Chapter 22: Reasoning, Decision Making, and Rationality

JONATHAN ST. B. T. EVANS, DAVID E. OVER, AND
KEN I. MANKTELOW

Introduction

The psychological fields of reasoning and of decision making are reported in different literatures, mostly by different authors and with little cross-reference. Is this just a matter of research traditions, or are the cognitive processes involved fundamentally different? On the face of it, a reasoning task is significantly different from a decision task. In the study of deductive reasoning, for example, subjects may be presented with the premises of some argument and asked whether or not a conclusion follows. For example, a subject may be asked to evaluate a syllogism such as

No A are B

Some B are not C

Therefore, some C are not A

and to indicate whether or not the conclusion follows. This is presumed to involve a process of reasoning from the premises which may or may not support the conclusion. If the subject has *deductive competence* – discussed below – it should be possible for him or her to solve the problem set without further information. In this sense, deductive reasoning tasks can be viewed as a special case of well-defined problem-solving tasks, whose main purpose is to investigate people's ability to understand and apply logical principles.

Decision-making tasks, on the other hand, involve choices between actions and normally involve commitment to particular acts at one point in time, whose consequences will only later be apparent. A simple example might be decid-

ing whether or not to place a bet on a horse. One might think that a "good" decision is one that works out, that is, placing the bet on a horse who wins, or withholding on one who loses, but it is not that simple. Because real-world events are uncertain, good and bad decisions must be judged on their theoretical merits, not on their outcomes (see von Winterfeldt and Edwards 1986). The standard normative principle is that of *subjective expected utility* (SEU). Subjects are assumed to make the choice that maximizes the expression $\sum s_i U_i$, where s represents the subjective probability of an outcome associated with a choice and U represents its utility, that is, subjective value or pay-off to the decision maker. Hence an objectively good decision is one which would pay off best on average if the decision could be made under the same circumstances a large number of times.

Both reasoning and decision-making literatures involve assessing people's actions against normative theories of "correct" behavior but in so doing they imply different notions of rationality. In one case it is apparently rational to reason logically, and in the other case it is rational to achieve maximization of expected utility. This distinction is discussed in the following section and we believe it is critical to understanding the relation between the two fields. Leaving this aside for the moment, it is clear that both reasoning and decision tasks involve high-level thought processes. On further reflection it is apparent that reasoning tasks usually involve making decisions, and that choosing between actions often requires one to make inferences. In real-world situations the distinction between reasoning and decision making is blurred.

Decision making, or at least rational decision making, usually involves *forecasting*. That is to say, one action is preferred to another because the chooser believes that he or she would rather live in the slightly different world that will exist when this action is taken. But what does forecasting consist of, if not reasoning? Consider the situation of a school leaver deciding which university to apply to for degree study. A number of factors will influence such a decision, including the academic merits of the courses offered and the advantages and disadvantages of different geographical locations. In reading prospectuses of different universities the chooser is trying to infer which course he or she will most benefit from. The sophisticated chooser will make allowances for the promotional techniques and biases in the literature read – this too is reasoning.

If we look at deductive reasoning in the laboratory, we find that the great majority of tasks given to subjects involve decision making (see the reviews of Evans 1982; Evans, Newstead, and Byrne, 1993). Subjects are asked whether a given conclusion follows or not, or which of a list of conclusions is the best candidate, or on the famous Wason selection task (of which more later) which of several cards should be turned over. (Researchers who ask subjects simply to generate inferences are in the minority, but see Johnson-Laird and Byrne 1991, for good examples.) These decisions have a goal structure, albeit one that is often implicit. If the subjects are trying to find the logically correct answer it is because the instructions have motivated them to do precisely that, or because they do not wish to look foolish, or because they want to enhance their self-esteem.

It is difficult to think of cases in the real world when we make inferences *except* to make a decision or achieve a goal of some kind. The apparent exception is that of inferences drawn in order to enhance our knowledge or revise our beliefs in some way. However, maintenance of coherent and accurate belief systems is fundamental to our survival and achievement of goals in the real world and is clearly motivated in its own right. Hence some of our goals are *epistemic* or knowledge serving.

In the following section we lay out our thoughts about rationality in reasoning and decision making and relate this to the distinction between theoretical and practical inference. We argue that the separation of the psychology of reasoning from that of decision making is primarily due to emphasis on the study of logical

competence and theoretical reasoning, and that more attention to practical reasoning will not only develop the link with the study of decision making but also enhance the ecological validity of reasoning research. To illustrate our arguments we present discussions of two major areas within the psychology of deductive reasoning – belief bias in syllogistic inference and deontic reasoning on the Wason selection task – whose findings are interpreted within the framework proposed. Finally, we present a critical examination of the value of decision theory as a criterion for rational choice and reasoning.

Rationality and Practical Inference

Evans (1993) has argued that the debate about rationality in human reasoning and decision making is confused by two different, but implicit definitions of rationality. These can be defined as follows:

rationality₁ (rationality of purpose): reasoning in a way which helps one to achieve one's goals;

rationality₂ (rationality of process): reasoning in a way which conforms to a supposedly appropriate normative system such as formal logic.

