkalinity than pH 9 (otherwise there is a danger of acetyl groups splitting). In regenerated cellulose with heavy metal ions catalytic hazards are possible during subsequent bleaching, thus the addition of complexing agents is advisable.

Primary cellulose acetate fibre → Triacetate fibres.

Primary colours

I. represent the three sensory powers ot the visual organ: yellow, blue, red; all other colours can be obtained from these by mixing. Mixing two primary colours yields the → Complementary colour of the third, e.g. yellow + blue = green = complementary colour of red.

II. The visual organ can achieve eight extreme sensory options. In a mixing system (→ Colour mixtures) for opaque colorants all eight colours are needed: cyan, black, green, violet blue, magenta red, white, orange red and yellow.

Primary energy carrier → Energy carriers.

Primary salts Acid salts of multivalent acids, in which only one hydrogen atom is replaced by metal; e.g. primary acid sodium phosphate NaH_2PO_4 derived from phosphoric acid H_3PO_4. →: Secondary salts; Tertiary salts.

Primer (bonding agent), if incompatible polymers (e.g. textile base fibre material and coating polymer) are nevertheless to form a composite material, a primer must be applied between the polymers. These bonding agents, in the form of block copolymers usually with two types of blocks distributed in the copolymer, are compatible both with the base material and the coating material. So the primer can be applied to the base material first, followed by the coating components (see Fig.: A coating facility for adhesive tape).

Principal valency In organic compounds each valency (→: Valency; Chemical bonds; Atomic bond) which, in contrast to the → Secondary valency forces, does not tend to dissociate and corresponds with the tetravalency of carbon.

Principal valency chains → Chain link number and chain molecules.

Print adhesives → Table adhesives.

Print bonding Procedure for the strengthening of nonwovens by the application of print pastes containing a binder and cross-linking by thermal treatment (→ Overall bonding). Print bonded fabrics are → Nonwovens, the fibre structure of which is bonded in patterns of dots. Better handle compared to full bonding. Disadvantage: lower strength.

Print coverage In textile printing the ratio of dye applied/printing area.

Print definition The so-called staying power of a print paste, i.e. the upper limit of possible thickener concentration for printing purposes (→ Flow properties of thickeners and print pastes) at which the print paste covers the fabric uniformly (not to be confused with full print penetration). At an even higher concentration, the print would already “grin”. On the other hand, the lowest limit of printability of a thickening agent is the point at which the print paste bleeds hopelessly making acceptable prints impossible. Comparative measurements of print definition (the actual extent of any tendency for the print paste to “run”) in extremely fine design contours can be carried out on the fabric to be printed or on standardised filter paper, with an appropriately engraved roller in roller printing, and with a ring, spiral or wedge stencil in screen printing.

Print-Dye process 2-stage process consisting of printing/drying and dyeing/rinsing for floor coverings. There are various processes, either mechanical displace or chemical change processes. Using the rotation printing machine, chemicals or resist agents are applied to the material in a colourless print paste. In the mechanical displace technique the fibre is coated with chemicals, so that no or only a small amount of dye take-up is possible at these points. In the chemical change technique, the paste application with resist agents brings about a change of the affinity of the polyamide fibre to the dye. Different effects, e.g. half and full tone resists, but also bright resists with a contrast effect, can be achieved. The colour change can be influenced by different concentrations of chemicals or resist agents in the print paste. After the printing process the paste application is fixed on the material in the dryer. The pre-treated material is now dyed in a dye vat, usually with a dark dye. At the points where no chemicals have been applied, the colour of the liquor in the vat appears, whereas at points where chemical has been applied, a lighter shade is generated in the upper area of the carpet pile and the base of the pile is dyed by the dyeing liquor.

Printed damask effects → Pigment printing.

Printed suede Silk screen printed suede fabric produced as piece goods for high quality womenswear and menswear.

Print flushing arises due to excessively deep engraving, inadequate absorbency of the printed material and excessive pressure by the printing roller on the material, either on one side or on both sides. Print flushings show up on the material as blurred, lacerated contours, which usually run opposite to the printing direction. Prints can be flushed by subsequent printing rollers if previous printing rollers have applied too much print paste to the material. The problem is rectified by altering the engraving depth, adding wetting agents, reducing the roller pressure or altering the viscosity of the print pastes.

Print impression method This was developed for examining the surface of engraved calender rollers and rotary screens for screen printing, and are based upon the creation of an imprint in polystyrene by means of a silicon rubber negative. The print impression method, originally developed for use with the scanning electron microscope, is now used with the stereomicroscope.

Printing Printing is local dyeing in zones according to patterns. Thickeners ensure that these zones defined by the engraved pattern are adhered to. The type and size of the artistic design determine the printing process and method of dye paste application. Various

Printed damask effects → Pigment printing.

Printed suede Silk screen printed suede fabric produced as piece goods for high quality womenswear and menswear.

Print flushing arises due to excessively deep engraving, inadequate absorbency of the printed material and excessive pressure by the printing roller on the material, either on one side or on both sides. Print flushings show up on the material as blurred, lacerated contours, which usually run opposite to the printing direction. Prints can be flushed by subsequent printing rollers if previous printing rollers have applied too much print paste to the material. The problem is rectified by altering the engraving depth, adding wetting agents, reducing the roller pressure or altering the viscosity of the print pastes.

Print impression method This was developed for examining the surface of engraved calender rollers and rotary screens for screen printing, and are based upon the creation of an imprint in polystyrene by means of a silicon rubber negative. The print impression method, originally developed for use with the scanning electron microscope, is now used with the stereomicroscope.

Printing Printing is local dyeing in zones according to patterns. Thickeners ensure that these zones defined by the engraved pattern are adhered to. The type and size of the artistic design determine the printing process and method of dye paste application. Various printing types (→: Direct printing; Discharge printing, Resist printing) and techniques (→: Roller printing; Flat screen printing; Rotary screen printing; Transfer printing) are available to the colourist for the realisation of a print idea. Each printing technique is performed according to a specific printing process, which is usually based upon a uniform sequence of operations (printing, drying, steaming, washing).

Textile materials in a wide variety of finishing stages, for example combed tops (tops printing or vigoureux printing), yarn, (yarn printing and warp printing), and hosiery goods (material or textile printing) and fleece, come into consideration as substrates for printing. The mechanism of dye take-up by the fibres in textile printing is largely identical to the procedures for dyeing in the dyeing bath. As is the case for dyeing, the dye is bound to the fibre by

- adsorption or adhesive van der Waals forces,
- formation of hydrogen bridges by dipolar forces,
- formation of salts (ionogenic bonds due to electrostatic attraction forces), e.g. between anionic dyes and ammonium or positively charged amino groups of the fibre or cationic dyes and acid groups of the fibre,
- metal-complex formation or dative bonds between dye, metal and fibre,
- homopolar or covalent bonding involving reactive hydrogen atoms of the substrate (of hydroxyl groups for cellulose or amino or imino groups for protein fibres) and reactive groups of the (reactive) dyes.

Often, however, several of these bond types work together. This gives rise to the possibility that by strengthening the auxiliary valence forces (metal complexes) that give rise to the adsorption bond or by enlarging the molecule by diazotation and coupling, the fastness properties will be improved just as much as by the conversion of a water soluble or temporarily soluble dye into a slightly soluble or non-soluble form, e.g. by splitting or conversion of the groups conveying solubility (vat leuco ester dyes, vat dyes). On the other hand, dyes from water soluble, more or less substantive components, can be synthesized into insoluble products (insoluble azo, oxidation, phthalogen dyes) on or in the fibre, for example by coupling or condensation. Reactive dyes can also be chemically bonded to the fibre. Pigment printing occupies a special position, with the insoluble pigment dye being affixed to the substrate by inclusion, i.e. incorporation into a synthetic resin film.

The most marked difference between the relationships during dyeing and printing is that dyes and chemicals are present in relatively low concentrations in the dye bath, whereas in printing they are usually combined in higher concentrations in a print paste (Fig. 1), which also contains a thickening colloid. The concentration increases still further when the print paste dries on the fibre after printing. The subsequent treatment to transfer the dye from the print paste into the fibre and for fixing is usually achieved by steaming rather than in a bath and is subject to totally different concentration relationships than is the case during dyeing.

There are three significant factors regarding the absorption of liquids by textiles: the capillarity of the substrate, and the absorbency and the wettability of the individual fibres. In order to achieve sharply delimited

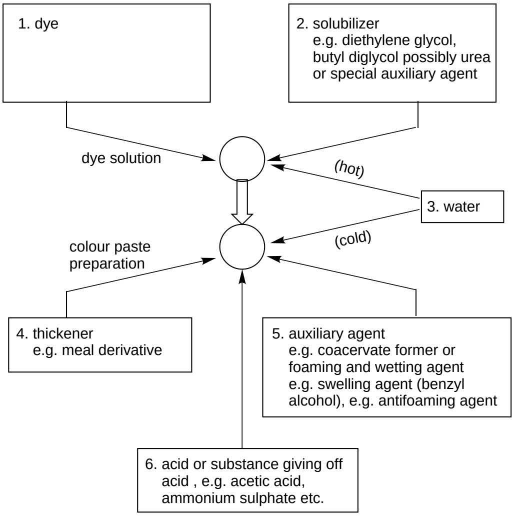

Fig. 1: Diagram of printing paste preparation for direct printing.

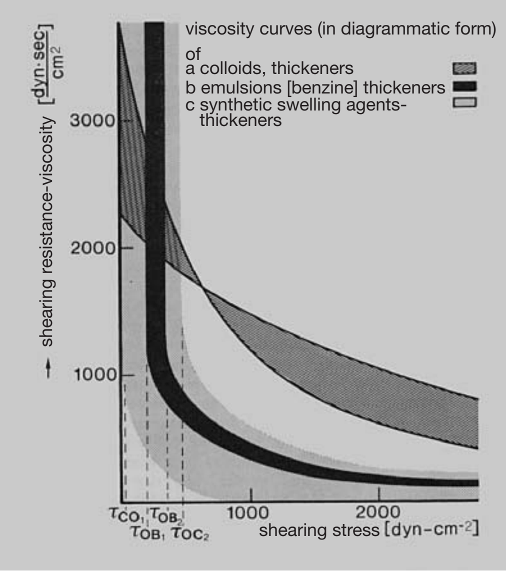

Fig. 2: Viscosity curves (in diagrammatic form, source Rasche).

print effects the capillarity of the substrate must be compensated by thickening the dye solution. Starch products, mucilages, flours, etc., which possess a high swelling capacity, are used as thickeners. The thickeners produced by adding water to these products are colloidal solutions (sols) or gels, whose main characteristic is a relatively high viscosity and a considerable, but not unlimited, water absorbency. If the environmental laws in force in the country in question still permit this, pasty emulsion thickeners of both oil-in-water and water-in-oil types with hydrocarbons (heavy gasoline, petroleum) are used as the oil phase. The dyes or chemicals are generally stirred into the thickeners in the form of aqueous solutions or dispersions.

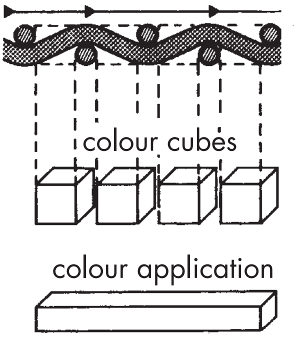

Fig. 3: Schematic representation of the printing process.

The characteristic feature of the print pastes used with thickeners is their structural viscosity (Fig. 2). If a highly viscous print paste is applied to the print screen, the tenacious print paste will not run through the screen holes provided until it is doctored. However, as soon as the doctor blade applies a shear stress to the print paste due to its pulling action the viscosity falls sharply. The thin solution flows spontaneously through the screen holes provided and comes into contact with the fabric (Fig. 3). The capillary forces of the textile now come into effect, and the solution is sucked out. However, a large proportion of the thickener remains on the surface of the fibre, because once the doctor blade has passed, the viscosity of the print paste spontaneously increases once again due to the reduction in shear stress. This prevents the print from running.

There is normally a drying process after the application of the print paste. Most of the water in the print paste evaporates during this stage; the paste dries to form a film, which adheres only to the surface of the fibre. Depending upon the type and composition of the thickener such films differ in their structure and their swelling capacity and water absorbency. In addition to these factors, the delivery of dye to the fibre when moisture is subsequently applied also depends upon the type of bond between dye and thickener and the penetration depth of the print paste into the textile material during the print process. This is the reason for differences in the quality of the colour depth and in the colour yield when different thickeners are used.

The dye and effective substances are usually transferred into the fibre by steaming, i.e. by a short or long period of residence in a steam atmosphere, and transfer can also be promoted by appropriate measures, such as the addition of wetting agents, dispersal agents, swelling agents or solvents to the print paste. During steaming both fibres and, in particular, the thickener absorb water from the steam and swell. The dye particles and chemicals are dissolved once again and diffuse. The diffusion of dyes and chemicals from the print paste

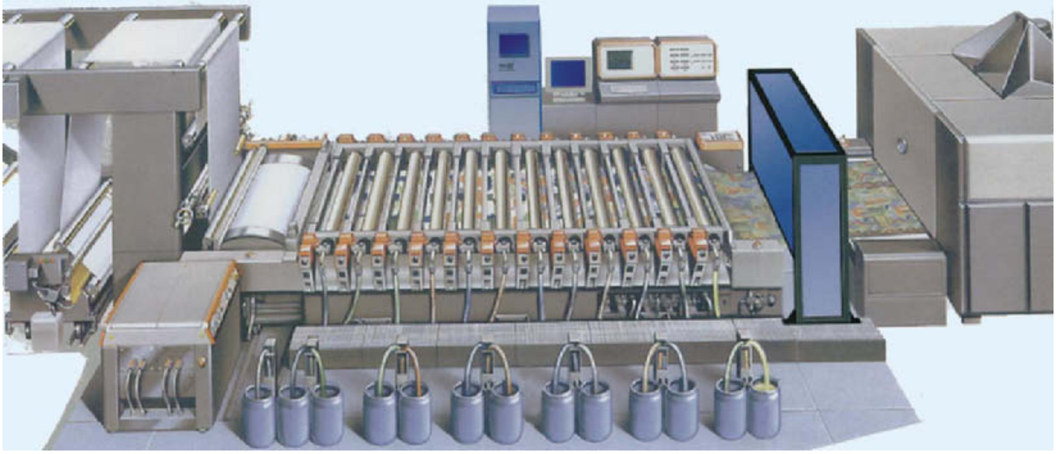

Fig. 4: Printed Fabric Monitoring as in-line defect inspection system (according to EVS).

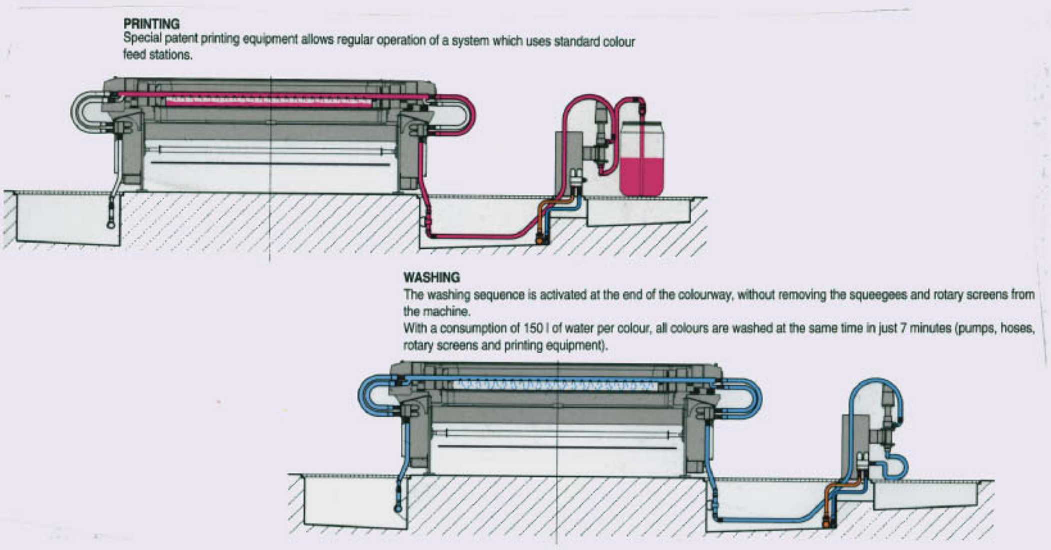

Fig. 5: Colourway or pattern change in printing.

into the fibres however occurs more slowly than the capillary absorption of liquids.

Printed Fabric Monitoring as in-line defect inspection system (Fig. 4) enables on-line detection of repetitive printing defects, thus improving the first quality yield. The system's proprietary processing technology enables it to process and analyse the extensive amount of data acquired by the sensors positioned over the moving printed fabric. Printed fabric faults are displayed in real-time on a video monitor enabling locating the fault and performing the required corrective action.

Every printing sequence (useful cycle) is always preceded and followed by colourway change or pattern change operations (squeegees and rotary screens washing, pumps washing) (down time). The Washing On-line system revolutionises the working cycle/down time ratio to the advantage of the former and this advantage is all the more evident the higher the number of colours and the shorter the run per colourway (Fig. 5). The data which support this revolution in productivity are simple:

– max. washing time:	7 min
– restart time:	5 min
– total water consumption:	150 l/colour
– equipment handling (rotary screens, squeegees):	none

Being able to rely on such figures and in every production cycle and every working environment means:
- the output is unaffected by short runs
- no seconds due to frequent start-ups
- no breakage due to rotary screens handling
- no handling (one person less)
- 2 to 4 times lower water consumption.

Printing area That part of the gauze of a screen printing screen that is permeable to print paste.

Printing auxiliaries These include: discharging agents, discharge printing assistants, mordants, printing oils, print thickeners, colorant binders, dye solubilizing and dispersing agents, after-treatment agents (to increase fastness), reducing agents.

Printing blanket Endless rubber coated fabric, which in roller printing is pulled over the lapping on the main cylinder.

Printing blanket seam join Using specific seam

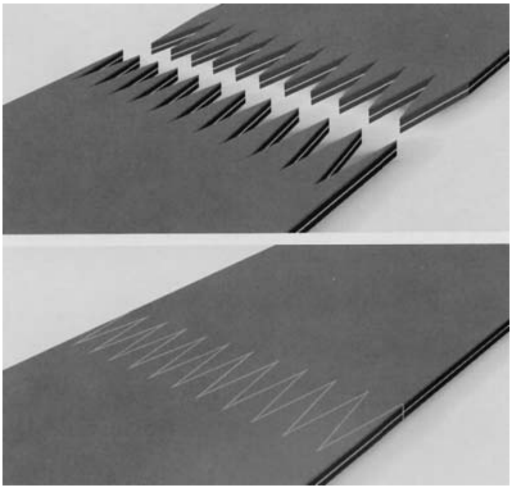

Fig.: Habasit printing blanket.

join systems high-performance pressure blankets can be directly seam joined in the printing plant. This dispenses with the need for dismantling and assembly work, and machine down time is correspondingly short. The actual seam join (hot pressing) is simple: The prepared ends of the printing blanket, which are stamped in a zigzag shape, are laid in the hot press device according to instructions, precisely fitted together and fixed. The heat compensation plate is put into place and the hot press device closed. After approx. 45 min the printing blanket is seam joined and ready for immediate use (see Fig.).

Printing carriage A movable carriage in which the printing screens are mounted one at a time. The carriage is supported on wheels running along rails at either side of the printing table. The printing screen is raised or lowered by lever action, and the squeegee (used to force print paste through the screen) is driven across the screen by a motor attached to the carriage. Printing carriages of this type represent a partial mechanization of the hand screen printing process.

Printing colour → Print pastes.

Printing cylinder A large cylinder (→ Central cylinder), which is not driven directly, but by the back cloth that runs around it and the printing rollers. In order to obtain an elastic underlay, it is wrapped in lapping. This is a cotton/wool fabric, which may be either gummed or ungummed. The lapping must be fitted with care. The start and end of the lapping must be at an angle and must mate up in such a way that there is no thickening at any point, which would later cause marking during printing. The printing roller is pressed against the printing cylinder. This is either done mechanically by springs and weights or pneumatically by compressed air. The printing roller may not be pressed on rigidly, but must be flexibly mounted, so that it can deflect when it encounters fabric seams (see Fig.). This elasticity is achieved in the lower roller using weights and in the upper roller by springs.

Printing gauze → Screen mesh, screen gauze.

Printing group Part of the printing machine where the actual printing process takes place.

Printing machines Tools are needed to transfer the print paste onto the pretreated material in the form of a pattern:

1. the model for letterpress or stamping printing (e.g. manual printing).
2. the engraved pressure roller for gravure printing (e.g. roller printing).
3. for screen printing, flat screens in the case of flat film screen printing or rotary screens in the case of rotary screen printing.

All these tools are the patterning elements for the printing technique in question. The mechanical pressure needed to liquefy the thickener and transfer it from the patterning instrument to the material is provided by doctor blade systems in modern machine printing. Because the output of printing machines is limited due to the required set-up times the material, possibly from several printing plants, is stored or collected after drying and is then fixed by a high performance steamer. The after-print washing takes place on a separate plant, which may even be a pre-treatment department. Procedural peculiarities include transfer printing and flock printing.

In flat screen printing the screens consist of wooden, metal or plastic frames and are covered with a sieve-like fabric (gauze) made of silk, phosphor bronze, polyamide or other synthetic fibres. The areas on this cover where the print paste should not pass through during printing are covered by a layer of lacquer. The print paste is spread through the open areas on the screen by a doctor blade; the doctor blade is usually made of rubber or plastic of differing degrees of hardness and the blade edge has a different polished section, allowing printing sharpness and penetration to be varied. Rod squeegees are also used. In screen printing on screen printing tables, approx. 40–60 m long and covered with felt, several layers of cotton fabric or a wax or rubber blanket, the material to be printed is pinned or glued down. The number of dye pastes can be as high as required for screen printing on tables; however it is limited by the length of the printing table and the printing costs, which increase with the number of

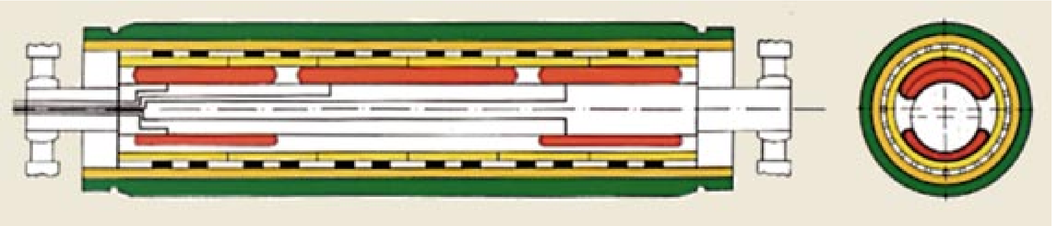

Fig.: Longitudinal and cross-section of a Bicoflex contact roller by Kleinewefers KTM as used in the gravure printing process as a printing cylinder to compress floor and wall coverings for the printing of coloured designs. The printing cylinder serves to ensure an even contact pressure against the gravure printing roller despite the large working width.

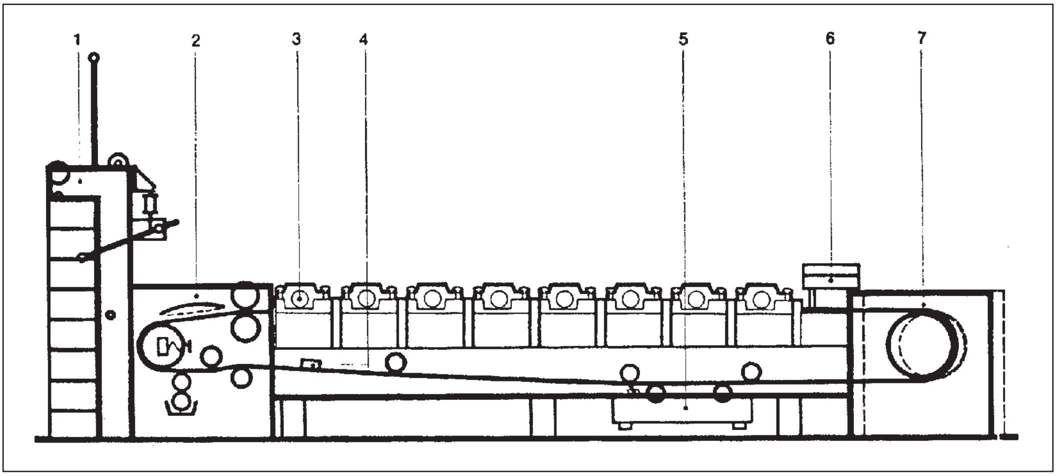

Fig.: Sectional drawing of woven fabric rotary screen printing machine (Buser).
1 = fabric entry stand; 2 = entry section with adhesive units, printing blanket guiding and drive motor for screen running only; 3 = printing head with print paste feed, screen mounting, squeegee system and individual operating station; 4 = interior squeegee; 5 = printing blanket washing machine; 6 = central operating station for printing machine and drier; 7 = exit section with printing blanket drive, screen synchronization, printing blanket tensioning unit and hydraulic station.

colours in the pattern. High-performance fully automated screen printing machines are characterised by repeat precision and high printing speed. In screen printing machines that use stationary flat printing screens, the material to be printed is mounted on endless conveyor belts made of rubber and repeatedly passed over the printing table, rhythmically moving and stopping. The screens can be lifted and lowered. Whilst the material is stationary, printing takes place using special doctor blades. This is therefore a semi-continuous printing process.

Rotary screen printing machines (see Fig.) work continuously using cylindrical screens and from the point of view of productivity are even more efficient than the fully automatic flat screen printing machines. The cylindrical screens consist of seamless, thin walled nickel foils; in perforated foils the print pattern is generated according to the same principles as in flat screen printing screens, in non-perforated foils the half-tone photoengraving process is used. Furthermore, patterned rotary screens can be produced by a photomechanical galvanoplastic method. The printing colours are inside the printing cylinder, as is the doctor blade (rubber doctor blade with special profile or magnet-roll doctor blade). These machines also have an endless rubber printing blanket, a glueing and material feed device and a connected drying device (→: Surface printing machines; Roller printing; Flat screen printing).

Printing path The length of fabric which occupies the printing zone of a printing machine during the printing operation.

Printing pressure In textile finishing this means the pressure at which the printing roller is pressed onto the central printing cylinder or various individual printing cylinders. Depending upon the design of the printing machine it is set by screw rods, disk springs, hydraulically, air-hydraulically or electromagnetically.

Printing pressure in roller printing Roller printing machines operate using oil or air-hydraulic pressure, which provides more protection to lappings, pressure blanket and material than is the case with screw spindles or plate springs. Furthermore, the applied pressure can be regulated from a control panel (can be read from manometers) and more quickly set for repeats.

Printing quality assurance The need to ensure uniformly high print quality on continuous lengths of material plays a decisive role in finishing. Colour deviations and printing errors of all types, for example, doctor blade, circulation and fabric faults, can be shown up by visualisation of the print pattern, thereby creating the conditions for precisely repeating printing, even in vat discharge printing. By monitoring the print pattern the production of quality material can be promoted and defects avoided. So, for example, a special video camera can be illuminated by a stroboscope synchronized with the machine. The amplified video signal permits the print surface to be represented on the monitor as a precise still. A zoom/macro function makes detailed monitoring possible. Such a system is also capable of saving picture sections (storage of a maximum of 90 camera positions and zoom positions and archiving in an order memory for repeat orders). Furthermore, reference pictures (masters) for example can be stored using picture technology. Using windows of selectable size and position the current picture can be compared with the stored pictures.

Printing result – parameters The decisive factors that influence the kinetics of the total process from the application of print paste to drying and fixing the dye depend both upon the type and composition of the substrate to be printed and the rheological properties of the dye thickener and the technical-procedural conditions. The mutual influence of these different printing result parameters on the quantity of print paste transferred or on the printing result in roller printing, is illustrated schematically in the Fig.

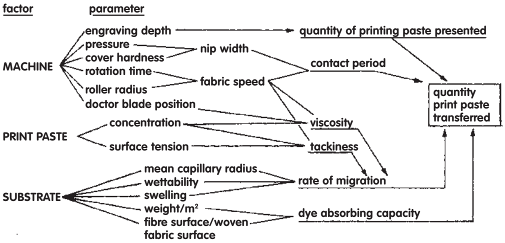

Fig.: Reciprocal effect of different parameters on the printing result in roller printing.

Printing rollers With regard to the type of colour paste application a differentiation is made between printing with deep engraved rollers, roller printing and relief printing, in which the rollers have the pattern embossed upon them.

Printing rollers, fitting on mandrels Pulling the print roller onto steel cores (spindles) with the aid of a roller forcing machine (mandrel jack, mandrel pedestal).

Printing rotation In roller printing the sequence of rollers that transfer the print paste to the material to be printed is known as the “1st, 2nd, etc. printing rotation”.

Printing screen locking units Printing tables are fitted with a U-shaped rail at the front, upon which repeat stops are mounted. The locking units fastened onto the screens fall into the repeat stops when the screen is lowered and thus hold the screen securely in the repeat.

Printing screens → Screens for screen printing.

Printing screen surface condition → Printing rollers resp. printing screens – determination of surface quality.

Printing speed and fabric quality In roller printing the quantity of print paste transferred falls as the printing speed increases, in a manner dependent upon the rheological properties of the print paste. At the same time, uniformity is improved. In rotary screen printing (regardless of the fineness of the screen gauze and diameter of magnetic-roll doctor blades) the amount of print paste transferred falls even more with increasing print speed (at 10 m/min, 30% > 40 m/min). At the same time print penetration is reduced and uniformity and contour sharpness are improved.

Printing styles Fundamental technical possibilities for printing fabrics→: Direct printing; Discharge printing; Resist printing; Blotch printing.

Printing table Support for the fabric to be printed in block screen printing and flat screen printing.

Printing table heating Electric heating below the printing blanket facilitates an increase in production of up to 300% in screen printing because of the accelerated drying of the printed repeat.

Printing thickeners Finished product of → Thickeners for printing (→ Print pastes). Every composition is dependent upon fibre material, fabric type, print pattern, dye group, printing process, etc.

Printing unit,

II. Dye factory (dyestuff manufacturer).

Printing without screens (digital printing) Trends today are sampling, agile manufacturing, quick response, improved quality (fastness properties), versatility, user-friendliness, flexibility, short printing runs, cost effectiveness, all of which are facilitated by digital printing. They are the driving forces to the modification of the printing devices. Today ink-jet technology for textiles is mainly being offered and used in the hitherto expensive and time-consuming procedure of design sampling. The aim is to create sample prints of 10–12 metres in length which have the feel and look of traditional prints without the costs of making traditional screens. In this way a final “go/no-go” decision can be made within a relatively short time and at a minimal expense. Only in very few cases is this technology being used for production scale printing.

Only a few Japanese and American companies (Seiren and Apparel Technologies) are particularly active and are, perhaps, able to demonstrate the viability of full production digital printing. The jet-printing technology has yet to make a leap into the mainstream. The relative slow development of this technology and hesitation to introduce these technologies in the textile industry are due to specific technological limitations (hardware, print head or nozzle, ink classes) which must be overcome for the commercial exploitation of these new technologies. However, even in its current limited state-of-art, this new technology provides for many new business opportunities and cost savings, most notably in sampling, strike-offs and mass customisation. This resulted over the past two or three years in an increasing interest in the application of digital printing technologies to textile substrates. This interest has been fuelled by the rapid advances that have been made in digital printing technologies in home and office computer printing systems. Recent conferences and publications suggest that a much broader range of companies and suppliers are now willing to undertake the work required to solve the technological problems in fabric printing. Also the entrance of new players and "hijackers" on the printing market has put an external pressure on the traditional printing machine makers. Such competitors (Canon, Encad, Iris, etc.) have the know-how concerning the ink-jet systems for paper.

Digital printing means flexibility and a quicker response to market demands. Before any design is finally accepted and the "green light" given, there are many stages it must go through. To begin with colour and scale are not immediately relevant. Only if the design has potential, will it be scaled and put into repeat and then some idea of colouring developed. Re-sizing, repeat setting and separating into defined colour elements can be done manually or by scanning and working on a CAD-CAM system. Colouration ideas can be created on a monitor screen, but fabric samples are then required in several colourways to allow a final choice to be made. At this stage, time and money have to be invested in sampling screens and strike-offs. This alone can influence go/no-go decisions. The time and money investment before a design appears on fabric is one reason why, for example, automotive printing has been slow to develop in Europe. Much of the design and colouration can be done digitally and of course colour printing on paper can also help in the decision-making process. However, this is not the complete picture. Numerous recent advances in ink-jet technology mean that it is now possible to print on textile substrates with good resolution and colour reproducibility using inks based on textile dyes that fix to the fabric itself.

Major interest and research has centered on translation of ink-jet printing technologies from paper applications to fabric. Several important differencs in textile printing and paper printing will impact the applicability of ink-jet engines.

– The volume of ink required to print a square metre of fabric is significantly higher than that required for paper. Estimates suggest that typical fabric printing will require at least 30 ml of ink per square metre at current colorant loadings. This difference has important implications in speed, drop size, drop frequency and nozzle life for ink-jet printing of fabrics.
– Issues of image quality are also vastly different in the two types of printing. Image quality is a function of both the resolution (dots per inch or dpi) and the number of levels of colour (grey levels) that can be achieved at a given point in the image. In ink-jet paper printing, improvement in image quality has been generally in the direction of increased resolution with some ink-jet printers now delivering 1440 dpi. Colour has been produced by mixing four primaries: cyan, magenta, yellow and black (process colour). Textiles have traditionally been printed at much lower resolution (rotary screen mesh of 125 to 150) but with individually formulated colours (spot colour) which in essence gives an extremely large number of grey levels. As a result, the colour gamut required for textile printing is greater than the gamut traditionally obtained in printing on paper.
– The number of picks and ends in fabrics will impose a structure on the image that will limit the resolution that can be achieved without regard to the printer's capability. It has been estimated that with spot colour a resolution of 200 dpi will give very good image quality in printed fabrics, but process colour may require in excess of 360 dpi.
– In addition to these considerations, demands for fastness properties are quite different in both systems. In textile printing high fastness levels, particularly the abrasion, rubbing, light, wash and dry cleaning fastness are mostly required.

These differences in paper and fabric as substrates for ink-jet printing and different approaches taken to achieve image quality have important implications in the design of print machines for textile printing.

Tab. 1: Overview of digital printing systems.

Commercial ink-jet engines – current systems: The different no-screen printing systems are summarised in Tab. 1. The earliest and most widely used system for commercial printing of textiles is probably the Millitron jet printer for carpets and upholstery fabrics. This machine operates on the continuous ink-jet principle with drop selection achieved by opening air valves to deflect the drops to the substrate. This machine operates with large drop sizes (to achieve the large volumes of dye required for heavy weight fabrics) and therefore is limited in resolution to about 20 dpi. It is an eight colours machine and uses spot colour rather than process colour. Colorants are predominantly acid and to a lesser extent disperse dyes with poststeaming and washing required. This machine has been successful because it can print at commercially acceptable speeds (up to 20 square metres per minute) with quality that exceeds standard carpet printing methods. Several other manufacturers such as Zimmer (Chromajet, now also available with a continuous moving textile substrate), Vutek, Technorama, Signtech, Big Image have produced similar machines for carpet printing.

The two most popular technologies being offered for modern digital printing on roll goods are direct and indirect digital printing techniques (Fig. 1): ink-jet and the indirect electrostatic sublimation transfer printing. The big difference between direct ink-jet printing and sublimation electrostatic printing is that electrostatic printing will only work on paper and the dye must then be transferred to the fabric by the sublimation process (indirect process). Ink-jet systems print on ink-jet paper with water-based systems or directly on the fabric and can therefore print other dyes such as reactive dyes, acid dyes or pigments. No sublimation dyes are required. In the direct digital techniques the pre- and postprocessing of fabrics are similar to traditional printing for the equivalent chemistries. Advantage of the transfer principle is that the transfer process does not require pre- or posttreatment.

- **Transfer printing (paper to textile)**
  - electronic printing
  - ink-jet printing (CIJ & DOD)
- **Direct printing (textile)**
  - ink-jet printing (CIJ & DOD)

Fig. 1: Digital printing for direct and indirect printing.

In the indirect printing different techniques can be used for printing the transfer paper: electrostatic printing and ink-jet systems (DOD, CIJ). Compared to conventional transfer printing these digital techniques have several advantages (Fig. 2) and are a cost-effective alternative to traditional processes, particularly where quick turn-around and complex designs are required. For short runs of flags and banners lead times of over a month would be typical with traditional offset or silk screening techniques. This can be reduced to a few days using the new technique, because it is not necessary to produce intermediate separation plates. This is a digital system, so photographs and files can be readily accepted, and any design change can be made quickly, on screen, prior to printing.

- Reduction of sampling costs
- Short production runs
- Simple technique and easy to use with a minimum of maintenance (support)
- Low investments and productions costs
- Flexibility
- Consistent and reproduceable printings
- Easy transfer of sampling results to production stage

Fig. 2: Transfer printing – digital printing compared to conventional transfer techniques.

Dye sublimation printing, often referred to as electrostatic or heat transfer printing, offers new opportunities for textile printers (p.e. Xerox 8054 DS) with the ability to transfer electronic images onto polyester fabrics. The dye is first printed onto paper using a digital electrostatic printing device then transferred onto the fabric using heat and pressure (a heat press). While dye sublimation printing has been used for many years and is not new technology, the big change is that the sublimable dye is now printed on the paper by the electrostatic process and not by an analogue offset printing process, avoiding the need to preprint a lot of paper and inventory, and facilitating the ability to print on demand. This technique demands dielectric paper (paper coated with dielectric components) and solvent-based toner systems (Fig. 3). Of course transfer techniques are restricted to thermoplastic material, especially polyester. The new process “Pictorico” developed by ASAHI Glass could extend this technique to other substrates. This technology treats fibres with a very thin PES coating so that a sublimation process without posttreatment becomes possible on these fibres.

Analogue printing uses a “master”. For textiles this is usually an imaged rotary or flat-bed screen. The image to be printed is separated into patterns of consistent colour, and screens are made, one for each different colour to be printed. A screen may be prepared by digit-

Fig. 3: Indirect systems for transfer printing.

al techniques but it ultimately becomes an analogue “master” from which prints are made. Generally, printing is performed by pushing paste-like inks through the open pores of the screen onto and into the fabric being printed. Each screen is placed sequentially onto the textile being printed and different colours are applied separately. The result is a design generally made up of a relatively small number of “spot” colours, which together make up the printed design.

Direct ink-jet techniques, that have been developed for paper and industrial printing, are a non-contact technology able to print on virtually any textile surface, regardless of its porosity, using nozzles to spray microdrops of coloured ink directly onto the fabric at a particular point. It is a direct printing technology, providing in a single step a method for directly printing variable information onto product materials, independently of repeat length. With these techniques no physical “master” is produced. Each image element in the final printed textile is an individual spot of ink applied by a digital ink-jet printing process. Ink-jet print heads pass over the fabric and deposit one or more droplets of each colour of ink required in a pattern designated by the computer driving the print heads. The “virtual master” resides in the computer memory. Generally “process” colours, for example cyan, magenta, yellow and black inks, are used to produce the colours required by the design. In a few implementations 6 to 8 colours are used. With screen printing the inks may be dried between colours, with ink-jet all colours are printed simultaneously, wet on wet. Essentially all jet-print systems put colour on the substrate in the same way: tiny drops of colorant are sprayed onto the substrate. However, the method of drop generation and their route to the fabric can vary. A simple classification is that of drop on demand (DOD) and continuous jet (CIJ). In both of these technologies, high numbers of nozzles are used for each colour: nozzles are between 10 and 100 micrometres diameter, thus ensuring a resolution of up to 720 drops per inch (dpi). Between a thousand and a million ink droplets are processed per second. Both systems generally operate with constant basic “process” colours (4 or even more, up to 8) which are mixed on the substrate. The depth of the shade is controlled by the number of dots applied and pale shades are created by more base fabric being visible at any given point in the design. Using the same primary colours all the time means that no colour kitchen is needed. Both of these types of engines have advantages and disadvantages for textile printing and both have served as the basis for the devolopment of prototype printers for textile applications. Different commercial ink-jet systems are summarised in Fig. 4.

Fig. 4: Digital printing systems.

DOD ink-jet engines deliver a drop of ink only when required for printing: it produces “drops on demand”, i.e. only when and where needed in the design. Although there are several technologies to generate a drop of ink on command from the control computer, the two of the most widely used are bubble-jet and piezo technology. A third less important is the valve-jet DOD system and uses solenoid valves to control the flow of ink to an air stream that carries the drops to the substrate. Resolution is limited to 25 dpi, and is only usable for special textile printing applications: to print banners, draperies, carpets and wall hangings.

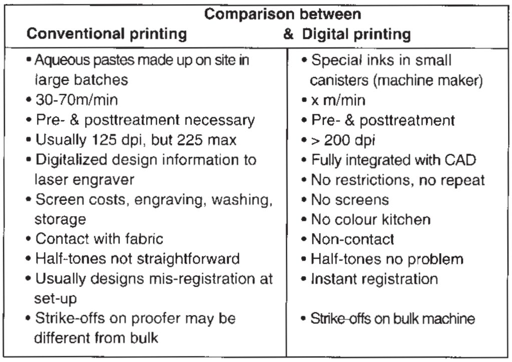
The largest number of DOD printers in current use rely on a thermal pulse to generate the ink drop: bubble-jet or thermal ink-jet system. In these engines, the computer signal heats a resistor to a high temperature (> 360°C) which creates a vapour bubble in a volatile component in the ink, the vapour bubble expands and exits the nozzle followed by a contraction of the bubble causing a drop of ink to be ejected on the textile substrate. The vapour bubble must then cool and collapse allowing the ink chamber to refill from a reservoir. Cycle time is limited to approx. 10 000 drops per second and the volume per drop of ink is typically 150 to 200 picolitres. Thus, a single thermal ink-jet can deliver approx. 0.1 ml of ink per minute. The major problem with the thermal ink-jet is the high nozzle failure rate. The high temperatures required for rapid drop ejection cause decomposition of ink components on the resistor which leads to poor heat transfer and/or nozzle clogging. Resistor failure resulting from rapid thermal cycling is also a major problem (head life of 50 to 500 ml of ink). The major advantage of the thermal ink-jet technology is the low cost of nozzle fabrication. Thus, thermal ink-jets offer low-cost print heads but suffer from unreliability and slow speed. The main suppliers are Canon, Encad, Colossal, Mechatron, Kamatsu, HP and Direct Imaging Systems (see Tab. 1). These companies have developed machines for proofing and very small production runs based on the thermal ink-jet technology. All of these systems reflect the inherent limitations of the thermal ink-jet technology.

Another important DOD ink-jet printing engine is the piezo-electric system. This type of printer uses electrostatic forces for the formation and spraying of the microdrops. The computer imposes an electrical potential across a piezo-electric material which causes a contraction in the direction of the electric field and an expansion in the perpendicular direction. The expansion causes a drop of ink to be ejected. The piezo on removal of the potential returns to its normal dimensions and the ink chamber is filled from an ink reservoir by capillary action. The cycle time of the piezo-based printers is limited by the ink replenishment rate and can be somewhat higher (14 000 cycles per second) than the thermal ink-jet but drop volumes are usually somewhat smaller (150 picolitres). The small drop size allows the piezo-based printers to produce very high resolution prints (1440 dpi is commercially available). These printers also have the advantage of much greater print head life than the thermal-based systems (100 times). Piezo-printing engines are now in use in a number of printers for textile substrates. A number of companies (Kodak, Idanit, Olympus, Konica, Shimaseiki and Mimaki, Fuji, Epson, Sharp (see Tab. 1 and Fig. 4) are producing and/or developing wide format piezo printers that could be modified to print on textiles. Further improvements in piezo-head technology could make this approach attractive for ink-jet printing on fabrics.

In continuous ink-jet systems droplets of ink are calculated and selectively printed. The ink is electrically conductive and as the ink passes between the charging plates, current flows in the ink column. As drops form they will have a net charge opposite to the charge on the plates. Continuous ink-jets produce a continuous stream of drops. Drop selection in most high resolution CIJ devices is achieved by inducing a charge on the drops and using an electrostatic field to select and deflect the desired drops for the image to the substrate and collecting the unwanted drops for recycle. Most CIJ devices for high resolution printing use mechanical stimulation to generate a uniform continuous stream of drops. This is usually achieved by subjecting the ink stream to acoustic waves generated by a piezo-electric operating at up to 1 000 000 cycles per second. The stimulated CIJ typically operates at high speed drops in the range of 50 to 100 thousand drops per second and with drop volumes that can be considerably larger than most DOD ink-jet devices so that the volume of ink delivered per unit time is an order of magnitude higher than with DOD printers. This can be a significant factor in printing on textile substrates that require high ink volumes.

The simplest system is the binary CIJ. In this approach drops are either charged or uncharged by the charging plates. The uncharged drops will be unaffected by the deflection plates which carry a charge opposite that of the charging plates. The undeflected drops then strike the substrate to form the image. Drops carrying a charge are deflected to a catcher or gutter by deflection plates for recycle. Main suppliers are Stork, Iris and Silver Reed.

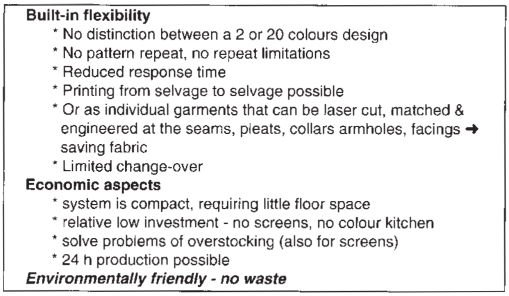
The multideflection CIJ has also been used for textile printing. This approach differs from the binary CIJ in the fact that the dye drops are given a variable charge that gives different deflections as the drops pass through the deflection plates. This allows multiple positions on the substrate (up to 30) to be printed from a single jet. This technology has been employed by Imaje in printers for industrial marking and served as the basis for T-shirt printers developed by Embleme.



Comparison between Conventional printing	& Digital printing
• Aqueous pastes made up on site in large batches	• Special inks in small canisters (machine maker)
• 30-70m/min	• x m/min
• Pre- & posttreatment necessary	• Pre- & posttreatment
• Usually 125 dpi, but 225 max	• > 200 dpi
• Digitalized design information to laser engraver	• Fully integrated with CAD • No restrictions, no repeat
• Screen costs, engraving, washing, storage	• No screens • No colour kitchen
• Contact with fabric	• Non-contact
• Half-tones not straightforward	• Half-tones no problem
• Usually designs mis-registration at set-up	• Instant registration
• Strike-offs on proofer may be different from bulk	• Strike-offs on bulk machine

Fig. 5: Comparison between analogous and digital printing.

The comparison between conventional and digital printing is outlined in Fig. 5. Digital printing offers many potential advantages, which are summarised in Figs. 2 and 6. The new systems can easily be characterised as creative, clean and competitive. The systems have a built-in flexibility. The principal attraction of jet printing is a means of transferring a design direct from CAD to textile. This means very quick customer response for both strike-off and bulk prints. Indeed, conventional printing suffers from the high proportion of unproductive time during make ready and design changes, a burden which jet printing does not share. The system does not distinguish between a 2 or a 20 colours design; nor does it care whether it prints one design or 10 on a given 100 metres of fabric. To add to this flexibility, there is no repeat and little change-over. Response times are very short, since there is no adjustment of equipment between runs. Engraving and sampling stages are eliminated entirely. Response time can



Built-in flexibility

- No distinction between a 2 or 20 colours design
- No pattern repeat, no repeat limitations
- Reduced response time
- Printing from selvage to selvage possible
- Or as individual garments that can be laser cut, matched & engineered at the seams, pleats, collars armholes, facings ➜ saving fabric
- Limited change-over

Economic aspects

- system is compact, requiring little floor space
- relative low investment - no screens, no colour kitchen
- solve problems of overstocking (also for screens)
- 24 h production possible

Environmentally friendly - no waste

Fig. 6: Digital printing – potential advantages.

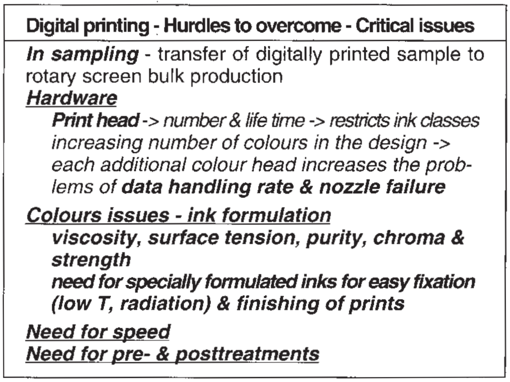
also be cut drastically. The system is compact, requiring very little floor space. The system also allows the textile printer to solve problems of overstocking simply by performing just-in-time printing on demand.

There is a close correlation between sample printing and bulk printing; knowledge of the component inks allows easier recipe formulation for ultimate bulk production. Any design can be scanned in and adapted by the software as required, and the equipment does not have to be cleaned between runs. In both ink-jet (DOD, CIJ) printing, printing is done on prepared (white) cloth which can dramatically reduce the investment required in piece goods as well as delay style decisions and minimise no-front commitments. It also creates some exciting opportunities to develop products that the market has never seen before. Whereas conventional textile printing requires a pattern repeat and printing of the fabric from selvedge to selvedge, printing of the fabric digitally has no repeat limitations other than the length of the fabric, and can be printed either from selvedge to selvedge or as individual garment parts that can be laser cut. This makes it possible to produce garments with highly engineered designs that not only can be matched at the seams, but can also be engineered around darts, pleats, armholes, collars and facings. It also saves fabric, as parts need to be laid only by the grain of the fabric, not the pattern repeat as well.

The system also features strong environmental benefits, since the inks are highly fast and no thickener, frequently no urea, are needed. Especially in DOD systems, there is no waste, since all the colour goes directly onto the fabric. There is also no recipe formulation involved. The engraving and sampling stages are eliminated and response time can be dramatically cut. Digital printing means also relative investment; no print kitchen and storage accomodation for screens are needed. Moreover, a special advantage is the cost effectiveness of short runs, which allows customised and personalised production at an acceptable price. In the current state of development, ink-jet printing provides far lower print speed than conventional by several orders of magnitude. It fits well today for sample, customisation and very short run markets. Increased speed will be needed before it can effectively address the main stream markets. Also the transfer of digital printed samples and rotary screen bulk production gives problems.

Reliability of ink-jet systems today has improved over that of only a few years ago, demonstrating how rapidly improvements can be made. To achieve the higher speeds required, work on effective reliability will be required. As the number of print heads and nozzles and their drop firing frequencies have increased, the demands on liability increase as well. Reliable printing is fundamentally a function of three parts of the system:

– the print head and its maintenance system
– the ink quality and its ability to avoid clogging of the nozzles
– redundancy in nozzles allowing non-performing nozzles to be replaced by functioning ones and/or randomisation of defects to render them invisible.



Digital printing - Hurdles to overcome - Critical issues

In sampling - transfer of digitally printed sample to rotary screen bulk production

Hardware

Colours issues - ink formulation

viscosity, surface tension, purity, chroma & strength

need for specially formulated inks for easy fixation (low T, radiation) & finishing of prints

Need for speed

Need for pre- & posttreatments

Fig. 7: Digital printing: technological limitations and problems.

The slow development of digital printing is due to specific limitations of the head or nozzle, which can also restrict ink classes (Fig. 7). Pigment and disperse inks cannot be used in continuous ink-jet systems in printers with a resolution of over 200 drops per inch (dpi). Dye-based inks are practically the only ones offered for drop-on-demand bubble-jet systems. The increasing number of colours in the design of systems for ink-jet printing of textiles is also problematic. Each additional colour head increases the problems of data handling rate and nozzle failure. It also significantly reduces the fraction of the printer that is not actively printing at any given moment, thus significantly reducing machine efficiency. Trade-offs in speed of printing, grey levels and number of colour heads will require significant additional thought to give machines the best combination of speed, image quality and cost.

Ink formulations for application by ink-jet heads to fabrics is probably the most difficult problem that must be solved for further penetration of this printing technology in the textile industry. All existing colorant systems have deficiencies that will limit their applicability to the wide range of fabrics that must be printed. The colorants must have very high strength and high chroma to achieve a broad colour gamut with a minimum number and amount of deposited colorant. Colorants need high built-up properties, if possible using the same chromophores as the traditional printing dyes. This means that there is a close correlation between sample and bulk printing. Knowledge of the component inks allows easier recipe formulation for ultimate bulk production. Fastness properties acceptable on printed fabrics should be achieved with no postprocessing. These requirements necessitate the development of textile colorant systems especially designed for ink-jet printing. This means also that there are several constraints on the physical properties of the inks that can be delivered by an ink-jet print head. Viscosities of ink-jet fluids must be quite low compared to rotary screen printing pastes. The viscosities of fluids for several typical types of ink-jet heads is shown in Tab. 2. High surface tension of the ink formulation and the need to use very high purity components (to prevent nozzle clogging in most ink-jet heads) are further limitations. Electrostatic deflection systems also require that the ink is electrically conducting which is difficult to achieve in organic solvent based systems.

	Viscosity (cPs)	Drop volume (pl)	Frequency KHz
Continuous	1-10	400	100
Thermal (aqueous)	1-3	200	10
Piezo	5-30	100	20
Valve jet	100	large	

Tab. 2: Typical operating parameters for ink-jet engines.

Colorants used for ink-jet printing on paper have typically been selected based on high water solubility and high chroma and with little regard for substantivity or wet fastness. Acid and direct dyes have been frequently used for printing on paper. These dye classes would not normally be used for printing on cellulosic fibre fabrics. Thus, most of the formulations used for ink-jet printing on paper are not acceptable for textile printing. In developing formulations for textile printing, most companies have gone to high purity reactive dyes or resin pigment systems. Both of these approaches have difficulties. Reactive dye systems require a pretreatment of the fabric and poststeaming and washing. The postprocessing, especially, presents a significant problem in the anticipated ways in which ink-jet printing will be used initially in the textile industry. Due to viscosity limitations of ink-jets, resin pigment systems require that a polymerisable resin is applied to the fabric and that the resin is UV or thermally cured on the fabric. Developing low viscosity resin systems with the required fastness and hand properties on the fabric has been quite challenging. Pigment resin systems have a number of attractive properties for fabric printing and will undoubtably be one of the systems delivered by ink-jet heads. Significant work remains in the development of resin systems that have the required viscosity for ink-jet printing and the hand, wet fastness and crock fastness requirements on the fabric.

The "process colours" approach produces the final colour on the textile by mixing and blending the primary colours on the textile drop by drop sequentially over a small area rather than being premixed in an ink kitchen prior to printing. In most cases the colour increments represented by single drops are too large to give the correct mixed colour. For that reason a larger area of fabric is chosen and the ink drops are applied over that area to give "average colour" which best matches the correct colour. This "dithering" and the effects of printing sequentially cause non-uniformities in the colour on the fabric in many instances, which may be objectionable. With screen printing as many as 10–12 primaries, mixed in any proportion, give the precise colour desired. Since they are premixed they do not suffer from variations due to order of printing the primaries. This gives screen printing the advantages of a closer match in colour, less variation in colour in solid areas and a "cleaner", brighter colour with less grey component to the mixture. Process colour involves substractive colour. Each primary must be transparent so that light passing one colour ink will not absorb or scatter the light from another colour ink beneath it. Pigments must be chosen which are inherently transparent and they must reduce particle size to less than half the wavelength of light. Larger particles will scatter light and cause "greying", making it appear dull and dirty looking. This is a much smaller particle size than is usually found in commercial spot colour inks used in screen printing. This attribute is also important when one wants to print variable information on coloured materials, like logos for example. Process colour inks will not hide the underlying colour since they are transparent.

The ink-jet technology and electrophotography have many potentials for textile applications, but textile-specific electrographic toners and ink-jet inks must be developed in order to gain acceptance of these technologies in the textile industry. The primary thrust of the research was in developing materials (toners/inks) for printing textiles. For indirect ink-jet techniques (drop on demand) BASF has recently introduced the "Baxifan inks". They are characterised by a well defined particle size and a minimum content of mineral products in order to avoid clogging of the nozzles. Some properties are summarised in Tab. 3.

Ciba has formulated special reactive inks (use of small canisters) for cellulose fibres (Cibacron MI),

	Viscosity mm²/s	**Surface tension mN/m**
Baxifan yellow TX4631	2,84	55,8
Baxifan red TX4347	3,17	54,8
Baxifan blue TX4633	3,56	57,6
Baxifan turquoise TX4634	3,22	55,9
Baxifan black TX4613	3,29	55,0

Tab. 3: Baxifan inks for transfer printing.

disperse inks for apparel and automotive applications (Terasil Di), disperse inks for special polyester applications (Terasil TI) and acid inks for silks (Lanaprint AI). Further developments will include specially formulated inks for the easy fixation and finishing of prints on all fibres. Ciba has long experience of textile printing and has developed economical preparation recipes for the ink-jet textile printing.

Pretreatment is still necessary e.g. to avoid bleeding of the print. In general, the fabrics are impregnated with alkali alginate in the case of reactive printing on cellulosic substrates and with alginate alone in disperse printing on PES. This could be performed with a minimum add-on device on the machine. Posttreatment consists of a conventional fixation (steaming) and washing process. In the case of pigments one can use radiation curing (UV and Electron Beam) or thermal processes (according to M. Van Parys).

Printing zone → Printing group.

Print oils Usually preparations containing mineral oil, used for making print pastes tacky and supple.

Printover Overpatterning of an undesired primary colour (red, yellow, blue) by suitable shading with dyes not listed in the recipe (orange, green, violet).

Print paste application Achieved in rotary screen printing by the interaction of the screen, which rotates around its own longitudinal axis, the doctor blade, the print paste and the continuously moving substrate. The print paste flows from the distribution pipe or channel on the inside of the screen. The doctor blade and screen together form a wedge-shaped open space. The rotary movement of the screen forces the flowing print paste into this space. In general one talks of the formation of a colour thread or print paste wedge. The print paste wedge has two main characteristics: There is a circulating flow and a build up of hydrodynamic pressure (back-up pressure). The circulating flow is caused by the print paste sticking to the screen and doctor blade. On the one hand the screen movement leads to a reduction in the viscosity of the normally structurally viscous print paste, and on the other hand more print paste is pushed into the open space than can flow through the holes in the screen. This causes back-up pressure, which allows the print paste to flow through the screen holes. The flow resistance of the screen and the penetration resistance of the substrate act against the back-up pressure (Fig. 1).

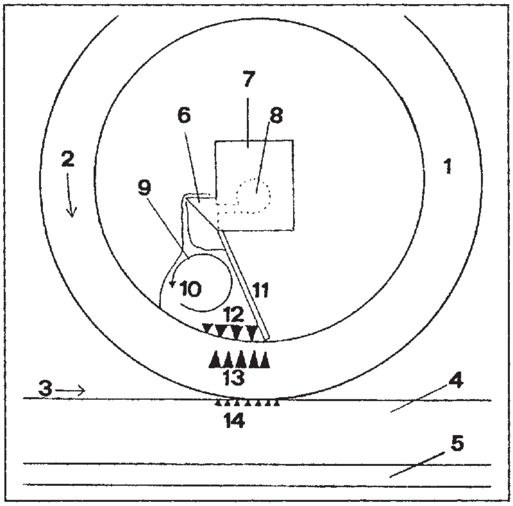

Fig. 1: Sketch of the principle of print paste application in rotary screen printing.
1 = screen; 2 = screen direction of rotation; 3 = substrate direction of movement; 4 = substrate; 5 = printing blanket; 6 = distribution duct; 7 = squeegee; 8 = feed pipe; 9 = print paste wedge; 10 = circulation flow; 11 = doctor blade; 12 = dynamic pressure; 13 = flow resistance; 14 = penetration resistance.

The basic prerequisite for print paste flow in screen printing generally is the generation of a back-up pressure. For print paste application to take place on and in the textile substrate the back-up pressure must overcome the resistances from the screen and substrate. This pressure, flow resistance and penetration resistance determine the print paste quantity that can flow out of the screen holes (available print paste). The absorbency of the

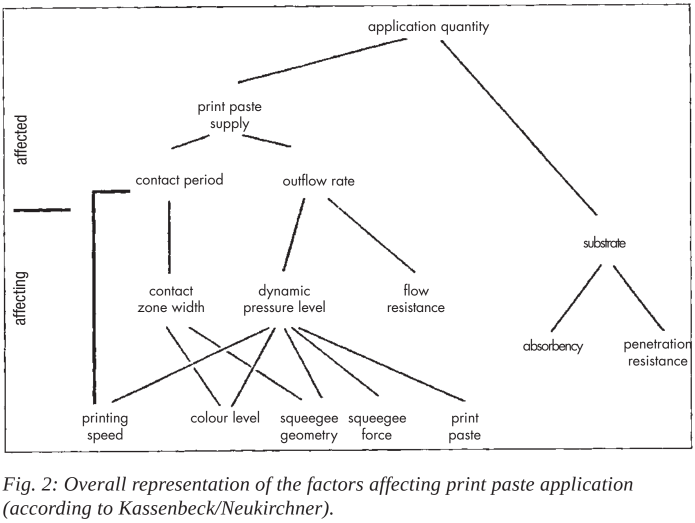

Fig. 2: Overall representation of the factors affecting print paste application (according to Kassenbeck/Neukirchner).

"substrate capillary system" determines the print paste quantity taken from the available quantity (application quantity).

The findings of Kassenbeck/Neukirchner yield the influence variables shown in Fig. 2. The contact time between print paste/screen/substrate and the flow velocity (flow velocity of the print paste as it leaves the screen holes) determine the print paste quantity which is available to the substrate (available print paste). The substrate characteristics determine how much of this available print paste is absorbed (application quantity). The contact time is determined by the length of the print paste wedge and the print speed. The length of the print paste wedge can be found from the quantity of print paste pumped into the screen (print paste level) and the doctor blade geometry (Figs. 3–7). The flow velocity is found from the level of back-up pressure and the flow resistance of the screen. The back-up pressure itself results from the doctor blade geometry, the doctor blade force, the printing speed and the flow behaviour of the print paste. The flow resistance is determined by the proportion of the screen that is open.

Tab.: Factors affecting print paste application in screen printing.

The influencing variables can be divided into variables and constants (see Tab). The constants cannot be altered, at least not without incurring significant time and financial costs. Variables, which can be altered during the process are costs which vary depending upon the doctor blade, are selected on the basis of these constants, to achieve the desired printing result (according to Hilden and Ferber).

Print paste application in screen printing,

I. Flat screens: discontinuous, repeating colour application (Fig. 1), the doctor blade moves on the screen. Knife coating may be repeated several times. Great variation of gauze finenesses, therefore print paste throughput is slightly variable.

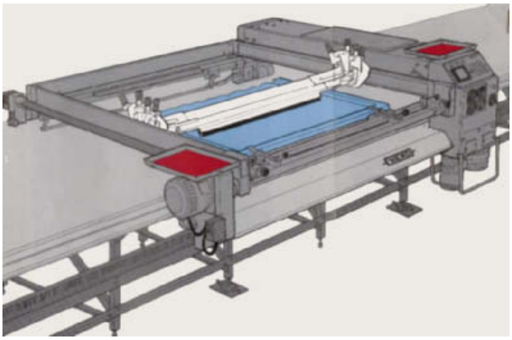

Fig. 1: VIERO print paste application carriage for table printing.

II. Round or rotating screens: continuous print paste application (Fig. 2), screen moves continuously, doctor blade fixed in position. Single knife coating, only small selection of relatively coarsely structured and easily deformed screens. Kinks may occur. Print paste throughput slightly variable.

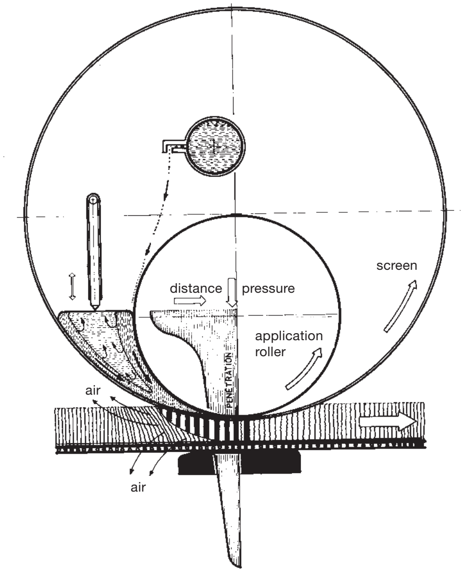

Fig. 2: Situation of a doctor roller in a rotary screen printing screen.

Print paste leftovers Remnants of unused print pastes.

Print paste pump system for printing machines According to the 38th appendix to the German Framework Administration Regulation of Waste Waters to the Water Resources Law (38. Anhang zur Rahmen-Abwasser-Verwaltungsvorschrift zum Wasserhaushaltsgesetz), residual print pastes are no longer allowed in waste water for indirect discharge, but must be collected, reused or disposed of as waste requiring special monitoring (TI-waste). If one bears in mind the fact that 1 kg print paste costs approx. DM 2.50, then for an average printing company the loss of residual paste, which was previously rinsed into the drains after each design or colour change, could easily amount to a sum of DM 1 million/year. Ecological reuse (e.g. by mixing to form black) therefore also represents a financial gain. In order to reclaim the residual paste left in pipes as dead volume after each printing process a switchable print paste delivery pump is required.

The starting position for the example (see Fig.) is a completed print paste application: At every piece of printing equipment used the print paste is pumped back from the doctor blade and the print paste hose. First the dye pipes and pumps are rinsed. Then pre-washing takes place – both processes use service water. Fresh water is only used for the final washing process.

1. Rinsing with service water: the print paste suction hose 2 and the dye paste feed hose 5 are put into the cleaning positions 8. With the slide 9 set to service water, the pump is switched on. In this manner, initially very dirty water runs into the rinsing water channel 11, through the open drain valve 12 and into the external waste water reservoir via the dirty water channel 13.
2. Prewashing: after the drain valve 12 has been closed the rinsing water, which is no longer as dirty, flows from channel 11 back into the service water channel 10. The pipes are thus prewashed with circulating service water.
3. Washing clean: by resetting the slide 9 the water supply is switched over to fresh water. The pumped water continues to flow via rinsing water channel 11 into the service water channel (it is guaranteed that this will overflow into the external pipe). When the washing cycle is finished, the rinsing water channel 11 is automatically emptied via drain valve 12 and the change-over slide 9 is set to service water again. The system is now back in the starting position.

The example shows the saving of fresh water (and the same quantity of waste water) with the Buser Oeko-System, for print paste pumps and pipes alone.

1. Assumptions: Buser Rotamac 4, 10 colours; capacity of pumps 26 l/min/ rinsing process 0.5 min; prewashing 1.5 min; washing clean 1.0 min (total washing time 3.0 min).

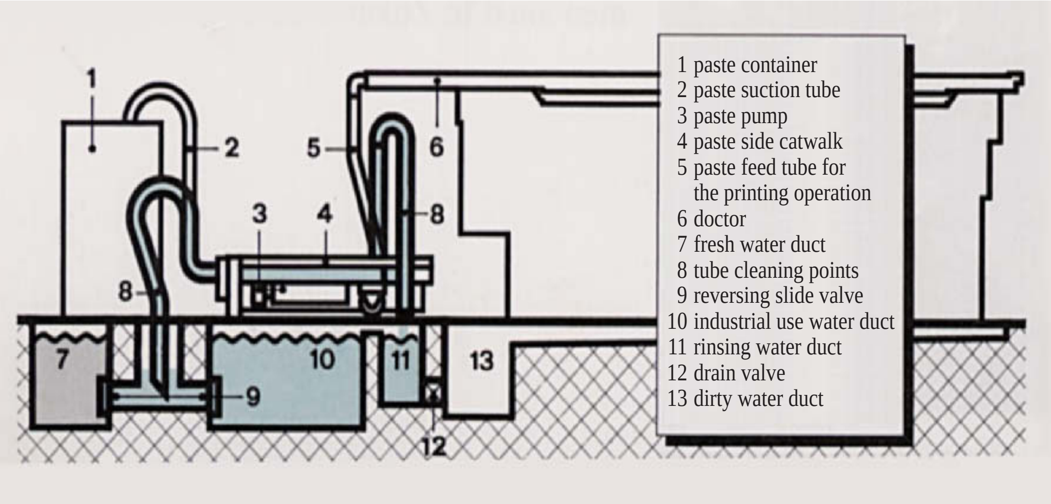

Fig.: Print paste conveyor system (according to Buser).

2 . Rinsing: 10 · 26 · 0.5 = 130 l service water.
3. Prewashing: 10 · 26 · 1.5 = 390 l service water (for filling the rinsing water channel: 100 l and circulation: 290 l).
4. Clean washing: 10 · 26 · 1.0 = 260 l fresh water. Without Oeko-System: 10 · 26 · 3.0 = 780 l fresh water.

Therefore approx. 500 l fresh water can be saved for each dye or design change.

Print pastes → Printing thickeners with or without dyes and chemicals, which are used in the printing of textiles.

Print paste sieving machine (sieving machine), is used for the →: Straining of print pastes; Printing thickeners and chemical finishing products. The method of operation can vary greatly; e.g. brush principle (with 1, 2 or 4 sieving points), pulsation principle, vacuum principle for sucking through the gauze at high sieving speed (vacuum filtering or screening machine), in which blocked screen sections cannot be ruled out however, and the colour grinding mill principle for particularly fine milling. For the purpose of screen printing, when print paste containers with replaceable silk cloth screens are used, the gauze one number finer than the screen gauze is always selected.

Print paste straining centrifuge The print pastes run into the centrifuge via a funnel. The inner screen mesh basket rotates and sieves the print pastes. In centrifuging, special inserts are used to separate the impurities from the print pastes by centrifugal force.

Print paste throughput of screen gauzes Decreases with increasing number of threads and decreasing thread cross-section. Further reduction of the print paste throughput is brought about by calendering the screen gauze (reducing the screen holes and thus reducing the proportion of free screen area).

Print paste wedge In screen printing, wedge-shaped area formed by the angle between blade/rod squeegee and flat/rotary screen. The print paste wedge is a determining factor for print paste application. If the blade squeegee is set at a shallow angle then a long, narrow wedge forms (print paste application is correspondingly lower); alternatively in rod squeegees of different diameters. The wedge is shorter in blade squeegees set at a steep angle. The wedge pressure created is decisive.

Print rollers resp. printing screens – determination of surface quality A non-destructive test method has been developed for microscopic examination of the surface quality of engraved printing rollers after etching and polishing operations. The method is likewise able to provide information on the motif dimensions and mesh openings of printing screens and allows measurements to be made.

Prints on dyed grounds Special type of direct printing on pre-dyed material, which does not involve the local destruction of the pre-dyed ground, as is the case in discharge printing. So, for example, light coloured material (pastel shades) are often printed like white material, whereby the print colours undergo a slight change in shade due to pre-dyeing, but are not spoilt. Very dark print colours on dyed grounds can be used on medium pre-dyed shades, e.g. dark brown on beige or light green, navy blue on pink, black on all light and medium shades.

Print steamers After the application of the dye paste and the drying of the printed textile the material passes through the print steamer to transfer the dye

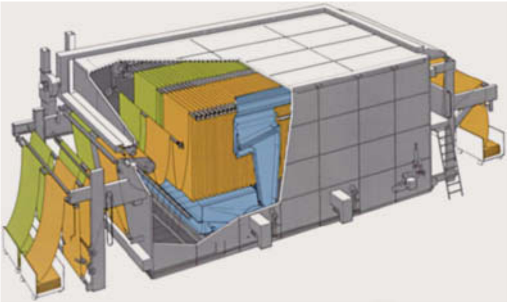

Fig.: Festoon-type print steamer for continuous operation (Stork).

from the thickener into the fibre. To achieve this the dried material is collected and passed onto a separate process, e.g. a high performance universal loop steamer with 2 adjacent tracks (see Fig.). If possible the moisture content of the steamer should be constant.

Prism If a beam of parallel, white light meets a triangular glass prism, it is broken up into its component parts and can be divided precisely into different colour lines (see Fig.).

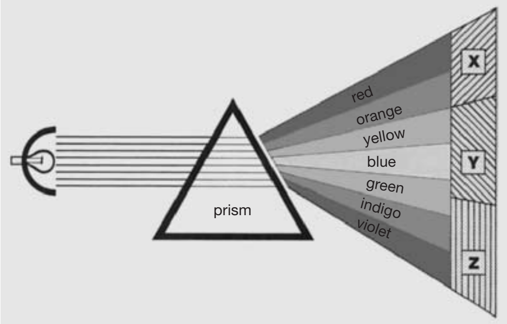

Fig.: The passage of light through a glass prism.

Probability Statistical frequency of comparable events in → Populations. The ambiguous term “probable” expresses the fact that there “appear” to be more arguments in favour of the prediction. The verification value is equal to zero in the individual case. We talk of mathematical probability because statistical probability evaluates the laws of large numbers (→ Stochastic).

Procambium In the structure of bast fibre stems (→ Flax stem structure), the parts still being created during growth (→ Phloem), which is also where the first bast fibre cells are formed (→ Cambium).

Process automation → Automation.

Process balance Once the discovery had been made that it is not a simple matter to set up eco balances for products for the entire process flow through all stages, a differentiated approach was tried. Attempts were made to create company, process and product balances with regard to current environmental compatibility of each (see Fig.: Systematics of preparing an ecological account in textile processing). The basic goals of an → Ecobalance apply. Ecobalance is as broad a comparison as possible between the environmental effects of two or more different products, product groups, systems, processes or modes of behaviour. It serves to expose weaknesses, improve the environmental properties of the product, aid decision making, procurement and purchasing, promote environmentally friendly products and processes, aid the comparison of alternative modes of behaviour and the justification of recommended actions. Depending on the underlying problem, there are further issues involved in this comparison, e.g. an assessment of the environmental protection efficiency of financial resources. A thorough investigation of the materials/preparations present, used and created at each process stage is necessary. The occurrence of environmental chemicals should be verified. It is the term used to describe substances that enter the environment, can exist there in large quantities and endanger the life of the ecosystem. These can be of natural or synthetic origin. A further, not uncommon classification of environmental chemicals, is made with regard to their origin, their field of use or effects. Last, but not least, a differentiation is made between natural and foreign substances. In this context it is important to note that predictions cannot be made regarding the hazardous nature of the substance based upon the classification. We should of course also consider harmful substances that can be differentiated according to the following criteria:

1. Harmful substances in terms of eco-toxicology are substances, which give rise to changes in the systems in question, which clearly exceed the normal variation range of population levels.
2. Harmful substances in the sense of emissions/immissions from the point of view of air pollution are substances that can occur locally, regionally or globally in higher concentrations and lead to acute direct or indirect damage to the biosphere.

All investigations of a process for a process balance should cover the following criteria:

1. Substance related criteria: this relates primarily to the propagation of substances in the environment, absorption/accumulation, degradation (biotic/abiotic), toxicological/ecotoxicological behaviour of substances.
2. Media related criteria: factors that should be noted here are the air-hygienic behaviour (observation of the TI-air, TLV values), local water pollution, the aquatoxic effect, global water pollution, soil pollution.

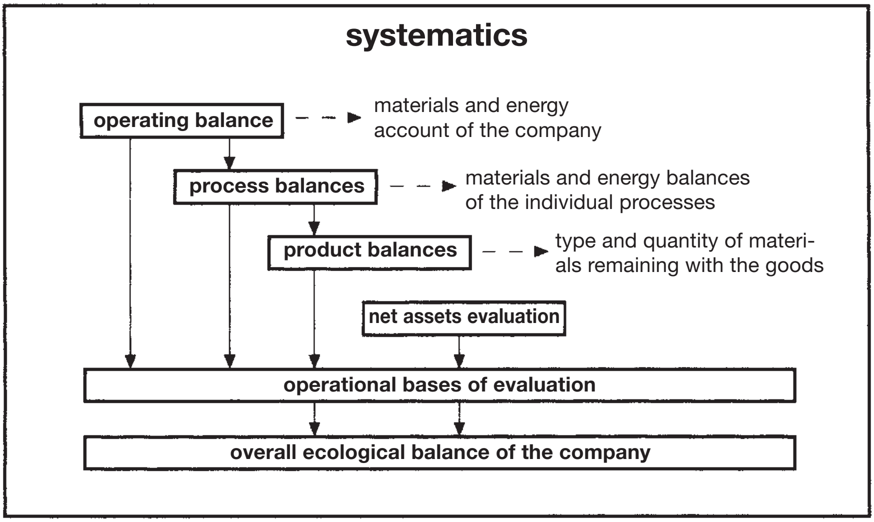

Fig.: Systematics of preparing an ecological account in textile processing.

3. Effect related criteria: important factors in this field are: mutagenicity, teratogenicity, carcinogenicity, absorption and retention, influence on ecosystems.
4. Evaluation principles: at the end of the chain are the evaluation of exposure, effects, and danger and risk effects.

Process control Instrument for the programmed control of largely automatic manufacturing stages. Such control systems often incorporate measuring and control devices; their target values are predetermined by the control system; they continuously regulate individual parameters in the process control sequence.

In contrast, the collection, registration and calculation of process data belongs to the field of data processing, not process control. The main difference lies in the cost of the necessary computer. Process control is an active aid to production and performs many activities previously performed by operating personnel (Fig. 1). Data processing, on the other hand, processes consumption rates, speeds, temperatures, etc. in a separate stage after the process, or in parallel to it, namely EDP (Fig. 2).

Process control engineering Electronic programming of any finishing process with regard to time, temperature, speed, pressure, addition or discharge of treatment liquors, dyes, chemicals, etc. that were previ-

ously manually controlled processes. → Automation in textile finishing helps to achieve economical and reliable production. On the basis of continuous monitoring of momentary quality measurements by the process computer, individual sub-systems should be produced automatically within a permissible tolerance range.

Processes were previously managed on the basis of modelling. If a plant is to achieve target values on the basis of a control algorithm, then it is necessary to develop a process model of the greatest possible accuracy. We can differentiate between theoretical and empirical process models. The theoretical models are based upon physical and chemical state equations. The advantages of theoretical models lie in the possibility of simulation and the calculation of non-measurable variables, the disadvantages are the high computing power needed, the high cost of development, the limited nature of predictions because simplified assumptions must be made and the difficulty of determining parameters of secondary conditions.

In the empirical model, the input and output behaviour of the system as a “black box” is statistically analysed. The advantages of this approach are the high level of precision and the low computing costs. The disadvantages are the narrow working range, the lack of extrapolation possibilities and therefore the impossibility of reacting to errors. Operating a system by heuristic methods requires a sufficiently good level of empirical knowledge. Based upon this knowledge, a process operator is able to specify target values for the process (Fig. 1). This type of process control operates in many plants. The plant manager has an overview of the process and is in a position to correctly interpret many secondary conditions. The disadvantages of this way of working are the different levels of qualification of different plant managers, who also have to concentrate on many other tasks.

In an → Expert system, the knowledge of the process operator is implemented on a computer, so that the computer monitors the process on behalf of the plant manager, using the knowledge base of the plant manager to input target values to the process. Even processes that cannot be modelled can be operated automatically and thus more consistently, more precisely and more economically.

The process operator therefore has to make a decision for every possible process situation. It is clear that a simplification must be made to enable one to deal with measured values in this world of infinite variation.

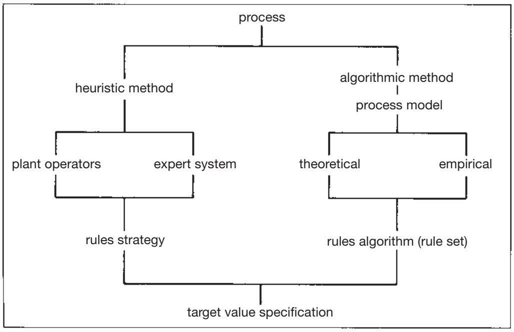

Fig. 1: Methods of specifying the target value.

Human thought is to a large degree characterised by the fact that it rests upon the use of concepts. Thus entities which can be differentiated are categorized and classified taking into account certain aspects and disregarding others. One can then react to membership of a group rather than the individual entity. The first stage of development is thus the grouping of the measured values into classes and thus concepts. This occurs on four language levels, from top to bottom:

- learning level,
- action level,
- monitoring level,
- object level.

The lowest level (object level) only contains information about the measured values of the process. The 2nd level (monitoring level) contains the compressed information about the object level. The primary observations of the process controller are structured in the form of concepts at this level. The first task is to uncover the relationship between process data and concepts. The definition of a trend is: a trend is indexed if the last two values (current and 2 h ago) change in the same direction as the third last (4 h ago) or the difference between the last and the third last value is at least 2% and the second last is equal to one of the two others. The information from the object level is thus compressed into the sentence “there is an upwards trend”.

The second important concept is the distance from a target value. Attributes such as “too high, much too high, normal, too low” are used. These attributes are described by the allocation of limits. The two concepts “trend” and “distance” have proved to be fundamental in this context. The rules in the 3rd level (the action level) are formed from these concepts: “If process situation, then action instruction”.

A further point is evaluating success. Human process control is largely characterized by the capacity to learn. There is often a lack of evaluation of the results of an action. This can occur on a fourth language level (learning level). To make an expert system capable of learning, it must evaluate past actions (reflection). This is achieved by introducing a new type of rules (“meta rules”) which use the results of the proposed target value to optimize the rules of the action level. The situation is as follows: if the old process situation and the completion of an action and the new process situation are “not equal to” the expected process situation, then the action must be changed.

Each action performed should achieve a goal. Each action is associated with an expected process situation. If this situation is not achieved, then the action instruction must be changed. In this manner, the rules of the action level can be increasingly modified to suit the current situation.

In order to implement the cognitive model described above on a computer, a shell is necessary that precisely describes these structures. An expert system consists of different modules linked together in a tree-like manner. Each module contains different states. A state consists of a number of actions, conditions and examples. The knowledge is input in a purely declarative form. The disadvantages of such a procedure lie in the generation of incomplete, redundant or contradictory rules. These disadvantages are eliminated in an expert system: An “If ... then ... else” structure is derived from the above declarative representation. A code generator now creates certain codes from this system.

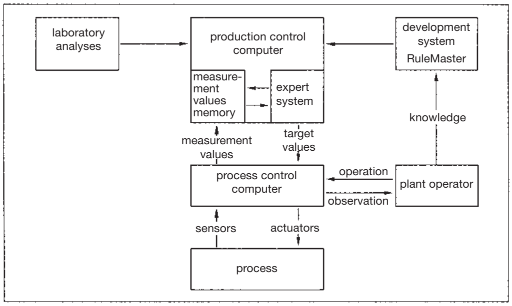

Fig. 2: Representation of an expert system in the stratification model of automation.

This code can be modified so that it runs on-line on a process computer. Fig. 2 shows the structure within the level model of automation. At the lower level, the so-called process control level, the process is controlled via the process control computer. The plant manager can monitor and control the process based upon flow diagrams. This level includes storage of measured values and the expert system. Furthermore, an operation laboratory computer is connected to the production control computer. This computer supplies the current laboratory analysis values from the system. The expert system analyses and interprets the process and analysis values and provides target values to the lower-level process control computer, which controls these target values using conventional algorithms (according to Soltysiak).

Process coupling The environmental problems associated with textile finishing have given a new significance to the need for process coupling. Where excess heat occurs in a process, attempts are made to control the quantity using → Process control engineering so that the correct amount of energy is consumed by a connected, heat consuming finishing process. Recycling requires a coupling of different processes via EDP (see Fig.), if all useful materials are to be optimally used.

Process data highway for the textile industry In textile companies an increasing number of production machines are connected to data systems. The machine

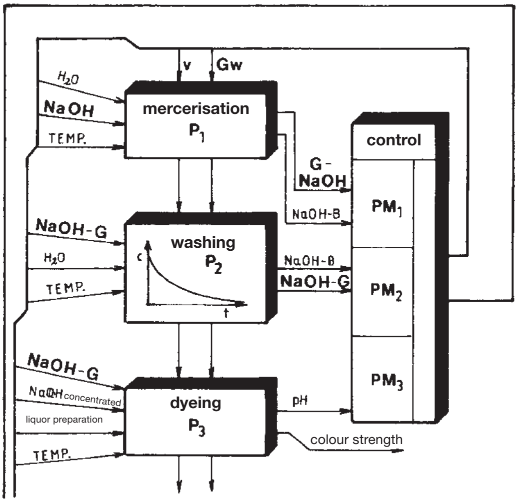

Fig.: Process coupling (NaOH-G = grams of NaOH/kg of cotton; NaOH-B = grams of NaOH/litre of liquor).

manufacturer's systems are designed to work with his own machines or machine groups and can only accept and process the data from these machines. There is a lack of compatibility. However, textile companies have many machines from different manufacturers installed in their company. This, therefore, leads to a collection of very varied data systems, which although they can capture and process the data from "their own" machines, they cannot understand the systems of the neighbouring machine. CIM (Computer Integrated Manufacturing) therefore represents an automation concept for textile companies, which provides a data connection between all sectors involved in production, from planning to quality assurance. Operational, quality control, process, and planning data, etc. must be taken into account. However, in order to achieve goals of this type, free data exchange throughout the whole company is necessary, i.e. between all machines and devices from all manufacturers. The different systems can only be connected at a significant cost or only to a limited degree in the event of manufacturer's data being unavailable. The costs incurred relate not only to the additional computer and programmes, it is often also necessary to modify buildings (cable ducts, space for computer). These expenditures are repeated each time changes are made to a company's machinery, i.e. each time a non-compatible data system is integrated. Such additional costs could become largely superfluous with the use of standardised data interfaces and bus systems for the textile industry. The guideline VDI 3665 for weaving and finishing (→ VDI) will be widely used for the current generation of machinery. For future generations of machines, however, an interface with bus capability without additional modifications is called for. Interfaces with bus capability permit the direct connection of several machines and devices to a common transmission cable. The huge amount of work involved in specifying a unified interface for the textile industry has led to a step-by-step process and to reliance on existing standards or standards under development.

The term field bus is used to describe a serial bus system, which possesses the technical and functional features necessary for the networking of individual machines and electronic devices for the capture of quality and production data to the process control level. The field bus covers the lower and middle performance range. The following goals should be achieved by the definition of a unified interface or bus system:

- free communication between the devices and machines from different manufacturers,
- low connection costs for individual machines and devices,
- forward looking and performance capability for the textile sector,
- based upon international standards,
- high transmission rates, to cope with future data quantities,
- high efficiency of transmission due to short messages,
- control of priorities for alarm handling,
- simple, economical cabling.

The Profibus has emerged as an option for further development from these and other criteria. The Profibus proposal also takes into account the efforts taking place on an international level to achieve free communication. As the basis, the ISO has published a reference model for the free, manufacturer-independent communication system, the OSI model (Open System International). The communication details are divided into 7

Fig.: The 7 layers of communication.

layers, with each layer having its own specific functions to fulfil (see Fig.).

A higher layer therefore does not need to be concerned about the tasks of the lower levels. The transition from level to level is precisely specified and described. The specifications for the individual levels thus describe how these should behave in relation to the outside world. This means for example, that if the physical transmission medium (e.g. from twisted wires to coaxial cable) is changed, only the control of the physical medium (level 1) must be modified, if the transition from level 1 and 2 is identically specified for all solutions. For the application of the Profibus standard in certain applications, e.g. in the textile industry, additional specifications must be made. The selection of so-called basic standards and the specification of the variable interface parameters give rise to the communication profile of the field bus for the textile industry.

Process data logging Covers all data within the processing sequence (see Fig.): physical data (rotation speed, temperatures, material non-uniformity), data regarding operating states (running, stationary, operating faults), data about quantity/quality of the processed material, personnel data, machine data (→ Data logging). Data falling under individual sectors can be utilized for various purposes: for process control at the lower stage, e.g. to change machine settings (either manually “off-line” in the laboratory or “on-line” by process computers), for the recognition of machine defects, errors or false settings in process stages that precede the monitored stage; for process control at a higher level (for planning based upon data concerning throughput times, product quantities produced and product qualities) and for long term process optimization.

Process field bus The developments of the 1980s have clearly shown that there is a need for a computer controlled data exchange between production and management in the textiles sector. The activities summed up by the term CIM (→ Computer applications in textile dyeing and printing) include, amongst others, the capture of all data generated at the production machines and automatic process control. The networking of the machines and the superior systems in the production sector takes place using a bus system. The tasks and usage options of bus systems in the textile industry are:

- transmission of information (e.g. production, machine and quality data, target and actual values, fault and operation messages, sensor and actuator signals);
- networking of machines and plants (e.g. spinning preparation, spinning, rinsing, knitting, weaving and finishing machines and plants);
- connection of devices (e.g. control system computer, PC; data capture- BDE/MDE terminals; operating/observer operating fields, process control systems, control/regulation automated systems; production sector sensors and actuators).

In the past, such networks have been based upon the

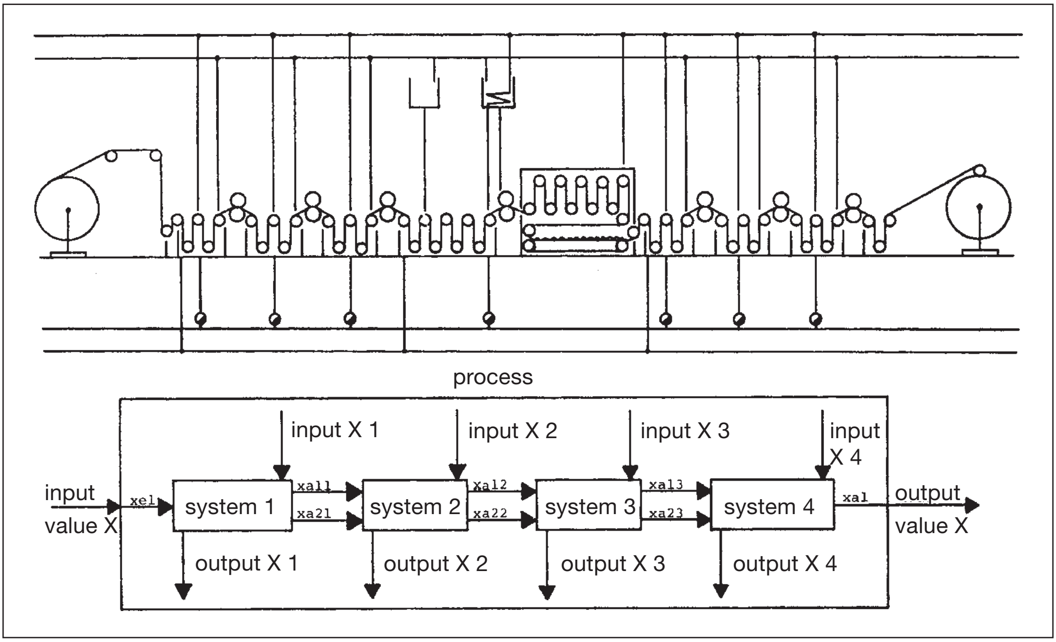

Fig.: Process data logging: diagram of a textile finishing process comprising several individual systems.

varied bus systems that were available on the market. In addition to the options offered by system houses, textile machine manufactures have incorporated their own solutions into their sales range. However, because a varied collection of machines from different manufacturers will be installed in a real textile company, this can also lead to a collection of very different bus systems. Although these can capture and process the data from their own machines, they cannot understand the systems of neighbouring machines. In the simplest case, even the cables and plug connectors necessary for data transfer are not compatible, so that different cables must be laid for each system. The case may also occur in which, although the data exchange can take place via uniform cables, the sending and receiving of data takes place in a different manner. This leads to problems in the entire network. The hardware and software can only be modified at considerable cost and huge expenditure in terms of time. The use of manufacturer specific systems in particular, for which the necessary documentation is not available, can lead to severe limitations.

The process field bus (Profibus) is recommended by the “Data interfaces to textile machines” committee. It aims to facilitate the linking of machines and systems from different manufacturers in the simplest manner possible. The basic principle behind the Profibus concept is based upon the following demands:

- communication functions of simple field devices (sensors) and also more complex units (automated systems) must be realised;
- the transmission technology used must be simple and good value for money;
- the application interface should possess a functionality that is based upon existing, international standards;
- high reliability of transmission with short reaction time.

(according to Bergmann).

Processing material directive (ArbStoffV – Arbeitsstoffverordnung). German directive regarding dangerous materials of 11 February 1982, which controls the trading and handling of dangerous materials and health monitoring of employees who work with dangerous substances; was replaced by the Directive for use of dangerous substances (→ Legislation on environmental protection) from 1 October 1986.

Processing sequence In the context of a work analysis this consists of individual processes: → Operating time, Production resources, Handling time factor. The processing sequence is also divided into a sequence of individual processes (examples Figs. 1–3).

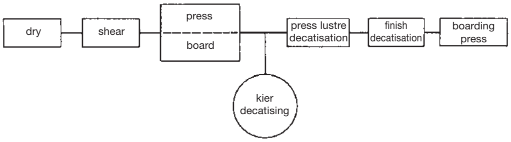

Fig. 1: Processing sequence (operational sequence) of the classic dry finishing of woven wool fabrics.

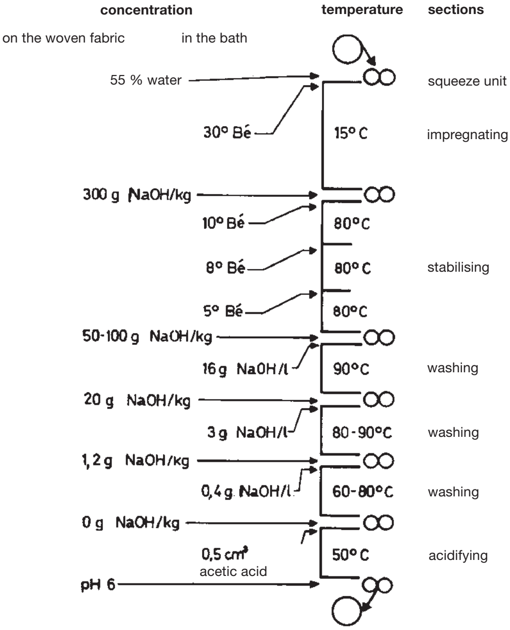

Fig. 3: Processing sequence of the classic mercerising process: diagram with detailed data on wet finishing.

Processing sequence in textile finishing Sequence of the individual working steps; these are often determined by the experience of the finisher. If the aims of the finishing process are specified in a logical manner based upon the profile of requirements for the finished material the processing sequence can be determined by factual arguments. Using the example of a polyamide warp-knitted fabric, which is to be used uni-white as a women’s outerwear item, the selection of

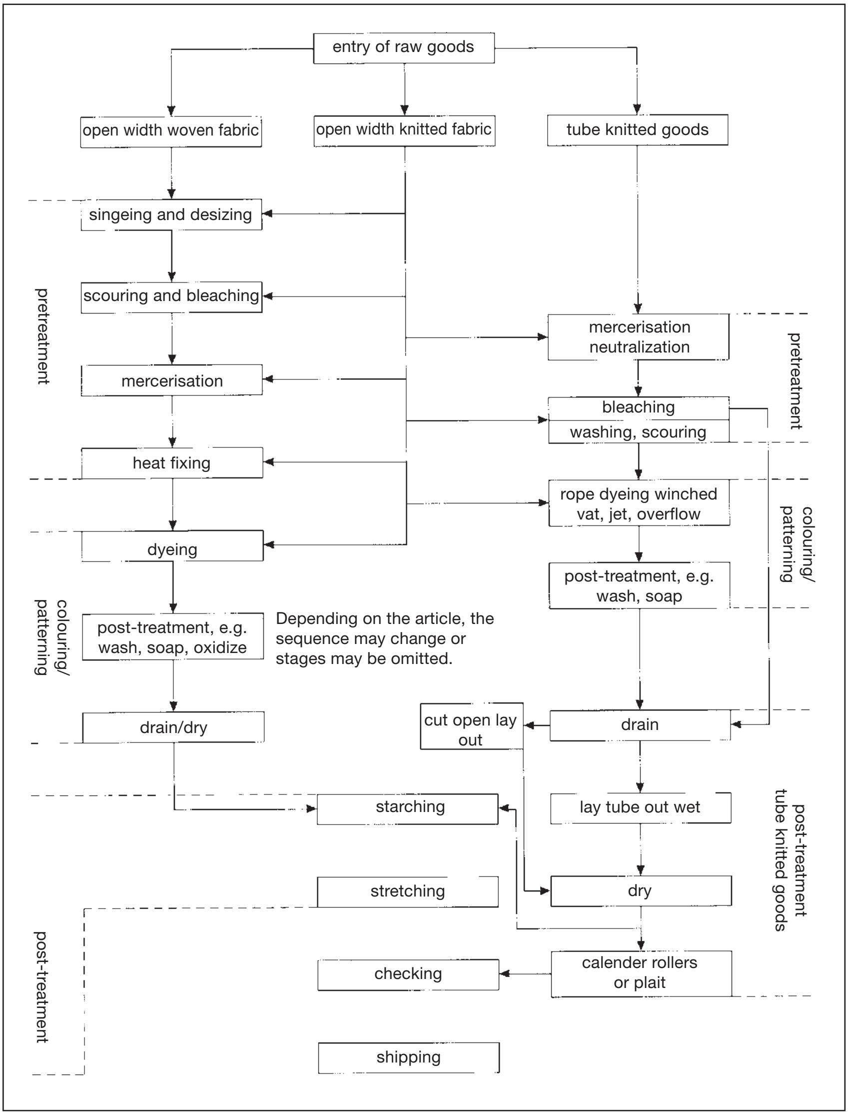

Fig. 1: Example of the processing sequence for piece goods in dyeing.

processing sequence (without pre-cleaning) can be represented as follows (Tab. 1).

Processing sequences A, B, C can be analysed with regard to their target properties. The subjective value of the equality factors is selected, whereby it is a prerequisite that the desired degree of whiteness is always achieved.

We can see from Tab. 2 that if a uniform equality is a specified objective, processing sequence A is the preferred alternative and processing sequence B should be rejected. Processing sequence C is a viable alternative for certain batch sizes (yardage).

However, the processing sequence not only breaks down the individual subsectors of textile finishing; rather from an integral point of view the entire system is structured in accordance with the areas of:

– pretreatment,
– colouring,
– post-treatment.

The processing sequence is significantly influenced by the type of colouring (dyeing or printing). Furthermore, the processing state of the material also determines the processing sequence, for example one critical factor is whether a knitted fabric is cut open or processed in tubular form. Fig. 1 and Fig. 2 show processing sequences for the finishing of fabrics in dyeing and printing.

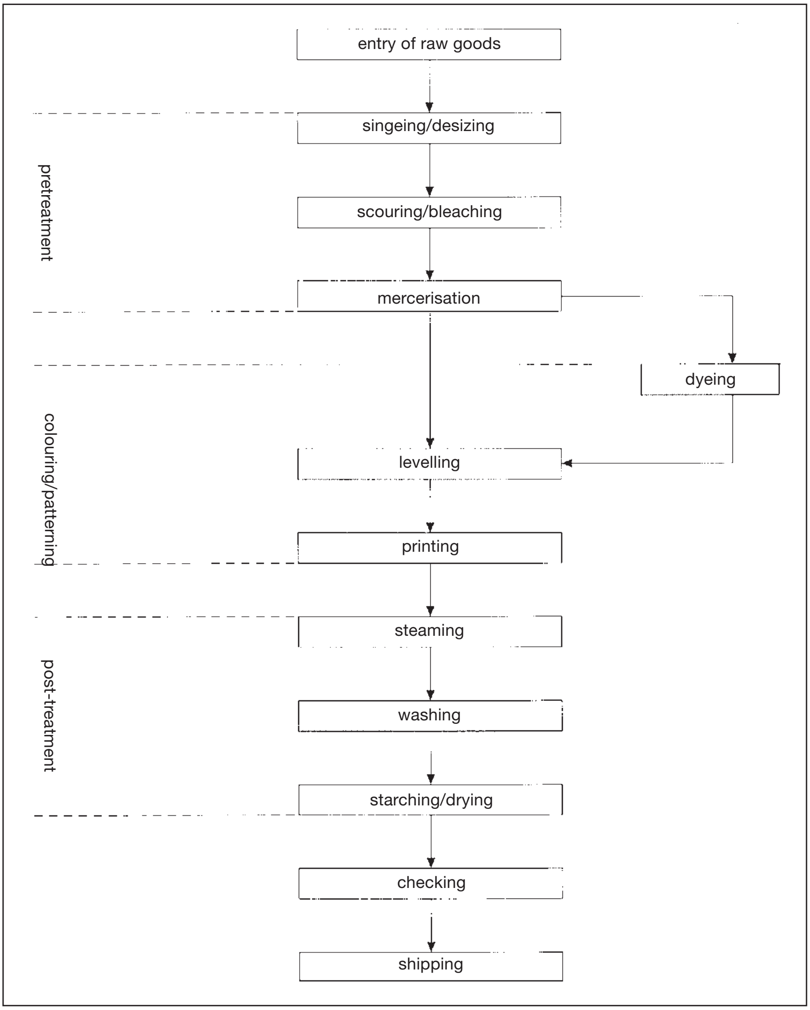

Fig. 2: Example of the processing sequence for piece goods in printing.

Processing time,
I. Part of the → Handling time factor or basic time for all direct processing operations on the material.

II. Operating time, usable life, gel time, → Working life; term for the period of time from applying a synthetic resin to when it is still just possible to process it, i.e. shortly before the onset of gelling. Important for condensation resins, because their viscosity falls sharply when the processing time is exceeded, whereupon they gel and then become unusable.

Process-integrated waste water treatment The increasing level of awareness regarding disposal technology has led to the recognition of various difficulties in an overall treatment of textile waste water. The considerations relate on the one hand to the enormous use of chemicals, associated with non-specific removal of pollution from the waste water, and on the other hand to the sludge load, the disposal of which is creating increasing difficulties. A decisive change to the situation can only be achieved by a process-integrated waste water treatment; only in this manner can the necessary biocompatibility be achieved, which is necessary for an unproblematic microbial disposal of the waste water. In principle biological treatment can be used for the waste water of all companies processing vegetable or animal substances. Examples include not only the food and sugar industry, but also the textile industry if the levels of inhibiting or toxic substances added during production are sufficiently low.

The great problem associated with aerobic decomposition is the use of oxygen, as power consumption is very high. So it is understandable that aerobic decomposition is only used in waste water with low to medium pollution levels (COD < 2000 mg O_2/l). The still fairly

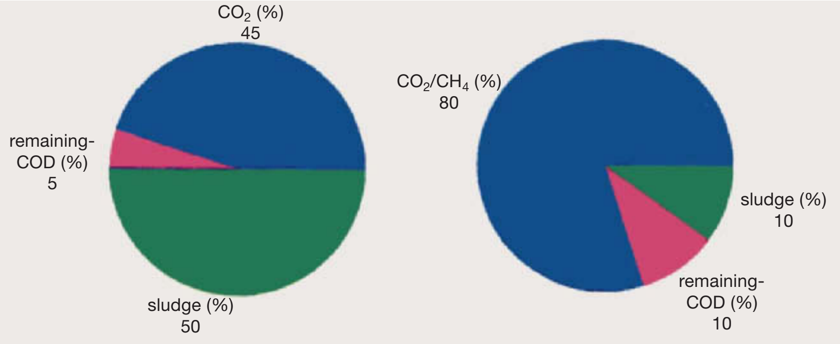

Fig.: The carbon balance for the aerobic (left) and the anaerobic (right) break-down of typical waste water from the sugar industry.

common practice of diluting highly polluted partial flows is an outdated technique and is no longer practical for cost reasons. The great advantage of anaerobic decomposition lies in the fact that high levels of waste water pollution (10 000–20 000 COD units) can be biologically treated using the stored chemical energy. In aerobic decomposition, by contrast, the chemical energy stored in the pollutants must be destroyed at even higher power consumption (addition of oxygen) (see Fig.). A particularly important advantage of anaerobic decomposition is the significantly lower sludge quantity in comparison to aerobic decomposition.

If we consider the pollution in the individual partial flows of textile production, then we find that the sizing and pre-treatment waste water is polluted with a high level of polysaccharide and that in fact the basic preconditions for anaerobic processing exist here. Exactly the same applies for many printing companies. The balance of substances in the partial flows and their mixtures facilitate decomposition results to be interpreted individually for each partial flow. The partial flows of textile waste water can be anaerobically pre-clarified with good results. In desizing and pre-treatment partial flows in particular, 80% decomposition can be expected as a result of optimization activities. This outcome means that a finishing company can expect a reduction of on average 50–60% of the total COD. Waste water from a printing company requires a different approach; for example, anaerobic decomposition is not possible if semi-emulsion thickeners are present, although pure alginate thickeners can be 90% decomposed. It appears that anaerobic disposal technology cannot be used with partial flows from dyeing, which means that one still needs to turn to conventional flocculation and precipitation techniques (according to Marte and Keller).

Process measuring and control plant Process measuring plant with measured value detection, measuring sensors, measuring transformer, measured value display and possibly measured value recording. Control plants control the process automatically or manually. Regulation plants perform automatic regulation of the process. Signalling, display of boundary states with acoustic or optical alarm signal. There are pneumatic, electric, electronic and hydraulic process measuring and control plants.

Process water In the past water was considered to be a consumable commodity that was available in top quality and unlimited quantities. Due to the ecological awareness that has now developed, great importance has been attributed to the sensible use and consumption of water. Water is still the most important auxiliary agent used in dyeing, which means that its properties have a great influence on the dyeing result. When speaking of fresh process water (service water) we differentiate between

- ground water (from wells and springs),
- surface water (from streams, rivers, lakes and ponds).

These two types of water can be used in the form of raw and treated water. In addition to fresh water and mains water, so-called

- recycled water

is also used. This term is used to describe water that has been cleaned after use and fed back into the production process without any intermediate stage as service water. Often one water type does not fulfil all the requirements, and then so-called

- mixed water

is created by mixing the different variants. The ideal service water for dyeing and bleaching would be distilled water, to which a little bitter salt (magnesium sulphate) has been added for the stabilisation of hydrogen peroxide bleaching baths. This type of water is, however, much too expensive and therefore is not used in dyeing. Condensate, under certain circumstances, is almost distilled water. It is a type of recycled water, because it has already performed work in the form of steam. If free of metals (iron ions from condensation vessels, pipes, etc.), it is an almost ideal process water. It contains no aggressive carbonic acids, no → Water hardening salts, no suspended matter or algae and it reacts almost neutrally. Of course, this condensate is too expensive for use as process water and is thus returned into the steam circuit. Cooling water could also be used as process water, depending upon the original water type:

a) Raw water, not used for dyeing. It cools and is discharged. The prerequisite is that enough raw water is available. Since the issue of communal directives stating that all water from a company must flow through the waste water treatment plants (waste water costs), this type of cooling is no longer relevant. Special arrangements allowing such cooling water to be fed into the main outfall are almost unheard of.

b) Untreated cooling water that can be used for dyeing.

c) Treated cooling water that is suitable for dyeing.

Ground water (spring and well water) is excellently suited for dyeing, if it is almost neutral (pH 6–7.5), has a low degree of hardness (5–7°d), contains no harmful, aggressive carbonic acids or metals and is free of suspended matter. However, such process water is a natural product and therefore varies in its composition, e.g. in its degree of hardness. → Water requirements for dyeing and finishing; Water as finishing medium.

Product (Lat.: productum), yield, result. From the point of view of value analysis also services.

Product application generally takes place in the form of solutions or dispersions/suspensions. Product application can be controlled indirectly by the measurement and control of the quantity of solvent or dispersant (generally water) with a few exceptions (e.g. due to high dye substantivity or differing dye take-up capacities of the fibre). A range of parameters should be consistently upheld:

- product concentration in the liquor,
- initial moisture of the fabric,
- fabric construction,
- dye take-up capacity by pretreatment (e.g. by mercerizing cotton, causticizing viscose, thermofixing polyester).

On the other hand, some variables influence liquor take-up such as:

- cross-linking capacity of the material,
- material speed,
- tension of the material run upon entry,
- padder-roller temperature,
- dwelling time in the liquor (without taking into account the dye substantivity effect or the “reversed tailing” effect).

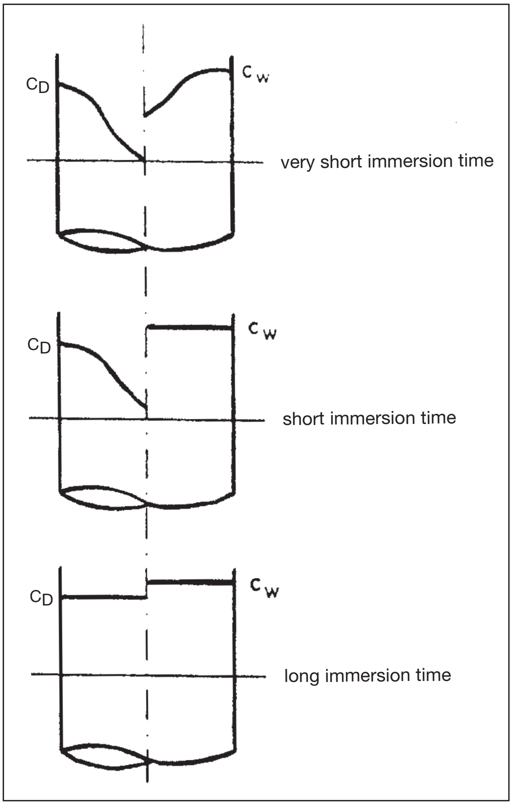

Fig. 1: Diagram representing the concentration profiles of both water (C_W) and dye (C_D) within a fibre during dyeing (according to Rüttiger).

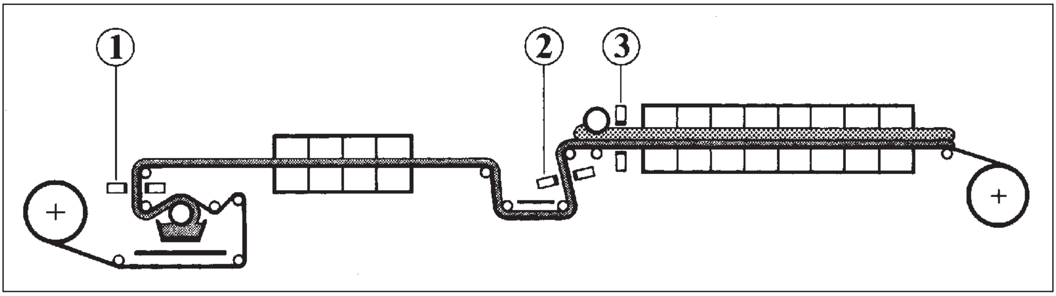

Fig. 2: The measurement and control of the application process as exemplified by tufted backing coating.
1 = high humidity measurement following nip padding; 2 = residual moisture measurement following intermediate drying; 3 = humidity measurement following foam application.

They can be compensated by the measurement and control of the dye take-up.

According to Rüttiger the exchange factor in the padder chassis depends primarily upon the submersion time, as is illustrated by the different diffusion coefficients of water and dye based upon the concentration profile in fibres (Fig. 1).

process	RL in %
nip padding technology MA process (Triatex)	<45 20 – 40
dip rollers engraved application rollers	from 40 up to 100, depending on type of roller
foam application direct, unpressurized foam application using blade or pad United Merchants and Manufac Dinting Engineering bubble colouration process Hoechst AG	
direct application of compressed foam Gaston County; FFT process Stork; RSF process Mitter; pile fabric 70 %, carpet	 10 – 25 20 – 30 40
indirect foam application Küsters, Janus Monforts, Vacu-Foam	 10 – 40 10 – 45
spray application jet-extrusion of liquor into an electrostatic field	30
rotor process Weko	<20

Tab.: Product application processes which involve a minimum application of product.
RL = liquor up-take.

In addition to the classic product application with the padder, high moisture product application (more than 100% liquor application) is significant in pretreatment (Flexnip, Super Sat, Optimax, Raco-Yet, etc.) and low wet pick-up (Tab.) is significant in resin finishing and continuous dyeing. Nip padding and foam application are also used in coating (Fig. 2). In special cases spotting is also used (Fig. 3).

Fig. 3: Liquor pouring as a method of product application (curved blade/West Point).

Product application must be checked for quality assurance. The example in Fig. 2 shows a tufted back coating plant in which

- measuring station 1 monitors and automatically controls the base coat,
- measuring station 2 monitors and automatically controls the intermediate moisture,
- measuring station 3 monitors and automatically controls the foam application.

The aim of measuring and controlling the continuous product application on textile material lengths is

a) to avoid lack of uniformity,
b) to improve the reproducibility of the material quality,
c) to quickly achieve matching of laboratory and production results,
d) to avoid excessive application.

Many product application machines can in principle be classified into mechanical processes, gas kinetic processes, capillary processes and low wet pick-up processes.

By the use of a size application measuring device it is possible to automatically regulate the squeezing pressure by continuous measurement of the actual size application (Fig. 4). A uniform degree of sizing can thus be achieved assuming there is a constant size concentration and temperature (viscosity).

The advantages for the weaver are:

- savings in size,
- uniform degree of sizing,
- higher weaving efficiency rate,
- recording of size application.

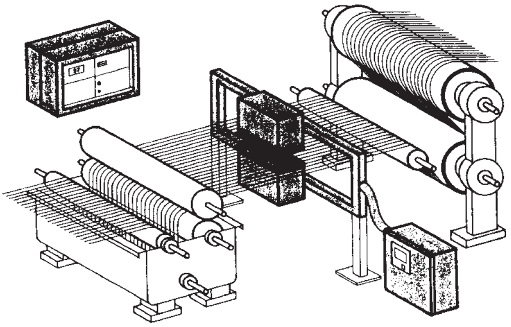

Fig. 4: Measurement of product application on sized warp yarns using a Pleva microwave high humidity instrument.

The advantages for the finisher are:

- savings in chemicals during desizing,
- lower waste water pollution,
- greater uniformity in pretreatment.

Product development is carried out by the textile designer (known as the designer in the cloth industry). After a creative phase, product development moves into the realisation phase; the pattern collection is developed (see Fig.). If the manufacturer has placed orders for blocks prior to the season and in the case of coloured material made colour classifications during the season, then the task of product development includes monitoring the production process, so that suitable conclusions can be drawn regarding the correct material construction. This also includes an attempt to monitor the behaviour of the item in use and its disposal routes.

Production Manufacture, generation of products from raw materials or semi-finished goods, e.g. by textile finishing. In a broader sense, factors of production as commercial service provision: purchasing, transport, stocks, manufacture, administration, checking; without financing and sales.

Production control,

I. The logging of process data and its processing and provision to the sender for decision making and influencing the process as part of manufacturing control. The automation devices used for production control consist of a central processing unit and a certain number of decentralized recording devices for manual entry or semiautomatic or automatic recording of data directly at work places, whereby the central processing unit incorporates at least a minicomputer.

II. → Quality control.

Production costs in textile finishing According to production cost classification in a static textile finishing company (in-house finishing), personnel costs are a significant cost factor in the production sector at 35%, min. 29%, max. 48%, depending greatly upon the type of finished item. 60% of the personnel costs or 21% of the total productions costs are spent upon internal material transport (textile material, finishing product). Requirements for reducing production costs: lowering the personnel costs for internal goods transport by shorter transport routes, lower frequency of transport and lower personnel related transport. → Production flow.

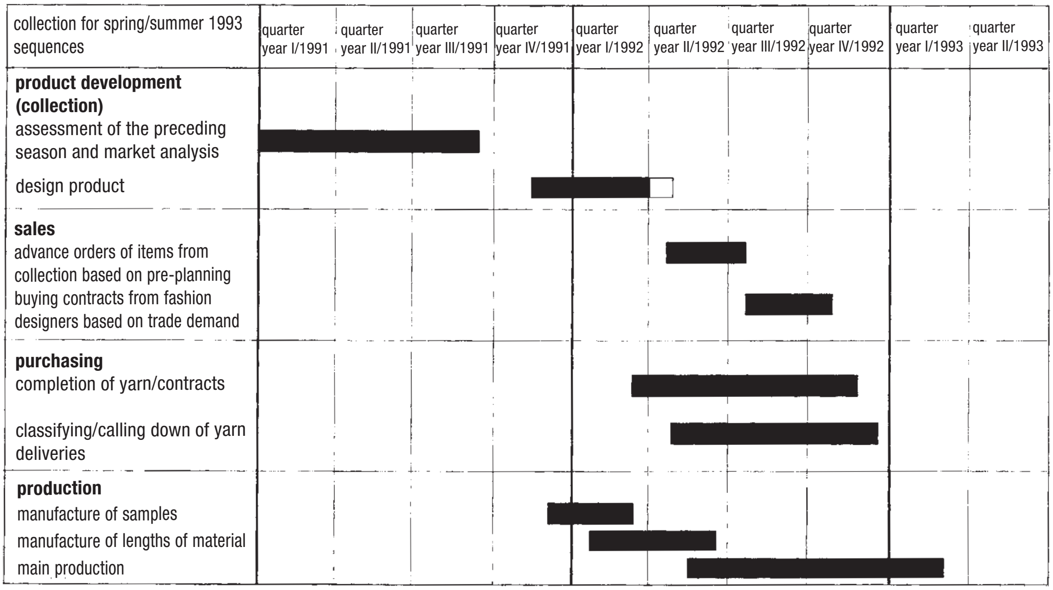

Fig.: The process of developing a collection by a fashion weaver.

Production data logging The logging of all determining variables and components necessary for production and follow-up calculations. The most important part of this is machine state logging, i.e. the logging of all data regarding the current state of the machine, e.g. rotation speed, infeed, etc. Information about the use of labour and data regarding material and planned process stages and procedures are also part of the manufacturing process.

Production flow A textile product, for example in the clothing sector, runs through the production sequence from raw material to sale in around 66 weeks (see Fig.). Of this, the proportion of storage and waiting time (approx. 80%) is significantly greater than the actual process time (approx. 20%).

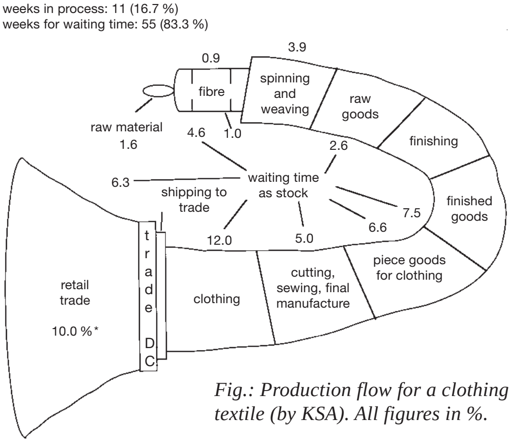

Fig.: Production flow for a clothing textile (by KSA). All figures in %.

Textile finishing is a transport intensive production process, in which 7 kg of textiles are impregnated per man and hour in static finishing operation, which at an average of eight treatment stations in the production flow represents a transport volume of approx. 53 kg material. Therefore, the personnel expenditure (→ Production costs in textile finishing) for transport is high at approx. 20% of the entire production costs. The cost-oriented production flow leads to targets for personnel expenditure, throughput time, production capacity and production quality. These lead to measures of an organisational, procedural, construction and production related nature, each of different importance. This is dependent upon the commercial structure and item range of the textile finishing. The aim of each measure and the goal of rationalizing the production flow should be to increase the profitability of the company. This is the predominant issue of a meaningful cost calculation.

Production planning After the priority, material group and colour number of a batch has been specified in accordance with the order, production planning prepares the reservation of equipment. Whereas in work planning, the weighed raw materials are made available and possibly put onto material carriers or converted into making up form, which are preconditions for the dyeing process, production planning is more concerned with the intellectual preparation for production. This phase is naturally fully integrated into the flow diagram, e.g. in dyeing (see Fig.). by means of EDP networking.

The reservation of equipment is continuously displayed to the operator on the screen, where it can however still be modified. Batches can be subsequently deleted, others added or batches swapped. Once all modifications have been made, a list can be printed out showing the sorted distribution of the batches on the dyeing equipment. It is up to the person in charge of the dyeing process whether to stick to the production plan in the proposed sequence. Any changes to the sequence are not checked by the system. Because, for example, adding an urgent order would lead to a new purchase order sequence, which would be more time-consuming than making a manual change, it is necessary to rely on the capabilities of employees. Because of the large number of boundary criteria (packages per machine, customers wishes, etc.), a computer generated reservation list is not produced for the equipment. The “purchase order” function can only be accessed from a viewing device, because operating the function from two devices would lead to undesired influences.

The preparation of raw materials, dosing of liquid dyes and weighing of powder dyes and auxiliaries belongs within the scope of production planning. The provision of materials is not computer-supported. The calculation of dye quantities and their dosing or weighing is, however, largely supported and controlled by the computer. The person in charge of the dyeing process inputs the material weight for the batch to be dyed; the resulting dye quantity is displayed. The computer calculates the quantities independently from the material quantity and the recipe. In addition to current values, past values for the same recipe are also displayed, as well as any after-dyeing that proved necessary in the past. With this additional information the operator can decide whether to correct the dye quantity or to add additional dyes, in order to avoid costly re-dyeing and to complete the dyeing process using less time and energy, thus more cheaply.

Only when the person in charge of the dyeing process has submitted a personal receipt, may the dyes be dosed from the hoppers. Liquid dyes are pumped into containers by dosing pumps. The warehouse worker initiates this process via the input keyboard of his monitor. The computer independently monitors the prescribed quantities based upon the recipe. Powder dyes and auxiliaries are weighed in the hopper itself. For this purpose there are weighing machines with different

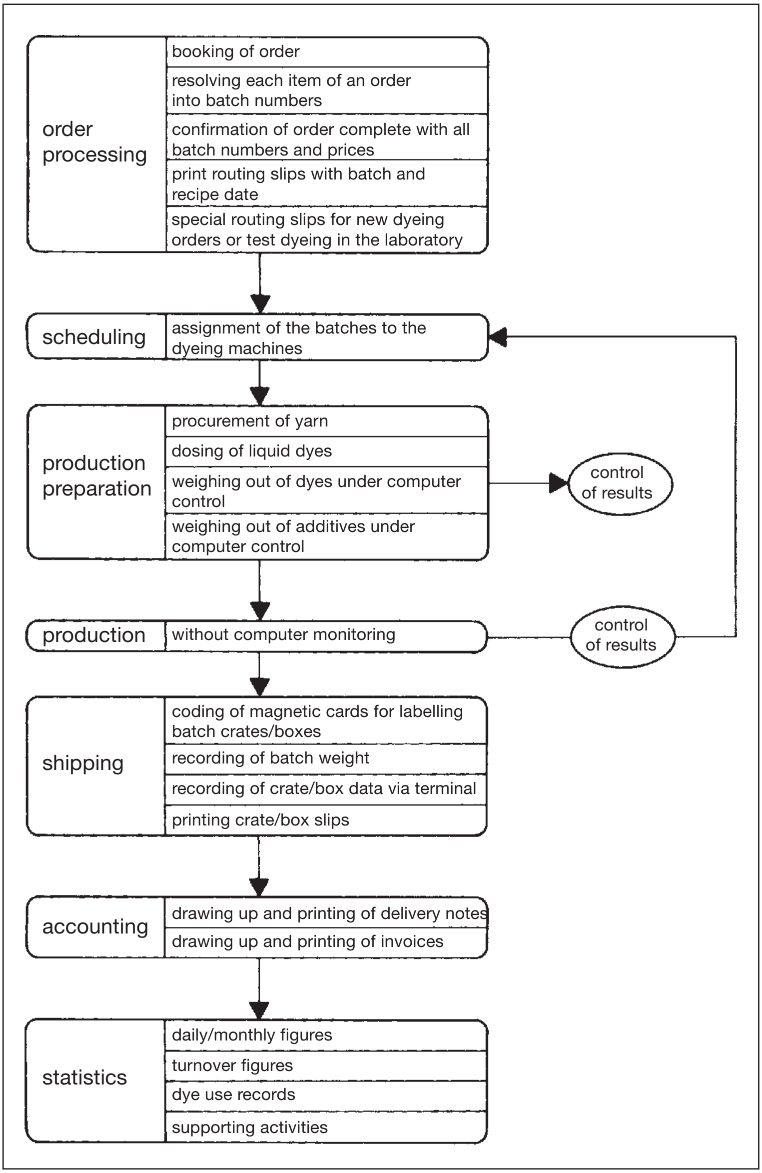

Fig.: Flow diagram for a dyeing company.

weighing ranges. The warehouse worker can see the product to be weighed on his monitor. The computer only accepts this process if weighing is precise and within a tolerance range. After the input of a completion message the computer checks the weighing process; if it has been done with sufficient accuracy the data for the next substance to be weighed is displayed upon the screen until the entire recipe has been processed. A check of the accuracy of the product does not take place.

Production quality control → Quality control in manufacturing.

Production resources Machines, equipment and devices necessary for commercial operation.

Production speed If we review technical developments in the second half of the 20th century, we see that there has been a qualitative and quantitative change: productivity viewed on the basis of production speed has increased significantly (see Fig.). On the other hand, a comparison between the different finishing stages is only possible logarithmically: The difference between weaving at max. 1 m/min and jet dyeing at around 400 m/min or continuous finishing at around 150 m/min is too great.

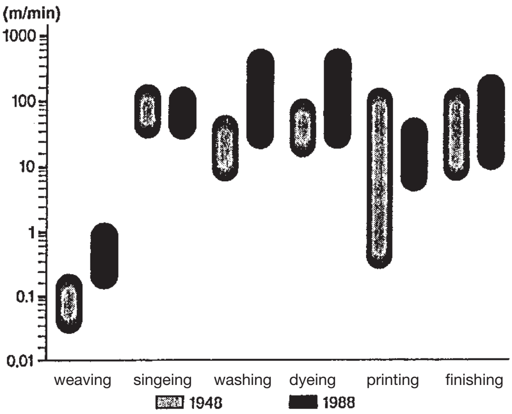

Fig.: The production speed of different operations in textile finishing (Kothe).

Production time table Textile products are produced according to a preplanned timetable in the pipeline of manufacturing to sale. The creation phase and implementation phase must be matched to the trade season. With a precisely determined process including the necessary consultation phase, production and delivery follow the plan as closely as possible (Figs. 1–3).

Productive time Component of → Operating time.

Product liability law In mid May 1985 new regulations came into force in the form of the “EC guideline for the harmonization of legal and administrative regulations for member states regarding liability for faulty products”. In August 1988 this law was incorporated into German national law. This new law tightens up product liability. The manufacturer is made liable for damage caused by faults in his product, even if it is not

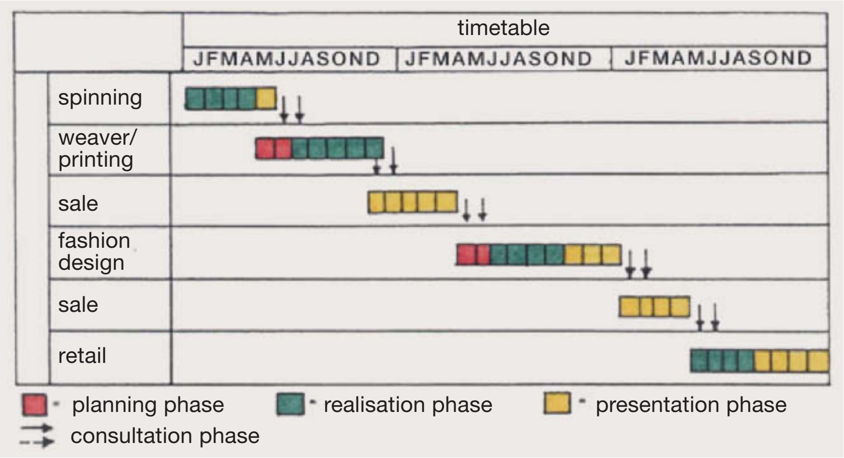

Fig. 1: Time table for the production stages between spinning and retail.

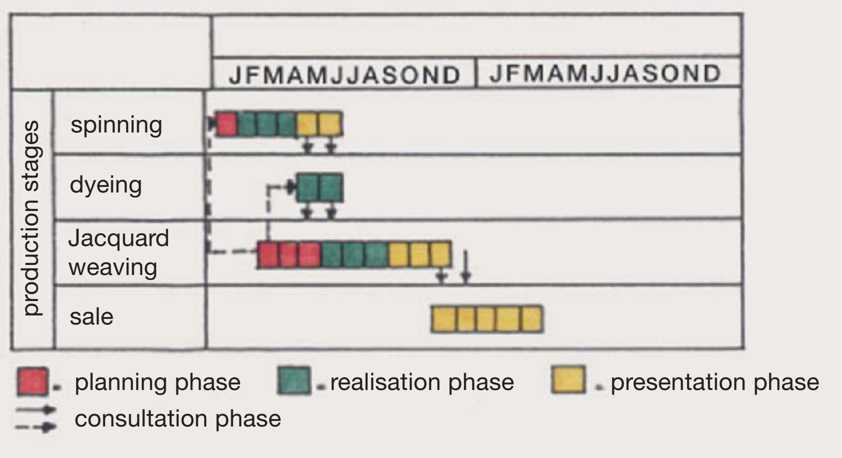

Fig. 2: Time table for the production stages between spinning and Jacquard weaving.

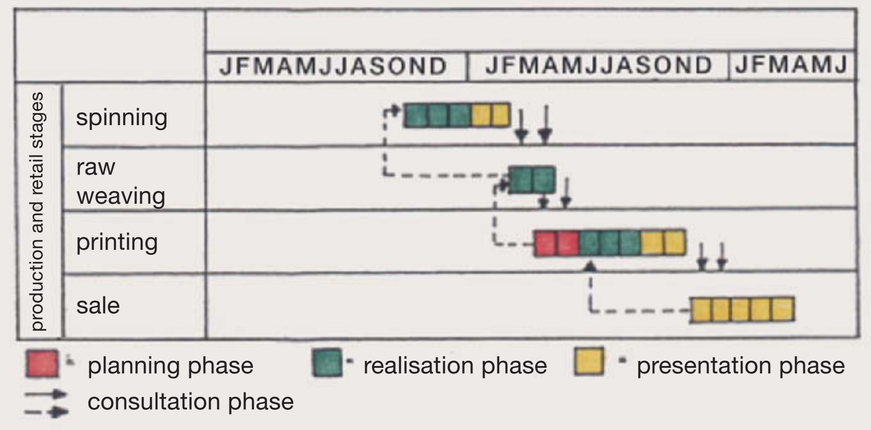

Fig. 3: Time table for the production stages between spinning and printing.

his own fault. The same applies to statements in technical information and advertising, which do not correctly reflect product characteristics. It is therefore necessary to carefully check all quality statements made by the company or its employees against the associated risk from a liability point of view. But it is also necessary to rethink production. Over and above the general duty of care, a quality assurance system with direct responsibility must be stipulated, similar to the GMP (good manufacturing practice) used in the development and manufacture of pharmaceutical goods. Quality assurance handbooks must be provided to customers upon request.

Product liability controls the rights a user has to claim against the manufacturer if damage occurs during the use of his products. It exists independent of consumer protection guarantee rights according to BGB (Bürgerliches Gesetzbuch – German Civil Code) and HBG (Handelsgesetzbuch – German Commercial Code) in the event of a notice of defect and thus does not require a binding contract (e.g. purchasing contract) for a liability claim (in contrast to warranty for defects). The German product liability law (Produkthaftungsgesetz – Prod. Haft G) thus represents an additional basis for a claim, which extends the liability obligations of a producer (called producer's liability). In the event of damage due to “faulty products”, German law distinguishes between three types of fault:

1. Design faults: despite observation of legal and technical standards the product is unreliable or dangerous in its design.
2. Fabrication faults: due to faulty production the product is unreliable or dangerous.
3. Instruction faults: use is unreliable or dangerous due to faulty instructions.

The liability arising, in accordance with § 823 BGB is a liability for intentional and negligent acts. However, culpability, and thus liability, only exists if the damage was caused by intentional or negligent action.

The main contentious difference between the absolute product liability law and the culpability related § 823 BGB lies in the following (the asterisks used have the following meaning: * = increase in liability; ** = no change to liability; *** = significant extension of liability):

– Intention or negligence are no longer a precondition for liability (culpability, burden of proof, etc. are without meaning, in contrast to earlier uses of legal language absconder is included*).
– The term “fault” used in accordance with regulations (expected safety due to design, product and instruction) is precisely defined (improper use excludes liability**).
– Both the manufacturer of the end product and the producer of raw materials and semi-finished goods are liable, as are “quasi-manufacturers”, i.e. importers and purchasers, who pass themselves off as manufacturers by putting their name on goods (extended meaning of the word manufacturer, even for import from countries of origin outside the European Community***).
– There is no liability where the fault only arose after the product was put onto the market, the faulty product corresponds with binding sovereign standards or there is no recognisable source of the fault according to the current level of knowledge and technology (development risk). The burden of proof for defence options lies with the manufacturer (***).
– Liability to pay damages covers all personal damage in the commercial and private sector, but damage to property only in the field of private use (enormously high maximum liability amounts apply for one or the same products with the same fault*).
– A claim for liability (liability to pay damages) expires 3 years after awareness of the damage, the fault and the liability, and expires 10 years after the

faulty product is put into service (if no summary judgement or lawsuit are pending*).

In the event of personal injury the product liability law also extends to the private sector (validity extends to all people suffering physical injury due to a product***); in relation to damage to property, on the other hand, it is a pure consumer protection law* with, not insignificant, own risk of the person suffering the damage (own risk). As before, liability for damage to property in the commercial sector can only be enforced according to the principles of liability for intentional and negligent acts (§ 459 BGB). Product liability law does not cover damages for pain and suffering. This must be enforced according to the conventional principles of liability for intentional and negligent acts (§ 823 BGB) (see Tab).

The development risk must be reduced as far as possible. In addition, the possible risks occurring during use must be thought out and tested in advance. In general, there will still be no liability for development risks in the future. "Faults" that are not yet recognized as such, but which would have been recognizable and avoidable according to current knowledge and technology, are not "development risks", and therefore liability exists for such faults.

If all these points must be considered for "normal" textile products, they become all the more important, e.g. in flame retardant textiles. These are associated with an increased risk of damage if they turn out not to be "flame retardant" in the event of a fire. Particular problems are encountered in the manufacture of flame retardant textiles, which did not previously exist in the manufacture of textiles for clothing and domestic textiles, or were of lesser importance. Burning behaviour cannot be tested directly on fibres and yarn. There are two reasons for this: firstly, all fibres and yarns are treated with preparations or assistants either during manufacture or with further processing. These usually burn well and thus give rise to false predictions regarding the burning behaviour of the fibre substance or the textile. Secondly, there are no burning tests for fibres or yarns. They must always be formed into a flat surface to be tested. Even a test often used in polymer development, such as the LOI (Limiting Oxygen Index), requires a surface for testing. In many cases where textiles are processed together with other burnable materials, e.g. in furnishing materials, even more expensive tests must be performed to obtain practical predictions regarding burning behaviour.

Flame retardant fibres contain, e.g. 0.6% phosphorus, which is sufficient to ensure flame retardance for

(BGB § 459 ff and following, also HGB § 377)	(Prod. Haft G of 15. 12. 1989)	(BGB § 823 ff, UHG and 2nd statute to counter environmental crime/in preparation)
warranty liability* – of the supplier – of the end manufacturer and/or – of a member of the retail chain	**product liability****	**environmental liability*****
faulty product	*damage or loss resulting from faulty goods*	*damage caused to the environment by a product*
(damage to the product)	(damages caused by a faulty product to other materials, goods, interests or persons; applies to – parties to a contract – their employees – users of the product and any persons not involved in the contractual arrangement)	(damages arising during manufacture, transport or use)
end user transportation trade etc.	end user	transportation trade etc also the end user under certain circumstances.

Tab.: The responsibilities of the producer with respect to liabilities.
**Adequate cover is posible through commercial liability insurance. **Adequate cover can be arranged through supplementation of commercial liability insurance. ***Adequate cover cannot, or can only in part, be arranged; legal protection for staff is also necessary.*
BGB = Bürgerliches Gesetzbuch (Civil Code); HBG = Handelsgesetzbuch (Commercial Code); Prod. Haft G = Produkthaftungsgesetz (product liability law); ff = and following §§.

the manufactured textiles according to DIN 4102, B1. For the user this means: he must bear in mind for each finish or dye that, ultimately, only the flammability of the entire system counts. The fibre manufacturer bears co-responsibility due to possible quality marks, which is why the fibre producer largely convinces the user about the responsible handling of his pre-product with the appropriate test certificate (according to Hemmpel, Zimmermann).

Product life span Product life spans in the textile sector are often short (see Fig.). Thus in many cases introduction, growth, maturity and death often overlap. Whereas, not so long ago there were two seasons in a cycle of six months, these phases have now been compressed into two to three months. To some degree, seasons no longer exist at all and have been replaced by a permanent pattern. The logical consequence of this is smaller, sometimes completely non-economic production batches, but of course, also greater stocks being held, if a company wants to work economically and, above all, deliver to the customer according to schedule. This also means that there will be some outdated products which are difficult to sell and can only be sold at a loss. It has been found that products and product groups develop differently. Individual products that immediately become winners have a high market growth and can be sold at a relatively low investment cost. Others are difficult to accommodate from the start and can sometimes only be placed on the market at high financial cost. Some products from the current range will remain on the market for a long time, produce profit, but do not have any particular growth rate. Only by a further expensive investment in marketing could a further increase in sales be brought about for such items. Finally, we should consider those products, which show a strong decrease in growth and returns. The latter are a burden to the company and sooner or later must be removed from the market, because they can only be sold at a loss.

Professional and technical organizations → Technical and professional organizations.

Professional organizations → Technical and professional organizations.

Profiled fibres This group, which includes hollow profiled fibres, consists of modified cross-section synthetic fibres, produced by spinning the melt from profiled jet orifices usually with a slit-shaped or pointed profile: Star-shaped, trilobal to multilobal, i.e. 3, 5, 6, 10 cornered/pointed, etc. (other cross-sectional variations, such as normal hollow fibre types, the straw type, flat shapes, large letter shapes, etc. are only associated in the broader sense). The development of “true” profile fibres opens up many possibilities due to the production of cross-section structures specifically designed for synthetic fibres (→ Polyester fibres, Fig. 5). Properties are for example: enlarged fibre surface, more subdued lustre, better thread endings, greater coverage and fullness (lower transparency), improved anti-slip properties, lower pilling tendency, greater stiffness; in hosiery lower thread pulling sensitivity, reduced tendency to run, increased serviceability and more comfortable wear, etc.

Profiled hollow fibres Hollow fibres based upon polyamide and polyester with additional cross-section profiling. Additional advantages compared to round cross-sections and also compact profile figures: further increased voluminosity (up to approx. 40%), greater stiffness, improved heat retention capacity (up to approx. 20%), reduced transparency of knitgoods (up to 50%), double the durability for hosiery. Recommend-

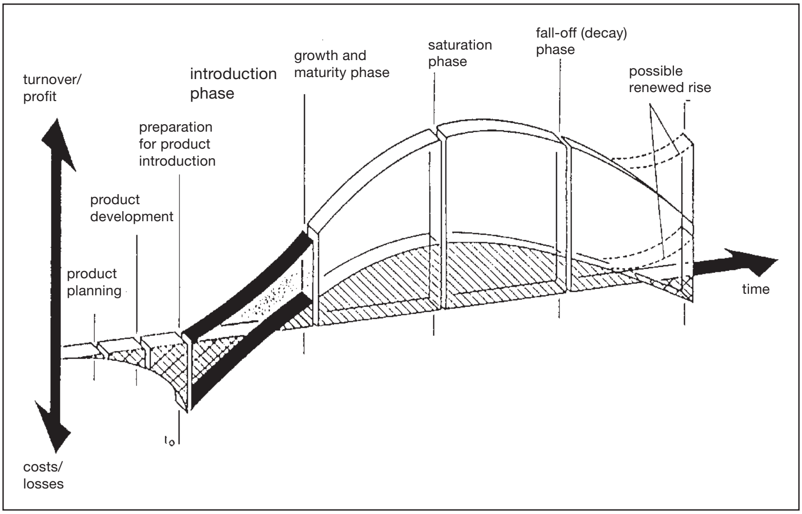

Fig.: Product life span (t_o = development costs).

ed: polyamide profile hollow fibres processed pure for the knitgoods sector, as mixed components for fashionable outer clothing, for hard wearing and work clothing. Polyester profile hollow fibres specifically for the carded yarn sector. Mixed yarns of other fibres with profiled hollow fibres possess a considerably greater cross-section, which makes it possible to save over 20% material for the same covering power and fullness.

Profiles The weighting of requirements as represented for profiles (→ Quality standards). This weighting is allocated as marks, for example, in concentric circles and the characteristics specified as requirements, in certain sectors (see Fig.).

Profitability level → Break even point.

Prograde mercerizing process Process patented by Coats under German Patent Number 1 136 417 for the mercerizing of sewing yarn on running threads (150–200 m/min). The yarn runs through liquid ammonia at –33°C for max. 10 s and the ammonia then removed by heat and steam, whilst the yarn is drawn. Ammonia consumption approx. 20–50% of material weight. The structural change of the cotton is similar to → Mercerizing with caustic soda liquor. A marked increase in breaking strength and dye take-up is achieved. The lustre, on the other hand, remains the same.

Program automation Equipment and mechanical procedure sequences are automatically controlled and

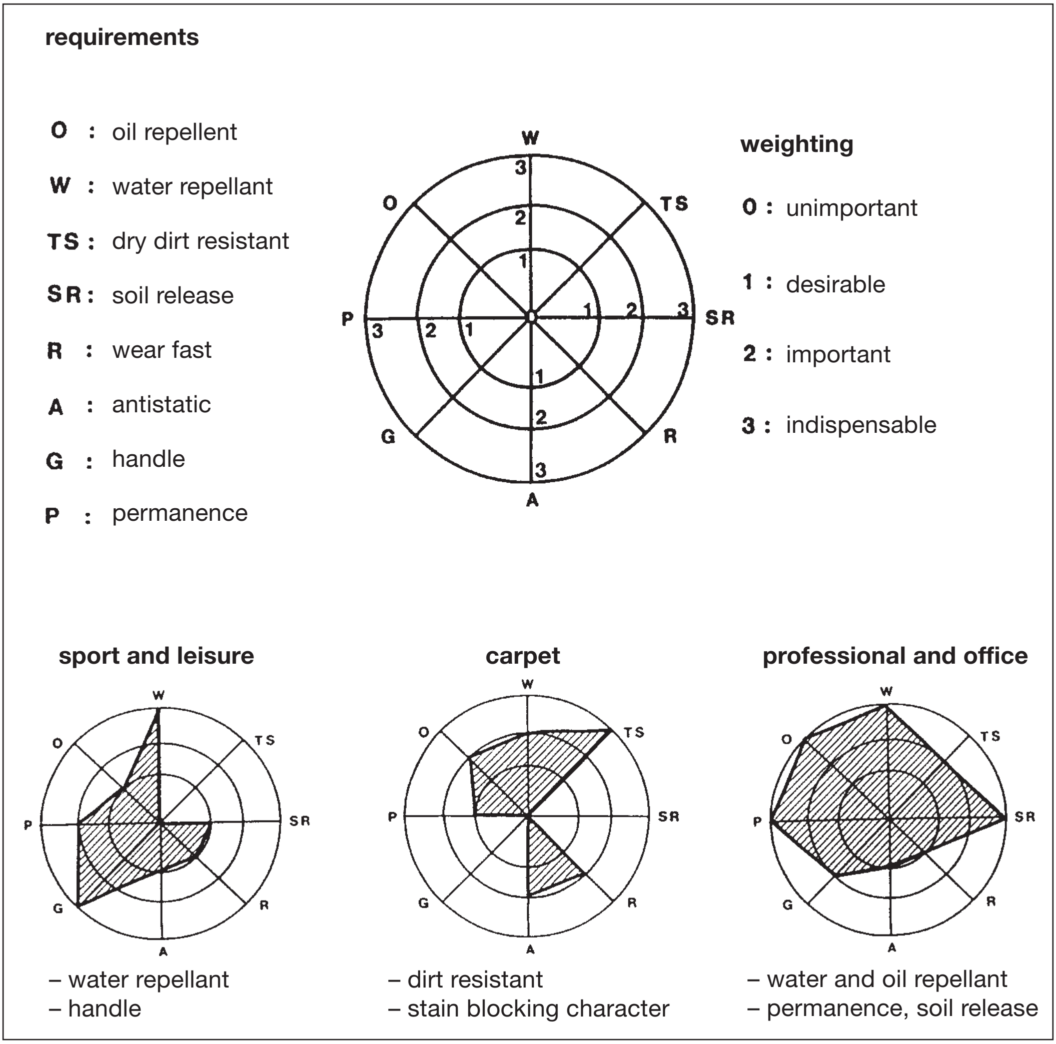

Fig.: Definitions and examples (below) of profiles.

regulated using program cards, rollers, etc. by means of → Control equipment. → Automatic control systems.

Program control → Control technology in dyeing.

Program matrix Matrix for the allocation of n input variables to m output variables. It is used in program control systems (→ Control technology in dyeing) and works according to the principle of crossbar distributor. There is usually a diode matrix, whereby the diodes are placed at the intersection points. The switching sequence can be altered by changing the diode layout.

Program regulator Precision regulators, which for example independently set desired temperature or humidity values in a certain sequence and at a desired level and maintain them for a certain time (→: Automatic control systems; Control equipment). For example, program regulators control the following sequence of processes: Filling a container, setting the steam, increasing the temperature curve according to specification, maintaining the dwelling time and turning off the steam after the completion of the program. In order that that no re-boiling occurs, the regulator also controls the emptying of the container, giving an optical or acoustic signal at the same time.

Progressive (Lat.: progressus = progress), increasing, continuing in stages; e.g. progressive feed of textiles, sequential wet/dry cycles, or progressing onwards from wash to wash, i.e. increasing shrinkage each time (in wool also as felting shrinkage).

Progressive jigger Machine designed according to the principle of the → Immersion jigger for the scouring of cotton and cotton/synthetic fibre mixed fabrics. Three batching rollers are arranged in line in an open tub. Material runs from roller 1 to roller 2 and from there to roller 3, while new material runs onto roller 1, etc.

Projectile weaving machines Weft insertion takes place from one side by means of so-called projectiles, i.e. non-positively moved bodies with a clamping device to accept the start of the weft thread (Fig. 1). The projectiles are accelerated by torsion bars, driven through the row and then driven back underneath the material (Fig. 2); generally several of these weft insertion bodies are in the row at the same time. Due to the high speeds, special oils are necessary, which guarantee fault free running of the projectiles, but any soiling of the material must be able to be washed out.

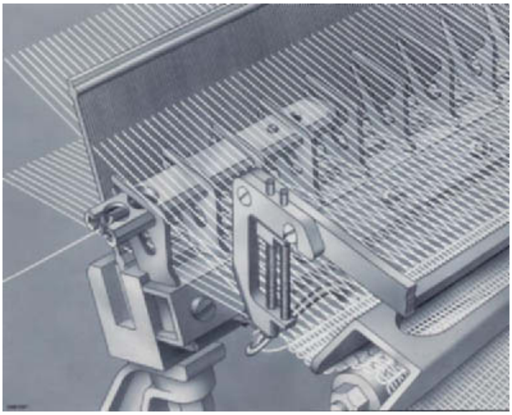

Fig. 1: Introducing the weft in a projectile weaving machine (Sulzer).

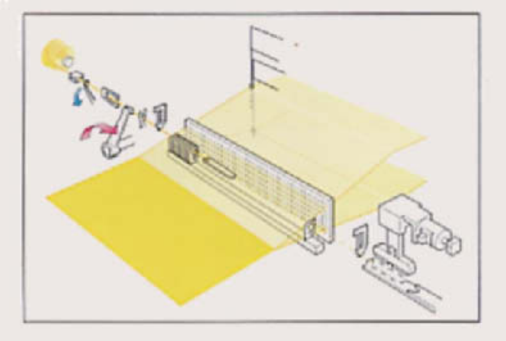

Fig. 2: The principle of the projectile weaving machine (Sulzer).

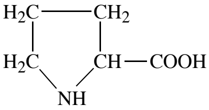
Proline An → Amino acids (monoimino-monocarboxylic acid), also pyrrolidine carboxylic acid,



contents in wool (6.75%) and silk (1.5%)

Proof sample Representative sample for the final quality of the goods.

Propane C_3H_8 → Saturated hydrocarbons.

Propane gas → Liquefied gas.

Propanetriol → Glycerol.

Propanol (propyl alcohol), C_3H_7OH; → Alcohols.

Propeller mixer Rapid mixer for mixing print pastes. The stirring body is shaped like a ship's propeller (this is why it is called a propeller mixer). During the stirring process the stirred material is drawn from above and propelled downwards.

Propene (propylene), C_3H_6; → Olefins.

Propenoic acid → Acrylic acid.

Propionic acid C_2H_5COOH. Present as organic fermentation product and in sweat.

Proportion (Lat: pro-portio = analogy), ratio; e.g. combining weights (→ Equivalent weight) of elements in relation to each other (law of so-called constant proportions).

Propoxy group $CH_3–CH_2–CH_2–O–$ (monovalent).

Propoxylation Addition of propylene oxide to compounds with active hydrogen for the production of surfactants.

Propyl C_3H_7 → Alkyls.

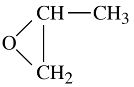
Propyl alcohol (propanol), C_3H_7OH or CH_3–CH_2–CH_2–OH; → Alcohols.

Propyl glycol Density 0.910–4; flash point 51 °C; relative evaporation rate 68. Miscible with water. Solvent for printing thickeners and lacquer.

Propylene → Propene.

Propylene glycol (1.2 dihydroxy propane), CH_3–CHOH–CH_2OH. Boiling point 102.5°C. Possesses similar properties to → Ethylene glycol. Good dye solubilizer and indicator, greater surface activity than in ethylene glycol, corrosion prevention capability, suitable as moisture holder and softener for foils. Also recommended for polyamide differentiation.

Propylene oxide



Condensation point 34.5°C, easily burnable liquid. Soluble in water, alcohol, ether. Application: as solvent for cellulose acetate, cellulose nitrate, vinyl resins, natural resins. Textile assistant primary product: oxyalkylising material (less important than ethylene oxide).

Propylene urea resins → Propylene ureas.

Propylene ureas Hexahydropyrimidone-2 and derivatives, in the form of dimethylol compounds an important reactive resin (propylene urea resins), e.g. DMPU; dimethylol-4-methoxy-5.5-dimethyl-propylene urea;-5-hydroxypropylene urea.

Prosthetic group → Co-enzymes.

PROT → Protein fibres, abbreviation according to → BISFA.

Protalbinic acid → Lysalbinic acid/protalbinic acid.

Protanopic So-called “red weakness”; → Anomalous colour vision.

Proteases → Enzymes from the main group of hydrolases, which hydrolytically split the peptide bond of protein bodies (→ Proteins and → Proteids) (so-called protein digestion) according to the diagram:

$$H_2N{-}R{-}CO{-}NH{-}R_1{-}COOH \xrightarrow{H_2O}$$
$$H_2N{-}R{-}COOH + H_2N{-}R_1{-}COOH$$

Proteases are also known as proteolytic or tryptic enzymes. We differentiate between the two subgroups depending upon whether only (poly) peptides are decomposed or higher proteins as well:

I. → Peptidases.

II. → Proteinases.

Proteases are contained in pancreas diastase, but are also generated by bacteria and mildew and play a significant part in the removal of protein, blood stains, etc. → Proteolysis.

Protease solubility of wool A certain proportion of keratin fibres can be dissolved by specifically acting proteases. The parts that are only weakly cross-linked by sulphur bridges are attacked by the protease, e.g. the endocuticula can be dissolved from the wool. The entire protease soluble proportion, 10–20% of the intact wool fibre, is made up, in addition to the proteins in the endocuticula, of proteins of the intramacrofibrillary complex, cell nucleus residue and cell membrane complex. The protease solubility has been proposed as a gravimetric determination method for the components in wool that are not resistant to enzymes, which are called non-keratins. Because protease only attacks areas which are only slightly cross-linked by cystine bridges, if the sulphur rich components are damaged we can expect to see an increase in the protease solubility compared to the undamaged fibre. So protease solubility lends itself to use as a method of quantitatively detecting the weathering depth for different fibre areas.

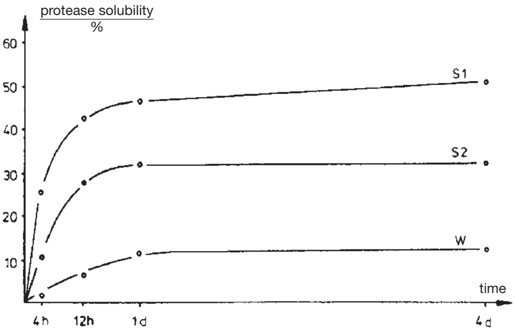


Fig.: The protease solubility with time of cut fibres of New Zealand wool (for explanation see text) (according to Höcker et al).

The Fig. shows the treatment of fibre sections from New Zealand wool with an enzyme/substrate ratio of 2 : 100 in relation to the incubation times of 4 h, 12 h, 1 day and 4 days. It is noteworthy that the high solubility of the 1st tip section (S1), which has been 25% dissolved after only 4 h and has achieved a maximum solubility of 51% after 4 days. The marked increase of the protease soluble proportion is not only promoted by the reduction in cystine content brought about by weathering, but the destruction of the outer cuticle layers allow the enzyme to diffuse in faster and dissolve out non-keratins and cystine damaged components. New Zealand wool shows more extensive damage along the fibre, because the path of the curve of the 2nd tip section (S2) shows a significantly faster reduction due to protease. At 16% after 4 days a protease solubility of the roots (W) was found, which corresponds with undamaged wool. As a result the protease solubility characterizes the different weathering along the fibre and is thus an indirect quantitative indicator for the skittery dyeing tendency (according to Klee).

Protective (Latin), preservative; for example in synthetic detergents relates to the electrical mechanism of the dispersing protective effect of the anti-redeposition agent components, usually carboxymethyl cellulose; the latter has an electrically negative reaction after adsorption by the cellulose fibres, like dissolved dirt surrounded by washactive molecules. The mutually repellent “protective” effect thus prevents the reattachment of dirt.

Protective clothing Clothing which provides protection against the effects of defined hazards, i.e. against harmful external effects. Its form and material are precisely specified to perform a particular protective function and it protects against specific effects. The type of protective clothing that meets the maximum possible number of protective requirements is the protective suit worn by an astronaut (see Fig.). The main protective functions of this type of protective clothing are as follows:

- protection against the vacuum of space, which without the suit would cause human blood to “boil”;
- protection against temperature differences, which range from –120°C to + 160°C on the moon;
- protection against micrometeorites and particles, which collide at high speeds;
- protection against the effects of fire due to accidental ignition of fuel;
- protection against ultraviolet radiation, which occurs to a degree that is unheard of on Earth.

Furthermore, the astronaut must be able to move, and heat and body moisture generated must be removed. He must also be able to breathe, i.e. in addition to a supply of oxygen being provided, the exhaled air must be removed. Initially, the oxygen supplied is passed from the helmet via the visor at a temperature of approx. 5°C and at a pressure of approx. 0.25 bar and then travels downwards along the body. At the same time, a liquid flowing through plastic pipes provides temperature balance. The suit incorporates two outlet valves, to the left and right of the body, to remove moisture and exhalation products. The oxygen supply and other technical devices that are part of the survival unit are located in a rucksack-like pack on the back.

Layers of material, like those used in the space suit for the “Apollo” project (from outer to inner):

- fabric made of polytetrafluoroethylene fibres: protection against impact and friction, as well as fire protection.
- fabric made of betaglass fibres, coated with polytetrafluoroethylene: fire protection; completely unburnable in an atmosphere containing oxygen.
- aluminized polyimide film, coated with a tulle made of betaglass fibres: reflective insulation, the glass tulle serves as a spacing and filling material.
- aluminized polyester film: reflective insulation.
- spunlaid fleece made of polyester fibres: filling material to provide a space between layers.
- polyamide fabric coated with chlorinated rubber: impermeable lining fabric.
- polyamide fabric: lining fabric/intermediate layer.
- polyamide fabric, coated with chlorinated rubber: sealing material, to retain the pressurized oxygen in the suit.
- light fabric made of temperature resistant aramide fibre: “comfort” lining.

Suit with additional cooling system:

- fabric made of elastane fibres: presses the pipe system onto the body.
- plastic pipes: flow of cooling liquid,
- light, porous polyamide fabric: creates space from the body.

Protective technology also uses textiles for other protective clothing. For example, fabrics to protect against heat and flames are covered with an aluminium film,

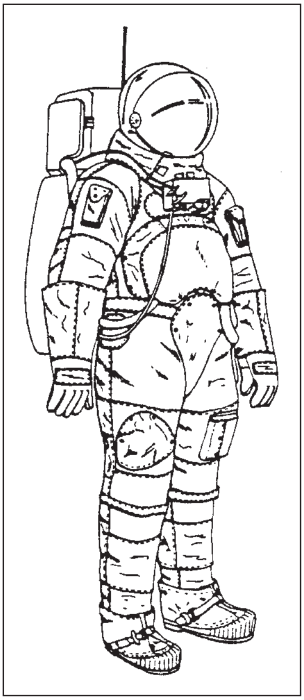

Fig.: Protective clothing of an astronaut.

this is achieved by laminating woollen or nonwoven fabric with a polyester foil containing aluminium particles. Other fibres such as glass filaments or aramide fibres can also be used as a carrier material if protection against metal spray is the primary requirement (blast furnace protection vests). DIN 66 083 applies. Fabrics can also be used to protect against cutting, for example to prevent saw injuries. Three dimensional textile construction incorporating air pockets is important to provide insulation against the cold in work clothing for polar regions. Chemical protection fabric (according to DIN 32 763) against toxic, corrosive or irritating substances must provide particular resistance against acids, lyes and solvents. Pure virgin wool is particularly suited for use in protective clothing due to the properties of the fibre (elastic, durable, water repellent, heat insulating) and can be optimized by flame retardant finishing. Such protective clothing made of virgin wool protects against a) heat stresses; b) hazards due to flames and flying sparks; c) hazards due to liquid metal spray; d) acids. There is functional protective clothing such as overalls, coats, protective gloves, but also knitted shirts, underwear, pullovers, hosiery, hats, which are made to meet the specific protective requirements of the different workplaces.

Protective colloids Lyophilic → Colloid, which delays the aggregation of the particles of a hydrophobic dispersion within certain concentration ranges. This tendency permits the protective colloid to attach itself to emulsified or suspended particles (precipitated lime soap, dirt, dye, delustring pigments, paraffin, etc.), envelop them and, because they have the same (negative) charge, to mobilize mutually repellent forces, which act against coagulation and keep them in a finely dispersed suspension. Natural colloids such as gelatine, glue, albumin, starch, etc. are very much classic protective colloids. Sulphite cellulose waste lye, oil sulphonate and fatty acid and protein condensation products and non-ionogenic polyether alcohols are synthetic protective colloids. Evaluation → Ruby number. Application as → Fibre protective agents.

Protective paint coatings Used in workshops, containers, machines, pipes, etc. to protect against corrosion or chemical decomposition (by water, acids, lyes, solvents, steam).

Protective paper is inserted in the transfer calender during transfer printing on the reverse of the textile material to be printed, in order to catch the dye that sublimates through the textile material.

Proteids So-called homogeneous → Proteins, which contain further components in addition to amino acids, e.g. paracasein also contains phosphoric acid (thus a so-called phospho-proteid).

Protein (conjugated proteins). Building blocks of all cells and organisms in animals and plants. Substances of high molecular composition (amphoteric) with characteristic nitrogen content in contrast to celluloses. Made up, on average, of 5% carbon, approx. 25% oxygen, approx. 16% nitrogen, approx. 7% hydrogen, 1–4% sulphur (not contained in silk). One differentiates between:

I. Simple proteins (→ Proteins) made of actual albumen (Protamines) or structural proteins (scleroproteins →: Fibroin; Keratin; Collagen).

II. Composite proteins (→ Proteids).

Proteins are typical colloids. They are relatively sensitive to physical and chemical influences (coagulation or congealing when heated, as a result of opposing electrical charge, due to alcohol, ammonium and metal salts, acids, tannin, etc.) The are "soluble" in alkalis (forming albuminate) and acetic acids or are decomposed with alkalis, acids, enzymes to form → Amino acids. Proteins, protein decomposition products, protein and fatty acid condensation products, etc. are very important in the entire field of textile finishing. Protein detection →: Adamkiewics reaction; Biuret reaction; Millon's reagent.

Proteinases Protein decomposing enzyme belonging to the group of → Proteases, which act specifically upon higher → Proteins, e.g. papain, pepsin, trypsin (tryptase).

Protein chemistry The fact that proteins are the basic substances of organic life is demonstrated for the textile finisher in the handling of animal hair wool. The wool finisher must get to grips with disulphide bridge chemistry, and dyeing wool is the fundamental application of protein chemical properties of wool. Protein chemistry also underlies the handling of other protein substances. So the food chemist uses thiol catalysed disulphide exchange as a differentiation criteria in the differentiation of casein and whey protein (there is a different EC subsidy arrangement for the latter than for casein).

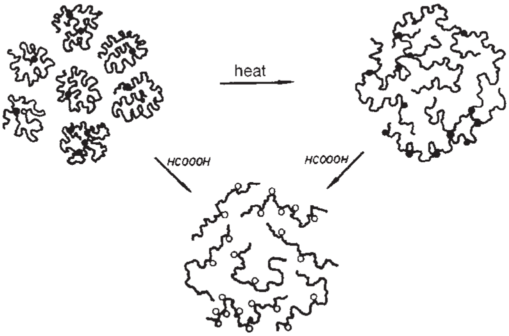

Fig. 1: The covalent cross-linking of proteins due to thiol-catalysed disulphide exchange and thiol oxidation during heating; oxidation with performic acid leads to the production of soluble monomers (according to Klostermeyer).

If such proteins are denatured during heating, e.g. milk protein bodies cross-link due to thiol disulphide exchange, they are then no longer soluble, which means that the solubility criteria for the differentiation of casein and whey protein no longer apply for heated milk (Fig. 1). However, if the heated mixture is subjected to a protective performic acid oxidation (cystine yields cysteic acid), the immunologic specificity can also be detected in oxidized casein, making a differentiation possible.

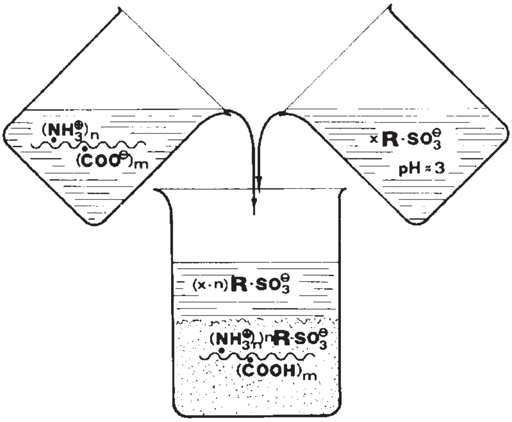

Fig. 2: The principle of rapidly determining the presence of dissolved proteins using acidic wool dye (according to Klostermeyer).

When dyeing dissolved milk proteins with amido black, an acid wool dye, the protein dye complex is precipitated, and the excess amount of dye in the filtrate that has not been used is measured (the quantity used is known in advance) (Fig. 2).

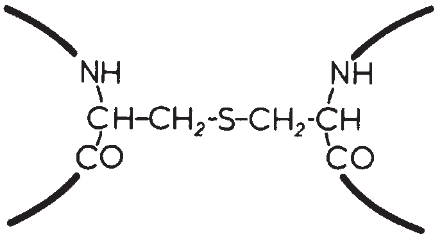

Fig. 3: The cross-linking of protein chains by lanthionine.

The occurrence of lanthionine in stored eggs (even in heated eggs) can be used analytically for quality testing (Fig. 3).

The examples document the close relationship between wool finishing and food chemistry; but studies on insulin also indicate many parallels between wool chemistry and the protein chemistry of insulin (according to Klostermeyer, and Brandenburg) (Fig. 4).

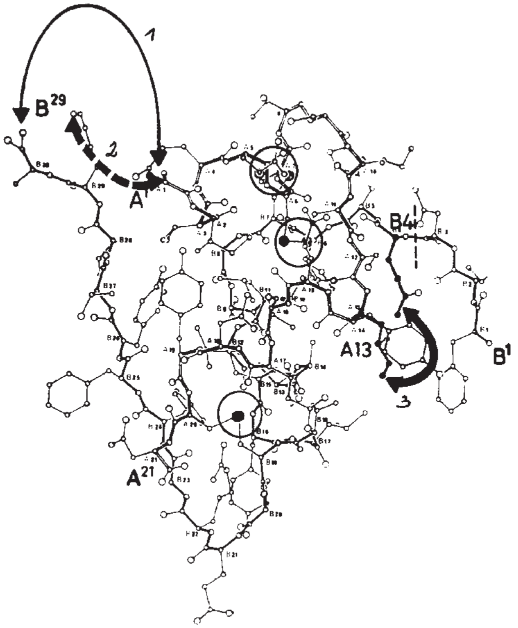

Fig. 4: The projection formula of insulin perpendicular to the three-number axis (according to T. Blundell, G. Dodson, D. Hodgkin and D. Mercola).
The disulphide bridges are marked with circles; 1 indicates the connecting peptide between the N terminus of the A chain and the C terminus of the B chain of proinsulin;
2 = dicarboxilic acid bridges in the insulins bridged between A1 glycine and B29 lysine; 3 = the location of bridges between the e-amino groups of the lysine residues included in the insulin derivative at positions A13 and B4.

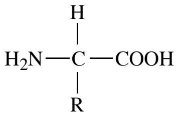
Protein cleavage products (protein degradation products) → Protein-fatty-acid condensation products.

Protein degradation or cleavage products → Protein-fatty-acid condensation products.

Protein-fatty-acid condensation products,

I. Protein decomposition products: When casein, albumin and glue, for example, are acid or alkali boiled, the protein molecule decomposes (in a similar manner to wool under alkaline conditions). Higher molecular amino acids extracted in this manner are converted and are used as so-called protein decomposition or protein cleavage products in the manufacture of high-value assistants.

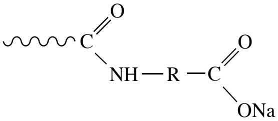
Amino acid type as the end product of the decomposition:



$$H_2N-\overset{\displaystyle H}{\underset{\displaystyle R}{C}}-COOH$$

Application: Excellent wool protection and levelling agent with high emulsifying and detergent power, specifically for wool dyeing, in stripping, etc.

II. Protein-fatty-acid condensate:



After the development of the first → Fatty acid condensation products the obvious next step was to condense high molecular amino acids with, for example, oleic acid. This created a new, larger molecule from the protein residue and fatty acid, which has excellent wetting, levelling and fibre protecting properties. Foaming and stable in hard water. Application: Typical fibre protective agent for wool used for washing (dirt emulsifier), milling, scouring, kier boiling, desizing, stabilizing of peroxide bleaches, as a fibre protective wetting agent in chlorine bleaching (in particular for delustring), handle improving substantive leveller, vat (also wool) and single bath mixed fibre dyeing, as a soaping after-treatment, etc.

Protein fibres →: Man-made protein fibres; Natural protein fibres.

Protein hydrolysates → Lysalbinic acid/protalbinic acids.

Proteins (Gk: protos = the first, original), general so-called single → Proteins, built only of amino acids. Molecular weights between 12 000 and 6 million. Although belonging to the “single” proteins, wool keratin and silk fibroin also belong to the group of proteins.

Protein sizes Usually based upon the decomposed protein substances; are often superior to starch sizes, but are losing ground to synthetic sizes.

Protein solvents → Proteases.

Protein substances → Protein.

Proteolysis Hydrolytic splitting of → Proteins by proteases. Enzymes capable of refining the physiochemical properties of the wool belong to the class of proteases. The reaction can be represented in simplified form as follows:

$$R_1-CONH-R_2 \xrightarrow[\text{proteases}]{H_2O} R_1-COOH + R_2-NH_2$$

There are two main groups of proteases (see Tab.):

- peptidases, which act specifically upon peptides and their derivatives, but leave proteins untouched. One differentiates between amino peptidases, dipeptidases, carboxy peptidases and prolinases, depending upon the substrate upon which they tend to act.
- proteinases, which split large molecular proteins into polypeptic chains or individual polypeptides. They act like endopeptidases, i.e. they split the –CONH groups not only at the chain ends, but also within the molecules. (Exopeptidases only attack the chain ends.)

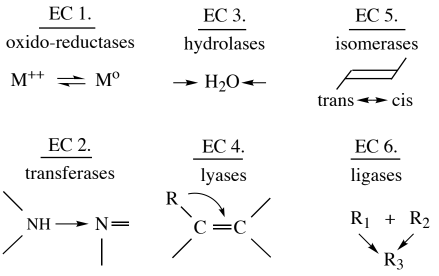
type	protease
pancreatic	trypsin, chymotripsin
vegetable	papaïn, ficin, bromelaïn
Bacillus type	subtilis, lichenformis, alcalophilus, cereus, natto, vulgatus, mycoïde
Aspergillus type	flavus oryzae, niger, saitoï usamii
Mucor and Rhizopus type	M. pusillus, M. mietrei

Tab.: The various proteases.

In order to name the large number of known enzymes (over 2000) and in view of the almost unlimited number of enzyme/substrate reaction pairs, the International Union for Biochemistry established in 1955 (or more precisely its Enzyme Commission) has developed a standardized nomenclature and classification system. This systems specifies the following for each enzyme:

- the reaction that can be catalyzed with it,
- a system name in accordance with official nomenclature,
- a register number (EC …), a four digit number, which provides information about the class (which in total covers 6 positions), the sub and sub-sub class and an ordinal number.

According to this system, proteases capable of proteolysis are allocated to the sub group EC.3, because they have a hydrolysing effect:



As is the case for all acid/base catalysts, the pH is of decisive importance here. The optimal pH range varies depending upon the enzyme type. There are different types:

- The enzyme EC.3.4.21.1, a serin proteinase, hydrolyzes amidic or ester compounds in the vicinity of aromatic amino acids. The optimal pH is 8.4.

- The enzyme EC.3.4.21.4, also a serin proteinase, acts upon amino and carboxyl groups of polypeptides in an alkaline environment, namely in the broad pH range between pH 8 and 11.
- The proteinase EC.3.4.4.10 has as its active centre the thiol group (–SH) of cysteins; it acts, at an optimum pH of 5–7, as esterase and amidase.

In the case of the proteases that act upon wool we can speak of a heterogeneous catalysis, because the (liquid) catalyst and the substrate (wool, solid) do not represent the same phase. At the beginning of the reaction the enzyme is adsorbed at the surface of the wool and migrates through the inside of the fibre. The reaction medium also plays an important role. The presence of unsuitable surfactants can interfere with the proteolysis, because the enzyme remains blocked in the surfactant micelles.

The natural colour of the wool ranges from white via cream, yellowy, brown to brownish-black. The function of the bleach (oxidative, reductive or combined) is to remove the natural colour pigments in order to achieve the correct shade. We can assume that the natural pigments of the fibre are stored at the fibre surface in the cuticle. During reductive bleaching the effect of the proteases on wool, or on its lightness and hydrophilicity, is tracked. A synergy effect occurs regarding the degree of whiteness, if hydrogen peroxide and protease are combined in a single bath. The selectively active enzyme hydrolyzes the lipo-protein fibre surface layer that contains the colour pigments. By dissolving away the hydrophobic substances in the lipoprotein surface, the peroxide is better able to bleach the lower part of the fibre (according to Fornelli).

Protolytic According to Brønsted → Acids and → Bases are grouped together as protolytes (from proton and electrolyte) and their acid/base function described as protolytic, in order to explain the acid and base character even of non-aqueous solutions. According to this, acids are substances which emit → Protons; bases are substances that accept a proton.

Reaction equation:

$$\text{acid} \rightleftharpoons \text{base + proton}$$

Proteolytic enzymes → Proteases, suitable → Desizing agent.

Protonation Due to their small ionic radius and their charge, hydrogen ions are mobile if they are attracted to an opposing charge or by free electron pairs. This property of acids is due to the electrolytic dissociation of substances, and thus to the fact that substances in aqueous solution decompose into electrically charged ions. Ions migrate in the electric field and always transport the same gram-equivalent quantity of electricity, namely 96 494 Coulombs. The conductivity of electrolytes is characterized by their strong temperature dependence, the ion charge number and the migration speed or mobility of the ions.

Ion	Λ^{o}_{+} $\Omega^{-1}m^{2}val^{-1}$	B^{o}_{+} $m^{2}s^{-1}V^{-1}$	Ion	Λ^{o}_{+} $\Omega^{-1}m^{2}val^{-1}$	B^{o}_{+} $m^{2}s^{-1}V^{-1}$
H^{+}	$34.982 \cdot 10^{-3}$	$36.3 \cdot 10^{-8}$	OH^{-}	$19.80 \cdot 10^{-3}$	$20.5 \cdot 10^{-8}$
Li^{+}	3.869	4.01	Cl^{-}	7.623	7.91
Na^{+}	5.011	5.19	I^{-}	7.68	7.95
K^{+}	7.352	7.61	CH_3COO^{-}	4.09	4.23
Ag^{+}	6.192	6.41	SO_4^{2+}	7.98	8.27

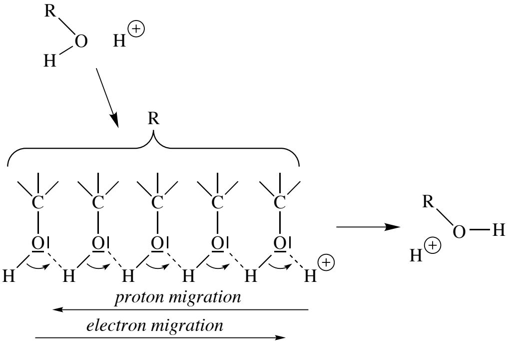
Ca^{2+}	5.950	6.16			
La^{3+}	6.96	7.21			

Tab.: The ion conductivity and ion mobility of some cations and anions at 25 °C.

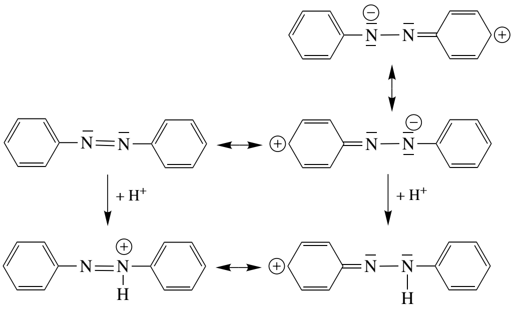
The Tab. illustrates ion mobilities of cations and anions. The most striking thing is the extremely high values for hydrogen protons and hydroxyl ions. Because both ion types are hydratized in the same way as all others, one needs to look for a reason for the high values. This reason lies in the particular movement mechanism. It can be traced back to Grotthus (1805) and is only possible for the medium of water; it is based upon a rapid proton migration, which is, however, effectively an electron migration.



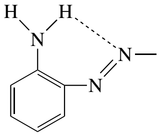
This movement cannot take place in other solvents, because ion mobilities of H^{+}- and OH^{-} ions do not differ significantly from those of the other ions.

Acids are characterized by the fact that they act as proton donors. If they are concentrated and strong enough they can attach to the nucleophilic points. These points are primarily characterized by free electron pairs and polar covalent bonds. A coordinative bonding of the hydrogen cation takes place. Azo groups, carbonyl groups, hydroxyl groups and amino groups plus the substituted hydroxyl and amino groups are carriers of free electron pairs in the dye molecule. A further characteristic of the points capable of protonation is the occurrence of mesomeric boundary states, which include an alternating polarization of the molecule. Protonation changes the resonance, and a charge transfer takes place. This is associated with a colour transition.

Due to the mesomeric boundary states of the azo group and of the free electron pairs on azo nitrogen in mineral acid, a proton attaches itself to the azo nitrogen atom. The dye molecule is thus given a positive polarity. The reaction is illustrated by looking at the example of azo benzene:



Just as a proton can be attached to a nitrogen atom of the azo group, it can also be attached to the amino group or to the substituted amino group by acid. The ammonium group $–NH_3^+$ is formed from the amino group $–NH_2$, which also generates a positive polarity in the dye molecule. When small quantities of acid are added in the presence of azo and amino groups, proton attachment occurs in relation to the basicity of the groups and the position of the amino group. In ortho amino groups a ring closure takes place via a hydrogen bridge bond to an azo nitrogen atom. This prevents the possibility of an ionic form being created.



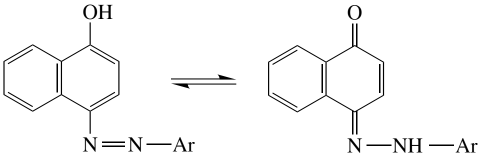
In contrast, non-ortho amino groups are easily protonated. The addition of hydrogen ions is made more difficult by acetylization or alkylization, which reduce the basicity. Because protonation also takes place at the point of greatest basicity, the hydrogen proton in this case is added to the azo nitrogen. In a strongly acidic medium, one proton attaches itself to the azo nitrogen and one to the amino group.

Carbonyl groups occur in polar limiting structures.

I *II*

In the bonding to an aryl group, electrons are also attached to the aromatic system (I) and, due to the strong electron negativity of the oxygen, electrons are attracted and the bond polarized (II). In the acidic medium an addition takes place to the oxygen atoms with greater electron density, as represented by limiting structure II.

The protonation of the hydroxyl group always takes place in connection with a hydrogen ion addition to an azo nitrogen atom. This can be illustrated using the example of a hydroxyazo compound. It is present in two tautomeric forms, the azo form and the hydrazone form.



azo form *hydrazone form*

In an acid medium a hydrogen proton is added to the carbonyl group of the hydrazone form. The change of the hydroxyazo compound however actually consists of the protonation of an azo nitrogen atom. Tautomerism also exists in the hydroxyazo bodies. It is not offset by the hydrogen bridges.

Proton bridges A typical example is → Hydrogen bonds.

Proton donor →: Donor; Protonation.

Proton number → Atomic number.

Protons → Atomic theory.

Protoplasm Primordial cell, the primary building block of physiological cells in the animal and plant kingdom. The latter consists of a cell nucleus (fine threaded lignin structure, chromatin as colour substance and nuclear sap), nuclear sap, cell walls (cytoplasms) and vacuoles (Fig. 1). In the primary wall of cotton this cell structure is the basis for a structure made up by the interweaving of glycoproteins, pectines, hemicellulose and cellulose (Fig. 2). Protoplast formation by enzyme mixture is the precondition for the enzymatic breakdown of the cell wall (Fig. 1).

Protoplasts are thus cell wall free cell residues, which loosen easily, i.e. can be dissolved out of the cotton fibre by water. Protoplast formation, i.e. the removal of the cell wall, takes place in two stages. First, the cells are dissolved out of the cell union. This is

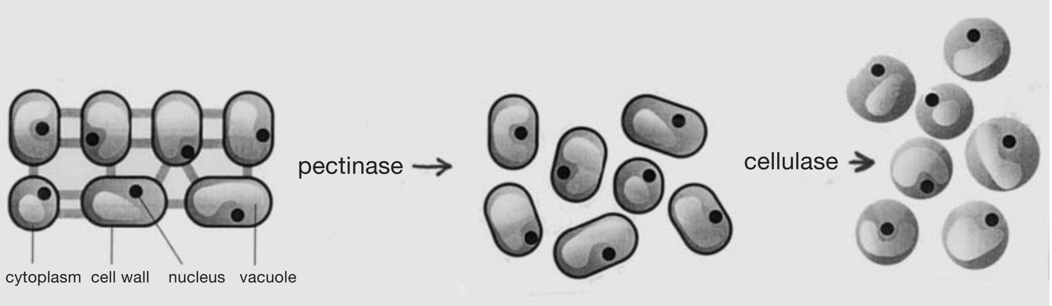


Fig. 1: Diagram showing the formation of protoplasts.

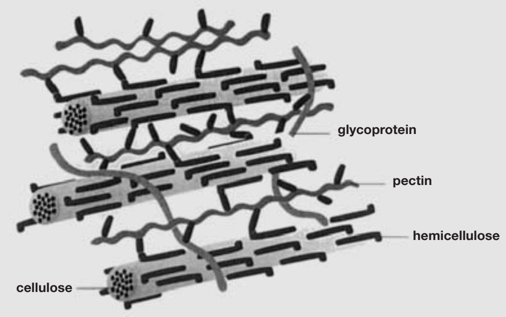

Fig. 2: Diagram showing the main constituents of the primary cell wall.

achieved using pectinase. This decomposes the polysaccharide chains of the middle lamella, which consists of pectines. Then the actual cell wall is digested by cellulose. The main components of the enzyme mixture made up of basidiomycetes are pectinase and cellulase. Xylanase, amylase, laminarinase and protease are also present as secondary activities.

Protoplasts can be generated and cultivated in this manner in isotonic solutions. Due to the composition of the enzyme mixture, protoplast formation can be performed in a single step. The conditions for protoplast formation vary significantly depending upon the origin and age of the vegetable cell material and must therefore be optimized from case to case (according to Merck).

Provenance (Lat.), origin, for example geographic origin as classification criterion for fibres of natural origin.

In cotton in particular there is a relationship between properties and provenance. As a relatively complex natural product made up of five different layers, cotton is subject to very different climatic and ecologically determined influences, so that quality differences based upon the area of cultivation are noticeable in the chemical and mechanical properties prior to resin finishing.

Prud'homme black → Aniline black.

Prussian blue → Berlin blue.

Prussian blue reaction, Turnbull's blue reaction Coloristic detection of hydrocellulose and oxycellulose. Two solutions are used, which should be manufactured cold and then stored in the dark.

Prussiate black → Aniline black.

Prussiate discharges → Oxidation discharges, e.g. for para red on indigo background. However, it only has an historical importance.

PS,

I. Pakistan standard.

II. Horse power. → Watt.

III. → Polystyrene.

PSA Philippine Standards Association, Manila; standards association for the Philippines; → Technical and professional organizations.

Pseudo- (Gk.), not genuine, imitation, apparent. Pseudo-hair: A "fake hair", for example the beard of a whale with its elastic-fixed intermeshed, scaly radial structure, which is similar to hair, but differs in its structure and purpose (filtering out plankton as food).

Pseudoplastic flow properties → Rheology.

PSI Pakistani standards association; → Technical and professional organizations.

PST → Polystyrene fibres, → Textile fibre symbols, according to DIN 60 001 until 1988.

Psychophysics links the two disciplines of psychology and sciences. The term psychophysics has been in scientific use since around the middle of the 19th century. Since then, leading scientists from different fields have contributed to the development of psychophysics, above all physicists, members of the medical profession and psychologists. Because the impetus for development came from different disciplines, the activities and findings of psychophysical research have been interpreted in different ways. Psychophysics has in the past been classed either as physics, medicine or psychology. However, psychophysics should no longer be viewed as part of one of the above-mentioned established disciplines, but as an independent science in its own right, which has a central, multidisciplinary, interdisciplinary role in relation to the sciences.

Psychophysical research concerns itself with the psychophysical relationship, i.e. the relationship between the spiritual and the material world. Accordingly, the term psychophysics can be understood as an amalgamation of the two Greek words “psyche” and “physis”. Today, the importance of psychophysics lies in its interdisciplinary, multidisciplinary approach to thinking, working and problem solving, which provides a basis for taking apart and solving even fundamental and multi-faceted problems. A typical example of creating relationships between subjective sensations and objective evaluations of a phenomenon in the human environment is the treatment of hair by the hairdresser to achieve a hairstyle with “body”.

The psychophysical property of hair normally described as “body”, is usually evaluated using subjective methods, which are themselves based upon visual or tactile sensations on the part of the hairdresser. A quantitative laboratory method is required if we are to make an objective evaluation that can validate and substantiate statements regarding treatments and products which claim to increase the body in hair. Numerous attempts have been made, taking into account both the visual and tactile aspects of “body”.

“Body” is a reflection of the resistance of a hair mass to external deformation and the ease with which it recovers from this deformation. We can measure the compression energy between two defined packing densities from a vertically hanging hair in a plane perpendicular to the axis of the hair. The capacity of the hair to recover from the compression is determined in a second compression cycle. The loss of compression energy in the first cycle depends upon the processes that occur during compression. In this manner the compression resistance and the degree to which the strand can recover from this deformation is determined.

In a hair mass, the fibre stiffness (modulus of bending) and the fibre/fibre adhesion or friction in relation to the resistance against external deformation due to lateral compression act in the same direction. However they oppose each other during the recovery phase, i.e. the fibre stiffness aids the recovery process, acting against fibre/fibre frictional resistance. Changes in the compression behaviour of a hair mass following different treatments can be characterized by the combination of changes in the compression energy in the 1st and 2nd cycle with a relative energy loss factor.

A method has been developed for determining the fibre/fibre adhesion, in which the force necessary to withdraw a single hair from a hair mass of defined packing density is measured. These measurements, in combination with compression parameters, are then used to quantify hair body. Furthermore, attempts have been made to correlate these measurements with subjective evaluations of hair body. The Kawabatas method of multiple regression was used, in a similar manner to its use for the interpretation of handle values for textile fabrics. With the aid of this method a significant model was developed, and the coefficient of the multiple determination was confirmed, which accounts for over 60% of the variation in body in the model (according to Röder, and Weigmann).

Psychrometer, wet and dry bulb thermometer Instrument for → Moisture content measurement made up of two thermometers (mercury or electrical resistance), of which one is kept continuously moist, the other continuously dry. The dryer the air passing the two thermometers (minimum speed 1.5 m/s), the greater the “psychometric difference” between the two thermometers. The values for absolute and relative air humidity can be read off from a table. The “aspiration psychrometer” is an internationally recognized standard instrument. The Siemens moisture measurement instrument, with direct display or remote transmission, is based upon the same measuring principle and is used for the measurement and control of absolute or relative moisture. Psychrometers based upon the principle of electrical resistance can be connected to control units (for air conditioning systems, etc.). Indicating psychrometers based upon mercury or bimetal designs are suitable for determining the relative air humidity, particularly in industrial companies, even for higher temperatures up to 200°C, and when fitted with an electrical contact device they can be used for moisture and temperature control.

Pt Element symbol for Platinum (78).

p/tex Pond pro tex, obsolete unit of force in relation to fineness. SI unit is cN/tex, (centinewton).

PTFE → Polytetrafluoroethylene fibres, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

P-type conductor causes current flow in a → Photoelement made of selenium due to positive (= p) charge carriers.

PU,

I. → Polyurethane, → Textile fibre symbols, according to the → EDP key system; → PUR.

II. Abbreviation for → Liquor pick-up, quoted in %, related to the weight of the dry or wet textile entering the machine.

Pu Element symbol for plutonium (94).

PUA → Polyurea fibres, → Textile fibre symbols, according to DIN 60 001 until 1988.

Public relations (PR). In the broader sense this concerns efforts to win public trust on the part of a company, a branch of industry, etc. In the narrower sense it relates to all measures to achieve and maintain this trust.

Puckering In the sense of shrivelled, curled, folded, crumpled, in hems, seams, edges, etc., for example due to poor ironing.

PUE → Polyurethane elastomer fibres (elastane), → Textile fibre symbols, according to DIN 60 001 until 1988; from 1991 → EL.

Pulled wool → Skin wool.

Pullman mode → Drum washing machine with D-type drum division = Pullman washing machine. Removal of the washing is made easier by the surface which is inclined forwards slightly (sliding emptying).

Pulp bleaching Usually occurs in the form of combination bleaching: Hypochlorite – H_2O_2 – reduction – sodium chlorite (preferably chlorine free for environmental reasons).

Pump characteristics Pumps are used to overcome head differences, distances and also system pressures when moving liquids. A pump is always set up so that the main movement is on the pressure side of the pump. The head difference is the difference between the liquid level on the suction side and the liquid level on the pressure side of the pump (suction head + pressure head = geodetic total lift).

The liquids either flow to the pump from a higher vessel (Fig. 2) or the pump sucks them from a certain depth (Fig. 1), e.g. from a well. In the latter case, however, the liquid is not actually sucked up at all, but rather the self priming pump merely evacuates the air from the suction pipe, or the normal suction pump brings a flow into motion, and the atmospheric pressure, which acts upon the surface of the liquid, presses the liquid in the pipe up to the level of the pump. Then the pump pushes the liquid further into the pressure pipe. Because the air pressure is greater in the valley than on a mountain, a pump in the valley can “suck” from a greater depth than a pump on a mountain.

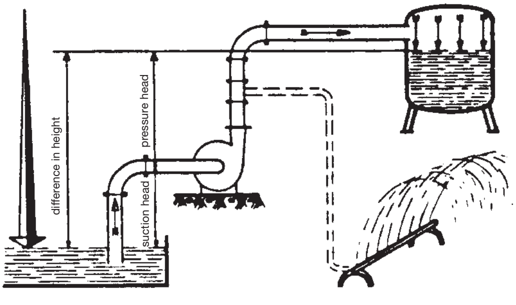

Fig. 1: Pressure pumping.

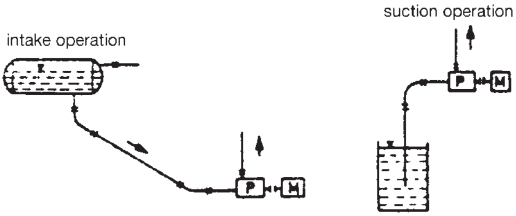

Fig. 2: The intake operation and the suction operation of pumps.

The flow rate Q is the useful liquid volume per unit time conveyed by the pump through its pressure connections:

$$Q = \frac{V}{t} \ [m^3/s]$$

The lift H of the pump is the increase of energy content in 1 kp (= 9.81 N) of conveyed liquid between inlet and outlet in mkp/kp, which corresponds to a head in m of the liquid head of conveyed liquid. A centrifugal pump thus conveys (at the same rotation speed) any liquid to the same lift, measured in m of the liquid head. The manometric pressure head H_{man} measured by a manometer is however dependent upon the volumetric weight of the liquid in question ($H_{man} = H \cdot \gamma$) .

In the most usual centrifugal pumps in textile finishing the lift is defined as follows:

$$H \equiv \frac{\xi}{g} \ (u_a w_a' - u_i w_i')$$

$$w_a' = u_a - v_a' = u_a - c_a \operatorname{tg} \alpha_v$$

$$w_i' = u_i - v_i' = u_i - c_i \operatorname{tg} \beta_w$$

$$H = \frac{\xi}{g} \ [u_a (u_a - c_a \operatorname{tg} \alpha_v) - u_i (u_i c_i \operatorname{tg} \beta_w)]$$

c_a and c_i are the radial components of the absolute liquid velocities w_a and w_i at the outer (a) or inner edge (i). The particle velocity w at the blade of the impeller results from the sliding velocity v caused by the centrifugal force and the tangential velocity u. g is gravity (9.81 m/s^2).

The lift H of the pump is made up of the difference between the heights of the outlet and inlet cross-sections of the pump

$$\frac{P_d - P_s}{\gamma}$$

P_d = pressure in the outlet cross-section of the pump in bar,
P_s = pressure in the entry cross-section of the pump in bar,
γ = volumetric weight of the liquor,

and the difference between the manometric lifts of the liquid between the outlet and inlet cross-sections of the pump

$$Z_d - Z_s$$

Z_d = loss of manometric lift at the pressure pipe in m,
Z_s = loss of manometric lift at the suction pipe in m,

and the difference in dynamic pressure of the liquid between outlet and inlet cross-section of the pump

$$\frac{C_d^2 - C_s^2}{2\,g}$$

C_d = flow rate in outlet cross section in m/s,
C_s = flow rate in the inlet cross-section in m/s.

Therefore:

$$H = (Z_d - Z_s) + \frac{P_d - P_s}{\gamma} + \frac{C_d^2 - C_s^2}{2\,g} \quad \{\text{m of liquid head}\}.$$

The head H of the system is the head to be achieved by the pump, in order to maintain the flow rate Q in the system. The positive pressure head tells us the minimum amount by which the total pressure head in the centre of the inlet cross-section of the pump must lie above the vapour pressure level of the conveyed liquid in order to guarantee a faultless functioning of the pump. If the positive pressure head of the system is less than that of the pump then the pressure will fall below the vapour pressure locally within the pump and part of the conveyed liquid will vaporise. The bubbles of vapour thus created reduce the performance of the pump, and furthermore the condensation of the vapour bubbles in areas of high pressure can also lead to the mechanical destruction of the internal components of the pump due to the sudden collapse of the vapour bubbles. This phenomenon is called cavitation. In order to prevent cavitation it is therefore particularly important to determine the maximum possible geodetic suction head or the minimum necessary feed height for the pump. As the temperature of the liquid increases (with increasing vapour pressure) the possible geodetic suction head falls and finally a geodetic feed head becomes necessary.

If a pump is used to move liquor at a given rotational speed, a defined quantity of liquor is conveyed per unit time; thus there is a typical relationship between flow rate Q (l/min) and manometric pressure H (m water head) for the pump, which is termed the pump characteristic. The flow rate is obtained at the cost of a certain power consumption (kW). The flow rate is reduced by resistance in the system. Resistance can be caused by: small pipe cross section, high viscosity of the liquor at low liquor temperature, or difficulties in flowing through dense material.

Due to the requirement that the same amount of liquor must flow through the wound package regardless of the size of equipment in the wound package dyehouse, different requirements are made regarding the shape of the characteristic curve for the liquor pump. Therefore, it is not possible to use the same type of pump for a whole range of equipment by merely increasing the impeller size. Fig. 3 shows a set of characteristic curves for the different centrifugal pumps used with increasing

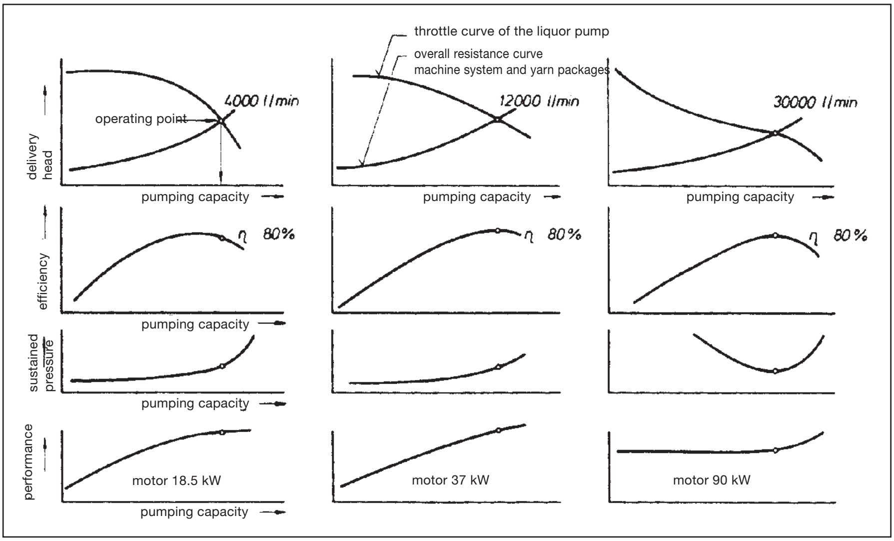

Fig. 3: The characteristic curves against batch weight of liquor pumps.

equipment size. The operating point, which is the intersection of the throttle curve with the total resistance line, lies within the optimum efficiency range of the pump. The total resistance line is found by adding all individual resistances in relation to the flow rate of the pump. The throttle curve of the pump shows the relationship between the flow rate and the lift of the pump and is termed the QH curve. If the flow rate at the operating point is higher than the desired flow rate through the textile, for example because of sensitive yarns, reduced dosage, or due to a treatment stage requiring a reduced flow, the flow rate must be adjusted. Depending upon the shape of the characteristic curve for the pump in question, this adjustment can take place by means of direct reduction of the flow rate, via a bypass, i.e. a return flow from the pressure side to the suction side of the pump, or by changing the throttle curve. Whereas the first two types of regulation are generally applicable depending upon the pump size, changing the throttle curve by means of a reduction in rotational speed is the optimal solution from the point of view of power consumption, because no throttle device or bypass is present. The desired flow rate through the textile thus still lies at the intersection between the total resistance line and the throttle curve for the adjusted speed. The extent to which the cost of a speed regulated motor drive for the centrifugal pump is justified depends on the field of application of the equipment.