In the classical decision-making literature (e.g., Savage 1954) the primary definition of rationality has been an idealized version of rationality₁: A rational person is believed to be one who chooses in such a way as to maximize his or her SEU. (We shall, however, later question the adequacy of decision theory defining rational choice.) In the literature on deductive reasoning, however, the rationality argument has focused on the concept of *logicality*, that is, validity or deductive correctness in reasoning, with the consequent adoption of the rationality₂ concept. There is, of course, a further implicit assumption, namely that rationality₂ serves rationality₁: in particular that logical reasoning will lead to the achievement of goals. This idea resembles Dennett's (e.g. 1978) "argument from natural selection" which is criticized by Stich (1985; see also Manktelow and Over 1987).

Leading researchers continue to equate rationality with deductive competence, as the following quotations from three very recent sources illustrate:

At the heart of rationality is the capacity to make valid deductions. (Johnson-Laird 1993, p. 2)

The concept of rationality assumes that people can engage in abstract deductive arguments and derive valid conclusions from a set of premises. (Stevenson 1993)

The classical Greek view of human nature included a rationality that allows for logical reasoning. My colleagues and I have argued elsewhere . . . that we have no adequate reason to abandon this view, and that this rationality includes a mental logic that accounts for our basic logical intuitions. (O'Brien 1993)

However, it is true that in addition to the current authors (Evans 1993; Over and Manktelow 1993) others have started to adopt a rationality₁ perspective in the study of reasoning. For example:

. . . what counts as human rationality: reasoning processes that embody content-independent formal rules, such as propositional logic, or reasoning processes that are well designed for solving important adaptive problems, such as social contents or social regulations? (Gigerenzer and Hug 1992, p. 129)

Many authors have argued that we should regard rationality as axiomatic (e.g., Cohen 1981; Dennett 1978). Humans are the most intelligent species on earth and have evolved into creatures extraordinarily capable of flexible response to their environment. Our ability to solve problems and to achieve goals is self-evident. The present authors accept this premise with two important reservations: (1) Rationality is only axiomatic in the sense of rationality₁, not rationality₂; and (2) the rationality we hold is highly *bounded* by cognitive constraints. Our position is thus similar to the argument for bounded rationality proposed by Newell and Simon (e.g., 1972): We assume that people try to achieve goals, and when they fail it is indicative of limitations in their processing capacity or ability. Due to cognitive limitations we also propose that goals are more likely to be achieved by *satisficing*, that is, finding an adequate solution, rather than by optimizing or maximizing utility across all possible choices and outcomes as proposed in classical decision theory. (For a philosophical treatment of satisficing, see Slote 1989.)

Recently, there has been increasing interest in a type of thinking in which the relation between

reasoning and decision making, and between rationality₁ and rationality₂, has been brought into sharp focus. This is the type actually known in philosophy as practical reasoning, and distinguished from so-called theoretical reasoning, the center of so much earlier psychological research. (See Audi 1989, on the history of the philosophical study of practical reasoning, which goes back to Aristotle.) People use practical reasoning to try to achieve their goals in the actions they perform, and when they do this in the right way, they display rationality₁. They use so-called theoretical reasoning to try to acquire true beliefs about matters of fact, and they have rationality₂ when they do this in the right way.

Theoretical reasoning, despite its name, does not have to be about scientifically theoretical entities, like subatomic particles, but may concern ordinary material objects, like cats and mats. You are engaged in theoretical reasoning if you are just trying to discover whether the cat is on the mat; you are engaged in practical reasoning if you are trying to decide whether you should kick the cat off your new mat. You have to have some basic ability to do theoretical reasoning, otherwise you would not know, for one thing, what is presupposed by your practical reasoning: that the cat is on your new mat. Only a quite bounded or limited logical ability is necessary to acquire such knowledge, and not even a much more sophisticated ability at deductive logic would be sufficient for it. Inductive inferences are also necessary, in general, to acquire empirical knowledge.

It is our purpose in this paper to concentrate on rationality₁ and practical reasoning. Before doing so, however, a little more must be said about the nature of rationality₂ and theoretical reasoning. We concede that the literature on deductive reasoning does contain evidence of deductive competence and that is one aspect of the evidence that theories of reasoning must explain (see Evans 1991). However, we also believe that an undue emphasis on rationality₂ and the belief in the logicity = rationality equation has not only dominated theoretical effort in the psychology of reasoning but has also led to widespread misinterpretation of much of the data which demonstrate "biases" and content effects. Detailed arguments against the "rationality = logicity" thesis are presented by Evans (1993) and will not be repeated here. Reinterpretation of literature in terms of practical reasoning will, however, be offered in the review sections of this paper.