The manometric differential pressure display can be read throughout the beam dyeing process and is a characteristic criterion for dye specific substance exchange processes. It is therefore recommended that the differential pressure display is used for checking and controlling or regulating the beam dyeing process. Fig. 4 shows the pump characteristic curve and the textile/batch characteristic curve, plotted on axes of the differential pressure Δp_L [bar] against the volumetric flow rate of the liquor Q_M [m^3/s]. It is clear that at a manometrically displayed differential pressure of $\Delta p_L = 2.0$ bar, 87% of the liquor flows through the package radially, i.e. producing a dyeing effect, whereas 13% flows away axially, i.e. from the front of the beam dyeing package.

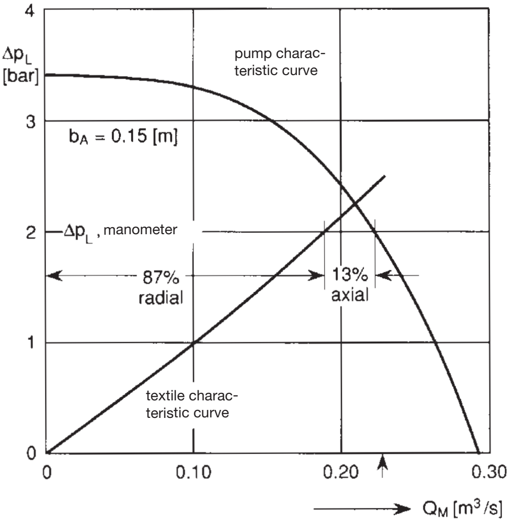

Fig. 4: Family of characteristics for the through-flow of a beam dyeing batch.
b_A = covering width of the cuffs.

Pump curve (equipment diagram, pump characteristic, QH curve), usually supplied by the equipment manufacturer in the form of a diagram. The liquor flow rate (for example) in l/min and/or kg/min or the liquor speed in m/s in relation to beam or dyeing tube diameter is plotted on the x-axis, whilst the feed pressure or differential pressure in mm WG or kg/cm^2 or bar is plotted on the y-axis (see Fig.). Using the pump curve it

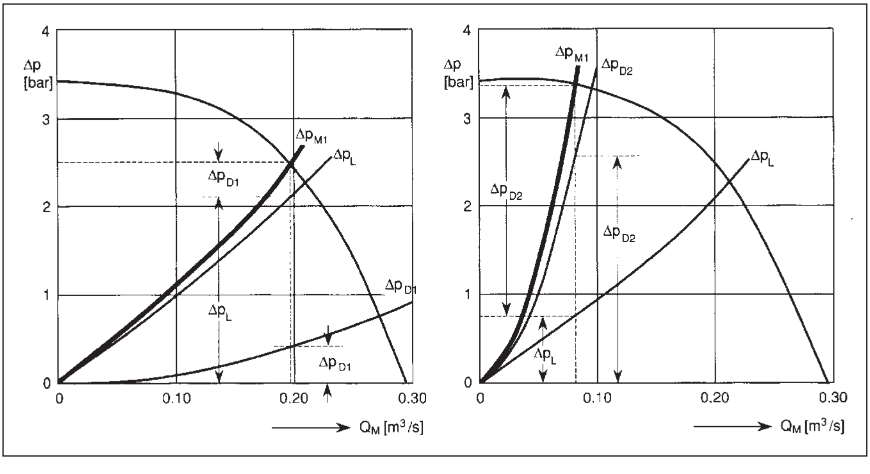

Fig.: Displacement of the operating point on a pump curve due to throttle valve control which produces too low a liquor throughput, whereby $\Delta p_M = \Delta p_L + \Delta p_D$. The picture at left shows a slight throttle valve effect, that at right shows a large throttle valve effect, both for the same differential pressure Δp_L across the beam dyeing fabric batch.

is possible to obtain a satisfactory approximation of the liquor speed in relation to differential pressure. → Pump resistance in dyeing machines.

Pump pressure process Japanese process, which is used particularly for Summer goods and requires a precise knowledge of the effects that can be achieved using individual dye groups (usually naphthol, sulphur, vat dye) and great artistic skill. A resist made of tough rice clay thickener is applied to 1 yard of material on a printing table with the aid of a screen (always 1 yard in length, clamped tightly in a frame fastened by means of folding hinges). Then (in accordance with the method of to and fro plaiting) the length of material is placed on the layer that has already been printed with the resist, the screen is folded back down, more thickener applied, etc., whereby the piece is resist-dyed by the thickener on both sides. So, in the end a pack of up to 48 stacked layers of material with the same number of thickener layers is created. This pack is now placed upon an iron grid (30 × 90 cm), which is above a basin, and the prepared dye liquor is poured over the pack. The dye naturally only penetrates areas of the material that have not been coated with the resist, and therefore these are the only areas that are dyed. Then the excess liquor is squeezed off, or the sides of the pack are covered with rubber strips and the liquor is pumped downwards by a suction device. The piece is again plaited and rinsed to remove the residual thickener. Single colour items with white patterning can be produced using this method, as can continuous multi-coloured patterns such as transitions from light to dark. Many variations can be achieved by the selection of different naphthols and different developers together with vat and sulphur dyes.

Pump resistance in dyeing machines In a dyeing machine the flow of the liquor from the pump is hampered by several sources of frictional resistance. In the normal pump diagram (Q on x-axis, H on y-axis) the pump resistance is found as the resultant of these interference factors, and to achieve optimal working conditions the → Pump curve should be adjusted to suit this (Fig.).

Pumps,

I. Are used for extremely varied transfer purposes. One differentiates between different pump types, e.g.:

1. Compressed air pumps: → Compressors.

2. Wing pump: at the left and right of the housing there are two flap-type suction and piston valves, with dual and quadruple action; suction and pressure. Application for water transfer purposes (suction head 7–8 m) in manual operation (capsule pump see under 8).

3. Piston pump: With suction pipe, suction valve, submerged piston, pressure valve, pressure pipe. Single and dual action. Suction head up to 7 m.

a) Pressure head up to 60 m or several hundred metres in special design triplex pumps.

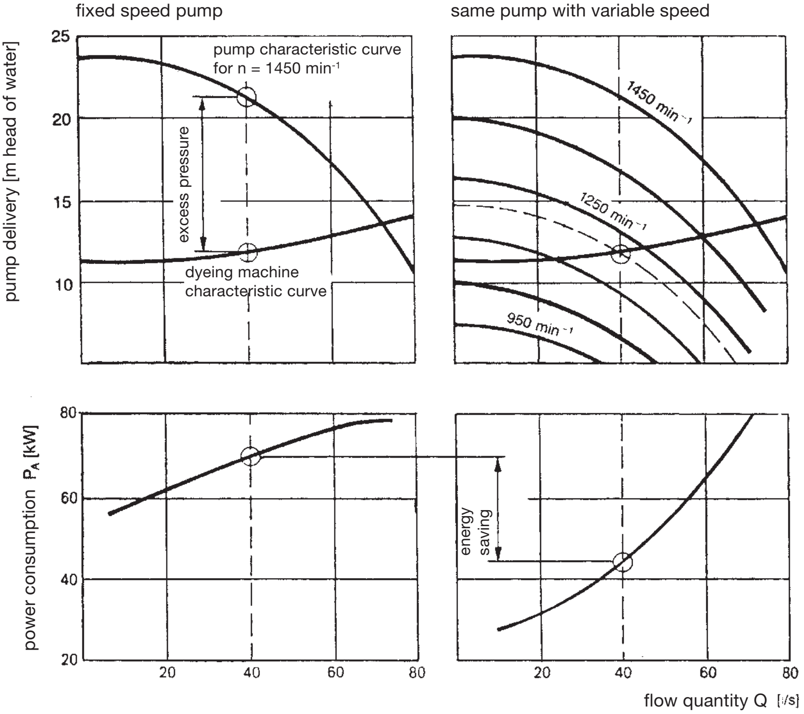

Fig.: Excess pressure between dyeing machine characteristic curve and pump characteristic curve and adaptation of pump characteristic curve by speed reduction to 1200 rpm, so that the power consumption of 71 kW falls to 43 kW (Thies).

b) As boiler feed pumps and pressure pumps. Generally more efficient than 4, but higher system costs and higher space requirement. Pressure can be as high as desired (also as hydraulic high pressure or press pump), is not (like 4) dependent upon the quantity pumped. Often preferred for small and medium output at high pressure heads, particularly with steam operation. Application , manual or power operation for water, acids, lyes (acid resistant grey cast iron or silicon cast iron, hard lead, bronze, vitrified clay). As steam pump in single or dual cylinder type; with so-called power pistons, single, double, triple, correspondingly known as simplex, duplex, triplex pumps; e.g. duplex pumps work smoothly without receiver.

4. Centrifugal pumps: With suction line, impeller (in annular or spiral housing) and pressure line. Usually not self priming like 3, therefore must first be filled with liquid and there is a foot valve on the end of the suction pipe. If put into service without the fluid, seals will seize. Preferred for continuous operation, higher flow rates and, depending upon this, greater lifts (up to 50 m). Efficiency 60–75%. Application usually with electrical drive for water, polluted waste water (also sludge), as a circulation pump for hot water, for acids and lyes (silicon cast iron, bronze, hard rubber, aluminium, vitrified clay, synthetic resin/asbestos; the latter is not suitable for caustic alkalis), similarly also for organic solvents. As high pressure pumps, single and multi-stage, with power drive for almost unlimited lifts, for boiler feed, for deep wells (running shaft in rising pipe, up to 30 m depth), for water supply, self-priming with back flow valve. With coupled direct drive (electric motor or steam turbine) for greater lifts, as vacuum circulation boiler feed pumps, etc. As extreme pressure pump up to 400 bar and 350°C water temperature. Multi-stage.

5. Membrane or diaphragm pump: With reciprocating membrane (instead of piston) made of, e.g. acid resistant rubber. Design varies, with or without pistons, without acid plug, with safety device, etc. Material vitrified clay, rubberized iron, silicon cast iron, hard lead, etc. With suction or suction and pressure, for manual or powered operation; lift up to 15 m; Application for water and aggressive fluids, also with dye components.

6. (water and steam) jet pump: Without moving parts, valve-free, suction (also as vacuum pump), pressure or dual action. Application for water up to 60°C, for acids, corrosive and sludgy liquids.

7. Deep well pumps: In the form of a centrifugal pump(IV) for 10–40 m lift or in the form of an underwater motor pump for up to 200 m (flow rates from 2–1000 m^3 /h).

8. Vacuum pumps: According to the piston principle, single or dual action, single stage up to 99% vacuum, with non-return valve and pressure compensation. Centrifugal principle single stage up to 95% vacuum. Generation of vacuum or pressure with a seal between impellor and pump cylinder achieved by the so-called sealing liquid (such as water, acid, lye or heavy vaporizing oil = oleo-pneumatic pump). Accordingly, optimal throughput of air up to 40 m^3/min. Usually belt drive or coupled with electric motor. Extraordinarily high suction of 36 m^3/s (with pressure of 1.33–0.0133 bar) , diffusion pumps, whereby the necessary high vacuum is obtainable in a relatively short time. According to other principles: for example (capsule pump) with an eccentrically rotating cylinder in a cylindrical casing with a gas-tight sealing. No moving parts also according to principle 6. With suction water jet, for even lower pressure with mercury vapour beam. Application for suction and conveyance of air (also for pneumatic conveying and control systems), gases and liquids.

II. Combed top or pressed conversion with a weight of 6–50 kg. Replace normal → Yarn package, whose weight only goes up to 5 kg. Pumps are pre-treated and dyed on circulation equipment using the pack system.

Pumps in textile finishing The following pump types are used in textile finishing:

I. Metering pumps of different designs:

– gear pump,
– rotary positive displacement pump,
– peristaltic pump,
– membrane pump,
– plunger pump.

II. Centrifugal pumps of different designs:

– radial pump (centrifugal pump),
– screw pump,
– propeller pump,
– axial-flow pump.

I. Metering pumps function as follows:

a) The gear pump is a positive-displacement pump (Fig. 1). The liquid is drawn into the gaps between the teeth, propelled along the housing walls, and forced out of the gaps into a compression area by the intermeshing of the teeth. This pump is used in the synthetic fibre industry for the conveyance of the substance to be spun to the spinning jets.

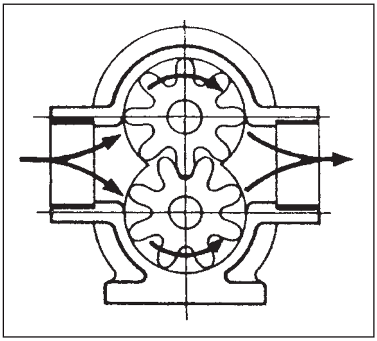

Fig. 1: A gear-type pump.

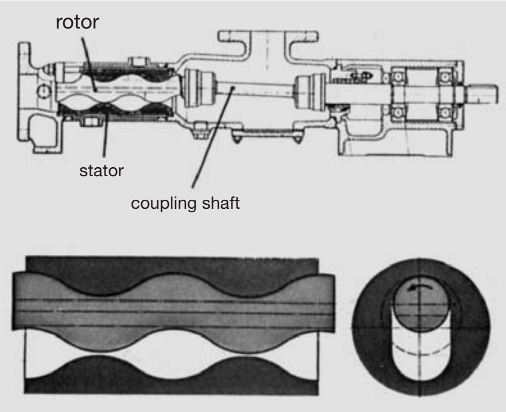

Fig. 2: A rotating positive displacement pump: principle as diagram.

b) A mixing device designed specifically for use in the CPB process, but is also used in foam generators, called the Netzsch-Mohne industrial pump, has as its main component a rotor made of chromium nickel steel and a stator made of special plastic (Fig. 2). The internal shape of the stator represents a double start round thread with large lead and thread depth. The rotor, in the form of a single-start screw with half the lead of the stator, rotates within the stator around its principal axis and thus around the axis of the stator cross-section. As the rotor turns, the transfer spaces thus formed between the internal shape of the stator and the rotor continually move axially from the suction to the pressure side. Stator and rotor can if necessary be easily exchanged on site. The disadvantage of this design principle lies in the low dry running capacity of the stator-rotor system. Even a short period of dry running of a few minutes leads to the destruction of the stator. In the recommended design, two ring sensors are fitted on the suction side in three sensitive areas, which immediately send a message to an electronic control device if there is an interruption to the supply of liquid.

c) Metering pumps are also in use in the form of a single plunger pump with fluid ferrule (Fig. 3).

d) A diaphragm is the heart of the metering pump (Fig. 4). The maximum deflection of the diaphragm through the piston is 3 mm.

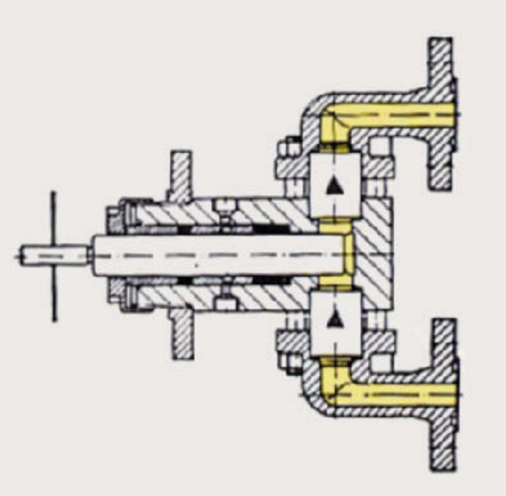

Fig. 3: Diagram of a plunger pump.

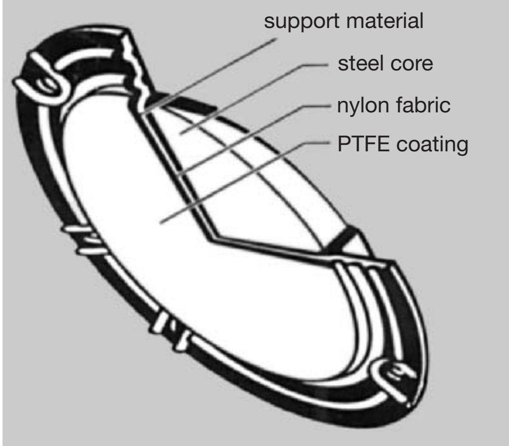

Fig. 4: The Developan metering membrane in the "Pro-Minent Varion" metering pump.
PTFE = polytetrafluoroethylene.

In specific CPB combination pumps there is a single diaphragm pump with two pump bodies made of polypropylene (Fig. 5). The membranes, which are each moved by a connecting rod, are characterized by high resistance to the specific chemical solutions used and thus a long life is guaranteed. The primary advantage of the diaphragm pump is that the drive, which runs in an oil bath and requires no additional lubrication, is completely sealed off from the conveyed medium by the diaphragm. The pump is thus maintenance free.

In other diaphragm pumps (Fig. 6) the plunger displaces a hydraulic fluid, which itself deflects a diaphragm that is in direct contact with the medium, thus bringing about the dosing process. In the multi-layer diaphragm pump head, two diaphragms are arranged behind one another. If a diaphragm breaks, the dosing medium or hydraulic oil penetrates from the pumping area behind the diaphragm into the area between the diaphragms and brings about a pressure increase. This is converted into an optical, electrical, or pneumatic alarm signal to indicate that the diaphragm has broken.

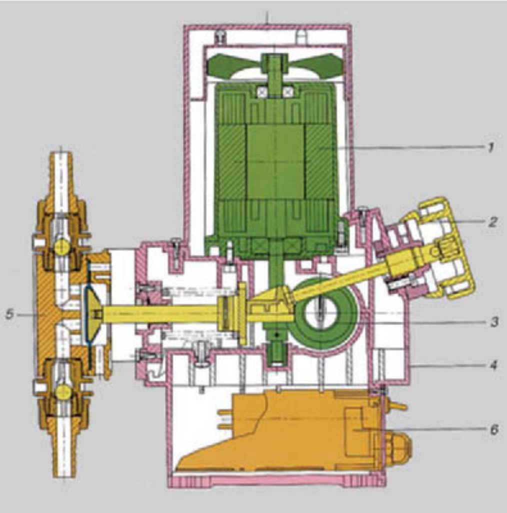

Fig. 5: A combination pump as a single membrane system with two pump bodies (Seybert and Rahier). 1 = motor; 2 = stroke adjustment; 3 = gear; 4 = housing; 5 = delivery unit; 6 = control insert.

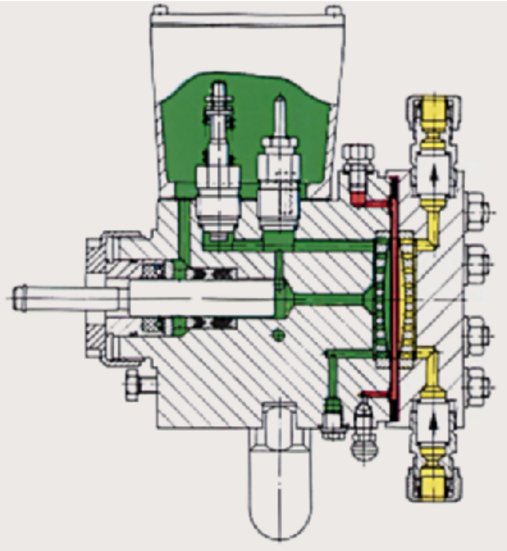

Fig. 6: A membrane pump by Bran & Lübbe.

Multi-layer diaphragm pump heads are used for environmentally problematic media.

The valves in a metering pump are always a potential source of problems. Although all devices are fitted with suction heads or filter systems, the risk that thread bundles or other foreign bodies can penetrate into the pump body cannot totally be eliminated. These can block valves, which under certain circumstances can lead to false dyeing. CPB combination pumps possess double valves as a special feature both on the suction and pressure side. This guarantees that these pumps will continue to function even if a valve does not close. The valves are spring loaded on the pressure side. This is normally sufficient for the suction operation. When working in liquor or where there is a large head between pump and padder chassis there should always be a pressure sustaining valve on the pressure side.

There are three designs available depending upon the desired field of application:

- with alternating current geared motor for on/off operation via level control. This is the cheapest design.
- with alternating current variable speed gear motor. The flow rate is mechanically regulated via a hand wheel on the pump. The control range is limited to 20–100%, i.e. it cannot be set at flow rates lower than 4 l/min.
- with variable direct current motor. The most expensive, but also most highly recommended design. A thyristor speed controller that can be connected separately controls the flow rate precisely and sensitively from 0.5–20 l/min. Even if a level control is connected, the flow rate can be optimally matched to the liquor requirement.

II. Liquor feed pumps for large quantities function as follows: in a centrifugal pump the fluid to be conveyed is transferred to a rotating paddle or impeller wheel. The kinetic energy of the liquid is converted into pressure.

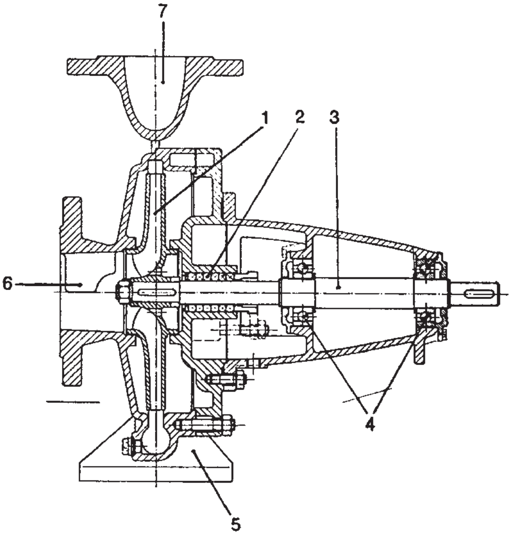

Fig. 7: A centrifugal pump.
1 = rotor; 2 = shaft seal; 3 = pump shaft; 4 = pump shaft bearings; 5 = housing base; 6 = suction side (intake side); 7 = pressure side (output side).

a) A centrifugal pump is a frequently used type of rotary pump, whilst the propeller pump is only used in modern textile finishing machines in individual cases. The centrifugal pump (radial pump) is suited for conveying large quantities of liquor over short distances. The centrifugal pump consists of the housing, impeller, an axial liquor supply and a side liquor discharge connection (Fig. 7). The liquid enters at the eye of the impeller. The rotating impeller sets the liquor to be conveyed in rotation. The centrifugal force that this creates accelerates the liquor to the discharging connections.

Centrifugal pumps have proved their value in most textile finishing machines due to their typical pump characteristic. The blades of impellers can have different shapes (Fig. 8). Self-priming centrifugal pumps are those that can independently evacuate a suction pipe and can therefore normally be mounted at up to 8 m above the liquid level. They are usually only filled with a priming liquid when starting and then can always prime themselves, because some priming liquid always remains in the pump when it is switched off again. Self-priming side channel pumps can convey air, and compress it.

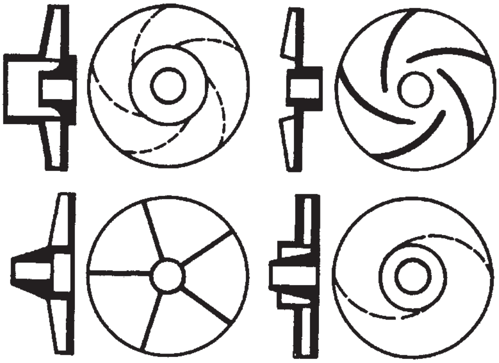

Fig. 8: Different forms of rotor blade to match different pumping media.

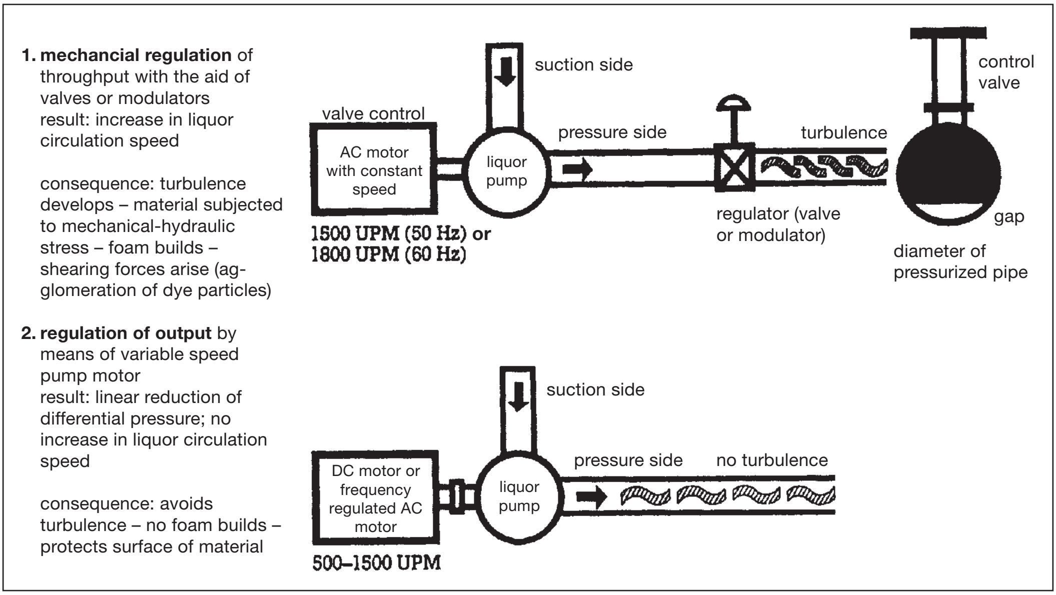
In contrast to self-priming pumps, when normal priming pumps are used the suction pipe outside the pump housing must be completely full of liquid. If the supply of liquid in the suction line is interrupted or air or gas bubbles form this type of pump will not draw in liquid. There must be a flow valve that closes properly at the end of the suction line, and the pipe itself must also be completely sealed. If air enters the pump will not work.

It is often necessary to adapt the supply data of a pump to changed operating conditions, i.e. to alter the head and flow rate. The simplest method of altering supply data is throttle control. The pump is initially designed for the max. flow rate and the associated head. A lower flow rate is achieved by throttling the pump, i.e. generating an additional head loss. Thus the operating point of the pump changes to the desired flow rate, whilst at the same time the head increases to a greater value than that required by the system.

Liquor pumps for piece and yarn dying equipment are normally connected to constant speed alternating



1. **mechancial regulation** of throughput with the aid of valves or modulators
   result: increase in liquor circulation speed

   consequence: turbulence develops – material subjected to mechanical-hydraulic stress – foam builds – shearing forces arise (agglomeration of dye particles)

2. **regulation of output** by means of variable speed pump motor
   result: linear reduction of differential pressure; no increase in liquor circulation speed

   consequence: avoids turbulence – no foam builds – protects surface of material

Fig. 9: Liquor control by means of the regulation of pump motor speed.

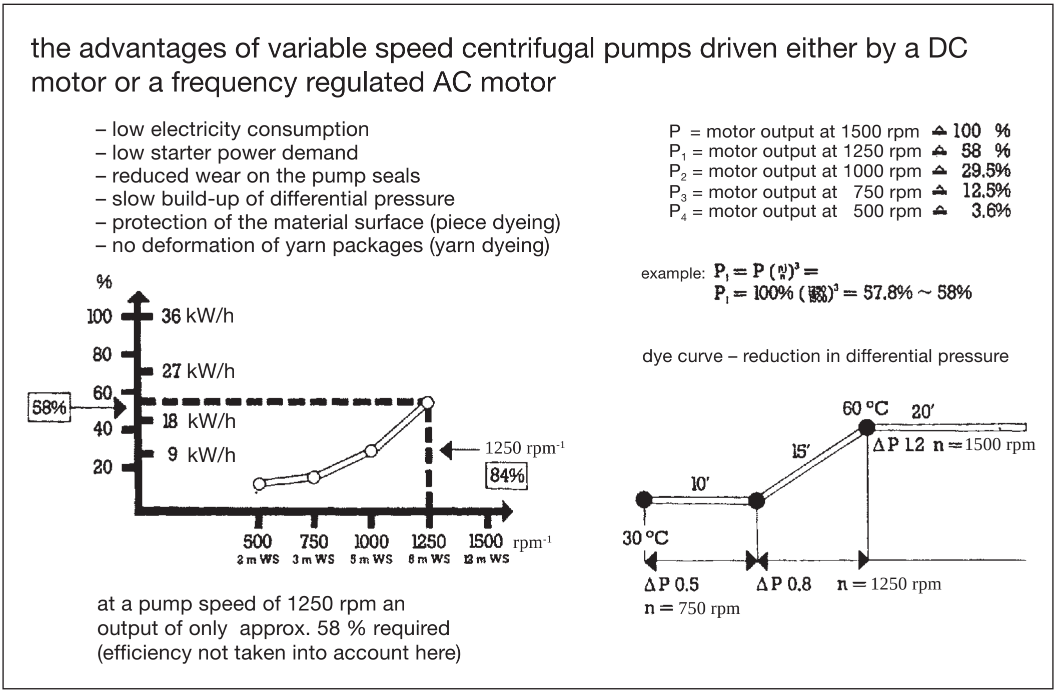


Fig. 10: Electricity consumption of an electric motor in relation to its speed or pump output.

current motors. They run continuously at the maximum speed, which, depending on the frequency lies at 1500 rpm (50 Hz) or 1800 rpm (60 Hz). In order to control the flow or the differential pressure the liquor stream must be mechanically reduced with the aid of valves or flow controllers. This increases the liquor velocity, which leads to turbulence in the pipe system. The result: the mechanical and hydraulic forces created contribute to generating roughening effects on the material surface in rope dyeing or to deformation of the wound package and yarn damage in yarn dyeing. Because of the high liquor velocities at the maximum motor speed, shear forces can also occur in the system, which can lead to agglomeration with some dye classes.

More beneficial is the precise control and programming of the flow rate (Fig. 9) or differential pressure. It is not limited to a slow reduction, but is adapted continuously to the kinetic parameters during the finishing process.

The liquor flow is regulated by controlling the speed of the pump motor. This is achieved either by thyristor control in direct current motors or by frequency converters in alternating current motors. The flow rate can thus be adjusted to suit the textile to be dyed, according to the pump characteristic. Despite higher investment costs for variable speed motors it is possible to dye more economically. The reduction of the speed of the pump means that the power consumption by the drive motor is lower (Fig. 10). The significantly re-

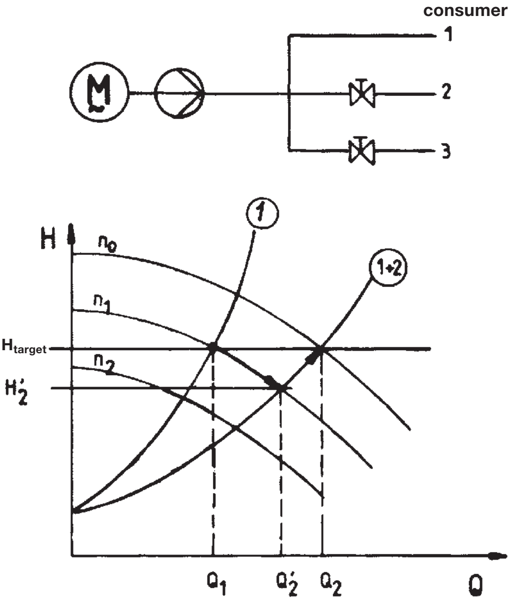

Fig. 11: Pump control lines for "H constant" (pressure).

duced power consumption brings about an energy saving, which justifies the additional cost for variable speed drive motors. An amortisation period of 4–8 months can be expected.

The speed of the pump can be controlled by two methods:

1. In the “H constant” control characteristic a target pressure is preset at the pressure regulator (Fig. 11). The actual pressure that currently exists in the plant is compared with the set point pressure and an adjustment signal sent to the frequency converter, whereupon the speed of the pump is altered such that it constantly runs at the desired pressure. Example: a pump supplies Consumer 1 at flow rate Q_1 and head $H_1 = H_{target}$. If Consumer 2 is also connected, the system works using the plant characteristic 1 + 2, whereby the pressure falls to H_2. When the pump is turned up to the new speed n_0, the pressure climbs back to the desired target pressure H_{target}, thus setting the flow rate at Q_2 (Fig. 12).

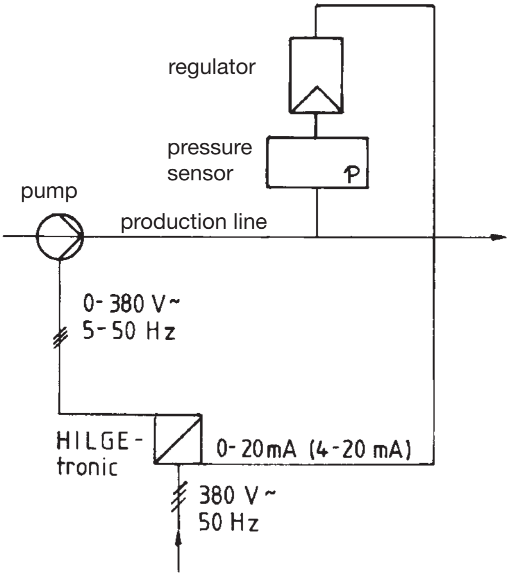

Fig. 12: Diagram showing pump control using a frequency transformer related to target pressure (Hilge).

2. In the “Q constant” control characteristic, a flow controller sets the desired flow rate (Fig. 13). The target value for the system is measured e.g. by an inductive flow rate sensor. The regulator compares Q_{target} with Q_{actual} and sets a constant flow rate at the pump by means of the frequency converter. Example: A pump provides a consumer with a flow rate $Q_1 = Q_{target}$. If the flow resistance in the system changes during the running time, the system characteristic 1 changes to system characteristic 2. In order to change the reduced flow rate Q_2 to the target value Q_{target}, the speed is increased from n_1 to n_0 (Fig. 14).

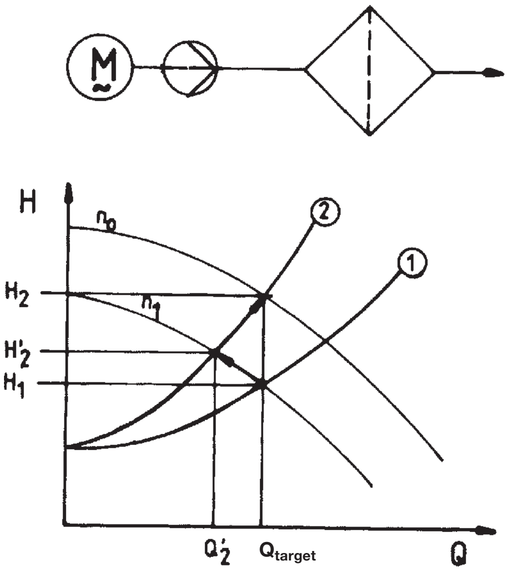

Fig. 13: Pump control line for “Q constant” (quantity).

b) Axial pumps: axial pumps gained importance when very high textile densities were introduced, which the liquor has to flow through on compressed crosswound yarn packages (specific volume 400–600 l/kg). Liquor feed and extraction takes place axially in such pumps. Unlike the centrifugal pump, the motor load increases as the resistance of the treated material increases. In the axial pump each stator has a rotor.

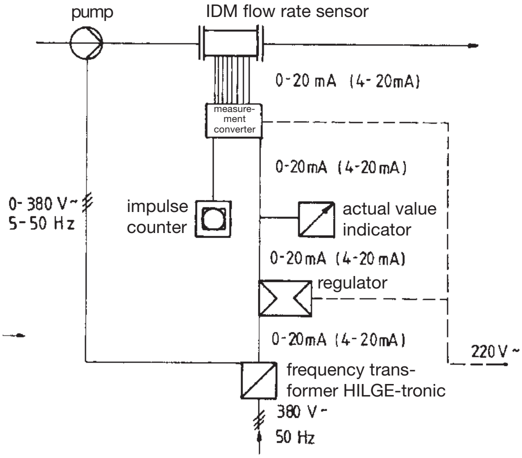

Fig. 14: Diagram showing pump control using a frequency transformer related to target delivery rate (Hilge).

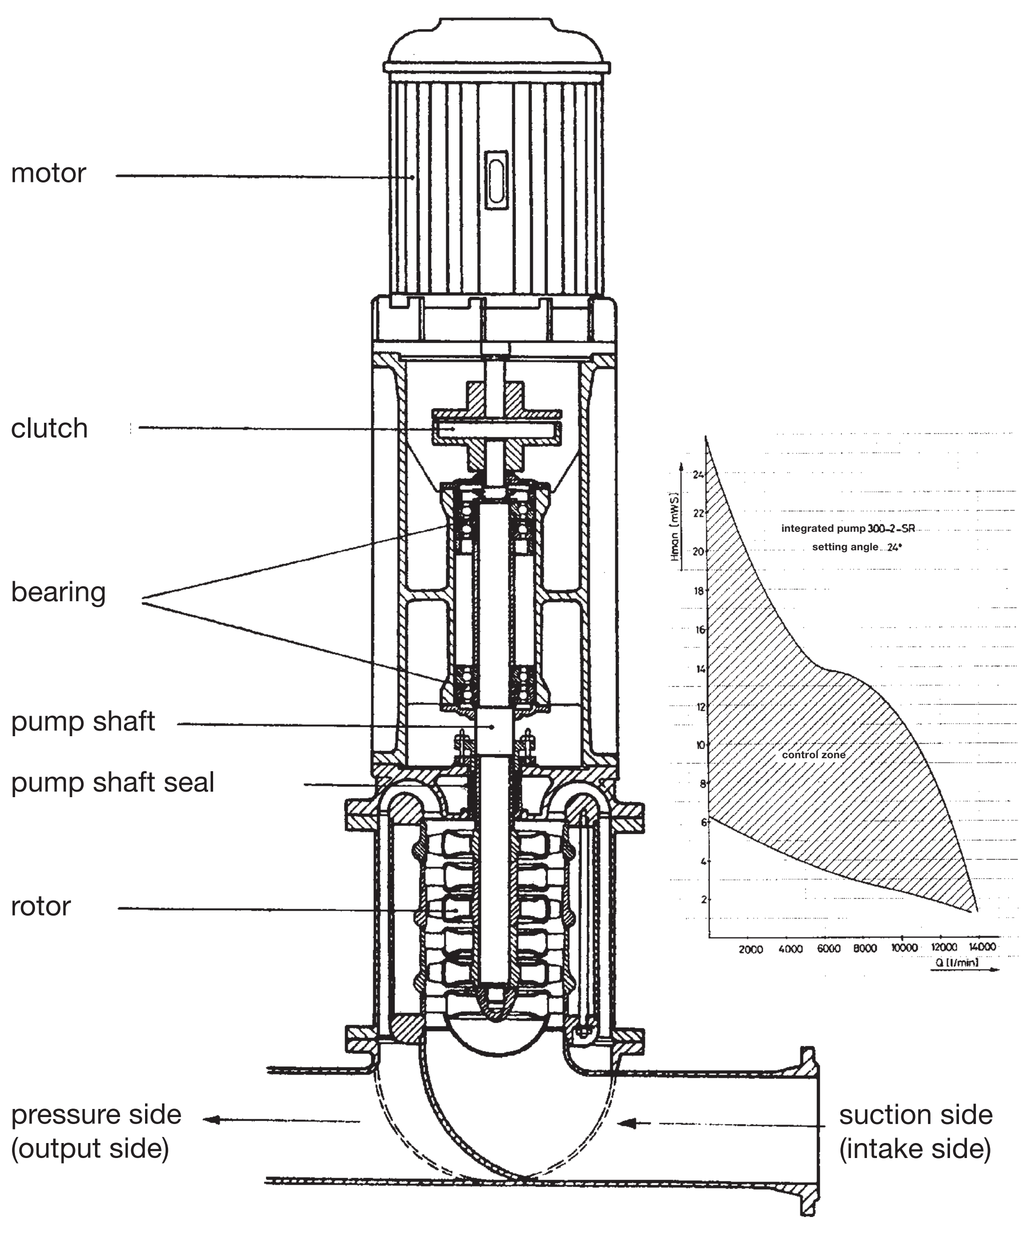

Fig. 15: A Krantz axial pump (control zone is shown below the pump characteristic line on the right).

Multi-stage axial pumps have several rotor-stator pairs in a row (Fig. 15). The pump characteristic can be altered by changing the speed of the drive motor. In the Turbo-rapid pump by Obermaier depicted in Fig. 16 the impeller is continuously adjusted by altering the position of the rotor blades.

A comparison of the common pump types (Fig. 17) shows: The pump characteristic becomes steeper as we go from propeller pumps via centrifugal pumps to multi-stage axial pumps (according to Kretschmar, Ungermann, Hedjans, Berdelle).

Pump speed control In order to increase the relia-

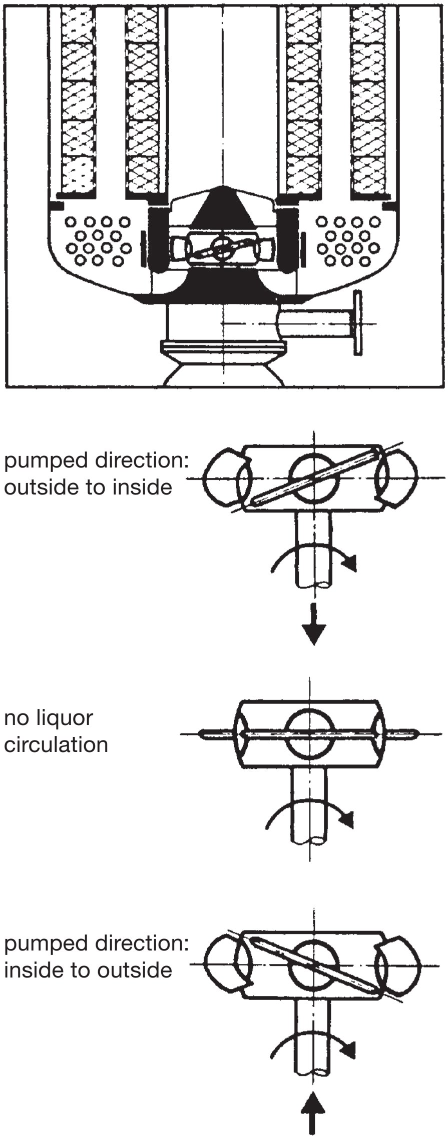

Fig. 16: The mechanism of the Turbo-rapid pump by Obermaier, showing the change in liquor circulation direction by adjustment of the rotor without stopping the pump.

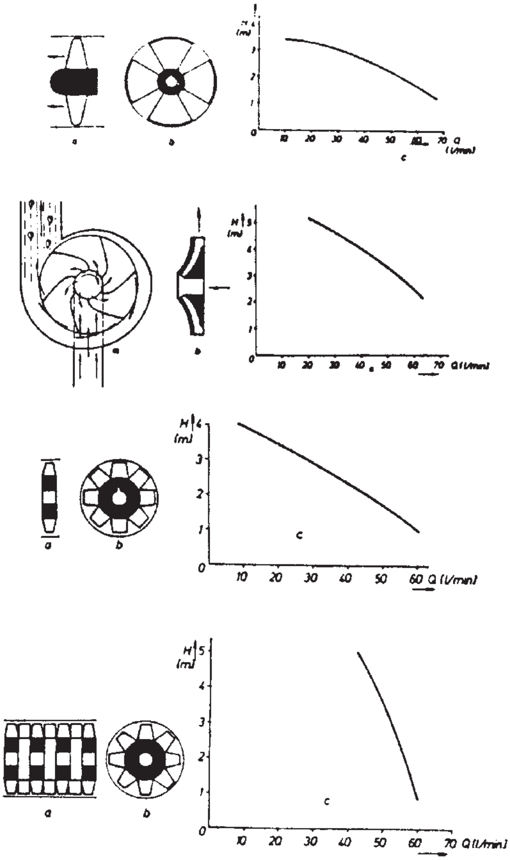

Fig. 17: Comparison between the gradients of the pump characteristic lines of a propeller pump (top), a centrifugal pump (centre) and an axial pump (below) of either the single stage (e) or multiple stage (m) variety.

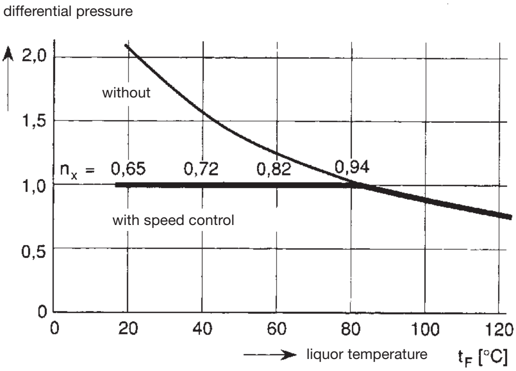

Fig: Plot of the differential flow pressure ΔpL [bar] relative to liquor temperature t_F [°C] (Kretschmer).

bility of dyeing with the beam dyeing system it is advisable to permanently regulate the pump speed from the start using the differential pressure programmed with the dyeing guide value F_F. It is clear from the Fig., that in this case the differential pressure can be reduced to around half. This significantly reduces the risk of dyeing problems, and this is achieved without influencing the time-temperature management or the heating up rate.

Permanent regulation is also recommended for yarn dyeing. In addition it is recommended that the differential pressure dependent pre-programmed regulation of the pump speed is also maintained for pretreatment, rinsing and aftercleaning. This reduces the colour specific spool delivery faults and increases dyeing reliability, without limiting process and temperature control.

Pump stripes Stripes on printed textiles in the direction of the weft, which can occur on rotary screen printing machines during the automatic pumping of printing colour paste into the distributor pipe of the rotary screen, if subsequently pumped print paste is of a different consistency to that in the doctor blade device or it has undergone a different change by the doctor blade process.

PUR → Polyurethanes, → Textile fibre symbols, according to DIN 60 001 until 1988.

Pure linen Fabric, in which the warp and weft must consist of 100% pure → Linen (usually in plain weave) and only in this case may be marked with the “Pure Linen” quality symbol of a hand raised in oath.

Pure new wool (South African), term for items made of pure → Virgin wool.

Pure soap content Proportion of pure, water free → Soap. Should be as high as possible for washing purposes (92–96%).

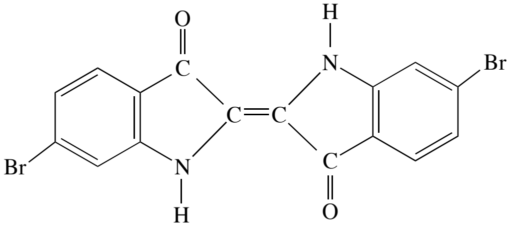
Pure spectral colour Optimal colour, which yields the lightest colour for a given → Type of colour and the most saturated colour for a given → Shade of colour. The colour valency associated with the shade is characterized by maximum brightness. According to Ostwald, every colour corresponds with the sum of pure spectral colour (P) (pure colour), ideal white (W) and ideal black (B) according to the equation P + W + B = 100. The so-called clear bright series is created from pure spectral colour + white and the so-called clear dark series is created from pure spectral colour + black (→ Chromaticity diagram).

Pure wool (South African). Fine → Animal hair fibres (mohair, alpaca, llama hair, cashmere).

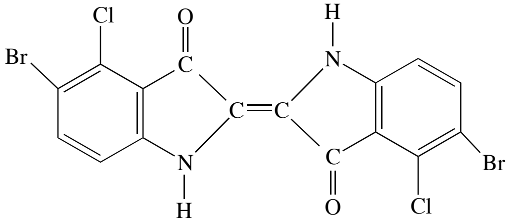
Purple Reddish violet → Natural dyes (vat dye) made of the gland secretion of dead murex snails (Mediterranean and West Indian coasts. 8000 snails provide just 1 g dye). Active component: Dibromoindigo.

Antique purple is not a brilliant red, but a somewhat red cast violet. This was shown by a colorimetrically measured dyeing of pure antique purple (6.6’-dibromoindigo) in comparison to a dyeing used for cardinals’ robes. This change of colour term is based on cultural and technological historical reasons and on the basis of biochemical findings about the creation of 6.6’-dibromoindigo and indigo from murex snails.

Irritations regarding the colour of purple arise above all due to the complicated biochemical and photochemical synthesis (see Fig.). Depending upon the snails, their glands contains various colourless pre-products of the dye, which only appear in the light as coloured compounds (different red, violet or bluish black).



antique purple



synthetic purple

In the Murex trunculus type these are the potassium salts of the sulphuric acid ester of 6-bromindoxyl and 2-methylsulphonyl-6-bromindoxyl (R = SO_2CH_3). In addition, however, murex trunculus also contains the comparable compounds without the bromine component, i.e. the forerunner of indigo. The female of this type of snail primarily forms the bromated, the male however almost exclusively the non-bromated product.

Purpurin (1,2,4-trihydroxyanthraquinone), madder purple. Naturally occuring together with alizarin in the → Madder (previous madder dyeing); provides reddish violet chrome lacquer.

Putrefaction, decay → Rot.

PVA → Polyvinyl alcohol fibres, → Textile fibre symbols, according to DIN 60 001 until 1988, from 1991 → PVAL.

PVA+ → Polyvinyl acetate fibres, → Textile fibre symbols, according to DIN 60 001 until 1988.

PVAL → Polyvinyl alcohol fibres, → Textile fibre symbols, according to DIN 60 001 T4/08.91.

PVC → Polyvinyl chloride fibres, → Textile fibre symbols, according to DIN 60 001 until 1988.

PVC+ Post-chlorinated → Polyvinyl chloride fibres, → Textile fibre symbols, according to DIN 60 001 until 1988.

PV dyes Selected pigments for the mass dyeing of plastics, particularly softened polyvinyl chloride.

PVM → Polyvinyl chloride copolymer fibres, → Textile fibre symbols, according to DIN 60 001 until 1988.

PVP → Polyvinylpyrrolidone.

PX → Trivinyl, symbol according to ISO.

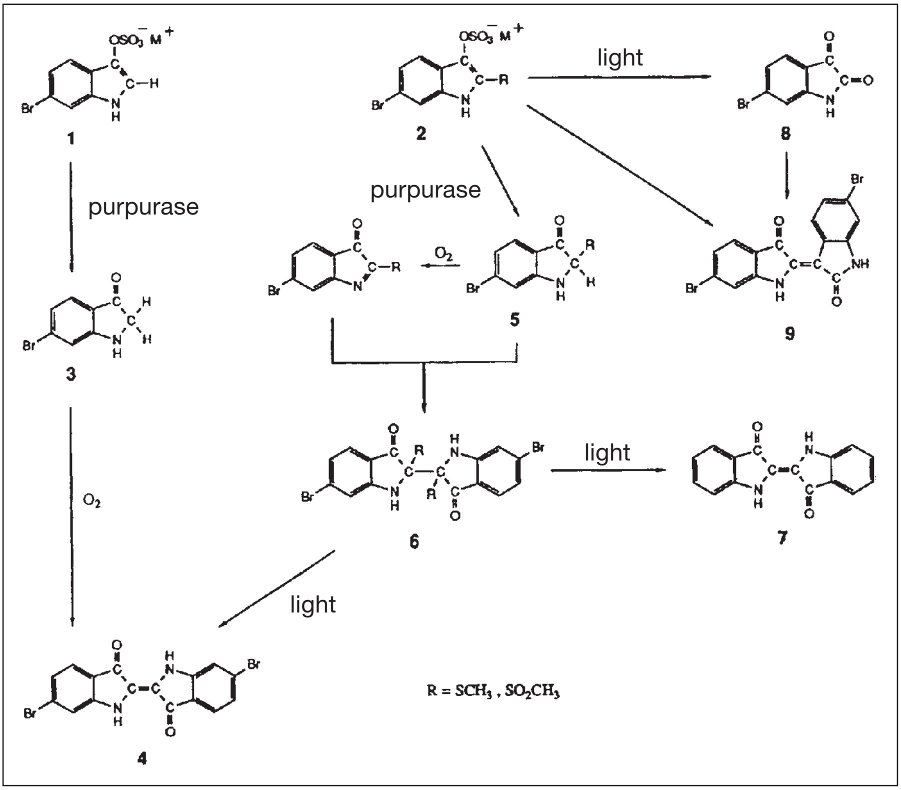


Fig.: Possible routes to the synthesis of purple.

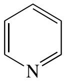
Pyranometer (also incorrectly called → Pyrheliometer), device for the measurement of sunshine in the form of heat generated in Langley units (gcal/cm^2). Often used in meteorology. Not suitable for use as a substitute for → Blue scale in light fastness testing.

Pyrethroids Synthetic functional analogy to pyrethrumates (= composites, similar to marguerites). The latter have for centuries been amongst the strongest vegetable → Insecticides ("insect powder" or spray against house pests and moths, carpet beetles, etc.) and plant pests. Pyrethrum is highly toxic to lower animals (stomach, contact, muscle, nerve insecticide), however it is not photostable and is relatively expensive, which is why numerous synthetic pyrethroids have been created. Since 1973, these also include photostable pyrethroids as potential preventative agents against moths, fur and carpet beetles. Good moth protection effect, however it has poor activity against carpet beetle larvae. → Antimicrobial finishes.

Pyrheliometer Light sensitive measuring cell for illumination equipment, a thermoelement photometer consisting of two concentric rings with a black or white surface (hot solder points of a gold-palladium and platinum-rhodium thermoelement battery, attached to the black underside of the ring). The temperature difference measured between the two rings is almost proportional to the quantity of light falling upon the sensor. Thermo-currents generated by irradiation in light fastness tests are measured with a voltage meter, recorded and totalled by a counter.

Pyridine C_5H_5N:



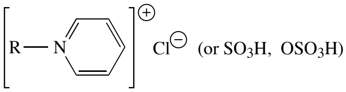
Molecular weight 69.09; density 0.977; boiling point 115°C. Colourless liquid (so-called heterocyclic base) with characteristic odour, slightly alkaline, miscible with water or alcohol; resistance against water hardness agents, acids, alkalis. Solvent and dispersant for substantive and acid dyes in particular (aids full penetration dyeing, levelling and generation of lively shades). Application: pasting up, dissolving, dispersing, full penetration dyeing of named dye classes (particularly for circulating liquor, clothing, felt, hat dyeing); for slight stripping of dyes (in hot liquor), etc. Can cause potency problems in the event of overdose by inhalation.

Pyridine test (dye detection), test with

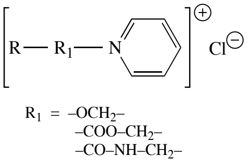
1. pure pyridine,
2. pour over diluted pyridine (30–50%) and boil for 1–2 min.

a) substantive dye (also after-treated): solution 1 not coloured, solution 2 strongly coloured.
b) cationic dye, naphthols: both solutions strongly coloured.
c) sulphur, vat dyes: both solutions not coloured or only slightly coloured.
d) reactive dyes: solution 1 not coloured or only slightly coloured (turquoise or blue types may be coloured), solution 2 not coloured or only slightly coloured.

Pyridinium compounds Quaternary pyridine complexes, which are derived from co-ordinative pentavalent pyridine nitrogen and yield a series of important cationic textile auxiliaries such as the alkyl pyridinium salt of the type:



For increasing the fastness of direct dyes, as a leveller and stripping agent for vat dyes, special emulsifiers, softening agent, etc. Waterproofing agents of the following type have achieved significant importance:



Products of this type are not thermostable; if the material is heated then the pyridinium compound would be split at the CH_2N bond and the hydrophobic, cationic part applied in such a manner as to be wash and dry cleaning fast.

Pyrimidine Heterocyclic six-membered ring compound, structurally similar to → Pyridine, however with two nitrogen atoms in 1.3 position. (→ Tetrahydropyrimidone resins).

Pyrithion Abbreviation for 2 pyridinthiol oxide C_6H_5NOS, in tautomeric equilibrium with 1-hydroxy-2-pyridinthion. Some commercially available metal salts have a fungicidal and bactericidal effect. Even better results are achieved by zinc complexes of this compound from aqueous polyethylene imine solution according to conventional pad/dry/condensation processes. If the solutions also contain urea, then the hydroxypyridinthion is bound to carbon monoxide. Materials treated in this manner prevent the growth of Staphylococcus aureus even after 50 washes; the fungicidal properties are however not so wash resistant.

Pyro- As a prefix in the designation of inorganic compounds created from water-containing ortho compounds by heating and the emission of water. Example: Pyrophosphoric acid $H_4P_2O_7$ (from $P_2O_5 + 2\,H_2O$) by the emission of 1 molecule of water from two molecules of ortho acid. Salts → Pyrophosphates.

Pyro acids/salts → Acid anhydrides.

Pyrocellulose Cellulose modification that has been damaged due to excessive heating. Always contains aldehyde and carboxyl groups. → Fibre damage (cellulosic fibres), tests for.

Pyrolignite of iron (iron liquor, iron mordant, black liquor), produced by dissolving iron waste in pyroligneous acid or double decomposition of iron (II) sulphate and pyrolignite of lime. Dark brown solution of 12–15°Bé = 50–55% iron. Application: Mordant for black dyeing of wool, silk and cotton using logwood.

Pyrolignite of lime (potassium acetate), brown lumps, produced by dissolving 5 parts lime in 25 parts water (→ Slaked lime) and 25 parts acetic acid 6°Bé, adjust to 5°Bé. Application: Cheap production of aluminium and chromium acetate for mordants (alizarin red), as additional mordant.

Pyrolysis Decomposition of substances by heat, for example dry distillation. In pyrolysis larger, heavier molecules are split into simpler, smaller molecules. Pyrolysis also takes place in fibre combustion processes (for example → Laevoglucosan) as irreversible chemical decomposition, caused by increasing the temperature without oxidation. → Burning behaviour of textiles.

The processes underlying the combustion have a physical-chemical nature. The combustion process is divided into five stages:

1. heating of the substrate,
2. decomposition (pyrolysis),
3. ignition,
4. combustion,
5. fire propagation.

The heating of the substrate is largely determined by

- specific heat,
- heat conductivity,
- heat of fusion,
- heat of vaporization.

The actual pyrolysis precedes the chain decomposition. At higher temperatures a slow pyrolysis starts, whereby a weight loss occurs, accompanied by the formation of low molecular, volatile and for the most part combustible compounds. As yet there is still no danger of fire. Only when a combustible gas mixture forms with air is there a danger of fire at the critical pyrolysis temperature.

External and self ignition bring about a change from the metastable state to the state of spreading fire (Fig. 1). In exothermic combustion the released energy con-

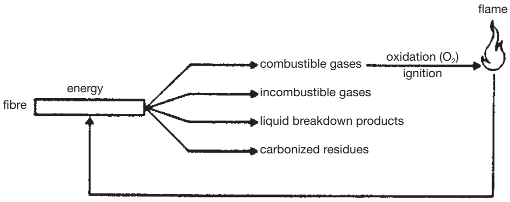


Fig. 1: Substrate combustion.

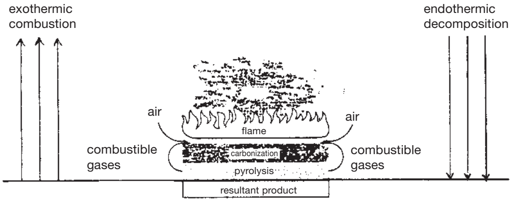

Fig. 2: Steady state.

tributes to an increase in temperature, whereas in endothermic decomposition absorbed energy, i.e. the transfer of heat to the inside of the substrate, is drawn from the heating process. Pyrolysis, for its part, feeds the flame with matter (combustible gases), and the flames feed the pyrolysis with energy. The actual burning process represents an equilibrium which is called the “steady state” (Fig. 2).

The thermal decomposition of plastic waste at high temperatures in the absence of oxygen is also known as pyrolysis. The plastic does not burn, but decomposes into petrochemical raw materials. All pyrolysis products can be used, so no waste gases are generated. The process is therefore particularly environmentally friendly. Fig. 3 shows the fluidized bed process.

Pyrometer Measuring instrument for high temperatures:

I. Thermoelectric pyrometer: The weak electric currents at the thermocouple junctions of two wires (thermoelements) are analyzed to measure the temperatures acting upon the junctions. Application: up to approx. 600°C in steam, hot water pipes, dry plants, waste gas

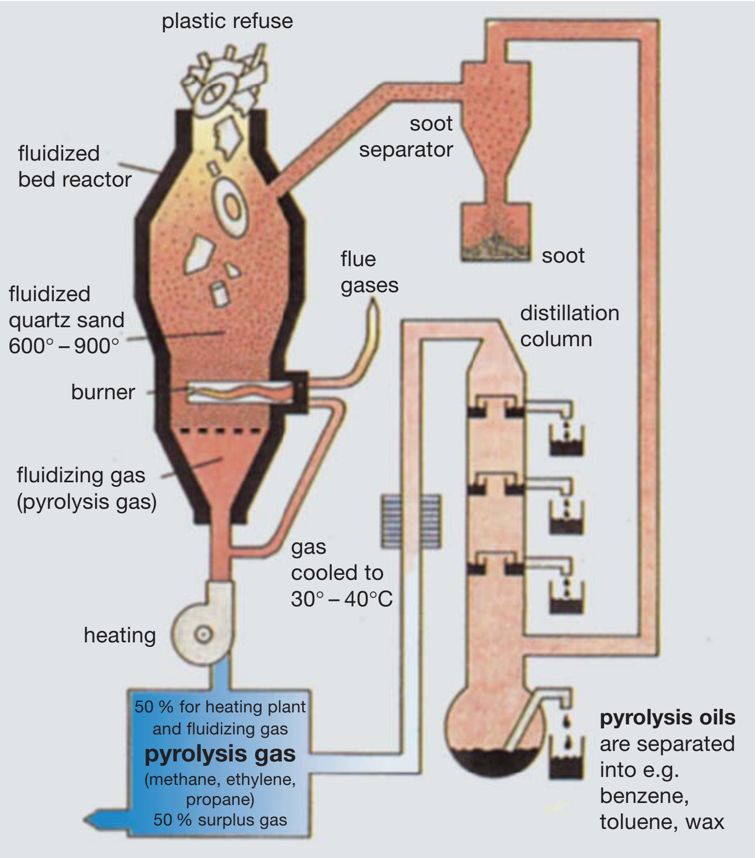

Fig. 3: Fluidized bed pyrolysis for the breakdown of plastic refuse into hydrocarbons.

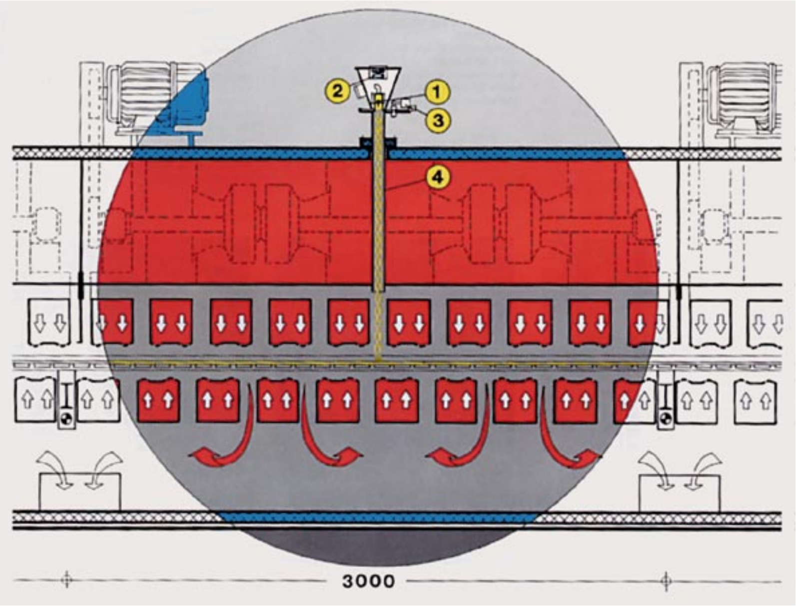

Fig. 1: Sensing head above flat stenter frames.
1 = radiation pyrometer;
2 = cooling ventilator;
3 = overheating safety device: if the cooling fan shuts down the sensing head swings to one side;
4 = pipe carrying measured radiation.

ducts, autoclaves, etc.; also available with remote and recording devices.

II. Optical pyrometer: measures the heat radiation by comparison with a filament lamp, the brightness of which can be regulated, whereby the lamp current produced is transferred to a current measuring device calibrated in °C.

III. Air pyrometer (vapour pressure, gas thermometer): Principle of expansion of enclosed air or gas; primarily for scientific work.

Normal thermometers are not suitable for the measurement of the material temperature of a moving length of material because they are influenced by the temperature of the surrounding air and by the frictional heat generated by the necessary contact with the material. However, the heat radiation from the material (Fig. 1) supplies a variable that is proportional to the temperature, which can be detected in a contact free manner independentl of distance (Fig. 2). Bodies and surfaces of all types emit a radiation depending upon their current temperatures, the energy of which extends from visible light well into the infrared region. The intensity of this radiation varies and depends upon the nature of the material. Textiles, regardless of fibre type, structure and colour, all have similar behaviour, which approximates that of the so-called “black body”.

The temperature dependent measuring signal is created in an optoelectronic receiver (radiation pyrometer), which collects the emitted energy and coverts it into an electric current. Because the distance of the radiation pyrometer from the measured surface is not a factor in the measurement, the pyrometer can be used

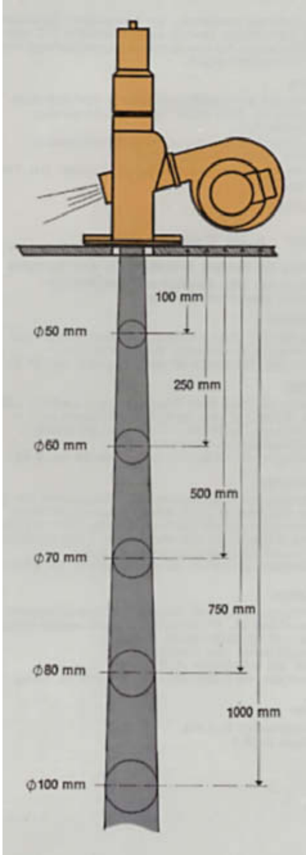

Fig. 2: The measured substrate (the fabric) may be at any distance from the pyrometer.

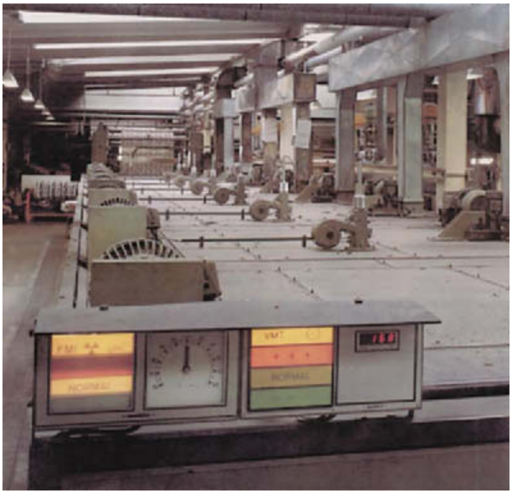

Fig. 3: Dwelling plant with 6 pyrometers on the ceiling of a horizontal stenter frame.

for example on the cover of a fixing machine, in which an opening has been cut for heat radiation to pass through (Fig. 3). The radiation is concentrated onto the converter by a mirror. The aperture of the mirror must be such that the pyrometer only receives heat radiation from the material and not from other objects in the radiation cone. An air curtain protects the detector from the hot air from the machine and ensures that the measuring equipment is largely maintenance free (Fig. 4). Colour, fibre type and structure of the textile have no notable influence upon measuring accuracy.

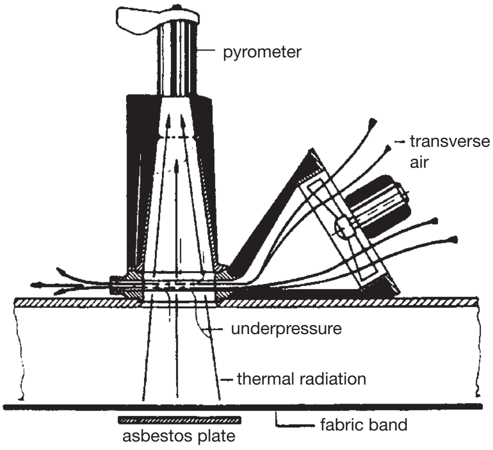

Fig. 4: Temperature measuring point on the roof of a drier, comprising a radiation pyrometer on the cooling tower with a transverse air barrier. The transversely flowing air prevents hot gases etc. penetrating as far as the radiation pyrometer.

The physical principle underlying temperature measurement by the radiation pyrometer is that every body emits heat radiation (Fig. 5) according to the formula

$$S = S_0 \cdot \varepsilon_r \cdot T^4$$

S = radiation power over all wavelengths, per unit time and area,
S_0 = constant,
ε_r = relative radiating capacity,
T = absolute temperature.

From this we can see that the radiation power is primarily influenced by temperature, because it is raised to the power of 4. According to its temperature the black body emits radiation energy, which depends upon the wavelength. Planck's radiation law sums up this relationship in the formula

$$E = \frac{c_1 \cdot \lambda^{-5}}{e^{c_2/\lambda T} - 1}$$

A total radiation pyrometer detects the radiation energy within a certain wavelength range, which corresponds with the area under the curve in question for a certain temperature. Different colours have no influence even in practice, because the energy contribution from the visible range is negligible (Fig. 5).

On a material surface passing through a stenter the cooling limit temperature of 50–60°C is maintained as long as water is still vaporizing from the surface

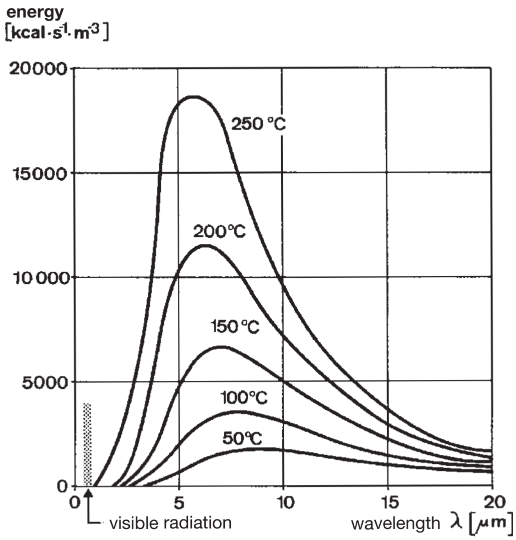

Fig. 5: Black body radiation energy as a function of wavelength at various temperatures.

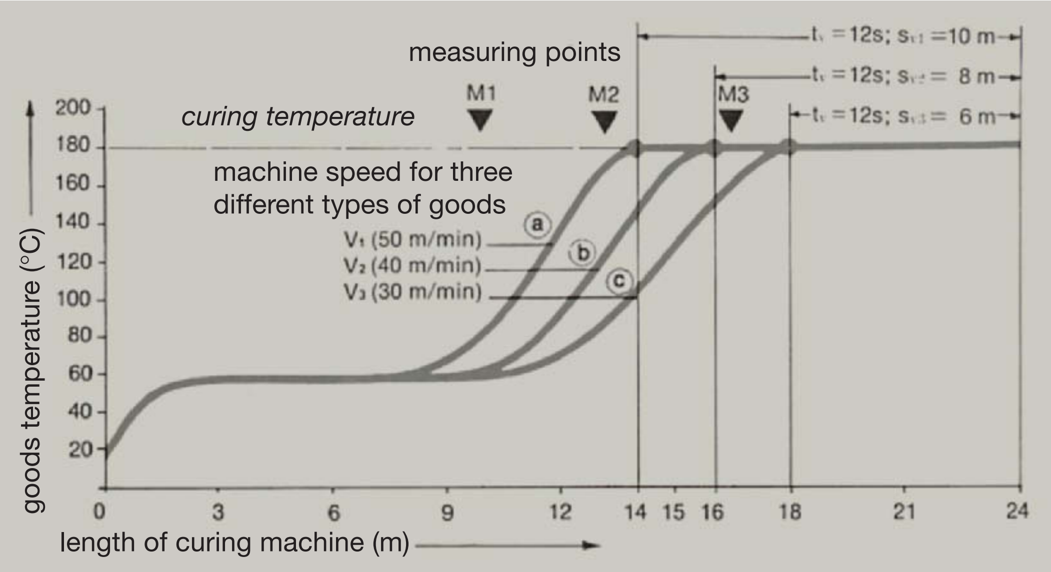

Fig. 6: The heating up curve for goods during the curing or condensing of initially wet goods.
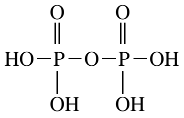
a = goods light and quick drying, high machine speed; b = goods moderately heavy, medium machine speed; c = goods relatively heavy and slow drying, low machine speed; t_v *= specified dwelling time;* s_{v1-3} *= dwelling zones.*

(Fig. 6). Only when there is no longer any residual moisture left does this cooling effect by evaporation cease and the surface temperature begins to rise. Within this range the temperature corresponds with a very definite material moisture content. This means that it is possible to maintain a defined material moisture level by maintaining a preset material temperature. This works not only on thin textiles, but also on voluminous carpets and even back coatings, front coatings and foam. The advantage is that measurement with pyrometers (M_1, M_2 and M_3 in Fig. 6) is non-contact and barely influenced by the material.

A dwell time apparatus requires the measured values from at least three radiation pyrometers, which continuously monitor the material temperature in the range of the heating zone. A microprocessor continuously calculates the heating curve for the material from these temperature values. It interpolates between the measured values and extends them into a continuous curve. By altering the machine speed the regulator alters the position and gradient of this curve (in Fig. 6) such that for each material the currently set dwell time is given under the preset conditions. The process speed is thus varied and is held as high as the properties of the material permit. The dwell time, however, remains constant.

The process is independent of the type of the material. It can be used both for fixing and condensation processes, and also for other time-dependent heat treatment processes, for example in drying, gelling, vulcanization of latex foams. The number of radiation pyrometers required depends upon the length of the machine and on the heterogeneity of the product. More temperature measuring points are needed for long plants and products that differ in width and weight than for short machines and largely uniform materials. At least three pyrometers are needed; up to eight measuring points can be connected.

Pyrophosphates (diphosphates), salts of the tetrabasic pyrophosphoric acids $H_4P_2O_7$ (→ Phosphoric acids).



$$\mathrm{HO-\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle OH}{|}}{P}}-O-\overset{\overset{\displaystyle O}{\|}}{\underset{\underset{\displaystyle OH}{|}}{P}}-OH}$$

We differentiate between:

I. “Neutral” pyrophosphates: type $Me_4P_2O_7$, only alkali salts soluble, with marked alkaline reaction: sodium phosphate.

II. “Acid” pyrophosphates: type $Me_2H_2P_2O_7$, soluble with acid reaction: disodium phosphate.

III. “Tertiary” pyrophosphates: type $Me_3HP_2O_7$.

Properties: pyrophosphates belong to the group of rare phosphates, and they possess the most marked metal corrosive behaviour of this group, particularly together with wash-active substances. Reactive behaviour like → Complex phosphates.

Pyrrole → Heterocyclic compounds.

Pyrrolidinecarboxylic acid → Proline.

Pyrrolidone → Polyvinylpyrrolidone.

Q

Q In the formula for nocuousness, the → Waste water quantity expressed as the amount of waste water in cubic metres per day.

QS-process Squeezing/suction technique in accordance with the principle of → Capillary dehydration developed by Pfersee. This is one of the low wet pick-up techniques; liquor reduction in the goods through capillary liquor exchange. Material which has been conventionally padded and squeezed in the first padder nip to the usual liquor absorption is brought together with the same, but dry, fabric, and pressed against it in the 2nd nip. This results in removal of the excess liquor (adhering liquor), leading to a reduction in the liquor uptake by a further 15–40%. Liquor treatment squeezing / suction methods on cotton approx. 40%. Advantages: → Low wet pick-up. Principally used in resin finishing.

Quadrant scales Yarn scales, for determining the weight of a certain reel length, by which the yarn count is determined.

Quality The definition of quality given in the standard DIN 55 350, part 11, which is derived from the English definition, as follows: Quality is the sum total of all characteristics and features of a product or an activity, which relate to their suitability for fulfilling set requirements.

The structure of the concept of quality shown in the figure can also clarify the concept of quality for the textile industry. The quality circle (according to Masing) is a model for intermeshing all measures and results which affect quality in the phases of the development and utilisation of a product or activity. Two of the terms named in the quality circle have long been differentiated in the English-speaking world, namely:

- quality of design
- quality of conformity.

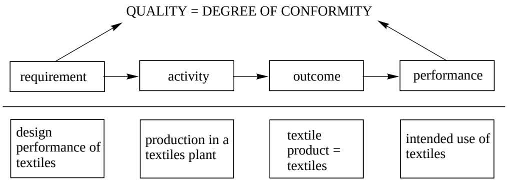


Fig.: The quality concept.

The latter is also known as quality of performance or quality of manufacture. When a textile item is sold, its technical (objective) and fashion (subjective) data play roles which are inseparable for one another. The fashion data are topicality, image-enhancing functions and wearability; whilst the technical data are defined by – amongst other things – strength, stability, fastness and processability. The task of each and every industrial production is to develop products which conform to a set quality standard (profile of requirements) in testing. The attempt to come to a clear definition of the term quality shows that quality is something mutable, dynamic. In contrast to the expert who is in a position to grade quality objectively to some extent, via measurable concepts, the consumer largely has to rely on the subjective assessment of the quality which he is purchasing. For the consumer, quality is not a physical parameter whose value can be measured, since it is a totality of many features and characteristics. Attractive products draw attention among textile consumers if the design is right, if one feels good in the product because of good physiological characteristics of the clothing, if the instinctive human desire for natural items is satisfied through the use of natural fibres, and the product is marketed in the right way. Specialities which arise through high expenditure on finishing in particular, appear to conform to these requirements for attractive products. For the textiles expert, these concern features whose values are recorded quantitatively and are compared with the quality standard. In terms of political economics, these economy-related quality criteria are supplemented by an increasingly important ecological quality criterion. According to conventional views of quality, the serviceable life of an article is at the fore. By contrast, a quality requirement in which fashion aspects have priority is less concerned with durability (high strength, fastnesses) of an article. Textile finishers often have to follow economic parameters; as manufacturers with an awareness of marketing, they will include the quality requirement in their economic considerations, and weigh up the attractiveness of the product. But the law increasingly compels them to take account of ecological quality criteria.

Quality assurance This is an essential measure for controlling production, to keep complaints about products within limits, to detect faults and eliminate them. In the textile industry, however, thorough quality assurance comes into conflict with ever shorter batch lengths and project times, and with ever smaller profits from finishing. In order to be able to produce economically in terms of time and costs, in the last few years, many firms have invested in the field of quality assurance, under the motto “quality is profitable”.

Quality is the condition of an item in respect of its suitability for fulfilling requirements which have been established and prescribed. For the prevention of faults, a number of points must be noted:

1. Quality planning in the design department, with performance checking.
2. Selection and appraisal of materials and suppliers.
3. Test planning, laying down responsibility for the Quality Control department and analysis of faults.
4. Quality training and promotion.
5. Incoming goods checking and supplier monitoring, to check qualification and performance of delivery.
6. Working out offers which are utilisation-related and process-technology oriented.
7. Establishing responsibility for checking documentation.
8. Final testing, packing and despatch, with test criteria.
9. Detection and elimination of product defects, customer service, and tracking of a product.
10. Environmental protection measures and product liability, for the purpose of risk reduction.

Manufacturing testing is subject to standards and technical rules for tests based on qualitative features. Here, rules are stated, to which one can refer between or during the individual operations and situations.

Manufacturing testing can be applied for the testing of:

- end products,
- parts and materials,
- work procedures,
- working materials and tools,
- warehouse stocks,
- repair capability,
- monitoring devices and measuring equipment.

Testing is the process of measuring, investigating or trying out an object, or otherwise checking it for conformity to requirements. During testing, the object is classed as either good or defective. Classification of defects requires grading according to the severity of their consequences.

Critical defects are defects of which one can assume or it is known that they will probably hinder the object in question in fulfilling its function. If an object is graded as important in terms of safety engineering or function, then 100% testing for critical defects is carried out. Minor defects are defects which will probably not significantly reduce usability for the intended purpose, or else they are a deviation from the applicable rule, which only slightly affects the use or operation of the object.

Deviations in quality which are established only at the final check can only be corrected at great expense. The final check must therefore primarily document for the client and for one’s own in-house quality planning, that all quality requirements are fulfilled with a high degree of certainty. If there is repeated failure to conform to minimum requirements, then quality assurance in production must be improved, rather than increasing expenditure on testing in the final check.

Most textile tests require considerable amounts of staff, material and time. They must be planned very carefully, taking into account the possible error risks. With production planning and production control systems, the frequency of testing can be specifically arranged according to these criteria:

- risks of process engineering
- production frequency and quantity
- customer requirements
- error rates in previous production.

The available testing capacity is deployed with considerably greater efficiency than with simple procedures which subject each batch to very extensive testing programmes, practically regardless of the construction and quality requirements of the article. Two testing programmes – short test and long test – are distinguished. The short test is always carried out for every batch, and is used to decide on release of the batch after finishing. For this, only the most important risk factors are tested. The long test covers all essential technological quality features of an article. It is used in the following cases:

- in the first production batches of new articles
- after process conversions
- after a certain production quantity, to check the overall quality standard.

The test specifications for a certain article may be, for example:

1. A short test, with the test criteria of finished width, tear strength, slipping tendency, and washing shrinkage per batch.
2. A long test, with the additional test criteria of thread count, mass per unit area, dry crease angle, smoothness profile, fastness to chafing, and colour fastnesses for every 10th batch, but at least once every quarter.

The test data are processed by computer. The testing programmes for all articles are thus stored together with the respective applicable target values and tolerance limits. After the test values have been recorded, the following evaluations can be undertaken: print-out of all test values outside the tolerance, for fast information for the departmental management, takes place in freak value records. The control card is the print-out of a selection of test values, represented in control card form. Statistical comparison of selected test data for specific clarification of questions such as “Change in the technological values following a process modification” or “Comparison of two production runs with differing provenance of raw materials” takes place regularly. The final colour of each batch is assessed visually and by colorimetry. With the so-called “sewing sample”, the colour evenness is visually checked over length and breadth. Where the client specifies the maximum permitted colour ranges, this test can also be carried out colorimetrically. Larger consignments are additionally sorted according to colour groups. This sorting generally takes place visually, since colorimetric sorting using measuring equipment is still relatively time-consuming and unwieldy.

Responsibility for the quality of the products and by-products is borne by the management of the textile finishing company. The management lays down the targets towards which quality assurance in all areas of the organisation is to be directed. This plan is called the quality policy. It determines, in concrete terms, the structure of the quality assurance system and the implementation of quality assurance. Quality assurance is the sum total of the activities of quality planning, quality control and quality testing. The aim of a quality assurance system must be “process under control”. The aim is to ensure that the product- and quality-related influencing variables are recognised and established in time. A monitoring system ensures that the individual stages remain standard. For this, standards which relate to the profile of requirements must be produced, and kept up to date with the latest developments. The reporting system includes the evaluation of the interim production yarn/raw fabric and, on a monthly basis, the evaluation of the manufactured production. Furthermore, customer complaints, returns, after-treatments etc. likewise form an important constituent, as information, for controlling production (Fig. 1).

A distinction is made between input, i.e. raw goods, performance of work, and output, i.e. the product. Included under product are the reports concerning quality outcome, analyses and any changes which result from this for manufacture. For the spinner, input includes the fibres which are necessary for a corresponding yarn; for the weaver, it includes the raw fabric standards, which also apply for the buying in of raw fabric. The finisher will subject the raw textile goods which have been supplied (knits, fabrics, yarn, flock), but also dyes and auxiliaries, to an incoming goods check. The article profile must be determined in writing, and this includes not just strength and error rate, but also statements about sizing, right down to selvedge construction. The information contains all work instructions. The aim of quality assurance is a “fault-free culture”, development in accordance with the quality requirements of the client; it can only be achieved with a corresponding attitude on the part of the producer. Condition, serviceability, reliability features and a usage-oriented level of requirements determine the required quality elements. The quality policy of a firm defines performance and application policies within the framework of quality assurance, through reliability planning, test planning, quality engineering, test procedure plans, supplier appraisal, materials testing and goods testing, and incorporates them into a quality assurance verification system. The DIN and ISO standards mentioned in this quality assurance manual are used on a case by case basis. They form the subject of the order, when they are mentioned (e.g. acceptance class) in the order confirmation.

Quality assurance is divided into:

- quality management
- quality planning
- quality control
- quality testing.

Within a firm, integrated quality assurance forms part of the duties of each employee (Fig. 2). It starts with the

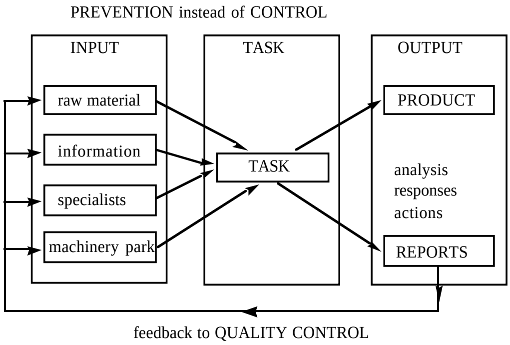

Fig. 1: Part of a control loop at Marks & Spencer aimed at avoiding defects.

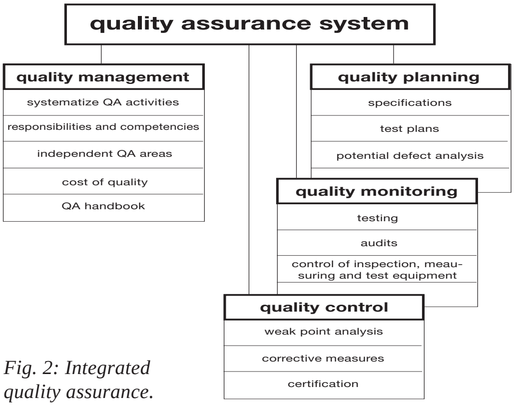

Fig. 2: Integrated quality assurance.

invention of new products and extends through their development, the purchasing of starting products, incoming goods checking and warehousing of raw materials, production, in-process monitoring, quality testing at the end of fabrication, the selection of suitable packaging, correct labelling and secure storage, orderly storage of reference samples, down to despatch and processing by the customer. Clear traceability of the individual batches, heeding facts relevant to quality assurance (such as customer and product specifications, standards, target values, packaging, warehousing regulations etc.) when drawing up contracts with subcontractors and customers, or the handling of products which do not conform to the quality, are an important part of quality assurance. It likewise includes periodic execution of in-house quality assurance audits. Quality assurance is a seamless system, running through all activities within a firm, which is also closely linked with its surroundings: with the market, product liability and standards, as well as with official stipulations and legislation. Quality assurance must, in accordance with this central topic, form part of the content of management board meetings, and the management board must fully identify with the chosen quality assurance system and its consequences.

The situation with quality testing is considerably simpler. It is necessary that both production and quality testing are integrated when drawing up specifications, target values, test schedules and test procedures; however, once they have been established by mutual agreement, performance of the duties resulting from them represents a routine which must be strictly adhered to. In order to preserve constancy of quality, changes to the test specifications, must consequently be avoided so that comparability with earlier results is not lost. However, if the quality of the available starting products should require process improvements, or should new measuring technologies, changed requirements in the market, a different type of profile of requirements for the product, or stricter, extended statutory regulations, amongst other things, call for corrections, then the possibility of a change in quality must be planned, and realised if possible. By agreement with the production and marketing departments, the quality testing department then sets up a new test standard, and the internal and external offices as well as the customers must be informed. Fundamentally, all test results and measurement results are subject to a certain error probability in comparison with the true value. For this reason, besides the reliability and reproducibility of test methods, particular attention must also be paid to keeping and checking test standards. This in turn is a quality-assuring measure for quality testing. It is recognised that those offices responsible for quality assurance and quality testing should report directly to the management board. In this way, they are independent of departments and functions, as well as from production. A logical conclusion from this is to embed the quality testing function in quality assurance. Final checks are insufficient for achieving far-reaching elimination of defective production, even if they are supported by statistics. To achieve this aim, more or less comprehensive quality assurance systems or quality assurance monitoring circles are absolutely essential. Fig. 3 shows an example of quality assurance in a larger company.

Quality assurance for a single finishing stage is shown in Fig. 4. Equipment and procedure for process monitoring should detect quality-reducing influences during the process, and eliminate their cause. Process monitoring systems work continuously. An example is temperature regulation or liquor application regulation. Production checks should detect errors which occur, so

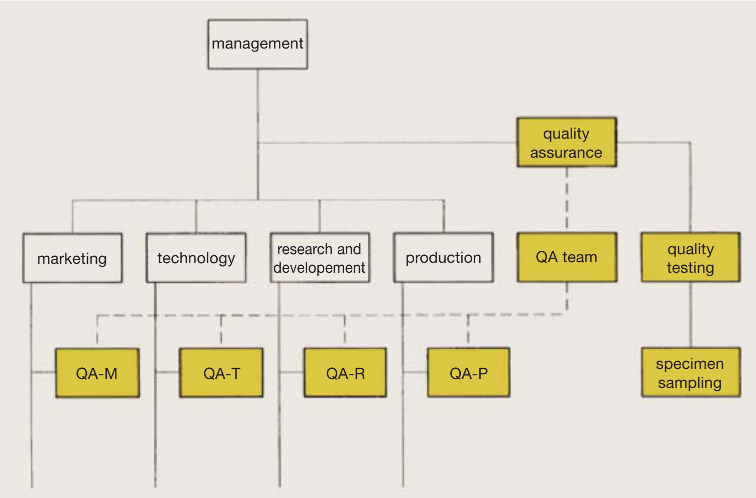

Fig. 3: Example of matrix organization for quality assurance in a large company.

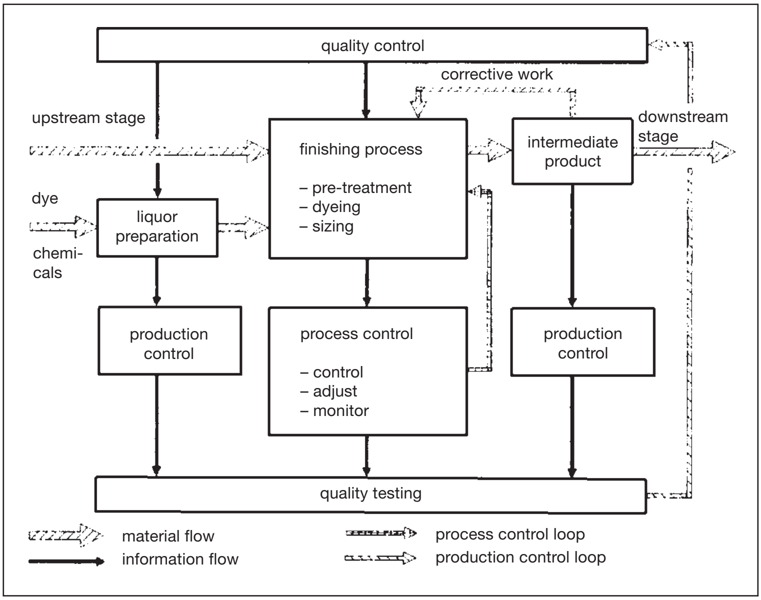
Fig. 4: Quality assurance system for a single textile finishing stage.



that these can be corrected by re-working the preceding stage or by special measures in the subsequent stage. Recurrent faults must be systematically eliminated by adjusting the process engineering. Production checks are carried out either on the entire production or on statistically secured random samples. Examples are checking the colour outcome after dyeing, or monitoring de-sizing after pre-treatment. Two important control loops of quality assurance are thus recognised in production. The inner control loop is formed by the finishing process and process monitoring system, whilst the outer control loop is formed by the finishing process, quality testing (production monitoring on the intermediate product) and quality control. Corrective measures via the outer control loop are always considerably more expensive that those in the inner, shorter, control loop.

Besides the overall reasons for a quality assurance system, ecological aspects, which naturally, in turn, have an economic background, speak for quality: warranty liability, product liability and environmental liability. Only company-specific quality assurance measures provide a guarantee that the profile of requirements agrees with the performance in textile production, and that suitability for the purpose can be guaranteed. Only through consistent quality assurance measures can one guard against even concealed defects, in order to prevent later complaints and recourse claims. In itself, product liability does not bring any new risks with it, but with regard to consequential damage due to faults in both domestic and foreign trade, a risk assessment is indispensable.

The product information system of DTB (Dialog Textil-Bekleidung) can provide important assistance in guarding against complaints and consequential damage due to faults. The aim of this product information is to secure the usage purpose, wearing characteristics and quality image with the aid of technical characteristic data, and thus at the same time to ensure that suitability for the intended purpose is in fact given. Six groups of data relating to construction features, finishing features, processing features, care labelling, colour fastnesses and mechanical-physical characteristics provide information about the quality features of goods, and what the goods are capable of (and what they are not).

Ecological risks can no longer be ignored by textile firms. Textile finishers in particular handle chemical substances; they store them, and carry out chemical processes. Waste water and exhaust air have claimed the undivided attention of the legislators. Careful and responsible handling of textile finishing chemistry within the framework of quality planning and quality control systems are unavoidable as technical elements of the quality assurance system. Short term but also medium term measures are necessary in order to be able to stand up to any future environmental liability and the environmental protection laws. Risk assessment, planning and control of the textile quality which is produced are of particular importance from the point of view of environmental legislation.

In view of the liability obligation of a producer within the framework of quality assurance, the question naturally arises as to how far the liability remains insurable. The new liability regulations contained in the German environmental liability law of 10.12.1990 caused the liability insurers (HUK-Verband), together with the BDI and the DVS (German insurance protection association), to re-work the previous system of liability insurance through the introduction of the environmental liability policy ’92. With the new environmental liability policy, environmental cover of the company liability insurance, water pollution liability insurance and the environmental policy ’78 are combined to form a uniform insurance concept. The general terms for liability insurance (AHB) were adapted to this new policy; thus an exclusion of compensation for environmental damage by the company liability insurance was inserted in the AHB. On the other hand, the extended product liability insurance continues to be covered within the framework of company liability insurance. Environmental damage due to products thus remains insured in the company or extended product liability insurance (exception: installation recourse). (Source: Korte, also Hohl, and Hemmpel).

Quality circle The quality circle is a model for the intermeshing of contributions which the various functions make to the quality of a product or service (Fig. 1). Quality arises as a result of activities or processes in the planning, realisation and utilisation phases.

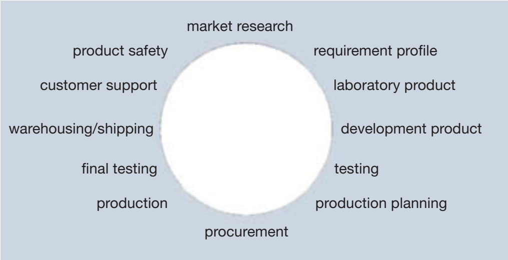


Fig. 1: The quality circle.

Fig. 2 attempts to illustrate the action area of product-monitoring and quality control in interaction, for the purpose of quality assurance for textile finishing. Quality control represents a checking of results, both at the start of the finishing chain and at the end of it. Product monitoring, on the other hand, has an immediate production-controlling function, in that it assesses the effect of individual finishing stages, and thus intervenes directly in the finishing procedure. Quality assurance represents a force for order in relation to article optimisation, process optimisation, and improvement of the economic result of a finishing process. This is possible only if quality assurance has direct access to the production and non-manufacturing departments such as plant engineering, laboratory, development and purchasing, so that questions relating to process engineering, substrates, chemicals, auxiliaries and dyes, concerning assurance and optimisation aimed at economy in articles and their production, can be solved quickly.

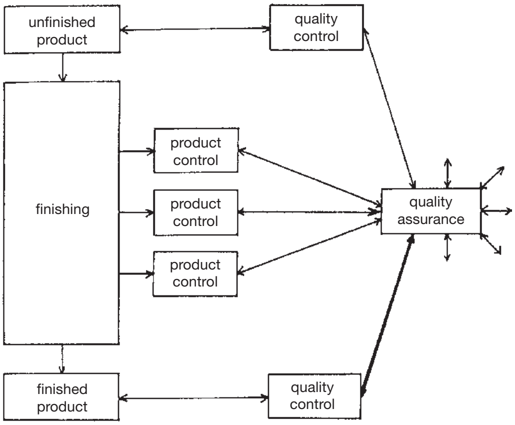

Fig. 2: Quality assurance as a function of product and quality control (Windel).

Quality circles Quality circles (QC) are working parties of approx. 10 people led by a chairman, which have grown to become a full-blown movement in Japan. In the USA and Europe too, they have been a permanent fixture for several years.

When setting up a quality system, the company management must be clear from the outset about how they can do justice to the demand for “continuous improvement” of quality management at all hierarchical levels. This requirement means that in the organisation in question, problems are continuously investigated, and where possible are solved by those employees who are most affected by the effects. When such a participatory concept is introduced, consideration must above all be given to the question of how the priorities are to be set, between those projects regarded as important by “the top” (the management) and the workplace-related problems which interest those “at the bottom” (those employees who carry out the work). In principle, intradisciplinary problems can be handed over for solving to individuals, hierarchical groups or groups composed of volunteers. The hierarchical group can be a problem-solving group which – if it consists of two people – is called a “dyad”. In the case of volunteer groups, this could be a modified quality circle, insofar as it accepts problems proposed from outside. Interdisciplinary problems are usually handed over to a project team or committee. In the normal case, the latter differs from a project team in that it has the restricted task of just submitting proposals for solutions. Project teams, on the other hand, should, wherever possible, also be entrusted with implementing the solution, or at least with monitoring the problem-solving process.

From the point of view of those responsible, the formation of groups of volunteers has, above all, the purpose of giving those employees mainly entrusted with hands-on work the opportunity to assume their own responsibility by being able to work through problems which they have themselves identified. This support for self-help and for reinforced self-confidence leads to increased motivation among individuals at work, and also has a considerable positive effect on the working climate in the quality circles. Both are requirements for the fulfilment of set performance targets and for constant improvement in productivity. From the company point of view, therefore, the issue is that the staff can effectively and continuously utilise their intellectual potential to constantly improve the work procedures and to deal with their tasks and problems.

Quality control (fabrication, manufacturing, production control). Quality values are recorded quantitatively and compared with a set quality standard (profile of requirements), or are merely assessed subjectively. A feature is therefore the characteristic which enables the units which form a whole to be distinguished, namely either quantitatively (quantitative feature, size) or qualitatively (qualitative feature). For each feature, one has to know the required and the observed values. Systematic testing and monitoring of → Quality before manufacture (incoming goods checking), during manufacture (quality control system) and afterwards (final testing, acceptance testing) are carried out. Statistical methods (→ Statistical quality control). are frequently used, or opto electronic testing plants.

Quality control for textile chemicals and dyes Textile chemicals and dyes are almost never chemically homogenous (reaction mixtures) and polyvalent. The quality of the product is defined by the requirements of the market. In the case of textile dyes, these can be for example coloristic tolerances (Fig. 1) as well as problem-free application, freedom from specks after application, low dust (in the case of powder dyes), dispersion stability in HT dyeing, stability in transit and storage, suitable viscosity, ecological and toxicological harmlessness, pad liquor stability, solubility (e.g. in the case of ionic and reactive dyes), fastnesses and redispersibility. To this list one could also add other desirable characteristics such as combinability and migration behaviour.

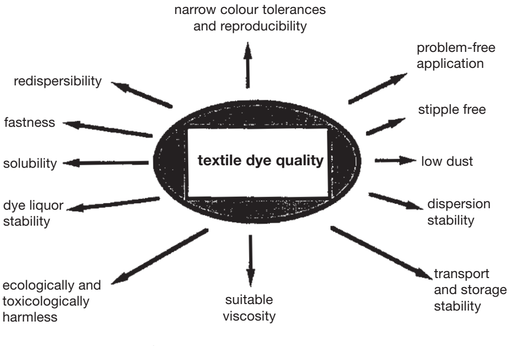

Fig. 1: Factors influencing dye quality.

adhesion dosible	**weaving**
wettability and washability extraction power bleach liquor stabilising power	**pre-treatment**
support of dyeing and printing processes	**dyeing and printing**
reactiveness tolerability influence on handle	**final finishing**

Fig. 2: Quality criteria for textile additives in various finishing stages.

A corresponding listing can, of course, also be made for the different auxiliaries for pre-treatment, dyeing or printing, after-treatment or resin-finishing (Fig. 2).

Products with these characteristics are developed to a high level with tight tolerances, depending on the range, formulations and strengths of the individual firms in the dyestuffs and auxiliaries industry, in partnership co-operation with the textile finishers, and are put on the market. This market supply is supported by the service and advice provided by the manufacturers. Taking an example from the area of “handling of dyes”, divergent – sometimes even contradictory – demands can be made of the quality of a product. In accordance with the various methods of application, the demands made of handling are wide-ranging, e.g.

- easy dissolution in the dyeing vessel,
- setting of stock liquors and pad liquors,
- stirring into printing pastes,
- weighing out the smallest amounts for tinting,
- processing with metering pumps.

In all these manipulations, the dye should not form dust, should not form lumps when introduced into water, should dissolve quickly and without leaving residues or be well miscible, should not be deposited or solidify anywhere. The manufacturer must also make sure that the dye’s characteristics do not change until processing, even under transportation and storage conditions which are sometimes extreme. For even when a dye preparation has left the works in which it was produced, it is exposed to hazards. Liquid preparations above all are, in extreme storage conditions, at risk of crystallising out, precipitation of components, and coarsening; also of changes in viscosity and thixotropy, which can lead to sediments. But granulate or powder brands too can change in the course of time by absorbing small amounts of moisture from the air, or by influences on the dust behaviour. Even the dispersibility of solid dispersion dyes can worsen when stored under unfavourable conditions, due to grain coarsening. Simple handling and safe processability are therefore determined to a high degree by the commercial form in which the dye is supplied (Fig. 3). Individual manufacturers use the most varied designations for commercial forms. They can be grouped according to external aspects.

Powder brands are generally supplied as largely low-dust. Dusting is frequently prevented by the addition of an emulsifiable oil. The de-dusting agent however has the peculiarity of migrating into the individual dye particles during storage, and thus over the course of time it can lose its de-dusting effect, depending on the character of the dye. Another way of achieving low-dust products is granulation. The glassy pellets produced during drying by spraying in hot air furnaces do not dust after manufacture. However, particularly during transportation, depending on the hardness and shape of the grain, dye can be rubbed off, which then becomes unpleasantly apparent as dust. For the manufacturer, granulation brings the additional difficulty that with drying through spraying of the dye solution, the standardisation must be concluded. A granulate cannot, by its nature, be tinted. Also, dusting fines have to be dissolved and returned to the manufacturing process of the dye. The advantage of powder brands of higher concentrations lies in their more favourable transportation weight and easier handling, when large amounts are to be processed. Less storage space is needed, and fewer drums accrue as waste. On the other hand, weighing errors and inaccuracies in the formulation have a far greater effect than with dyes with weaker settings. Many powder preparations have the common feature that they are hygroscopic and can take up moisture from the air in the room when drums are not hermetically sealed. Sometimes the dye solids bring hygroscopic characteristics with them ; often, however, there are also salts or surfactants which are used as setting agents or dispersing agents, and which attract moisture from the air. A low amount of moisture absorbed from the air is sometimes still undetectable in the outer aspect of the dye powder, but through weight increase it can become unpleasantly apparent in a notionally low dye strength. Pastes traditionally have a firm place in textile printing. Ease of working into the printing paste is the main advantage. Difficulties are to be expected with granulates, particularly coarse-grained ones, which do not distribute themselves evenly in the printing paste without prior dissolution. Liquid brands are however welcomed by continuous dyers, who have to set a large amount of dye in a concentrated pad liquor. Liquid brands can largely be handled without dust problems, and in this respect are also to be preferred for reasons of work hygiene. In the quality control of his dyes, the dye manufacturer must therefore, because of the overall complexity of the application, check the characteristics shown in Fig. 4.

The quality records play an important role in quality assurance. The description of the test procedure represents the basis of quality testing. For this reason, descriptions of the methods according to which textile dyes are tested are obtainable from all dye manufacturers. The recording of test results must be accorded par-

ticular attention, since they will be required for the evaluation of samples in subsequent re-testing, for example in the case of complaints, and for statistical methods. Test parameters relevant to evaluation include e.g. the result of transmission measurement or reflectance measurement (i.e. colour strength, brilliance and shade) in various methods or data concerning solubility, viscosity, density, finish etc., which result from additional physical-chemical tests. In this way, several hundred thousand pieces of data are collected per year, with the number of original data (i.e. those resulting directly from the measurement process) and the raw data (after analogue-digital conversion) not being recorded. Dealing with this amount of data efficiently is only possible these days with the aid of data processing. An efficient option for this is provided by laboratory data collection systems or laboratory information and management systems (LIMS).

LIMS are systems for computer-aided

- sample administration,
- method administration,
- order production,
- protocol production,
- administration of reference samples.

Saving data in databases enables

- recording of the raw data from the analytical equipment,
- monitoring of calibration,
- research,
- long-term statistical evaluation,
- monitoring of costs.

With this system, complete sample administration is possible, from receipt of samples to protocol production and the administration of reference samples to the calibration of systems (Fig. 5). The storage of data, which sensibly also includes the raw data of the connected analytical equipment, ensures adherence of the calibration, enables research and long-term statistical evaluation, and – if applicable – monitoring of costs.

Important requirements of DIN ISO 9003, namely test equipment monitoring, checking the state of testing, quality records and the possibility of carrying out statistical methods, can thus be dealt with. They therefore satisfy not only the customer demands for quality assurance, but also in-house necessities. LIMS can only be employed efficiently if practically all analysis results of the various investigation points are included.

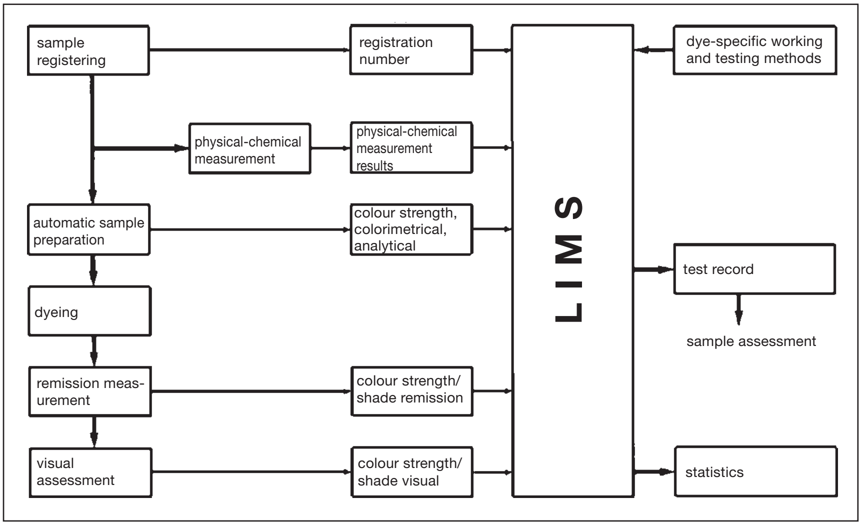

Fig. 5: Inclusion of LIMS in the quality control of textile dyes.

The possible integration of a LIMS into the organisational procedure of the quality control laboratory for textile dyes is shown in Fig. 5.

The LIMS is a central component for monitoring the work sequence. First of all, in the introductory phase the work methods and test methods for each dye must be precisely defined. The general work sequence of a sample, from registration through sample preparation and coloristic processing, right down to visual assessment, including the necessary physical measurements which include also qualitative and quantitative chromatographic methods of analysis, is emphasised. The values obtained for monitoring and evaluation parameters are transferred to the LIMS either automatically in-line, or via diskette transfer. The values of certain physical-chemical measurements, such as e.g. those of solubility determination and of visual assessment, have to be entered manually. As soon as the work list defined at the outset has been fully equipped with results, comprehensive sample evaluation can be carried out on the basis of the test protocol. The result of quality testing can then – possibly via in-company networks – be made available to all those sections which depend on them, e.g. in Production, Operations Planning and Despatch.

The heart of the plant is the automatic sample preparation, which due to the large number of data which accrue, is linked directly with the LIMS. Automatic sample preparation is to be regarded as an important step in the test sequence. Particular attention must be paid to it with regard to increasing the accuracy which can be achieved. Particularly in dyes which can be dyed with good reproduction, such as e.g. dispersion dyes, the reproducibility of sample preparation represents a decisive input into the overall reproducibility, and must therefore not be neglected. In order to determine the reproducibility of an automatic sample preparation system or laboratory dosing system, it is not sufficient to determine the metered amounts or concentrations of a dye by means of spectrophotometric determination. Balance-controlled testing of the reproducibility of a dosing system is absolutely necessary. This yields better reproducibility of automatic dosing systems in comparison with the average manual method. Through their higher level of reproducibility, dosing systems then also have their legitimacy for dye classes which can be dyed with less good reproducibility.

Besides this general increase in accuracy, by using automatic sample preparation systems, one is also freed of other human-related faults which come about through error. Thus with the introduction of laboratory dosing systems, there is an influence both on random, statistically controllable faults as well as on the systematic faults which are not statistically controllable. Laboratory robots which can take over the entire procedure of sample preparation are available for use as sample preparation systems in various versions. Sample registration takes place on the monitor by means of a barcode reader pen. It can also be carried out automatically from the sample vessel, with a laser scanner. Weighing in of solid or liquid dyes is carried out automatically by the robot. The addition of water in the case of balance-controlled solution and thinning is carried out with a hose pump, and in the final phase through jets controlled by stepped motors, to achieve the required accuracy. For transmission measurement, an aliquot amount is taken automatically, the weighed-in amount is determined precisely, thinned accordingly, and this solution is measured.

On the basis of the measurement results, dosing of the dye solution into the dyeing tubes takes place. The dosing of dye solution and auxiliaries into the dyeing tubes is monitored by means of a balance. At this point, the weighed substrate can be assigned if necessary.

Colorimetric determination of colour strength, i.e. transmission measurement, represents a partial stage within automatic sample preparation. The transmission measurement is therefore of particular interest in quality control, since it enables fast, orienting determination of colour strength and, within limits, the shade too, with good reproducibility. In the case of dye classes which take up more or less completely from the bath to the fibre, and in which standard and sample behave identically, it leads to good results. Specifically in the case of reactive dyes, transmission measurement has recently achieved increased status through its use in combination with chromatographic methods of analysis. This modern type of colour strength determination, based on purely analytical methods, should in the future appear alongside traditional colour strength determination by means of coloristic methods. In reactive dyes, the problem is well known that during synthesis, it is inevitable that a certain proportion of non-reactive hydrolysed dye arises, which contributes to the overall chromophore content in the transmission measurement. If one is able to determine quantitatively this non-fibre-reactive constituent, or better, to determine the overall reactive proportion of a sample, then this can be placed in relation to the transmission measurement, and the coloristic colour strength can be determined analytically. The possibility of quantitative analysis of dye samples is provided by quantitative thin-layer chromatography and HPLC.

The reproducibility of dye strength determination is determined by the quality of the separation of the individual components present in the sample. The method has to be optimised for each dye, in relation to the stationary phases and mobile solvent mixtures used. If the involvement of the dye components in question in the dyeing process is known, and if good chromatographical separation of the constituents is achieved, then a smaller standard deviation of the colour strength determination compared to the coloristic method is to be anticipated, i.e. the dye strength can then be determined with greater accuracy. This requires extensive preliminary analytical work for each dye. The standard deviation of the photometric-chromatographic determination of the colour strength is – due to the problems already mentioned – not generally smaller than that of coloristic colour strength determination. Since in the coloristic determination method too, dye-dependent fluctuations in the standard deviation can be detected, to achieve optimum reproducibility one must select the most suitable method in each case. It can therefore be said with some certainty that the quality control of textile dyes will in future not move exclusively towards purely analytical methods. Dyeing methods will retain their legitimacy, particularly because shade determination can be carried out by analytical methods only with great difficulty. As is known, dye-active secondary components of the order of <0.1% can cause a discernable shade displacement of the dyeing, through which the tolerance range of the shade can be exceeded. In this concentration range, the reproducibility of the chromatographic methods is not yet sufficient to make an accurate prediction. (Source: Varwig, as well as Leube, and Kunze).

Quality control in the textile finishing industry This is necessary in order to guarantee quality within the field of textile finishing. Quality can be guaranteed, because the textile expert has learned to take account of unevennesses, e.g. in the case of different consignments of raw materials, through the use of finishing technology, in that evaluation criteria are used to characterise the raw goods and the finished goods. Quality assurance starts with the selection of quality characteristics, and establishing required and reliable values for them. For example: measurable (quantitative) features, e.g. mass per unit area; countable (qualitative) features, e.g. defects in the goods; (subjective) classifiable features, e.g. handle; mixed forms (if a colour is evaluated in a colour measuring device, this is a quantitative feature, but if it is appraised visually with a limiting sample, then this is a qualitative feature). The corresponding test methods are laid down in DIN standards.

Quality control system (quality regulation). The control of manufacturing processes to achieve the required → Quality.

Quality costs An essentially incorrect expression used to denote costs which arise in the course of efforts to secure the → Quality of satisfactory services, and as a consequence of quality standards which have not been maintained. Quality costs thus relate to services which have been or are yet to be rendered. Quality cost groups according to the DGQ (German Society for Quality) include: error prevention costs, testing and evaluation costs, error costs.

Quality criteria in pretreatment The pretreatment of cotton fabrics influences the quality of the fabric, above all in the case of boiling off and bleaching. The success of bleaching is measured by determining the degree of whiteness (by colorimetry). To determine the quality, the absorbency is tested after boiling off. For this purpose, one can also determine the residual fat content by means of Soxhlet extraction (see table). True absorbency should be achieved. Complete removal of the fatty substances is not recommended, since this results in an unpleasantly brittle and rough handle. In some cases it is necessary to determine the residual content of mineral substances (residual ash content). If damage from alkaline treatment is suspected (e.g. the formation of oxycellulose), then the decrease in the degree of polymerisation or the tear strength must also be checked. In many cases, boiling off is sufficient as a preparation for coloration (e.g. for dark dyes or covered, full print surfaces); bleaching is not necessary.

goods	unfinished	desized	scoured
absorption	0	0	60 mm
whiteness	52,0	52,2	58,2 (Elrepho 46)
fat content	1,02%	0,80%	0,19%
size content	6,75%	0,55%	0,33%
ash content	1,26%	1,01%	0,22%
iron content	62 ppm	53 ppm	11 ppm
degree of polymerization	3020	2940	2810

Tab.: Measurement of quality factors.

The consequences of pre-treatments which have been improperly carried out are often problematic. First and foremost are the formation of creases and marks. Individual patches which have dried on during the boiling off stage, or residues of sizing agents, also leave visible traces after dyeing. Partial or irregular removal of the fats or mineral substances leaves traces in the form of uneven or weak dyeing, changes of shade from selvedge to centre, or poor penetration of printing. In the case of boiling off under unfavourable conditions, the risk of the formation of oxycellulose increases. In the case of polyester / cotton fibre blends, the delamination effect on the polyester must definitely be taken into account.

Quality number for fibres,

I. Conventional reference value for (tensile) strength, titre strength in cN/dtex (previously g/den; p/dtex). Conversion to (substance) tenacity: quality number multiplied by 9; conversion into substance strength: quality number multiplied by 9 multiplied by density.

II. In the quality number, 5 characteristic, mechanical, technological properties of different fibre types are assigned to a so-called ideal fibre = 100 reference basis. From this, the characteristics for each fibre type its are expressed as percentages, and their mean value represents the quality number. With the rankings which are thus calculated, polyamide fibres for example are assessed at 82.7, polyester fibres at 75.8, cotton at 53.2, polyacrylonitrile fibres at 50.6, and PVC fibres likewise at 50.6, etc. This classification according to this evaluation principle does not take account of the actual material quality and important characteristic properties.

Quality protection This covers the establishment of quality features which are decisive for serviceability, and the organisation for monitoring these features, with the aim of achieving assured reproducibility. → Quality symbols.

Quality-related abbreviations,

TQM = Total Quality Management
CAQ = Computer Aided Quality Assurance
QA = Quality Assurance
PSG = Problem-Solving Groups
FMEA = Failure Mode and Effects Analysis
SQC = Statistical Quality Control
SPC = Statistical Production Control
LIMS = Laboratory Information and Management System

Quality sample Representative sample for the final quality of the goods.

Quality standards → Requirement profiles.

Quality symbols These are logos or symbols, or both, which are used as a guarantee mark to label goods or services which fulfil certain characteristics generally regarded as important for the quality of particular goods or services, and which are measured on objective scales, and the bearers of which are quality associations which set up publicly accessible quality conditions, and monitor their fulfilment, or which are based on statutory measures. The quality conditions result from the principles for quality symbols issued by the RAL (RAL = German Committee on Conditions of Supply and Quality Assessment), which have been set up by the leading organisations of the Germany economy together with the Federal Ministry of Finance, in accordance with the prevailing view. Examples: charmeuse quality symbol, creaseproof, rapid iron, Scala d'oro, Schwurhand, Super Cotton, attested.

Quality testing Determination of the degree to which goods meet the requirements made of them. → Quality assurance must be guaranteed.

Quantitative dye determination on textiles,

I. Extraction method: With the aid of a solvent or an azeotropic mixture, the dye is loosened from the fibre by means of extraction. The concentration is determined via a photometric assessment of the extract, by comparison with known extinction coefficients. In this method, there is the risk of dye changes through the long reaction time at high temperatures. Also, there is only a limited number of solvents and azeotropic mixtures available. This method is uneconomic for small substance samples.

II. Solvent method: Dissolution of the fibres and the dye in a suitable solvent (e.g. polyamide in 85% formic acid and in m-cresol, or cellulose in 80% sulphuric acid). This method is quick, but not universal. There is the risk of clouding through dulling agents, discoloration through substrate decompositions, and lack of solubility of the substrate after cooling.

III. Residual liquor method: This is based on determining the dye which has not been taken up. This method is somewhat cumbersome, since dye which is removed during rinsing also has to be taken into account.

IV. Repeated boiling out in solvents or solvent mixtures. The fibre material is heated up repeatedly together with fresh solvent. This method is very versatile and saves dye, and there is a greater choice of solvents, since the fibres can be allowed to swell or even lose their shape.

V. Specific detection methods for some characteristic elements, such as, e.g. the colorimetric determination of copper, nickel, iron, cobalt, etc.

VI. → X-ray fluorescence.

Quantity of heat →: Joule; Radiant energy.

Quarter,

I. English measure for carpet width: 1 quarter = 9 inches = approx. 23 cm.

II. German carpet measure, now obsolete, equivalent to $^1/_4$ cubit, or approx. 17 cm.

Quartz In the case of glass, an isotropic mixture of silicates. However, there are also uniform, glass-like compounds such as quartz glass (silica glass), an amorphous silicon oxide. For this glassy state, it is characteristic that - in contrast to crystals - it does not have the space lattice consisting of strictly regulated repeating elements, but that the connection of its particles is irregular. This is also clear from an X-ray diagram, which is similar to that of amorphous substances.

The characteristic feature of such a compound consists of the fact that it is composed of the spatial network of SiO_4 tetrahedrons, in that each Si^{4+} ion is surrounded tetrahedrally by four O^{2-} ions. These tetrahedrons connect with one another in such a way that two tetrahedrons have only one oxygen ion in common. Such a network is present in quartz, but also in other modifications of silicon oxide, where however the arrangement is strictly regular. In glass, the tetrahedrons form irregular rings which consist of groups of different numbers and which are not periodic, but which have sufficient space in their clearances for alkali ions and alkaline-earth ions (see Fig.).

Since this network is irregular (amorphous), its physical attributes do not depend on its direction, since through statistical compensation each individual direction will have the same value. The glass is thus isotropic, and does not have double refraction. A further feature of this amorphous body is that glass does not have

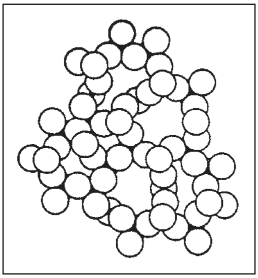

Fig.: Tetrahedral-like spatial reticular structure of quartz.

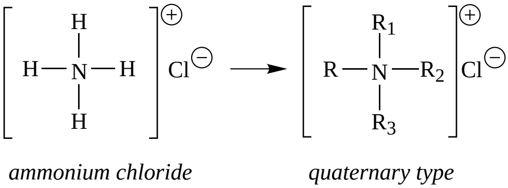
a fixed melting point. Rather, during heating its characteristics change gradually, with weakening strength.

Quartz fibre (quartz wool) Quartz fibres represent a special form of → Glass fibres. Quartz is a fusion product of silicon oxide, which does not show any crystal arrangement when cooled slowly (lattice silicate). The way in which these are obtained corresponds to that for glass fibres. Quartz fibres are stable up to a temperature of 1200–1300°C, and the melting point lies at around 1700°C. Resistance to acids is very good, and resistance to alkaline solutions is good. The remaining characteristics are similar to those for glass fibres. Used mainly for insulation purposes, filtration, and sensitive measuring instruments. Due to their high level of brittleness, quartz fibres are not used for textile purposes.

Quartz lamp (quartz mercury lamp). → Ultraviolet lamp.

Quaternary (from the Latin quattuor = ‘four’). Quadruple substitution, e.g. by alkyl groups, such as with the most important → Quaternary ammonium compounds and phosphonium compounds, where the alkyl complex occurs as a cation.

Quaternary ammonium compounds Bases and salts which are derived from the ammonium group (NH_4), in which all four H atoms are replaced by → Alkyls, as shown in the following example diagram:



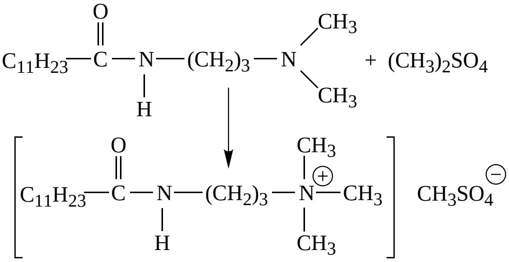


Fig.: Quaternary ammonium salts (lower alkylamine/-amide).

The free ammonium bases are, similarly to caustic soda, strong bases and are water-soluble even with higher-molecular alkyl residues. Their salts form neutral aqueous solutions, practically do not hydrolyse, behave like soaps (so-called invert soaps), but are decidedly cation-active. Products of this type thus lead to a range of well-known textile auxiliaries as cation-active softeners, for increasing the wet-fastness of direct dyeings, for levelling out cationic dyeings, and for stripping. Also of interest are discharge salts and bactericides.

Characteristics:

- well soluble in water,
- high adsorption tendency on surfaces,
- anti-microbial action,
- high derivation ability for electrostatic charges.

For this reason, quaternary ammonium compounds are used as:

substance	symbol	R code	S code	water endangerment category	special characteristics	remarks

10–100 mg/l	moderately toxic
100–1000 mg/l	slightly toxic
1000 mg/l	barely toxic

Tab. 2: Determination of the water endangerment category of quaternary ammonium compounds, alkylamine-EO.

- soft handle agents,
- retarders in polyacrylonitrile dyeing,
- discharge agent additive in vat dyeing,
- colourfastness improvers,
- anti-static agents,
- bactericides, fungicides, algicides,
- flocculants in waste water treatment.

Certain amines (see Fig.) are toxic, however, and are therefore to some extent classified in lower water endangerment classes (Tab. 1).

The particular toxicity in relation to aquatic life forms (Tab. 2) is based on a blocking of gill breathing through interface activity in combination with a marked tendency towards adsorption. In relation to mammals, some species develop a subcutaneous toxicity similar to that of the arrow poison curare used by South American Indians (Tab. 3). Once they have entered the bloodstream, a competitive effect occurs at the polysynaptic acetylcholine receptors, which leads to neuromuscular blocks e.g. of the respiratory musculature, and thus to death with full consciousness. Examples of this are the recently developed silicon polyquats, which with increasing quat modification to improve softness, bath exhaustion rates, water solubility, electrolyte stability etc. suddenly become highly toxic when certain neuronal distances are fulfilled, in the manner of the lock-and-key principle.

beef-tallow:	no value found
stearin acid:	10000 mg/kg
stearyl alcohol:	2000 mg/kg
stearylamine:	2000 mg/kg
oleylamine:	200 – 2000 mg/kg

Tab. 3: Oral toxicities.

If one follows the evaluation diagram for substance classification into water endangerment classes in accordance with section 19 of the German water resources law (KBwS), quaternary ammonium compounds should be assigned to classes 2 and 3. If the legislator acts in accordance with the principles of consistent environmental protection, as has already happened with non-ionic and anionic surfactants, then a global classification of all quaternary ammonium compounds under class 3, may be expected although on the basis of the evaluation diagram only individual representatives would be placed here. In accordance with the catalogue of requirements for “storage”, this circumstance may result in considerable investment costs, associated with a prohibitive explosion in costs.

Quaternization of monochlorotriazine reactive dyes Normally, monochlorotriazine reactive (MCT) dyes react with cellulose only under alkaline conditions. However, if one adds tertiary amines to a neutral printing paste, the reaction can proceed during steaming even below pH 7 (Fig. 1).

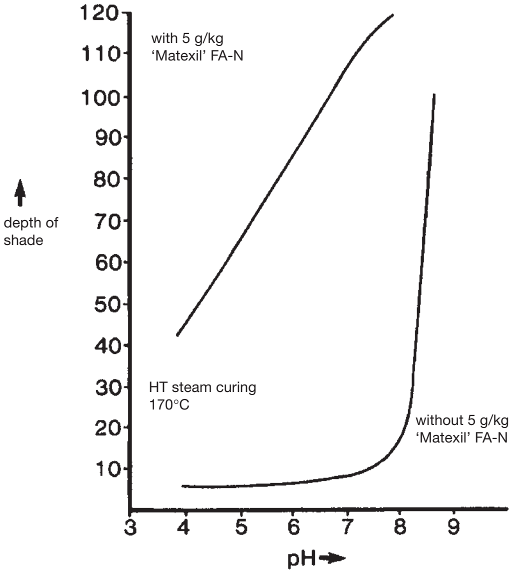

Fig. 1: Dye yield in relation to pH for the reactive dye component of Procilene-Red-N-4G-mixed dye (ICI) in liquid form on mercerized cotton (Matextil FA-N is a class 3 quaternary catalyst).

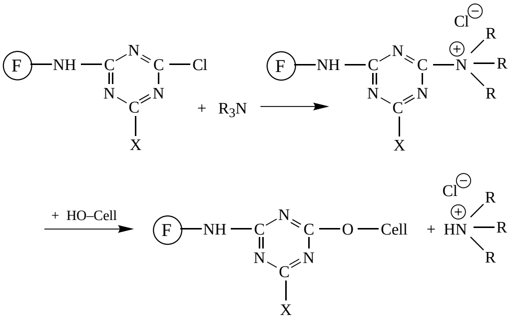
Here, one can establish a basic reaction in the four classes of differently active amines (Fig. 2).



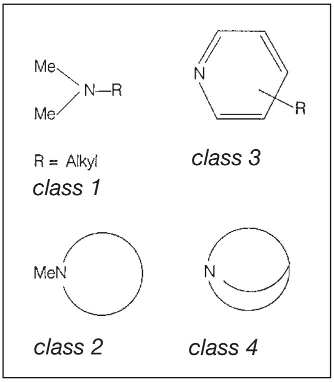


Fig. 2: Classification of typical quaternary compounds. Class 1: e.g. simple aliphatic amine; Class 2: e.g. N-methylpyrrolidin; Class 3: e.g. alkylpyridin; Class 4: bridged structures such as that of 1,4-diazabicyclo-(2,2,2)-octane (DABCO).

Quats → Quaternary ammonium compounds.

Quick-action drain valve enables a plant to be drained even at temperatures of 135°C, without the contents of the apparatus having to be cooled to at least 80 °C, as is usually the case. Drainage is thus accelerated. In the case of polyester, the oligomers are largely removed at the same time. Waste water can be used to cool the liquor which has been drained off, which saves on costs. The HT quick-action drain valve (Fig.) can be retrofitted onto plants of all types, and in some cases 2–3 machines can even be drained one after another by means of one device.

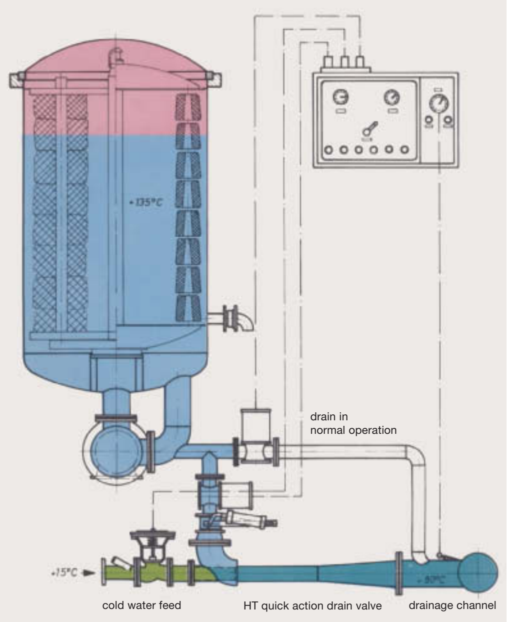

Fig.: HT quick action drain valve by Jasper.

Quick-action stop valve Actuating drive with high regulating speed. Used for example on otherwise hand-operated valves, in order to effect fast closure of the valves.

Quick copper detection in effluent or water 50 ml of the water to be tested is added to 2 ml of a light coloured oleic acid. After the mixture has been thoroughly shaken, the creaming oil layer reveals a weak to strong green discoloration in the presence of copper (copper oleate). The presence of more than 1.2 mg/l of iron upsets this colour reaction of course.

Quick dyeing Rapid dyeing process for synthetic fibre material. The reduction in time is enabled by rapid heating of the dyeing liquor and by a rapid cooling phase. It is predominantly polyamide fibres which are dyed by this method.

Quick lime (calcium oxide). White to grey in colour, formed through heating and roasting of calcium carbonate (chalk, limestone, marble) $CaCO_3$. Very fire-resistant, melts only at 3000°C. Used for furnace lining, etc.

Quick response (QR). Sales-oriented flexibility of textile production works, aimed at responding quickly to the market. In contrast to "just in time" solutions, QR does not aim at minimising warehouse stocks, but attempts to keep the production aligned as optimally as possible to the customer's requirements, in both technical terms and by integration into holistic business management procedures. In practice, this results from the acknowledged necessity of flexible production, which derives from a profile of requirements:

– more variants,
– higher quality,
– more economical offers,
– rapid delivery;

in other words, requirements which, according to classical business management wisdom, make the manufacture of large batches almost impossible.

Key points of the quick response strategy in the textile and clothing sector are new forms of inter-company co-operation in a vertical direction (possibly also horizontally), in order to be able to serve the markets faster and in a more targeted manner. The aim is thus a concretisation of strategic alliances, taking account of the "textile pipeline". It is to be expected that further reserves of synergy can be opened up through vertical and interdisciplinary co-operation.

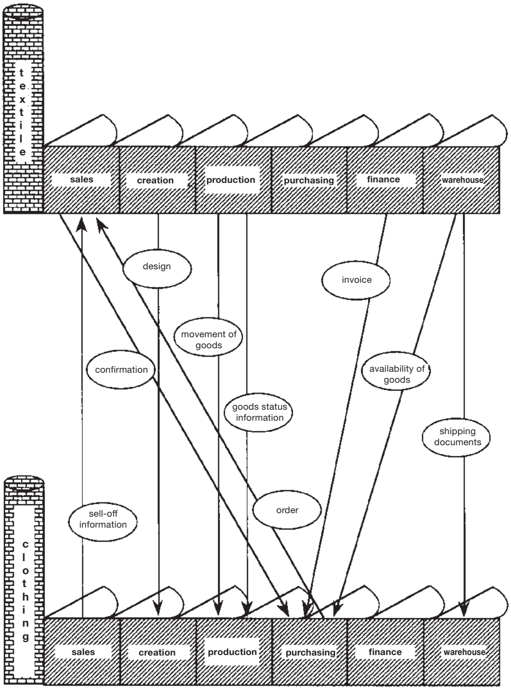

Fig.: Only the complex networking of the textile and clothing industry by means of EDP makes "quick response" possible.

Quick response is to be regarded as a marketing strategy which combines technical and economic areas with one another via a thorough information system. However, this information connection must also be seen as extending across production stages and across companies (see Fig.). This requirement includes dealing with two problem areas: a) On the one hand, the problems of technical data exchange between firms (data formats, synchronisation etc.) must be solved. An initial standardisation is emerging in the form of the EDI format (Electronic Data Interchange), for which initial sector-specific adjustments are in progress. The data format EDIFACT (Electronic Data Interchange For Administration, Commerce and Transport), developed for the textile industry, is relatively unknown at present, and has only limited circulation. It is expected that EDIFACT will become the standard in the future. b) On the other hand, it must be acknowledged that the free exchange of data can also bring with it business management problems. The possibility of being able to have free access to suppliers' data demands responsible handling of this information by all those involved. Without an understanding of the co-operation as a "risk partnership", this concept barely stands any chance of realisation, since smaller enterprises will hardly take the risk of "master-slave co-operations". Whether this risk can be applied to smaller firms without a market-controlling position remains controversial for the time being. Current observations suggest that QR initiatives are particularly to be found in larger enterprises with important market positions (e.g. Benetton, Schiesser, Bogner).

In-house logistics optimisation is an important prerequisite for the functioning of QR. There are initiatives for computer-aided warehouse administration as well as chaotic warehouses; the use of barcodes is aimed at. In the area of production planning and control, there are at present no standard solutions available on the market. Individual company solutions require a high expenditure on implementation. An essential part of a production planning and control system is the order processing, order tracking and the organisation of queues, on the basis of disposition which takes account of need. Simulation is available as an instrument for this; the first simulation solutions can already run on PCs. The aim is "knowledge-based production planning", which cannot be realised without the use of databases. Also, production planning can only develop its full effect if it is realised in connection with quality planning.

Quillaya bark → Panama soap.

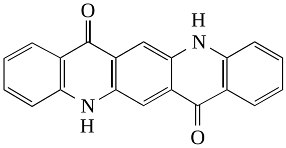
Quilt fabric → Piqué.

Quilt in, to Transfer of the printing dye paste from the chassis to the → Blocks for printing (hand printing).

Quilt lining Lining material from quilted non-woven fleece (padding), wadding or foam material on lining material, duchesse, serge, etc.

Quilt wadding Goods of the → Maliwatt fabrics; for wadding, lining purposes, layer base for tensioning purposes, insulating material, etc.; 200–425 g/m.

Quinacridone Sub-group of the → Carbonyl dyes, as a dicarbonyl compound:



Since 1957, they have played a large role as pigment dyes, in various crystal modifications. The excellent solvent fastness as a consequence of their low solubility is, in turn, attributable to the strong dipoles of the acridone rings and the intermolecular hydrogen bonds between the associated, planar molecules.

R

R (formula residue), used in chemical formulas as abbreviation for "residue" e.g. residual fatty acid with a simple or branched (hydrocarbon) chain.

ºR Degrees → Rankine.

RA → Ramie → Textile fibre symbols, according to DIN 60 001 T4/08.91.

Ra,

I. → Ramie, → Textile fibre symbols, according to DIN 60 001 until 1988; → RA.

II. Element symbol for radium (88).

Rabbit hair →: Hare and rabbit fibres; Angora.

Racemates (racemic compounds). Lat. acidum racemicum (grape acid), where this phenomenon was first investigated. They occur in chemical reactions in which optically active compounds are involved, by releasing and re-linking bonds. So-called racemates or racemic mixtures are produced from sterically unique compounds (dextrorotatory or laevo-rotary) as mixtures of both types. → Optical Activity.

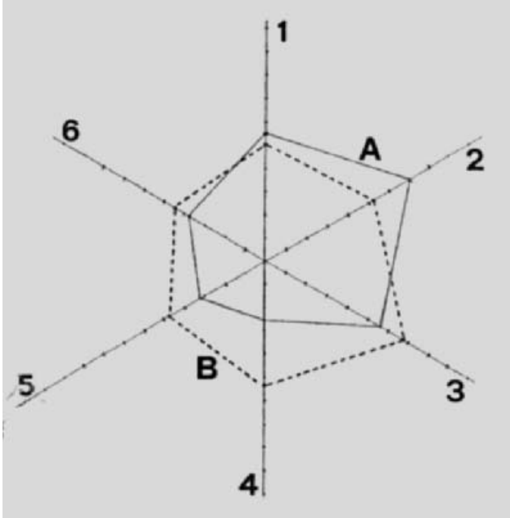


Fig. 1: Rader diagram showing the assessment of handle (as by Kawabata) of a material made from super-microfibres, both in the raw state (A) and following treatment with alkali. 1 = stiffness (koshi); 2 = poor fall (hari); 3 = body and softness (fukurami); springy elasticity (shari); 5 = silkiness (kishimi).

Rader diagrams Used for depicting handle, determined on 6 axes using the → Kawabata system, for example. Fig. 1 shows a Rader diagram comparing the handle of a rough and of a finished fabric. Although there is a reduction in the stiffness value (hari/koshi), there is an increase in flexibility, handle (shinayakasa), volume and softness (fukurami) and elasticity (shari).

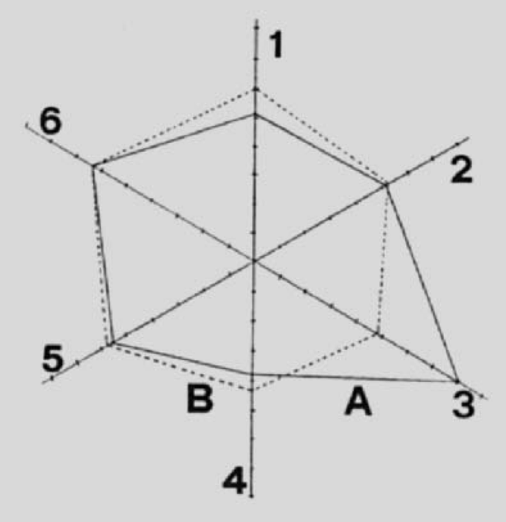

Fig. 2: Rader diagram of a super-microfibre fabric (A) and a silk fabric (B).
1–5 see Fig. 1; 6 = elasticity (shinayasaka).

Fig. 2 shows a Rader diagram comparing the handle of a super-microfibre fabric to that of a silk fabric. It is assumed that the elasticity of the super-microfibre fabric is less than that of the silk fabric; however, the fullness and softness are much better, whereas both the stiffness and flexibility with a soft handle are almost the same.

Radial Radiating from the centre (of a circle) to the periphery; e.g. the horizontal radial section of the → Flax stem structure.

Radial dyeing machine Packing system dyeing machine with circulating liquor. Either (older version) as round dyeing machine made from cast iron for dyeing hank yarn or made from stainless, acid-resistant steel with liquor recirculation (see Fig.). Usually heated indirectly by steam. The material block is lifted after dyeing on the material carrying plate and is spun in a conventional centrifuge, the upper rim of which can be removed. This kind of special centrifuge is no longer in use, since a normal centrifuge can be used after a batch has been dyed in the radial dyeing machine. This includes other batches such as piece goods, hanks, bobbins. Radial dyeing machines are also used for dyeing wool, cotton, viscose, polyamide, acetate, polyacryl nitrile, hair and rags.

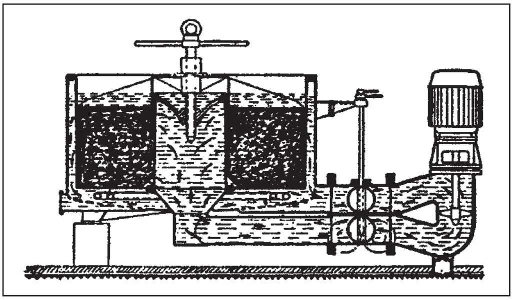

Fig.: A radial dyeing machine (Krantz) for loose fibres.

Radiant energy, quantity of heat In the → SI System of Units the radiant energy watt (W) or joules per second (J/s) and multiples; as a unit of quantity of heat the watt second (Ws) or joule (J) and multiples (i.e. also kilowatt seconds).
W = 1 J/s = 0.86 kcal/h
1 Ws = 1 J = 0.239 cal = $0.239 \cdot 10^{-3}$ kcal
1 kWh = 3.6 MJ = 860 kcal

Radiant intensity per unit area → Brilliancy.

Radiant-Panel-Test (heat radiation shield) combustion reaction at an elevated temperature is measured by subjecting a horizontal sample to heat and burning it. The minimum heat flux at which the carpet starts to burn is assessed.

Radiation One differentiates between wave radiation (e.g. electromagnetic radiation) and particle radiation (e.g. radioactive radiation); →: Light wavelengths; Radiation, comparison of different types. For textile applications, e.g. in drying or measuring and control technology, different types of radiation are utilized, e.g. →: Infrared; Microwaves; Radioactive emission; Ultraviolet radiation.

Radiation, comparison of different types Energy rich or ionizing → Radiation (see Tab.) from a few kiloelectron volts keV to a few megaelectron volts MeV is of interest for radiation chemical applications (electronvolt definition: 1 eV is the energy which an electron possesses, if the potential energy of 1 Volt passes through it).

radiation type character	type of radiation	energy	wavelength
electo-magnetic radiation	infra-red	0.01-1.6 eV	780-1000 nm
	visible light	1.6-3.3 eV	380-780 nm
	ultra-violet	3.3-6.2 eV	200-380 nm
	vacuum ultra-violet	6.2-310 eV	4-200 nm
	X-radiation	keV-MeV	< 100 nm
	γ radiation	keV-MeV	< 100 nm
corpuscular radiation	α radiation	1-10 MeV	—
	β radiation (electron radiation)	keV-3 Mev	—
	accelerated electrons	0.25;15 Mev	—
	neutrons (^{1}n)	1 to a few MeV	—

Tab.: Comparison of radiation types.

Radiation heat losses from dye liquors and dyeing machines Radiation and evaporation at open liquor surfaces:

equation for the calculation of heat loss:

$$Q_2\ [\text{Joule}] = q_2 \frac{[\text{Joule}]}{[\text{m}^2] \cdot [\text{h}]} \cdot F_2\ [\text{m}^2] \cdot T_H\ [\text{h}]$$

Q_2 = radiation and evaporation losses [joules],
F_2 = radiating open liquor surface [m^2],
T_H = temperature retention time [h] (in this equation minutes are also used instead of hours and divided by 60),
q_2 = temperature dependent radiation coefficient for open liquor surfaces [joules/m^2/h].

The following temperature dependent values apply for the radiation coefficient q_2 [kJ/m^{2}h]:

20°C	440
30°C	2055
40°C	4735
50°C	8590
60°C	13 575
70°C	21 200
80°C	31 720
90°C	43 030

These figures are valid for air temperatures above the liquor surface of 25°C and air speeds < 1 m/s.

Some findings from this: at air temperatures higher than 25°C, which almost always prevail in the layers of air above the liquor surface, e.g. in preparation and overflow vessels, due to heat radiation, the air humidity absorption power is correspondingly higher, which equates to higher evaporation losses. The same also applies if a stronger air flow carries away the moisture saturated air in the overflow vessel. These influence variables have been disregarded here. However, comparing the radiation values of q_1 with q_2 for uninsulated vessel surfaces, then one finds that open liquor surfaces that are not absolutely necessary must be eliminated for reasons of energy economy.

Radiation at uninsulated autoclaves:
equation for the calculation of heat loss:

$$Q_1\,[\text{Joule}] = q_1\,\frac{[\text{Joule}]}{[m^2]\cdot[h]}\cdot F_1\,[m^2]\cdot T_H\,[h]$$

Q_1 = radiation losses [joules],
F_1 = radiating surface of the equipment [m^2]
T_H = temperature retention time [h],
q_1 = temperature dependent radiation coefficient for uninsulated equipment surfaces [joules/m^2h].

The following temperature dependent values apply for q_1, the radiation coefficient of uninsulated equipment surfaces [kJ/m^2 h]:

30°C	80
40°C	755
50°C	1215
60°C	1680
70°C	2265
80°C	2850
90°C	3480
100°C	4110
110°C	4775
120°C	5450
130°C	6285

These figures only apply with static environmental air. If the temperature varies over time, e.g. heating up, cooling down, then the temperature dependent radiation coefficient q_1 also changes. In this case, the heat loss is calculated based upon average temperature for heating up (from 40°C to 130°C, thus by 90°C), working with the corresponding q_1 value. Alternatively, the heating up curve may be divided into several vertical temperature increments and a corresponding number of horizontal retention times, whereby it is possible to detect the heat loss during the heating up phase in as many individual calculation operations as desired (iteration). The smaller the "step height" of the "temperature stairway", the more calculation operations have to be performed. The number of calculation operations determines the precision of the result.

Radiation intensity of a light source corresponds to its power. It is significant for the illumination times in copying processes (contact printing process) for pattern transfer on rotary screen printing screens, however it does not influence the copying definition. Because the radiation intensity should be distributed as uniformly as possible during the illumination of a round screen cylinder, which is most true for parallelized light that falls at a radiation angle of 90°, screens are used to aid uniform distribution (e.g. honeycomb screens).

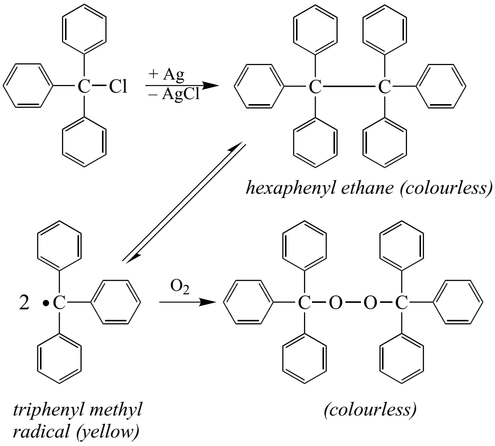
Radiation meters Electrical devices for the direct detection of radiation, e.g. radioactive emission, ultraviolet radiation, X-rays, etc. Usually so-called counter tubes, in which the locally scanned radiation impulse (due to the ionization of the contents of the counter tube, a discharge impulse occurs, which triggers a voltage impulse at a working resistance) is measured via an amplifier by the deflection of the pointer of a normal current measurement instrument, or by means of a counter if there are low particle numbers. One common radiation sensor is the so-called Geiger-Müller counter, with which the intensity distribution along a length of material, length of thread, etc. can be measured.

Radiation pyrometer Instrument for non-contact measurement of temperature of bodies, e.g. of textiles during heat treatment.

Radiation singeing Indirect → Singeing, without contact between material and flames. The effect is achieved by re-radiation from bricks heated to high temperatures.

Radicals (Lat: radix = root) groups of atoms with free valency that cannot exist under normal conditions (unbound electrons). For example, if triphenyl methyl chloride is treated with finely-distributed silver in benzene in a vacuum, a yellowy solution is produced. If this solution is treated in air, the yellow colour disappears.

Radicals contain unpaired, free electrons that cannot be localised in the molecular structure because more than one valency structure (and therefore mesometric stabilisation) guarantees the existence of the radical. The free valency (the unpaired electron) is stabilised by the exchanging of many atoms (resonance) in the molecule.



Radioactive density determination

The greater the number of possible mesomer forming limits, the greater the delocalisation of the free electron, thus reducing the total energy level of the radical and making it more stable (long-lasting). In the triphenyl methyl radical the unpaired, free electron can occur in ten different positions, namely in methyl carbon and in all other o and p positions in the three phenyl nucleii. The resulting resonant energy of the radical is about half as great as the binding energy of the C–C bond in hexyaphenyl ethane. The stability of the two triphenyl methyl radicals is so great that the equalisation reaction is displaced to the side of the dissociated substance. The colour of the triphenyl methyl radical results from the mesomer structures' capability of absorbing light energy.

In magnetic measurements radicals proved to be paramagnetic, because the spin of the lone electron is not compensated for. Organic compounds are normally diamagnetic.

Radioactive density determination If emissions from radioactive isotopes penetrate material, its intensity is weakened in accordance with the mass of the irradiated layer (Fig. 1). The surface weight, thickness or density of the measured material can therefore be determined from the change in energy received from a radiation source of known intensity. The measurement is continuous and non destructive and has no effect on the properties of the tested material. The accuracy of surface weight measurement using isotope radiation and the measurement resolution are so good that changes of < 1 g can be determined in a material with a weight of 150 g/m^2, for example.

The radiation source is in a stable, radiation-proof housing whose efflux window is only opened when the device is switched on. If the power fails or is turned off, a steel disk covers the window automatically in order to protect the operators. Surface weight measuring systems also comply with the relevant radiation safety regulations. Special models can be provided (Fig. 2) for various measuring tasks such as monitoring and controlling the surface weight per square metre of effective material, measuring the thickness of coatings and other application techniques.

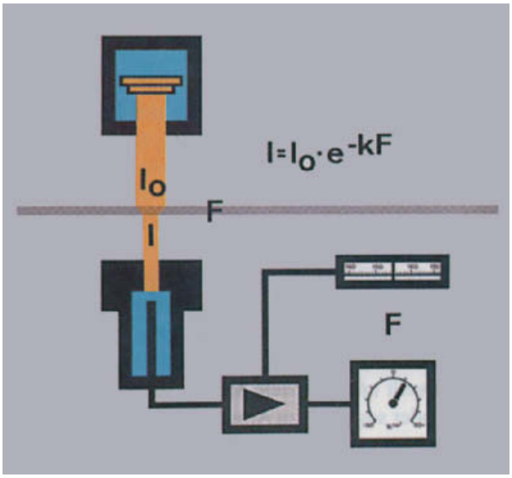


Fig. 1: The principle of determining the density of planar structures with the aid of radioactive emissions (Mahlo).

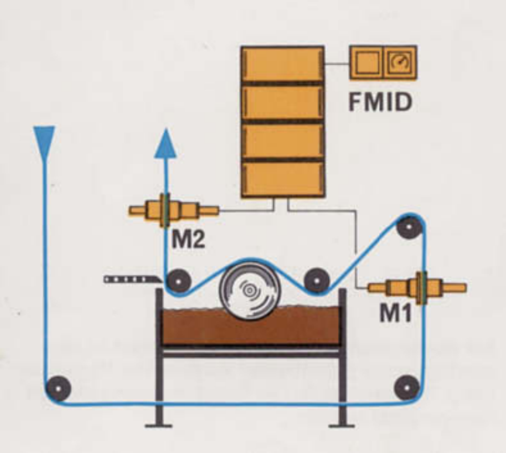

Fig. 2: Control (FMID) of product coating using a kiss roller by means of radioactive density determination (Mahlo) before (M1) and after (M2) coating.

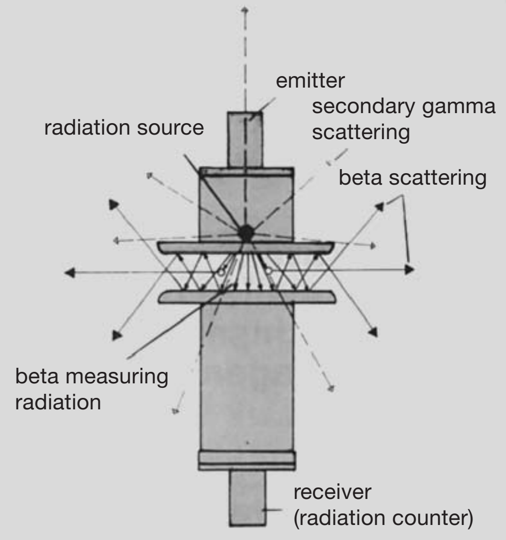

Fig. 3: The pattern of emissions from a Gravimat (Mahlo) for radioactive density determination when the radiation emission window is open.

During normal operation (device switched on, radiation efflux window open) most of the radiation originates from the transmitter, passes through the material into the receiver and is absorbed by both. Only a small proportion of the β-radiation crosses the measuring gap after several reflections. This rogue radiation only travels a short distance before it is absorbed by the air (Fig. 3). The effective quantity (dosage) of radiation around the measuring device with the radiation efflux window open and closed can be read off from so-called iso-dosage diagrams (Fig. 4). The curves in the diagram are calculated by combining values for the same dosage. The control range limit is also entered.

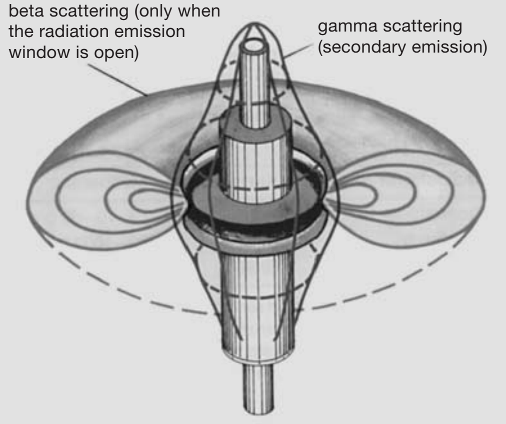

Fig. 4: The distribution of radiation emission surrounding the measuring device (Gravimat by Mahlo).

Since radiation is only emitted at the level of the material, hands and lower arms may be exposed to radiation during normal use at the stenter outlets (Fig. 5), on coating and laminating machines (e.g. when pulling in the material). The limits for partial exposure therefore apply when defining the monitoring area.

The currently applicable radiation safety legislation specifies radiation dosage limits for various groups of people, adherence to which ensures, with a high degree of probability, that radiation damage will not occur. In the eyes of the law, operators of machines and systems that are equipped with radiometric monitoring devices are not considered to be exposed to radiation at work, even if they occasionally come into contact with radiation. This group of people may only be subjected to a maximum dosage of 0.5 rem per annum if the entire body is exposed, and 6 rem per annum if only the hands, lower arms, feet and lower legs are affected. Starting from these limits, the radiation safety legislation defines a so-called monitoring area around a radioactive source. A dosage that is higher than the permitted body dosage may be received in this area; for this reason people are only allowed to be present in this area for a limited period. The maximum period is calculated from the radiation dosage at the location (local dosage) and the permitted limit. There are no access time restrictions outside the area.

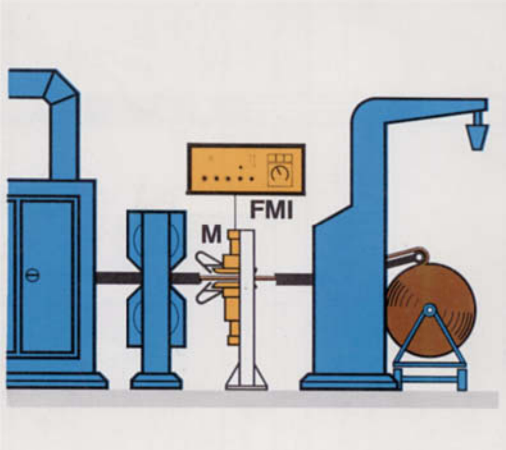

Fig. 5: Installation showing a Mahlo radioactivity based density determination device at the exit from a drier.

As with anything else to do with radioactivity, radioactive density determination is subject to strict monitoring by the relevant supervisory body, which only issues short-term usage authorisations that have to be renewed at certain intervals.

Radioactive emission Energy emitted by so-called nuclear reactions from naturally radioactive elements (radium) or artificially produced radioactive → Isotopes of different elements. Consists of the following three types of radiation (neutrons, protons, etc. also occur in artificial radioactivity):

I. Alpha radiation (α radiation) emitted at considerable speed (initially approx. 17 000 km/s) by positively charged helium nuclei; considerable amount of ionisation, therefore only short range (approx. 3–8 cm), energy approx. 5 million eV.

II. Beta rays (β rays) are negatively charged electrons; they are extremely fast (initial speed 100 000 km/s. to almost the speed of light), penetrate much thicker layers than alpha beams (medium range), energy approx. 1 (– 3) million eV.

III. Gamma rays (γ rays) are extremely energy-rich light quantums (photons) with extremely short wavelengths (10^{-12} m), identical to x-rays from an x-ray tube operated at high voltage; they have little ionising effect (approx. 100 times less than beta rays, therefore long range and intensive penetration capability (including metal, water, etc.); much stronger than alpha and beta rays, gamma rays have an essentially destructive effect on fibres.

Radioactive isotopes Isotopes that are used industrially for measuring textile coating thicknesses or other volumes and for measuring residual moisture. The density of the surface structure is always measured. → Radioactive density determination.

Radioactively-contaminated clothing, cleaning of According to a Japanese study on clothing contaminated with $^{60}CoC_{12}$, polyphosphates, minerals from inorganic polyacids and surface-active substances were investigated as possible “decontamination agents”. It was proven that chelate formers with higher stability constants are the best decontaminating agents. The decontaminating effect of the chelate formers depends on the pH of the solution.

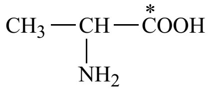
Radioactive tracers →: Isotope; Radioactive tracing.

Radioactive tracing One of the goals of biochemical research is to explain the reaction mechanisms of the chemical process that occur in human, animal or organisms. Basically, everything that is absorbed by or built up in the organism is broken down after a time and excreted. Metabolism takes place between absorption and excretion. Among other things, the organism’s dynamic state is characterised by the fact that no molecule stays in the same environment for a long period of time and many types of molecule are broken down into groups of atoms or even individual atoms and used by the organism to form other molecules. In order to trace the progress of the metabolic processes (e.g. sewage treatment) the use of radioactive molecules is usually unavoidable. Since the biochemical properties of the substance are not altered in any way by suitable marking, the molecules entering the organism can be differentiated from identical molecules that are already in the organism. Because of the radiation that they contain, marked substances can be identified at any time in any location without interfering with the progress of the metabolic process that is being investigated.

Using the tracer method it is possible to trace the route of a molecule type through the organism and determine any changes to which it may have been subjected. Kinetic investigations of the reactions in which the molecule is involved can also take place. As well as these possible applications, radioactive isotopes can also be used as indicators in various biochemical analysis methods in order to improve the accuracy thereof.

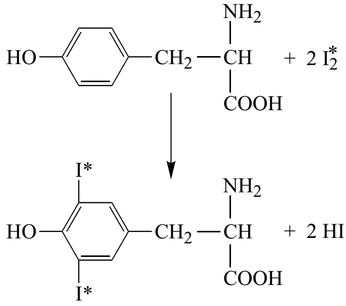
A distinction can be made between four basic marking methods using radionuclides:

1. Uniform marking (these kinds of marked compounds are identified with “U” in the literature). C-14 activity, for example, is statistically evenly distributed to all C atoms.
2. General marking (identified with “G”). This means that when using tritium marking, for example, all identical atoms are marked but the activity is not necessarily evenly statistically distributed.
3. Specific marking (marked by specifying the position, e.g. Alanine-1-C-14). In this case not all identical atoms in a compound are marked, e.g.



$$CH_3-\underset{\displaystyle NH_2}{CH}-\overset{*}{C}OOH$$

4. External marking. A radionuclide that is external to the molecule has been introduced, e.g.



These types of markings or combinations thereof can also be found in double marking. Double marking means that isotopes of different elements have been introduced in the same molecule, e.g.

2–^{14}C–5-di–^{3}H mevalonic acid or

$H_2{}^{15}N–{}^{14}CH_2–COOH$.

Radio-frequency drying → High-frequency drying.

Radiometric control systems Testing procedure using isotopes such as → Radioactive density determination.

Radiometric emission dust monitoring Portable device for the continuous measurement and registration of mass concentration of dust in exhaust gases, e.g. from chimneys. The surface weight increase of a filter through which air or exhaust gas is flowing is determined by absorbing β rays. The following can be measured: dust quantity in kg, dust flow in kg/h, dust concentration in mg/Nm^3.

Raffia bast (raffia fibres), leaf bast (fibres) from the rapia palm (South Africa, Madagascar, South America). Flat, brown/yellow bast strands (for gardener bast and as braided bast for arts and crafts), easily divided lengthways to form solid fibre elements (for string and coarse yarns).

RAG RUG → Allgaeu carpet.

Rags Term for the remains of worn, more or less worn-out items of clothing from households. Usually end up in approx. 200 kg balls for further processing, which consist of grades (Class I = Shoddy, II = Tibet wool, III = Mungo, IV = Alpaca or Extract) and is used for manufacture of → Reclaimed wool, also → Reclaimed cotton.

Rain-Grown-Cotton Cotton cultivated under natural climatic conditions (→ Irrigated cotton).

Rain resistance → Water spotting fastness.

Raised finish (brushed finish, napped finish) → Brushed fabric.

Raised resist print Printing of pigment white and/or pigment dyes. Subsequent drying is followed by friction texturizing, condensing and raising. Produces a raised pile in non-printed areas, whereas printed areas are not raised.

Raising This finishing work is used to create a different feel and a velvety material surface on fabrics and knitwear by loosening a large number of individual fibres from the fabric and subsequent raising (velour raising) and napping (nap raising) in order to create a dense raised surface. This also produces more fullness and softer handle. A distinction is made between card roller raising (see Fig.) and table raising. Table raising machines are used to open knitwear, whereas card roller machines are used for raising threads (flat fabric or knitted fabric) or for raising felt (for milled woollen fabric) (→ Raising machines).

Depending on the kind of material, raising is carried out on right and/or reverse side of woollen materials, before milling in order to produce an extremely dense hair cover (for foulé), after milling for raising, the milling felt and also raising the face weft (for floconné) in cheap semi-woollen materials also without milling, before and/or after de-tanning (Melton character) in cotton materials, in order to give a woollen appearance and handle.

Raising is carried out on the raising machine, using either natural teasels or metal cards. Natural teasels are the heads of the teasel thistle (→ Raising machines). They have small hooks that are flexible and resistant and are suitable for achieving fine raising effects. The teasels are either placed in rods in rows (rod teasel raising machine) or put on small, rotating spindles (roller teasel raising machine) and arranged in an appropriate position on the raising cylinder, over which the material runs until the desired result has been achieved. Rod teasels produce a combed raising surface in the nap, and roller teasels produce more of an uncombed upright raising surface. In the first case the material is raised when damp and in the latter case is carried out when dry (for blankets, flannels, paletot materials). Coarse raising effects are achieved using metal cards. Cards are small wire hooks that are pulled over small rollers as a covering (→ Raising elements). Approximately 12–36 rapidly rotating card rollers are distributed around the large raising cylinder. The roller (card) raising machine has alternating nap and counter-nap rollers, i.e. with teeth that move with and against the direction of movement of the cylinder and the material. In universal card raising machines the cylinder moves in the direction of movement of the material and the card rollers run in the opposite direction, whereby counter-nap rollers also run between the latter. Raising machines have fine material tension, material web, raising roller speed, nap and counter-nap torque conversion (felting raising) control. The procedure can be simplified by arranging several successive machines, possibly with shearing machines at the end (raising shearing line). Raising machines allow the desired raising effect to be accurately set. Patterned high/low effects can be achieved by means of a combination of printing and raising. The low-lying areas are protected from the effect of the raising rollers by printing on a resisting agent and can also be dyed. A coloured or colourless artificial resin pre-condensate can be printed onto the raised material, calendered, condensed and then the nap brushed up again. The printed areas are now visible and embedded into the material.

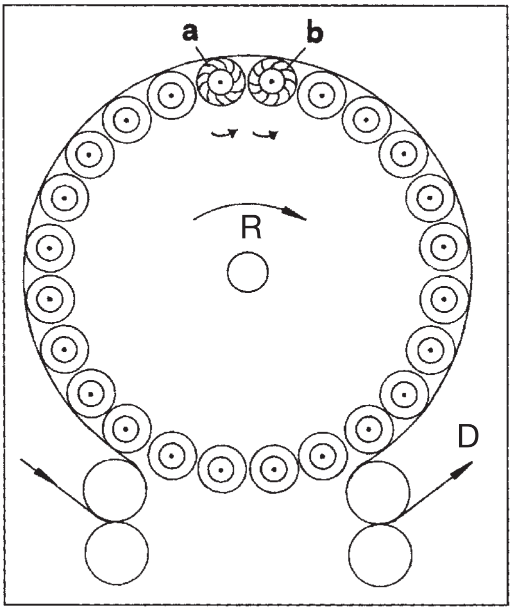


Fig.: The method of working of a raising machine fitted with carding rollers.
R = reel drum; D = direction of goods; a = counterpile roller; b = pile roller.

Raising apparatus Small → Roller card raising machine before the rod teasel machine (wet brushing machine) central cylinder for pile lifting.

Raising effect Correct material tension is a decisive factor for a good raising result. If the tension is too high, the raising card cannot easily grip the weft thread, and if it is too loose the material may become tangled or even wrap around the raising rollers. The material must therefore always run at the best possible tension for the item that is being manufactured. On a PLC-controlled raising machine the material tension is automatically kept constant depending on the torque.

In a normal case, approximately equal amounts of nap and counter-nap energy are used on the nap/counter-nap raising machine. More nap energy is used to achieve certain material effects such as napped velour and less energy for a short, covered material surface. For nap velour, blankets and articles with voluminous raising, the raising machine is fitted with an additional lifting device above the cylinder. This equipment splits the cylinder into two zones; the raising capacity is increased and more volume is produced on the surface of the material. In this case too, the material tension is automatically kept constant depending on the torque.

If the raised surface of the material that has been raised using nap/counter-nap is to be made even denser, a semi-felting process is frequently carried out using a nap/counter-nap raising machine. In this case the nap energy is under zero and low-grip counter-napping is carried out. If the surface of a material has to be extremely compact, the full felting raising procedure is used. In this case the cylinder rotates against the direction of movement of the material, and all the raising rollers operate in the nap direction. It is important that the elements are symmetrical, i.e. both banks of rollers are at the same angle.

Different raising elements are used for certain materials. As well as the shape of the wire (round, oval, sectoral or biconvex wire) the embedding and straightness of the wires, the number of naps, the row and the density of the braiding must be taken into consideration for further characterisation. The wire shape and straightness are important criteria for raising card wires, and the grinding of the tip of the card wire is also extremely important. During the processing of woven materials, equalised, side-ground and polished raising elements that have been ground outside the tambour raising machine must be used. In knitwear where raising and velouring take place using a raising card wire tip, the raising card wire tips (controlled by a preselected PLC program) are ground in the raising machine.

An important parameter during raising is also raising energy. This generally refers to the set nap and counter-nap roller speeds. Because of the complicated kinematics of a wire raising machine, these speeds cannot be directly measured. Most machines have dimensionless scales for setting the raising energy, which make it possible to reproduce the settings that have already been used.

Raising energy is the rotation energy E_{rot} of a raising roller:

$$E_{rot} = {}^{1}/_{2} \cdot l \cdot w^2$$

l = moment of inertia of the roller,
w = angular velocity of roller.

If w is expressed as the rotating speed, the following applies to E_{rot}

$$E_{rot} = 2\,\pi^2 \cdot l \cdot n^2$$

For a certain roller, E_{rot} is proportional to the square of its rotating speed.

$$E_{rot} = \text{const.} \cdot n^2$$

No raising energy is transferred at the “zero point” of the respective machine, since the hooks embedded in the covering roll off the material without carrying out any raising work. The energy figure EZ is used as a measure of the raising work carried out on the material by the covering:

$$EZ = \frac{n^2 - n_0^2}{1000}$$

n = roller speed at any setting (rpm),
n_0 = zero point speed (rpm).

The energy figures are > 0 for counter-nap rollers and < 0 for nap rollers. The speeds of the individual sets of raising rollers can only be measured using expensive measuring equipment. In most cases, the sets of rollers are driven using toothed wheel transmission and a slip-free belt drive. Since the energy figure that is only significant for the examined machine for a defined roller drive transmission, the speed of an easily accessible toothed wheel outside the tambour can also be used. Additional speed sensors with an appropriate display must be installed for the nap and counter-nap rollers at this measuring point. Another benefit of these measuring points is that they can also be used for monitoring and adjusting the zero point of the machine (according to Hübner and Kux).

Raising effect dependence on grey fabric The physical characteristics of the fibre are extremely important during raising, since the stress on the fibres to be pulled out is mainly mechanical. The fibre resists being released from the composite yarn to a certain extent. This means that the fibre must not be broken but merely pulled out at one end. The other end must be well engaged in the spun yarn. In order to achieve this the fibre must be extremely strong. The loosening of the individual components also depends on the shape and surface of the fibres. For example, the friction coefficient of wool (flaky surface structure) is greater than that of smooth synthetic fibre. Regardless of the material that is used, loss of strength in the weft direction can be expected when raising fabrics since it is essentially the weft fibre that is raised. The rigid bonding is disturbed by raising. The weft yarn that produces the raising pile must be carefully selected. The choice of weft yarn depends on staple length, fineness, twist and yarn number.

1. Staple length: in order to make weft yarn raising easier, a material that has as short a staple as possible must be used. The many fibre ends can be pulled to the surface of the fabric after relatively few raising passages, where they form a dense raised fleece. However, using short-stapled material rapidly reduces the tearing strength of the fabric in the weft direction because the fibres have not internal cohesion. An unstable pile is also created. More passages are required if long-staple material is used, but this produces better tearing strength and a balanced, stable raising surface. Raising loss is also minimised.

2. Fibre fineness: the fineness of the fibres must be tailored to the respective grey material. Coarser, long-staple fibres are the most suitable for carpet and blanket manufacture. Finer material is better for clothing, since it has to form a short, dense pile surface. The fineness and length of the fibres play an important part with regard to the density and length of the pile.

3. Yarn twisting: the harder a yarn is twisted, the further the raising wire has to engage into the bond. This characteristic can be used to positive effect if a light, short surface pile is all that is required. Attempting to obtain a voluminous surface may cause loss of fabric tearing strength and raising. The number of raising passages also increases, which is undesirable from an economic point of view. With regard to the effect of the yarn number on raising fallout, it can be said that the coarser the weft yarn, the better the grip of the small raising hooks, thus making the raising process easier. For warp yarn a finer yarn number must be selected, since the warp thread should be covered as little as possible.

4. Fabric binding: the raising effect mainly depends on the binding of the material. A correctly selected binding plays an important part in retaining fabric tearing resistance in the warp direction. Bindings with long weft floats make raising easier, but there is a risk of irregular pile formation. Cloth binding, which is frequently used in raising, is extremely suitable because its floats are not too long and the fact that the number of intersection points is adequate. Since every thread crossing counteracts the loosening of the fibres, cloth binding does not produce a tight pile. Cloth binding is therefore used in cases where short, wash-fast raising fleeces are required. Tight surfaces are achieved using weft satin. More raising density is achieved, which is given a velvet-like character by shearing. A large number of other binding types are used in raising (Köper, Atlas, etc.). The choice always depends on the article's requirement profile.

In raising a distinction is made according to the type of material to be processed (cotton, wool, synthetics) and according to the type of raising.

- raising of threads,
- raising of felt.

When raising threads a pile cover is formed by pulling out fibres from the threads or by lifting or tearing the thread, which is bound into the surface as floating or raised loops. The raising of felt, on the other hand, is only used in wool raising, i.e. the wool is given a short, dense fibre pile cover in the milling process. Wool felts during milling, because of its flaky surface structure. In this case raising does not have the task of pulling fibres out of the bonding but loosening the felted surface pile. A distinction is also made between different raising procedures:

- raising with/against the nap,
- nap raising,
- felting.

Raising effect tester Used to measure the raising effect (pile height) so that this effect can be reproduced under the same conditions.

Raising elements A distinction is made between nap and counter-nap rollers as far as raising rollers is concerned. An alternating series of these rollers lies against the raising drum. Basically, the two types of roller differ in that the card teeth are bent in different directions in relation to the direction of rotation. On the basis of the direction of movement of the material, the direction of rotation of the cylinder and the nap and counter-nap rollers, it can be seen that the bent card runs against the material in the counter-nap, whereby the nap roller merely strokes the material.

The raising cards have to grip into the fabric, and the nap and counter-nap rollers have to be separated in order to do this. The raising effect can be increased by:

- reducing the speed of the nap rollers,
- increasing the speed of the counter-nap rollers,
- reducing the tension of the material so that the material to be raised has contact with the raising rollers over a larger area (Fig. 1).

The following principles apply:

a) The lower the speed of the nap rollers, keeping the rotating speed of the raising drum constant, the longer and more powerful the effect of the counter-nap effect on the fabric.
b) The greater the speed of the counter-nap rollers, the greater the raising effect.

The raising machine can also be set up such that the nap and counter-nap rollers just roll against the material. This is called the zero effect, i.e. there is no raising effect in this setting (Figs. 2 and 3). The effect of a raising machine can therefore be varied from no raising effect in the zero setting up to an intensive nap and counter-nap roller effect until actual damage is caused to the material, whereby the fabric tearing strength in the weft

Raising elements

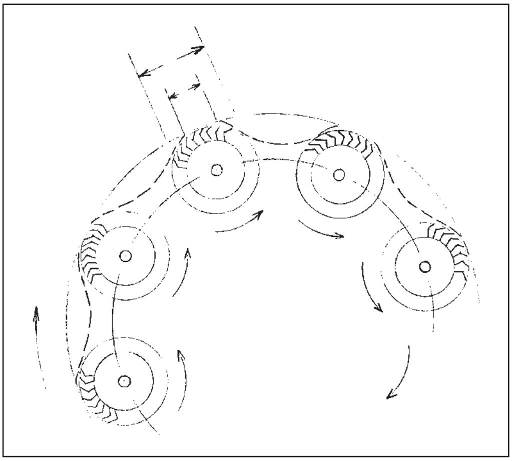

Fig. 1: Nap and counter-nap rollers and the influence of the tension of the fabric.

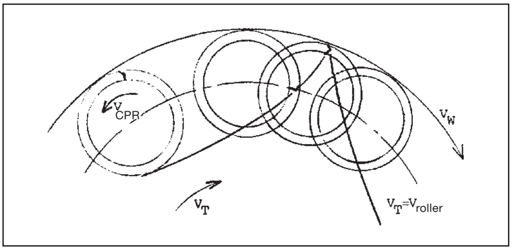

Fig. 2: Curve showing the motion of a raising roller (here a counter-nap roller) where $v_T = v_{roller}$ (zero effect).

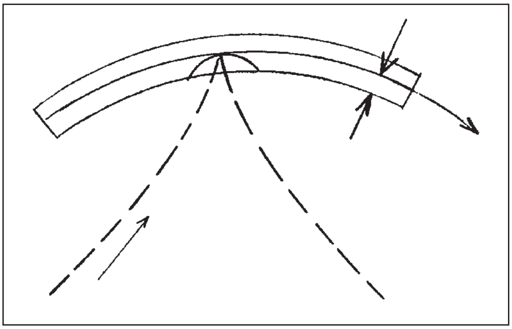

Fig. 3: Curve showing the motion of a carding hook against the fabric at the zero effect point.

direction falls below an acceptable level. Because the raising rollers and the cylinder move in opposite direction, hypo-cycloidic movement curves occur, i.e. a curve that forms at a peripheral point on a circle if this circle rolls off the inner side of another fixed circle. The shape of the curve is determined by the cylinder speed to roller speed ratio. The material speed and tension (depth of raising hook engagement in fabric) also play a part in determining the movement curve of a raising hook in the fabric. When the material speed changes, the movement of the card hooks in the fabric is no longer identical with the hypo-cycloids of the free-running raising roller. In order to guarantee that the nap rollers have a raising effect, the circumferential speed must be reduced (Fig. 4). In the operating position, the card hook approaches the material web in a slightly bent line (Fig. 5). When the card touches the material web it has time to scrape along the surface of the fabric over a short distance. It is then removed from the material web. On the counter-nap roller the roller speed is increased in order to achieve the raising effect (Fig. 6).

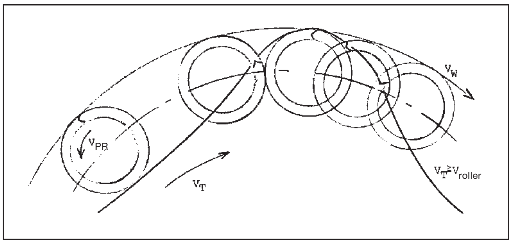

Fig. 4: Curve showing the motion of a carding bristle on the nap roller at the working position ($v_T \geq v_{roller}$).

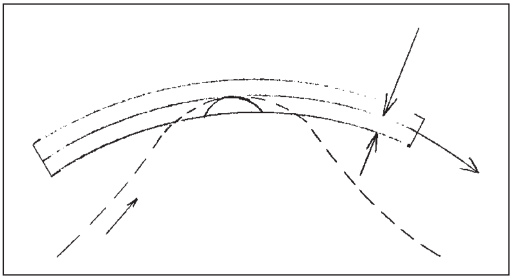

Fig. 5: Curve showing the motion of a pile roller hook against the fabric.

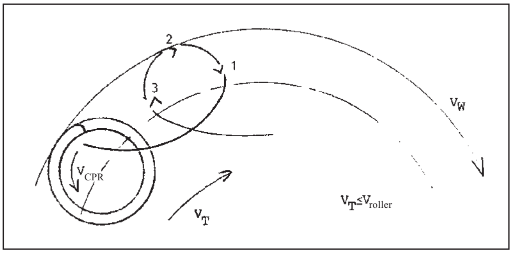

Fig. 6: Curve showing the motion of a carding bristle on the counter-nap roller at the working position ($v_T \leq v_{roller}$).

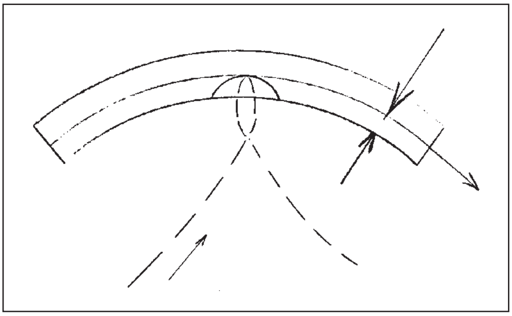

Fig. 7: Curve showing the motion of a counter-nap hook against the fabric.

The tip of the card, which is aligned against the material direction of travel and at an angle to the cylinder movement, runs along a loop-like route when it approaches the fabric (Fig. 7). After a brief, rounded engagement into the surface of the fabric, the card tip is removed from the material extremely rapidly. The greater the speed, the larger the loop. This causes the raising card to engage in the fabric for a longer period. In summarising it can be said that the material (v_W), cylinder (V_T) and raising roller speeds (v_{roller}) influence the raising effect. If one considers the movement of the raising cards, the regularity of the actual raising speed and the operating speed of the raising rollers V_{OCPR} and V_{OPR} can be calculated. The formula for calculating the operating speed of the nap and counter-nap rollers is:

$$V_{OPR} = V_T - V_{PR} - V_W$$
$$V_{OCPR} = V_{CPR} - V_T + V_W$$

V_{OPR}; V_{OCPR} = operating speed of nap and counter-nap rollers
V_{PR}; V_{CPR} = circumferential speed of nap and counter-nap rollers
V_T = cylinder speed
V_W = material speed

A distinction between raising cards is made according to the type of wire and the carrier material. As far as wire is concerned, a distinction is made between round wire, biconvex wire, sector wire, ovoid wire and flat wire in different sizes. Card wires are made from high quality cast steel with carefully controlled alloys. Carbon (0.57–0.62%), manganese (0.5–0.6%), silicon, phosphor and sulphur are used as alloying materials. These additions produce a wire that meets all elastic, hardness, durability and processing (polishing) requirements. Depending on the use, rubber or felt covered plates are used as the carrier. The selection depends on the type of raising material and the required raising effect, i.e. the card elements must meet the following requirements for the article concerned:

- adequate strength,
- the required elasticity,
- the required card tooth angle effect.

The carrier materials consist of various layers of textile fabric that are bonded together. As far as rubber plates are concerned, the layers of material are covered with a mineralised and vulcanised rubber plate. The thickness of the rubber plate depends on the use (usage area). As far as felt covering plates are concerned, the layers of material are bonded with felt. The choice of carrier material depends to a great extent on the required elasticity of the raising card.

The needles that are used are subject to the following requirements:

- adequate strength,
- required elasticity,
- high degree of wear resistance,
- same angle and tip height.

Selecting the correct type of steel can meet the first three requirements. The first two items are also influenced by wire thickness and cross section. Wear resistance can be improved by hardening the element tips. Galvanised elements are available for wet and damp raising. Particular attention must be paid to the last item, since it is responsible for raising failure and performance. A distinction is therefore made between two types of trimming elements:

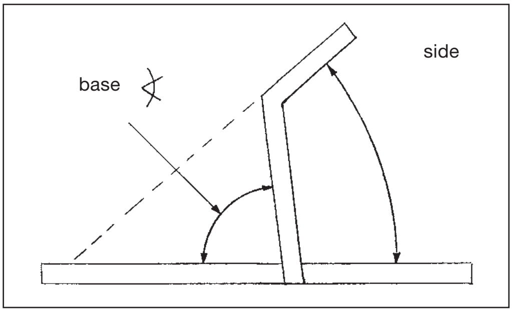

Fig. 8: Normal trimming elements.

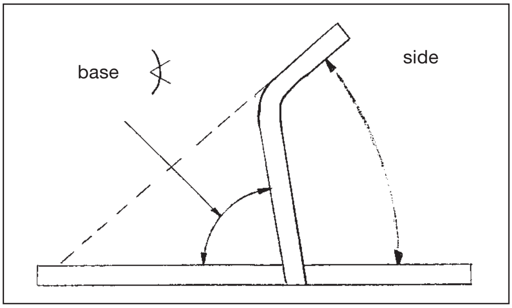

Fig. 9: Round knee trimming elements.

Raising elements

a) normal elements (Fig. 8),
b) round knee elements (Fig. 9).

The basic angle setting is intended to give the trimming elements more elasticity. If the basic angle is reduced (wire bent backwards) the raising card has more elasticity. Normal versions have basic angle settings of 75–85°. If a less elastic version is required, a curved needle (round knee elements) is chosen rather than a needle with a sharp bend (normal elements).

The raising elements get their appearance (angle, wire length, rows of carding teeth) during the manufacture of the raising card belts in setting machines. The wire is cut to the required length and bent into a "U" shape; this creates two element needles. Holes are punched into the carrier material into which the bent wire is subsequently inserted. When the wire is inserted the card is given its final shape, angle position (basic and leg angle) and arrangement of rows of carding teeth (Figs. 10, 11). The row of teeth describes the arrangement of the element needles in the carrier material.

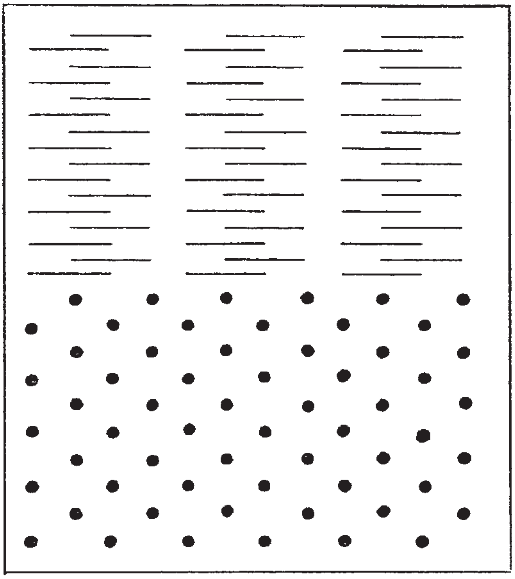

Fig. 10: Rows of carding teeth for raising: two column pattern, 12 rows of teeth.

The occupied element belt is not yet capable of raising, since there are not yet any tips on the legs of the element needles. The wire ends (legs) are ground on large drums by the card belt manufacturer. During grinding a distinction is made between equalising (also known as level or surface grinding), side grinding and polishing.

During equalising an even tip height is first produced. This is not always guaranteed when the element belt is manufactured, since erroneous wire lengths may be produced. The back is given its shape by the grinding disc pressure and the grinding time. A distinction is made between: grinding, thin grinding and flat grinding (Figs. 12–14).

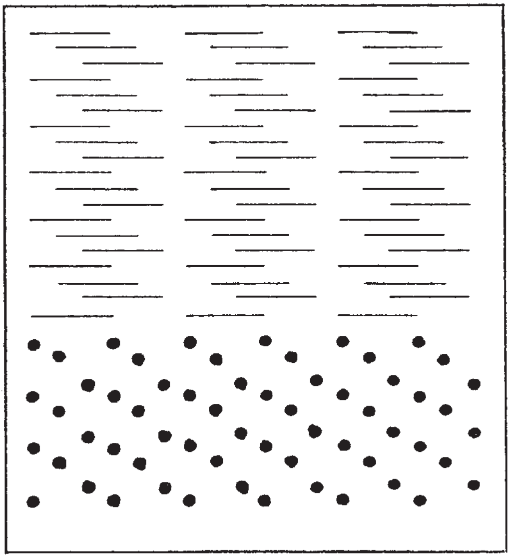

Fig. 11: Rows of carding teeth for raising: three column pattern, 18 rows of teeth.

The tips and card edges are formed during side grinding. For some time, raising experts were not certain whether side grinding was required. In the meantime it has been established that side grinding makes raising more economical and does not affect quality. This is why card manufacturers always supply side-ground raising elements. Here too a distinction is made between grinding, thin grinding and flat grinding. The advantage of side grinding is that the element needle can penetrate the fabric more easily. The needle stays sharp for longer. The disadvantage is that a burr is created on the underside of the leg. The fibres to be loosened can catch on the sharp edge and plucks and holes can appear in the fabric. In practice, new elements are initially used for pre-raising only. In order to prevent this problem the card elements are polished. The card elements wear during long periods of use, i.e. they become blunt, the card tips slowly back in the direction of the wire shape. The wearing process is accelerated by harder materials and weft yarns with a stronger twist. The continual wear of the card tips reduces the performance of the raising machine. This results in multiple passes being required. On the other hand, open bindings and softer weft yarns increase the service life of the raising card and reduce the need for grinding.

Worn raising elements are ground in, thus produc-

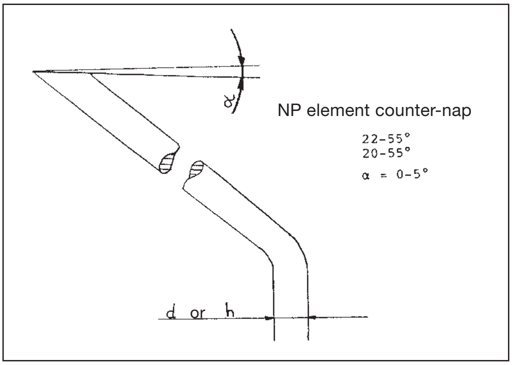

Fig. 14: Grinding forms for levelling: flat grinding.

ing a good raising effect. There are two ways of grinding raising rollers:

1. Grinding the removed raising card roller on a grinding stand (Fig. 15).
2. Grinding the card elements in the raising machine (Fig. 16).

Both grinding methods work according to the principle of equalising, side grinding and polishing. The raising card elements that have already been used must first be cleaned. Flocks, threads, dust, etc. obstruct the grinding process. This leads to different grinding results that are subsequently noticeable on the article to be raised

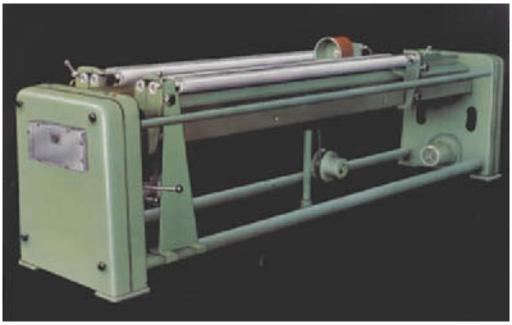

Fig. 15: A card grinding machine AH 5 (grinding stand) by Franz Müller.

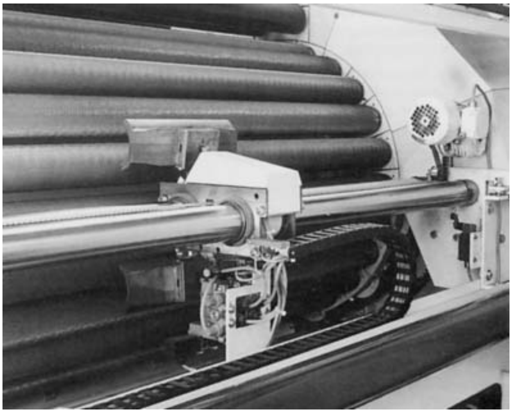

Fig. 16: An automatic raising element sharpening device from the Sucker-Müller company.

(e.g. unequal nap). The grinding procedure for raising cards on the grinding stand is as follows. If there are uneven areas on the raising cards, they must be evened out. Two rollers are placed in the machine such that a grinding spindle with an equalising head (grinding stone unit in grinding stand) and the raising rollers rotate in the same direction. The tips of the cards must point backwards. The raising rollers must then be positioned so that they lightly touch the equalising head. The grinding procedure continues until the needles are of equal height again.

In order to perform side grinding the equalising head is removed and replaced with a grinding head consisting of grinding discs. The grinding discs must engage approx. 1–1.5 mm between the card tips. When enough side grinding has been done the grinding head is removed. Then de-burring (polishing) is done. In this case the raising rollers are allowed to run into each other, whereby a certain quantity of oil and fine grinding paste must be added, since polishing would otherwise not be possible. When in-machine grinding is carried out, equalising, side grinding and polishing is carried out using so-called grinding blocks. These blocks have different grain sizes. A special grooved grinding stone is used for side grinding, unlike other grinding stones. These grooves rub past the side edges of the card.

The card belts are pulled onto bare, smooth metal tubes, each winding in turn coated with adhesive in a spiral. For safety reasons the ends are held down by screws. Tightening must be done with the same tension so that the belt winding is flexible and the surface evenness of the raising card therefore guaranteed. The strength of the tightening is partly responsible for the flexibility of the cards. Flexibility is decisive for quality and evenness. If the tightening is too strong, the card loses the required flexibility, i.e. it does not give way when it engages into the material, resulting in multiple passages and inadequate nap formation. The tightening force is controlled by suspending tightening weights in a belt loop. These weights vary between 5 and 20 kg. The reason for the large difference is that hard and heavy materials have to be raised and tightened harder (less flexibility, more weights). For looser and softer material more flexibility is required, and fewer weights are used for tightening. Too weak tightening an element (without weights) causes running, i.e. the element starts to wander and runs off the roller. The result is that the material tears and the element is destroyed; it gets caught up in the other raising rollers and the element needles break off. The screw-shaped tightening of the elements positions the wire leg at a certain angle to the direction of travel. If all the raising rollers were bent in the same direction, the material web would wander off to the side. For this reason alternate right-hand and left-hand rollers are installed. If possible, the change should take place within the two groups, which thus guarantees that more nap and counter-nap effect can be achieved. Since the width of the elements is rarely the same as the material width, the material is allowed to run on the one side and then the other in an attempt to produce even raising element wear.

Raising energy Classic raising machines of the card roller type vary the raising energy using the following facilities:

1. Ratio of nap rollers (non-raising, but regulating) to counter-nap rollers (raising). Fig. 1 shows six options:

A: All raising rollers against the nap.
B: Roller ratio 1 : 1; one roller with and one against the nap.
C: Roller ratio 1 : 2; one roller with and two against the nap.
D: Roller ratio 1 : 3; one roller with and three against the nap.
E: Roller ratio 1 : 4; one roller with and four against the nap.
F: Roller ratio 1 : 5; one roller with and five against the nap.

Depending on how many rollers the raising machine concerned contains, configurations B to F produce the roller number ratio shown in the Tab.

In the multisystem cylinder raising machine shown in Fig. 2 the number of nap and counter-nap rollers in the operating position and the relative positions thereof can be individually varied. On this 24-roller machine there are twelve triangular locating devices in each side section of the roller, in which a total of 36 raising rollers are arranged. Two of the three raising rollers in each of these locating devices lie against the edge of the cyl-

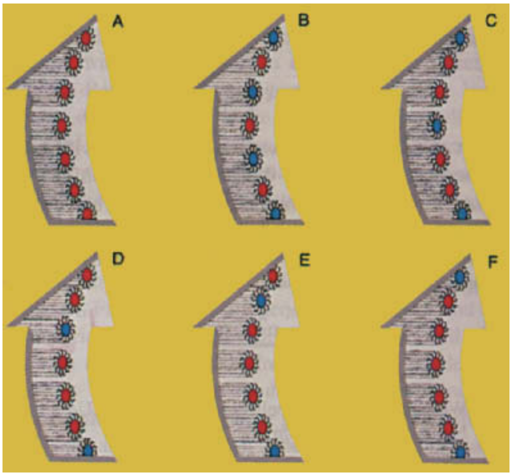

Fig. 1: The ratio of counter-nap rollers (red) and nap rollers (blue) on the reel drum determine the level of raising energy applied.

	24	28	30	32	36

inder and perform raising work on the surface of the textile that passes over them, whereas the third magazined raising roller facing the inside of the cylinder runs at a set speed with the cylinder rotation. The swivelling and arresting of the triangle of raising rollers by 120° in the locating devices is carried out by the central control system during slow cylinder running, depending on the angle of rotation of the cylinder by pneumatically operated mechanisms, in accordance with the desired raising method. The patented raising roller arrangement therefore provides the option of using different raising procedures within a raising process on a textile surface that is being raised.

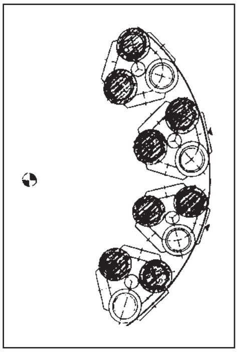

Fig. 3: Raising roller ratio 1 : 1 (12 nap and 12 counter-nap rollers).

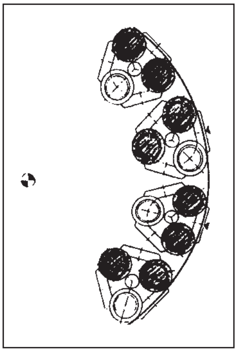

Fig. 4: Raising roller ratio 1 : 3 (6 nap and 18 counter-nap rollers).

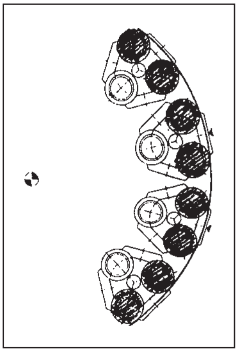

Fig. 5: Raising roller ratio 0 : 24 (24 counter-nap rollers).

Figs. 3–5 show three methods, in which the shaded circles represent counter-nap rollers and the non-shaded circles represent nap rollers. The raising roller arrangement shown in Fig. 3 depicts a 1 : 1 nap to counter-nap roller ratio as the starting point. Fig. 4 shows how a raising roller ratio of 1 : 3 is achieved by swivelling alternate locating devices by 120°. Rotating the mounting device, that has been arrested since the starting point, places all counter-nap rollers in the operating position, as shown in Fig. 5.

2. The raising energy can be varied by altering the circumferential speed of the nap and counter-nap rollers because both can be driven separately. If the counter-nap rollers and nap rollers alternate on the cylinder, a V-belt on the one side drives the nap rollers, whilst the V-belt for the counter-nap rollers runs on the other side

Raising energy

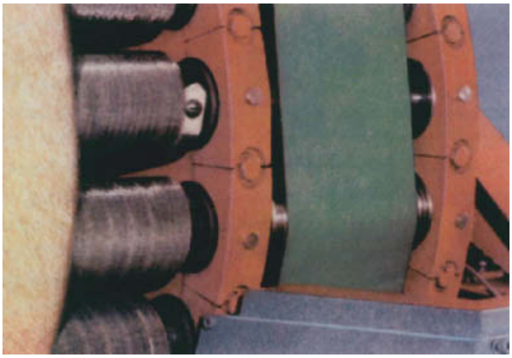

Fig. 6: Flat belt driving counter-nap rollers.

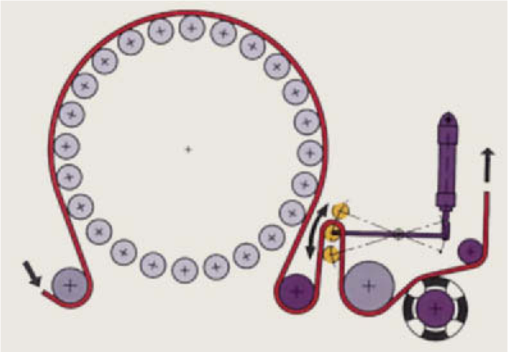

Fig. 8: An automatic fabric tensioner fitted to a raising machine from Aue Textile Machine Manufacturers.

(Fig. 6). These two V-belts run at different speeds, independently of the cylinder and material speeds.

3. Nap and counter-nap rollers can rotate either in the direction of travel of the material or against the direction of travel and therefore influence the raising energy. In Fig. 7 the energy of the rollers running with the nap is shown as "P" and the energy of the rollers running against the nap as "CP". The raising energy that is used when the raising roller (or group of raising rollers) rotates in the same direction as the fabric is shown in red, whereas the energy that is used when the cylinder rotates in the opposite direction to the material is shown in blue. "C" indicates the zero energy point (or zero point), which is used in all cases.

4. The raising effect on electronic raising machines can be influenced by the material tension: the lower the material tension on the raising rollers, the greater the amount of raising energy that can be transferred. The material tension can be measured using dancer rollers (Fig. 8).

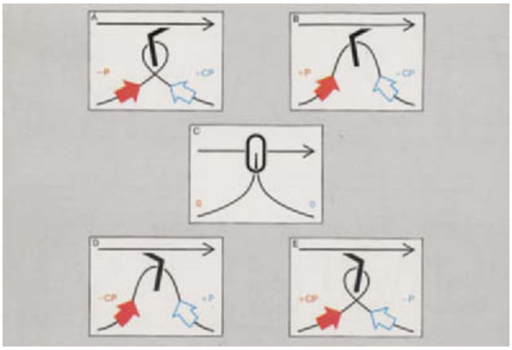

Fig. 7: Diagrams showing raising energy.
P = the energy of the rollers turning with the nap; CP = the energy of the rollers turning against the nap with "CP".

Compared to other methods, raising on electronic raising machines requires a certain rethinking process. In this case the expansion effect produced by raising is exploited and evaluated by a microprocessor control system. The slack that is produced in the rear cylinder area is distributed along the entire cylinder by reducing the raising energy. More material is wound round the counter-nap rollers, which improves the raising effect. The AGT raising effect (Menschner) has the task of creating an optimum raising effect at the minimum material tension around the entire circumference of the cylinder at all raising rollers (Fig. 9). Furthermore, an attempt is made to find a balance between nap and counter-nap rollers so that evenly distributed winding on all raising rollers is achieved in the entire cylinder area. From this knowledge it becomes clear that the optimum raising effect cannot be achieved using the measures that were previously state of the art, namely by maintaining a constant material tension between the cylinder area entrance and exit. It now becomes difficult or even impossible for the raising machine operator to react to all these parameter settings in order to achieve the above-mentioned ideal situation. Consistently making the correct judgement to attain the best possible settings is made even more difficult if raising materials with different expansion characteristics are used. The operator cannot be expected to judge whether and how much the ratio between the circumferential speeds of the material tensioning rollers (VII/VI) and/or above all the ratio between the nap and counter-nap energy (VGS/GS) must be adjusted, since the optimum point can only be found by chance, even if the operator had a great deal of experience and knowledge. In the AGT raising procedure, raising effects are reproducible by the microprocessor control system.

The desired raising parameters can be retrieved from memory using an item number, for example. The diagrams shown in Fig. 9 are intended to indicate a sim-

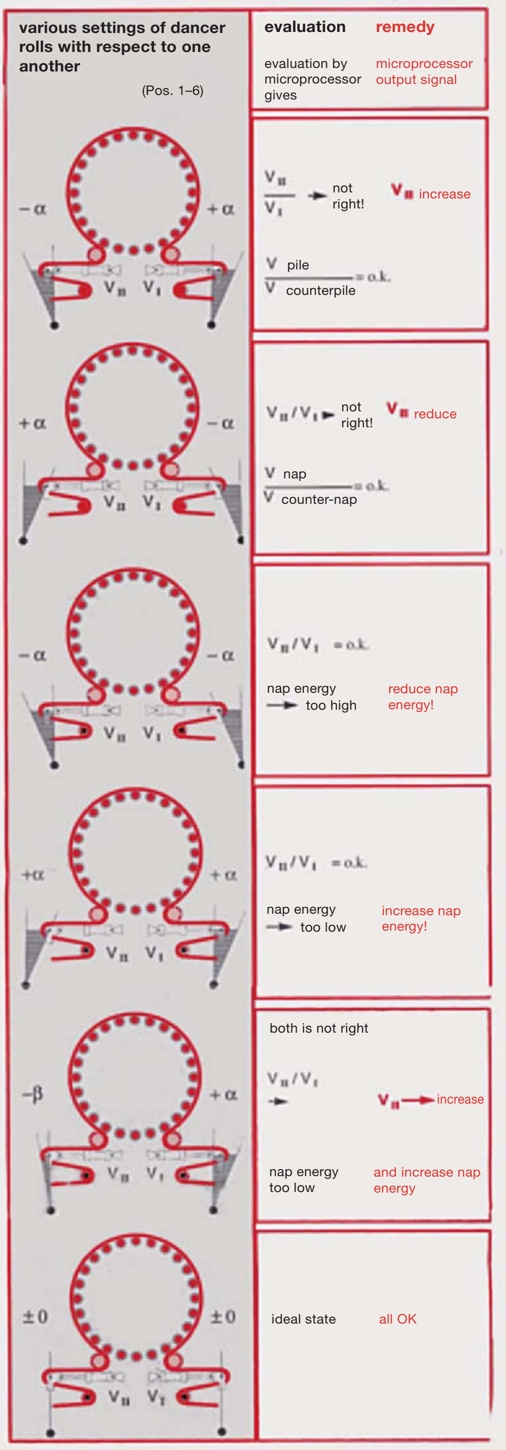

Fig. 9: Settings of dancer rolls with respect to one another (Sistig).

plified form of the possible dancer roller positions and the commands which the microprocessor issues to the nap energy and/or material speed VII, adjusting mechanisms after evaluating this input data. The AGT does not have central drive systems. All the rollers have their own electronically controlled servo drives, i.e. the material pull-in roller, the counter-nap rollers, the nap rollers, the material pull-off roller and the cylinder itself. Two dancer rollers are controlled as sensors, one between the material pull-in roller and the cylinder and the other between the cylinder and the material pull-off roller. Depending on the position and trend of the dancer roller settings, the nap roller energy and the material speed are controlled by the material pull-in roller so that the specified counter-nap roller energy is increased or decreased depending on the amount of winding. This is how the AGT machine independently controls the raising energy depending on the quality of the material.

Raising machines are categorised into teasel and card raising machines. There are also table raising machines for pile fabrics. The former have natural teasel as raising or carding elements, which are either fixed or attached to rods (rod raising machine) or rotate around their longitudinal axis (roller card raising machine). Both types are used in wool finishing – rod raising machines are used for nap raising and roller card raising machines for velour raising. Natural teasels are only used in the manufacture of extremely fine brushed fabrics; they can also be replaced by metal roller teasels.

Unlike fabrics and knitted fabrics made from other fibres, woollen and semi-woollen fabrics are raised in a slightly damp condition. In a rod raising machine only the warp is raised, and in the roller card raising machine both the weft and the warp are raised.

Card raising machines are used to raise fabrics made from wool, cotton, chemical fibres and mixtures thereof. Bent steel wire hooks that are embedded in belts,

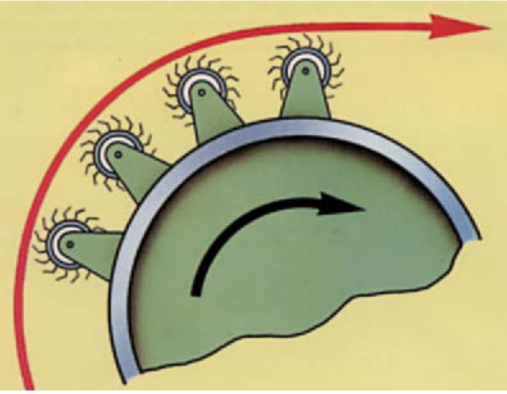

Fig. 1: Normal nap/counter-nap process: the reel drum rotates with the direction of travel of the fabric (Sucker-Müller).

thus forming the carding element in card raising machines. The belts are pulled onto metal rollers in a spiral, thus forming the card rollers. There are special raising elements for the various types of fabric. Card raising machines are categorised into universal (nap/counter-nap) raising machines (Figs. 1–2) and felt raising machines (Figs. 3–4).

A typical universal card raising machine consists of a cylinder, around which 24 or 36 card rollers are distributed (Fig. 5). The rollers rotate clockwise, whereby the circumferential speed is greater than the material speed.

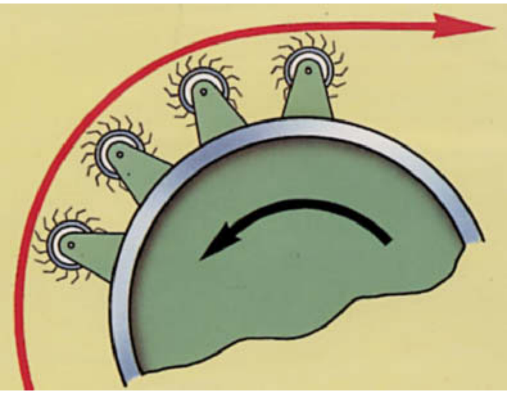

Fig. 2: Contra nap/counter-nap process: the reel drum rotates against the direction of travel of the fabric (Sucker-Müller).

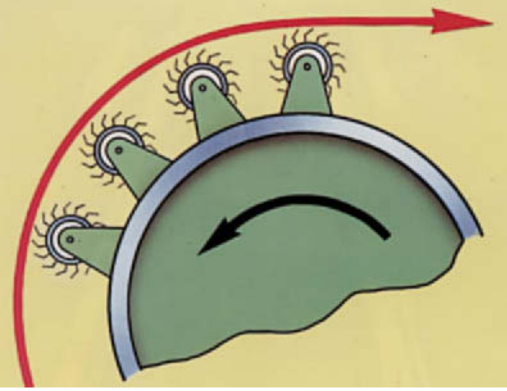

Fig. 3: The normal full felting process (Sucker-Müller).

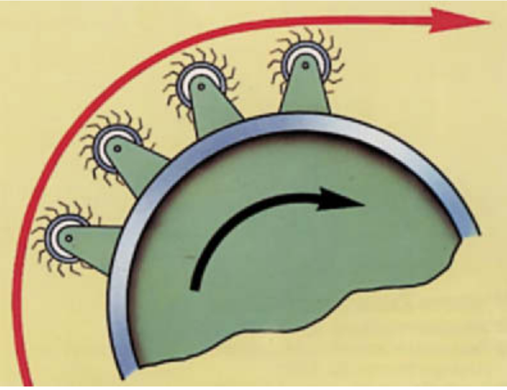

Fig. 4: The contra full felting process (Sucker-Müller).

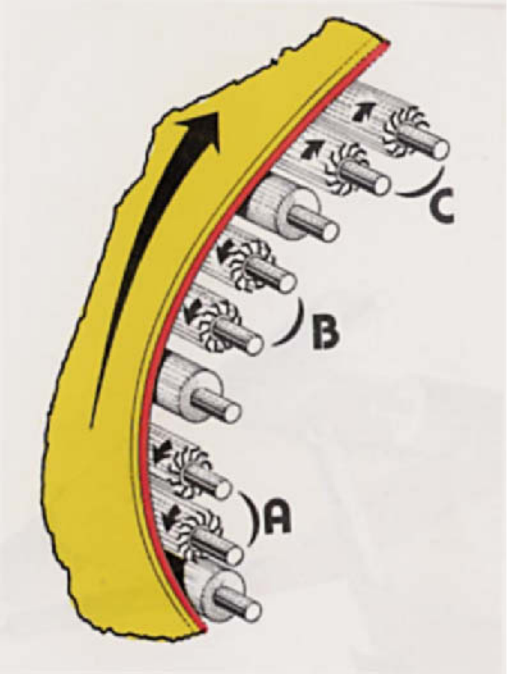

Fig. 5: The Lamperti combination of nap rollers (A), counter-nap rollers (B) and rollers with felting effect (C).

The card rollers rotate in the opposite direction, engage into the material and pull out the fibre ends. In order to achieve a more even raising effect each counter-nap roller is followed by a nap roller, whose wire hooks are not bent in the direction of movement of the material but in the direction of movement of the cylinder. These hooks are there to loosen and disentangle the fluffed-up fibres that have been pulled out by the counter-nap rollers. The raising effect depends on the rotating speed of the nap and counter-nap rollers and the tension of the material. No raising effect is present if the nap and counter-nap rollers have the same circumferential speed as the fabric, i.e. they just roll off it (zero point). The rotating speed of the nap and counter-nap rollers is independently controlled (continuously adjustable). Normally the counter-nap rollers run at a faster circumferential speed than the nap rollers. Pulling rollers transport the material to be raised over the raising cylinder. The material speed is also adjustable. Raising machines operate at up to 60 m/min. The speed of the card rollers and the material can be adjusted in a reproducible way using a microprocessor. This makes raising considerably easier. Furthermore, machines also exist which make it possible to automatically set the same raising intensity at different material speeds. In spite of this, considerable experience is still required for this finishing process.

In order to provide continuous operation for the required number of passages, pieces of smaller items are continuously sewn together and a material collector used at the end of the machine. If both sides of the material are to be raised, an in-line turning device is also used (Fig. 6). For larger production runs several raising machines are combined to form a continuous raising line (Fig. 7). Raising is often continuously combined with subsequent shearing.

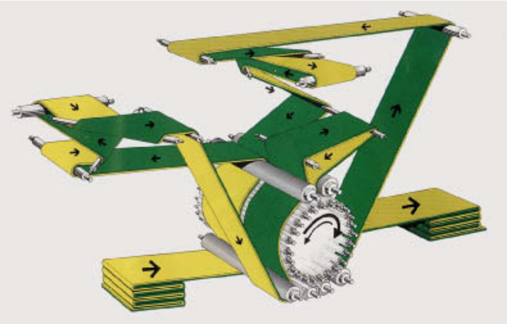

Fig. 6: A Lamperti raising machine with turning devices for tube knitted goods.

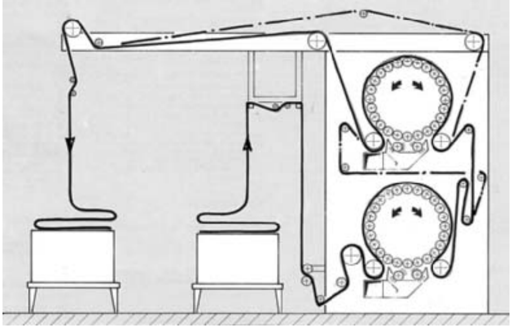

Fig. 8: A duplex raising machine by Lafer.

The moisture content and tension of the running fabric web have a considerable influence on the raising effect. If knit tubing is to be raised, a special wide holder is required that extends over all the raising rollers. The creases remain unraised. Raising both sides in one operation without turning can be achieved on a dual-cylinder raising machine (Fig. 8–9). The cylinder is replaced by a table in table raising machine used to manufacture high-nap materials such as plush. Higher efficiency is reached by cleaning brushes inside the drum (Fig. 10).

Working on the Sistig (AGT 1) raising machine requires a certain re-thinking process. Normally the material tension is an important factor for the raiser in controlling the raising effect. If the material tension is increased, one would assume that the counter-nap rollers would work harder. If the material tension is reduced, as must be the case when raising sensitive knitwear for car upholstery, the amount of material wrapped around the counter-nap roller increases. The raising effect on the Sistig raising machine is controlled by control loops by correctly setting the raising intensity of the nap roller and controlling the material infeed tension. In order to do this, the machine is equipped with two main elements:

1. The rollers are no longer driven by a central drive, but each roller (material infeed roller, counter-nap rollers, nap rollers, material pull-off rollers and cylinder) has its own electronically controlled drive.

2. Two dancer rollers are used as sensors, one between the material infeed roller and the cylinder and another between the cylinder and the material pull-off roller, and are controlled by the material tension. De-

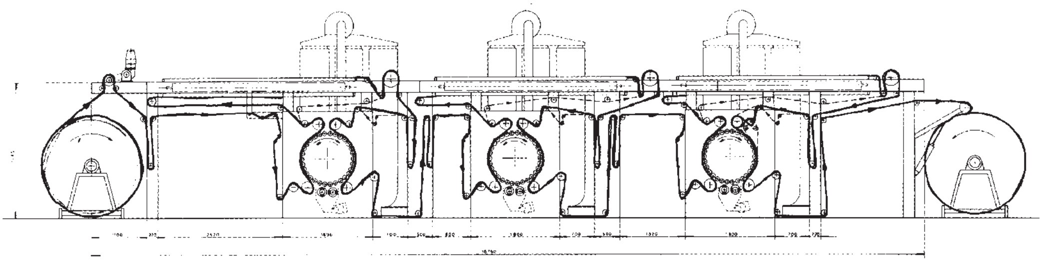

Fig. 7: Raising machine line (Lamperti).

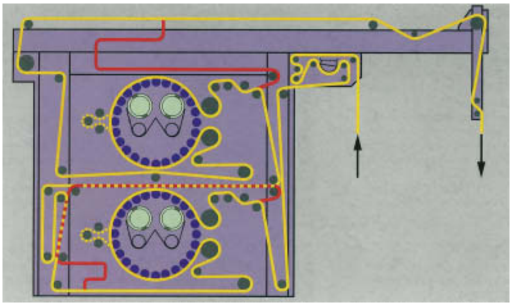

Fig. 9: Double drum wrapping machine (Gematex).

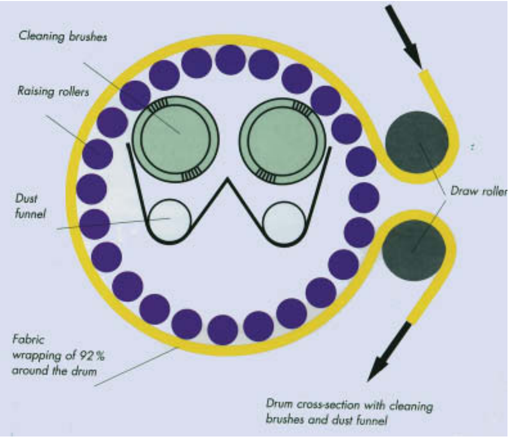

Fig. 10: Higher efficiency by cleaning brushes inside the drum of a raising machine (Gematex).

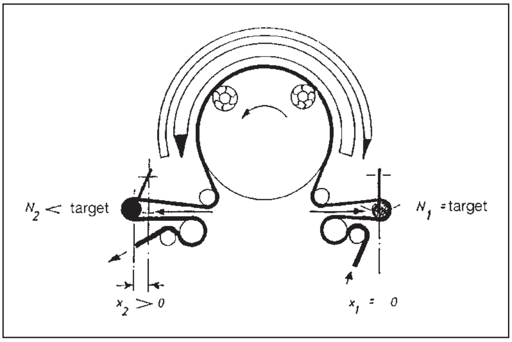

Fig. 11: On the Sistig AGT 1 raising machine absolute stability is sought by using separate drives for the reel drum, the counter-nap rollers and the nap rollers together with sensor dancer rollers N_1 and N_2 for goods take-up (x_1) and output (x_2).

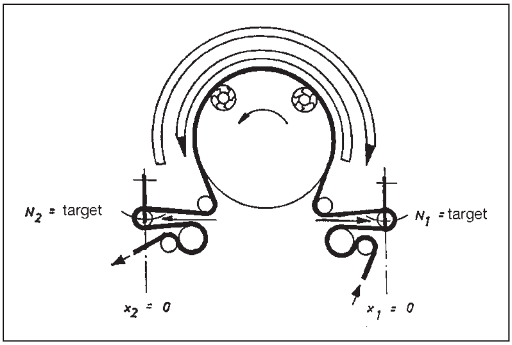

Fig. 12: If there is too little tension-sensitive product in the machine and the raising energy is too low, the product output rate is reduced and thus the raising energy increased.

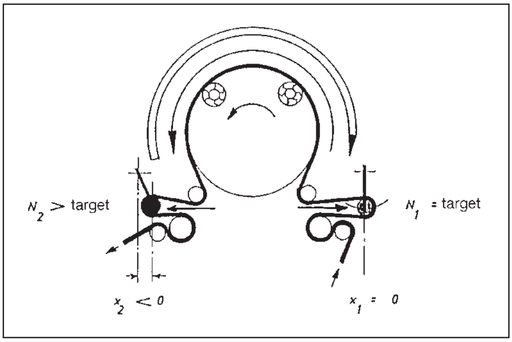

Fig. 13: If there is too much tension-sensitive product in the machine and the raising energy is too high, the product output rate is accelerated and thus the raising energy decreased.

pending on the position and tendency of the dancer rollers (Figs. 11–13) the nap roller energy and the speed of the material movement are controlled by the material infeed roller, so that the specified counter-nap roller energy is used more or less depending on the amount of looping.

In this way the Sistig machine controls the raising intensity independently depending on the material quality. Of course, like all raising machines the degree of wear of the raising rollers in these systems must be occasionally checked by a raising expert in order to carry out subsequent sharpening by grinding off if necessary.

The automation of the Sistig machine is so good for high quality, tension-sensitive raising materials, that two different processes can be considered:

a) Longer-term retention of all machine settings with regard to certain processed items in order to draw conclusions about the state of the cards from the number of passages that are required and therefore set the point in time when the cards need to be sharpened.

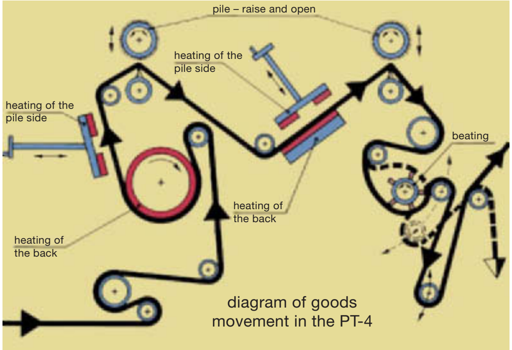

Fig. 14: The POL-Therma PT-4 bench raising machine (Sucker-Müller).

b) “Jigger”-type raising of velour material, whereby the Sistig machine can raise forwards and backwards from batch roll to batch roll, without switching the material from back to front. This method is made possible by the machine’s individual drive facilities.

A distinction must be made between card roller raising machines and table raising machines. Fig. 14 shows a table raising machine for cotton warp velvet for pile opening before dyeing and for preparing the pile after dyeing. When processing articles made from synthetic fibres, the back of the material is formed thermoplastically by steam heating, and the nap side using IR radiation.

Raising machines for yarns provide voluminous appearance before insertion into the fabric, particularly in the case of weft yarns.

Raising needle felt cloth According to DIN 61 205, raised fabric whose raised surface is reinforced by needles.

Raising teasels Natural teasels on thistle heads that are used for → Raising. The thistle heads can be inserted into rods (rod teasels) or attached to rotating rollers (roller teasels) that themselves rotate on a cylinder.

RAL Ger.: (Reichs-)Ausschuß für Lieferbedingungen und Gütesicherung (e.V.) beim Deutschen Normen-Ausschuß (DNA – German Standards Committee).

Ramie (China grass, nettle), → Bast fibre, formed in the stems of nettles. Method of obtaining fibre: manually or automatically (Ramie decorticator) from freshly-cut stems and by cottonizing. The Ramie stem structure is comparable to that of the → Flax stem structure. Raw fibre: pure white, fine, silky gloss. Individual fibres: 50–260 mm long, ∅ 20–100 µm. Microscopic: tape-like, conspicuously wide and uneven, irregular longitudinal stripes, also cracks in longitudinal and lateral directions, often has wall displacement, possible twisting. Tearing resistance: dry 40–60 cN/tex, 10–20% more when wet. Breaking elongation 2–3%. Chemical: (raw fibre) 66% cellulose, 10% water, 10.5% water solubles, 0.5% fats and waxes, 13% pectin/lignine/hemicellulose, 1.2–5% ash. Chemical properties similar to flax (particularly with regard to sensitivity to alkalis and bleach), has similarities to cotton when dyeing. Usage: for lingerie, tablecloths, fishing nets (rot-resistant), carpets, etc.

Ramina Braiding made from Ramie for hats, bags, arts and crafts, etc.

Random crease photographer → Photographic standards for fabric creasing.

Random sample/chemical According to DIN 50 001 is only for orientation purposes and in itself is not to be evaluated as an average sample, because it is usually only based upon two or three values. → Chemicals, sampling of.

Random sampling/textile If an appropriate number of individual values (random sample size) are taken, this should provide a reliable estimated value for the dispersion of individual values, which can be drawn upon in the evaluation of variations in characteristic values (e.g. tolerances). Precondition: defined sampling with representative probability, correspondingly unified confidence interval and confidence factor. → Technical textile sampling.

Random Tumble Pilling Tester Device for testing → Pilling behaviour, consisting of six round containers lined with cork or plastic. Three samples of a type of material whose edges have been bonded with glue are placed in each round container, together with 25 mg of cotton lint. The samples are tumbled around for 1 hour by a paddle rotating in the round container (1200 rpm). The cotton lint is used to make the pilling effect visible. Visual evaluation. Graded from 1 (extremely strong pilling) to 5 (no pilling).

Random webs → Nonwovens without preferred fibre orientation.

Random winding →: Package winding systems; Yarn packages, preparation.

Range (statistical) Statistical difference between the greatest and smallest values of n (random sample range): $Rn = x_{max} - x_{min}$.

Rankine scale (°R). Degrees Rankine is a normal unit of temperature in England and the USA: start of the scale (like → Kelvin) at absolute zero is 0°R, freezing point 491.67°R, vapour point 671.67°R. Fundamental difference between freezing point/vapour point is 180°R, which is equivalent to 180°F; 1°R is therefore equal to 1°F:

1 Rankine unit = 1 Fahrenheit unit
= $^5/_9$ Celsius unit
= $^5/_9$ Kelvin unit.

Ranking test General test method for evaluating characteristics that are difficult to record objectively, such as handle of textiles, visual evaluation of optically brightened samples, smells, etc. For example, it can be said with defined statistical certainty whether there is a difference in the effect of two products made from different raw materials. Principle: pair-wise comparison of two test samples in a series by at least three checkers. The "better" sample is given a mark of 1, and the "worse" sample is given a mark of 0 (in cases of doubt, both samples are given a mark of 0.5). The overall rating totals for the individual test samples can be combined into a ranking and mathematically/statistically processed. This method is better than simply ranking test subjects, according to increasing or decreasing characteristics, by making a continuous decision between three test subjects.

Rapid ager Most common continuous steamer especially for brief steaming (1–10 min) and high outputs in roller printing for vat and developing dyes, also for discharge printing. There is a row of driven guide rollers above and below. The fabric runs in a zigzag arrangement, alternately downwards and upwards, each facing the rollers with the reverse and printed side of the fabric, therefore cannot be used as a screen printing steamer. The oven roof is double-walled and steam heated (protection against spotting), with an exhaust duct or fan. Oven base has perforated steam pipes and condensate collector, the level of which can be regulated externally. This provides the option of generating saturated steam (steam supply from the condensate) and acid steaming (addition of volatile organic acids, or alternatively by spray nozzles). Steam temperature usually 101–103°C. The material is preheated and the air is evacuated (particularly necessary for vat printing) in a heated pre-chamber.

Rapid bleach processes All processes, in which the material to be bleached is exposed to the bleaching bath for less than 10 min.

Rapid cleaning of padders The automatic rapid cleaning of padders makes it is possible to economically dye even small dyeing batches on a continuous dyeing plant or in accordance with the pad batch process. The squeezing and guide rollers are automatically cleaned according to a pre-selected program when the batches are changed. The padding trough is automatically emptied, cleaned and filled with new liquor. The cleaning time is less than 8 min (see Fig.).

Rapid cross-linking → Shock-cure process.

Rapid desizing Continuous → Desizing by a large quantity of desizing agent (usually bacterial amylases) and subsequent steaming, whereby the starch is decomposed at an accelerated rate.

Rapid drier In the rapid drier (see Fig.), in contrast to the → Pressure boiler, heated fresh air is blown through crosswound yarn packages and discharged as moist exhaust air and is not reused.

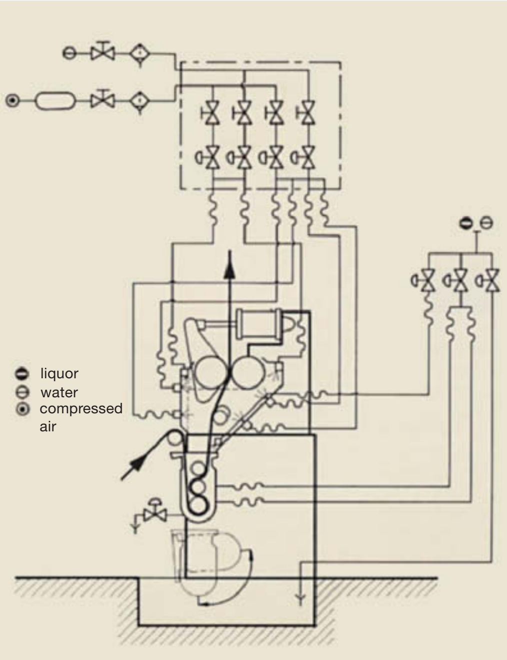

Fig.: Rapid cleaning system in dye padder (Monforts).

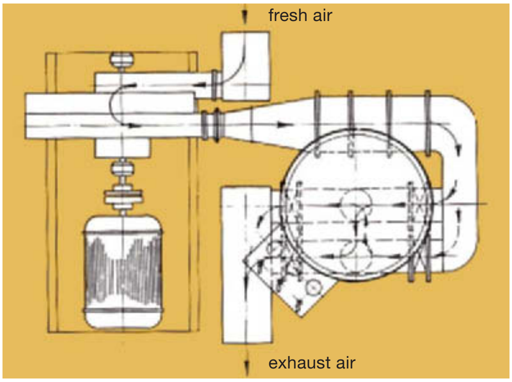

Fig.: Rapid drier (Krantz).

Rapid dyeing machines serve to increase production (prerequisite: low set-up time, sufficient material feed) and as multi-purpose rapid dyeing machines. They differ from conventional dyeing machines because of the use of high performance pumps (increase in liquor throughput to approx. 150 l/min/kg), heaters (heating-up rate of approx. 15°C/min), heat exchangers, shock dyeing devices, short liquors up to 1 : 5 and less (e.g. due to dividers), change of liquor direction, etc. (see Fig.). On the other hand there is an increase in

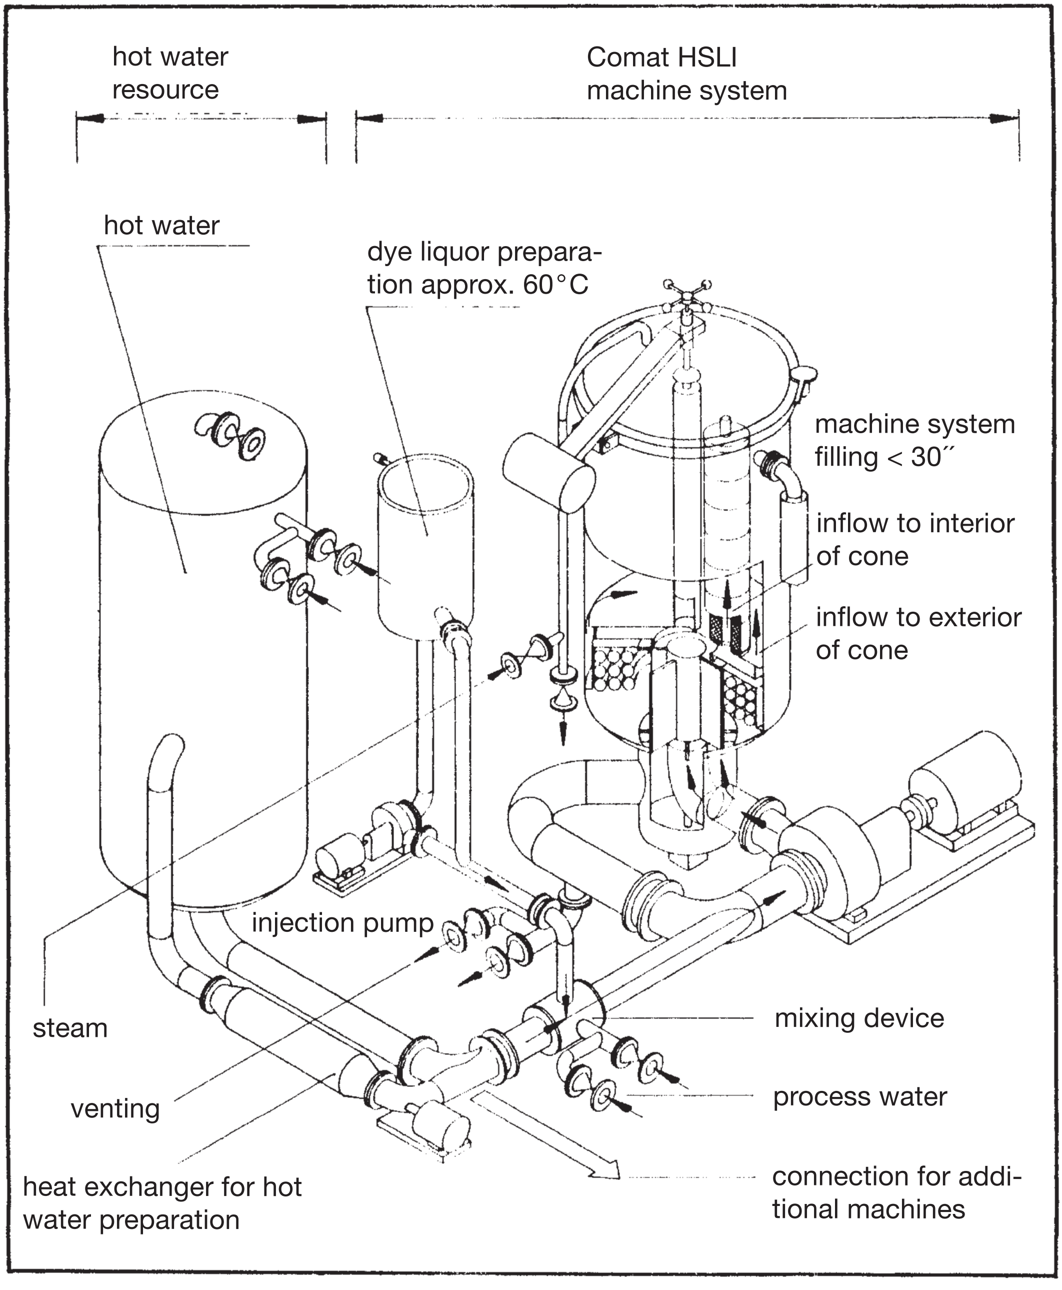

Fig.: The Then-Comat HSLI, a typical example of a rapid dyeing machine.

the energy used for heating (HT = although the temperature is slightly higher, time is reduced) and pumps for higher liquor throughput (compensated by shorter pump running time).

Rapid dyeing of loose wool CSIRO continuous process (derived from the cold dwelling process for wool): high concentration of urea is padded together with the dye, then steamed for 5–10 min, washed and dried.

Rapid dyeing processes Term for shortened dyeing processes. Thanks to reduced treatment times, rapid dyeing processes make it possible to notably reduce

Rapid dyeing processes

Fig.: Dye properties and application requirements for the purpose of rapid dyeing (by Bayer).

finishing costs. However, it is only possible if operating reliability and reproducibility are retained.

In controlled exhaust dyeing processes, the heating-up time can be reduced if heating takes place faster outside the critical exhaust range of the dye (see Fig.). The location of the exhaust range is dye-specific and moves to higher temperatures as the quantity increases. It is common to divide disperse dyes into groups according to the location of their exhaust range. The exhaust range can usually be calculated sufficiently accurately from the group and quantity. In combination dyeing the relative location of the exhaust range of the individual dyes should be taken into account. Tone-in-tone exhaustion should be viewed as a significant criterion for uniform dyeing. Normally, tone-in-tone exhaustion only occurs with disperse dyes in certain application quantities (shades). However, virtually tone-in-tone exhaustion is possible with some dyes over a wide range of shades: Dyes with higher solubility, those that have a mutual influence over each other or can be levelled by auxiliaries, i.e. mixtures of components of close shades with displaced exhaustion ranges. Almost tone-in-tone exhaustion is beneficial for levelness, because shade differences are avoided. It is not so important in disperse dyes as it is for ionic dyes, because disperse dyes do not block each other; it is therefore often only of secondary importance for their levelling capacity.

The V numbering system of the Yorkshire Company is worth mentioning in this connection. With the aid of this system so-called V factors, which ensure a uniform shade structure in combination dyeing, are calculated for dyes. The V factors are determined for the dye in question as follows:

1. A dyeing is performed under precisely defined conditions.
2. An exhaust curve is determined for the dye by taking adsorption measurements of the liquor at certain temperature and time intervals.
3. Based upon this information, the time is determined at which half the final colour separation was achieved ($t^1/2$). This value is converted to a parameter V, which represents a negative function $t^1/2$.

It is easy to reach the following conclusion from this: The greater the V factor, the faster the exhaustion rate. These measurements are repeated at many concentrations of each dye. In this manner the V factors are determined for all desired dyes of different shades and the results represented in graphical form. Due to the rapid increase in the V factors for shades < 1%, the V factors are represented logarithmically in relation to concentration. Specific curves are found for each dye. At a dye concentration < 0.05%, the precision of the measurement falls due to the definition of the V factor, because this has a limited maximum value of 7 at 0 % dye concentration and, therefore, all graphics relate to this value. Combinability, and therefore, a tone-in-tone colour structure, is expected if all individual dyes in a recipe have similar V factors. A difference of 0.5 is tolerable. The V factors are not applicable on dyes which are themselves a mixture.

A further option for guaranteeing the combinability of disperse dyes, and thus the levelness of dyeings, is the concentration error diagram. Concentration differences in the dye are the main cause of non-uniformity at various points on the textile. Concentration differences are caused by:

- differences in liquor circulation,
- temperature differences,
- differences in penetration,
- different auxiliary influences.

However, when measuring non-uniformities it is difficult to associate differences in visual impression with specific differences in dye concentration on the textile material. Directly applicable quantitative guidelines can be obtained from a concentration error diagram. The colour differences of off-shade dyeing, which are dyed using defined concentration differences in comparison with a basic recipe, are plotted on this diagram. This diagram can then be used to find the magnitude of the expected colour differences with a defined deviation in the dye concentration from the initial recipe consisting of several dyes. It is easy to deduce from the total colour difference which components of a combination will give rise to concentration errors and may be particularly visible due to differences in the speed of exhaustion and which shades are particularly sensitive to errors with regard to non-uniformity.

In order to create a concentration diagram (according to Leube and Rüttiger), defined concentration errors are predetermined (starting from a certain recipe). Fibre samples are dyed in liquors, which contain the dyes measured with concentration errors; the colour difference from the standard recipe is then determined by colorimetry based upon the spectral reflection of the finished dyeing. The following can be derived by considering the concentration error diagram:

- The diagram forms a bridge between colorimetrically measurable concentration differences and coloristic evaluation practice.
- The same concentration error, which can be expressed in dye percentages, will have a different effect due to the variable sensitivity of the human eye and due to shade dependency of the colour differences.
- The measured colour differences do not allow conclusions to be drawn regarding the observed non-uniformity.
- In the optimization of the recipe, particular attention is paid to the dye for which the concentration error caused the greatest colour difference in the error diagram.

With the introduction of the Ku_{20} factors, characteristic quantities became available in polyester HT dyeing works for disperse dyes, which allow predictions of practical value to be made for short period techniques.

$$\mathrm{Ku}\,[\%] = \frac{c_{max} - c_{min}}{c_{min}} \cdot 100$$

c_{max} = max. dye concentration on the fibre,
c_{min} = min. dye concentration on the fibre.

The non-uniformity of a standard depth dyeing can be calculated using this formula. Dyes with Ku_{20} values of 2–5 are particularly well suited for an efficient dyeing process with a high heating-up rate and have been collected together to form a range.

The Hoechst Rapidcolor process is an isothermal dyeing process which takes place at the fixation temperature of the dye. This type of procedure is made possible by a previous steaming phase and a rapid filling of the dyeing kettle in the HT range. The dyeing process can be subdivided into the following process steps:

1. preheating of the textile and dyeing kettle,
2. filling process,
3. dyeing and aftertreatment.

The cooling of the incoming dyeing liquor should be avoided as a precondition for the immediate start of dyeing at the fixation temperature of the dye. If complete impregnation and uniform dye distribution is to be achieved, no trapped air should be present in the wound package. Therefore, the textile is steamed at the beginning of the treatment process, whereby the position of the steaming process in the sequence of flow is such that that volumetric expansion and density differences in the two media cause the air to escape from the textile and is vented from the machine. Condensation of the steam in the material being dyed and at the machine components gives rise to a very rapid heating up of the entire system.

In practice, the steam is allowed to flow into the dyeing kettle containing the dyeing batch at a pressure of approx. 4 bar. As the steaming time increases the steam pressure increases within the dyeing kettle and is limited to 1.5 bar. At the beginning of the process the HT discharge is opened briefly, until the air initially present in the system has been removed. Then the actual heating-up process takes place in an atmosphere of saturated steam. Temperature measurements within polyester wound packages with inserted thermoelements have shown that there is a uniform temperature distribution in the different yarn layers across the diameter of the wound package, which remains constant and the temperature reached depends upon the saturation state of the steam (i.e. in this case 127°C). This creates good preconditions when the dyeing kettle is subsequently filled with dyeing liquor.

The water quantity necessary for the dyeing is heated to 140°C in a water heater. A cushion of steam is maintained above the liquor level in the water heater. The steam cushion is maintained at slightly above the saturation pressure. Dyeing auxiliaries can be added to the hot water receiver. When the connection line to the dyeing machine is opened the hot water at 140°C flows into a mixing device due to differential pressure. The disperse dye batch, prepared in an open preparation vessel and heated to 160°C, is simultaneously dosed into the incoming stream of hot water via a mixing device with the aid of an injection pump (this procedure excludes the possibility of thermal stress in the dye dispersion prepared in the preparation vessel). The finished dyeing liquor with all additives enters the dyeing kettle, and liquor feed takes place to both the inside and outside of the wound package due to the suitable positioning of the liquor return unit. The purpose of this type of filling process is to achieve a uniform liquor supply and to avoid hydraulic pressure differences during the filling phase. Since there is no air in the system during this process, no foaming takes place; therefore there are no irregularities in the flow through the wound package due to foaming. The sequence of the filling process is as follows: after running through the feed line behind the mixing section the dyeing liquor at approx. 135°C enters the steam atmosphere at 127°C, which corresponds to a saturated steam pressure of 1.5 bar. The saturation pressure of the dyeing liquor at 135°C corresponds with 2.2 bar. As the level of the liquor within the dyeing kettle increases, the steam volume above the liquor falls, with a corresponding increase in steam pressure. When the saturation pressure of the liquor is reached, the steam pressure cushion begins to condense. The steam condenses continuously, because the pressure difference due to the superimposed pressure in the water heater is maintained until the final level in the dyeing kettle has been reached. Then compressed air pressure is applied and liquor circulation starts at 60 l/kg/min. A mixing temperature of 129–130°C is soon set after the beginning of liquor circulation.

Rapid fill Rapid transfer of dye liquors into a dyeing machine.

Rapid fixation dyeing units Small continuous plant for universal application or as washing/rinsing machine for pre-treatment (desizing, bleaching). The steamer can be flooded and used as a washing plant. Counter current principle; extremely low water consumption. Modular structure.

Rapid mixers, rapid stirrers are high speed mixers. They differ due to the size and shape of the stirrer assembly (mixing heads), upon which the fine distribution depends: stationary, portable or transportable. In textile finishing above all for the application of printing thickeners and dye solutions.

Rapid steam generator Boiler with up to 1000 kg/h performance (→ Steam boiler).

Rapier loom Weft insertion takes place by means of so-called rapiers, i.e. positively moved rods (Fig. 1) or belts (Fig. 2), with rapier heads attached to the tip, which convey one weft thread through the weaving line for each weft. The rapiers can be fitted on one side (in this case they cross the entire weaving line) or on both sides (the thread is transferred from one rapier to the other in the middle of the line). Furthermore, we differentiate between tip and loop insertion or transfer.

The principle of a rapier weaving machine can be explained as follows based upon the example of a Dornier rigid rapier with tip insertion and controlled central transfer: The rapier movement is derived from complementary double cam centres, which have curve paths that optimize the rapier movement and thus minimize the strain on the weft yarn. Both rigid rapiers work without lead teeth in the weaving line. Before entry into the line the left-hand rapier grasps the yarn presented by the passing needle with an open clamp. After the clamp has closed a clipper cuts the weft thread on the fabric side. The weft thread is transferred from the left-hand to right-hand rapier in the centre of the machine. Two independently adjustable opener levers, each of which is driven by cams and roller levers, serve for the positive control of the weft transfer. The opener lever dips under the weaving line before the laminar

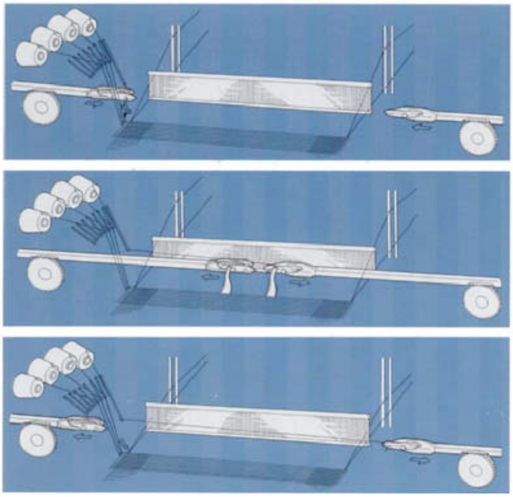

Fig. 1: Rigid rapier principle (Dornier) in a gripper loom.

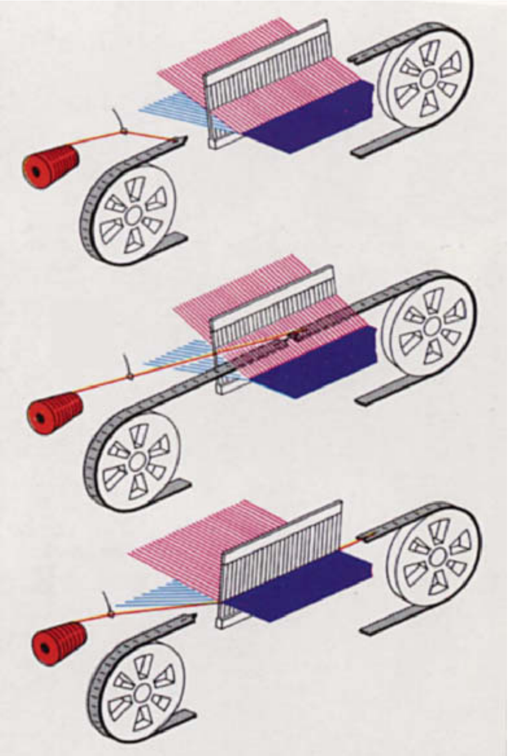

Fig. 2: Flexible rapier principle (Nuovo Pignone) in a gripper loom.

stroke, so that no fabric striping occurs. After the low tension thread transfer the taker rapier takes the weft to the right-hand edge of the fabric. During the insertion phase the weaving line remains open. The weft thread is only released from the controlled rapier clamp when it is held by the claw strip.

Rare earth metals Metals belonging to the rare earth group, e.g. cerium (Ce), lanthanum (La). They are described as rare earths due to chemical relationship with aluminium, “alumina”.

Raschel batt-on-base carpet Textile floor covering. Instead of pile yarns a fibre nonwoven is used in combination with auxiliary yarn using the raschel technique to form a bouclé carpet, which is then shorn to produce → Velvet pile carpets.

Raschel carpet (knit-woven carpet), a velour carpet manufactured on a raschel machine, where the ground weave is woven at the same time. The pile threads, which are loose in the base material to start with, are fixed in place using reverse-sided coating (latex, artificial resin). Similar appearance to tufted carpets. Usage: e.g. stair carpet material.

Raschel-knitted fabrics → Warp-knitted fabrics made on the raschel machine (from the French: Rachel) for curtains (raschel curtains), lace, carpets, tulle, fashion materials (outerwear, underwear), etc.

Raschel tulle Net-like knitted fabric that is manufactured with two retracted guide rails in accordance with a pattern. Each warp thread has a weft thread assigned to it. The effect of the honeycomb-like openings is not shown to its best advantage until finishing has taken place.

Ratchet effect Relates to wool scales and the fact that they hook onto each other as in the so-called directional friction effect (DFE) assumed to play a major role in → Felting.

Rate of dyeing Rate at which the dyeing bath is exhausted. A suitable measure is the inverse of the → Time of half-dyeing or the time after which 70% of the dye has been absorbed.

Rate of evaporation Increases with increasing temperature, because the average molecular speed increases at the same time, and therefore so does the percentage of molecules with above average speed, which can escape from the surface.

Rate of fixation,

I. In reactive dyes the fixation speed is characterized by the period of time in which a stable bond is formed between the dye and fibre molecule. It is dependent upon the reactivity of the reactive group in the dye molecule, alkalinity of the fixation medium and temperature.

II. In disperse dyes the fixation speed depends upon the diffusion speed of the dye in the synthetic fibre, which is determined by the dye concentration and temperature and pressure relationships during fixation.

Ratiné (French: crimped), carded yarn-like double cloth with small knots, knops or twisted ringlets; also in the form of compressed waves (= Welliné), manufactured as woven or knitted fabrics. Usage: for winter coat materials.

Ratiné finish Woollen fabric character with wave-like appearance on the surface.

Rationalization Meaningful organisation of working processes with the aim of optimising the cost/result ratio. For example, this includes conversion to continuous operation, increasing the speed of the material, use of the → Combination process, utilisation of the heat in sewage and exhaust air, use of water-saving washing machines, avoiding intermediate drying, i.e. use of wet-in-wet process, etc.

Ravensberg process → Bleaching of linen.

Raw cotton composition 83.71% cellulose, 6.74% water and impurities 0.61% grease, wax (→ Cotton wax), 5.79% hemicellulose, pectins, 1.50% proteins, 1.65% ash. According to Bowman: 91.35–90.80% cellulose, 0.40–0.42% wax-oil-grease, 0.53–0.68% protoplasm, 0.22–0.25% mineral components, 7.50–7.85% water.

Raw cotton dust Contains a considerable proportion of dust (fragments of cotton, cellulose, stalk, leaves, seeds, seed leaves, bolls, mineral components, etc.). Dust is created throughout the processing of the raw cotton, from the opening of the bales by the preprocessing machines to the carding machine, and this enters the lungs and can cause an illness, so-called → Byssinosis, in workers. Therefore the total amount of dust (fibrous and non-fibrous components) in the air of the processing areas should not exceed the TLV value (maximum workplace concentration).

Raw hide Untanned leather, from which the outer and inner skin connective tissue has been removed by lime soaking. Quickly decays in damp air, becomes stiff like horn in dry air and swells in boiling water to form glue. Tanning is vital to counter these effects.

Raw linen → Unbleached linen.

Raw silk Non-degummed → Silk (grège silk), still glued with silk gum and non-twisted individual threads.

Raw wool (greasy wool), is shorn → Wool, which still contains dirt. It contains 20–50% pure fibres, 6–17% wool fat, 10–30% wool grease, 20–40% impurities and (air dried) up to 18% water.

Raw wool scouring Preliminary washing process for the removal of wool fat, wool grease, dirt pigments (Fig. 1), etc., e.g. on the leviathan with soap and sodium carbonate. Soap can be replaced by lime resistant synthetic products, which facilitate clear rinsing, particularly in the final baths, or gentle acid scouring or scouring with solvents. Additives of ammonia or grease solvent washing agents are used for wool containing pitch tips. The wet process can be made significantly

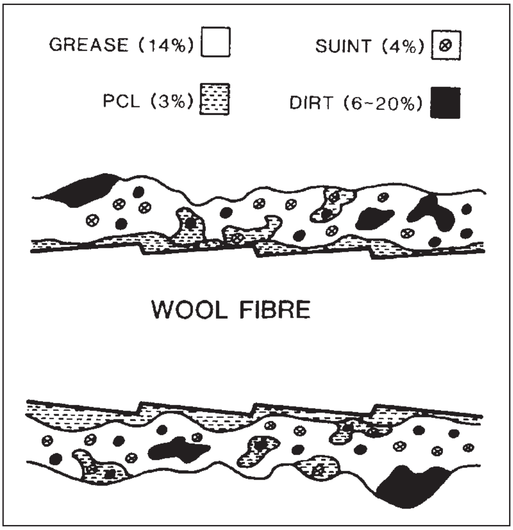

Fig. 1: Diagram as suggested by CSIRO (C. A. Anderson, B. O. Batenp, I. R. Christol, I. I. Wanner) to describe the soiling of raw wool.

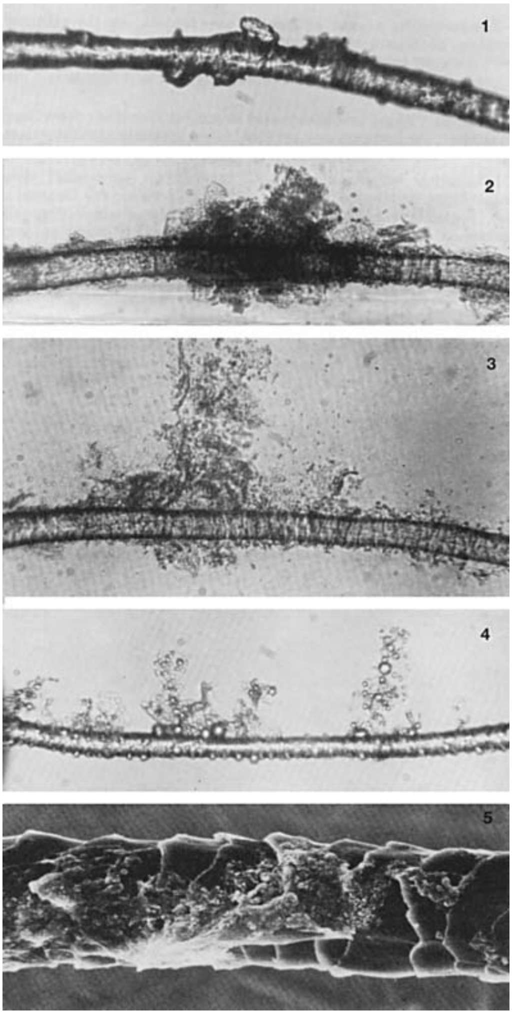

Fig. 2: The progress during the scouring of a wool fibre of 21 μm thickness (according to CSIRO).
1 = greasy wool; 2 = initial swelling of the inpurities; 3 = removal; 4 = advanced scouring stage; 5 = protein contamination of a scoured fibre.

easier if the maximum possible amount of vegetable impurities and sand is removed beforehand by a mechanical treatment (Morolan process). DIN 60415 describes the different work processes in wool scouring and combing works.

Raw wool is washed in aqueous liquor. Solvent scouring is of lesser importance. The pH of the aqueous extract from wool varies between 5.5 and 9.5. Attention should be paid to this in the composition of the washing baths.

Warm water is used for the 1st bath (approx. 40–45°C), the primary aim of which is to remove the wool grease (Fig. 2). The potassium carbonate contained in the wool grease influences the wash activity of the baths. Washing baths, the temperature of which lie a little above 38°C, the melting point of the wool fat, follow the soaking phase. In most companies, washing is managed in such a way that soap and sodium carbonate are used in the first degreasing trough, but a lime resistant washing auxiliary is used in the second. This measure makes the subsequent rinsing process easier. In some companies the wool is treated with a sodium hydrogen sulphite solution before the last rinsing section. No clear conclusions can be drawn about the harmful influence of sodium carbonate in wool scouring. If the temperature of the washing baths does not rise significantly above 38°C, little fibre damage can be expected. The greatest degree of fibre protection should be achieved at the isoelectrical point of the wool, i.e. at approx. pH 4.6. Various acid resistance, non-ionogenic washing agents are used for this purpose. However, wool washed in this manner will exhibit worse behaviour in the combing and spinning works than wool washed at pH 9.5. Acid scouring is not important in practice.

Previously, washing took place continuously on the so-called leviathans; these are component groups consisting of several washing and rinsing vats interspersed by squeezing units (Fig. 3). The mechanically loosened wool flock was moved forwards in the vats by conveyor forks. In a system by Fleissner suction drums, of which there are 5–6 one after the other, replace the conveyor forks to achieve gentler transport of the wool (Fig. 4). The Charpentier and Chaikin systems use con-

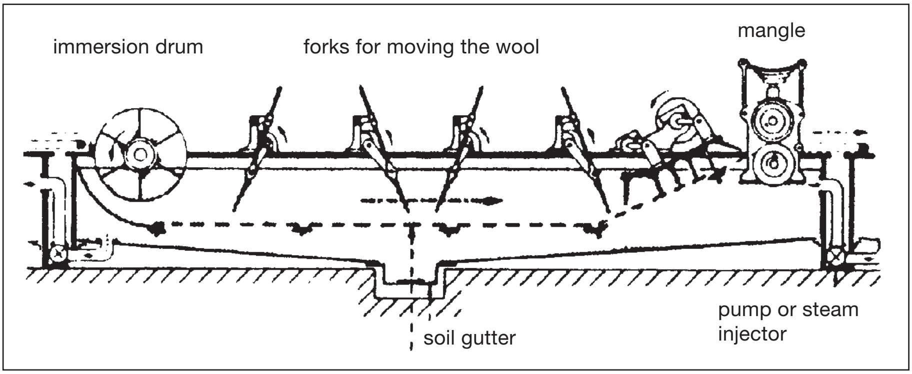

Fig. 3: Part of a leviathan used for scouring raw wool.

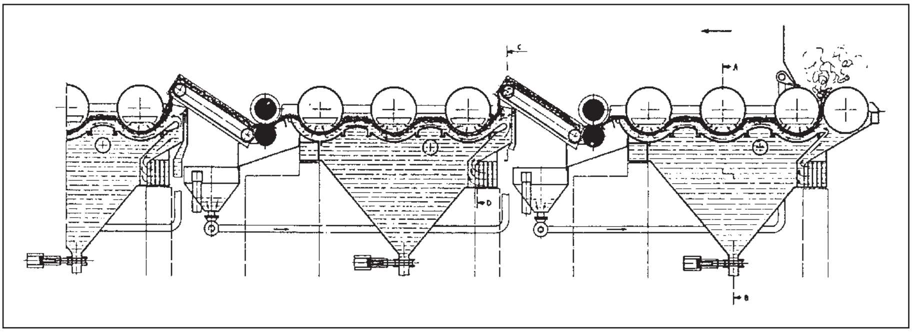

Fig. 4: Diagram of a three-tup wool scouring machine with suction drums to transport the wool (Fleissner).

veyor belts, as do Australian “flat bed” washing machines, which do not use jets or squeezing rollers; these processes are called “hydrodynamic wool washing” processes. Drums, connected by steel pipes are used in the CSIRO “jet scouring” processes.

The wool fat (lanolin) is reclaimed from the baths used in raw wool scouring. In the past it was assumed that raw wool auxiliary substances consisted only of wool fat, dried sheep sweat salts (wool grease) and mineral impurities. Investigations by CSIRO proved that a further, previously unknown, impurity was present, a protein substance that plays an important role in raw wool scouring and also in general washing processes. Amino acid analyses of this protein component proved that it most probably consisted of flakes of skin and possibly also the inner root sheath of the sheep skin follicle. Although such flakes of skin do not form a continuous layer around the entire fibre (Fig. 1), there is still contact with the fibre at various points, and it is into these flakes and fibres that wool fat, grease and other impurities embed themselves. It is also possible that the flakes overlap at various points on the fibre and thus form a barrier, which is difficult to overcome during washing.

This model of the structure of wool impurities has, with the aid of microscopic investigations into raw wool fibres in the washing liquor, led to new considerations with regard to the functional mechanism underlying the removal of impurities by washing in hot water. The mechanism consists of the penetration of water and the added surfactant into the impurity, which rapidly makes the fat and protein substance swell, the formation of balls of grease and the removal of the easily removed grease, dirt and protein components, which do not adhere to the fibre surface, together with the grease and dirt particles contained within them.

Experiments by CSIRO have shown that the highly soluble impurities can be removed in the first two hot washing sections of a conventional washing line. The difficult to remove pollutants on the other hand remain on the fibre. They cannot be removed in the subsequent rinsing sections either and have a detrimental effect on the properties of the washed wool, particularly on the ash content.

CSIRO proposes a solution to this problem by the concept of a two-phase washing process (Fig. 5), in which the two categories of impurity are removed in two separate sections of the washing line. Ideally, in the first section the washing liquor should contain an active surfactant and a washing agent booster, which dissolve the easy to wash out dirt particles from the wool. In the second washing phase, the wool should be exposed for

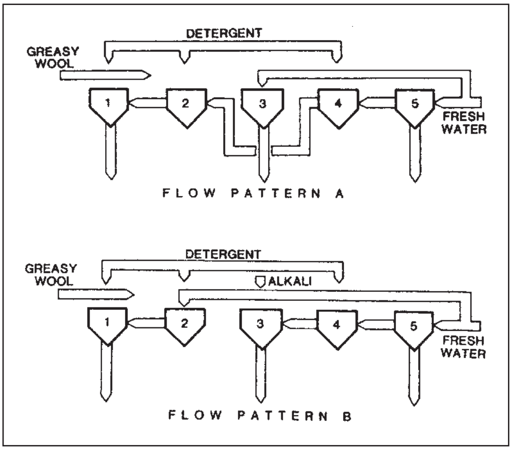

Fig. 5: Two among several possible configurations of the two-phase washing process. Significant features are the addition of surfactants in the 1, 2, and 4 scouring stages and the separation of stages 2 and 3.

as long as possible to a special liquor consisting of surfactants, washing agent boosters and enzymes, with which the difficult to remove dirt particles are removed from the raw material.

Raw wool scouring machine Further development of the → Suction-drum washing machines (suction-drum leviathan). The main component is the discharge drum. The propeller pump starts the washing liquor circulating, takes liquor from the discharge drum (Fig. 1) and conveys it back to the bath. Liquor thus flows through the washed material on the drum and the material floats freely between the drums. Several individual components can be connected in raw wool scouring lines (Fig. 2), which are computer controlled.

Rayon (reyon), designation for viscose filaments (fibres) that is no longer permitted. Also generally used for regenerated cellulose fibres in older literature (pre-1953).

Rayon staple fibre No longer permissible term for viscose staple fibres.

Rb Symbol for the element rubidium (37).

R-clauses (risk phrases). Risk instructions according to the working-substance regulations in accordance with EC Directives, i.e, identification of particular risks associated with dangerous working materials. In each case, the substance in question is provided with a number or number combination, for example, R9 = risk of explosion if mixed with flammable substances.

Re Symbol for the element rhenium (75).

Reactant-fixable dyeings Crosslinking agents

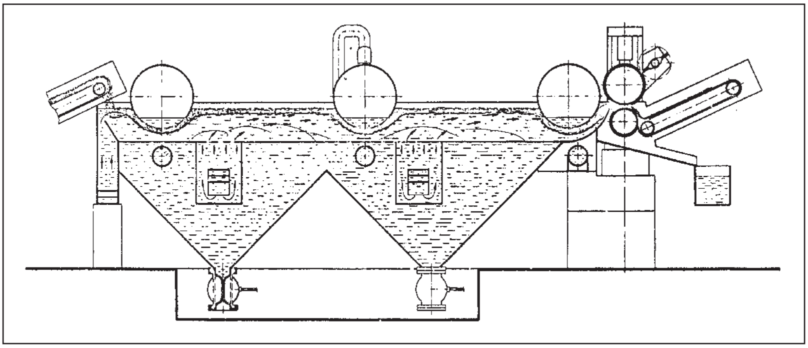

Fig. 1: The liquor circulation in a sieve-drum raw wool scouring machine (Fleissner).

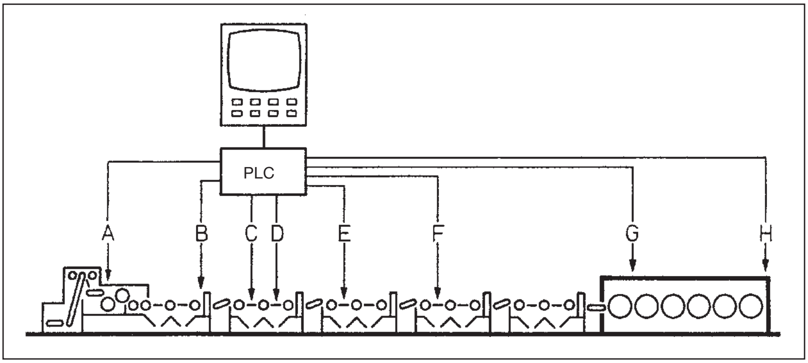

Fig. 2: A Fleissner raw wool scouring line system. A = steady feed of material; B = transportation drive and circulation pump revolutions; C = temperature (all baths); D = chemicals and fresh water dosing; E = reverse flow control (all baths); F = clarification (all baths); G = extraction air humidity and quantity; H = final humidity and drier temperature.

are used to bond direct and reactive dyes to cellulose in order to improve their wash fastness.

step A: the cellulose fibres are dyed with reactant-fixable dyes in a similar way to direct dyes.
step B: the reactant fixer is used to fix the dyeing.

During the fixing process, the dye is linked to the cellulose fibre via a special bond (Fig. 1). At the same time, the cellulose fibres are crosslinked via their active OH groups. Apart from the above-average wet strengths, easy-care properties are imparted to the product such as reduced crease acceptance, improved dimensional stability, reduced fibre swelling and, therefore, increased drying speed after washing.

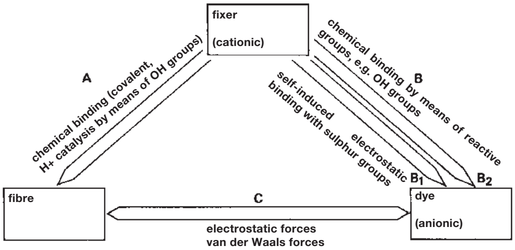

Fig. 1: The hypothetical mechanism of a dyeing system using reactant-fixable dyes.

During the fixing process, it must be ensured that the following reactions take place simultaneously (Fig. 2).

1. Crosslinking of the cellulose fibre, in association with a reduction in the swelling properties in both neutral and alkaline aqueous liquors.
2. Blocking of the free sulphonic acid groups ($–SO_3$) of the dye which has been applied.
3. Reaction of the dye with the active groups of the fixing agent.

The cellulose fibres are crosslinked by polycondensation of the fixing agent with the active OH groups on the cellulose. These are genuine covalent bonds. The water solubility of the complex is reduced by blocking the dye's water-affinity groups, such as sulphonic acid groups. The blocking process is an electrokinetic reaction triggered by the formation of salt from the anionic dye with the cationic side of the fixing agent. The changes which occur while the dye reacts with the fixing agent are not completely explained. A chemical reaction must also be involved, i.e, bonds must be formed which give the whole dye/fibre/fixing agent structure new properties.

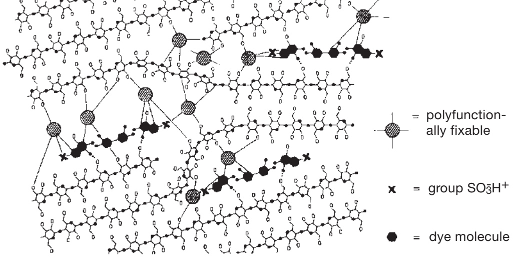

Fig. 2: The hypothetical fixing mechanism during dyeing with reactant-fixable dyes.

Reactions 1 and 3 must be catalysed by proton donors; Reaction 2 does not require a catalyst but takes place most efficiently in acid media. Evidence for the reactions mentioned can be obtained on the one hand by comparing the fastnesses achieved with state-of-the-art techniques (the new fastness specifications cannot be met even by the cationic post-treatment of direct dyeings) and on the other, by checking the individual reactions.

The crosslinking of cellulose fibres can be seen from the reduced fibre swelling in water or, for example, in 10% caustic soda. Conclusions can also be drawn from the stability of the bond achieved after repeated washings. The blocking of the water affinity groups of the dye can be confirmed by means of precipitation reactions between the reactant fixer and an aqueous solution of the dye or by analyses using chromatography. The new bonds formed between the fibre by the reactant fixer can be established by means of the DIF test (boiling in a dimethylformamide/water mixture), as is the case for reactive dyeings. It has been shown that only dyes with certain properties and groups in the molecule are suitable for reactant fixing.

Complete fixing is best achieved in the padder process with a 30 s condensation period (180°C) for dried goods. 80–130 g/l reactant fixer is used depending on the application, depth of colour, effects desired and substrate. All chemicals required for the finished goods, such as softeners, auxiliary aids, elastomers, hydrophobic or oleophobic agents and products to improve sewability, etc. are added to the dyebath at the same time as the fixing agent.

Reaction chamber Chamber, usually mobile, for heat and moisture treatment (hot air and steam heating) of piece ware batch rolls after padding with bleaching agents or dyes on a pad-roll machine.

Reaction, chemical Chemical conversion which takes place between two or more mutually interactive substances (atoms, atomic groups or molecules). The substances produced by the reaction are called reaction products.

Reaction product Substance produced by a → Reaction.

Reaction, rate of The rate of a reaction is equal to the change in concentration of chemical reactants divided by the time it takes for them to react and depends on factors such as the distribution of the reactants, their concentration and the temperature of the reaction. Because the rate of reaction, r, generally changes during a reaction, it is defined as the differential flux in concentration of a substance involved in the reaction divided by the stoichiometric number v_i (the reaction volume is regarded as a constant).

$$r = \frac{1}{v_i} \frac{dC_i}{dt}$$

where the stoichiometric number vi is negative for the reactants on the left and positive for the reactants on the right. The reaction rate of a generalised reaction

$$v_A A + V_B B + v_C C + ... \rightarrow v_L L + v_M M + v_N N + ...$$

is

$$r = -\frac{1}{v_A}\frac{dC_A}{dt} = -\frac{1}{v_B}\frac{dC_B}{dt} = -\frac{1}{v_C}\frac{dC_C}{dt} = \cdots$$

$$= \frac{1}{v_L}\frac{dC_L}{dt} = \frac{1}{v_M}\frac{dC_M}{dt} = \frac{1}{v_N}\frac{dC_N}{dt} = \cdots$$

If the external conditions (P, V and T) are constant, the rate of reaction usually depends on the concentration of one, several or all of the reactants taking part. The equation which describes this relationship is called a rate equation. For many reactions, it has been found empirically that the dependence of the reaction rate on the concentrations can be described by functions of the form

$$r = \frac{1}{v_i}\frac{dC_i}{dt} = k \cdot C_A^a \cdot C_B^b \cdot C_C^c \cdots$$

if it is assumed that the reaction goes from left to right only. The parameter k is the rate constant, the exponents a, b and c are partial orders and the sum of exponents (a + b + c ...) the order of reaction. The partial orders may be whole numbers or fractions; in general, they are not identical to the stoichiometric numbers. Thus, it can be seen that the overall reaction need not be identical to the reaction mechanism. → Reactivity in textile finishing processes.

Reactive and vat dyes on the fibre These behave differently on the fibre according to the following tests:

I. Solvent (→ Reactive dyes on the fibre, test for): Reactive dye = no or little bleeding; vat dye = significant bleeding.

II. Blank vat: azo-based reactive dye (usually red or yellow) = decolorizing or discoloration. The colour does not return to its original shade (unlike vat dyes).

III. Zinc chloride/nitric acid test (for phthalocyanide derivatives only, i.e, blue and green proprietary brands): reactive dyes react positively and vat dyes react negatively.

Reactive dyeing Reactive dyes form covalent bonds with the free neucleophilic groups of fibres. In the case of silk fibroins, the dye mainly reacts with the tyrosine residues which are located at the end of the crystalline zones. These present the dye with a hydroxyl group as the active counterpart. Here, there is a certain degree of similarity to the fibre chemistry of cotton. Other amino acids such as threonine and serine also present the dye with hydroxyl groups. As well as forming bonds with the hydroxyl groups, bonding also takes place via the amino and imino groups of the fibroin, lysine in particular. In spite of this, the N terminal amino acids and the amino acid histidine have other amino or imino groups available for bonding. Similar groups play a part in the case of reactive dyes for wool, but these are mainly amino groups. Cellulosic fibres also have OH groups.

There are two types of reactive dyes and these can be distinguished from each other by their reaction mechanism: those that react by addition and those that react by substitution.

1. Addition reaction of reactive dyes. On the one hand, these dyes react with the fibre via a nucleophilic addition reaction such as, for example, the vinylsulphone compounds. A prerequisite for reaction with the fibre is the formation or presence of unsaturated vinyl sulphones. These are produced from sulphonatoethylsulphone with the addition of an alkali. The active vinylsulphone can now react both with hydroxyl groups, such as those of cotton, and with amino groups, such as those of the fibroin of silk. Reaction with hydroxyl groups produces an ether linkage (R–O–R) without generating any side products. The reaction with the vinylsulphone group follows the following route:

$$\textcircled{F}\!-\!SO_2\!-\!CH_2\!-\!CH_2\!-\!O\!-\!SO_3Na + NaOH$$

sulphatoethylsulphone

$$\longrightarrow \textcircled{F}\!-\!SO_2\!-\!CH\!=\!CH_2 + Na_2SO_4 + H_2O$$

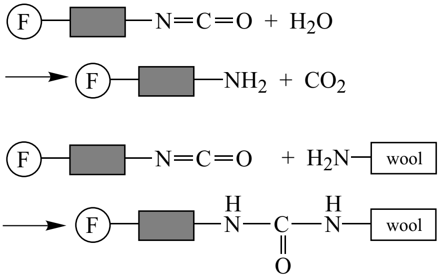
reactive vinylsulphone

$$\textcircled{F}\!-\!SO_2\!-\!CH\!=\!CH_2 + H_2N\!-\!\text{silk}$$

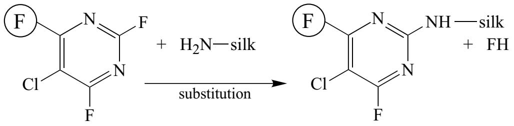
$$\xrightarrow{\text{addition}} \textcircled{F}\!-\!SO_2\!-\!CH_2\!-\!CH_2\!-\!NH\!-\!\text{silk}$$

An isocyanote active group can also react according to the addition mechanism (see structure).

2. Substitution reaction of reactive dyes. Nucleophilic substitution is another reaction route. In this case, the reactants are halogen-substituted, nitrogen-containing heterocyclic groups, the nucleous of which usually consists of a triazine or pyrimidine ring. These

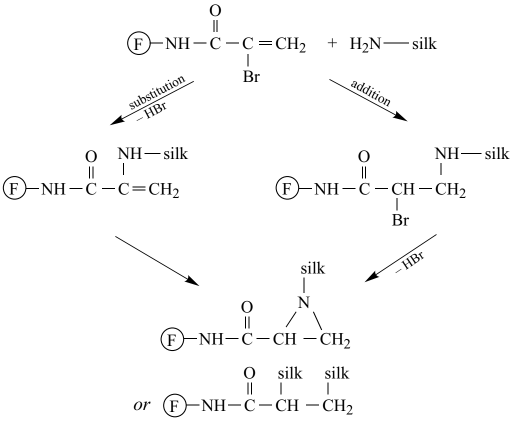


active groups are already available to react because the halogen atoms (chlorine and fluorine) are immediately replaced by an active basic group on the fibre:



The reactivity of this dye is determined by the active halogen atoms. Due to its reactivity, the fluorine atom in position 2 reacts first. The reactivity of the fluorine atom in position 4 is only high enough to take part in a second reaction with nucleophilic groups.

3. Combined substitution and addition reaction of reactive dyes. Dyes which react both according to a nucleophilic substitution and a nucleophilic addition at a double bond represent a special case. The active group is an α-bromoacrylamide. The end product of both reactions is the same aziridine three-member ring but theoretically, crosslinking of the substrate is also conceivable.



Another characteristic feature of reactive dyes is the number of active groups. In considering a monoreactive dye (dye A) with a selectivity of 60% (degree of fixing approx. 60%) and a dye with two reactive groups per molecule (dye B) each showing a selectivity of 60%, then the degree of fixing achieved by dye B in practice is 85% against the barely 60% achieved by the monoreactive dye, dye A (Tab. 1).

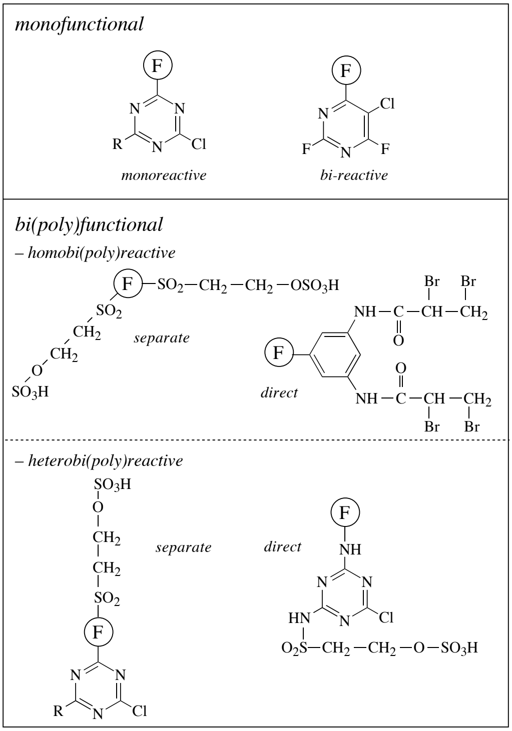
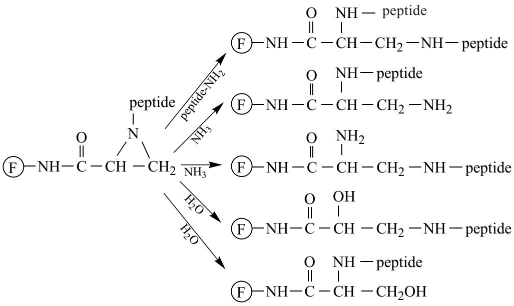
Tab. 1: Differences in the fixing yield depending on the functionality and the structure of the reactive dye.

Bi-reactive dyes are capable of producing the following reaction products:



In regard to the active site on the fibre, → Bi-functional reactive dyes are capable of anchoring at two sites on a single polymer chain or linking two chains together (crosslinking). No differences can be found between the two cases based on the fixing ratios or stabilities of the dye/fibre bond. In general, however, crosslinking leads to a significant change in the solubility of the polymer. Where the amount of fixed → Dual-anchor dye has exceeded a certain boundary limit, correspondingly reduced solubility has been established in the case of, for example, silk in 49% aqueous lithium thiocyanate. The two solubility curves shown in Fig. 1 represent a series of mono- or bi-functional dyes.

In order to achieve the high wet strengths required by the International Wool Secretariate, it is necessary to post-treat the reactive-dyed wool with alkali to wash out any non-covalent bonded fixed dye after dyeing at dye concentrations greater than 1% of the fibre weight. During this process, the pH increases from around 4.5 to 8.5 by addition of ammonia which leads to a sudden increase in the number of deprotonised amino functions of the lysine or ornithine groups by a factor of 10^3 to 10^4. This and the additional ammonia present and higher concentration of hydroxide ions make it possible for additional reactions to take place on the azidine system which lead to crosslinking of the fibre or hydrolysis of the azidine ring to give the following products:



The wash-fastness of a reactive dyeing does not only depend on the degree of fixing or the efficiency of the washing out of hydrolysed or reactive dye, which is still intact. The stability of the dye/fibre bond also affects the wash fastness according to the pH (Fig. 2).

Since the invention of vat leuco ester dyes, the emergence of reactive dyes in 1957 has been the most important event in the area of cotton dyeing and printing. For the first time, ICI and CIBA chemists were able to manufacture dyes which formed a genuine chemical bond with cellulose. A number of reactive dyes were characterised by a high purity of shade. In this, they were similar to cationic dyes but differed by their far superior fastnesses on cellulose. The fact that these dyes had a greater affinity to the hydroxyl groups of cellulose than to those of water was so surprising that the chemical reaction between the cellulose and the dye was doubted by some experts for a long time.

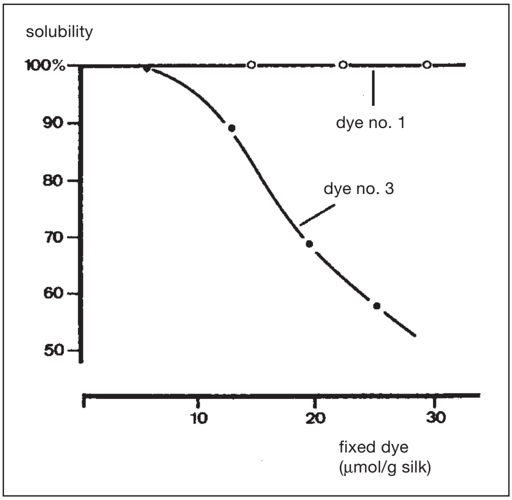


Fig. 1: The solubility of dyed silk in 49 % lithium thiocyanate in relation to the quantity of chemically fixed reactive dye. Dye no. 1 = monofunctional; dye no. 3 = dual-anchor dye.

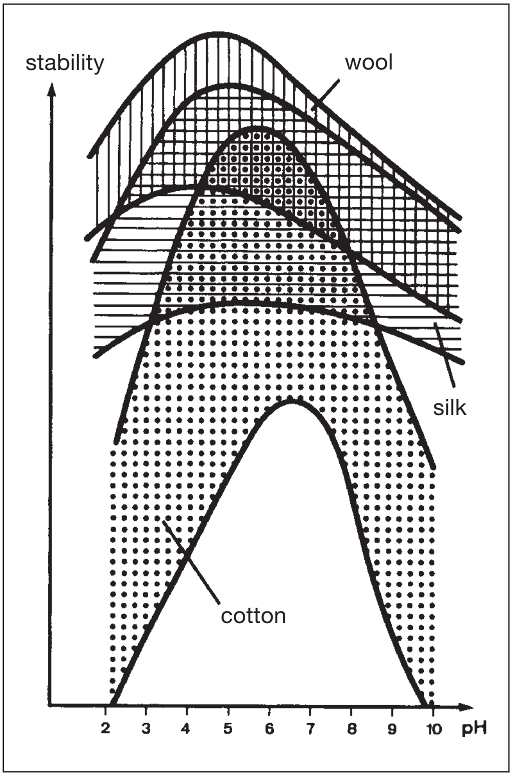

Fig. 2: Crude comparison of the binding stability of reactive dyes on silk, wool and cotton. Stability = reciprocal of the quantity of dye separated out in the stability test (according to Zollinger et al.).

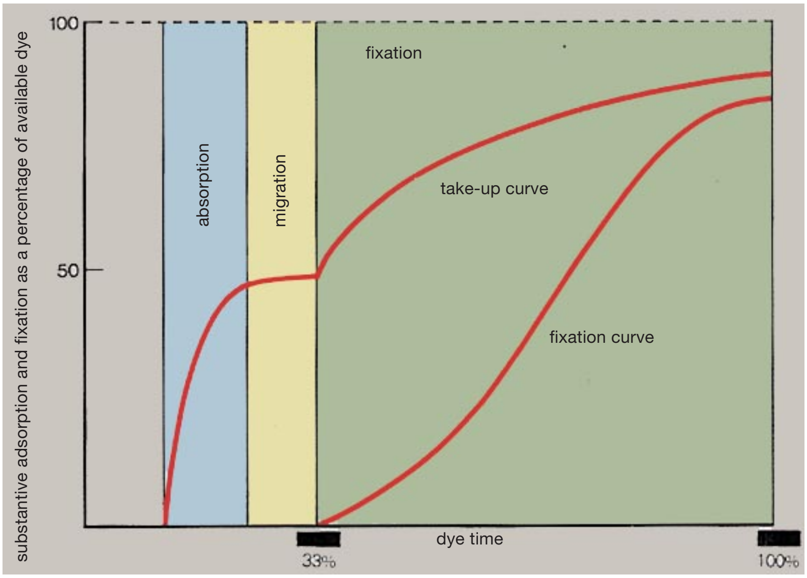

Fig. 3: The three phases in the dyeing of celloluse fibres with reactive dyes (sodium carbonate added at 33% of way through dyeing time) (by Bayer).

All reactive dyes have one feature in common: a colour-producing group or chromophore, usually an azo or anthraquinone derivative, and a reactive group. The application properties depend on both the chromophore and the reactive group, the reactivity of which is effected by, among other things, the reaction time. Thus for example, dichloropyrimidine dyes react significantly faster than monochlorotriazine dyes. The shade and substantivity both depend on the colour-producing group. The last mentioned determines, among other things, the ease or difficulty with which non-bonded dye is washed out after dyeing is finished. The substantivity of a reactive dye increases with the formation of reactive groups (for example, when alkali is added) and this alters the shape of exhaust curve (Fig. 3).

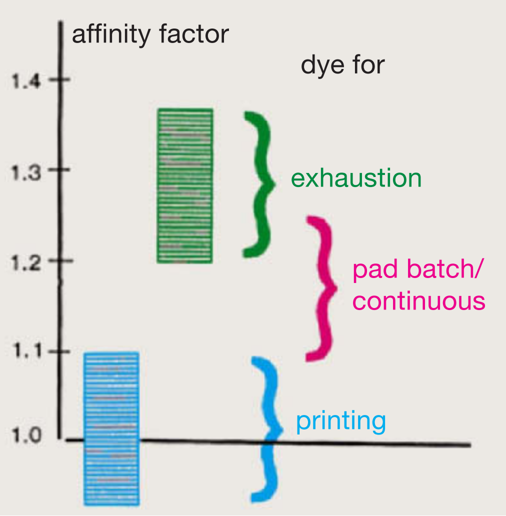

Fig. 4: The use of different affine reactive dyes in different colouring processes.

Optimised chromophores and custom-made reactive groups give the dyes a low to average affinity which considerably reduces the risk of tailing (difference in shade and colour intensity between the beginning and the end of the batch), dichroism and migration. Fig. 4 shows the affinity factors of reactive dyes intended for continuous dyeing (which characterise the affinity and therefore the tailing and combination ability), compared with dyes for the exhaustion process (which normally have a higher affinity) and dyes for printing (which must be of lower affinity). The reactivity of the commercial product varies according to the reactive group of the reactive dye used (Figs. 5–6).

Before the reactive dye which is being used in the exhaustion process (Fig. 3) attains its reactivity, it may migrate. The dye does not begin to react with the fibre until the reactive group has been activated (fixing curve in Fig. 3) and when the dye bonds to fibre it is no longer able to migrate (becomes immobilised).

The reactivity can be controlled via the temperature and pH. Both factors affect the fixing of reactive dyes because they influence the reaction between the reactive group with the fibre as they do with water. The reaction between the hydroxyl groups of the cellulose and the dye takes place via substitution or addition depending on the class of dye. The reaction proceeds in an alkali media. One exception to this is Procion T dye

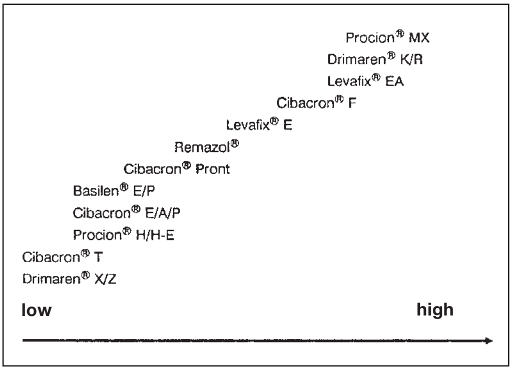

Fig. 5: The reactivity of various trade products.

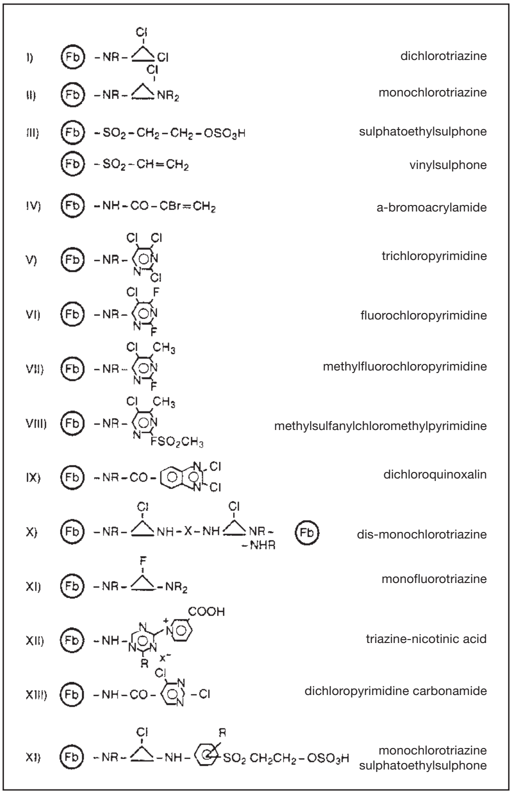

Fig. 6: Important reactive systems.

(ICI) which fixes both in neutral and in weakly acid media. This dye is never 100% fixed and requires greater quantities of alkali and/or higher temperatures to complete the bonding, depending on its reactivity (Fig. 7). The alkali used is either caustic soda, sodium carbonate, tri-sodium phosphate or waterglass, either alone or mixed together depending on the process.

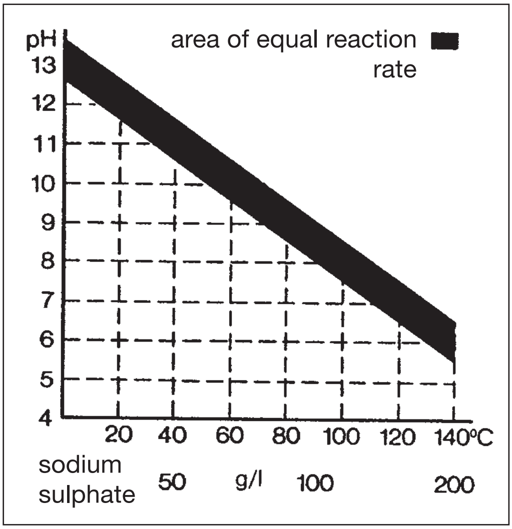

Fig. 7: The relationship between pH and temperature during the fixation of Levafix dye (Bayer) in exhaustion dyeing.

The degree of saturation on the cellulose is small for reactive dyes: less than $^1/_{100}$ of the available hydroxyl groups may be occupied. For this reason, the chemical properties of reactive-dyed cotton are no different to those of the undyed cotton. Small differences can, at most, be traced to the relatively high alkaline conditions required for fixing.

For this reason, reactive-dyed cotton fabrics can be treated with reactant resins and crosslinking agents, as are fabrics dyed by other methods. The stability of the bond between the fibre and the dye depends on the reactive group which also governs whether the resistance of the bond to acid or alkaline hydrolysis is high or low. The ester linkage, for example of mono or dichlolorotriaxine dyes, is stronger in the alkali range than it is in the acid range. With the ether linkage of vinylsulphonate dyes, the situation is reversed. Thus, the initially perfect wet fastness of a dyeing or print may be impaired if the goods are stored in acid atmospheres. The bond can also be broken at high temperatures (thermocracking). If a reactive dyeing is exposed to direct sunlight while wet, under certain circumstance, in a few cases the dyes may rapidly bleach (wet light-fastness). The chemical reaction between the cellulose and the dye does not proceed quantitatively (Fig. 8). Some of the dye is hydrolysed in the dye bath. Dye which has not been used or has hydrolysed must be washed out when dyeing is finished. Not until then does the dyeing achieve its wash-fast and non-bleed properties. The washing and soaping process is therefore very important.

Tab. 2: Processes for the application of reactive dyes to cellulose fibres.

Tab. 2 shows the methods of application used for reactive dyes on cellulose fibres. From this, the advantages of reactive dyes can be seen in regard to the range of shade and variety of application methods. This class of dyes has made possible completely new applications in piece dyeing, such as the cold-pad-batch process. The suitability of a reactive dye for a certain process is not only determined by the reactive group but also by the diffusibility and substantivity of the dye in question. These properties depend on the chromophore which accounts for there being dyes with different properties in every range of reactive dyes. Thus, some are suitable for both exhaustion and padder methods and others which are appropriate for just one or the other. The specific suitabilities are indicated by the class number of colour shade. Reactive dyes with different reactive groups should not be used in combination. Methylol compounds are special groups which are fixed in acid media. They can only be used in thermofixing processes.

The medium and high substantive dyes are the most suitable for the exhaustion process (Fig. 9). Despite this, they require fairly high salt concentrations in comparison to substantive dyeings. The dyeing and fixing temperatures vary between 30° and 40°C depending on the dye group. The alkalis used for fixing are sodium carbonate, sodium hydrogen carbonate, tri-sodium phosphate or caustic soda. With some classes of dye, dyeing and fixing are carried out at the same time (all-in), with others, the process is initiated by adding alkali after the period of dyeing is over. In a few cases, separating the exhaustion and fixing periods has its particular advantages, as in the case of dyeing-machine dyeing, when yarn packages which are difficult to penetrate have to be dyed, especially those of regenerated fibres. Fibre swelling is at its lowest at high temperatures where the rate of diffusion is at a maximum. In the case of the shortest and simplest but not always usable method, the dye, salt and alkali are added at the beginning, dyeing is started cold and the

Reactive dyeing

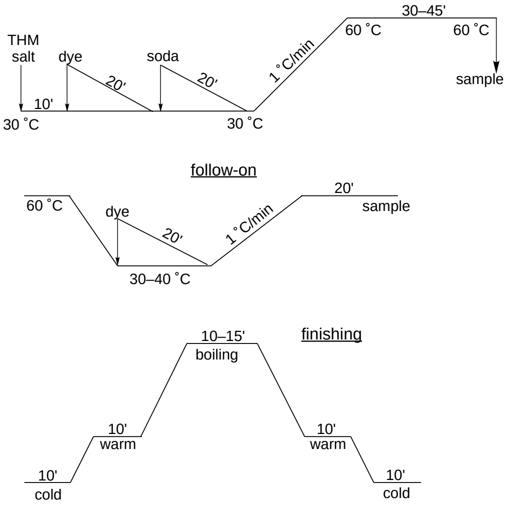

Fig. 9: The "all-in" process for dyeing cotton with reactive dye in a modern jet dyeing machine (by Bayer).

temperature raised later for fixing. In order to promote the actual reaction between the reactive dye and the fibre and suppress the competitive hydrolysis reaction, the reactive form should come into contact with water for the shortest possible time.

When analysing the reaction rates of hydrolysis and fibre reaction (Fig. 10) it appears that the slope for the fibre reaction is flatter than it is for the hydrolysis, which leads to the conclusion that the activation energy is less for hydrolysis. The distance between the slopes increases with increasing standard depths. This means that the portion of dye which becomes unviable for fixing in the case of processes where energy is added, i.e, hot-fixing processes, must be greater than that for processes carried out at room temperature.

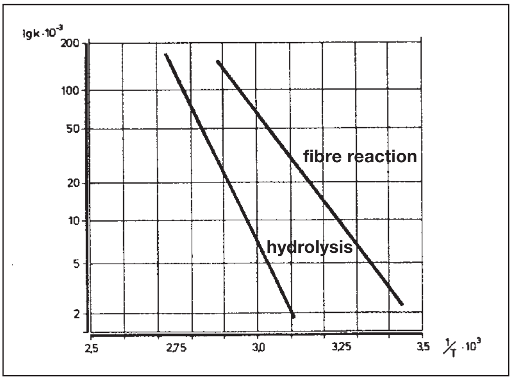

Fig. 10: The temperature dependence of the reaction rate constants for vinylsulphone dyes (Remazol, Hoechst).

Dyes which develop their reactive form under alkaline conditions only (vinylsulphonate type), can be optimised in this respect by temperature and alkali addition (Adcon/Then dosing system ADC 100). For the following reaction route:

$$\text{Ⓕ}-SO_2-CH_2-CH_2-O-SO_3H$$

ester form
low substantivity
no reactivity

$$\downarrow \text{+ alkali}$$

$$\text{Ⓕ}-SO_2-CH{=}CH_2$$

vinyl form
high substantivity
high reactivity

it is advisable to use automated, progressive alkali addition at constant temperature in order to avoid the rapid increase in fixing during the start phase which would otherwise give rise to the risk of uneven dyeings. Because the individual dyes in a range always have their own individual diverse dyeing behaviours, the fixing curve of a selected dye mixture can be controlled individually so that the alkali dosing curve is correspondingly flat or steep (Fig.11).

Thorough rinsing with hot water is important for good wet fastnesses. Cold water is sufficient only for the removal of salts. Reactive dyes which are suitable

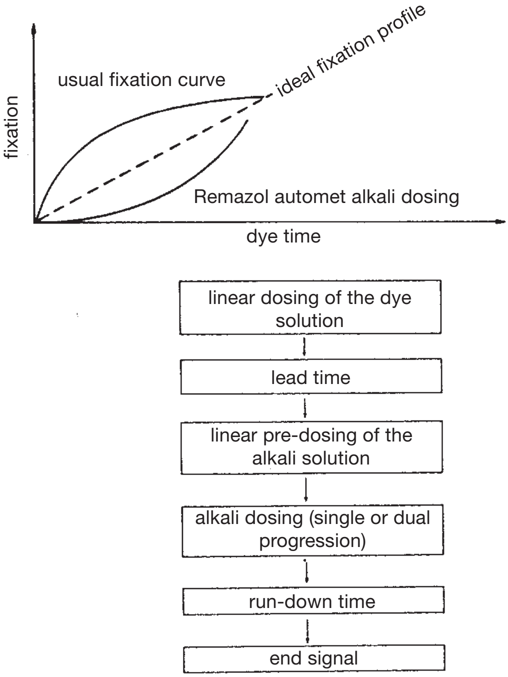

Fig. 11: Remazol automet, ADC 200; programming the entire dyeing process.

for the exhaustion process must have a certain degree of substantivity. As this depends on the chromophore rather than the reactive group, the hydrolysed dye also is correspondingly substantive and therefore more difficult to wash out than products with lower substantivity which are used in the padder process. Temperature, time and the number of bath changes have an effect on the thoroughness of rinsing. Post treatment using a cationic agent is frequently recommended for preventing subsequent deteriorisation in wet fastnesses caused by thermo-cracking, etc. This also fixes a small amount of the portion of hydrolysed dye remaining on the fibre after rinsing.

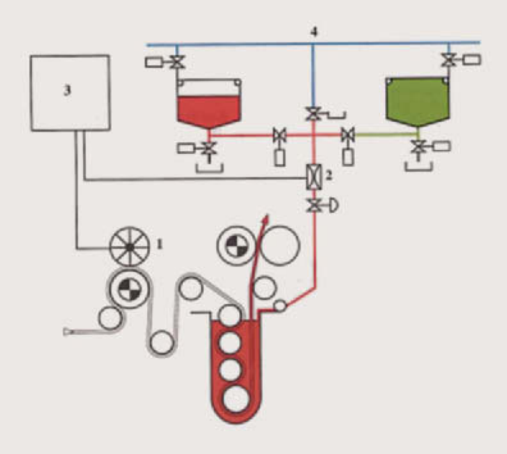

Fig. 12: The principle layout of dye liquor usage analysis for a pad dyeing machine: only an extremely small amount of active dye liquor is to be found in the padding trough. The dye solution (red) is activated with alkali (green) immediately before flowing to the trough.
1 = metre length counter; 2 = throughput metering;
3 = processor; 4 = water connection for automatic flushing (Küsters process technology).

Padder processes: the impregnation methods with their variations are numerous. Either the dye is padded together with the alkali or the dye is padded alone and then the alkali is padded afterwards. In the case of very reactive dyes, the first method has the disadvantage that the batches hydrolyse in the padder too quickly which means that mixing equipment has to be used for dosing (Fig. 12). The equipment requires precise monitoring and careful maintenance. All methods have their advantages and disadvantages. It must be left to the dyer to discover the methods most suitable for his works and quality of goods. The dye yield can be quite different depending on the method used, so this point must also be checked.

The cold-pad-batch method is of interest from the point of view of economics. The following relationship exists between bath stability and dwell time: with a low bath stability, only a short fixing time is possible but if the bath stability is high, a longer fixing time can be used. In order to achieve level dyeings with a short fixing time, the goods must first have an even absorbancy, i.e, the pre-cleaning must be particularly good. For large batches and long dwell times, the batches must not be allowed to remain in acidic atmospheres as this will give rise to light edges due to neutralisation. In order to achieve the optimum dyeing, the fixing time must not be too long or too short for the particular temperature in question. The dwell times range from 2 h (in the case of dichlorotriazine dyes) and 48 h (in the case of trichloropyrimidine dyes). The method is particularly suitable for dyeing knitware. Circular knitted goods in particular can be padded in the raw state, providing they are not contaminated. A wetting agent and retention aid must be added to the liquor. The dyeings are more level the longer the liquor remains on the goods (110–130%).

The padded goods can either be stored in box trucks or batch rotated. The washing, neutralising and soaping processes can be carried out on a single batch. These devices are equipped with a centrifugal pump for circulating the liquor. A two-step cold-dwell method with intermediate drying has been suggested to avoid the uncertainties in the bath stability. Padding is carried out during the first step with dye and during the second step with a waterglass solution. However, the drying which takes place between the two steps increases costs and can give rise to undesirable migration effects. In most cases, when using multi-component dosing equipment for dyes and alkali in the single-bath process, stability problems do not arise.

In principle, the dwell process can also be used for hank yarn and cross-wound yarn packages according to the dip/extract method using little in the way of substantive products. In the thermo-fixing process the dye yield is very good – even dead cotton is covered. Now and again, difficulties arise when there is insufficient ventilation in the condensation box. The urea vapour (hydrotropic agent) then solidifies in the box. Dicyandiamide, which does not vaporise so much, has limited use as a substitute due to its corrosive effect. Before heat treatment, the goods should already have a moisture content of 10–15%. The yield is greater in the presence of water. The conditions for fixing are 2–6 minutes at 140–160°C. Before the wash out, the dried goods must be protected from direct sunlight as certain reactive dyes are sensitive to light in the presence of alkali. Dyeing carried out in accordance with the thermofix method may have somewhat lower light and chlorine fastnesses than those carried out according to other application methods. For all processes using drying between stages, a migration-free operating dryer must be used.

The single-bath vapour method is of interest only when a large evaporator is available and background dyeing and print can be fixed together. In the case of fabrics which show high liquor-retention behaviour (cord and terry cloth, etc.) the method can also be carried out on pad-steam plants. The steaming may be by saturated steam or superheated steam. ICI and Artos have worked out a high-temperature wet steam method for high-reactive dyes. In the wet-heat-dwell method developed by Hoechst, fixing is carried out in an air/steam mixture with controlled moisture and drying temperatures in a steamer designed by Brückner with a steaming duration of 1 minute. In the pad-steam process, a loss in yield may occur under certain circumstances in the case of reduction-sensitive dyes. An addition of an oxidising agent is suggested to prevent this from happening. With all hot-fix methods, the specified temperatures and times must not be exceeded otherwise the fibre/dye linkage may break (deterioration of wet strength due to thermo-cracking).

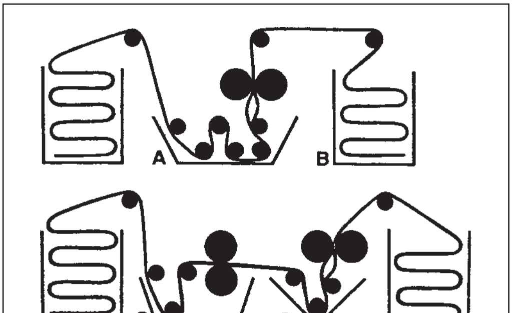

Fig. 14: Sequence diagram for the continuous Vicontin I process for tubular tricot (Sandoz).
A = dyeing process (soft rollers, ballooning); B = cold dwelling (16 hours); C = rinse (cold water, hard rollers); D = fixation with Indosol E-50 (soft rollers, ballooning).

When developing the VH-Tric-O-Steam method, Henriksen started by reducing the salt loading of the effluent while dyeing with reactive dyes. In the plant padder, a dosing system is used to apply 1.2 l/kg water, 20 g/l sodium carbonate and the dye (Fig. 13). The steamer is circulated with 75 l liquor which is maintained at a salt concentration of 250 g/l. In this case, the temperature of the liquor is 80°C while saturated steam at 103°C is used. The plant consumes 25 kg salt per hour for 300 kg tubular knitgoods per hour, and 23 l/kg rinse water for the washing out which follows.

Reactant-fixable dyes can be applied in the same way as direct dyes. The nucleus of these dyes contains groups which react with polyvalent fixers so that in addition to crosslinking the fibre, the dye bonds to the cellulose fibre, while the solubilising SO_3 groups on the dye are blocked at the same time. This fixing method produces high wet fastnesses and easy-care properties which make further resin finishing superfluous. Accordingly, there are two steps (Fig. 14):

step 1: dyeing with direct dye;
step 2: fixing.

Reactive dyeing, process control by metering

Three objectives are pursued when → Metering dye in the reactive dyeing process:

1. automation of the dyeing process,
2. matching of the addition functions to the distribution and mixing capacity of the machine,
3. control of the kinetics of the reaction mechanism.

Carrying out this three-point programme while using a simple linear addition controller when dyeing with reactive dyes is achieved by dosing by alkali. The course of the reactive-dyeing process is determined by the dye concentration, salt concentration, temperature and pH. In order to transfer the dyeing of specified laboratory formulations to an industrial finishing process in a manner which is reproducible, level and economic, the sequence of conditions which occur in the dyebath must be established exactly. As reactive dyeing processes are not defined according to the principle of dyebath exhaustion but by the fixing yield in % of the dye supplied, any change in the kinetic conditions of the reaction in the dyebath will result in a change in the final fixing yield. Because three dyes with non-identical substantivities and reactivities are generally used during the usual tri-chromic dyeing processes, the dyebath is subject to a continuous change in composition and reaction conditions throughout the dyeing process. The momentary reaction rates of each individual component is dependent on the pH at any one time. For this reason, reproducibility of results on an industrial scale can only be achieved by reproducing all of the steps in the process. This can only be realised by using a programmed sequence of process functions.

At the same time, the main problem in process control is the addition functions for dyes and chemicals. The supply and distribution of energy in the dyeing machines is regulated by heat exchangers. The addition of dyes and chemicals, on the other hand, has been carried out manually both from the time in the dyeing process and as a time function with insufficient adjustment to the mixing properties of the machine. Thus, the most important functions in the reactive dyeing process depend on the room for manoeuvre for each machine operator in making his decisions. Because reactive fixing is irreversible, differences in the kinetic behaviour of the reaction cannot be evened out later by long periods at high temperatures. Thus, the manual control of reactive dyeing processes demands a high degree of reliable operation and, therefore, a high proportion of cost in terms of labour.

For this reason, a change to controlling the reactive dyeing process exclusively by temperature as an all-in process took place early on. However, this mode of operation cannot be applied generally and has some disadvantages:

- When the goods are running badly and transfer and mixing is insufficient, the dye, salt and alkali are added at high temperatures.
- The amount of chemical used is high because more salt is required for fixing at high temperatures.
- The control route is only suitable for temperatures ≥ 40°C.
- The quality of the goods is impaired.

In order to dye at constant temperature, i.e, under constant running and transfer conditions, the addition of dye and alkali must be adjusted to the transfer, mixing and distributions characteristics, i.e, to the goods turnover and liquor circulation. Programmed addition of dye and alkali produces new process conditions in the exhaustion method. Programmable dyeing units are characterised by control valves, metering valves or metering pumps in moving or static goods depending on the dyeing principle.

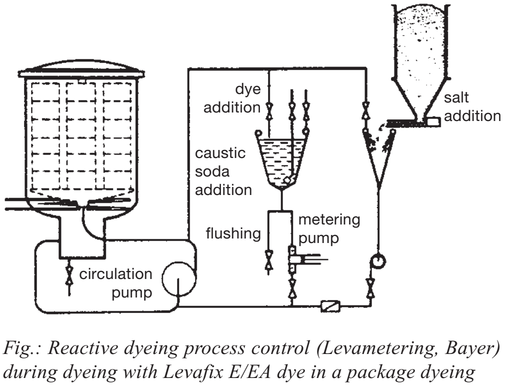

Fig.: Reactive dyeing process control (Levametering, Bayer) during dyeing with Levafix E/EA dye in a package dyeing machine.

When dyeing with or without liquor circulation or with or without static pressure, dosing is carried out directly using a distribution tube, via the addition vessel or in the main circulation stream on the suction side of the pump (see Fig.).

From looking at the metering processes which are required (Tab. 1), the automatic addition of solid salt must be achieved with a relatively high outlay in costs under the conditions which exist in most factories. There are basically two possible ways of adding the salt:

- before adding the dye,
- after adding the dye.

process types			process
I	II	III	
dye	salt	alkali	controlled pH
dye	alkali	salt	controlled salt
alkali	dye	salt	controlled salt
alkali	salt	dye	controlled temperature
salt	dye	alkali	controlled pH
salt	alkali	dye	controlled temperature

Tab. 1: The systematics of reactive dyeing; process sequences.

If the salt is added before the dye, it does not need to be metered. Automation can then easily be achieved by using brine. If the salt is introduced first, the dye must be metered in order to guarantee level absorption on at least 10 circulations of the goods.

If the salt is added afterwards, it is added manually as a solid or automatically by a solids metering unit. In the manual case, these additions are frequently progressive, for example, $^{1}/_{10}$, $^{2}/_{10}$, $^{7}/_{10}$. Mechanically automated salt dosing does not need to be progressive and can lead to real operating problems if the maximum delivery rate is over loaded in the steep part of the dosing curve. In this case, simple holding periods in combination with linear delivery are considerably more robust and more reliable. When dosing is complete, 40–70% of the total amount of dye is evenly distributed on the goods in the case of reactive dyes.

The second step, so-called fixing, is essentially easier to carry out. While the addition of dye is a function of time and represents a simple distribution function (because it takes place under conditions in which there is no reaction), the dye/fibre reaction starts with the addition of alkali. The addition of alkali determines the increase in pH in the bath and the final pH required for the fixing yield and fixing time (Tab. 2). The final pH at

colour depth	liqour ratio	salt g/l	NaOH g/kg	final pH 45 ˚C
1 %	1 : 5–1 : 15	5–30	10	11.0
3 %	1 : 5–1 : 15	40–50	11	11.1
5 %	1 : 5–1 : 15	60	13.5	11.2
> 5 %	1 : 5–1 : 15	70	15	11.4

Tab. 2: Reactive dyeing process control (Levametering, Bayer): Alkali metering in relation to colour depth and quantity of salt (temperature: 45 °C; water hardness: 0.5 g/l sodium hydrogen carbonate).

45–50°C is between 11.0 and 11.5, depending on the dye, and is correspondingly lower at higher temperatures. The amount of alkali required to adjust the final pH is determined empirically, and for normal industrial process water, must be adjusted by elementary measurements.

Programs are characterised as 1-, 2- or 3-step dosing programs according to whether it is 1, 2 or 3 additions which are made. The longer the dosing continues, the greater the certainty that the machine is applying the solution evenly on the fibre. For a dyeing time of 120–135 min, the dosing time is in the region of 60 min.

In comparison to the dilution and distribution capacities of the dyeing machine, the shape of the dosing curve is of secondary importance. During the development of metering technology, the time-dependent delivery characteristics were considered to be particularly important, in addition to selecting a suitable controllable pump. This has led to the drawing up of a whole family of curves for progressive and digressive metering programmes (source: Bayer).

Reactive (dye) printing Direct printing with reactive dyes. After suitable pretreatment, fabric or knitwear goes through the same sequence of operations for reactive printing as for any other printing processes (Fig.). However, when the reactive dye is used on a suitable fibre, such as wool, silk, cotton, viscose or polyamide, chemical bonding of the dye to the fibre during the fixing (steaming) process is assured. The after-print washing process increases the fastness of the reactive print because the dye which is not fixed is washed out. Reactive printing is then followed by a finishing process appropriate for the substrate.

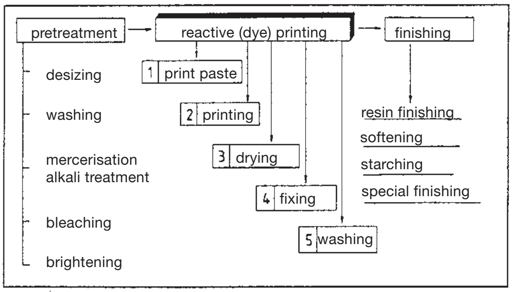

Fig.: The sequence of operations in reactive (dye) printing (by Hoechst).

Reactive dyes, compatibility The characteristics of a reactive dye for exhaustion dyeing are usually divided into its substantivity in the electrolyte phase and the exhaustion and fixing values after the addition of alkali. Fixing involves the formation of the covalent bond between the dye and the fibre. These characteristics significantly depend on the structure of the dye molecule and the reactive system. Thus, a homobifunctional monochlorotriazine dye (bifunctional reactive dye with identical reactive groups) is characterised by an average to high substantivity, a relatively low reactivity and a high fixing value. These provide an excellent profile of properties for exhaustion dyeing. Production which is to run properly at the first attempt requires even dyeing and the right degree of colour tone reproducibility. The “natural” property of bi-monochlorotriazine dyes of even dyeing can be attributed to their low reactivity which gives rise to a high level of migration. Apart from this, because the substantivity of the dye is high, there is a high proportion of dye which is available for diffusion into and out of the cellulose fibre during the neutral migration phase.

Using a linear addition of alkali to fix the dye on the fibre requires almost linear fixing behaviour during this phase. This can cause simultaneous secondary exhaustion and reduce fixing to a minimum, thereby reducing the danger of non-level dyeing. The compatibility of dyes with similar characteristics in combination produces exhaustion, migration and fixing properties which are similar to a single dye and maintains a similar dye angle throughout the whole process, thus ensuring that dyeing is even in the exhaustion process as well.

In the case of combinations of dyes for binary and ternary colour tones, the degree of compatibility of the individual characteristics and the interactions between the dyes must be taken into account. Dyes with molecules designed with the compatibility of characteristics in mind can at least be classified and are random variables during production. The behaviour of individual dyes in combination can be tested using on-line, through-cell light transmittance measurements.

Reactive dyes, Fibre-reactive dyes Dyes for dyeing and printing which have been commercially available since 1956 and which bond with substances via reactive groups (such as OH and NH_2). Reactive dyes are among the most important groups of dyes used for cellulose fibres because they give fast results and, to some extent, brilliant shades.

A reactive-dye molecule consists of a chromophore and a reactive group. The chromophore is the compo-

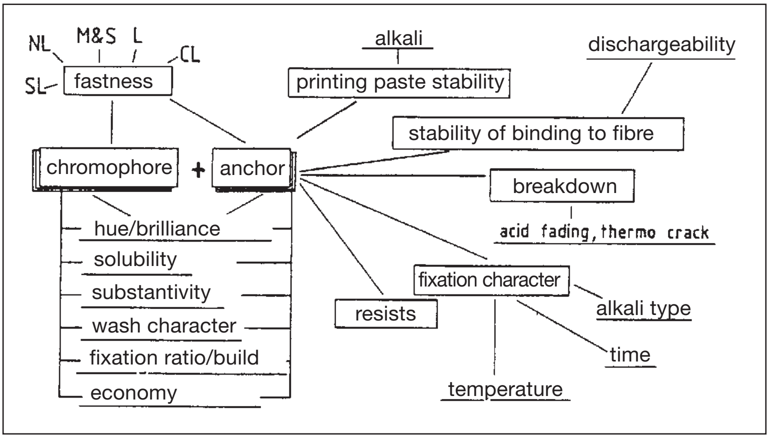

Fig.: Factors influencing the use of reactive dyes in printing (by Hoechst).

nent responsible for the colour, most of the performance characteristics of the dye (such as substantivity, wash-out properties and rate of diffusion, etc.) and most of its fastness properties (Fig.). The reactive group is responsible for bonding the dye to the fibre. It is therefore also responsible for the high wet fastnesses of reactive-dye dyeings or prints. The type of reactive group determines the reaction rate, saponification rate (reaction with water) and stability of the dye/fibre bond to acids or alkalis. Within a certain range of reactive dyes, however, differences are found between the dyes. Apart from their reactivity, reactive dyes can be classified into three main groups:

I. Cellulose reactive dyes.

II. Reactive dyes for wool, silk and polyamide.

III. Dispersion reactive dyes for polyamide.

The reactive dyes in Group I form covalent bonds with the fibre substrate in the presence of alkali (either ester or ether linkages depending on the nature of the reactive group) but not all of the available dye is fixed. Some of the dye reacts with water during the dyeing or printing process. In order to achieve the optimum wet fastness, dye which is not bonded (dye which is hydrolysed and cannot be fixed) must be carefully washed out. The dye/cellulose fibre bond can be hydrolysed in both acid and alkali media – the stability depending on the reactive group in the dye molecule. Hydrolysis results in a reduced wet fastness. → Reactive dyeing.

Reactive dyes in direct printing A universal class of dyes both in relation to substrate, cellulose fibres, wool, silk and with regard to processes.

I. Steam method: method most commonly used. Printing paste: dyes, urea, thickener, mild oxidising agent and alkali (sodium hydrogen carbonate or sodium carbonate).

II. Thermofixing method: as for Method I. but with more urea.

III. HT steam method: printing paste as for Method I. Fixing in flash agar (without padding liquor) or in the HT universal loop steamer at 140–160°C.

IV. Short-steaming method: printing paste as for Method I. Fixing by brief periods of steaming at 102–103°C. Method reserved for fast-reacting reactive dyes.

V. Print-dry method: printing paste as for Method II. Energetic drying at 140–160°C is sufficient for fixing. Only suitable for fast-reacting dyes on cotton.

VI. Print-lay method: printing method as for Method II. Leaving exposed to the air for several hours is sufficient for fixing (depending on the reactivity of reactive dye). Only suitable for fast-reacting dyes on cotton.

VII. Prepreparation method: printing paste contains no alkali and is applied to the goods before printing. Energetic drying at 120–130°C is sufficient for fixing. Only suitable for fast-reacting dyes.

VIII. Two-phase printing method: thickened dye (possibly with urea) printed on to substrate, dried, padded with alkaline solution containing electrolyte, steamed in flashagar for 20–60 seconds at 120–140°C without intermediate drying, then washing out. Variant: spraying the solution on instead of padding.

IX. Caustic shock method: printing paste as for Method VIII. Print, dry, treat in roller vat with boiling alkaline liquor containing electrolyte for 20–40 seconds and wash out.

X. Cold-pad batch method: printing paste as for Method VIII. Print, dry, pad with cold, strongly alkaline liquor containing electrolyte, roll up or fold. Fixing is achieved by storing at room temperature and then washing out.

XI. Steam-wet-fixing method: as for Method IX. However, short period of steaming before treatment in the roller vat. Preferred method for viscose.

XII. Print on naphthol-treated goods: reactive dye alone, with or in a mixture with diazo salts. Sodium hydrogen carbonate as alkali. Steam or caustic-shock method.

Reactive dyes in direct printing – fixation by hanging → Fixation of reactive dyes in direct printing by hanging.

Reactive dyes in discharge printing Used as coloration for white discharging, neutral or strongly alkaline discharging paste depending on the dischargability of the reactive dye. Used for vat dye coloured discharge pastes according to the usual sulphoxylate potassium carbonate method. → Discharge printing.

Reactive dyes in resist printing,

I. As a colorant: printing acid-splitting substances (such as ammonium chloride) which neutralise the alkali contained in the dye liquor and therefore act as a resist against the reactive dye fixing to the printed fabric (white resist). For vat dye colour reserving; method according to the usual sulphoxylate potassium carbonate process. Principle: print resist, dry rapidly, nip-pad in the padder with reactive dyes (printed side faced down), dry, steam for 5–8 minutes and wash.

II. As colour resists: a) with aniline black with increased amounts of alkali (e.g. sodium carbonate) as a resisting agent (possibly with additional zinc carbonate); pre-print or over-print resist. b) with naphthol with resist agents such as potassium sulphite, sodium hydrogen sulphite; preferred overprint resists. Formulation of pad baths according to the ammonium thiocyanate method.

III. As resin resists: white and colour resists (with reactive dyes) using pad dyeing method with reactive dyes. While reacting with the dye, the synthetic resin pre-condensate also reacts with the cellulose. This prevents the reactive dye from the padding liquor from fixing on the printed areas. Principle: printing paste containing reactive dye (or white pigment), synthetic resin pre-condensate, acid donor and emulsion thickener, dry, thermofix (at 180–200°C), nip-pad with padding solution consisting of reactive dye, urea and alkali, dry, thermofix and wash.

IV. Half-tone resists: pre-print of thickener and glucose or mat white. Overprint reactive dye is brightened.

Reactive dyes on the fibre, test for,

I. Boil for 2 minutes in 5% NaOH together with a cotton piece (mercerized). Zero to significant desorption of dye from the dyeing.

II. Solvent: dyeing for 3–4 minutes in each of the following solutions one after the other (with a cold rinse between each bath): glacial acetic acid and ethanol mixture (1 : 1), 1% ammonia solution, dimethylformamide and water mixture (1 : 1) and dimethylformamide. Staining of solution in the case of reactive dyes: slight or non existent.

III. Boil dyeing together with wool piece, with 1 ml concentrated sulphuric acid and 1g/l sodium sulphate calc. Wool coloration by ester-forming dyes (monochlorotriazine, dichlorotriazine and trichloropymidine dyes, etc.). No coloration by ether- and oxyethylsulphone-ester forming dyes.

IV. Boil for 2 minutes in a solution of 20 g sodium formaldehyde sulphoxylate, 50 g ethylene glycol and 150 ml water.

V. Heat slowly to boiling point in 10 g sodium dithionite and 10 g/l caustic soda.

VI. Observe colour change in cold solution of 100 g tin (II) chloride, 100 ml conc. hydrochloric acid and 50 ml water then slowly heat to boiling point and continue to observe colour change.

Reaction in the case of IV, V and VI: decoloration or colour change. With the addition of peroxodisulphate, either no change or no further colour change (return to original colour only occurs in rare cases).

VII. Tin (II) chloride/nitric acid tests: positive for phthalocyanine derivatives (blue and green marks).

Using these methods, practically all groups of reactive dyes and their individual brands can be identified. Black brands are tested and identified in a similar way based on their decoloration or change in colour after treatment with concentrated nitric acid, concentrated sulphuric acid, concentrated hydrochloric acid and tin (II) chloride/hydrochloric acid solution.

Reactive groups for dyes The chromophore component of a reactive dye produces the colour shade and determines its substantivity. The reactive group determines the type of bond between the dye and the fibre and, therefore, some of the dye's performance characteristics. In addition to the fastnesses, dye/fibre bond and performance characteristics, the reactive groups also determine the fixing value when dyeing with a reactive dye. Basically there are two types of reactive group:

1. The reactive groups which exchange basic nucleofuges for a dissociated hydroxyl group. Among these are the heterocyclic aromatics such as triazine, pyrimidine and benzopyrazine derivatives.
2. The reactive group which can add a functional group and a proton to the fibre. This group is represented by the vinylsulphones.

The trichlorocyanidine derivatives are the ones most used for the reactive component. The trichlorocyanidine ring has a deficiency in π electrons caused by the electronegativity of the nitrogen atom and, therefore, has a reactive halogen which can undergo nucleophilic substitution with an OH group on cellulose or an NH_2 group on wool or silk. The reactivity of the chlorine atom on the cyanuric ring decreases in stages, which explains the lower reactivity of a monochlorotriazine dye in comparison to a dichlorotriazine dye. For steric reasons, the nucleophilic substitution which takes place between the ring system and cellulose favours the formation of an ester linkage with the primary alcohol group (at position 6 on the glucose unit). In addition to the triazine derivatives, there are still other heterocyclic reactive components based on pyrimidine and benzopyrazine compounds. Of the last mentioned, only the difluorochloropyrimidine components have been introduced commercially. A significant advantage of the ester-forming reactive dyes is the stability of the bond to acids.

Among the reactive groups which form ether links between the dye and the fibre, it is almost only the vinylsulphone links which are of importance. The generalised formula for this group is as follows

$$\textcircled{F}-X-CH_2-CH_2-Y$$

X = $–O, –SO_2, –CO, –NH, –SO_2NH,$

$–NHSO_2, –CONH, –CH_2–S$

Y = $–Cl, –Br, –OSO_3H, –OPO_3H_2,$

In the case of vinylsulphone dyes, the sulphone group functions as the link member X. Aliphatic reactive groups preferably undergo substitution in two parts on cellulose as this is the most reactive. The reactivity of the dye is largely determined by the reactive group (Fig. 1).

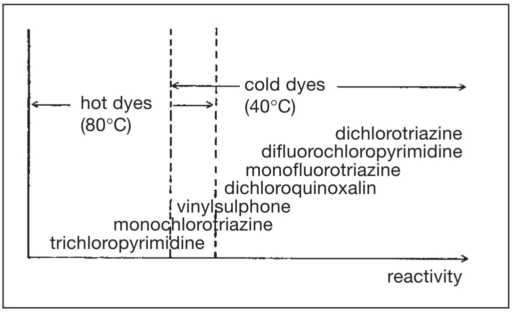

Fig. 1: The reactivity of the different reactive groups.

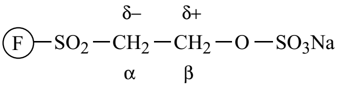
In organic compounds, a sulphone group causes the aliphatic residue to which it is bound to polarise so that the carbon atom in the α position to the sulphone group becomes electronegative and the β position becomes electropositive in character.



$$\textcircled{F}-SO_2-\underset{\alpha}{\overset{\delta-}{CH_2}}-\underset{\beta}{\overset{\delta+}{CH_2}}-O-SO_3Na$$

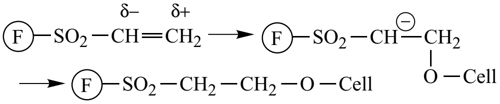
In the β-sulphatoethylsuphone the electron attraction of the SO_2 group makes this group easy to remove. In alkali media, this leads to the formation of unsaturated vinylsuphones:

$$\textcircled{F}-SO_2-CH_2-CH_2-O-SO_3Na + NaOH$$
$$\longrightarrow \textcircled{F}-SO_2-CH=CH_2 + Na_2SO_4 + H_2O$$

In alkali media, the reaction starts immediately and is necessary for the reaction of the dye with the fibre. The fact that cellulose is also activated in alkali media is an advantage:

$$\text{Cell}-OH + {}^{\ominus}OH \longrightarrow \text{Cell}-O^{\ominus} + H_2O$$

The cellulose attaches itself at the polarised vinylsulphone double bond. The nucleophilic cellulose anion, which is present in the alkali medium, attacks the positive polarised carbon atom and is added in the second step.



$$\textcircled{F}-SO_2-\overset{\delta-}{CH}=\overset{\delta+}{CH_2} \longrightarrow \textcircled{F}-SO_2-\overset{\ominus}{CH}-\underset{\displaystyle |\atop O-\text{Cell}}{CH_2}$$
$$\longrightarrow \textcircled{F}-SO_2-CH_2-CH_2-O-\text{Cell}$$

Two requirements must be fulfilled for this to come about:

a) an activated double bond

b) a labile proton.

In addition to the desired bond formation with the fibre, hydrolysis of the double bond in particular takes place as a competitive reaction:

$$\textcircled{F}-SO_2-CH=CH_2 + H_2O$$
$$\longrightarrow \textcircled{F}-SO_2-CH_2-CH_2-OH$$

The resulting oxyethylsulphone dye does not play any part in the dyeing process. The activated double bond of the vinylsulphone group is still viable for side reactions, such as those with amines and alcohols, which may also be present in the dye liquor. In comparison to the hydrolysis reaction already mentioned, the remaining competitive reactions only play a subordinate role.

Vickerstaff attempted to explain why the reaction between cellulose and the reactive group is dominant: the internal pH of the cotton is one pH unit lower than that of the dyebath, so the reaction rate of the dye ↔ fibre reaction is higher than that of the dye with the water. On the other hand, Hildebrand explained the strong preference for alcohol hydrolysis in comparison to water hydrolysis as being due to the higher nucleophilicity of the cellulose anions.

The ether-type β-ethylsulphone/fibre bond shows a greater resonance in comparison to acids, whereas the stability of the ether bond to alkalis under certain conditions is insufficient. This instability of the bond in regard to alkalis is a significant disadvantage for ester-forming reactive dyes. The cleavage of this bond in two parts by the sulphone group substituted ether proceeds

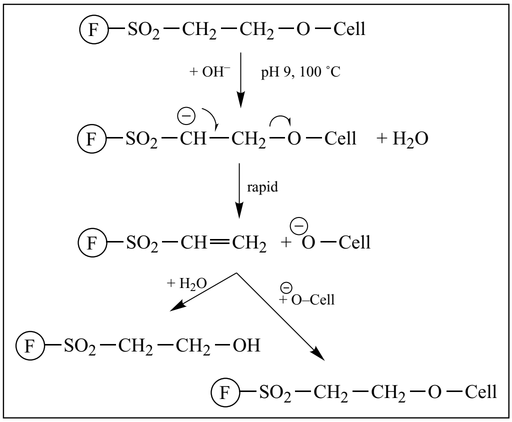


Fig. 2: The hydrolysis of a vinylsulphone dyeing.

via the vinylsulphone as the second step – the release of the proton from the carbon atom next to the SO_2 group being the rate-determining step (Fig. 2).

Undyed cotton may be soiled in a side reaction by the vinylsulphone which has been released. However, the low resistance to alkalis no longer represents a problem in today's applications as the sodium carbonate in household washing has been superseded by milder but more effective products which make boiling superfluous. Moreover, most vinylsulphone dyes are stable up at temperatures of 75°C.

In the acid pH range, the stability of the ether linkage is greater than the glucosodic cellulose bond. Thus, the cellulose will decompose before the ether linkage is broken. For this reason, it was possible to demonstrate the covalent nature of the dye/fibre bond by breaking down dyed cellulose to the glucose unit. The ether bond is so stable that it remains intact even in acidic, industrial atmospheric environments and at high temperatures. This group of dyes is therefore of particular interest in the case of polyester/cotton mixtures which are over-dyed with dispersion dyes at acidic pH.

In the presence of certain reducing agents, the azo groups on azo dyes are reduced to amines and the ability of the dye to form a bond is lost. This means that the dye can be stripped in the case of possible defective dyeings. With discharge printing, which is becoming increasingly important, the dyed goods are treated with alkaline reductive printing paste. This can break the azo bond and the alkali attacks the ether linkage at the same time (→ Dye cleavage products).

Unlike the ester-type bonding dyes, in the case of vinylsulphone reactive dyes, no decomposition products remain on the fibre during reduction when carried out in alkali media. In the case of → Bifunctional reactive dyes, the crosslinking is destroyed due to the effect of reducing agents. The properties created by cross-linking are lost at the same time. It is plausible that bifunctional reactive dyes have a greater opportunity to form covalent bonds than monofunctional reactive dyes, because the loss of one reactive group through hydrolysis does not prevent the dye from performing its actual function as a dye. Bifunctional reactive dyes are characterised by their outstanding fastnesses and the considerable comparative ease with which the shades they produce can be reproduced. Due to the higher degree of fixing, their washing out properties are significantly improved.

The degree of fixing of monofunctional dyes on the fibre is around 70% while that for bifunctional dyes can be as high as 98%. Within the range of products offered by dye producers, bifunctional or even polyfunctional alternatives are appearing more and more in addition to the monofunctional reactive dyes. Reactive dyes with at least two reactive components are assigned to new groups of dyes.

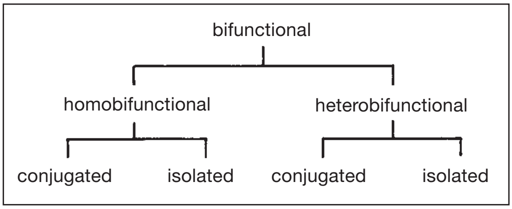

Fig. 3: The fixation possibilites of bifunctional reactive dyes.

Bifunctional reactive dyes are classified into two groups: the homobifunctional and the heterobifunctional dyes. These are subdivided again into conjugate-bonded and lone-bonded reactive dyes (Fig. 3).

The following bifunctional reactive dyes can be distinguished (R1, R2, are either identical (homobifunctional) or different reactive groups (heterobifunctional)):

Type 1: chromophore–R_1–R_2.
Type 2: R_2–chromophore–R_1.
Type 3: chromophore–R_1–R_2–chromophore.

Both aromatic heterocycles and vinylsulphones are used as reactive groups. The following combinations are known:

MCT/MCT	monochlorotriazine /monochlorotriazine
MCT/VS	monochlorotriazine /vinylsulphone
VS/VS	vinylsulphone /vinylsulphone
FT/VS	fluorotriazine /vinylsulphone
FCP/VS	fluorochloropyrimidine /vinylsulphone

In the case of bifunctional dyes, it is understandable that the number of reaction possibilities is significantly greater than it is for monofunctional dyes. In the case of simple reactive dyes, only two reaction products are really possible: the hydrosylate and the cellulose deriv-

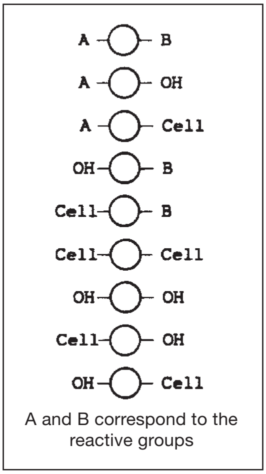

Fig. 4: The reaction possibilites of bifunctional reactive dyes.

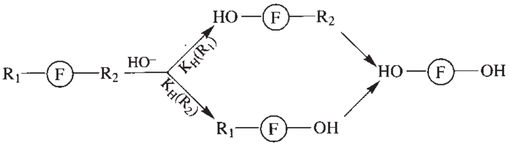
ative. Bifunctional dyes, on the other hand, can statistically produce eight compounds (Fig. 4).

The partial hydrolysis of the bifunctional dyes with water leads to two different secondary products. Total hydrolysis produces a uniform dye which can no longer react with the cellulose (Fig. 5).



K_H = speed constant of hydrolysis

Fig. 5: The hydrolysis of bifunctional reactive dyes.

The speed of all hydrolyses is equal to the sum of the individual reaction rates. For the heterobifunctional dyes, this is the sum of two different rates but for the homobifunctional dyes it is the sum of two identical rates. This indicates that bifunctional dyes could undergo a further undesirable reaction. In this case, several reactive dye molecules link together intermolecularly to form oligomers. Before a reactive dye forms a covalent bond with cellulose, it is absorbed on to the fibre by van-der-Waal forces. For steric reasons, it is possible for the second group of a bifunctional reactive dye to react with water rather than the OH group on the cellulose. Under these circumstances, crosslinking cannot take place although the dye is fixed on the fibre. The dyeing process in the case of heterobifunctional reactive dyes must be oriented to the specific properties of the reactive components. Thus, the vinylsuphone group of the MCT/VS combination has to react first before the slower monochlorotriazine group. The sequence for homobifunctional dyes is essentially of no consequence.

Bifunctional reactive dyes are a useful development from an ecological point of view, because the high degree of fixing means that the proportion of dye lost via the effluent can be minimised. This also means that the costly treatment of effluent contaminated with dye can, in some cases, be drastically reduced. For this reason, the increasing pressure from stricter environmental requirements will lead to the increased use of dyes with high fixing properties. In general, from an ecological point of view, attention must be directed towards the contribution of halogen-containing reactive dyes to the AOX value in effluent.

Using vinylsuphones in multi-anchor dyes is a good way to improve the stability of the dye to acids in particular. This reaction group differs from aromatic heterocycles by the way it reacts and, for this reason, can significantly increase the number of possible applications when combined with other dye reaction groups. The VS/VS group double-anchor dye is used especially in the marine/black range. This class of dyes is characterised by the benefit of its almost CPB fixing. The ease with which these dyes are synthesized and their efficient use makes the marine/black range of colour tones more accessibly economic than any other.

Reactive resin (reactive crosslinker, reactant). Resin finishing agents which, under certain crosslinking conditions, preferably react with cellulose and to a lesser extent with itself (unlike → Self-crosslinking resins) such as certain methylol compounds (e.g, → Dimethylolethyleneurea) or epoxides, chlorohydrins and divinylsulphones. For example:

$$-\mathrm{N}-\mathrm{CH_2OH} + \mathrm{OH}-\mathrm{Cell} \xrightarrow{H^+} -\mathrm{N}-\mathrm{CH_2}-\mathrm{O}-\mathrm{Cell} + \mathrm{H_2O}$$

$$-\mathrm{O}-\mathrm{CH_2OH} + \mathrm{OH}-\mathrm{Cell} \xrightarrow{H^+} -\mathrm{O}-\mathrm{CH_2}-\mathrm{O}-\mathrm{Cell} + \mathrm{H_2O}$$

Reactive sensitivity →: Detection limit; Limit concentration.

Reactive-under-reactive resists The properties of reactive dyes, which contain vinylsulphone groups, of reacting with sulphur dioxide and, because this reaction proceeds very quickly, of losing their ability to react with cellulose, are exploited. Reactive-under-reactive resists are achieved by combining reactive dyes, which are insensitive to sulphur dioxide, with compounds which release sulphur dioxide or sulphurous acids on slow heating, and printing this combination on sulphur-dioxide sensitive reactive grounds (Fig. 1).

For example, it is possible to pre-print using monochlorotriazine dyes and reactive resists under alkaline conditions (sodium carbonate) and produce the wet-on-wet overprint using vinylsulphone dyes. This is the simplest and most economic method of patterning. Wet-on-wet printing is of particular interest from the point of view of cost because there are no other machine costs involved, as this is a single print-run proc-

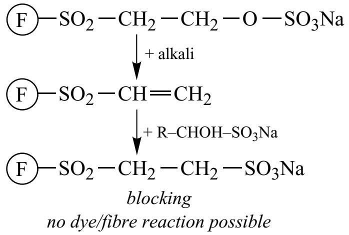


Fig. 1: The blocking of a vinylsulphone dye for the purpose of resist printing.

ess. Another advantage is the flexibility and speed of design. The wet-on-wet print is done so that the different resists can be pre-printed and then the grounds printed afterwards (Fig. 2).

Printing on dried ground padding is carried out so that the vinylsulphone dye is continually dyed as the ground (not dried above 100°C) and then overprinted with monochlorotriazine dye and reactive resist. Patterning using this method fully imitates classical vat-discharge prints. However, the following advantages of this reactive-resist printing method should be pointed out:

- simple handling (formation of halos in the case of high overdoses of resist),
- long shelf-life of pad baths which can still be used after several weeks storage,
- because the optimum pH is reached automatically, the padded goods can be stored for several weeks before they are printed,
- simple monitoring between drying and printing because boiling washout of the padding immediately provides information about resist capacity. It is therefore no longer necessary to dye test pieces, and good reserve capacity is ensured.

(according to Opitz).

Reactivity in textile-finishing processes A reaction in a homogenous system is described by the reactivity of the reaction components and in particular, by the restructuring of molecules through the dissolution and reformation of chemical bonds. The reaction mechanism describes the hypothetical behaviour of all atoms in the reaction. The reaction is force driven. In order to describe a reaction as precisely as possible, it is necessary to calculate the energy relationships of the educts and products. An energy balance, such as this, can be represented by an energy profile in which the abscissa describes the reaction co-ordinates which show the progress of the reaction quantitatively. The ordinate describes the (Gibbs) free energy G (sometimes identified as E) and indicates the thermodynamic stability of the educt or the product as the total energy content (vibration (wave) energy, heat content, kinetic energy and light energy, etc.). If G cannot be quantified in absolute terms then at least ΔG, the difference between free energy at the beginning and at the end of the reaction, can. This can be obtained either via the maximum possible yield of reaction products under the given reaction conditions or by a definition of the equilibrium constant K of the reaction as follows:

$$\Delta G = -RT \ln K$$

R = gas constant
T = temperature in Kelvin

According to the law of mass action, the equilibrium constant is dependent on the concentrations of the educts introduced and the concentrations of the products produced:

$$K = \frac{[P_1] \cdot [P_2]}{[E_1] \cdot [E_2]}$$

The equilibrium constant is temperature dependent. From the above, a negative value for ΔG indicates a

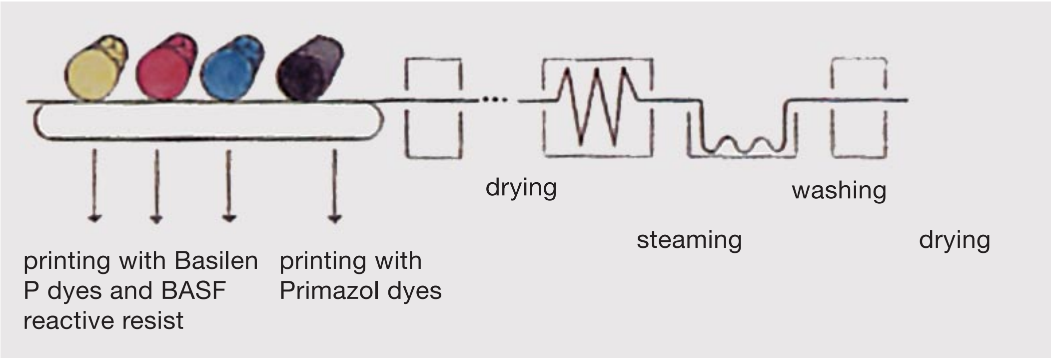

Fig. 2: The possible processes for resist printings (wet-on-wet with a ground).

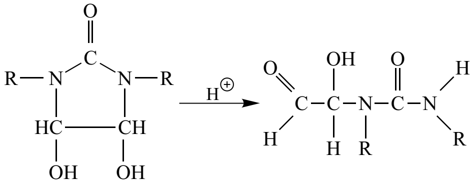
large product yield and a positive value indicates a small product yield.

ΔG, the free energy differs from ΔH, the heat energy or enthalpy for the reaction, but they are related to each other by the Gibbs-Helmholtz equation as follows:

$$\Delta G = \Delta H - T\Delta S$$

If the heat content of the educt is greater than that of the product, then the reaction is exothermic, and if the heat content of the product is greater than that of the educt, then the reaction is endothermic. S denotes the entropy of a system and ΔS is a measure of the difference in the degrees of order between the educt and the product. If ΔS is large, then the product is in a less ordered state than the starting materials. When a crosslinking agent is used in finishing cotton, for example, the acid catalyst may open the ring substance as a side reaction and the entropy increases, i.e, ΔS is large:



With a high negative value for ΔG the reaction equilibrium is almost completely moved to the right in favour of the products. However, strictly speaking it is assumed that even in this case a fraction of the product is taken up in the reverse reaction as every reaction is chemically reversible.

$$A + B \rightleftharpoons C + D$$

Because there are several possible reaction routes for each reaction, they show different reactions for the same educts, products and therefore, the same K.

The reaction route appears in the energy profile as the "energy barrier" or activation energy ΔG*. This is the energy required to bring the educts (and in the case of the reverse reaction, the products) and the atoms taking part in the reaction into a state suitable for the breaking and reformation of the chemical bonds. This does not represent any possible intermediate products. Normally, the overall reaction is made up of several steps each with their intermediate products because a single-step reaction would require far too high an activation energy for completion and would take far too long to yield the final products. As the reaction splits up into several stages, the activation energies for each stage are significantly lower which makes it possible for the overall reaction to take place via the individual intermediate products (in finite time). However, as the rate-determining step, the reaction component with the highest activation energy is crucial in defining the rate for the overall reaction. Generally, the rate is determined by the step which takes the longest, together with all the previous steps. In this connection, by taking part in the reaction, catalysts reduce the activation energy to such a degree that the reaction proceeds spontaneously (i.e, by forming a new transition state of low energy as the transition state for the non-catalysed reaction). Thus, hydrogen peroxide is relatively stable providing no iron ions are present to act as a catalyst for its explosive decomposition. Catalysts have a considerable effect on the speed of the reaction without changing the equilibrium position because, after taking part in the new transition, they are released as the products are formed and are able to intervene again in the reaction of educts.

The position of the equilibrium for a reaction can be influenced in the form of an increase in the yield by:

- removing from the homogeneous system of the reaction in solution one of the reaction products in the form of a gas or precipitate or
- adding one of the reaction educts to excess.

The equilibrium constant K is not altered by this but is altered by changing the reaction medium, for example, the solvent. In order to increase the rate of a simple reaction without using catalysts, it is possible to affect the rate constant k as the proportionality factor for the relationship of all concentrations taking part in the reaction:

$$k = \frac{k'T}{h} \cdot e^{-\frac{\Delta G^*}{RT}} \qquad ; \frac{k'T}{h} = A$$

k' = Boltzmann's constant
h = Planck's action constant

The rate of a reaction is defined as the change in concentration per unit of time. The rate with which a reaction proceeds in a single direction via its transition state depends on the concentrations of all the educts taking part.

$$[A] \rightarrow [Z]$$

For example, Z is formed as quickly as A is consumed. The decrease in [A] therefore equals the increase in [Z]:

$$-\frac{\Delta[A]}{\Delta t} = +\frac{\Delta[Z]}{\Delta t}$$

Because all reactions are reversible, the rate at which the concentration of a substance taking part in the reaction changes is always equal to the difference between the rate of formation and the rate of decomposition of this substance:

$$A \underset{v_{-1}}{\overset{v_1}{\rightleftharpoons}} Z$$

$$v_Z = \frac{d[Z]}{dT} = v_1 - v_{-1} = k_1[A] - k_{-1}[Z]$$

The following applies to the equilibrium state

$$\frac{k_1}{k_{-1}} = K = \frac{[Z]}{[A]}$$

By increasing the temperature of the reaction and therefore the energy content of the educts by activating a large proportion of the reaction components, the activation energy of the new increased initial energy level of the transition state will be lower and therefore the rate of reaction will be faster as ΔG^*, as defined by the equation:

$$k = A \cdot e^{-\frac{\Delta G^*}{RT}}$$

becomes smaller. Thus, the reaction rate can be increased by

- catalysts,
- increased temperature,
- increased concentration of reaction components.

The following pre-conditions apply to the reactivity of textile fibres which are to react with a liquor of dissolved educts in a heterogeneous system:

1. $\Delta G \leq 0$. Both the absolute energy content and changes in ΔG for the fibre modification are difficult to determine, which means that calculation of the equilibrium constant is also difficult. Therefore, exactly which reaction steps control the process is difficult to assess from the point of view of the kinetics and thermodynamics of the reaction.
2. In a heterogeneous system, the transport of educts out of the solution to the functional groups on the fibre substrate immediately precedes the actual chemical reaction so that the reaction-controlled process may actually become a diffusion-controlled process.

The heterogeneous system is further complicated by the fibre matrix where the transport is affected by laminar and turbulent flow. The reaction is characterised by the rate constant k whereas the transport phenomena are described by the diffusion coefficient D. The two parameters can be compared via the relaxation processes of both processes. In each case, this represents the time, within which, both processes subside to $^1/e$ (to be distinguished from the half life). For a simple first-order reaction, the relaxation (or decay) time is $^1/k$ and for the associated diffusion it is

$$\frac{L^2}{D}$$

where L is the average distance covered by a dissolved compound before meeting a co-reactant in the fibre matrix.

Semi-quantitative statements on the limiting relationship can be made as to whether

- a textile finishing process is influenced by the reaction and not the diffusion processes, i.e, is reaction controlled:

  $$\frac{D}{k \cdot L^2} > 1$$

  In this case, the breaking and making of bonds (according to the definition of the reaction) is the rate limiting phase.
- a textile finishing operation is controlled by diffusion processes but the actual chemical reaction is considerably faster once the educts have arrived at the functional groups:

  $$\frac{D}{k \cdot L^2} \leq 1$$

  In this case, the diffusion process is the rate limiting phase.

For solutions, small molecular compounds apply where the diffusion coefficients $D_{real} = 10^{-6}$ [cm^2/s]. However, those in porous substances become still smaller than the apparent diffusion coefficients because the free diffusion is superimposed by adsorption/desorption processes which slow it down ($D_{sch} \approx 10^{-7}$ [cm^2/s]. A typical rate constant for textile finishing reactions is $k = 10^{-3}$ [s^{-1}] (corresponding to a relaxation time of around 16 minutes).

As individual fibres represent a porous substrate with radii smaller than 10^{-2} cm, processes are reaction-controlled on individual fibres and the diffusion effects are not significant. In the fibre matrix, however, this situation can change crucially.

If the radius of the individual fibres increases above 10^{-2} cm, then the fibre will be populated from the outside inwards in shells. If the reaction is interrupted, the reaction will be found to have taken place in the mantle zone while the core of the fibre remains unmodified. This reaction can be accelerated by increasing the porosity of the fibre above the normal values (0.1–0.4).

An increase in the porosity of 100% will increase the apparent diffusion coefficient by a factor of 2.

Increasing the temperature does not have a significant effect on the diffusion process because of its low activation energy. Diffusion into the fibre matrix and into the porous structure of the fibre is accelerated considerably if the absorption processes can be suppressed. This can be achieved by

- raising the temperature,
- blocking the absorption sites, using compounds which do not actually take part in the chemical reaction, making it possible to prevent ring dyeing by the addition of levelling agents when dyeing cotton.

The amount of absorbed substance can be calculated when this substance is to react with the starting concentration C_0:

$$C_{absorbed} = S \frac{C_0K}{1 + C_0K + C_BK_B}$$

S = total concentration of absorption sites,
C_B = bath concentration of blocking agents (e.g, levelling agents),
K_B = absorption equilibrium constant of the blocking substance,
C_0 = bath concentration at the start of the reaction.

(according to Rys).

Reactor drum steamer Type of steamer with a large, teflon-coated, steam-heated steel drum (standard reactor drum steamers are 2.50 m diameter) over which the approx. 100% squeezed off fabric, which is to be treated, is run. The fabric is fully covered with a continuous overlapping rubber belt which seals it from the outside and provides a steam environment directly on the fibre, where it accelerates all the reactions taking place. An impregnating roller vat, padder and continuous washing machine can be added. Thus for example, it is possible to de-size broad widths of cotton fabric as a continual process (contact time 4–6 s at 130–135°C, fabric speed 75–112 m/min). The reactor drum steamer can also be used for steam fixing prints (two-phase print method) and for pad-dyeing with vat, substantive or reactive dyes or for condensing aminoplasts in a steam atmosphere (Manuf.: Monforts).

Re-adhesion Supplementary to → Strike through, in particular, the undesirable sticking together of two wrong sides of lining material which lie against each other, as in the case of external sandwich-fixing. It is the effect of steam from a steam iron or a steam ironing press or edge press within the temperature range of 100–130°C, for example, when ironing the lapel on a finished or semi-finished garment. This is particularly diadvantageous in the case of lapels when the wrong sides of lining materials are more or less stuck together and should be separated after ironing. Even if the coating is reduced, a small amount of re-adhesion is not entirely avoidable. Adhesives such as these have so far been based on polyamide copolymers. It will require a different adhesive system, such as a so-called non-polar based double-spot adhesive, to avoid lapel re-adhesion completely.

Ready for making-up A terms used for goods which combines the terms “pre-shrunk” and “decatized”. Ready for making-up goods are those which can easily be manufactured, ready for wear.

Ready-made curtains → Net-curtain fabrics in fitted sizes, 1–2 m wide and 2.5–4 m long.

Realgar → Orpiment.

Real net product Production costs, less payment in advance (purchased material and services).

Real-Wax → Batik printing; indigo styles in African print.

Rebatching steamer Steamers for wide treatment with two batchers which unroll and roll goods at the same time. Longer dwell times are made possible with a continuous run of goods. Rebatching steamers are designed for batches of 600 and 1100 kg dry goods and reaction times up to 2 hours. Used for desizing, drying off and bleaching cotton and cotton blends.

Recalcination Recovery of lime, for example, in the → Kaloz process (effluent treatment). The precipitation aid, lime (milk of lime), is recycled from precipitated sludge: the organic component is burnt and calcium oxide recovered while the carbonic acid produced is used for neutralizing the effluent.

Recipe scales The electronic scales prints out a record of the net weight together with the date, formulation no. and dye no. Weighing systems such as these are a valuable aid in monitoring formulations. They are available with ranges from 10 mg to 60 kg and include a dialogue weighing system for connection to a calorimetric unit and computer.

Recirculating tumble drier A combination of tumble drier and heat pump (single stage) (see Fig.).

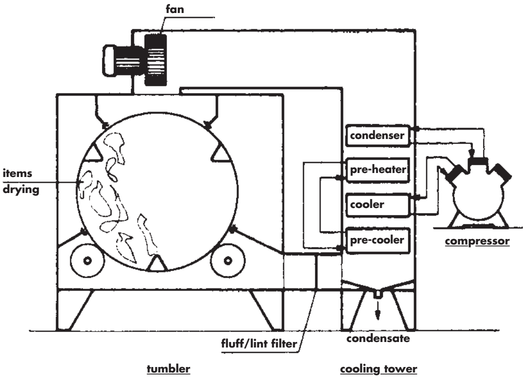


Fig.: Schematic of a recirculating tumble drier.

In contrast to a conventional tumble drier, saturated extracted air (still carrying a significant amount of energy) is not vented externally but instead ducted into an attached “cooling tower” where it passes over a “pre-cooler” and “cooler” and its temperature is reduced in stages to approximately +5°C. By lowering the temperature below the dew point, the major portion of the water vapour carried by the air is caused to condense out, resulting in a relative humidity of the air downstream of the cooler of only approximately 12–13%. This drier air is then warmed in stages by the “pre-heater” and “condenser” to 70–75°C and returned to the tumbler. The cooling of the air is achieved by means of a closed water circuit in the “pre-cooler” (pre-cooler/pre-heater) and by a refrigerant in the “cooler”. The refrigerant is drawn through the cooler by the compressor, expands within the heat exchanger piping of the “cooler” and in the process extracts energy from the air passing over the piping. The first stage in re-heating the dried air is achieved by the “pre-heater” by means of transfer from the water circulation it shares with the “pre-cooler”. Final heating is done by the condenser, whereby compressed refrigerant warms air passing over the condenser to a maximum of 75°C. Compared to a conventional tumble drier requiring about 6300 kJ/l of condensate, the energy consumption of a recirculating tumble drier, which requires only about 1700 kJ/l, is approximately 26%. These figures justify a slightly longer drying time (approximately 15%). The low drying temperature of the operation is of advantage for, in particular, natural fibres (wool, cotton) through improving handle, reducing yellowing and so on.

Reclaimed cotton (effilochées), cotton reclaimed from cotton rags.

Reclaimed fibre bonding with phenolic resins New textile off-cuts, textile ready-to-wear hosiery goods and washed rags are used as hard die-moulded components for special applications in car manufacture. The textiles are identified chemically according to quality and visually sorted in an elaborate process. In the reclamation process, the textiles are mechanically reduced to fibres. At 15–35 mm, the resulting reclaimed fibre is relatively long stapled. At this point in the technical process, it is possible to include additives or extra materials which either affect the manufacturing process or even impart special properties to the finished product. These may be fusers, scrooping agents, fungistats or water repellents.

The low melting point of the phenolic binder facilitates preliminary adhesive bonding of the raw nonwoven, which is necessary for handling the material. The grain size and the grain-size distribution of the resin powder in particular are important both for even distribution within the nonwoven fibre and the statistical frequency of bonding where the individual neighbouring fibres meet one another at a tangent. Additives can even be mixed with the resin which make it easier to work, or mixed with other additives, such as dust bonding agents or substances which affect the finished product, such as inorganic fillers; fire retardants (borates) and fungistats, etc. can be added.

The recovered fibre and phenolic resin powder are mixed in different proportions depending on the special requirements of the finished product. The usual proportions lie between 80 : 20 and 60 : 40 wt.%. The mixing itself is carried out by mechanical means (extreme homogeneity being necessary) separately or while the nonwoven is being formed. Formation of the nonwoven is achieved using either a mechanical or aerodynamic process or possibly a combination of the two. Carding machines (combing, etc.) and aerodynamic random-web machines are used for this purpose. In each case, the following are necessary for the formation of nonwoven:

- quality of the recovered goods in regard to type, degree of break-down of the original material, length, previous history and additives;
- performance in regard to degree of break-down of original material (uniformity) and rate in kg/hour;
- quality of the prefabricated component in terms of the uniformity of the physical properties.

The nonwoven is formed directly after the preliminary curing of the phenolic resin. During this time, the resin should on the one hand be partially adhesive bonded (in order to facilitate handling of the nonwoven) while on the other, retaining its latent capacity for chemical reaction during the final pressing process. Once the nonwoven has been consolidated in hot air, it is cut into panels and can be stored in this form for two months providing the temperature is less than 25°C. The pre-consolidated, plan-shaped, nonwoven panels are moulded under mechanical high pressure in heated moulding presses in which the resin (Duroplast), which is incorporated into the panel, is melted and finally cured.

Components without any defects are considered for a subsequent finishing process (Fig.). This involves coating them with polyvinyl film, stitch-bonded pile fabrics or tufting (previously provided by stamping) or something similar. Direct coating is carried out with pigmentation systems using pastes, Either from an aqueous phase or from a solution consisting of organic solvents. Either immersion or electrostatic spraying is used or a method along the lines of a curtain coater. During the laminating process, the fabrics are moulded to shape and fixed to the hard-pressed moulded component which is to serve as a base using adhesive. Mechanical shaping and vacuum techniques are in common use. Latent crosslinking adhesives, reactive adhesives and solvent-based adhesives are used for the fixing. They are sprayed on, coated using curtain coaters or printed on one or both sides of the substrate.

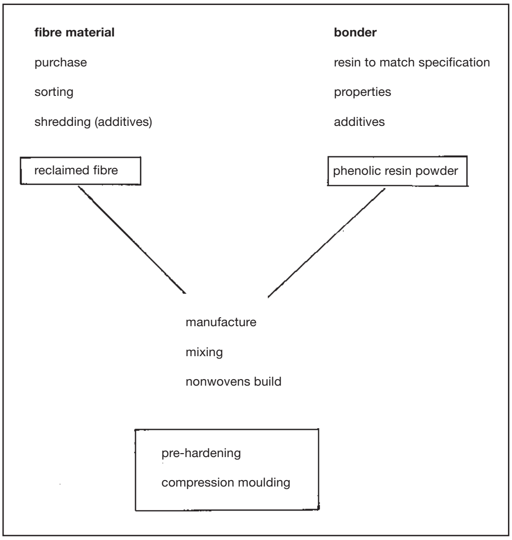

Fig.: The production sequence for the manufacture of hard compression moulded parts.

After complete curing, phenolic resins (phenolplasts) behave as typical Duroplasts. They are manufactured via acid or alkaline condensation of phenol, cresol, hydroxyxylene, other alkyl phenols or polyhydric phenols with aldehydes (preferably formaldehyde). The various different morphological states which the phenolic resin passes through on its way to complete curing are of particular importance in the process used for manufacturing hard-pressed moulded components. In practice, the transition between these states is smooth. These are as follows:

– A-stage: initial state, resinol (one-stage) or novolak (two-stage), liquid or fusible and soluble.
– B-stage: intermediate state, resitol, non-fusible but still mouldable when heated, swellable with low mechanical strength.
– C-stage: final state, resite, non-fusible, insoluble, high mechanical strength and high chemical resistance.

(according to Eisele).

Reclaimed wool Produced from various types of wool products, waste fibres from the spinning mill, weaving mill, knitting mill and hosiery mill as well as (→ Rags) domestic waste fabrics, waste new fabric from the weaving mill or tailoring shop, etc. Types of woollen spinning yarn recovered by mechanical processing (carbonizing and dyeing, etc.) are classified as follows: Grade I = shoddy; Grade II = Tibet; Grade III = Mungo; Grade IV = alpaca and extract and golfers.

Recontamination Contamination of fabric after disinfectant washing or disinfectant cleaning processes or an breakdown of these processes. Recontamination can be judged according to two types:

a) unavoidable recontamination by rinse water and ambient air, depending on the amount of adherent water and exchange volume, or lime sediments;
b) avoidable recontamination by machine operators and animals (insects).

Recovered wool (reused wool). Recovered wool is similar to → Skin wool but is produced from tanned pelt wastes and wool rags. The quality and extent of damage of recovered wool varies widely (inferior to fleece wool) and is dependent on the amount of wear-and-tear and degree of tanning. The material is therefore generally unsorted. The following disintegration processes are used to recover the wool:

I. Acid disintegration (treatment at the boil, cheap, quick, increased damage).

II. Enzyme disintegration (treatment requires several weeks, causes no further damage).

III. Vacuum steaming disintegration (virtually no damage).

Recovery and reuse in textile processing The → Recycling of operating materials and raw materials is becoming increasingly important in the textile industry. Examples of this are:

1. Water economy in a textile finishing works which may include the reuse of treated effluent (→ Waste water treatment).

2. Dyeing in a standing bath uses well exhausted dye liquors for the next dyeing of the same class.

3. After dyeing or printing a textile, chemical finishing is frequently carried out in order to impart special performance characteristics to the material. Multi-component systems are generally used for this purpose, i.e, a finishing liquor contains a plethera of different substances. For this reason, residual liquors cannot be used again in most cases. Appendix 38 of the German Framework Administration Regulation for Waste Waters (Rahmen-Abwasser-Verwaltungsvorschrift) is particularly relevant to the use of residues in textile finishing. The possible reuse of finishing liquors is therefore of great interest.

4. The reuse of textile effluents as operating materials may also be appropriate, for example:

– in collar linings (blended textile),
– in dusters (not products made from filament yarns),
– in moulded components in the car industry (identical grades or similar grades of textile are better for reuse than blended textile),
– in sound insulated walls (blended textiles),
– in park benches (identical grades of synthetic materials),
– in heat-insulation materials in residential buildings (blended textiles; fire protection)
– as a raw material in a textile fibre recycling process (identical grades of synthetic materials, undyed;

cotton waste in viscose production and cellulose processing).

Recovery capacity of fibres All fibres under tension (→ Tensile elasticity) experience tensile recovery which, at least, to some extent, can be reversed (except in the case of an invevitable albeit normally very small degree of irreversible elongation). This is the so-called elastic recovery or secondary effect, the quantitative comparison of which between different fibres is significantly dependent on the conditions under which the extension and relaxation takes place. The recovery capacity of fibres is related to the magnitude of the force applied, its duration and the time available for recovery. → Relaxation.

Rectification Special type of solvent distillation used for solvent recovery where high levels of purity are achieved by multi-stage evaporation.

Recuperative energy recovery → Heat recovery.

Recuperator (Lat.: recuperatio = recovery), preheater, heat accumulator, → Heat exchanger.

Recupra process Used for the recovery of polyacrylate finishes. BASF/Benninger process (→ Recycling) facilitates recovery of 60–80% of the coated finish. The goods to be desized no longer pass through the desizing bath. Application is by small counter-rotations in three stages and squeezed out and concentrated in a heavy press. The remaining desizing can be combined with the next finishing stage.

Re-Cure (recuring permanent press process). It is a variant of the pre-cure process (→ Permanent press process). Fully cured synthetic resin coatings (aminoplasts) are partially hydrolysed by subjecting them to particular cycles of steam ironing ("re-crosslinking" the cotton component) and curing them in the new shape simultaneously. This produces wash-resistant creases and fitted shapes and can be used to bond, for example, the polyester component by thermo-plasticization. Principle: ready-to-wear manufacture, pre-cure-finished goods, then steam on special ironing presses, dry by extraction and subject to conditions for post-condensation at 180°C for about 20 seconds.

Recycling Recovery of used raw materials for re-use in a similar or different form. In order to make a contribution to overcoming the problems of waste production, recycling concepts are being sought in the textile industry in addition to the strategy for the avoidance of waste. In the clothing industry, apart from the efforts to build up collections using biodegradable textiles, attempts are being made to control the logistical route for packaging films and clothes hangers in such a way that it will be possible to re-use them. Increasing numbers of driving licences means that there is an increasing number of old cars. The environmentally friendly disposal of this scrap has become more important with the increasing proportion of plastics. The reprocessing of worn-out vehicles and their components is also a requirement for preserving global reserves of raw materials. Reprocessing means the recovery of raw materials and reintroducing them into production. The term "recycling" describes this figuratively in the sense of a circulation of materials. The following distinctions are made between the different forms of recycling (for example, of vehicles):

1. Direct recycling: the raw materials are recovered from vehicle components and used in the manufacture of new vehicle components. The most familiar example of this is the recovery of steel from vehicle scrap or recycling of PVC-based composites (Fig. 1).
2. Indirect recycling: old vehicle components are recovered, processed and used for other industrial purposes not in the car industry.
3. Inverse recycling: while 1 and 2 represents the recycling of vehicle waste which is re-processed for manufacturing purposes, it is also possible to use particular recycling components for vehicles, the recycled raw-material of which has come from other manufactured goods. In this case, the circulation of materials is in reverse (inverse).

I. Recycling fibres: recycling includes both in-house routes as well as used textiles. If these are composed of natural fibres, there are no problems – wool is used to produce shoddy and silk is used to produce schappe or bourette. Even in the case of cotton, recycling should be possible in the OE spinning process. Fibre dust from spinning mills can be used in nonwoven products. Thermoplastic synthetic fibres can be turned into granules.

In a few areas in the textile industry, waste materials have always been reprocessed (for example, shoddy). When waste materials (or secondary raw materials) are re-introduced into textile production, the type of material used must be matched with the article being made. A whole industry emerged a long time ago for mastering the distribution between the volume of secondary raw material and material requirements and, if the preparation of raw materials is included, even an international, secondary raw-material textile industry. The terminology used for the materials was introduced internationally and is understood worldwide.

Collections of old clothes are sorted into those which are in good condition and distributed for social purposes until they are worn out and those which cannot be used any longer. These are disintegrated by an opening machine and used again for textile purposes (shoddy). The reprocessing of textiles by tearing has been carried out on an industrial scale for more than 100 years. So-called reclaimed fibre has also been processed with plastic as a binder for twenty years. Another development has now opened up possibilities for numerous applications for this combination of materials, particularly in the car industry.

An example of this is phenolic-resin bonded non-

wovens made from reclaimed fibre which are in use at densities of 50–100 kg/m^3 and weights of 500–1200 g/m^2. In the form of flat stampings, self-adhesive combined with thick solids, they are used to absorb airborne sound or vibration. They are always applied to the lower surface. Preformed components of similar composition (with or without textile covering) have been used for 10 years. Sometimes covered and sometimes visible, they serve equally well for sound absorption and, if necessary, in the form of self-supporting elements. With densities ranging from 100–250 kg/m^3, their handle is therefore more-or-less soft, elastic on compression, or firm. The following is a list of applications in car production:

- engine bonnet insulation,
- end wall insulation,
- panel insulation,
- leg space (up to the bulkhead),
- tunnel covering,
- wall, dividing the boot from the passenger area,
- floor of the boot and roof deadening.

Spacing fabrics with decorative side are knitted fabrics used for cowlings or other places in the vehicle and are given a padding effect during manufacture. Additional layers of polyurethane foam, separate backing fabric or nonwoven, and the entire prefabrication process becomes superfluous. Thus, this is economic in the case of items specially developed for special applications. For articles such as these, the huge diversity of possible patterns with yarn-coloured material on the decorative side appear to be a promising route for the future. After successfully concluded trials, materials such as these were used for the inner-lining of cabrio-hoods from 1992. For the purpose of sound and heat insulation, the hood is put together in three layers: the external layer, which is a three-layered hood material, then a thicker coarse fibre felt and finally an inner lining. However, spacing fabrics will be found in a broad range of uses as

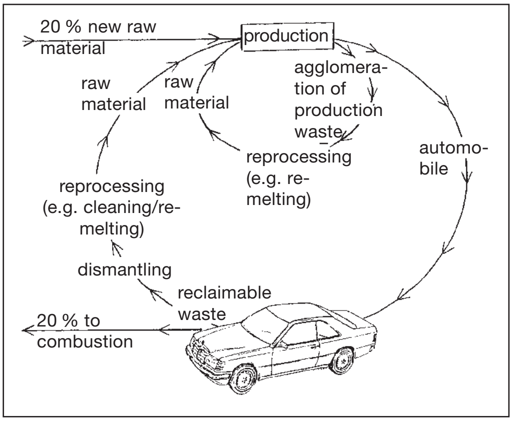

Fig. 2: The cycle for the recycling of production waste and used materials from automobile interior fittings.

a covering fabric and will first be seen on pillars, door linings, seat-back covers including the pockets, seat-base coverings as well as the inner lining of the roof as the main areas. It will not be used for hat racks or possibly instrument panels and seat covers until the testing and optimization phases are over. It is of particular interest because of its decorative finish and outstanding permeability to air (an improvement on seat air conditioning in comparison to polyurethane-foam pre-fabricated parts). These types of covering components for the internal furnishings can be pure grade and yet manufactured as a laminated product. The two resulting recycling processes – production waste and used material – are shown in Fig. 2. Theoretically, this means waste-free production and utilisation of resources introduced just once. In practice, it would be good if 80% is recycled and 20% is new material with 20% burnt to produce so-called recycling energy. This would correspond to a total of 6 1/2 cycles in the recycling process (five cycles in used-material recycling and one cycle (corresponding to 5 x 20% waste) in the production waste circulation, and one half use for combustion).

II. Recycling effluent constituents: in the textile industry, apart from heat recovery and the use of secondary growth raw materials (vegetable and animal fibres, natural thickeners, etc.) it is also possible to recycle water and textile auxiliary aids such as sizes. Recycling process water in its entirety is a comprehensive solution for conserving water resources and taking account of the water resources law, which also restricts substances in effluent which is discharged indirectly. In the meantime, apart from mechanical-biological clarification, a series of methods has become available for reprocessing, in which case, combinations of oxidation, adsorption and precipitation phases have proved to be successful.

Total recycling of process water is possible, for example, by distilling the effluent or reintroducing condensation. When recycling process water which has been purified, the residual organic content can be neglected. On the other hand, the effect of salts on process control and the specified finishing objective is regarded as definitive. These salts are essentially the non-precipitating or partially precipitating alkali and alkaline earth (Group I & II metal) salts of chlorides, carbonates and sulphates. Although so-called salt accumulation during treatment does not have to be performed by the purification process itself, this has been unavoidable when trying to introduce re-circulation. A demineralization step would basically resolve this problem but this would involve a considerable increase in cost.

Envi-col-ex method (Fig. 3): The heavily loaded effluents (liquors and baths, etc.) are fed into special buffer and holding ponds and extracted by level control and then fed to processes where they are treated fully automatically. The process consists of flocculation/adsorption treatment which preferably removes dyes, hydrocarbons and particulates. The resulting slurry-free water can either be discharged into the drains directly or returned to the plant as recycled water via a fine neutralization step and adsorption treatment process. Rinsing waters which are not heavily loaded flow via a heat-recovery plant into separate buffer and holding ponds from which they are extracted via level control and returned to the plant via a continuous neutralization and adsorption unit. The activated carbon adsorption step in the percolation process selectively removes the organic lipoid constituents (hydrocarbons and dyes) so that these waters can be re-used for rinsing purposes. If the waters are not required for re-use, they can be discharged into the drains in compliance with the law without the need for an adsorption treatment step. With the special decoloration flocculation method used in the Envi-col-ex process, both the genuinely dissolved dyes (such as the reactive or vat dyes, etc.) and the dispersion and pigment dyes as well as hydrocarbons can be extensively removed at minimum cost. Harmful substances are removed using methods which are based on adsorption and precipitation and, depending on the composition of the effluent, these reduce the chemical oxygen demand (COD) or total organic carbon (TOC) by a considerable amount.

III. Recycling liquor residues: an important aspect in print shops and the dyeing of textiles in continuous

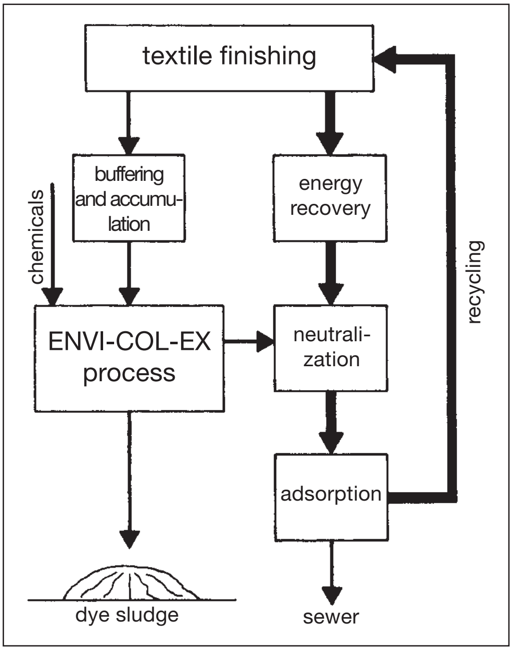

Fig. 3: Waste water processing scheme for the textile finishing business (Enviro-Chemie AG).

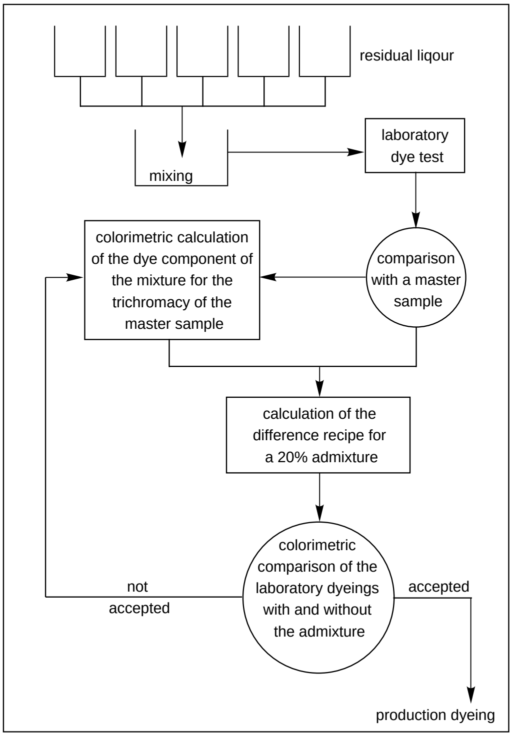

Fig. 4: The recycling of residual liquor in pad jig and pad steam dyeing by including a maximum 20% contribution of residual liquor to the mix in preparation for the following batch (according to Marzinkowski).

plants is the re-use of residual print pastes (print-paste residues) or residual liquors. In the case of pad-jig dyeing of viscose linings for example, up to 10% of the liquor results in residual liquor (Fig. 4). It consists of residues from the padder trough (in spite of the economy trough) and a "safety pool" as the liquor pick-up may vary due to fluctuations in the composition of the material. The discharge of this residual liquor not only means high loading for the effluent but a loss in terms of unused dye. However, as the residual liquor from the padder trough contains an unknown concentration of dissolved size, its re-use so far has been very rare and is usually confined to black dyeing. However, it is possible, using colorimetry and interdisposed laboratory dyeings, to re-use any mixtures of residual liquors. The mixture is first used for laboratory dyeing. This is then compared with the pattern of the next larger production batch which should be as close as possible to the colour tone and shade of the mixed dyeing. A recipe is calculated colorimetrically for the dyes in this pattern so that dyeing can be carried out using the mixture. Using this recipe, the amount of dye can be calculated while taking a maximum of 20% of the mixture into account in the new batch of liquor. This is dyed again and compared colorimetrically with a dyeing without making allowances for the mixture. This procedure is necessary because the concentration of dye at the end of the padding process is different from that at the beginning of the treatment. There are limitations in the method in the case of brilliant and pure colour tones. This must be taken into account before mixing. As well as this, several collection and mixing tanks must be available. The fact that not more than 20% mixing liquor can be worked into the next batch also has to be taken into account, otherwise sizing components and spin finishes contained in the mixing liquor will have a detrimental effect on the result. This method of recycling liquor residues is also more labour intensive.

Multi-use of dye liquors is only possible to a limited extent. When dyeing in standing baths, which is only possible for similar sequential dyeings, the chemical consumption during the first dyeing is increased by corresponding subsequent additions of reducing agents. However, as it is not possible to remove the secondary products of the reducing agents, the chemicals continue to concentrate in the liquor. Using dyeing liquors for different colour tones and complete recycling is currently not possible.

IV. Recycling sizes: In Germany, sizes are recycled according to two methods:

a) In the "wash-out method" a recycled product with increased liquor concentration which can be used for sizing is produced by modifying the conventional washing process. However, the recycled product contains only a part of the total amount of sizing agent to be dissolved during the pre-treatment. The term used therefore is "partial recycling".

The principle of the Recupra method relies on the fact that the size is not washed out but swollen up and squeezed out by heavy squeezing units (Fig. 5). Standing liquors are never used. The running cloth is beaten only to swell the size with water or diluted size solution and after a short dwell time, the swollen size solids are squeezed out. The plant is constructed in three stages so that the fresh water added at the third stage acts as a counter current, concentrates at each stage and is then recovered from the first squeezing unit in the form of a high-concentration sizing liquor. The first stage functions as a swelling zone. The reduced level makes it possible to operate with a small amount of standing liquor and shortens the warm-up time for concentrating the bath. The simple textile feed increases access to the rollers for the required cleaning operations. Subdividing the liquor in the first swelling zone is not necessary, as a washing process is not expected during the swelling phase. After the first stage, the squeezing unit removes about 40% of the swollen size. In the second stage, washing takes place according to the counter-current principle and then the swollen size is squeezed again.

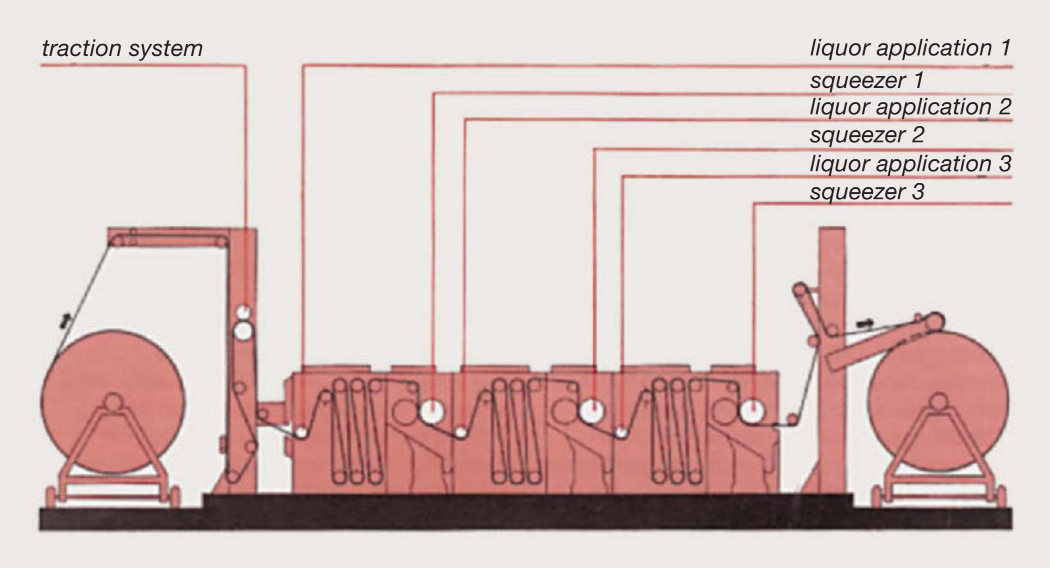

Fig. 5: The path of goods through the Recupa facility for the recovery of size, System BASF.

b) When recycling using ultrafiltration, a recyclable concentrate is produced from the de-sizing liquor by the selective removal of water at the ultrafiltration membranes (Fig. 6). This concentrate contains all of the sizing substances released from the fabric. Thus, in this case, the term "full recycling" can be used.

Ultrafiltration is a method of separating the solvent (water) and dissolved substances (size). The separation take place on a semi-porous membrane, the pores of which are so small that they retain the macromolecules of the size, while allowing the smaller water molecules to pass through. In order to separate the two types of molecule, the de-sizing liquor must stream through the membrane under pressure. Fig. 6 shows a schematic example of this process in a tubular membrane. The "concentrate" remains inside the tube while the "permeate" passes through the walls to the outside.

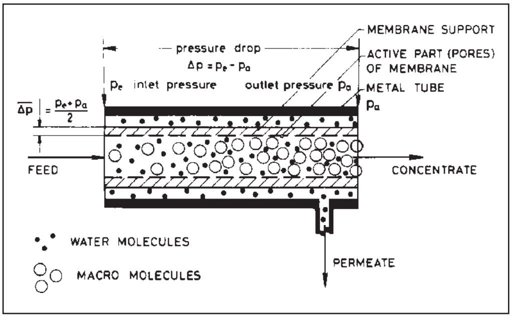

Fig. 6: The principle of ultrafiltration for the recycling of process water. Feed = an approx. 5% solution; concentrate = an approx. 15% solution.

Full recycling of the size makes sense for the following reasons:

1. The ultrafiltration membrane technology is proven and has been successfully used in different industrial sectors for many years, both in the production and in the recycling of valuable materials.
2. From an ecological point of view, this technology is preferred above all others because the effluent (and ultimately the surface waters) are completely freed from size loadings, unlike partial recycling where approximately 50% of the size on the fabric continues to find its way into the effluent. With full recycling, the two circuits, concentrate and permeate, are closed; 100% of the concentrate is returned to the sizing plant and 100% of the permeate is returned to the washing machine.
3. Under certain pre-conditions, the ultrafiltration plant makes it possible to save a considerable amount of the costs relating to the sizing agent. It is significantly more economic than washing out and, of course, cheaper than the conventional method where sizing agent, water and thermal energy are consumed during disposal.

In the USA, water-soluble size is recycled by evaporating the de-sizing liquors until the sizing concentration has been achieved.

However, recovery and recycling size is only possible in the case of sizing agents which can be dissolved from the fabric without any loss in viscosity and which do not alter their viscosity during repeated boiling and stirring during reprocessing. A prerequisite for the swelling and complete dissolution of the sizing agent is a sufficiently long dwell time for the goods in the washer unit. The recycled product recovered from the de-sizing plant must be more or less concentrated depending on the amount of sizing liquor the sizing plant is able to process. At the same time, a high concentration of recycled product means a low rate of recovery. The maximum possible concentration of size [g/l] in the wash liquor is given by:

$$C_0 = \frac{x}{FV}$$

Here, x represents the size loading on the goods in g/kg and FV the liquor ratio, i.e. litres of wash water per kg goods. Another formula shows the increase in concentration of recycled material [g/l] in relation to the wash-water addition I [l/min], amount of liquor in the washing machine V [l] and time [min.].

$$C_t = C_0 \cdot \left(1 - e^{-\frac{l \cdot t}{V}}\right)$$

From this it can be seen that, for example, a large volume of material in the washing machine greatly increases the time required to reach 95% of the maximum concentration C_0. An increased amount of added water shortens the time but reduces C_0 and C_t. A few examples with figures can be used to illustrate this point.

Assume that goods at 240 g/running meter are to be de-sized at the rate of 100 m/min. The goods would have a loading of 7%. The goods throughput per minute = 0.24 x 100 = 24 kg/min. The liquor ratio FV = 1.5, i.e. the amount of water added I = 24 x 1.5 = 36 l/min. The liquor ratio in the wash compartment is 10 00 l.

$$\mathbf{C_0} = \frac{\mathbf{70}}{\mathbf{1.5}} = 46.7 \text{ g/l max. possible concentration.}$$

Steady state in the plant has been reached when 95% of the maximum possible concentration has been achieved.

$$t = -\frac{V}{l} \cdot \ln\left(1 - \frac{C_t}{C_0}\right) = 83.2 \text{ min.}$$

During this time, 8320 m goods have passed through the system.

Recycling tumbler Special tumbler with solution recovery device (condensation principle) for drying in the so-called → Cold unit of dry-cleaning cabinets. The time required for drying, ventilation and recovery is between approx. 12–20 minutes for a 90–98% solvent recovery.

Redeposition Redeposition of material, for example, already dissolved particles of dirt on textile goods (→ Soil suspended property).

Redevelopment of former industrial sites When textile finishing plants move site, the old site may be encumbered with problems arising from finishing-products residues left behind in open waters or soils.

The clearing up of old deposits which are actually classified as inherited burdens, according to risk assessment, represent a great challenge to municipalities as well as trade and industry, both locally and nationally. These sites have to be cleaned up so that they no longer pose any risk to the environment. This discipline, which has only recently been introduced, must pursue numerous starting points together. Apart from the structural development, among others, thermal, extraction, biological and hydraulic methods of treatment must be considered as well. These methods of soil renovation are applied according to the conditions found (Fig.):

- on site after excavating the contaminated soil,
- after dispatch at the central treatment plants as well as
- on site in its original position without excavation.

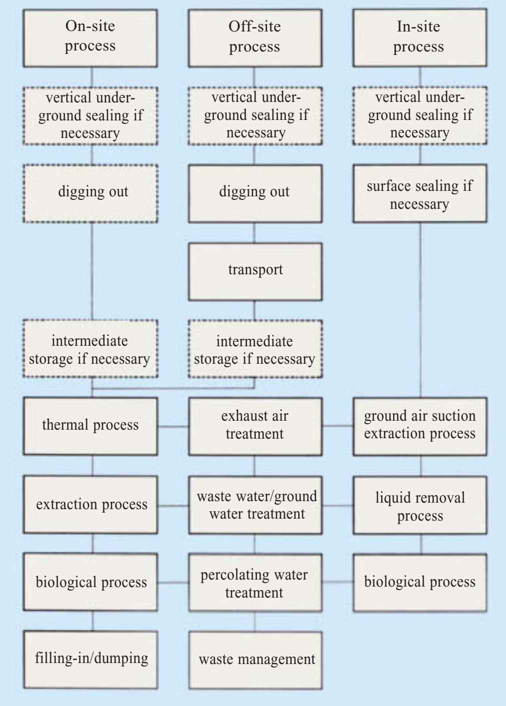

Fig.: Redevelopment of former industrial site process.

Red-green test Another term for the → Goldthwaite test.

Red mordant (red liquor) → Aluminium acetate.

Red oils → Turkey red oils.

Redox meter An electrical instrument with a direct readout which is used for → Redox potential measurement.

Redox potential (expressed as r_H). “Redox” is an abbreviation of the term reduction-oxidation. The redox potential scale is used for classifying reduction and oxidation processes in solution, the electrical voltage (potential) in question being measured in volts or millivolts against a reference electrode (→ Standard electrode potential). A scale is produced which is based upon the r_H according to the energy and rate of reduction as well as the, often very strong, dependence on the pH of the solution. Because the number of electrons which can be donated by a reducing agent is decisive for the reaction strength of a solution, the r_H expresses the activity of the electrons taking part in the reduction as a negative logarithm. Thus, at 1 bar pressure, the activity of the reducing electron for hydrogen has been set at 1, which corresponds to log 10^{-0}, so $r_H = 0$ for the hydrogen electrode. For oxygen, the activity is about 10^{-42} (oxygen electrode). The potentials of most other reducing and oxidizing agents lie between these two values. In general, stronger reducing agents (lower r_H values) will reduce weaker ones (higher r_H values), or to put it another way, a substance with a higher redox potential will appear as an oxidising agent to a substance with a lower r_H. No pronounced oxidizing or reduction properties can be expected within the redox potential range $r_H = 17–25$ (the so-called neutral range). Consequently, a particular redox system may be reducing or oxidizing depending on the reaction conditions. In most cases, it can be assumed that solutions with $r_H = 17$ more or less reduce whereas those with $r_H = 25$ clearly oxidize (see Tab.).

Redox potential measurement The → Redox potential is monitored as follows:

I. Using colorimetric-type redox indicators where the change in colour is characteristic for the reaction. The reduction state of vat dyes is monitored according to this principle using indanthren yellow paper (does not respond in the range below $r_H = 4$ which is important for many vat dyes). Dissolved redox indicators are not stable, i.e. they are sensitive to light and oxygen.

II. The potentiometric measurement of r_H is best carried out using a measurement instrument which has a glass electrode. In this case, the reduction potential (E) is the value in millivolts in relation to the hydrogen electrode potential which equals zero. r_H measurement instruments are relatively sensitive devices which are either portable or permanent and are available with or without a recorder and controller. Application of r_H measurement: apart from redox titrations, there are numerous applications in dyeing which involves reduction processes (such as vat, sulphur and vat leuco ester dyes) and oxidation processes (such as diazotization, aniline black dyes and colour-lake formation), in dye stripping and printing (such as vat dyes and reductive discharges), for maintaining favourable conditions during reduction and oxidation bleaching, and recording reductive capacities during boiling and kier boiling (oxycellulose r_H 14–20), etc. Continuous monitoring of the state of reduction in vat dyeing has proved itself in particular. This is mainly of interest in continuous processes.

Redox reactions Important redox reactions in textile finishing, such as the reaction of sodium dithionite with oxidizing agents, are often written using a single arrow in the equation pointing from left to right (Fig.).

Effectively however, redox reactions only exist as a redox equilibrium. Even when the starting product and

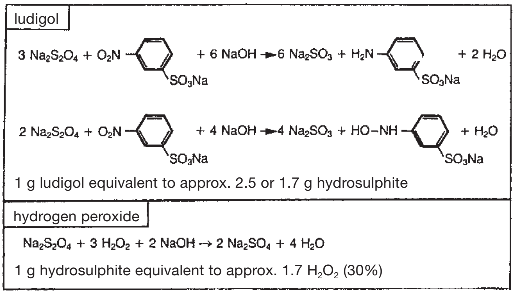

Fig.: The reaction of sodium dithionite (hydrosulphite) with an oxidizing agent (by BASF).

reduction zone		neutral zone	oxidation zone	
← 0–8.5 → strong	← 8.5–17 → weak	← 17–25 → indifferent	← 25–34 → weak	← 35–42 → strong
sodium dithionite	sodium hydrogen sulphite sodium thiosulphate	water hydrochloric acid sodium hydroxide	iodine solution	potassium dichromate potassium permanganate bleach liquor, ozone

Tab.: The redox potential r_H of various chemicals.

the end product are known from the frequently problematic determination of the stoichiometric coefficients, a redox reaction cannot readily be clearly described. A redox reaction is made up of two so-called half-reactions. One half-reaction is the oxidation reaction where the substance (reductant) looses electrons. The other reaction is the reduction reaction where the substance (oxidant) accepts electrons. Both reactions must be coupled together to form the complete redox reaction as electrons cannot exist in solution in isolation. This procedure is explained using the oxidation of Fe^{2+} ions with permanganate as an example. The individual steps in the reaction are as follows:

1. Equations for the reactants and products:

$$\begin{array}{lcll} \mathrm{Fe^{2+}} & \rightleftharpoons & \mathrm{Fe^{3+}} & \text{(oxidation half-reaction)} \\ \mathrm{MnO_4^-} & \rightleftharpoons & \mathrm{MnO_2} & \text{(reduction half-reaction)} \end{array}$$

2. Balancing the number of oxygen atoms taking into account the water:

$$\begin{array}{rcl} \mathrm{Fe^{2+}} & \rightleftharpoons & \mathrm{Fe^{3+}} \\ \mathrm{MnO_4^-} & \rightleftharpoons & \mathrm{MnO_2 + 2\,H_2O} \end{array}$$

3. Balancing the hydrogen atoms with H^+:

$$\begin{array}{rcl} \mathrm{Fe^{2+}} & \rightleftharpoons & \mathrm{Fe^{3+}} \\ \mathrm{4\,H^+ + MnO_4^-} & \rightleftharpoons & \mathrm{MnO_2 + 2\,H_2O} \end{array}$$

4. Charge balance with free electrons:

$$\begin{array}{rcl} \mathrm{Fe^{2+}} & \rightleftharpoons & \mathrm{Fe^{3+} + e^-} \\ \mathrm{3\,e^- + 4\,H^+ + MnO_4^-} & \rightleftharpoons & \mathrm{MnO_2 + 2\,H_2O} \end{array}$$

5. The first half of the reaction is multiplied by the coefficient 3 and then the two half-reactions are added together:

$$\begin{array}{rcl} \mathrm{3\;(Fe^{2+}} & \rightleftharpoons & \mathrm{Fe^{3+} + e^-)} \\ \mathrm{3\,e^- + 4\,H^+ + MnO_4^-} & \rightleftharpoons & \mathrm{MnO_2 + 2\,H_2O} \\ \hline \mathrm{4\,H^+ + 3\,Fe^{2+} + MnO_4^-} & \rightleftharpoons & \mathrm{3\,Fe^{3+} + MnO_2 + 2\,H_2O} \end{array}$$

6. However, this reaction takes place in alkaline solution and so another equation for the dissociation of water is also taken into account:

$$\begin{array}{rcl} \mathrm{4\,H^+ + 3\,Fe^{2+} + MnO_4^-} & \rightleftharpoons & \mathrm{3\,Fe^{3+} + MnO_2 + 2\,H_2O} \\ \mathrm{4\,H_2O} & \rightleftharpoons & \mathrm{4\,H^+ + 4\,OH^-} \\ \hline \mathrm{2\,H_2O + 3\,Fe^{2+} + MnO_4^-} & \rightleftharpoons & \mathrm{3\,Fe^{3+} + MnO_2 + 4\,OH^-} \end{array}$$

7. Finally, in alkaline conditions, $Fe(OH)_3$ precipitates out. The final step is therefore:

$$\begin{array}{rcl} \mathrm{2\,H_2O + 3\,Fe^{2+} + MnO_4^-} & \rightleftharpoons & \mathrm{3\,Fe^{3+} + MnO_2 + 4\,OH^-} \\ \mathrm{(Fe^{3+} + 3\,OH^-} & \rightleftharpoons & \mathrm{Fe(OH)_3)} \\ \hline \mathrm{2\,H_2O + 3\,Fe^{2+} + MnO_4^- + 5\,OH^-} & \rightleftharpoons & \mathrm{Fe(OH)_3 + MnO_2} \end{array}$$

In this case, Fe^{2+} is oxidized (it losses electrons) while the permanganate ion is reduced (it receives electrons). The Fe^{2+} ion is the reductant and the MnO_4^- ion the oxidant.

Redox reactions with inorganic starting products are generally clear and relatively easy to formulate. If the oxidant and reductant are either inorganic or organic, which is frequently the case in aqueous chemistry, or organic and inorganic, then the relationships may be complex. The oxidation of Fe^{2+} with dichromate, which is often cited, should be examined as an example of redox equilibrium. In detail, it is as follows:

$$\begin{array}{rcl} \mathrm{6\,e^- + 14\,H^+ + Cr_2O_7^{2-}} & \rightleftharpoons & \mathrm{2\,Cr^{3+} + 7\,H_2O} \\ \mathrm{6\,(Fe^{2+}} & \rightleftharpoons & \mathrm{Fe^{3+} + e^-)} \\ \hline \mathrm{14\,H^+ + Cr_2O_7^{2-} + 6\,Fe^{2+}} & \rightleftharpoons & \mathrm{2\,Cr^{3+} + 6\,Fe^{3+} + 7\,H_2O} \end{array}$$

Hexavalent chromium (VI) in the dichromate ion is reduced to trivalent chromium (III); while, the divalent iron (II) ion is oxidized to the trivalent iron (III) ion. During this change, the orange colour of the dichromate ion turns into the green colour of the trivalent chromium ion. The equilibrium constant for the reaction, $K = 10^{57.2}$ is large, i.e. the equilibrium lies completely on the right-hand side of the equation. The thermodynamic expression

$$G^0 = -RT \ln K$$

shows that the standard free energy of this reaction is strongly negative and the direction of the reaction is clearly established as being towards the right (according to Peschel and Belouschek).

Redox systems as polymerization initiators Numerous radicals produced during redox reactions trigger polymerization reactions. Organic and inorganic per-compounds are mainly considered for use as oxidizing agents and low-valency-state multivalent metal ions or non-metal compounds which are easily oxidized (such as a few of the sulphur compounds) are used as reducing agents. Apart from these, redox systems also exist which consist of a per-compound, metal ions (such as Fe^{2+}) and another reducing agent (such as hydrogen sulphite). The hydrogen sulphite reduces the Fe(III) ion, which has been produced during the redox reaction between the per-compound and the Fe(II) compound, back to its divalent state. Thus, in most cases, only small amounts of iron ions are required for the reaction.

The radicals which trigger the polymerization are produced, for example in a redox system, from per-compounds and an iron(II) salt by the transfer of electrons from the divalent iron to the per-compound, the peroxide bond being split while the radical is formed:

$$\mathrm{R{-}O{-}O{-}R} + \mathrm{Fe^{2+}} \longrightarrow \mathrm{R{-}O^{-}} + \mathrm{Fe^{3+}} + \mathrm{R{-}O^{\bullet}}$$
$$\mathrm{R{-}O^{\bullet}} + \mathrm{CH_2{=}CH{-}X} \longrightarrow \mathrm{R{-}O{-}CH_2{-}CH^{\bullet}{-}X}$$

Suitable oxidizing agents for triggering a radical polymerization would be, for example, hydrogen peroxide, peroxide sulphates and diacyl peroxides, and suitable reducing agents would be Ag^+, Fe^{2+}, Ti^{3+}, hydrogen sulphite, sulphite, thiosulphate, mercaptans, sulphinic acids, amines (such as N,N-dimethylanilin), endiols (sugars), benzoin/Fe^{2+} or hydrogen sulphite/Fe^{2+}.

Red prussiate of potash → Potassium hexacyanoferrate (III).

Reducing agents Either have the effect of adding hydrogen or removing oxygen. In practical terms they are important, for example, a) in → Reductive bleach-

reducing agent	advantages	disadvantages
sodium dithionite $Na_2S_2O_4$ »Hydro«	– adequate reduction potential for vat, sulphur and indigo dyes – good liquor stability of the attached liquor	– waste water contamination (hinders the biological breakdown of the waste water and leads to a strong oxygen depletion) – expensive – over-reduction at higher dyeing temperatures as well as alteration in hue – expensive storage (safety)
sulphinic acid derivatives	– adequate reduction potential – particularly suitable for high temperature dyeing – good stability in air	– potential strongly dependent on temperature
hydroxyacetone CH_3COCH_2OH	– biodegradable – easily metered (liquid) – relatively stable	– does not achieve its full reduction potential (particularly suitable for indigo and sulphur dyes) – intrusive odour – expensive manufacture (price)
sodium sulphide sodium hydrogen sulphide Na_2S, NaHS	– favourably priced	– intrusive odour due to hydrogen sulphide – toxic – poor reduction potential (particularly suitable for sulphur dyes) – large quantitites required
glucose	– no environmental effect – favourably priced – non-toxic	– poor reduction potential (particularly suitable for sulphur dyes) – only at dyeing temperatures of approx. 90°C

Tab.: Overview of the most commonly used reducing agents.

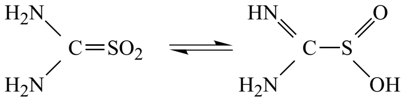
ing (sodium sulphite, pyrosulphite, sodium dithionite, sulphur, sulphurous acid and oxalic acid); b) in fast dyeing for converting vat and sulphur dyes into water-soluble leuco forms suitable for dyeing (dithionites, sulphoxylates, sodium sulphide); c) in dye stripping. The water-soluble analogues (leuco compounds) are formed from the corresponding dyes which are more or less water soluble; d) in printing, either added to the printing pastes in the form of stabilized sodium dithionite preparations of sulphoxylates (→ Reductive discharges) or for post-development of prints with non-reduced vat dyes using dithionites.

The most important reducing agents in regard to their applicability are shown in the Table. Different problems with products currently in use must also be taken into account. The agent used must not only reduce the dye in question but also remove oxygen from the air already present in the dyebath as well as that dissolving in the dyebath during the dyeing process. The reduction potential, between – 500 mV and – 1000 mV depending on the dye, required by silver/silver chloride must be maintained during the whole period of treatment. This means that altogether, a relatively high excess of reducing agent is needed.

In order to convert the reduced dye back into its insoluble oxidized form, the dyebath is to a great extent removed or drained. After removing the liquor, the dye is oxidized by flushing through with fresh water containing oxygen or by using liquors containing oxidizing agents. Because the liquor which has to be replaced contains excess reducing agent, effluent originating from vat and sulphur dyeing has a very high level of oxygen consumption.

Commonly used reducing agents are as follows:

1. Sodium dithionite, which is used as a standard agent for the colour yield and quality of dyeing, especially micro evenness, in vat dyeing.
2. Hydroxymethanesulphinic acid has proved itself as a reducing agent in printing. It is a sodium dithionite derivative with significantly reduced redox potential. The advantage of this compound over 1. is that its use results in only half the sulphur loading in the effluent.
3. Glucose has been known for a long time as a reducing agent. However, its low reactivity requires high addition rates, high alkali concentrations and prolonged steaming times. The COD loading in the effluent is relatively high.
4. Acetol is a reducing agent which has now gained favour in certain areas. It has the advantage of being free from sulphur but the disadvantage of having a strong unpleasant smell.
5. Formamidinesulphinic acid or aminoiminomethanesulphinic acid has been known in textile finishing since the early fifties. However, it has not been able to overtake 1. on account of its high price. One advantage is that it has half the sulphur loading of 1. The tautometry of formamidinesulphinic acid is important for the single-bath process:



In the product and in neutral solution, formamidinesulphinic acid exists alone and this does not have a reducing effect. Sulphinic acid only forms under alkali conditions.

Reducing valves (pressure reducers), are used, for example, for safely extracting compressed gases from high-pressure steel gas bottles (up to 150 bar) by reducing the operating pressure to the order of 0.5 bar (cylinder heads).

Operation (Figs. 1–3): when the adjustment spring (1) is eased off, the return springs (4 and 11) hold the main valve (2) and the control valve (3) closed.

Steam reaches the control valve chamber via the hole (A) and the dirt filter (5) (Fig. 1). When the low pressure is adjusted using the adjustment screw (6), then the adjustment spring (1) is compressed and the membrane (7) bulges downwards, presses on the control ram (8) and the control valve (3) opens. Steam flows into the chamber (Fig. 2) above the piston (9) and forces it downwards. The piston ram opens the main valve so that steam can flow to the low-pressure side. Before reaching the main valve, the steam flows

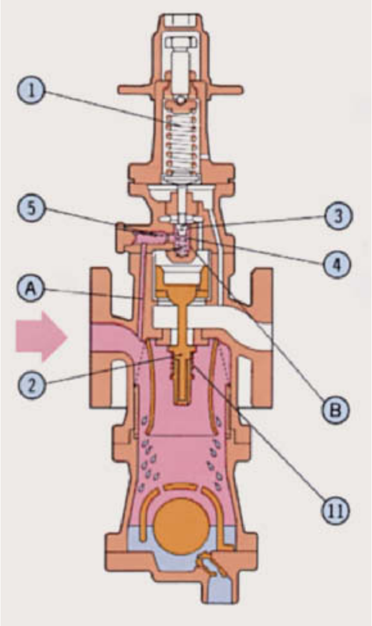


Fig. 1: The working mechanism of a reducing valve when at rest.

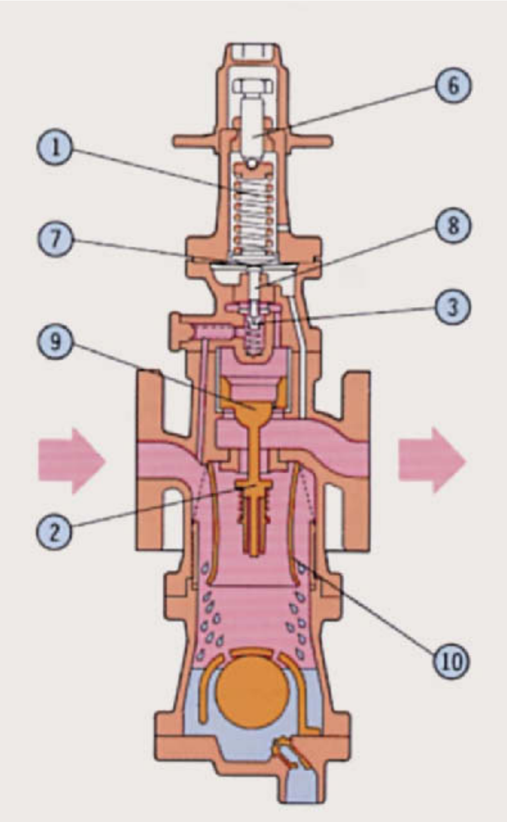

Fig. 2: A reducing valve under the influx of steam.

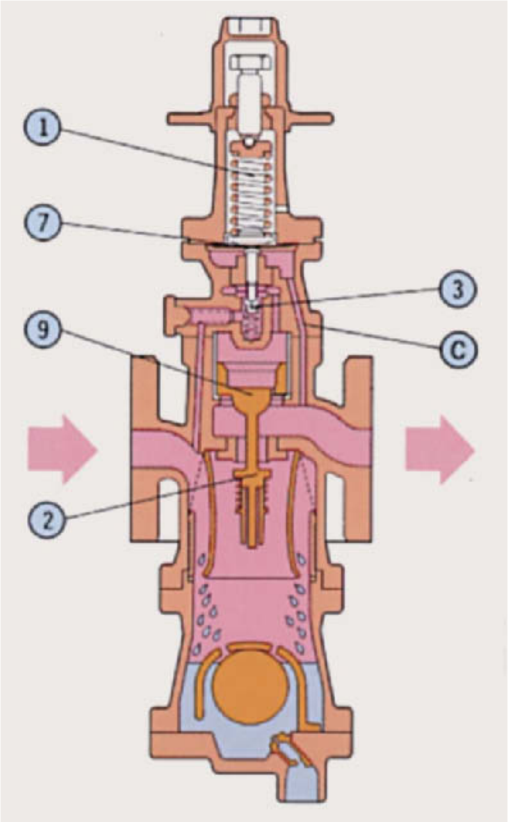

Fig. 3: The means by which reduced pressure is created in a reducing valve.

through the drier (10). The drier control device causes the stream to rotate, the condensate is discharged and immediately fed away from the condensate drain. On the low-pressure side (Fig. 3), the steam flows through the hole (C) and under the membrane (7) to which it transfers the low pressure. The position of the control valve (3) is determined by the balance between pressure acting on the membrane from underneath and the counter-pressure exerted by the spring. The position of the control valve (3) determines the pressure above the piston (9) and the position of the main valve (2), so dry saturated steam is produced at a constant low pressure.

Reduction The bonding of hydrogen or receiving electronegative charge or release of oxygen or electropositive charge in chemical compounds. Typical example: lead oxide + hydrogen = lead + water ($PbO + H_2 \rightarrow Pb + H_2O$). Opposite → Oxidation.

Reduction potential The main reducing agent used for reduction processes is sodium dithionite ($Na_2S_2O_4$), which has a reduction potential of –1000 mV (against the Ag/AgCl/3M KCl- reference electrode) in alkali media. Sulphinic acid derivatives are used for reductions at higher temperatures (such as steam processes or HT processes) (reduction potential at 50°C approx. –1000 mV). At temperatures below 80°C, the reaction rate of sulphinic acid derivatives is relatively small but compounds such as these can be activated by adding heavy-metal compounds (such as nickel cyano complexes and cobalt complexes, etc.). Other reducing agents are thiourea (–1100 mV), acetol (–810 mV) and sodium borohydride (–1100mV).

As the reduction potential of indigo dye (approx. –600 mV) lies within the required range between vat dyes (approx. –950 mV) and sulphur dyes (approx. –500 mV to –600 mV), among other organic substances with low reduction potentials, acetol/sodium hydroxide can be used as a reducing agent as well as sodium dithionite. Sodium sulphide (Na_2S) and sodium hydrogen sulphide (NaHS) (approx. –500 mV) can be used with sulphur dyes. Glucose/sodium hydroxide mixtures, among other organic reducing agents, can be used because of the low reduction strength required.

Reductions in printing Paler colour tones obtained by cutting back a full tone (→ Reduction thickener).

Reduction thickener (blend), addition of a thickener with reduced chemical activity for a printing paste (stock colour or full colour) to obtain lighter printing inks, for example, 1 : 9 = 1 part printing paste + 9 parts thickener (1/9).

Reductive bleaching Bleaching with → Reducing agents, predominantly for animal fibres. With other fibres, possibly used in a second bleach bath in combination with oxidising bleaches (→ Bleaching).

Reductive bleaching agents → Bleaching chemicals and products.

Reductive bleaching of wool The aim of bleaching wool is to destroy the yellow chromophor by oxidation or reduction. This is carried out as a separate process or jointly with other wool processing steps (for example, during dyeing or washing). Bleaching improves the brilliance of the colours, particularly in the case of pastel shades. Often, bleaching counteracts yellowing of the wool which develops during processing. Bleaching agents differ depending on whether they are oxidative or reductive. So-called full bleaching is a combination of the two processes.

In addition to sulphite, sodium dithionite, sodium hydroxymethanesulphinate and formamidinosulphinic acid are usually used for reductive bleaching.

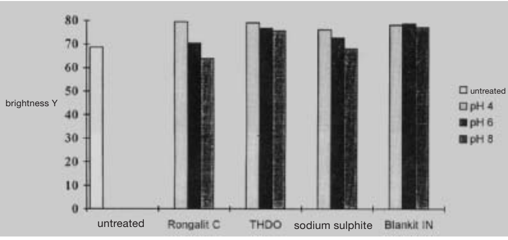

Fig. 1: The standard colour value Y of bleached wool in relation to the reducing agent and the pH of the bleaching liquor (according to Höcker et al.).
Blankit IN (BASF) = stabilized Rougalit C (BASF) = sodium dithionite; sodium hydroxymethane sulphinate.

The effects of bleaching a woollen fabric with different reducing agents at different pH are compared in Fig. 1.

Stabilized sodium dithionite and formamidinosulphinic acid also give good results in a weakly alkaline pH range. Sodium sulphite and sodium hydroxymethanesulphinate are not suitable for bleaching in weakly alkaline liquors. Indeed, fabric “bleached” using these reducing agents is darkened.

The effects which impair the quality on wool fibres can be established both by chemical methods, such as cystine determination or solubility in alkalis, and mechanical measurements.

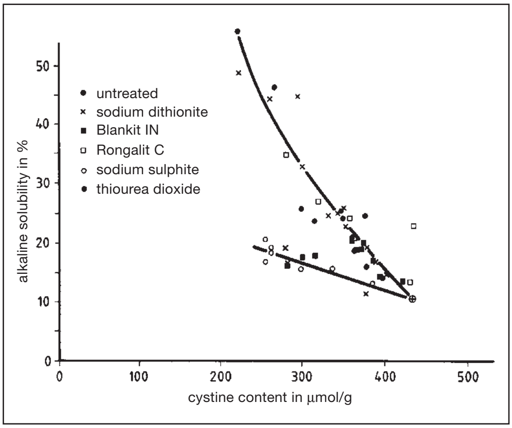

Fig. 2: The relationship between alkaline solubility and the cystine content of reductively bleached wool (according to Höcker et al.).

In the case of reductive treated wool (Fig. 2), there is a linear relationship between the cystine content and alkali solubility. The curve steepens at higher degrees of reduction. For all bleached samples containing Bunte salt, the solubility in alkali is less for the same cystine content. Bunte salt is produced in addition to thiol as a result of the reductive cleavage of wool cystine with sulphite:

$$\text{R–S–S–R} + \text{HSO}_3^{2-} \rightleftharpoons \text{R–S–SO}_3^{-} + \text{R–SH}$$

(according to Kwasny, Deutz and Höcker).

Reductive discharges Discharges (→ Discharge printing) based on a reduction effect where the dyes in question, a) are split up into colourless soluble compounds, i.e. fully destroyed and have to be removed by subsequent washing (for example, direct, acid and mordant dyes or naphthols) or, b) because of their solubility, particularly in alkaline solution, are more or less removed before the fibre is re-oxidised, i.e. are not destroyed (for example, indigoids and anthraquinoid dyes, such as indigo and vat dyes as well as cationic dyes as derivatives of triphenylmethane).

Redyeing Dye packages may have to be dyed a second time because of faults or stock packages may have to be redyed as they cannot be sold due to their particular shade. In both cases, → Stripping of dyeings is usually necessary first.

Reel →: Yarn package; Winch.

Reeled silk Silk winched from the cocoons of the silk worm as → Grège derived from almost continuous elemental fibres.

REF Fibres (REF = Roll Embossed Fibre), made from → Tape yarns by embossing the yarns with longitudinally-grooved profile rollers followed by width stretching, where the areas on the fabric that have been thinned by the embossing process tear open, forming multi-filaments (elemental filaments with a high degree of uniformity and high strength).

REFA Darmstadt. Function and objective: to continue the work of the German "Reichsausschuss für Arbeitsstudien [National Committee for Work Studies]" founded in 1924. The abbreviation of this committee has been adopted by the current institution carrying out this work. Conditions and methods of efficient structuring and payment compensation for human labour based on efficiency is researched, developed and disseminated among all branches of the business sector and management on a new and extended basis. Other functions include the publication of reference books and journals for work studies (REFA Nachrichten [REFA News] and Fortschrittliche Betriebsführung [Advanced Factory Management]) and the organization of courses, meetings, presentation and consultation evenings. The association functions on a non-profit making basis. → Technical and professional organizations.

Reference number That is to say, "industrial data collated using a reference number". Absolute reference numbers within a company are independent parameters such as the number of hours of production or turnover of a financial period. Relative reference numbers give information about the relationship between certain data such as turnover per hour of production or real net output per employee. The source data are either the company's internal sources (tax accounts, purely commercial accounting, fully extended accounting) or figures external to the company (such as available statistics, reference comparisons and external analyses). Basically, it makes sense to decide on the reference number within the company which helps the company's own management to improve quality and lower production costs. Reference numbers are only useful if they are critically discussed, if they are seen in the larger context (graphical presentations ease the interpretation of the relationships) and if they are used as target parameters in planning. Reference numbers which relate to the process are useful for quality and production control and require suitable measurement equipment.

Reference sample An order sample for the → Colour matching of dyed/printed samples.

Reference temperature A fixed point on a scale of temperatures, for example, the melting point of ice ± 0°C and the boiling point of water + 100°C at ntp (→ Temperature).

Reflectance → Reflection of rays in the form of reflected coloured light. The reflectance properties express how incident light has been modified by the refection, i.e. (except in the case of fluorescent dyes) depending on the type of body, the incident light is weakened by different amounts in different parts of the spectrum. The degree of reflectance is the reflection parameter, as the quotient of intensities of the reflected ray and incident ray or, as the sensation of brightness (→ Colour measurement) the ratio of the → Lightness or radiant intensity per unit area of a coloured surface (body colour) to a surface seen as matt white under identical conditions of illumination. All results from reflectance measurements are quoted in relation to → Standard white = 100%. An exemplary presentation of reflected colour tone is obtained by plotting the reflection value (degree of reflectance) against the wavelength. This procedure produces the so-called dye curves (transmission or reflectance curves) which are fundamentally characteristic for any particular dye.

A pair of colours are only identical to all observers under all conditions of illumination if their reflectance curves are in agreement. This is only possible by using identical dyes at the same concentration on the same substrate. Dye curves for dyehouses are important for dye tests. The addition of curves yields additive mixtures and curve multiplication leads to subtractive mixtures.

Reflectance curve The point associations (from a spectral photometer or automatic recording) of the per-

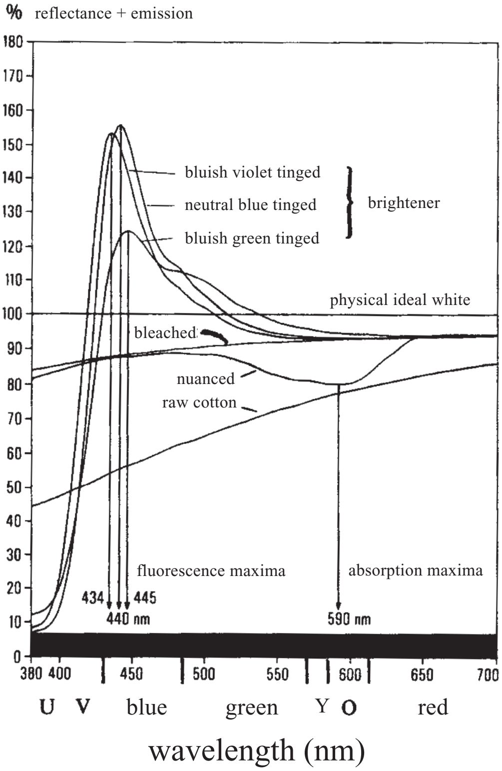

Fig.: The reflectance curves of variously pretreated cotton fabrics.
U = ultraviolet; V = violet; Y = yellow; O = orange

centage → Reflectance plotted against the wavelength in a coordinate system produces the reflectance curve. In the visible range (400–700 nm), these characterise the ratio of reflected light to incident light, thereby yielding calorimetric information on the physical parameters of each dye or dyeing. In the case of fluorescing dyes, the emitted light adds to the reflected light, i.e. light energy is absorbed by optical brighteners in the UV range in order to be emitted in the visible range as bluish violet light. The colour tone of brighteners can be roughly assessed by the position of the fluorescence maximum, as shown by the characteristic reflectance curves for different brighteners in Fig.

The rather dull brightner is noticeable with its flat longwave decent on the fluorescent curve.

Reflection Component of incident light meeting a surface which is neither subject to → Absorption nor → Transmission (→ Reflectance). In the case of reflection, the incident energy is only briefly absorbed by the individual atoms in order to be reflected again as potential energy. The angle between the reflected ray and the surface is the same as that of the incident ray. On bent surfaces, reflection takes place at a tangent to where the incident ray meets the surface. The visibility of illuminated non-self-illuminating bodies and their colours relies on selective absorption and reflection in the visible spectrum. Diffuse reflection is the splitting up of parallel incident ray bundles into different directions and this determines the colour of the object. In fact, most surfaces are not ideally smooth, so in practical terms reflection is almost always diffuse. Contrary to this, mirrored reflection gives the sense of glaze which, for example, implies that a matt pattern of the same colour as a shiny pattern is always experienced as being darker and vice versa. As well as reflection in the visible spectral range of wavelengths there is also reflection in the non-visible ultraviolet and infrared ranges.

Reform weave A weave which results in warp-reinforced fabric with main warp.

Refraction → Refraction of light.

Refraction of light (refraction), guiding or changing the direction of light as it passes through the boundary between different media such as light/water. While doing so, the long wavelength light (red) is not so strongly refracted as the short-wave light (violet/blue). The standard scale used for measuring refraction is called the refractive index (refractive exponent): quotient of the sine of the angle of incidence and the sine of the angle of refraction:

$$\frac{\sin \alpha}{\sin \beta} = \text{const.} = n$$

In most cases, refractometric determinations are carried out using light of a single wavelength or monochromatic light. The yellow D line of sodium is predominantly used, from which is derived the symbol nD for the refractive index. The refractive index of air (in comparison to vacuum) is practically equal to nD 1; as, for example, the refractive index of solutions varies with concentration, this parameter can be used to determine the concentration. The refractive index is also utilised in fibre microscopy in the so-called immersion system where immersion fluids are used with a refractive index matched to that of the test fibre.

Refractive index (refraction exponent) → Refraction of light.

Refractometer Instrument for measuring the → Refraction of light.

Refractory (Lat: refractarius = contrary), insensitive, unimpressionable: refers, for example, to non-biodegradable refractory carbon compounds in effluent.

Refractory metals High purity, heat-resistant metals (alloys) which in super fine capillary form have a high surface-area-to-volume ratio (e.g. niobium capillary filaments of the smallest diameter, until now 0.6 μm). Used for metal filaments.

Refractory residues These are (persistent) residues which remain in water after biological treatment by water treatment plants or natural processes. They are not decomposed by bacterial enzyme systems and, under certain circumstances, may concentrate in certain places. As they concentrate over time, they may become locally toxic if they exceed the toxic threshold value. Below this threshold value, they appear to be harmless. The Zahn Wellens Test (up to 400 mg/l DOC) is the test which is most suitable for assessing the biodegradability of highly concentrated → Segregated streams with the aim of determining the relationship between the input in segregated streams and their residual refractory loading. The German Chemicals Act does not recognise biodegradablility as a risk factor although it must be regarded as the main test criterion for substances. The German Water Resources Law (WHG, Wasserhaushaltsgesetz) mentions "dangerous substances according to § 7a WHG". In general, substances under this description are, or can be understood to be "poisonous, long-lived, carcinogenic, embryotoxic or genome modifying". The most comprehensive interpretation of § 7a WHG would be that only one of the effects mentioned would have to apply for it to be regarded as "dangerous according to § 7a WHG", in which case, the inability of a substance to biodegrade would suffice. The basis of the draft statute for the fifth amendment of the WHG also allows this view. However, the current national and local interpretation is that one of the "biologically harmful effects" mentioned must be included in the property "refractory". In any case, according to the § 7a WHG, the substances of so-called List I and II of EC Directive 76/464/EEC are counted as dangerous. The lists contain heavy metals, organochlorine compounds, pesticides and aromatic compounds. However, there is a “transition area” which ranges from the substances in Lists I and II to harmless substances. According to the WHG draft statute mentioned above, harmless substances are “substances which are biologically harmless or can rapidly be converted into substances which are biologically harmless”. According to this statement, refractory substances which have a biologically harmful effect are counted as dangerous substances. However, the last mentioned has so far not been precisely defined (according to Schönberger).

Refrigerants Volatile liquids (flourochlorohydrocarbons) or vapours which, because of their thermal properties, are suitable for use in refrigeration plants.

Regain → Moisture regain.

Regenerated cellulose “Recovered cellulose” which, unlike native cellulose (cotton) has a lower degree of polymerisation (and correspondingly different characteristic properties). Identical to → Cellulosic fibres, regenerated (viscose, acetate and cupro fibres).

Regenerated fibres → Cellulosic fibres, regenerated; → Man-made protein fibres.

Regenerated protein fibres → Man-made protein fibres.

Regenerated protein fibres distinguishing reactions → Man-made protein fibres, distinguishing tests.

Regenerator Heat exchanger with reverse flow, one way being heated by the exothermic cloth flow, and the other being cooled by the heat-absorbing cloth flow.

Registered design Creations based on three-dimensional shapes or colours, which are intended to create a positive aesthetic influence. Patent law or registered design law can be applicable simultaneously if, apart from the construction which is protected by the patent, the object is designed in such a way that its external appearance creates an aesthetic impression, and it fulfils the requirements of registered design law.

Registered trade mark → Trademark.

Register in printing,

I. Re-drawing of a pattern drawing to the correct repeat size (→ Repeat for printing, design drawing).

II. Correct alignment of pattern to fabric in screen printing or roller printing. The printing machinery is adjusted to take into account lengthways, crosswise and diagonal repeat.

Register in screen printing,

I. Matching (congruency) or likeness of the print pattern between the original pattern (slide) and the pattern printed on the fabric, also between the print at the beginning and end of a piece.

II. Position consistency of the print pattern = unchanging position of print pattern. The screen is the main factor that determines congruency, although not the only one; position consistency is also strongly influenced by the accuracy of the printing machinery. Size differences in film material are caused by temperature and humidity. If there is an increase in temperature or humidity the slide increases in size, which is mainly caused by expansion of the photo-emulsion, slowed down by greater stability of the polyester carrier; blank polyester film is used as a base mounting and exhibits almost completely stable behaviour.

Register marks In roller printing, the pattern being reproduced is broken up into a large number of dots using a reproduction camera with a traverse or shading screen, so that the dots are graded in size according to the shades.

Registration accuracy Factors upon which registration accuracy in screen printing is dependent:

I. Dimensional stability of the slide.

II. Dimensional stability of template (dependent on template frame, frame material, type and tension of template gauze, template manufacture, atmospheric conditions in preparation and printing rooms, treatment and maintenance of templates).

III. Printing process: print stretching, dependent on strain properties of fabric, type, position, hardness, length and speed of squeegee, viscosity of print paste, surface condition of print fabric.

Registration requirements for hazardous substances Since January 1982, the Hazardous Substances Protection Law (Gesetz zum Schutz vor gefährlichen Stoffen – Chemikaliengesetz, ChemG, Chemical Law) has been applicable in the Federal Republic of Germany. Any new materials that are to be used in consumer articles are subject to this law, which incorporates a catalogue of test procedures for assessing the risk involved with the materials. The scope of these tests is incrementally linked with the production quantity of that material, annually or cumulatively, and the results of the initial orientation tests.

The German Federal Health Office (Bundesgesundheitsamt) has not published any specific recommendations for consumer articles concerning tests to establish that either man-made fibres, or articles/substances containing or having been treated with these, cause no detrimental effect to health. However, such recommendations have been published for plastics that come into contact with food, for instance. To clarify that there is no detrimental effect to health for the consumer, the tests used are orientated to a direct textile effect, e.g. abrasion, pressure, hydration, temperature blocking, etc., and the after-effects thereof. Local and systemic effects that are of toxicological relevance must also be addressed by means of extractable samples. In other words it would be of particular interest to establish the qualitative and quantitative composition of a global extract of the final product. This type of migration test is carried out, for example, during the analysis of plastics that come into contact with food, where the substance or product undergoing testing is brought into contact with various food simulants (distilled water).

Certain finishing plants have also been required to register since 1st January 1992. Registration includes description of location and facilities, as well as waste water, residual substance and exhaust air quotas, etc.

Regression analysis Test of structure-effect relationships, recording as many parameters as possible, such as solubility and distribution coefficients, influence of substituents, etc.

Regular-Dyeing Polyamide → Differential dyeing polyamide fibres.

Regulators for peroxide bleaching Peroxide decomposition can be influenced by the use of appropriate bleaching agents, known as regulators. Regulators mean substances or substance compounds that are able to preserve the perhydroxy anions (HO_2^-) responsible for the bleaching effect for as long as possible, and largely suppress decomposition. The essential point of this is to prevent uncontrolled peroxide decomposition during the bleaching process, by means of regulators acting on the reaction sequence. A regulator has to fulfil a large number of requirements, the main ones being the following:

- predominant stabilization of perhydroxy anions,
- anti-catalytic effect by means of complex formation,
- to maintain alkaline earth metal ions in a sufficient quantity in homogeneous distribution by means of dispersion,
- stability in bleaching conditions (oxidation, pH and temperature),
- biological degradability,
- economic efficiency.

The way many regulators function is not understood in fine detail. Some stabilizers can be categorized as catalyst poisons, others as protective colloids and possibly buffer substances. As well as this, the way they function depends significantly on the physical and chemical substances. Stabilization is essentially dependent on two factors:

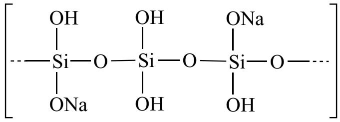
- the alternating attraction forces which are active between the activated HO_2 ion and the alkaline earth metal ion,
- the extent to which the heavy metal ion is masked by the stabilizer, or the formation of hydrogen peroxide radicals is prevented.

Regulators can be categorized as inorganic and organic substances.

1. Inorganic:
    - silicates (water glass) in association with alkaline earth metal ions,
    - phosphoric acid, alkali phosphates, polyphosphates and pyrophosphates,
    - stannates,
    - borates.
2. Organic:
    - products based on complexing agents, e.g. polyaminocarboxylic acids, polyoxycarboxylic acids and phosphonic acids,
    - products based on dispersion agents, e.g. fatty acid condensation products, fatty alcohol sulphates, ethoxylates, organic sulphonic and phosphonic acids.
3. Combinations of inorganic and organic compounds.

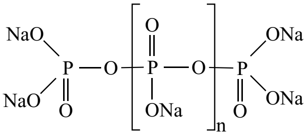
The following text will describe in more detail the properties and the effects of this class of substances, inasmuch as they are known and relevant to alkaline peroxide bleaching.

I. Silicates: The waterglass frequently used in peroxide immersion bleaching is a water-soluble sodium silicate with a ratio of: $Na_2O : SiO_2 = 1 : 3.3 \equiv Na_2SiO_3 \cdot 2\,H_2O$.



The advantages of waterglass are its low cost and high performance, and the fact that hardly any stabilizing agents are as good as waterglass in combination with alkaline earth ions, at least not in pad-steam processes. As an inorganic compound it is resistant to oxidization and heat. It has the additional advantage of buffering significant quantities of alkali, in other words an alkali reserve is generated without altering the pH and thereby the activation of the bleaching bath. However, it does exhibit certain disadvantages, and for this reason alternative substances are being sought as a replacement. The main disadvantage is the tendency to dehydrate at high temperatures. When this happens, the polysilicic acid chains stick together to form silicates that are not easily soluble. As a consequence of this, deposits are left on fabric and machinery parts. This has a detrimental effect on the handle and absorbency of textiles. Furthermore, dye resistance and stains can arise during the subsequent dyeing process. Silicate deposits in the bleaching equipment, particularly on the rollers, can cause raising, creases both lengthways and crosswise, and under certain circumstances even tearing of the fabric.

II. Polyphosphates: These are produced as a result of the condensation of orthophosphates. The following example illustrates the condensed polyphosphate group (inorganic):

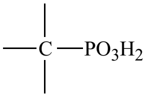


The properties of these substances usually change depending on the length of the chain. The advantages of this group include detergent and soil-suspending properties, solubility properties, and complexing characteristics for calcium, magnesium and polyvalent heavy metal ions. However there are several disadvantages. At temperatures above 80°C and in a strongly alkaline medium above pH 11, polyphosphates exhibit low stability. Particular problems include sensitivity to hydrolysis in hot, strongly alkaline bleach baths, and the lack of selectivity for heavy metal ions in the presence of alkaline earth ions. Furthermore, there are ecological considerations with respect to water eutrophication.

III. Aminopolycarboxylic acids: The best-known compounds in this group include the following: nitrilotriacetic acid (NTA), ethylene diaminetetraacetic acid (EDTA), diethylenetriaminepentaacetic acid (DTPA), and hydroxyethylene diaminetriacetic acid (HEDTA). The aminopolycarboxylic acids form water-soluble complexes in combination with alkaline earth and heavy metal ions. These compounds have an increased stability at high temperatures, as well as high selectivity for heavy metal ions. However, at high temperatures (> 90°C) and in strongly alkaline solutions they only have limited resistance against oxidation. This has a negative effect on their complexing properties. The alkali salts of type Na_4-EDTA aminocarboxylic acids exert a fibre-protective action if oxygen is present, peroxide or atmospheric oxygen. They do not have protective colloids or dispersing action. Furthermore they only function in stoichiometric numbers, in relation to the heavy metal ions.

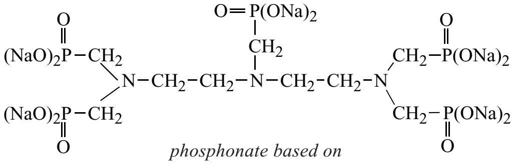
IV. Polyhydroxycarboxylic acids: These compounds include citric acid, oxalic acid and gluconic acid. The advantages of these are exceptional sequestering properties; in other words they are able to maintain a solution of metal ions even in the presence of precipitation agents where acid/lye concentrations are very limited. They also exhibit high selectivity for individual metal ions. The main disadvantage is that the effect of this type of compound is strongly dependent on the pH, and for this reason only limited use is possible.

V. Phosphonic acids: The salts of phosphonic acids are known as phosphonates, and are derived from the following group of phosphonic acids:

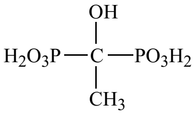


$$-\overset{|}{\underset{|}{C}}-PO_3H_2$$

There are many different phosphonic acids, and an exemplary selection of the important ones is featured here:

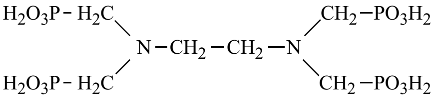


phosphonate based on diethylene-triamine-penta-methylene-phosphonic acid (DETPMP)



$$H_2O_3P-\overset{\overset{OH}{|}}{\underset{\underset{CH_3}{|}}{C}}-PO_3H_2$$

hydroxy-ethylene-diphosphonic acid (HEDP) without nitrogen



ethylene-diamine-tetra-methylene-phosphonic acid (EDTMP)

Contrary to many other complexing agents, phosphonic acids have a high level of thermal stability. They are stable whether the liquor is strongly alkaline or oxidizing, and they act selectively on heavy metal ions. With regard to detergent and dispersing efficiency, they exhibit average to good builder properties. They also act in the same way as sequestering agents, which are able to prevent or at least delay precipitation or crystallization. In addition to this, phosphonic acids exhibit a "threshold effect"; in other words they are effective even in sub-stoichiometric concentrations. Of the phosphonate group (aminophosphonates, hydroxyphosphonates and carboxyphosphonates), the ones considered to be the best are the aminophosphonates with nitrogen substituents and at least two phosphonate groups. Compounds based on phosphonic acid have a wide range of applications; among other reasons, this is due to the broad pH spectrum in which they can be used, and because of their hydrolysis stability. In addition to their application as stabilizers and complexing agents, they can also be used as softeners, exchangers and corrosion agents. However, although these compounds are very effective, which is influenced by the bleaching conditions, they are not comparable pricewise with waterglass. Where bio-degradability is concerned, there have so far only been problems in a few cases. From a toxicological and dermatological point of view no problems have yet occurred.

Re-impregnation process → Water-impermeable test. Today solvent impregnation is more widely used.

Reinforcement strips on printing screens Made of gauze, fabric or adhesive tape as a reinforcement to protect against tearing or splitting at the delicate points where the gauze meets the frame.

REK Russian fastness commission → Technical and professional organizations.

Relative humidity (RH) → Air humidity.

Relaxation (Lat.: relaxatio = easing), time-related reduction of fabric tension whilst maintaining a constant length. During textile production, the textile is subject to tension resulting from mechanical processes, which is partially reduced during storage, for instance. Some finishing processes aim to achieve total relaxation, → Relaxation shrinkage. Insufficient → Dimensional stability is a consequence of insufficient relaxation.

The problem of dimensional stability in knitted cotton fabrics became particularly apparent as tumble-dryers have become increasingly popular, as they can trigger latent shrinkage potential in textiles. The behaviour of certain knitted fabrics that exhibit significant dimensional changes after washing and tumble-drying is firstly due to the technology, and secondly because of the finishing techniques (→ Dimensional change). The Fig. shows a schematic flow chart depicting the behaviour of cotton rib knit during the manufacturing process. It shows firstly that identical knitted fabrics aim towards one final dimensional status (relaxation theory), and secondly that deviating shrinkage potential occurs at the end of varying process curves. After each stage of the process there are more or less effective opportunities to correct shrinkage potential, but also to make it worse (broken line).

Relaxation shrinkage Refers to the fact that if woollen cloth, for instance, is moistened, then any tension originating from processing (spinning, weaving, finishing) will return to a state of equilibrium, in other words without any external work. The principle factors that determine relaxation shrinkage are humidity, temperature and time.

Fig. 1 shows classic shrinkage behaviour in a two-phase pretreatment plant. The fabric being treated was single jersey quality (120 g/m^2), which is very sensitive to stretching. The theoretical curve represents the stretch resulting from stress-strain behaviour, as well as the shrinkage properties of the fabric. The curve represents a linear connection between individual measurements recorded at the plant under production conditions. A comparison between the two shows a relatively high level of coincidence between the two behaviour curves at the measured points.

However, the most important conclusion drawn

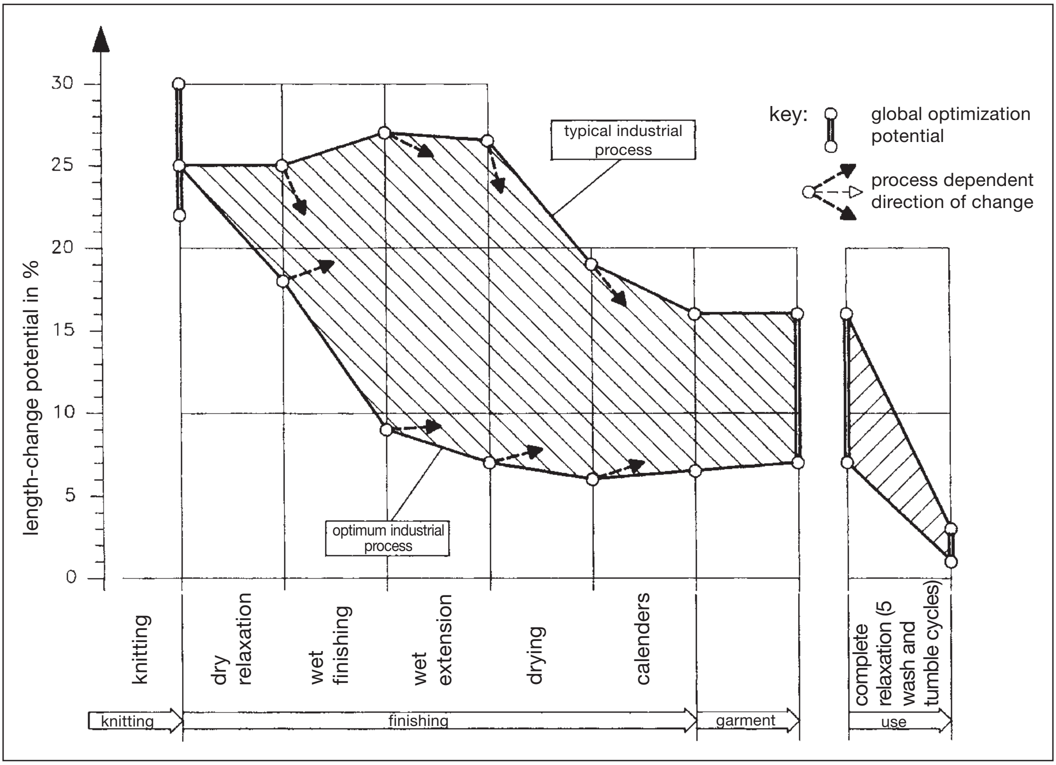


Fig.: The longitudinal behaviour of cotton rib knit in the course of both manufacture and use.

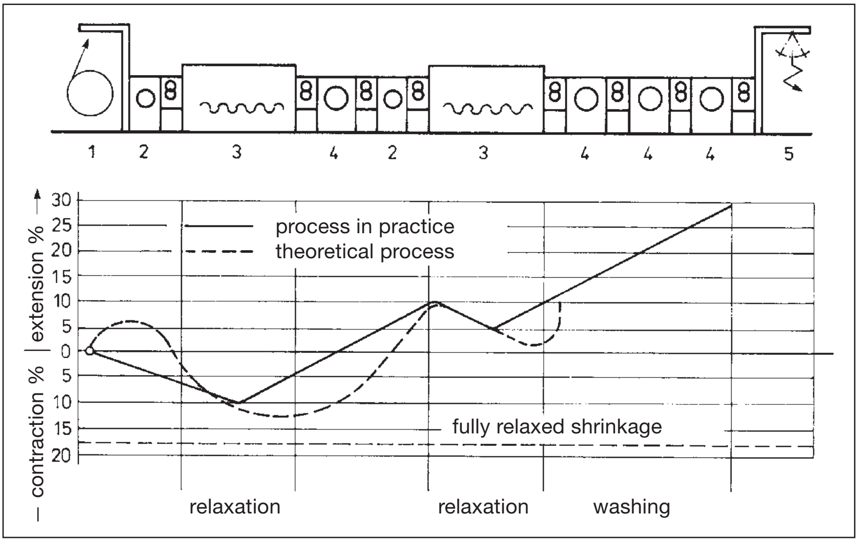

Fig. 1: The shrinkage process.
1 = entry;
2 = impregnation section;
3 = dwell section;
4 = wash section;
5 = exit.

from this is that the fabric shrinkage in the relaxation sections, which is caused by the fabric guide forces, is more than compensated for in the subsequent processes.

A relaxation section is situated at the beginning of a plant for the purpose of shock-shrinking fabric and knits. The dry fabric is guided via a traction device with adjustable overfeed onto the first ribbed drum with ∅ 620 mm (Fig. 2). At the same time, the run of cloth is coated with hot liquor from the spray and pumping equipment (30 m^3/h), and then immersed in liquor to relax further. This procedure must be carried out with a fixed fabric guiding system to avoid marking.

The hydroshrinkage determines the subsequent quality of the textiles. There are integrated swing rollers to compensate for dimensional changes in the fabric run itself, and these compensating rollers are also responsible for controlling the precise speed of cloth feed in and out (Fig. 3.).

Relaxation time In order to compare the kinetics of different processes, for example to test reactions occurring in a finishing process for possible diffusion control, the relaxation time τ (the time after which all processes being compared have decayed to $^1/_e$) is defined instead of the half-life period. In the Fig. this method is used to compare the reaction speed of cotton crosslinking with formaldehyde, at different degrees of swelling and with different catalytic effects of the hydrochloric acid used in acetic acid / water mixtures, with the diffusion speed of formaldehyde in cellulose with no reaction. During the relaxation period it becomes apparent that crosslinking is a controlled reaction when over 25% water is present in the system, but below 25% water in the system means that fibre swell-

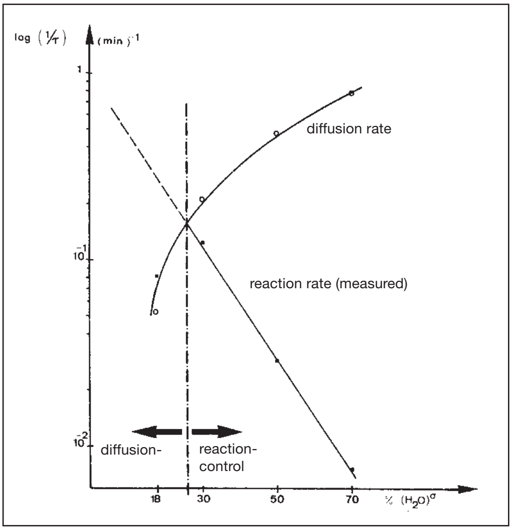

Fig.: Application of the relaxation time τ for diffusion and reaction in order to compare the two processes in a system of cellulose/formaldehyde/hydrochloric acid in water/acetic acid mixtures as dissolvent (swelling agent for cellulose) (according to Zollinger et al.).

ing is so negligible that formaldehyde diffusion in the pores is the factor affecting speed (diffusion control).

Relay Automatic switching device (→ Control equipment):

I. An electrical relay transfers electrical impulses in one circuit to another or (electromagnetic relay) makes contact with a second circuit. a) Control relay or relay controller: controls resistance (e.g. electronically in line with comparative resistance set point). Also as signal relay for automatic control of a variety of different applications (pressure, flow, humidity, concentration, quantity, temperature, vacuum, etc.). b) Cut-out relay: Safety switch for low or high-current electrical circuits to protect against overload, short circuits, etc.

II. Pneumatic relay: Controlled by compressed air.

III. Mercury relay: e.g. Contact-pointer thermometer with a mercury vertical relay.

IV. Thermal relay: Contact control by bimetallic strips carrying current.

Release In wool wet finishing: before dry finishing, a final complete wet finish cycle, carried out almost exclusively for high quality wool cloths in order to improve quality. Covalent bonds imposed to set the cloth in a particular form (e.g. width) are removed by water to enable this form to be modified.

Release emulsions These are responsible for preventing "sticking" or adhesion of material in certain work sequences, e.g. when garments are ironed, mangled, etc. so that they do not adhere to heated metal surfaces, the mangle cloth, press cover, etc. This type of release emulsion can consist of high-molecule polyoxy compounds, for example.

Release paper Carrier paper for coating compounds or foam for → Transfer coating.

Relief engraving machine → Engraving.

Relief printed effects (three-dimensional printing). This does not refer to roller printing with relief rollers, which is widely known, but to the combination of chintz printing or → Emboss printing with particles of crêpe prepared in caustic soda on cotton fabrics. With this technique, there is a local shrinkage effect on parts of the fabric that have not been treated with synthetic resin, and any areas that were protected by the synthetic resin appear raised. Essential requirements: no pre-mercerized fabrics; appropriate fabric adjustment; suitable choice of print design (spots, dots or circles generally stand out in relief and long, stripe-type motifs produce concave and convex relief patterns); acute pre-tension before printing; gloss-preserving thickener must be used (locust bean flour or polyvinyl alcohol; starch and methyl cellulose are not suitable).

Relustring Restoration of gloss finish. Aftertreatment, particularly for modacrylic fibres, partly combined with the drying process.

Remaflam drier Drier specially designed for the → Remaflam process, situated directly above the dye padder to save space, environmentally friendly drying duct. Fabric temperature always < 100°C; heat required for drying is generated by methanol combustion (see Fig.) – Manuf.: Brückner.

Remaflam dyeing plant Continuous dyeing and drying plant for piece goods. Impregnation padder with 36% methanol and required additives, contact-free in short IR heating duct until methanol reaches flash point, ignition in combustion chamber causing water to evaporate, combustion temperature 750°C, fabric temperature 45–70°C (never as high as 100°C if no dye setting), air cooled. – Manuf.: Brückner.

Remaflam process Drying process developed by Hoechst and Brückner, in which methanol is used as an energy carrier (→ Methanol/Water flashpoint). Process for padding and drying textiles, in which textiles are soaked in a flammable liquid (e.g. methanol). At the next stage, combustion of the liquid takes place, causing the water to evaporate. Remaflam drying has an initial speed of 10 m/min; after approx. 5 min the speed is 70% of the ultimate speed (which is reached after approx. 20–30 min). The average drying speed is therefore dependent on the length of the cloth run. As a result of extended tests (polyester/cotton, 320 g/m) it has been established that the optimum speed had been reached after approx. 30 min. The volume of air extracted by the fan reaches equilibrium after approx. 45 min; the residual moisture of the fabric shows constant values from the start of the test. The combustion chamber reaches the selected temperature, based on experi-

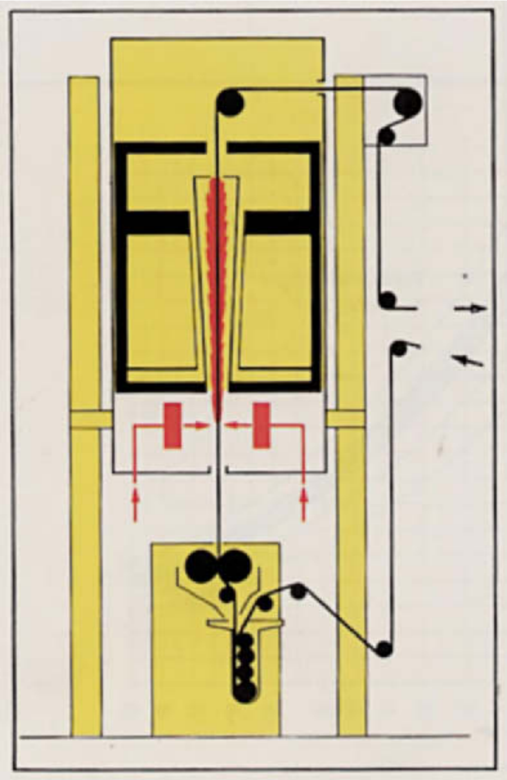

Fig.: A Remaflam drier from Brückner (red = methanol combustion).

ence, after only a few min; however the post-combustion takes 30 min to reach optimal conditions. Driers based on the Remaflam process are not only economical in operation for high volumes; short fabric runs can also be processed very economically using this equipment.

Remaflam-Thermocontact process Combination of the → Remaflam drier with a thermocontact plant. The exhaust gases generated in the Remaflam plant as a result of incomplete methanol combustion are used to heat the cylinder in the thermocontact plant. This means that they are burnt for a second time, thereby achieving optimum utilization of energy as well as incorporating the Remaflam plant in the continuous thermosol process.

Advantages:

- a short fabric heat-up time by means of thermal contact transfer reduces the overall time taken;
- heat transfer by convection from surrounding hot air on the contact cylinder both externally and internally ensures that the cylinder heats up absolutely evenly;
- small cylinder spacing ensure that the fabric rapidly changes sides on contact with cylinder surfaces, increasing dyeing evenness;
- undesirable fabric shine caused by contact occurs much less frequently, if using contact cylinders with a large diameter, than with smaller-diameter rollers;
- relaxed cylinder operation ensures that fabric runs without stretching or creasing with no lengthways tension;
- the equipment is of a compact design with a relatively low fabric content, and therefore saves energy and space.

Manuf.: Brückner.

Remobilization Aminocarboxylic acids that bond cadmium or mercury in sediments or sludge release these heavy metals successively. If a purification sludge is deposited in which heavy metals are temporarily immobilized by means of adsorption, they can be remobilized by extraction through seepage water, and thus accidentally be transferred to the ground water.

Remobilization potential R Ecological parameter for phosphate substitutes. Definition of the maximum quantity of heavy metals to be remobilized from sediments under defined conditions. For ecological requirements the following applies:

$$\mathbf{R < \frac{300}{100 - B}}$$

R = remobilization potential,
B = biodegradability.

The standard remobilization value can be defined as follows

$$\mathbf{R_{St} = \frac{\mu Mol\ metal}{\mu Mol\ complexing\ agents} + 100\ R_{St}}$$

= relative conversion in % for concentrations of 100 μ Mol/1 complexing agents.

Remobilization potential R of nitrilotriacetic acid ≈ 100, of citric acid = 96–138, of polyhydroxyacrylic acid = 7.5, of maleic acid ethylenecopolymer = 1.

Render fast to hot pressing → Decatizing.

Rendering hydrophilic Interfaces can be classified according to their wettability as follows:

a) hydrophilic interfaces, that form a wetting angle with water of $\theta < 90°$, in other words the immersion energy with water is positive;
b) hydrophobic interfaces, that form a wetting angle with water of $\theta > 90°$, in other words the immersion energy with water is negative.

Paraffin is the most hydrophobic, with $\theta = 105°$ and an immersion energy of –0.027 N/m. Glass, quartz and aluminium oxide are hydrophilic, in other words the wetting angle is so minute as to be insignificant, the

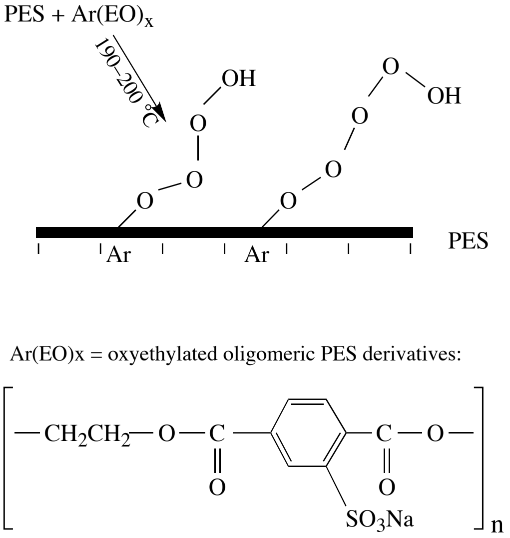

Fig. 1: Making polyester (PES) hydrophilic by co-crystallization.

immersion energy is 0.077 N/m. Hydrophobic fibres can be rendered hydrophilic so that they become wettable in water, which is recommended for garments made of synthetic fibre as it improves washability and ensures greater wearing comfort. Polyester fibres can be treated with alkali. For all synthetic fibres, treatment with hydrophilic polymers is known as soil-release finish. An interesting mechanism for permanent fixing of hydrophilic polymers to hydrophobic fibre surfaces is the principle of co-crystallization of the copolymers with the fibre surface, which has been softened at fixing temperature (Fig. 1).

There is also the theory that soil-release polymers are deliberately washed out gradually from the fibre surface; during this desorption process they take the soil particles with them more easily into the wash liquor.

1. Improvement of water absorption capability: hydrophilization can be achieved using several different techniques, e.g. by incorporating hydrophilic groups (such as the “Antron” polyamide fibre made by DuPont), by means of appropriate yarn structure in spinning, or bonds in the weaving. During the finishing process it is possible to graft hydrophilic groups onto the fibre, or to coat it with a hydrophilic film. The “Refresca” process (Surface Activation Corp.) belongs to the first category; polyacrylic acid is grafted onto polyester using cold electric beams in a vacuum. To create a hydrophilic film on the fibre, anionic, cationic and non-ionogenic products can be used. A further advantage of hydrophilization is the reduction of soilability and electrostatic charge.
2. Soil-release finish: When an oil-soiled fibre is washed, it can be seen under a microscope that the water-based washing liquor forces the oil out of the fabric surface, and subsequently the surface energy is saturated by the water molecules. This process is known as a roll-up or re-wetting mechanism (Fig. 2).

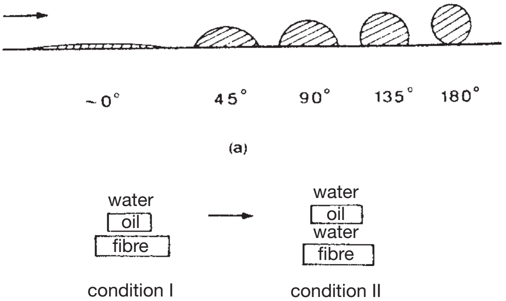

Fig. 2: Displacement of oil soiling by the washing liquor during re-wetting.

The oil, which initially coats the surface in the form of a thin layer, is joined together to form droplets by the wash liquor, and finally removed by the current. Re-wetting can be explained using thermodynamics. To simplify, the energy forces in situation I and II, can be regarded as the total sum of all interfacial energy forces.

$$E_I = \gamma_{water/oil} + \gamma_{oil/fibre}$$
$$E_{II} = 2\,\gamma_{water/oil} + \gamma_{water/fibre}$$

Performing the subtraction E_{II} - E_I results in the energy equilibrium value for the oil desorption and subsequent water adsorption.

$$\Delta E = E_{II} - E_I = \gamma_{water/oil} + \gamma_{water/fibre} - \gamma_{oil/fibre}$$

If energy is released during this process (ΔE negative), then the conversion will occur spontaneously. To fulfil the condition ΔE negative in the above equation, $\gamma_{oil/fibre}$ must be a high value and $\gamma_{water/fibre}$ must be low. This can be achieved by rendering the fibre surface hydrophilic with polar groups. The interfacial energy $\gamma_{water/oil}$ is dependent on the type of surfactants and concentrations used. Normally the value $\gamma_{water/oil}$ is small in comparison with the other interfacial energy values. Where acidic acrylates are present, the primary carriers of hydrophilic characteristics are carboxylic groups. Their bonds to the fibre or to large chains of molecules can be of a physical nature (van der Waals forces). There are basically three categories of compound that are used for soil-release finishing:

a) Copolymers derived from acrylic acid (or methacrylic acid) and from comonomers such as alkylacrylates (or alkylmethacrylates): There are various different methods of producing this type of product synthetically. In every method, acidic acrylates are generated, which exhibit an optimum carboxylic group content for soil-release effectiveness. Systematic tests have shown that products with the same molecular weight and the same ratio of carboxylic and ester groups, but with different methods of manufacturing the polymers, lead to varying soil-release properties. Bonding of this type of product is adsorptive; however there are also acidic acrylates containing reactive groups, causing a chemical bond with the substrate.

b) Oxyethylation products that are polymer-based (specifically for synthetic fibres) or based on alkylphenol derivatives (specifically for cellulose fibres): An interesting mechanism for bonding polymers physically to a thermoplastic substrate has been suggested for these products. When a polyester fibre, for instance, is heated above the glass temperature, the polymer diffuses into the less ordered components of the fibre. If the polyester fibre is subsequently cooled, the level of arrangement of the polyester increases slightly. Since the internal friction during the cooling process increases exponentially as the temperature drops, a separation can no longer be assumed, making the diffusion of the soil-release polymers during the washing process more difficult.

c) Modified fluorocarbon polymers (e.g. poly-[N-methyl-perfluoro-octanyl-sulphonamido-ethylene-acrylate]): this type of block polymer with hydrophilic and hydrophobic blocks guarantees dual action in air, i.e. during use, an oil-repellent effect is achieved, suspended in water because the chemical groups of polymers dedicated to each medium are re-arranged, so that the hydrophilic groups allow soil release.

Initially the textile substrate is coated with soil release agents in emulsion form (usually in association with cellulose-based resin finishing chemicals). It would be possible to apply soil-release finishes in solution form. In contrast to low-molecular chemicals, a macromolecule has some freedom and is therefore capable, even in a state of adsorption, of a considerable degree of mobility, and within the adsorption layer it is even capable of deformation and creasing. In addition to this, it is possible for a macromolecule to form a multiple physical bond with the surface of the substrate because of the number of atoms in the polymer. The macromolecule of the soil-release agent with this arrangement is able to adsorb soil particles preferentially, depending on their chemical composition, so that they do not accumulate in non-accessible areas of the substrate. The solvent used influences the mobility of polymer segments, degree of convolution, and the space they occupy. If the competitive adsorption of the solvent at the substrate surface is strong, the adsorbed layer of the polymer will remain small. If possible the solvent should not swell the substrate excessively, so that the soil-release polymer is retained on the fibre surface. The influence of the solvent used for finishing can be tested for wash permanence using the desorption curves of an acrylic acid -n- butylacrylate copolymer applied on polyester/cotton mix fabrics with different solvents. Alcohol and ether-base solvents seem to be unsuitable, because only a few polymers are adsorbed from the substrate. Strongly polarized solvents such as water, pyridine, glacial acetic acid and dimethylformamide cause initial high quantities of the polymer on the substrate, so that any partial desorption that occurs is insignificant.

The polymer adsorption at the substrate surface is also influenced by the molecular weight of the polymers. Low-molecule polymers tend to be irreversibly adsorbed because of their rapid surface diffusion, thereby preventing polymers of a higher molecular weight forcing their way in at a later point. However an increase in the quantity of substance adsorbed with higher molecular weight was observed. Evaluations of the polymer additives and the carboxylic group content on treated polyester/cotton mix fabrics showed that copolymers with a molecular weight of between 50 000 and 100 000 are the slowest to desorb, and that their desorption equilibrium (after approx. 10 washes) was much higher than copolymers with a higher or lower molecular weight. The adsorption strength is based on the type of adsorbed polymer molecules, for which convolution and solvency are influential factors. In extreme cases convolution and bristles are visible; however most observations indicate macromolecule adsorption in the form of loops or severely deformed convolutions. In polymers, the conditions for complete miscibility are particularly unfavourable. This is known as commonly occurring polymer incompatibility. Polymer separation is more likely to occur the larger the molecular weight. Even minimal differences in the chemical composition of polymers can cause incompatibility. It is therefore evident that a soil-release copolymer, for instance, one based on acidic acrylates, and a polyester fibre, cannot be mixed. For this reason, highly intensive contact of the two polymers to ensure a permanent finish is difficult. However, the polymer systems described here retain their oil-in-oil emulsion character even after removal of the solvent. This type of polymer mixture consists of the two polymers being blended together and a block or graft copolymer, which is responsible for stabilizing the “frozen” emulsion. As one would imagine, the application of emulsion-based soil-release agents due to the presence of this type of emulsifier is permanent, and has advantages in comparison with solvent-based applications. If the correct type of emulsifier is used, an oil-in-oil emulsion of the soil-release polymer in the fibre polymer is created.

Renforcé Also known as dense plain weave cotton fabric; medium-fine cotton quality, finer than cretonne. Available as raw material, bleached, dyed and printed. → Plain weave cotton fabric.

Renovation dyeing → Job dyeing.

Rental linen Textiles and → Industrial workwear hired from rental laundry firms (such as hospital linen, hotel linen, etc.). Examples of hirers are hospitals, institutions, caterers, commerce, industry and civil service.

Re-oiling agent for dry cleaned leather Oils and fat liquors necessary for leather after treatment in drycleaning to restore the soft handle and shape stability of the leather.

Repeat Generally: Unit of pattern or pattern repeat, e.g. weave repeat (woven fabric) and pattern repeat on printed textile runs.

Repeat for printing, design drawing Before screens can be made, all design drawings must be redrawn to the correct → Repeat size. The entire surface of a screen can be filled with a single repeat, or several evenly distributed repeats can be fitted onto the screen. The definition of the repeat limits must be dependent on this; in the case of open and geometric patterns they are usually in straight lines. Separation of essential parts of the pattern must be avoided at all costs, to ensure that the pattern does not tear during printing if screens are set badly to the repeat limits. In such cases, the designer plots a selection of repeat lines that are the same on the facing sides, to guarantee that the repeats will match up. Guidelines on the drawing and screen simplify the transfer process.

Repeat length setting systems in screen printing After each print impression, the → Screen must be offset by a certain amount (screen repeat). In order to define precisely where the screen must be placed, various repeat systems can be used. With only a few exceptions, these consist of → Repeat rails with repeat stops, and a repeat stop on the screen.

Repeat rails in screen table printing Located on the long side of the printing table. The repeat stops, which are adjustable, are fixed to it, so that the screen position can be set to accommodate varying repeat sizes. → Printing screen locking units.

Repeat size Extent of → Repeat in the direction of warp (repeat height) and in the direction of weft (repeat width).

Repeat stops,

I. (guide pins) Tool used in screen printing, to ensure that the print screens are offset precisely and to accommodate the repeat.

II. → Printing screen locking units.

Repeat wheel Cogs on → Embossing calender to adhere to positive and negative on embossing rollers and elastic rollers.

Repellent (repellate), substances with specific repellent, but non-damaging, properties, such as → Insect repellent finishes.

Replacement cost standard market price → Service life of textile plant and equipment.

Reproducibility Capacity to repeat the properties defined in the specification, such as colour shade. The evenness of dyeing is assessed on the padder (see Fig.).

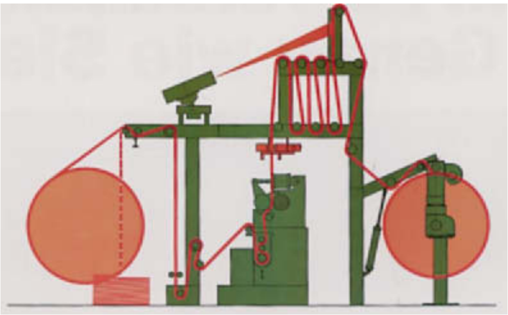

Fig.: Wet colorimetry on the Monforts Matex-Colour-Foulard.

The system used for monitoring and correction is → Colorimetry. Measurements are carried out from a safe distance, independent of external influences such as steam, temperature, light reflection, or fluttering of the fabric. Colorimetry can detect differences in fabric properties, as well as in the pretreatment immediately after the fabric has been squeezed off and is still moist. If required, a high-humidity measuring instrument with one or three measuring heads can be used as a supplementary tool for early error detection. In the next stage, the software, which has been appropriately configured and is directly interactive, is responsible for rapid adjustment to the required standard and ensures an ongoing even distribution of colour. As well as correct point precision of colour correction, it is also possible to perform edge/middle/edge corrections to the colour liquor application. This results in rapid control from batch to batch. For knitted fabrics, guidance is monitored up to the point of rolling. Residual liquor is minimized by the use of a small trough and measurement of liquor utilization.

Reproduction camera For the manufacture of → Photographic colour separations, print patterns are photographed on film using a reproduction camera, so that the repeat size can be corrected by enlargement or reduction.

Requirement profiles Designing clothing is a creative process which must nevertheless take into account how certain ideas can be realised. Thus, for example, under certain circumstances, the highest demands can be made of textiles which are specifically to be used in certain areas. Influences such as clothing

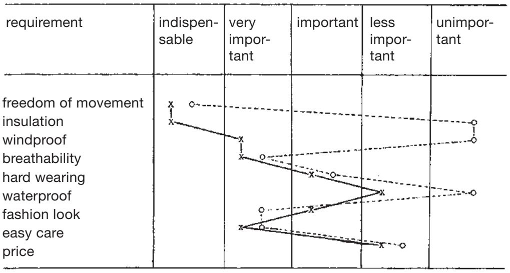

Fig. 1: Possible requirement profile for sportswear.

physiology, movement sequences, climatic conditions, the textile fabrics envisaged, must all go into the model design. This means engineering design of the overall clothing system, for example. Specifically in the case of functional sports clothing, it has been shown that pragmatic considerations must take precedence over fashion. In order to do justice to this principle, it is necessary to produce a profile of requirements for the clothing which is to be designed, containing all the features which need to be taken into account (Fig. 1).

The profile of requirements for the made-up piece yields the choice of material, i.e. the choice of the textile fabric as well as the ingredients. The wealth of textile fabrics on offer, e.g. for sports clothing, also brings the risk of confusion. It is therefore sensible to produce a profile of requirements for their choice too (Fig. 2).

For home textiles which are used directly as textile fabrics, e.g. curtain fabrics (Fig. 3), the textile finisher also must produce a profile of requirements for retail for these textiles.

For hygiene articles in the contract sector in particular, e.g. hospital linen, the profile of requirements (Fig. 4) is decisive for the correct choice of textile finishing processes.

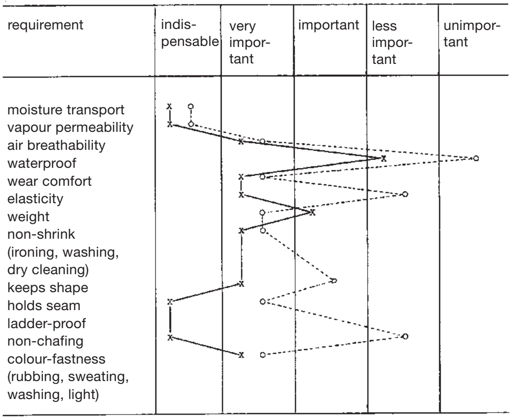

Fig. 2: Possible requirement profile for fabric for sportswear.

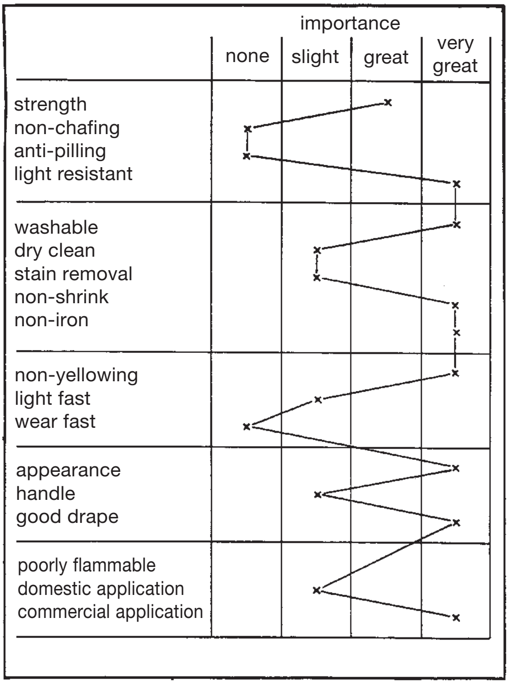

Fig. 3: Possible requirement profile for a curtain.

The disposal aspect must also be taken into account in a profile of requirements.

Research Intellectual activity of individuals or groups, with the aim of making new discoveries using methodical, systematic and verifiable techniques. Experts redefine this to the effect that research encompasses all work where it is initially unclear how it could be applied in practice and for proof purposes, and where the methods used to reach the objective are unknown (fundamental research).

Specialist journals record the dialogue between research and industry. Research encompasses new areas of science and technology, and by exchanging ideas with industry, as well as by means of important scientific and technological achievements and marketing of discoveries and inventions, research establishes the prerequisites for these to be used viably in industry (Fig. 1). Imparting knowledge, for instance via scientific/technical publications, means there is a broad information and application base. The transfer of technology as a specific, organized process for passing on experience, research results or achievements, sets the parameters for economic use of these principles. The solution of scientific/technical problems and the development of new technologies are essential for the preservation of competition in industry. The high proportion of quality technical goods from Germany can only be maintained if research and industry aim towards the

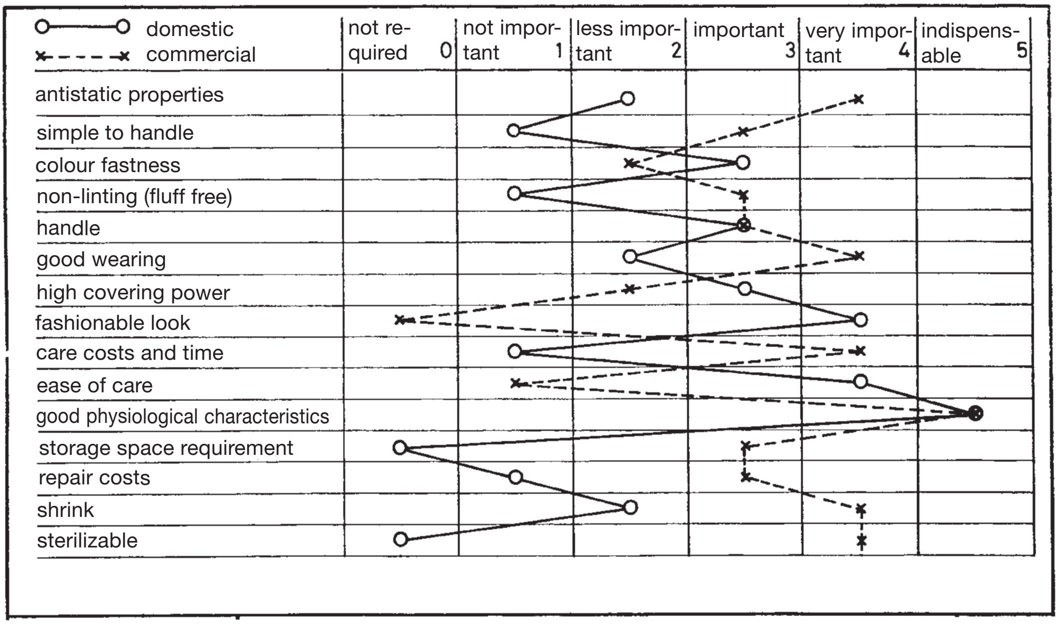

Fig. 4: Possible requirement profile for domestic and commercial bed linen.

shared objective of systematically reaping the full benefits of innovation potential and consistent utilization of "the 4th most important production factor, knowledge". This is apparent in the increasing level of co-operation between research and industry in many future-orientated technologies, where there is intensive implementation and marketing of research results, as well as joint development of solutions. In this complex technical/scientific environment, technology transfer as an organized, process facilitating co-operation between industry and research is gaining in importance.

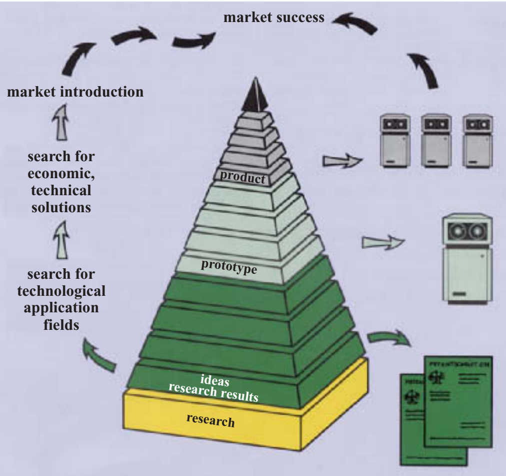

Fig. 1: From the idea to market sucess: research and development (R & D).

Research plays an important key function in the implementation of scientific discoveries into industrial practice. It provides significant contributions towards closing the gap after the scientific result and before industrial production. Research is a supplier of industrial standards, and as such it provides contributions towards further specialist development as well as scientific/technical results to enable standardization and reproducibility, for example. Research itself is a complex co-operative system, with a hierarchical structure from the level of international co-operation down to the efforts of individuals and institutions. The discoveries resulting from the research of complex systems can be applied to the research system itself (so-called self-reflection). The method of controlling research by "decree", which is sometimes recommended, is obviously a linear approach, which reflects a classic technomorphic philosophy. Nothing can be built up with this approach, only destroyed; research success, as is the case with any complex system, cannot be simply "made to order", research is open by nature. However, with this omen it is a great challenge to address present and future problems, and scientists worldwide, particularly in areas of specialist research such as textile chemistry, have to meet this challenge.

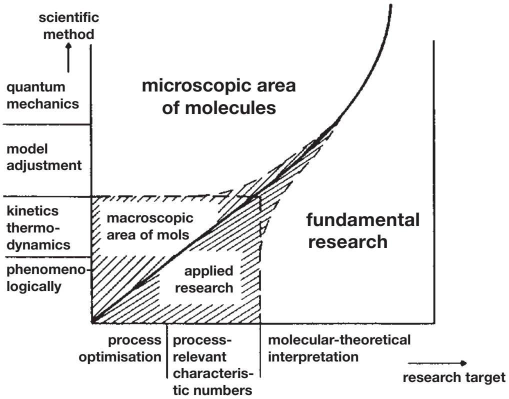

Fig. 2: Fundamental research and application technology overlap in a varied form.

A typical approach to research in the field of textile finishing is empirical recording of the significant, fundamental, mechanical phenomena for which an appropriate interpretation is required (Fig. 2). By its very nature, when this optimization method is applied, the search for a coherent interpretation that is as comprehensive as possible, into which the fundamental phenomena not only fit easily, but which can also provide a basis for prediction, remains unresolved. Another possible way of carrying out research into textile chemistry is to couple the fundamental phenomena of a textile finishing process with scientific facts derived from structural research as a comparison with the standard model. However, using this method of interpreting phenomena theoretically has relatively rarely proved to be a success. It can be assumed that the reason for being unsuccessful is the fact that there is not enough exchange of ideas between experts and structural researchers. Experts unmistakably let their aversion to so-called fundamental research be known. Although for instance there are some very sophisticated, substantiated structural theories on the morphological structure of cellulose, experts have doubts about using these models as a possible way of interpreting fundamental, mechanical processes theoretically. On the other hand, structural researchers lack some of the practical experience necessary for them to be able to test the models they have developed themselves for viability in practical application. The finisher tends to regard the final result of treatment to be of the most significant. However, in fact, a systematic investigation of the processes during the course of treatment would provide an insight into how application conditions, chemical reactions and textile-related, mechanical properties operate together to influence the final product. As an example, an attempt was made to classify the fundamental phenomena observed during the application of formaldehyde to cotton using a structural model of the cotton, a situation that arises frequently in the field of structural research. The main emphasis was on establishing the chemical structure of the crosslinked cotton. In this way, the morphological quality can be linked with the textile-related, mechanical properties of the final product of the reaction. A further way of describing a phenomenon using theoretical prediction is based on statistical, thermodynamic considerations, and results in a description that is independent of every model and therefore precisely correct from a mathematical point of view.

The difference between fundamental research and applied research is purely arbitrary and therefore artificial. Assuming that many of the major technical innovations have their roots in fundamental science, the following must be realized: An idea that originates in physics or chemistry can be applied in more and more different forms over a period of time, until it eventually comes to fruition in its final form in a product or process. However it is impossible to define boundaries between fundamental research/development/applied research, because there is no point at which it can be said that “the idea is no longer scientific, but technical”. Chemistry-based textile research must not be approached on a statistical basis. In fact it is rather the case that carrying out the working methods discussed shows that flexible cut-off points between each stage of the suggested scale are possible, in fact in some cases necessary. However if this continuous spectrum is accepted, it is important to be aware that the outcome hinges on how the task is approached. If somebody uses empirical methods, his work is often regarded as applied in nature. If another person bases his work on theory, it can easily be categorized as fundamental research. However it is the objective of the work that is the important factor.

Due to the current legal situation and the urgent significance of the subject, one major aspect of research is environmental protection and the problems associated with it. Since short-term solutions are necessary for textile finishing in particular, the existence of fundamental and application-orientated research is clearly justified. In 1991, Gesamttextil published research objectives for environmental protection in the textile industry, which are as follows:

I. Objectives: the target for environmental research is to develop process techniques that are both environmentally friendly and suitable for industrial application in all areas of the textile industry. Any substances or combinations of substances that cause damage to the environment or constitute a health hazard should be replaced or eliminated, natural resources should be used as sparingly as possible whilst fulfilling the quality standard of German textile products. Environmental research in the textile industry should enable known process techniques that are already implemented in other industries to be converted for the requirements of the textile industry. In the current globally interwoven climate, international co-operation should be further intensified.

1. Avoidance:
   a) forgoing certain substances and processes,
   b) reducing input of substances and energy by means of exact process control,
   c) using process techniques with minimalized substance quantity and energy consumption.
2. Recycling: Reclaiming substances and energy by means of
   a) controlled process operation,
   b) making optimum utilization of appropriate recycling procedures,
   c) integrated utilization of internal and external resources.
3. Minimization: reduce utilization of substances and energy in existing processes as far as possible by optimizing recipe formulae, machinery and processes.

Avoidance, recycling and minimization must be the primary research interests. The primary reason for this is because assessing and optimizing internal process techniques as well as stringent process control and monitoring mean that significant reductions in the discharge of environmentally damaging substances and in energy consumption can be achieved. Secondly, it is because in the long term industrial activity should not be based on the concept of "end of the pipe" philosophy, i.e. using more and more extensive purification plants situated peripherally in the company.

II. Emphases, e.g. in the category water, waste water:

1. General topics:
   a) recording and logging of individual processes according to type and quantity of environmental pollution, as well as the amount of water required and discharges into polluted waste waters;
   b) purification and decolorizing of textile waste water, with the objective of lowering BOD and COD, as well as dye and solid substance content;
   c) development of processes with integrated purification stages (filtration, ion exchange, energy reclamation, chemical treatment);
   d) development of computer-controlled process operation with the objective of minimizing waste water (integrated analysis);
   e) utilization of emitted heat for distillate concentration of liquor desizing;
   f) utilization and expansion (technical) of existing waste water treatment plants for chemical-physical purification of waste water from processes (circulation);
   g) possible utilization of surface water, rain water (cisterns);
   h) possible utilization of internal overlapping water circuits.
2. Specific themes:
   a) reduction of liquor quantity in textile finishing processes;
   b) increase in dye extraction quantities in dyeing processes by improving machinery and mechanical aspects of process operation, as well as improving chemical and chemical/physical aspects of the process;
   c) analysis of the physical bleaching processes (UV light).

Research institutes → Technical and professional organizations.

Reservoir fabric e.g. Made from polyester, functions as re-dyeable dye carrier (typewriter ribbon principle) in the → Transfer dyeing unit.

Residual additives Overall amount of residual surfactants, sizing agents and scrooping agents on fabric of print-ready quality. The quantity of residual surfactants is a significant factor affecting textile properties during the printing process. If the quantity of residual surfactant preparations in general use increases, the rate of increase of use at a monomolecular adsorption level measured using the capillary rise method remains continuous, with a maximum rate of 0.5–1.0%. There is a linear, degressive link between the absorbency of a fabric treated with anionic and non-ionogenic surfactants by padding and air-drying, and the sharpness of outline and print penetration. For this reason the printing treatment should be adapted according to the required result.

The application of a skim-coat to a polyester fabric (with negative zeta potential) using surface-active compounds is categorized by a layered structure, as shown in the Fig. This illustrates how, after the monomolecular adsorption layer is formed, increasing the level of surfactants as a result of interaction between the principle hydrophobic surfactant molecule groups (with possible influence from cations), successive adsorption sub-layers are formed, so that water-repellent finishing can continue because the residual hydrophobic groups have an affinity to the solution. If the problems arising during build-up of multi-layers are taken into account, then the hydrophobic characteristics of the polyester and the hydrophilic surfactant characteristics determine the surface properties when there are small amounts of residual additives. However, if there are large quantities of residual additives, both the hydrophobic and hydrophilic properties of the surfactants will be the decisive factor (according to Schollmeyer).

Residual chemicals control in running webs Any untreated cloth contains extraneous substances because of the type of fibre, yarn scrooping and warp yarn finishing. These organic and inorganic extraneous substances can cause problems in the various different

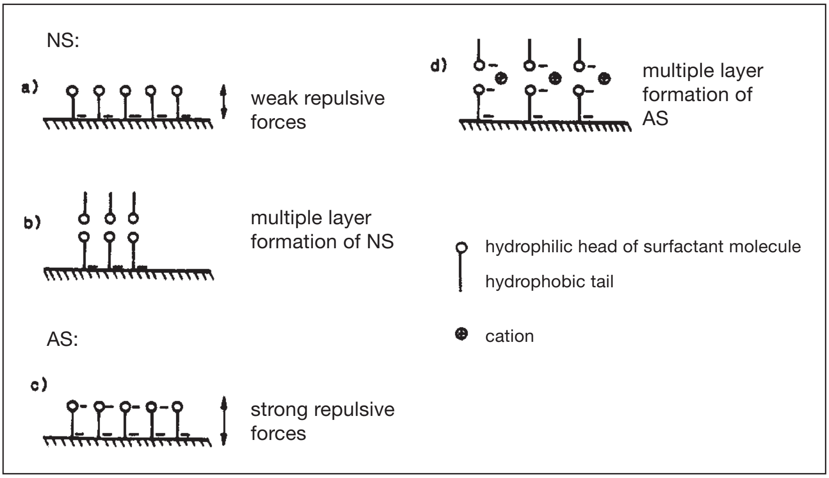

Fig.: Diagram showing the adsorption of surfactant residual additives on polyester fibres in an aqueous solution (according to Berth and Schwuger). NS = non-ionogenic surfactant; AS = anionic surfactant.

stages of fabric finishing (pretreatment, dyeing, print finishing, etc.) if they are not removed sufficiently. The same applies to chemicals used in finishing for an additive or subtractive effect, which can cause problems as residual chemicals, or even become very destructive.

Example:

- Residual alkali can cause problems in subsequent dyeing, printing, and particularly final finishing (catalytic toxins, etc.).
- Residual alkali can lead to yellowing and other negative effects to the fabric during the drying process and other types of heat treatment.
- Residual acid can damage cellulose during the drying process, and during finishing can result in unwanted intensification of catalysts.
- All extraneous substances can influence effect and fabric strength.

The consequences for the finishing trade are high costs for necessary after treatment (i.e. corrections and repairs), exceeding delivery deadlines and reduction in profit as a result of lower quality and rejects. Residual chemical control systems use special sensors so that they can detect and record the condition of the fabric run continuously (see Fig.). The measurement values are obtained by blowing steam onto the fabric run while it is being processed. The steam is subsequently sucked back up, and the condensed material is then collected in a container where it is analysed with special sensors:

- residual alkali and acid by means of pH electrodes;
- degree of electrolyte buffer effect (more or less) by means of conductivity;
- all types of ions by means of ion-selective sensors;
- measurement of organic load by means of oxidation;
- colour and turbidity status by measuring extractions at 350–900 nm.

The recorded measurement values are displayed digitally on a screen or on an analogue display if preferred, so that information is available constantly.

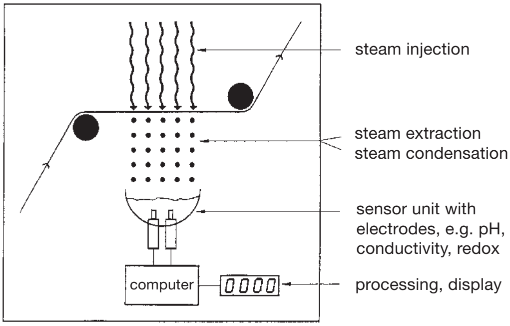

Fig.: A residual chemical control system (the Mahlo Chemocon CMC-9).

Residual grease content Content of wool grease (% of the washed wool weight) after → Raw wool scouring. Dependent on the organic solvent being used. Can also be defined as extract soluble in dichloromethane.

Residual liquor method → Dyes on textiles, quantitative determination.

Residual liquor minimization In practice, when applying dye or finish in the padder, frequently too much liquor is used, so that a large quantity of liquor is wasted at the end of the batch. This increases production costs and pollutes the environment unnecessarily.

As a first organization measure, it is a good idea to summarize batches (Fig. 1). Tightening up on the variety of products and recipe formulae is often an essential step in textile finishing optimization, with the objective of mimimizing residual liquor. However, the ideal or-

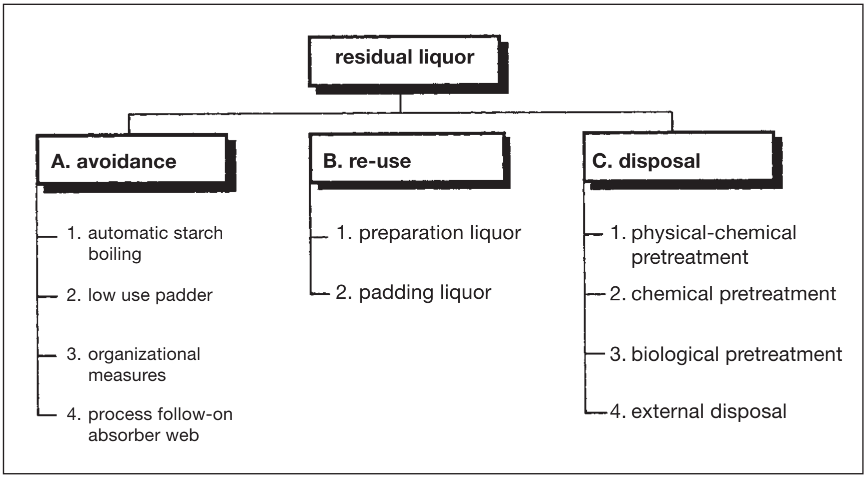

Fig. 1: Overview of proposed solutions to the problem of residual liquor in the textile finishing industry.

ganizational improvements can often not be implemented because of timescales and deadline pressures, unusual customer requirements (particularly in commission finishing) and the typically short lives of fashion textiles. The drastic limitations of recipe formulae and the use of less products, but ones that are optimized from a technical and ecological point of view, is a sound basis for a production process that is close to ideal from an automation and organizational point of view, and generates very few residual substances. A production process that is organizationally optimized not only has a positive effect on the environment, but also saves wages, since interim cleaning of the finishing machinery is no longer necessary, and the logistics of the fabric for finishing are not as complex. As a result of the reduction in textile agents, the number of containers also drops correspondingly. The required finishing chemicals, being implemented on a larger scale, can be delivered by tanker, which is of better value and more convenient from the point of view of packaging. The future of modern, effective and high quality use of liquor is based on the automated finishing kitchen. Some of the necessary experience for this technique can be drawn from printing and dyeing, where this process technique has already become established, and transferred to textile finishing.

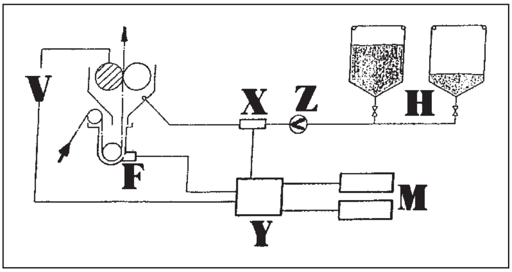

Fig. 2: Control of residual liquor in the dye trough. F = pressure sensor; H = liquor feed tanks; M = display and printer; V = metre counter; X = through flow meter; Y = PLC; Z = pump.

From a technical point of view, residual liquor from the padding process can be minimized as follows:

The amount of liquor required can be reduced to about 10–20 l using new types of construction, whilst retaining the same finish quality. In the case of older plants, the same effect can be achieved by installing dividers. For technical reasons related to the process, there are geometric limits to colour box construction, meaning that further residual liquor reduction aiming at zero is not allowed. In addition to this, rinse water is produced during the process of padder cleaning, which is also highly concentrated and therefore needs to be treated. A reduction in the volume of rinse water can be achieved by using high-pressure purification equipment. If the predicted liquor requirements are wrong, disposing of an excess of finishing liquor can be avoided by last-minute adjustment to the liquor consumption forecast (Fig. 2)

On-line measurement of liquor utilization with specific liquor level monitoring facilitates a reduction of residual liquor (Fig. 3). These measurements provide a constant record of liquor used per metre of fabric, actual consumption in litres, and the remaining fabric meterage. The trend display on the monitor shows at the start of the process whether enough liquor is being used, both as a graphic representation and as a unit of volume (litres). If the trend display indicates that the amount of liquor is insufficient for the current batch, the precise volume of additional liquor required can be dispensed without interrupting production.

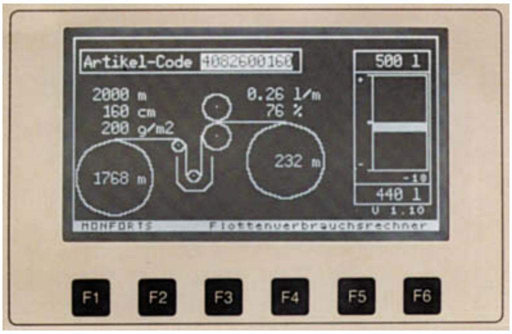

Fig. 3: An on-line liquor use prediction system from Monforts.

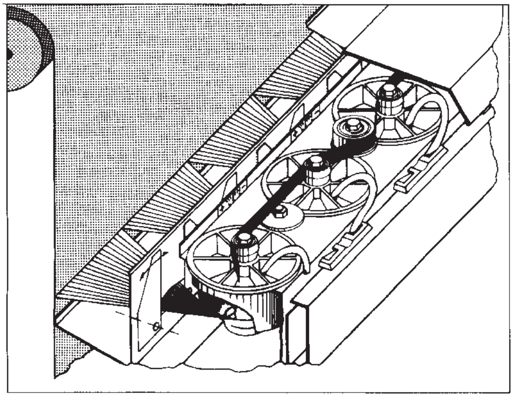

Fig. 4: Diagram of the Weko rotor dampener.
a = rotors; b = spray chambers; c = material web; d = rotor carrier; e = shutters.

The most reliable way of cleaning the padder is the end-cloth method. A highly absorbent run of fabric is put through immediately after the fabric that is being finished, to remove the residual liquor from the padder. During the subsequent drying passage, approx. 90% of the liquor is removed, primarily in the form of water, via the ventilation system. Obviously organic impurities will be released from the water as well as vapour, but if ecologically optimized methods are used, the level of organic impurities will fall well within the stringent limits of the technical instructions to prevent air pollution (TI-Air). The concentrated impurities on the end-cloth can be disposed of as water-free waste.

There are other liquor application techniques apart from padding, which generate less residual liquor. If spray application is used (Fig. 4), the liquor in the dispensers can be monitored so that they can be topped up if necessary towards the end of a batch, meaning that there is hardly any residual liquor left at the end.

Residual moisture content Moisture content of fabric after the drying process. In practice the residual moisture levels are generally between 20 and 40%, depending on fabric composition. Pre-driers should be designed so that fabric moisture after drying is maintained at the same level so that, among other reasons, dye migration at the fibre surface is kept constant throughout the dyeing process.

The residual moisture can be measured by means of → Microwave moisture measurement, for instance; equipment suitable for this can be affixed behind the pre-drier (Fig. 1). Another possibility is isotopic radiation measurement.

If the values measured by the residual moisture device are implemented, and a controller is installed, the performance in the IR duct can be controlled, or in other words the moisture requirements can be kept at a

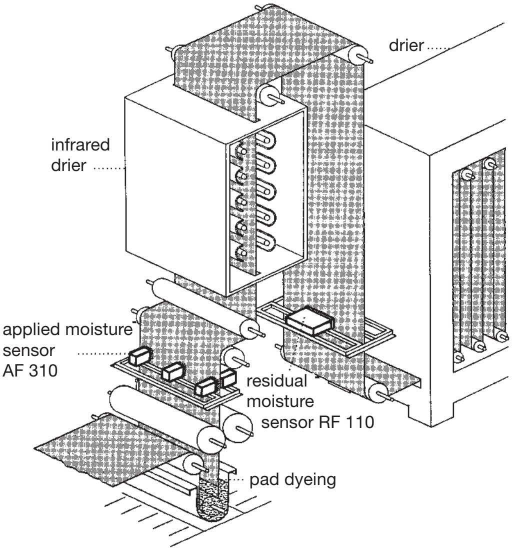

Fig. 1: The determination of residual moisture content downstream of an IR drying shaft by means of microwave absorption using the Pleva AF 310.

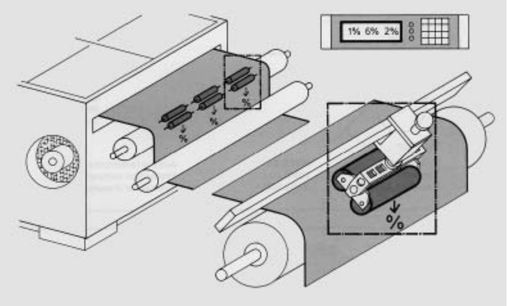

Fig. 2: Residual moisture measuring unit PR 1.3 (Pleva).

constant level. It is not recommended to control the power of the IR radiator by switching off individual radiator lines, it is better to control the voltage of the predrier. New equipment based on conductivity measurement have been introduced which are more reliable than before (Fig. 2), because electrostatic side effects are avoided.

Residual print pastes (print paste returns). Unused print paste left on the print machinery or printing table because a greater quantity than necessary for the meterage was applied for safety reasons. In areas where there is little awareness of environmental issues, the residual print pastes are usually mixed with solvent and released into the sewerage system as a disposal method, or alternatively the residual print pastes can be mixed together to form a black print paste (→ Recycling). This is usually the case in pigment printing. In the 38th Waste Water Management Standard in Germany (Abwasserverwaltungsvorschrift), it is stated that residual print pastes must no longer be disposed of with waste water, instead they should be treated as hazardous waste. Hazardous waste can be disposed of either by taking it to disposal sites, or incinerating it. Both methods of disposal can involve high costs and considerable amounts of additives, and for this reason both the chemical industry and textile printers are trying hard to develop ways of minimizing residual print paste, and in an ideal situation to avoid it completely. To achieve this, the following options must be considered:

a) avoidance and minimization of quantities of residual print paste;
b) reduction in the cost of residual print paste disposal.

The following considerations could be addressed to achieve avoidance and minimization of residual print pastes:

– trichromatic printing could be used if there is a problem with residual print pastes;
– more precise calculation of level of coverage;
– colour measurement to help cope with residual print paste problems;
– use of the most modern colour kitchens and automatic dye dispensing stations;
– printing the design on a short fabric meterage, and subsequently calculating the precise quantity of print paste required for the entire print consignment.

In the context of residual print paste, the shelf life of print pastes should be mentioned, as it is significantly dependent on the thickener. The shelf life of the thickener is in turn closely linked with the problem of conservation. This can lead to problems if, for instance, different thickeners are used, because, if the residual print pastes are mixed in order to use them up, it will result in the mixing of thickeners from different suppliers that have been conserved in different ways. If this happens, it could possibly lead to polymer incompatibility between thickeners.

Residual shrinkage Dimensional changes to the surface of a textile after the first wash. → Shrinkage.

Residual substances Any energetic conversion process involves an unavoidable increase in entropy, which is irreversible and cannot be converted back into useable energy. If this fact is applied to the circulation of chemical substances, it is obvious that even with the implementation of ingenious methods of recycling, energy conversion in any production process will involve an increase in entropy, and in parallel with this valuable substances are irreversibly converted to residual substances.

Residual substances are defined according to § 5 Sec. 1 No. 3 of the Bundes-Imissionsschutzgesetz (BImSchG – German Federal Immission Protection Law) which regulates pollution, as substances that are generated during the processing of other substances, but which are not required. This includes solid substances, liquid substances, industrial waste water, etc. However, waste gases have not yet been classified as residual substances. The BImSchG Law encompasses more than just pollution control. It includes hazards, disadvantages and nuisances that are not caused by pollution. The third principle defines avoidance of residual substances as a legal obligation, which like the other principles must be observed during construction and operation of any plants requiring approval.

This is supposed to ensure that production of residual substances is avoided, even if they can be re-used where they are produced, or elsewhere. Recycling strategies are permitted to reduce the quantity of waste which arises (recycling must comply with regulations and not present a hazard). However if avoidance and recycling are not possible or reasonable, waste may be disposed of in line with regulations. This means that the legal obligation can be treated with a degree of flexibility.

In this context, the BImSchG is relevant to other legal standards, such as waste legislation and water economy legislation (→ Legislation on environmental protection). In particular, Appendix 38 of the General Management Standard Guidelines on minimum requirements for the introduction of waste water into ground water (Anhang 38 AbwVwV zu der Allgemeinen Rahmen-Verwaltungsvorschrift über Mindestanforderungen an das Einleiten von Abwasser in Gewässer) stipulates extremely comprehensive technical requirements that affect the textiles industry, which is indirectly responsible for waste water introduction. According to this legislation, the residual contents of treatment baths after the finishing process must be disposed of as waste if recycling is not a possibility. In addition to this, waste legislation states that the avoidance principle takes precedence over reduction or recycling/disposal. Appendix 38 of the German Administration Regulation of Waste Waters (38th AbwVwV – Abwasser-Verwaltungsvorschrift) will include a radical amendment – the stipulation of more stringent threshold limit values for waste water, not only for textile finishing as a whole, but also the definition of threshold values, and if these are exceeded it will indicate an underlying tendency towards a requirement for treatment. The reason behind these standards is that almost all process techniques have a higher standard of cleaning action the higher the concentration of the waste water to be treated. If the concentrates are allowed to be thinned by the rest of the waste water, the communal purification plant, which also has to cope with more stringent parameters as well as a constantly increasing volume of waste water, will not be suitably equipped to eliminate the hazardous substances to a satisfactory level. In addition to this, a conventional purification plant is generally not equipped to deal with industrial waste water. Its purpose is to purify the broad spectrum of waste water from different sources in compliance with the law and drainage requirements, over a period of only a few hours.

Residual substance handling should be based on an integral concept of technical optimization of the relevant textile finishing processes. The implementation strategy for all optimizing action should be planned in the sequence which is generally applicable in environmental protection: firstly avoidance or minimization, then recycling, and disposal only of residual substance components that can be reduced no further. This hierarchy should be borne in mind when planning strategies, because the first two suggested optimization points can be implemented relatively quickly, and also relatively inexpensively. Any type of disposal process will always incur costs for setting up the necessary infrastructure, running costs, and under certain circumstances, extra personnel costs.

The term “avoidance” should be understood in such a way that raw materials, agents, processes, techniques and machinery that generate no residual substances, or only small quantities, are implemented. Incorporation of residual substances in products manufactured at a plant is also regarded as avoiding action. If the textile finishing plant incorporates its own biological purification plant into its disposal strategy, it should be borne in mind that residual substances can still remain in waste water that has been purified in this way. These so-called refractory residues consist of residual substances that cannot be broken down by the biological microorganisms in the purification plant (Marzinkowski).

Residual valency →: Secondary valency forces; Van-der-Waals forces.

Resin Term for the physical quality of compounds with very different composition, usually vitreous-amorphous in form, insoluble in water, have a specific solubility in organic solvents, fusible, have thermoplastic properties and notable film formation properties from organic solvents.

I. Natural resin is an amorphous waste product of plants, particularly coniferous woods such as →: Colophon; Dammar resin; Copals; Mastic; Succinates, Tall oil, or of animal origin e.g. → Shellac. Plant resins are complex compounds consisting predominantly of resin acids that can be crystallized and non-volatile, with a volatile proportion; so for instance pine resin can, in principle, be termed an incomplete solution of native resin acids in turpentine oil. The composition of commercial resin formed as a product of the distillation residue (e.g. colophony with possibly in excess of 90% abietic acid) is not precisely identical to non-processed plant resin of the same origin. For this reason, pine resin stains, from oxidation and polymerization changes, are particularly difficult to remove. Application: restricted to exceptional cases for technical reasons specific to textile finishing (for oil sizes, silk ribbon finish). Inappropriate or excessive addition of resin can cause unwanted stickiness. → Resin soaps (in combination) are more important.

II. → Synthetic resins (for textile finishing).

Resin acids The major component of natural → Resin, particularly those derived from coniferous wood. There they occur in the form of native resin acids or so-called turpentine acids (primary and sapinic acids) which, after volatile components have been distilled off (→ Turpentine oils), remain in the residue (→ Colophony) in the form of colophonic acids. Those that have the empirical formula $C_{20}H_{30}O_2$ are for the most part isomeric hydroaromatic monocarboxylic acids of the type abietic acid, which has many derivatives that are useful in the textile industry.

Resin alcohols (abietinols), products of the → Abietic acid type (as di- or tetrahydro-) abietyl alcohols, which bear a certain resemblance to fatty alcohols. Sulphation leads to the formation of alkyl sulphates, which are similar to fatty alcohol sulphates. Resin alcohols are also condensed with ethylene oxide, polycarboxylic acids (crosslinking and emulsion agents), etc.

Resin antifelting finish → Antifelting finish of wool on the basis of synthetic resins. → Hercosett process.

Resinates →: Resin ester; Resin soaps.

Resin dyeing process → Dyeing and finishing combination processes.

Resin ester (resinates), esterified → Resin acids, in the form of ester alone or in combination (in a large number of modifications). Used frequently for resin varnishes, sometimes for slip-resistant finishes, for instance in the form of modified →: Phenolic resins; Modified resins; Maleic resin, either on their own or in the form of a glycerine compound as glycerine resinates, or just as resin ester in the form of methyl or ethyl resinate for plasticizers, etc.

Resin exchangers Synthetic → Organoliths.

Resin finished German → Quality symbols issued by the → GüTV for garment and outerwear fabric made of viscose, as well as cotton cloth, with guaranteed minimum requirements.

Resin finishes, analysis of Qualitative and quantitative analytic definition of resin finishing agents on fibre. Test reactions are usually not carried out on the fabric directly, but in the hydrolysate or distillate after boiling treatment with hydrochloric acid, e.g. formaldehyde, hydrolysates of resin finishing products in chemical, chromatographic, electrophoretic or spectroscopic analysis (see Fig.). In the context of quantitative analysis, the parts that can be stripped with hydrochloric acid (resin additives), and the nitrogen and formaldehyde parts, are significant.

I. Synthetic resin test according to Schliefer and Valk: In this test, separation is by means of thin layer chromatography. Method:

1. Detaching the resin from the fabric by means of acidic hydrolysis: treatment for a period of 60 min in a boiling water bath with 0.1 n hydrochloric or sulphuric acid. For amino-formaldehyde products, carbonyl compounds and acetals.
2. Alkaline hydrolysis: 1 hour in a boiling water bath with 0.1 n NaOH. For crosslinking agents containing sulphur in combination with amino-formaldehyde products, carbonyl compounds and acetals. Sulphurous products are stable during acidic hydrolysis.
3. Acidic total hydrolysis: Hydrolysis-resistant finishes on cellulose (very stable bonding with fibre, crosslinked polymers, etc.) can be defined after total hydrolysis of the fibre. Method: total hydrolysis or acetylization of fibre material with conc. sulphuric acid, then subject material to a chromatographic or IR-spectroscopic analysis. Suitable for testing: stable crosslinking, e.g. epichlorohydrin, graft copolymers (acrylic and vinyl compounds), crosslinked polymerisates or polycondensation products (polyvinyl alcohols, polyacrylates, polyvinyl chloride, etc.).

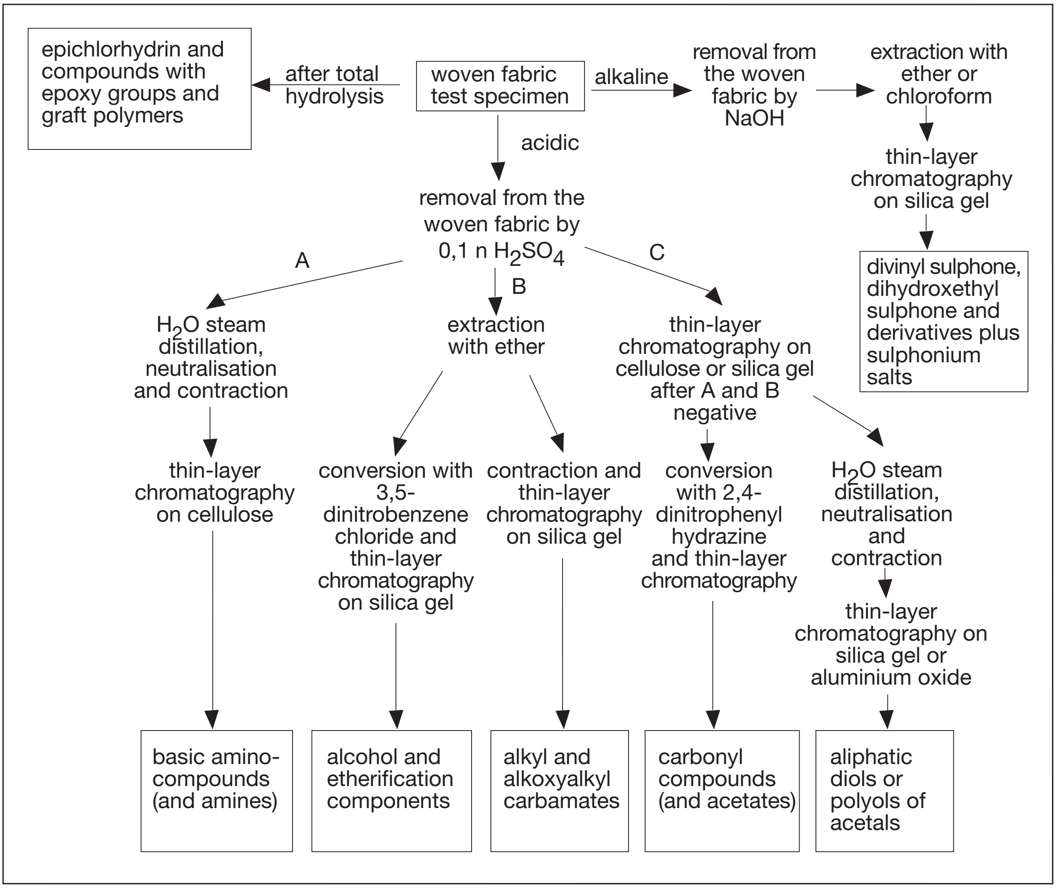

Fig.: Chart of the analysis process for the chromatographic detection of resin finish products on textiles (according to Schliefer).

II. Test for aldehyde and aminoplasts: Initial sampling: mechanical/technological tests (wet and dry creasing angle, swelling value, water retention properties, breaking strength, etc.), cloth construction, solubility in copper oxide ammoniac (cuoxam), chlorine retention analysis, test for formaldehyde (or carbonyl) compound (carbazol/sulphuric acid reaction), nitrogen test, urea test, etc. Procedure of analysis: distil a fabric sample for 10–30 min in gently simmering 0.1 n hydrochloric acid.

Testing the acid extract:

1. nitrite reaction indicates urea, thiourea, dicyandiamide and glyoxalurine.
2. hypochlorite reaction in an alkaline medium: Generation of gas = urea and thiourea (with possible sulphur separation). Yellow to brown colouring after standing for a period, no gas generation = melamine and acetoguanamine.
3. picric acid (basified with sodium acetate): clouding or precipitation = melamine.
4. copper (II) sulphate (at 80°C): blue-green clouding on cooling = thiourea (copper compound).
5. silver nitrate with ammoniacalized acid extract: black-brown clouding or precipitation (silver sulphide) = thiourea.
6. → Ninhydrin reaction = triazone, primary amines, imidazolidone and triazone.
7. → Ehrlich's Reaction = urea, amines, imidazolidone and triazone.
8. methylene blue-sodium hydroxide reaction = reduced sugar.
9. methylene blue-potassium cyanide reaction = glyoxal and glyoxalmonourine.
10. paper chromatic test.

Test of the distillate:

1. carbazol/sulphuric acid reaction = aldehyde.
2. Fuchsin-sulphuric acid (Schiff's reagent) reaction = aldehyde.
3. chromotropic acid reaction = formaldehyde.
4. paper chromatic test.

Resin finishing General finishing that gives each fibre additional properties depending on requirements (soil-release, moth repellent, antifelting, creasing resistance). Finishing that has a significant practical value, and causes permanent improvement in wear resistance (wash and dry-cleaning resistant), particularly shrinkage stability and crease recovery, of textiles made out of cellulose or cellulose compounds, by means of intercalation and/or modification of the cellulose (→ Resin finishing processes) with certain finishing products (→ Resin finishing agents). Also known as: → Permanent press process, Wash and wear finishing, Anti-crease finish, Non-shrink finish, Swelling resistant finish, Easy-care finishes, No iron, Non-iron, durable press, minimum-iron, and rapid-iron finishes. Originally only considered for regenerated cellulose fibres, has only in the past 30 years become important for other cellulose types, such as cotton and linen, as well as synthetic fibre mixes. As a result of resin finishing, there is a more or less significant reduction in abrasion resistance, breaking strength and resistance to tear propagation, particularly in textiles made from native cellulose. However acceptable limits can be maintained, for instance by means of the type and quantity of resin finishing agents, the process technique, and the addition of so-called additives. In order to increase the fastness and effectiveness of a finish, a chemical conversion can be performed with the finishing chemicals themselves, or with the fibre. This type of finish can be comprehensively termed resin finishing, even though in practice this expression is used for anti-crease finishing of cotton, which also comes in this category. The products and process techniques used in resin finishing in the broadest sense of the word, are of course, orientated to the specification of the article.

The behaviour of components, which are primarily cellulosic, in chemical reactions can be explained from knowledge of the structure and properties of cotton. It is assumed that the conversion of cellulose fibres is a case of reactions in a heterogeneous system. These can progress to a greater or lesser degree, depending on accessibility of the different cellulose areas. The reactivity and accessibility of the hydroxyl groups in the glucose rings play an essential role, particularly the primary hydroxyl group on the C_6 atom, and the secondary groups on the C_2 and C_3 atoms. These groups exhibit different levels of reactivity, and it is assumed that substitutions occur particularly on the C_6 atom, further on the C_2 atom, but also on the C_3 atom. Three different situations are possible in the reaction:

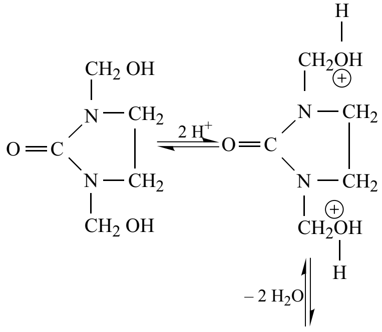
1. Formation of a covalent bond between a monofunctional or polyfunctional reagent and a cellulose chain.
2. Formation of at least two covalent bonds between a polyfunctional reagent and a cellulose chain (intrachenary bridge).
3. Formation of at least two covalent bonds between a polyfunctional reagent and two cellulose chains (intrachenary bridges).

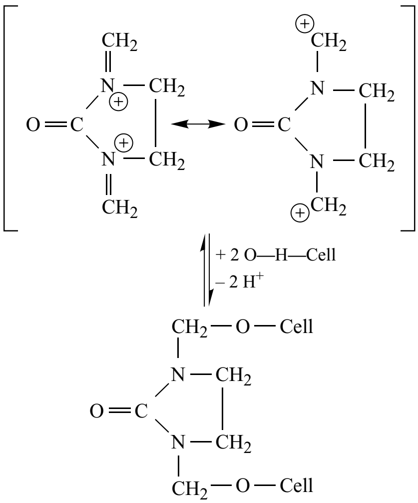
The last type of reaction is called crosslinking. All of these reactions that lead to covalent bonds have the effect of improving crease properties, but crosslinking does so the most distinctively. However, if this type of bond is used, polymer intercalation and the formation of adjacent monofunctional and bifunctional bonds commonly occur.

A large proportion of the properties of cotton are dependent on its high swelling capacity, which is caused by the tendency of hydroxyl groups to retain water. A reduction in swelling capacity can be achieved if a part of the hydroxyl groups is blocked by chemical reactions. This is possible in resin finishing. N-methylol compounds that are created by converting formaldehyde with compounds containing NH or NH_2 groups are used almost exclusively as resin finishing agents. They are mostly derivatives of urea and melamine (self-crosslinkers), as well as cyclical urea derivatives (reactive crosslinkers). This type of cellulose modification is based on two different procedures:

1. Polycondensation of a low-molecule chemical whilst depositing a high-molecule synthetic resin; only a few bonds are formed between the polycondensate and the cellulose (self-crosslinker). Example:

   The mesomeric-stabilized carbenium-imonium ions (carbenium = $CO(NH)_2$; imonium = NH), 2 mol dimethylolurea reacts to methylolmethyleneurea, for instance, if further condensed to polymethyleneurea; if this reacts with further methylolureas, a high-molecule, three-dimensional synthetic resin, polymethylolmethyleneurea, is created. This resin formed in the fibre contains methylene bridges (>N–CH_2–N<) as well as methylene ether bridges (>N–CH_2–O–CH_2–N<), and high temperatures and a low pH are favourable conditions for the first type. The synthetic resin is mostly bonded to the fibre by hydrogen bridges; it is also possible that a small quantity of covalent bonds will be present.
2. Crosslinking of the cellulose hydroxyl groups with reactive groups of the crosslinker, whilst forming stable atom bonds between different cellulose molecules (reactive crosslinker). Example:





As the reactive resins have no hydrogen atom on nitrogen, for further reactions like self-crosslinkers, they do not form resin, but tend to become bound to the hydroxyl groups of the cellulose as monomers. It is also possible that linear self-crosslinking of some monomers will occur. However most of the products being used will react bifunctionally by forming transverse bridges (crosslinking). This reaction mechanism of these compounds in the methylol groups with the hydroxyl groups of the cellulose is known as ureidomethylization. The crosslinking of the cellulose limits the possibility of chain molecule displacement, which means that crease recovery and dimensional stability improve correspondingly with the level of crosslinking. However, at the same time the elasticity of the fibre is reduced, which results in brittleness and therefore a reduction in abrasion resistance, breaking strength and resistance to tear propagation. These depletions in strength are particularly common in native cellulose fibres. Regenerated cellulose exhibits different properties because it has a different morphological structure. Water retention in these fibres is significantly higher and can be reduced considerably by the finish, causing the relative wet strength, which is low in comparison with cotton, to increase (if there is water permeation, less hydrogen bridges can be split, because the hydroxyl groups are blocked by the crosslinker). Resin finishing of modal fibres encompasses two fibre types, HWM fibres (= high-wet-modulus) and polynosic fibres. The former are similar to viscose, and like viscose they are usually finished with self-crosslinkers. Characteristic features are greater strength and less shrinkage. The latter behave in a similar way to cotton, and are usually finished with reactive crosslinkers.

The type of crosslinker chosen is primarily dependent on the fabric specification, the type of process and the construction of the substrate. In addition to having good finishing effects such as crease recovery together with low strength reduction, and low residual shrinkage as well as good handle quality, a crosslinker should not exert a negative influence on the textile quality. So, for instance, the colour shade should not be altered, and the colour fastness should not deteriorate. At the same time the crosslinker should exhibit a good level of resistance to chlorine and fluorescent brightening agents. N-methylol compounds largely fulfil these requirements. As many different products are available, crosslinkers are classified according to their chemical constitution in the context of process techniques. The processes that are mainly used in practice are dry crosslinking, moist crosslinking and wet crosslinking. However it is only the first process type that has established commercial significance. The crosslinkers used in this method are the following:

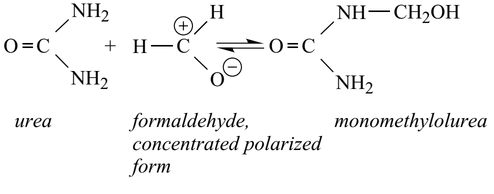
1. In dry crosslinking:
   dimethylol or dimethoxymethyl compounds of
   - urea,
   - melamines,
   - carbamates,
   - cyclic ureas with 5 or 6 ring atoms,
   additionally
   - carboxylic acid amides,
   - alkane dicarboxylic acid amides,
   - alkane diol diurethanes.
2. In moist crosslinking:
   - methylolized cyclic ureas with 5 or 6 ring atoms.
3. In wet crosslinking:
   - methylolized cyclic ureas,
   additionally
   - epichlorohydrin,
   - sulpho-betaines (intramolecular salts).

In order to convert these compounds to an active form, the presence of protons is necessary, as is the case with the ureidomethylization reaction. These are mostly provided by acid donor catalysts.

Resin finishing agents Finishing products with varying chemical composition, used in various different process techniques for → Resin finishing (→ Resin finishing processes), to improve wash and wear properties, shrinkage stability and crease recovery in textiles, for permanent pleat and calender finishes (embossing-chintz-grooved effects), in hydrophobic and oleophobic finishes, for permanent fixing of finishing agents such as polyvinyl alcohol, starch and starch derivatives. Resin finishing agents are usually water-soluble, low-molecular, polyfunctional products that, in the presence of → Catalysts for resin finishing, which work in an acidic or alkaline environment, are converted to either water-soluble, high-molecular compounds that are resistant to washing and dry-cleaning (→ Self crosslinking resins), and/or crosslink with the cellulose fibres (→ Reactive resin). The most significant compounds are acidic crosslinking → N-Methylol compounds, and also →: Aldehydes; POM derivatives; O-Methylol compounds and compounds containing →: Chlorohydrins; Acrylamide group and epon, and sulphurous compounds.

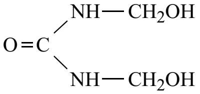
As a result of much debate about formaldehyde, more and more textiles are available that are not resin-finished. Terms such as “bio-finish” and “green cotton” reflect this tendency. This debate has ultimately motivated textile finishers to consider whether they should reject resin finishing as an option. Approximately 180 000 t of crosslinkers are manufactured worldwide, which for the most part are used in resin finishing. The fact that this is such a large amount shows that there is obviously a demand for it. The success of resin finishing was and is possible, although the formaldehyde debate began in the seventies, and this type of treatment also has disadvantages, such as loss of strength, colour shade shift, whiteness influencing and reduction in hydrophilic properties, etc. Resin finishing has become widespread because resin-finished as opposed to untreated textiles, have a range of advantages after washing, dimensional and shape stability being the top priority.

I. Self-crosslinkers: The primary reaction is with themselves, forming high-molecular condensates, and only secondarily do they react with the hydroxyl groups of the cellulose. This type of product is generally used for crease-resistant finishing of textiles, for which a high level of dry creasing angle recovery and elasticity is required, and which are not usually washed at temperatures in excess of 60°C. The self-crosslinker group includes urea formaldehyde curing products that are available non-etherized, or partially or completely etherized with methanol. To manufacture urea formaldehyde pre-condensates, 1–2 mol formaldehyde is allowed to react with 1 mol urea in a neutral or mildly alkaline bath. Where the ratio is 1 : 1, the resulting product is monomethylolurea, from 1 : 2 dimethylolurea.



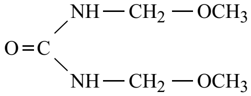
This exothermic, reversible reaction represents the addition of formaldehyde to the free pair of electrons of the amino group (NH_2) of the urea. If the temperature is increased, the equilibrium is shifted to the left. The self-crosslinkers that are usually used in resin finishing are structured on the following basic formulae:

a) dimethylolurea (DMU):



Characteristics: extremely reactive, however it reacts scarcely at all with the cellulose hydroxyl groups, but mainly with itself as a self-crosslinker, resulting in three-dimensional, high-molecular condensates. This type of product is principally used for regenerated cellulose finishing. The finishing liquor, which contains catalysts, can only be kept for a limited period because of its high level of reactivity.

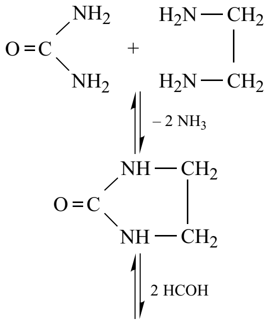
b) dimethoxymethylurea:

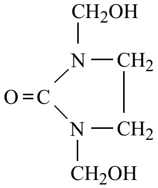


This type is manufactured by etherizing dimethylolurea with methanol. Characteristics: More stable than DMU, both in storage and in the finishing liquor. In comparison to DMU-finished textiles, the fabric has a softer handle.

II. Reactive crosslinkers: reaction is primarily water release with the hydroxyl groups of the cellulose. Under normal condensation conditions they exhibit no self-condensation, because there are no amino groups present, as is the case with self-crosslinkers. The reactivity of individual types varies, generally they are inert in reactions. The fabric handle is not usually altered significantly by reactive crosslinkers, elasticity is less pronounced than with self-crosslinkers. This type of product has distinguishing features such as anti-crease effects that are resistant to boiling washing, chlorine resistance and hydrolysis stability. The best known are cyclic ethylenes and propyleneureas, e.g.

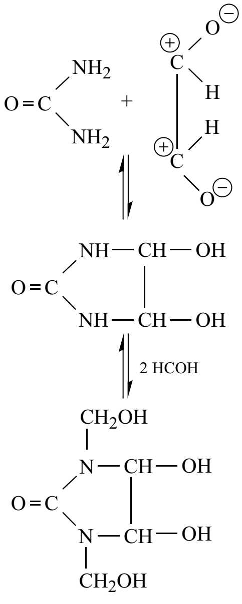
a) Dimethylolethyleneurea (DMEU): The most simple compound in this series; manufactured from urea, ethylenediamine and formaldehyde at a reaction temperature of 250°C.





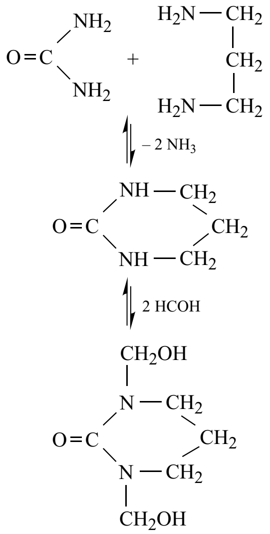
Characteristics: high avidity compared with cellulose, crosslinking occurs even at low temperatures (approx. 100–129°C). The possible fields of application are limited substantially because of its poor chlorine resistance, significant reduction in breaking strength, and deterioration in light fastness of substantive and reactive dyes.

b) dimethyloldihydroxyethyleneurea (DMDHEU): This compound is the most commonly used; made from urea and glyoxal; the reaction is in two phases, i.e. after conversion of the first aldehyde group, ring closure of the second aldehyde group occurs.



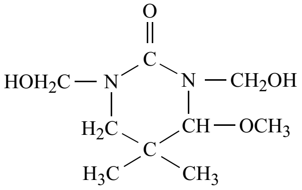
Characteristics: offers great technical advantages in application, such as no worsening in light fastness of substantive and reactive dyes, good wash and wear effects, good resistance to hydrolysis, etc. Slightly less reactive than DMEU, so a higher energy level is required for the reaction (catalyst, condensation temperature). Has the basis of a permanent finish.

c) dimethylolpropyleneurea (DMPU): made from urea, propylenediamine and formaldehyde.



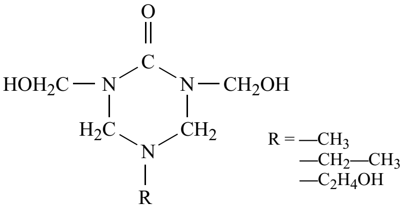
Characteristics: has similar properties to a) and b). Outstanding resistance to chlorine is achieved as a result of the six-ring system, making it suitable for high-quality white fabrics. The crease recovery behaviour is not quite as good as DMDHEU; the light fastness of substantive and reactive dyes is negatively influenced.

d) dimethylol-4-methoxy-5.5-dimethyl-propyleneurea:



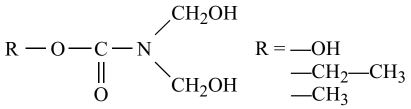
Characteristics: this propyleneurea, which has undergone multiple substitution, combines the advantages of DMPU and DMDHEU. It is very resistant to chlorine and hydrolysis, produces insignificant deterioration in light fastness of substantive and reactive dyes. Very inert, so a strong catalyst is required (thereby possibly forfeiting breaking strength).

e) dimethylol-hexahydrotriazinone (DMT):



Characteristics: sometimes split into initial components during the crosslinking reaction, releasing amine, which can cause a fishy odour on the fabric. Washability is good, chlorine resistance is satisfactory, good crease recovery properties.

f) dimethylolcarbamate (DMC):



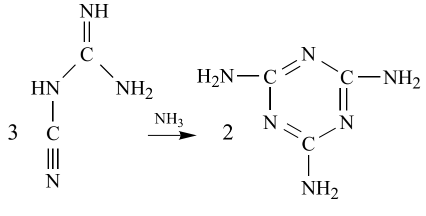
Characteristics: chlorine and hydrolysis-resistant finishes are manufactured in strongly acidic conditions (which are required due to extreme inertness). Excellent crease recovery properties. Reduction in strength with pure cellulose, but very high, therefore usually used for polyester/cotton mixes.

g) others: further acyclic reactants exist, such as dimethylol compounds of aliphatic dicarboxylic acid diamides, however these are not significant.

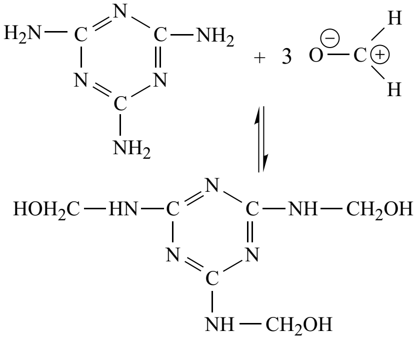
III. Self-crosslinkers/Reactive crosslinkers: these types of crosslinker with mixed reactivity contain self-crosslinking groups as well as reactive crosslinking groups. The most commonly used are methylol melamines. These are so-called pre-condensates. Depending on the level of methylolization, there are different categories from trimethyl to hexamethyl melamines. The higher the degree of methylolization, the less pronounced the self-condensation, and the more priority can be given to cellulose crosslinking.

Solutions of urea or melamine-formaldehyde precondensates only have limited stability even at low temperatures, particularly if catalysts are present. After a certain period, which is influenced by temperature, concentration and type of catalyst, high-molecule compounds begin to form in the finishing liquor. These compounds cannot permeate the fibre, and they form a deposit on it. Stability can be increased by using etherized melamine formaldehyde resins. Etherization is carried out in an acidic medium at low temperatures (50°C). The alcohol most frequently used for this is methanol.

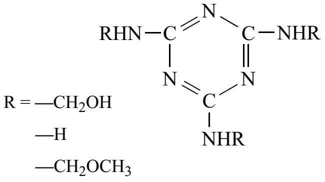
Melamine (2,4,6-triamine-1,3,5-triazine) is manufactured by heating dicyandiamide to 200–300°C under pressure in the presence of ammoniac. The reaction mechanism is not yet fully understood.



With formaldehyde, the melamine amino groups react to methylolmelamines. With 3 mol formaldehyde and 1 mol melamine in a weakly alkaline medium, the resulting product is trimethylol melamine.



All 6 hydrogen atoms in the amino groups can be replaced by methylol groups. However the only product to have any technical significance in application is trimethylol melamine:



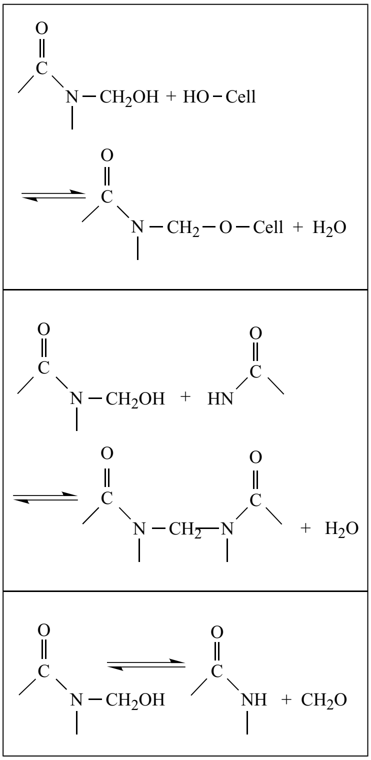


Fig.: Reactions of N-methylol compounds depending on degree of crosslinker and store conditions.

Characteristics: etherization with methanol results in relatively stable liquid products. The finishing effects achieved are similar to those of dimethylurea products, however they are significantly more washable, hydrolysis-resistant and chlorine-fast. The resulting fabric handle is much harder and fuller, making it suitable for stiffened finishes. At the same time, melamine resins are used as additives.

IV. Low-formaldehyde crosslinking: if cellulose molecules are crosslinked with N-methylol compounds, self-condensation and formaldehyde release occur as a secondary reaction depending on the type of crosslinker (see Fig.).

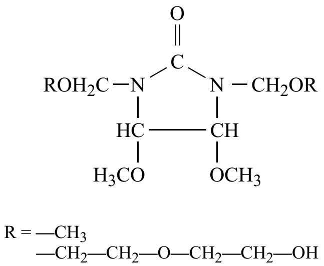
The content of free formaldehyde in the product and in the finishing liquor is dependent on chemical constitution, concentration and temperature. The formaldehyde release from the finishing agent or the finished fabric depends on the hydrolysis stability of the carbon-nitrogen bonds. If these bonds split, formaldehyde is immediately released. Additionally if there is a residual content of non-crosslinked N-methylol groups in large quantities, it results in formaldehyde release, which occurs particularly if the finished fabric is stored in a moist, warm place. Care should be taken that free formaldehyde is adsorptively bonded to the dry cellulose fabric. Since water or vapour has a stronger tendency to bond, if moisture is present, a formaldehyde/water exchange will occur. There are technical methods that can be applied during the process to reduce formaldehyde content, and a wide selection of products is available to achieve this:

a) Technical methods during process:

- aftertreatment washing of finished textiles,
- addition of formaldehyde acceptors to the finishing liquor,
- aftertreatment of fabric by spraying on a urea solution.

Aftertreatment washing does not just remove the free formaldehyde, it also removes some of the N-methylol groups that are not crosslinked with the cellulose. However many garments cannot be subsequently washed because of the fabric quality (altered handle, reduction in fullness and stiffness) and also mainly for cost reasons. One method that has been used for a long time is the addition of substances to bind the formaldehyde, such as urea and ethylene urea, to the finishing liquor. Taking this action achieves a reduction in formaldehyde release during the finishing process and in storage. There is a further option of spraying the finished fabric immediately after curing with a 10% urea solution (approx. 10% spray application); further drying is not necessary afterwards.

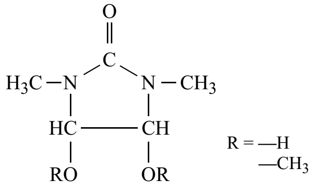
b) Product variants: this covers crosslinkers that exhibit a high level of hydrolysis stability of the methylol groups, and also as little free formaldehyde as possible in crosslinking solutions. This type of product includes partially-etherized dimethyloldihydroxyethyleneurea and modifications of this type.



partially-etherized DMDHEU

The partial-etherization of the hydroxyl groups has the effect of limiting avidity, which can be largely compensated by the addition of free acids or sodium fluoroborate (for instance) to the catalytic reaction with magnesium chloride. Although low-formaldehyde products certainly offer ecological advantages, a successful finish is even more dependent on the pH of the fabric than it is in "normal" resin finishing. Adding acetic or citric acid to the liquor resolves the problem only up to a point, because the neutralization products, such as sodium acetate, have a buffering effect on the catalyst, so that crosslinking may possibly be worse and therefore cause higher levels of formaldehyde on the substrate.

V. Formaldehyde-free products for resin finishing typically have the following composition:

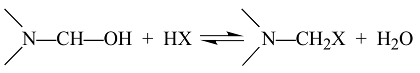


Resin finishing catalysts Inorganic or organic compounds to speed up reactions in → Resin finishing. Selection of catalyst particularly dependent on type and reactivity of → Resin finishing agent and crosslinking compounds. The most commonly used are ammonium salts such as ammonium chloride or ammonium nitrate; metallic salts such as zinc nitrate and magnesium chloride; inorganic and organic acids such as specific mixes for wet crosslinking and shock-cure processes (→ Shock catalyst). However alkaline catalysts such as caustic soda liquor and sodium carbonate are not significant. In addition to good dimensional stability and minimal creasing tendency, the requirement for a low proportion of potentially releasable formaldehyde is also an important factor in the resin finishing of cellulose textiles. Crosslinkers that are stable in hydrolysis are inert crosslinkers, and they require active resin finishing catalysts if they are to be used in single-phase drying/curing processes. Resin finishing requirements:

- low creasing tendency or good crease recovery,
- dimensional stability during processing and after treatment,
- low quantities of free and potentially releasable formaldehyde, as well as being odour-free,
- no chlorine retention,
- no change to the colour shade or grade of whiteness, either directly after curing or after storage,
- minimal strength reduction.

All these desired effects cannot be realistically achieved just by using conventional resin finishing catalysts based on magnesium and zinc salts, with short curing periods and at temperatures of 160–180°C, depending on the type of crosslinker. However, a method that has proved successful is the activation of magnesium chloride ($MgCl_2$) with citric or glycolic acid, as well as sodium borofluoride ($NaBF_4$). If the magnesium chloride is activated in this way, condensation is possible within approx. 20 s at 150–180°C. The reliability of this method is extremely limited, as in practice colour changes are possible (after condensation/storage) at condensation temperatures that are still very high. For this reason, the ideal catalyst systems are those that permit shock drying condensation because of higher activity levels.

Resin finishing is based on the condensation of N-methylol compounds of ureas, carbamates, melamines, etc., which is accelerated by catalysts (α-ureidoalkylization), where the reactions either take place on a polycondensation of the crosslinker itself (self-crosslinking), or on cellulose crosslinking by means of a non-polycondensing crosslinker (reactive crosslinker). In principle these condensation reactions can be catalysed either by acids or bases, because the condensation reaction mechanism for methylols is largely analogous with the α-aminoalkylization reaction (Mannich reaction). For this reason the direction of the reaction and the conversion are dependent on the basicity difference between the attacking reagents HX and the emerging OH group:



Crosslinking with acid catalysts has proved to be of practical use, since crosslinking that has been catalyzed on an alkaline basis under comparable curing conditions results in a finish that is not wash-resistant, because of the low level of crosslinking. Of the acidic catalysts, mineral acids and strong organic acids are not economically viable as an option for dry crosslinking, firstly because they decompose cellulose under normal curing conditions, and secondly because a further subsequent washing process is required, which is economically inefficient. Latent acidic catalysts only become active in curing conditions; this applies to ammonium salts as well as magnesium and zinc salts, which are preferable. However ammonium salts have the disadvantage of causing secondary reactions that shift the pH of the finishing liquor to lower values after standing for only 1 h, which in the case of methylolurea, for example, results in the formation of insoluble methyleneurea. As well as this, ammonium salts react with the crosslinker, depending on type, in the proofing liquor, and the formaldehyde present in the textile is converted to methylamine, causing the unpleasant fishy odour typical of this type of finish.

The varying levels of activity of metallic salts are determined by the cation as well as the anion. The effectiveness of the cations is correlated with the level of acidity ($Al^{3+} > Zn^{2+} > Mg^{2+}$), which makes the free acid available to the anions with the dissociation constants ($BF_4^- > NO_3^- > Cl^-$). For magnesium and zinc salts, catalysis occurs by means of a metallic ion/methylol component complex. Crosslinking that has been catalysed with magnesium salt is more stable during washing than zinc salt catalysed crosslinking. The reason for this behaviour is related to the varying reaction properties of these two salts with cellulose. Magnesium salts only react with the primary hydroxyl groups, however zinc salts (particularly zinc nitrate) also react with the secondary groups (oxidative release in the presence of alkali). Since in the latter case a lower level of crosslinking in comparison with magnesium chloride is found to occur, it is assumed to be the result of intramolecular crosslinking of the hydroxyl groups on the C_2 and C_3 atoms of the cellulose, causing formaldehyde release. If the magnesium chloride is activated with aluminium chloride, the fabric will have a lower level of free formaldehyde.

In order to carry out crosslinking under curing conditions which put as little strain as possible on the fibre and/or with as short a condensation period as possible, catalyst combinations consisting of magnesium chloride and other metallic salts or organic acids have become more widespread in use. The higher catalytic activity resulting from this additive is based on an effect resulting from the combination of Lewis acid (magnesium chloride) and Brønstedt acid (organic acid). If the additive is sodium borofluoride ($NaBF_4$) it is based on a solely synergetic effect, since $NaBF_4$ on its own does not cause crosslinking. Borotrifluoride (BF_3) is considered to be the effective catalytic agent, which is generated during the drying and curing processes.

drying:

$$NaBF_4 + 3\,H_2O \rightleftharpoons B(OH)_3 + 3\,HF + NaF$$

curing:

$$B(OH)_3 + 3\,HF \rightleftharpoons BF_3 + 3\,H_2O$$

As well as the strong nature of Lewis acid, which is essential for catalysis, the easy bonding of BF_3 to aldehyde is clearly responsible for the low level of free formaldehyde. The high catalytic activity of zinc borofluoride ($Zn[BF_4]_2$) and magnesium borofluoride ($Mg[BF_4]_2$) is a positive factor, but on the other hand this activity results in pH lowering of the finishing liquor. This in turn causes decomposition of the hydrolysis-stable crosslinkers, as well as a significant loss of strength in the cotton. Zinc salts cannot be activated in such a clear-cut way using additives, because unlike magnesium salts, this metallic salt hydrolyses under curing conditions, and the resulting hydrogen ions already provide the same effect as Lewis acid/Brønstedt acid. It is not yet fully understood how the combination of magnesium chloride and hydroxy/cyanic/aminoacetic acids works. If citric acid is used for activation, a magnesium/ citric acid complex is formed, if glycolic acid is used for activation, a co-reaction with the crosslinker and formation of terminal carboxyl groups can be detected in the finished fabric.

Despite good finishing results, the use of trichloroacetic acid as an additive is out of the question, because chloroform is produced during condensation, which creates a new set of problems. Activation with phosphoric acid or its ammonium salts requires a subsequent wash, and is therefore uneconomical. In practice, the best method of activation is magnesium chloride with glycolic and citric acid, with single phase drying/ curing processes, where condensation conditions are approx. 150°C/3 min. The important factor to consider when selecting from a spectrum of possible additives, such as maleic acid, glycolic acid, hydrochloric acid, phosphoric acid, etc., is that the pH of the fabric after curing (from 120°C/3 min) should be approximately 6. This is because some of the acids are volatile during condensation, and some of the released basic crosslinker components are neutralized (according to Heidemann).

Resin finishing of cellulosic knitgoods Good dimensional stability and good sewability are the crucial factors in resin finishing. N-methylol compounds of ethylene and hydroxyethylene urea (60–90 g/l, 45%) and melamine formaldehyde compounds, usually partially etherized and often as additives with a buffer function, are often used as resin finishing agents for improving shrinkage stability. Reactive catalyst systems (→ Shock catalyst) are preferable. It is difficult to use additives based on polyethylene dispersions, fatty acid condensation products and dimethylolpolysiloxanes - whether on their own or in combination with another substance - to improve sewability or to influence the fabric handle. Finishing procedure: impregnation, with sufficient overfeed and low-tension across the guide rail width. Drying and curing at 150–160°C in one process on the stenter (→ Shock-cure process). Mercerization of knitgoods during pretreatment has positive effects on dimensional stability and strength.

Resin finishing processes Process techniques in → Resin finishing. Application of → Resin finishing agents under specified crosslinking conditions. Largely responsible for defining intended finishing effects. Major processes: → Dry cross-linking, moist crosslinking, wet crosslinking. Used alone, they represent multiphase crosslinking processes. When selecting crosslinkers and catalysts for a process, there is a range of combination possibilities from a technical point of view. In industrial production there are two basic condensation types – high temperature condensation and cold dwell condensation. In general, condensation in resin finishing is a chemical reaction between crosslinkers and cellulose, usually causing water release.

$$\text{Cell–OH} + \text{HO–CH}_2\text{–N}< \longrightarrow \text{Cell–O–CH}_2\text{–N}< + \text{H}_2\text{O}$$

The objective from a chemical point of view is to allow the crosslinking reaction to progress with as high a yield as possible, whilst restricting the damage caused to the cellulose chains by the crosslinking catalyst.

I. High temperature condensation: dwell treatment of the textile at a temperature range of approx. 130°C to a max. 200°C, between 20 s and 6 min on “curing machines”. Normally these consist of a heat-up zone with a high level of heat transfer, a dwell zone, in which the target temperature of the textile is kept constant without much interaction with the medium, and a cooling device (e.g. cooling drum). Usually curing is carried out on a stenter with programmed process control. Dry crosslinking is the most common crosslinking type for reasons of economy. In this process, the standard procedure is impregnation, drying, curing. The characteristic feature of this technique is that the material is crosslinked while it is dry, i.e. in a de-swollen state. Latent acid catalysts, such as metallic and ammonium salts, are used as accelerators for the reaction. The pH must be between 5 and 6. The different crosslinking processes differ in that there are extra operations between the phases, or sometimes two phases are amalgamated into one (such as drying and curing).

a) The following variants of classic finishing can be defined (Fig. 1):

– normal classic finishing,
– wet-on-wet finishing,
– mechanical finishing,
– classic finishing with after-washing and scrooping.

Of these variants, the one portrayed here is normal classic finish. The diagram shows how the dry textile (humidity only) is fed into a padder, and a defined amount of crosslinking liquor is applied to the fabric. The drying process takes place in the stenter to ensure that the shape is fixed (overfeed ensures end width and start in warp direction). After drying there is a cooling process – in particular for quality articles (cooling fan, cooling drum), and the fabric is batched, or if it is not fold-sensitive, it can be plaited down. Finally the curing process takes place, with strict adherence to process conditions. Cooling is the last finishing process. The fabric is then given a basic after-wash to improve handle, and can then be scrooped.

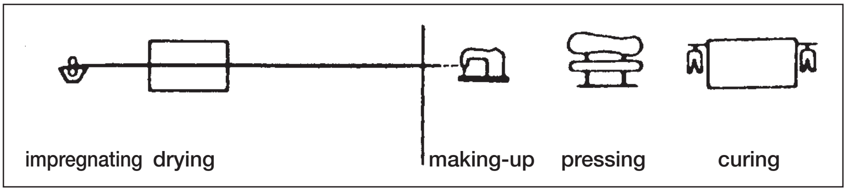

Fig. 4: Post-curing process.

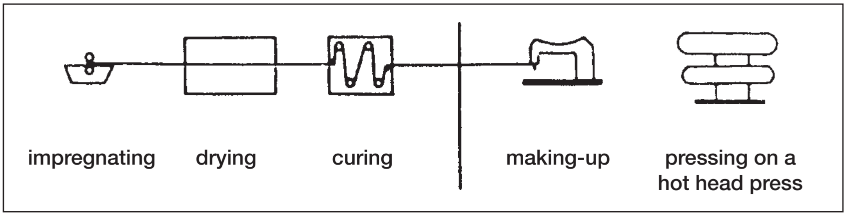

Fig. 5: Pre-curing process.

After-washing (Fig. 2) is mainly done on open-width washing machines. This treatment gives the fabric a much better handle. The subsequent wet-in-wet scrooping process can improve the handle even further.

Classic finishing usually aims to achieve the best dry and wet creasing angles, and a good level of dimensional stability.

b) Shock-dry curing process: The amalgamation of drying and curing into one phase is characteristic for this process (Fig. 3). The throughput time for the combined process of drying and curing is dependent on the type of crosslinker, fibre type and fabric settings. The effects achieved are similar to classic finishing if the same catalysts are used. If stronger catalysts are used, the curing period of this process can be shortened even further. Specific complex catalysts are used in this context. The aim of this is rapid curing. If the speed and temperature of condensation increase, it can lead to fluctuations in the stenter temperature, uneven absorption of the liquor and machine interruptions cause major catalytic damage to the fabric. If coloured goods are being treated using the shock-curing process, it is highly likely that there will be colour shade shifts due to the high temperature, and yellowing is a strong possibility in the case of white fabrics for the same reason. For that reason, this type of process is not particularly common.

c) Durable press process: Until now this type of process has had little commercial significance, however it is interesting because of unusual techniques. In conventional synthetic resin finishing, the textile fabric is cured in widths with the crosslinker. When the fabric is later re-shaped by the clothier, it has a tendency to return to its original shape (“flat memory”). If this phenomenon is applied to a garment, it means that a deliberate crease will only remain in place for a short time. The durable press process is based on the following principle: The textile finisher pads and dries the fabric. It is important that the crosslinker being used can tolerate storage, because the curing process is not complete until the clothier has pressed the fully-fashioned garment in a specially designed method of pressing using high temperature ironing presses (temperature up to 200°C). This process can be divided into three principle groups:

- post-curing process,
- pre-curing and thermoplasticizing process,
- 2-phase process (BASF P2 process).

For the post-curing process (Fig. 4), the fabric is impregnated with crosslinker plus catalyst, and dried. The resulting fashioned garment is pressed at a low temperature (120°C) and cured in special curing ovens.

The pre-curing and thermoplasticizing process (Fig. 5) is used for mixed fibres (cellulose with synthetic fibre). The finisher impregnates, dries and cures the fabric, and after fashioning, the synthetic fibre content is thermoplasticized on high temperature presses.

In the 2-phase process, the fabric is impregnated with finishing liquor containing two chemicals (crosslinkers) with very different curing properties. After the fabric has been impregnated and dried, the first finishing phase is curing at a temperature of up to 130°C, during which one of the two products condenses. The fabric retains dimensional stability. The second phase is the condensation of the second product on the press after the garment has been fashioned.

II. Cold dwell curing: a long-term reaction that is normally carried out at room temperature on the batch roll. As opposed to most high-temperature curing processes, the cold dwell process is carried out discontinuously, meaning that it takes much more time. The advantage is that condensation reactions take place at low temperatures, meaning that the fabric is subjected to less stressful treatment.

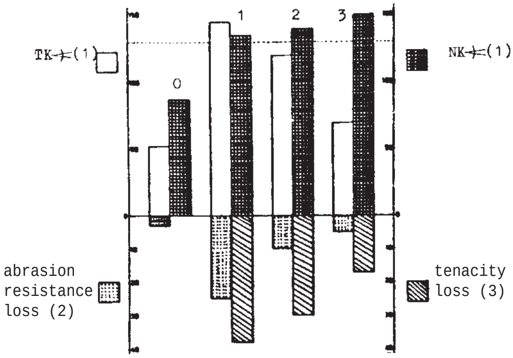

Fig. 6: Relation of crease recovery to loss of strength of different resin finishing processes.
0 = untreated cotton; 1 = classic dry finishing; 2 = moist cross-linking; 3 = wet cross-linking (acid).
(1) = mean warp and weft; (2) accelerotor 3000 rpm; (3) = weft.

If dry crosslinking is used, a high dry and wet creasing angle is achieved, which is associated with relatively high loss of strength (Fig. 6). In contrast with this, moist crosslinking results in less loss of strength, but a similar creasing angle value. Wet crosslinking provides very little strength reduction and a good wet crease recovery. The high strength loss in dry curing result from the fact that the fibre is kept at a temperature in excess of 140°C for long periods, which means that an unnatural state of dryness must be maintained for the reaction to take place. The fabric undergoes structural and dimensional changes. In a normal climate, crosslinking prevents the fibre from returning to its original shape, due to the inner tension produced which affects the strength. The low levels of strength reduction that occur after moist and wet crosslinking can be attributed to the even distribution of the crosslinking bridges across the fibre cross-section. Bunching of the crosslinker in certain places results in a negative influence on the strength according to this theory.

a) Moist crosslinking: variant of the process, in which reactions occur on partially swollen fibres with a specific level of residual moisture, the temperature is below 50°C and room temperature is the ideal. The dwell or reaction time is correspondingly longer (over 10 hours, frequently 16–24 h). In moist crosslinking, fabric moisture, reaction temperature and liquor pH are closely related to each other. If the temperature is lowered, a longer reaction time and a stronger catalyst is required. If moisture levels increase, acid concentration in the liquor must also increase. Working pH levels should be between 1 and 2. The essential phases of the moist crosslinking process are impregnation, drying (to residual moisture levels), dwelling and washing. The technical problems associated with the process are mainly in the following areas:

– recipe formulation,
– drying phase,
– residual moisture retention.

The problems associated with recipe formulation are selecting the crosslinker and the catalyst. The crosslinker must be hydrolysis-resistant because of the low pH level. 5 and 6 link N-methylol compounds (reactive resins) are used almost exclusively for this. So-called “caustic catalysts” are used; these are usually a mix of metallic salts with medium-strength organic or inorganic acids. It is also important to maintain a constant drying temperature (100 – max. 120°C) because of the low pH level. Higher temperatures result in extreme or unacceptable reduction in breaking strength and abrasion resistance, even if the residual moisture level remains constant. If catalytic salts or compounds are used in the drying process, the problem is avoiding troublesome early reactions. In addition to this, residual moisture has a significant effect on the final quality of the fabric. The dry creasing angle increases in proportion to the decrease in residual moisture, and in this instance the reduction in breaking strength and abrasion resistance. The “safe area” can only be defined approximately because of differences in the equipment used for measurement and control, and because of the large quantity of articles. The level of moisture that is the closest to ideal must be defined individually for each plant, depending on the circumstances. If residual moisture is to be maintained at an exact constant level, devices for measuring and controlling moisture must be installed on the drying machines.

b) Wet crosslinking: as is the case with moist crosslinking, the crosslinking reaction takes places during the dwell period, i.e. in a swollen state (long-term reaction). Usually a very high wet creasing angle, a moderate dry creasing angle and low strength loss are targeted in wet crosslinking. If cellulose that has been swollen in water is crosslinked, the more permeable areas between the fibrils (amorphous) are opened up to such a degree that the intervals between neighbouring micro-fibrils of the crosslinker molecules can no longer be bridged. For this reason, crosslinking occurs mainly within the denser area (crystalline) of the elementary fibrils, in other words it is an intramicellar reaction. The wet crosslinked fibres can undergo interim drying and then re-swell when water penetrates into the amorphous areas where hardly any crosslinking has taken place.

Resin-free finishing High-grade (resin) finishing process, which leads to cellulose crosslinking, in other words, self-crosslinking of the finishing agent is eliminated. In practice, resin-free finishing is almost impossible. Resin-free finishing includes → Formaldehyde finishes.

Resin migration Migration of pre-condensates and catalysts within the yarn and between thread systems during the drying process in resin finishing. The main effect of this is worsening of abrasion resistance in crosslinked cotton fabrics.

Resinous cement Melt 1 part colophony and 1 part beeswax in an iron bowl. After cementing, residue is removed using spirit or carbon tetrachloride. Application: Cement for bonding metal/wood.

Resin resist printing → Wax resists.

Resin soaps (resin acid metals, resinates, colophony soaps), manufacture by boiling → Colophony with caustic soda liquor. If pre-made commercial soaps are bought, they must be guaranteed free of resin, or the resin content must be declared (x% fatty acid, x% resin acid). Although resin soaps foam well and have good cleaning properties, they only represent moderate soaping qualities (extreme hydrolysis), which can be significantly improved if they are used in combination with fatty acid soaps. Resin soaps are used as a basis for anti-slip and anti-snagging treatments, and are sometimes incorporated with ordinary hydrophobic agents. Manganese and cobalt resin soaps, etc. can still be used as drying agents.

Resin-soluble dyes →: Synthetic resins; Oil- and-fat soluble dyes.

Resin stains Fresh: sticky; older: sensitive to fingernail pressure; becoming darker in colour on ironing. Removal: a) initial softening with turpentine oil, then benzene or (warmed) tetrachloroethylene (perchloroethylene); b) benzene/carbon tetrachloride 1 : 1–5; c) acetone, particularly with benzene 1 : 1; d) carbon disulphide, followed by benzine or benzene; e) sulphurized ether, poss. with chloroform. Must be repeated several times.

Resin sulphonation products Direct sulphonation of resins (e.g. colophony) results in products of a sticky nature that are suitable for sizing and anti-slip finishes. Under intensive conditions, lime-resistant resin sulphonation products with wetting agent characteristics are produced. Sulphonate compounds of abietic acid and castor oil have good wetting and foaming properties. The sulphonate of abietine, combined with terpineol or pine oil, also has excellent wetting properties. Decarboxylised resins generate non-oxidized oils suitable for use as scrooping agents, etc. Finally hydroabietinols are sulphated, forming similar products to fatty alcohol sulphates for wetting, sizing, crease elimination, etc. However they have not achieved the significance of other surfactants.

Resin varnishes → Lacquers.

Resistance thermometer (resistance pyrometer, → Thermometer). Resistance thermometers are the most suitable instruments for measuring temperature precisely (see Fig.). These thermometers use a conductor (e.g. platinum coil with 100 Ÿ at 0°C) to measure the temperature dependency based on ohmic resistance. The stability over a period of time, measured over a year, is better than ± 0.5°C. Since the measuring insert with an internal conductor and resistor is contained within a protective tube, and the mass of the protective tube is usually far too great, the response time is usually correspondingly high. For this reason, resistance thermometers of this type are unsuitable for an environment where measurement and control needs to be rapid.

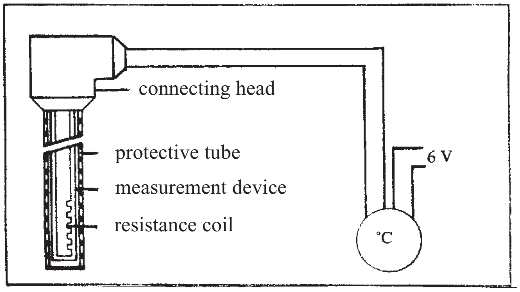

Fig.: A resistance thermometer.

Resistance to creasing Scale for measuring the resistance of textiles to → Creasing. → Crease resistance.

Resistance to deformation If an external force acts on a textile, it will be stretched or compressed; the usual measure for resistance to deformation is the modulus of elasticity (→ Tensile elasticity).

Resistance to tear propagation Required strength when → Tensile force is applied to the bearing width for sudden tear propagation of a fabric section from an initial cut. There are various different methods of testing this.

Resistance value, flexing fatigue limit (flexional resistance). Fibres, yarns and fabrics are tested whilst subject to initial tensile stress, under a certain bending or flexion angle (generally ±180°) by bending in alternate directions until breakage point. The result is what is known as the flexing fatigue value or flexional resistance value, for which Böhringer gives the following rounded figures:

flax	880
jute	1050
acetate filament	300
viscose filament	2500–7000
viscose spun fibre	800–1400
cuprammonium rayon	20 000
cotton	65 000
silk	75 000
sheep's wool	156 000
polyamide 6.6	45 000
polyamide 6	500 000

It should be noted that small differences in grip pressure and grip quality can give rise to widely varying values. In principle the level of the flexing fatigue value depends to a great extent on the type of raw material and yarn, the fabric structure and also from any finish effects. Lower values indicate high brittleness and low chafe resistance (especially at fabric edges and folds). Equipment for testing the flexing fatigue limit is therefore not only used for the evaluation of the wear resistance of textiles, i.e. the practical wear resistance and durability, but also to test the effectiveness of finishes of all kinds.

Resist effects by reversible fibre modification Bi-colour cellulose fibre formation arises as a result of printing of crosslinking agents, initiating crosslinking by means of heating, fabric dyeing with cellulose dyes, where crosslinked areas will resist the dye. Subsequent hydrolysis of crosslinking agents with acids, and finally re-dyeing of the entire fabric.

Resist fibre stripping Stripping of fibre areas where a resist effect is required when dyeing mixed fibres.

Resist printing (resists, reserve print). There are two different types, pre-printed and over-printed resists, depending on whether the resist print paste was applied before or after preparation of the fabric with dye solution. In both cases, the dyeing of printed areas is prevented. The most suitable context for application is in conjunction with non-dischargeable dyes. The following categories can be distinguished:

I. Mechanical resists (paste resists): wax reserves (resin, wax, etc.) block dye access to the printed areas mechanically.

II. Chemical resists: break down the chemicals required for dye-fixing on printed areas.

III. Chemical-mechanical resists: combination of I and II. As well as breaking down the dye-fixing chemicals, insoluble salts are usually formed as well as an extra layer of protection.

All resist processes can be divided up into white and colour resists. With white resists, only resist agents are used, for colour suitable dyes or dye combinations are added to the resist agent (colour illumination). In addition to selecting a good dye combination, the pH should be monitored very carefully. Adhering to the appropriate parameters for ground and resist is imperative to ensure that a high standard of reproducible resist effects is achieved. Dispersion dyes can be used under certain circumstances as well as anionic dyes for colour illumination in the resist printing of polyamide carpets. Since no resist is necessary for dispersion dyes, their fixative action is not negatively affected either by the resist agents used or by the pH. Further variants are possible if cationic dyes are used, which in turn are capable of dyeing resist agents with fibre affinity. However, the light fastness is usually insufficient.

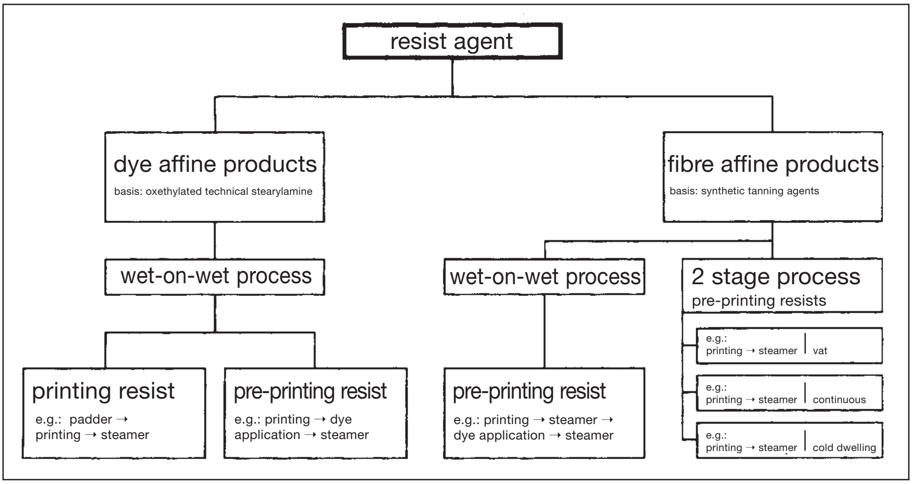

Fig.: Resist agents and resist processes as shown by the example of polyamide carpet resist printing (Bayer).

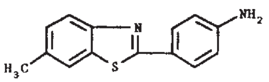
The resist agents can be split into two chemical categories (see Fig.), i.e. during the process there should be a differentiation between the use of resist agents with dye affinity that alter dye uptake and the compatibility of dyes in combination with each other, and resist agents with fibre affinity that are used for instance to block the amino groups in polyamide fibres (Wirtz).

Resist techniques in transfer printing → Transfer printing resist effects.

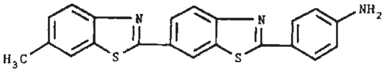
Resolution Optical: interval between two points of the object (specimen), so that they can still be distinguished as separate entities under the microscope, for instance. Calculated by dividing the wavelength of light used for illumination (in the visible spectrum resolution limit approx. 0.4 µm) by the selected numerical aperture (formula for centrally-positioned illumination, almost double the resolution for angled light).

Resonance spectroscopy → NMR Spectroscopy.

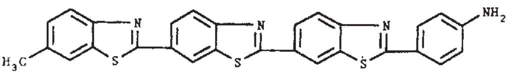
Resonance structure Dye molecules are chemically structured so that a large number of π electrons in conjugated double bond systems can be excited by light energy. So there are a number of limited mesomeric forms, which are captured by the π electrons in a very short period due to oscillation (→ Mesomeric resonance). The most stable form of energy is thereby the limited mesomeric structure formula with the lowest energy level. The benzolthiazol group causes resonance in each molecule and the transmission of one resonance form into another in turn results in the colour of the compound. With a larger number of resonance forms, the transmission of one resonance form into another requires less energy. This leads to a colour enhancement, as was observed in the transmission from mono- to di- and tri-dehydrotoluidin.



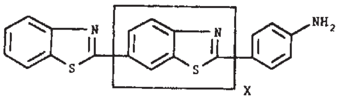
I



II

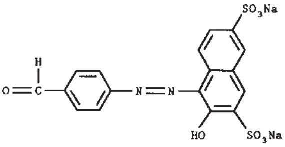


III



IV

If the formation of a colour can be due to the resonance within a molecule, dyeing on the other hand, is likewise due to resonance, namely between molecules, e.g. between dye and cellulose. An intermolecular resonance system is therefore formed, which determines the affinity of the dye to the fibre. With intermolecular resonances, the space in which they can be active is increased to two molecules. An increase in the possible resonances and a reduction in the energy demand when transmitting from one resonance into the other therefore results. This follows a deepening of the shade as is the case with benzaldehyde-p-azonaphthol-disulphonate (V), whose red dyeing on cellulose fibre turns into violet when lightly heated using water.



V

(according to Riesz).

Resorbable yarns Medical sewing thread should normally be removed from the body by extraction. Work is in hand to develop sewing threads, which are resorbed after healing especially for stitches on internal organs. These may, for example, be collagen sewing threads, which are not rejected as similar protein by the body or polyvinyl alcohol threads, which are gradually dissolved and eliminated as a water-soluble polymer.

Resorcinol (metadioxy benzene), $C_6H_4(OH)_2$; molecular weight 110; density 1.283; colourless crystals, slightly sweet tasting, water-soluble; also soluble in alcohol, ether, glycerol; melting point 110/111°C. Gives violet dyeing with iron chloride solution. Use: solvent (phenol considered) for cationic, united chrome dyes and tannic paints; for the fixation of cationic dyes on acetate; saponification of acetate; antiseptic (finishing effectiveness practically the same as phenol).

Resorption (to absorb). Drawing in and/or soaking up, e.g. of dirt particles distributed in the liquor by laundry articles. The washing agents should counteract this effect through their soil suspending property.

Respiratory poison (odour poison). Poison, damaging to the respiratory organs, such as ethylene oxide (tear gas), chlorine gas, phosgene and carbon disulphide. Respiratory poison health hazards: → TLV values. Respiratory poison for textile parasites: → Mothproofing.

Response factor In environmental analysis, certain analysis methods reproduce true content with a certain error. Above all, in exhaust gas analysis, a one-hour test with silica gel or activated carbon in the bypass of an exhaust air outlet should, for example, be

Response factor

substance	proportion of carbon	response factor r_S	correction factor K
methanol	0.38	0.77	5.5
ethanol	0.52	0.90	3.4
i-propanol	0.60	0.70	3.8
propane diole	0.47	0.80	4.3
formaldehyde	0.40	0.30	13.4
decane	0.85	0.95	2.0

Tab.: The response factor and correction factor for FID (far infrared) measurements.

carried out by gas chromatography/mass spectroscopy (GCMS). The exhaust air contents so adsorbed must be extracted in the laboratory (off-line) using a solvent (e.g. carbon disulphide) before the resulting solution is injected into the gas chromatographs. The answer (response) to this complex isolating operation is a material loss in the individual steps; above all only a percentage of the harmful pollutants are desorbed depending on the chemical structure of the adsorbed molecules. The Fig. shows such vapour space material analyses, which are discharged from polyurethane fabrics at 180°C.

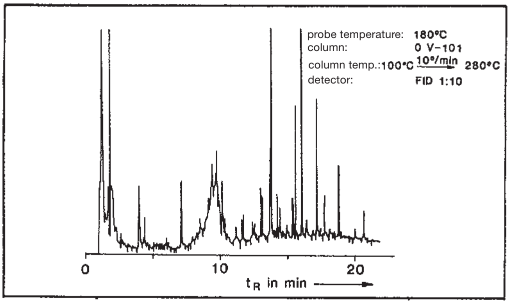


Fig.: Head-space-analysis of the drying of polyurethane raw goods and their heat fixation at 180°C.

The test was carried out in a commercial apparature by head/space gas chromatography. It reveals that a multitude of individual components is emitted into the surrounding air at high thermofixation treatment temperatures. These can be identified and quantified in a full analysis with the aid of comparative materials. In identification, the combination of gas chromatographs with a mass spectrometer and/or an IR spectrograph could considerably alleviate the analytical task; but even then the qualitative and quantitative analysis of the contents of exhaust gases still remains an extensive job, as the evaporable substances of other fabrics or of fabrics with other dyes may have a completely different composition. Due to this costly separation, identification and quantification, it is customary to determine so-called summation parameters such as methane or propane equivalents. In this connection the organic contents are not separated, but directly detected using an FID and the common signal compared with a corresponding methane or propane concentration.

The FID signal is proportional to the carbon concentration of the reference substance, e.g. propane c_{CP}, and the substance to be determined c_{CS}, if the measuring test only contains one substance:

$$r_P \cdot c_{CP} = r_S \cdot c_{CS}$$

The respective response factors r_P and r_S are firstly unknown. The response factor of the reference substance is arbitrarily assumed to be r = 1. The carbon concentration of the substance to be determined is consequently

$$c_{CS} = \frac{c_{CP}}{r_S}$$

The conversion into the mass concentration of the substance to be determined c_{MS} results in

$$c_{MS} = \frac{(MG)_S}{r_S \cdot n_{CS}(AG)_C} \cdot c_{CP}$$

$(MG)_S$ = molar weight of the substance to be determined,
n_{CS} = number of C atoms in the substance to be determined,
$(AG)_C$ = atomic weight of carbon.

This is calibrated to the volumetric concentration of the reference substance propane c_{VP}, so results in

$$c_{MS} = \frac{(MG)_S\, n_{CP}}{r_S \cdot n_{CS} \cdot \text{molar volume}} \cdot c_{VP}$$

and with the carbon proportion of the substance to be determined

$$(\mathbf{C\ proportion})_S = \frac{n_{CS} \cdot (AG)_C}{(MG)_S}$$

This is how the connection between mass concentration of the substance to be determined and the volume concentration of the calibration gas propane is obtained

$$c_{MS}\ [mg/m_N^3] = \frac{1.6}{r_s\ (\text{C-proportion})_s} \cdot c_{VP}\ [ppm]$$

$$= K \cdot c_{VP}\ [ppm]$$

Some response factors determined using propane as a reference substance are compiled in the Table. The correction factors given result from the factor 1.6, divided by the respective response factors and C proportions of the substance to be determined. These correction factors can be very different depending on the substance. In particular the low responsiveness (factor 13.4) of the FID to formaldehyde is emphasised. That is why formaldehyde is not directly determined in the exhaust gas. On the assumption that the exhaust gases from fixation processes in textile finishing, for example, contain principally long-chained aliphatic compounds with low concentrations of functional groups, the correction factor 2 can be used approximately for the conversion of the directly determined propane equivalent in the mass concentrations of organic substances.

Retarder Auxiliaries, which decelerate the uptake of cationic dyes, e.g. in polyacrylonitrile dyeing, and thereby have a levelling effect. These are colourless cationic substances, which enter the fibre with the dye in competition for binding sites, or systems of anionic and non-ionic auxiliaries, which have a dye affinity.

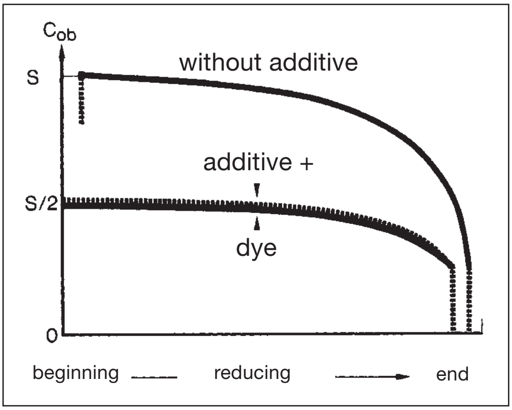

Fig.: Change in the concentration of dye C_{ob} on the fibre surface during the dyeing of polyacrylnitrile fibre (a) without and (b) with a retarder, having the same dyeing properties and in the same quantity (according to Bayer).

Retarders influence the adsorption characteristic (see Fig.). With the correct choice of retarder and quantity used, the impoverishment of the liquor only has a small effect on the fibre surface. Added to this is the fact that temperature differences have less effect, as the retarder also influences the diffusion in the fibre, which encourages migration. Uptake control devices and retarders complement each other. The retarder quantity can be reduced if higher affinity products are used, which uptake before the dyes. This is rarely exploited, as it involves the risk that the dyes uptake too quickly in the 2nd half of the uptake phase. Control devices and/or the use of these drafted temperature programs can avoid this risk. Retarder quantity and uptake time can be optimised this way.

Retarding Slowing down, decelerating, braking; e.g. the dye uptake speed, which occurs in all dyes involved in the sense of levelling, but which is also capable of having a selective effect on certain dyes and would at least severely disrupt the levelling of such dye combinations.

Retarding agent (retention agent), is used to prevent staining of a fibre type when dyeing textile blends. Retarding agents mostly have properties of mordants, which effect the textile fibre to be retarded before or during dyeing and consequently cause a change in the dye affinity (→ Mordanting). This in practice has the effect that in blended fabrics the retarded portion appears white or a different colour, if already dyed before retarding. So-called sulphurised phenols (thiophenols), sulphurised oils (for retarding polyamide), phenol condensates and inorganic salts (as well as e.g. ammonium thiocyanate and the like), are chiefly considered as retarding agents.

Retention Retentivity of fibres, e.g. →: Chlorine retention; Water retention.

Reticulation process is used to remove spurious glittering of the surface of foam coatings, which is caused by the network structure.

Retouching,

I. Removal of blank, yellowed, colourless fabric areas or those altered in colour, caused by intensive → Stain removal on non-colourfast parts or by concentrated chemicals, by possible careless stain removal or by the effect of perspiration (armpit areas), etc. Implementation:

a) using retouching pencils (coloured → Wax crayons and/or pastel crayon) especially for smaller areas on rougher materials;
b) using concentrated dye solution (benzine or alcohol soluble dye) soaked soft small woollen pieces of cloth or
c) by means of compressed air spray gun, which repre-

sents a considerable enhancement to stain removal and requires a lot of knowledge and practice because it should be "invisible", although its colour fastness is usually only low.

Final steaming of retouched areas encourages better durability.

II. Processing or levelling of defective textile fabrics or garment panels. Improving visible defects by artistic means.

Retouching inks Distinctions are made between liquid, paste and powdery retouching inks. Liquid retouching inks usually contain alcohol or oil soluble dyes. Retouching print pastes, for example, represent substances pulped with oleic acid, which are used directly or possibly diluted with benzine. Retouching ink powder (→ Spotting agent) are chiefly so-called coloured → Talcum varieties, mostly dust-free, for dusting and rubbing in, for refreshing dry-cleaned gloves, etc.

Retouching of rollers in roller printing Manual work to restore damaged printing rollers.

Retouching pencils For retouching, repairing afterdyeing and/or darkening of light materials or of dyeing faults, even in ready-made fabrics. Pressure-fast and fast to hot pressing pastel chalks/wax crayons are chiefly used as retouching pencils in large ranges of colour or with pencils filled with retouching ink. Permanent retouching pencils should be suitably sharpened in the form of a flat spatula before retouching. Finally a little re-levelling by hand or small pieces of cloth in order to achieve better colour transmission.

Retroactive (Lat.: retro = backwards), retrospective.

Retrogradation Degeneration. Common term for, e.g. retrograded starch. Usually starch liquors, after a short time, become cloudy again at low temperature and insoluble starch flocks fall out. This retrogradation of amylose molecules (through strong secondary valency forces) can cause just as unfavourable shifting of the sizing effect as possibly later aggravated desizing after a longer dwelling period. However, only liquors (pastes) made from natural starch and not those made from alcoholic precipitated starch, which are frequently for sale as soluble and/or partially decomposed starch products, can retrograde.

Retting (maturing stage). Biological degradation (rotting process due to bacteria and/or pectinase and fungi) for the exposure of → Bast fibres by decomposition of the vegetable glue and/or locking of the cellulose cells and exposure of the fibre bundles. Varieties: dew, water, hot water retting. Duration (days or weeks) dependent on variety and type of bast fibre, temperature, etc. → Flax processing.

Returns Batches rejected by the customer due to deviations from the quality standard, with the condition of remedying the faults.

Reusable dye tubes Dye tubes made from plastic can be used several times (reusable) for the dyeing of yarn reels (particularly in full range plants). However → Disposable dye tubes are subject to the recycling process (melting and repressing).

Potential problems from reusable dye tubes:

- staining with disperse dyes,
- costly storage space,
- deformations with shrinking fibres,
- in-house logistics.

Reutlinger matte Network made from thin textile fibres for the separation of oil from waste water.

Reutlinger pillstandard (RPG). For the visual assessment of pill formation (→ Pilling behaviour, test methods). Contains 8 stages: RPG 1 = stippled, bobbly fibrous; RPG 8 = maximum pilled. During the test operation, the degree of pill of the sample is visually assessed at certain intervals using the RPG and the value found, input into a diagram depending on the pill duration in the tester. The pilling tendency of the processed fibres can be developed from the pilling curves obtained in this way.

Reverse coloration method (RCM). The colour is applied onto the pre-padded, wet carpet material from the back side using dye liquor. It is also possible to carry out the dye liquor application repeatedly using different liquors.

Reversed-tailing-effect Designation for end unevenness in padder dyeings, is caused by the fact that the fabric takes up more dye than corresponds to the absorbed liquid volume; dye concentrate increases in the colour box so that the end of the batch is darker than at the beginning.

Reverse Dyeing Process for polyester/cellulose Discontinuous dyeing process for bright to medium shades of colour in machines, winch becks and jet equipment. In contrast to the customary dyeing methods of polyester/cellulose materials, in the reverse dyeing process the cellulose fibres are dyed first and then the polyester fibres. This process can only be used in cases in which a reductive after cleaning treatment is not applicable. The reverse dyeing process saves energy and time. In addition, it can be processed using simple machinery.

Reverse osmosis (hyperfiltration). Membrane separation process (→ Permeation), which is used for filtrating waste water. The process is becoming ever more widespread, as the level of development of membranes permits correspondingly large cleaning rates (tubular membrane modules for example, promise greater throughputs).

The reverse osmosis results from a pressure (of 40, 60, 80 bar) exerted by the concentrated solution on the semi-permeable membrane (polyamide 6.6-/acetate sheets). The solvent (water) migrates from the concentrated solution through the membrane and is described as a permeate. The dissolved substances remain as a

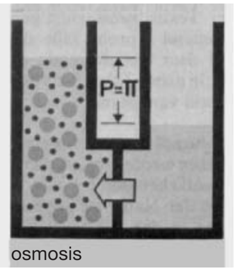

Fig. 1: The principle of the process of osmosis.

concentrate. This process is called “osmosis”. After some time, this process reaches a state of equilibrium, at which a hydrostatic pressure is adjusted by the volume shift, which is described as the “osmotic” pressure (Fig. 1). If a pressure is exerted on the concentrated solution after the state of equilibrium has been achieved, which is higher than the osmotic pressure ($p > \pi$), the process of osmosis can be reversed (Fig. 2). Then solvent from the higher concentrated solution migrates into the diluted solution. The membrane retains the dissolved materials, which accumulate into a “concentrate” in the residual solution. The “permeate” (and/or “filtrate”) penetrates the membrane. This process is suitable for the separation of ions or small organic molecules; adjacent macromolecules are likewise retained.

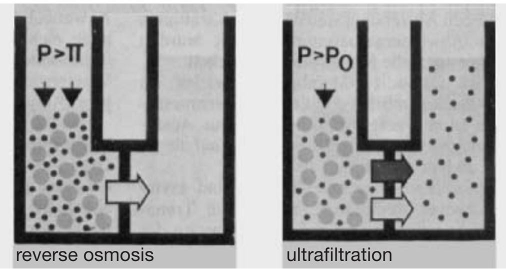

Fig. 2: Diagram showing the processes of reverse osmosis and of ultrafiltration.

The separation process is carried out by → Ultrafiltration similarly as in reverse osmosis. The difference lies in the separation of dissolved particles of different sizes. Totally dissolved macromolecular substances and emulsions are included; ions and smaller molecules pass through the membrane. The osmotic pressures of solutions of high molecular materials are much smaller than those of solutions of low molecular substances of equal weight concentrations. That is why the osmotic pressure in ultrafiltration is negligibly lower and the operating pressures are considerably lower than in reverse osmosis.

The membrane is the most important element in the application of this process technique. Besides its chemical resistance to substances occurring in the textile waste water it should also be mechanically robust and not susceptible to breakdowns as well as have a permeate output as high as possible.

This process is used for the separation of macromolecular substances, such as polyvinyl alcohol, of the solvent (water), of ions and low molecular substances. Chemical changes do not take place in the course of the process.

Reverse roller coating Coating method, in which the coating preparation is not directly applied onto the substrate, but firstly on rollers. In the reverse roller coating in Fig. 1, a doctor blade cleans the roller, which comes into direct contact with the fabric, while a third roller in the Reverse Roll Coater operates without being cleaned (Fig. 2).

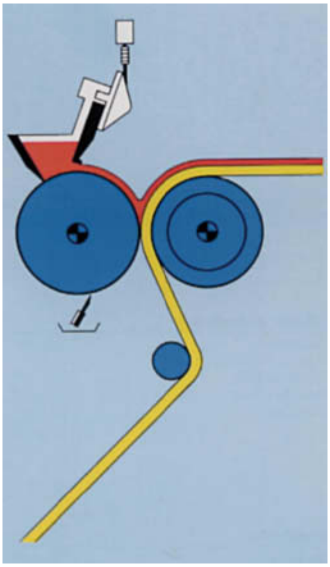

Fig. 1: Reverse coating (Kleinewefers KTM: Universal Coater).

Reverse winder is used for the turning of rounded or piece goods sewn in the tube.

Reversible Reversible; opposite to → Irreversible (not reversible). Designation for state of equilibrium in chemical reactions with corresponding properties; e.g. a precipitate formation, which under certain conditions (e.g. temperature) results in re-dissolution and the converse; also in colour formations. Example: base exchange water-softening processes, in which the working method of the zeolite (filter) has a typically reversible character.

Reversible carpet Jacquard patterned, thick → Flat carpets made from two or more interwoven warp and weft systems. The design on the top appears col-

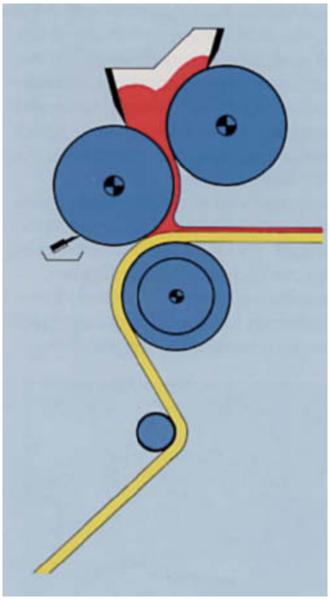

Fig. 2: Reverse roll coating (Kleinewefers KTM: Reverse Roll Coater).

ourwise to be a negative of the bottom (Kidderminster carpet, treeply or double-faced carpet).

Reversible fabrics Garment and coat materials, which can be used on both sides and are distinguished by weave (e.g. on the right, twill weave, on the left, satin weave; also double binding of materials such as in coat materials with woven lining), lustre or colour. Reversible crêpe e.g. →: Crêpe reversible; Crêpe satin.

Reversible methylene blue method For the determination of the → Methylene blue number. The methylene blue absorbed on the fibre is removed from the fibre using diluted hydrochloric acid and determined by colorimetric measurements.

Reversing action Intermittent change in direction of rotation of machines, in contrast to → Rolling.

Reversing drum A drum, for example, in multi-stage stenters and drying machines for the controlling and reversing of piece goods.

Reversing, stenter Stenter with non-contact, air-supported reversing of the material web (see Fig.). Entry and exit of the material length at the same end of the machine. Operating area corresponds to that of the → Single-layer stenter.

Rewetting Important part of the washing process, which runs in the opposite direction from previous → Wetting, because a fibre, for example initially "wetted" by oil, is wetted by the aqueous detergent solution at the end of the washing process, after removal of the adhesion forces of the oil smuts (ball formation). This phenomenon is described as rewetting.

Rewinding machine For the rewinding of dyeing muffs on reels for sale, with an outlet velocity of 200 to approx. 500 m/min, electric shutdown devices for thread breakage and when reel diameter is reached.

R_f (retardation factor). The distance between substance starting point and migrated substance stain (stain centre) in paper and thin layer chromatography, divided by distance between starting line and front of flowing material.

The dissolved substance examined is characterised by R_f value and colour of the substance stains migrated on the adsorbent. R_f is regarded as a substance-specific constant Ï with a strong deviation tendency (usually restricted reproducibility demand) depending on operating conditions; it is especially not ideal to depend on the subjectively established stain centre, but more oval or diffuse stains. It is therefore better to talk of an R_f range and consider this only as a reference point for the suitability of the fluid agent, i.e. whether the chromatographic compound is not too close at the start or migrates along in the front of the flowing material. Working with comparative substances or at least with test mixtures is recommended in order to eliminate the most likely errors. Only completely dissolved substances are clearly suitable for the formation of stains, as undissolved particles dissolve again in the flowing material and encourage an irritating "tail formation".

RF-Drying → High frequency drying.

RF value (degree of wash whiteness) → Whiteness, degree of.

RGB colour measurement system This so-called “international trichromatic RGB system” is based on the law that any four types of radiation can have a known relative light composition, but an unknown light intensity from any two are independent from three types of radiation in the corresponding mixture. The following radiation components were selected for filters in this system:

R = red = 700.0 nm
G = green = 546.1 nm
B = blue = 435.8 nm.

Rh Element symbol for rhodium (45).

r_h → Redox potential.

Rheological behaviour of solutions Newton’s law of viscosity is the starting point:

$$\text{dynamic viscosity} \quad \eta = \frac{\tau}{D}$$

I. Newtonian fluids obey Newton’s law of viscosity. The viscosity is a constant at constant temperature. The flow curve is straight. The angle ϑ is a measure of the viscosity.

II. Non-Newtonian fluids (high polymer solutions especially in higher concentration) do not obey Newton’s law (only very few exceptions). The viscosity η is not a constant; it depends on the shear gradient D and possibly on the stress period t. Model:

1. η depends on D, i.e.
   a) η grows with increasing D = dilatant behaviour.
   b) η decreases with increasing D = structural viscosity (pseudoplastic) behaviour.
2. η depends on D; a flow limit τ_0 exists (minimum stress), below which the substance behaves like a solid = plastic behaviour, often connected with structural viscosity.
3. η depends on D and t (time) (often connected with a flow limit τ_0), i.e.
   a) η grows with t = rheopexic behaviour.
   b) η decreases with increasing t = thixotropic behaviour.
4. Viscoelastic behaviour, if besides ultimate shearing strain (characterises viscous behaviour and permanent deformation) compressive and tensile stresses (characteristic of flexibly reversible deformation) also have an effect on the solution.

→ Rheology in printing and coating.

Rheology (Gk.: rheo = to flow), describes how a body is deformed by externally loaded forces. In the case of print pastes and coatings, for example, it concerns fluids, which are subject to ultimate shearing strains. The paste is made to flow by an applied shear force, i.e. the polymer molecules move past each other. The resistance to this forced irreversible volumetric change is called → Viscosity. This is substantially influenced by the molecular weight and density of the particles. →: Rheopexy; Thixotropy; Viscoelasticity.

Rheology in printing and coating Laws of rheology play a crucial role both in printing and in coating as the basis for these textile finishing processes. The flow behaviour of the print pastes influences the print quality. In many cases empirical methods for the assessment of print paste consistency no longer fulfil the requirements in accordance with production safety and reproducibility. It is possible to record the parameters of a print paste which determine quality, viscosity and flow characteristics of printing thickeners and print pastes metrologically using rotary viscometers.

The coating process may be regarded as a complex process. The rheological characteristics of the print paste should be regarded as factors which determine quality if the adjustable and influential sizes on the machine such as printing speed, squeegee setting, squeegee pressure and level in front of the doctor blade are kept constant. So the following factors are significant for the metering of the applied quantity by means of an air blade system:

– viscosity of the paste,
– rheological behaviour of the paste,
– tensile stress of the fabric,
– development of the coating knife bevel,
– inclination of the coating knife,
– speed at which the fabric is moved under the coating knife.

Coating pastes generally represent complex rheological bodies: They do not obey Newton’s law over a large measuring range, but show dependencies on the demand period and the shear gradient. The apparent viscosity and a likewise shear dependent elasticity are declared as the characterisation of the pastes. The thickness of the coating depends on the following sizes in the direct application method:

– distance between doctor blade and base material,
– type of base material to be coated,
– type and shape of doctor blade (roller doctor blade, air blade, etc.),
– viscosity of the paste,
– outlet speed of the base material.

As is obvious from these parameters, the rheological properties of the coating pastes are of particular importance: rheological processes, interfacial processes and drying processes are basic functions, in which the rheological processes should be observed under the machine conditions.

The flow of coating and print pastes corresponds to the model of the flow between two parallel sheets, in which one of the sheets is reduced to the size of the cutting width of a doctor blade and the other sheet corresponds to the substrate. Substrate or doctor blade can be moved alternately. A laminar flow is produced in the fluid between the sheets. The main values of the vis-

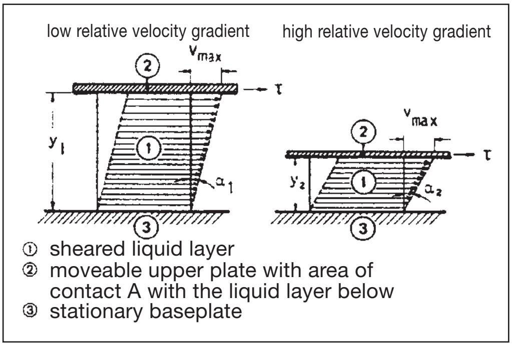

Fig. 1: Flow within the space between two parallel flat plates moving in opposite directions.

cosimetry, the shear stress τ and the shear gradient D can be defined via the sheet model (Fig. 1).

The basic law of viscosimetry is:

$$\eta = \frac{\tau}{D}$$

The shear stress τ is the ratio of the force F relative the surface A of the liquid contained beneath. An effective shear stress allows the liquid to flow according to its internal resistance. In this laminar flow (i.e., infinitely thin fluid layers move in parallel to each other) a shear rate D develops at right angles to the gap y. These correlations show that not only are the effective forces important in fluids, but also how quickly they are applied. One therefore talks of the dynamic viscosity η. The unit of dynamic viscosity η is the pascal second Pa s (1 Pa s = 1 N s/m^2).

The flow properties of a fluid can also be represented as a flow curve (rheogram) or via mathematical conversion of the measured results in a viscosity curve (viscosity characteristic curve). Fig. 2 shows the simplest case of a flow curve and the corresponding viscosity curve.

The viscosity of print pastes or coating agents, i.e. the physical behaviour of the fluid while it is in shear, may depend on four parameters:

- physical/chemical quality of the substance,
- temperature,
- shear gradient,
- time.

These parameters result in the fact that the viscosity is not a constant, but varies. Various viscosities therefore, appear in a paste at rest or during brushing. Liquids may have distinct rheological differences. Only Newtonian fluids show a viscosity behaviour as in Fig. 2. These are, for example, water and sugar solutions. The rheology of pastes or solutions of macromolecular substances differs significantly. The viscosity flow is not linear, but depends on the shear rate (Fig. 3). Such “non-Newtonian” liquids are more common by far.

1. Materials, which degrade their viscosity due to increasing shear rates, are called structurally viscous or pseudoplastic. A lot of technical and commercial substances such as emulsions, suspensions or dispersions belong to this group. The particles or molecules adapt themselves and may slide more easily over each other, i.e. the viscosity is reduced during shear.

2. Dilatant substances, which increase their viscosity with increasing shear rate, show contrary behaviour. Dilatancy is found in highly viscous suspensions, e.g. polyvinyl chloride plastisols; it is, however, relatively rare. It complicates the production processes in coating, as the flow resistance may be so high that the fabric webs to be coated may tear or even break machine parts.

3. The flow curve of plastic substances does not start at the zero point, but runs on the ordinate in order to be dissolved at the yield point. Plastic substances have a solid character at rest. As internal forces are greater than external acting shear forces, no flow at first takes place. Only when the flow limit is exceeded, i.e. with a certain applied force, can the volume elements

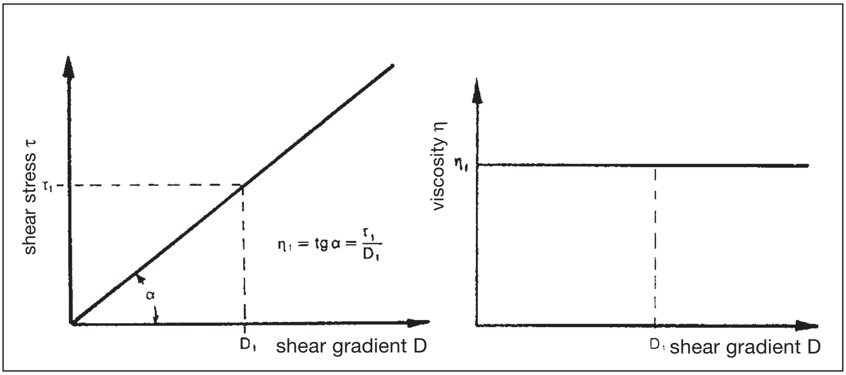

Fig. 2: The flow curve of a Newtonian fluid together with its corresponding viscosity curve.

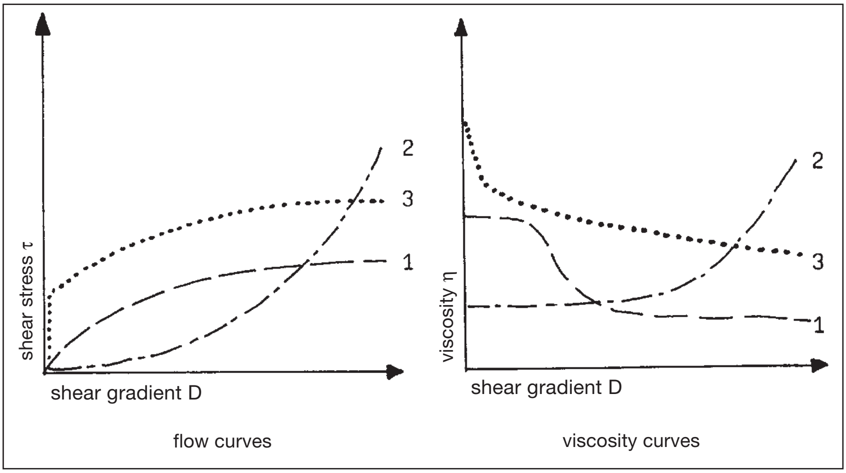

Fig. 3: Different types of common fluid behaviour. 1 = liquid with structural viscosity; 2 = dilatant fluid; 3 = plastic fluid.

change place. Plasticity is found in dispersions with large internal bonding forces. For example fats are typical representatives.

4. Over and above this, there are also substances with a flow behaviour, which strongly depends on the treatment period, e.g. shearing or regeneration time. These fluids usually also have a flow limit. Thixotropic or rheopexic liquids require a regeneration time in order to develop their typical viscosity, i.e. their internal forces, against a load (Fig. 4). Many dispersions show one of the degradation and/or structure dependent shearing times of bonding forces between the molecules or particles in the form of thixotropy. True rheopexy, i.e. increase in flow resistance with the shearing duration, is found extremely rarely. Rheopexy is often broken down by mistake, e.g. by setting or gelling. These processes, however, show no coincident hysteresis curves in a multiple program run as is the case in rheopexic and thixotropic liquids.

It is clear that the viscosity of print pastes or coating agents represents an essential parameter for the resultant textile finish. The viscosity has a significant effect on the coating strength and is considered in the choice

– of size of the doctor blade gap,
– of the shape of the doctor blade and
– the working speed.

In print systems, correlations can be combined between macromolecular structures in the colloids, their rheological phenotype and the print result, as shown in the Tab.

Two tasks fall to the softeners in coating pastes. They should give the necessary degree of softness to the finished coating and transfer the polyvinyl chloride into a paste state for workability. These kinds of paste produce highly viscous suspensions. Plastisol polyvinyl chloride powders are thereby mixed into liquid softeners. The viscosity of a paste for a given polyvinyl chloride softener system depends on the quantity of the freely available softener for the movement of the polyvinyl chloride particles in suspension. As this firstly divides the existing agglomerates into primary particles, a large specific surface area develops in the system.

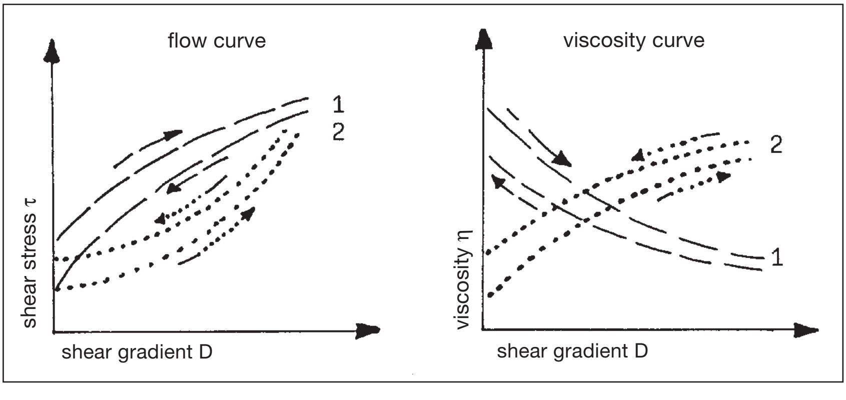

Fig. 4: Thixotropic (1) and rheopexic (2) flow characteristics.

Rheology modifiers/thickeners

structure of the network solution	recognition features	rheological characterization	printing outcome	remedies
	polymer concentration $<c_{critical}$ free liquor	viscosity: low shear susceptibility: slight elasticity: none	colour density: high contours: poor ground: bleeding of free liquor into the fabric capillaries	increase the concentration of thickener consequences: viscosity increases, shear susceptibility increases, elasticity increases
	polymer concentration $>c_{critical}$ no free liquor few solid bodies small gel tangles	viscosity: medium shear susceptibility: n>0.5 elasticity: weak	colour density: high contours: good	optimum high dry material content
	polymer concentration $>c_{critical}$ no free liquor many solid bodies large gel tangles	viscosity: medium shear susceptibility: pronounced elasticity: strong	colour density: low contours: poor ground: inadequate colour density	increase doctor blade diameter, increase concentration of thickener since water may be removed from the network solution consequences: high to very high viscosity, shear susceptibility increases further, elasticity increases further

░ bound dissolvent ▨ free dissolvent ∞ chain material ⬚ volume of tangles

Tab.: Thickeners without a liquid limit: flour derivatives, alginates, cellulose derivatives, vegetable gums, hydroxycelluloses (according to DITF).

Because of this, rheologically more effective softener is extracted from the system due to the adsorption on the primary particles. As this process is executed, an increase in viscosity, controlled by diffusion, ensues with storage time.