The Belief Bias Effect in Syllogistic Reasoning

Real-life reasoning is not, in general, well modeled by laboratory reasoning tasks. In everyday life we do not reason in order to be logical, but are logical (when we are) in order to achieve our goals. We often do not restrict ourselves to information given in premises, and frequently go beyond any information we have in inductive reasoning. Rational₁ reasoning in the real world means that it is applied to the achievement of a practical goal, or the selection of a decision, and that as much relevant knowledge as possible is retrieved and applied to the problem at hand. It is in this context that laboratory studies must be interpreted. If logical errors occur then we must ask first whether these result from processes which would be adaptive (i.e., goal-fulfilling) in application to real-world problems. Only if the answer to this is negative is it sensible to consider what the "errors" tell us about the cognitive constraints on human inference.

We illustrate the problem of illogicality in experimental studies of reasoning by reference to the belief bias effect in deductive reasoning – a phenomenon which appears on first inspection to render people inherently irrational. First, we will present a brief review of the recent research findings in this area and then we will offer an interpretation of the effect in the context of the current argument. In a typical deductive reasoning task, subjects are presented with the premises of an argument and asked whether a particular conclusion follows logically from them. Alternative procedures involve asking subjects to choose from a list of putative conclusions or asking them to generate a conclusion of their own. With the first method, belief bias consists in tending to endorse conclusions which are *a priori* believable as valid and those which are unbelievable as invalid, regardless of the logic of the problem.

Belief Bias: The Phenomena

The belief bias effect was first reported by Wilkins (1928) and replicated a number of times during the following 30 years or so. Unfortunately, a number of these studies were marred by methodological errors (see Evans 1982, pp. 107–111; Revlin, Leirer, Yopp, and Yopp 1980). Paradoxically, recent interest in the phenomenon was revived by Revlin et al. (1980), whose motivation was apparently to discredit the belief bias effect. In particular they argued that subjects

might be converting premises, for example, reading "All A are B" as "All B are A." In their own experiments, with new controls, they did produce significant, if small, effects of belief bias which they play down in discussion. Revlin et al. asked subjects to choose from a list of conclusions which leads to problems of interpretation as to what is the correct answer and may have led them to underestimate the size of the bias.

Evans, Barston, and Pollard (1983) used carefully constructed syllogisms whose premises were logically unaffected by conversion, and presented a single conclusion for evaluation. Instructions to subjects included the following sentences, intended explicitly to preclude the use of prior beliefs about the problem material:

You should answer the question on the assumption that the two statements are, in fact, true. If you judge that the conclusion necessarily follows from the statements, you should answer "yes" otherwise "no".

An example of an invalid syllogism with a believable conclusion used by Evans et al. is the following:

No addictive things are inexpensive

Some cigarettes are inexpensive

Therefore, some addictive things are not cigarettes

By reordering the words, the same logical form can produce a syllogism with an unbelievable conclusion as follows:

No cigarettes are inexpensive

Some addictive things are inexpensive

Therefore, some cigarettes are not addictive

If the terms in the conclusion are reordered without altering the premises then the argument is valid. Thus it is possible to construct four classes of syllogism: valid-believable, valid-unbelievable, invalid-believable, and invalid-unbelievable. In spite of the use of explicit deductive reasoning instructions and an intelligent undergraduate student population, massive effects of belief bias were observed. The basic acceptance rate of conclusions in these four categories observed by Evans et al. is shown in Table 1. There are three substantial and highly significant effects: (1) Subjects endorse more conclusions which are logically valid than invalid; (2) subjects endorse more conclusions which are believable than unbelievable; and

Table 1: Percentage Conclusions Accepted by Subjects in the Study of Evans, Barston and Pollard (1983) Averaged Over Three Experiments

	<i>Believable</i>	<i>Unbelievable</i>
Valid	89	56
Invalid	71	10

(3) logic and belief interact in their effect on subjects' choices. The latter finding reflects the fact that the belief bias effect is much larger for invalid syllogisms.

Subsequent research has been mostly theory driven. Evans et al. (1983) favored an account of the findings which was later named as the selective scrutiny model (see Barston 1986; Evans 1989). The other major account is based upon the mental models theory of reasoning (Johnson-Laird 1983; Johnson-Laird and Byrne 1991) and was first developed by Oakhill and Johnson-Laird (1985). The selective scrutiny model assumes that subjects first evaluate the believability of the conclusion. If it is believable, they usually accept it without an attempt to assess the logic of the syllogisms. If it is unbelievable, then they are more likely to check the logic. This predicts the interaction shown in Table 1 due to the "selective scrutiny" of arguments with unbelievable conclusions.

Evidence in favor of the selective scrutiny model is provided first by verbal protocol analyses reported by Evans et al. (1983). They found that subjects who referred only to the conclusion showed most belief bias, while those who referred to the premises and then the conclusion showed the least belief bias. Intermediate levels were associated with subjects who referred to the premises *after* reference to the conclusion. Hence, belief bias was associated with conclusion rather than premise-based reasoning. A second source of evidence was that of Evans and Pollard (1990), who predicted and found that increasing the logical complexity of the problems – and hence the overall error rate – did *not* increase the size of the belief bias effect. This surprising finding is predicted on the grounds that in the selective scrutiny model belief bias occurs prior to an attempt at reasoning. Hence, any subsequent failures in reasoning due to logical complexity will add only random error.

The mental model theory of deductive reasoning (see Johnson-Laird and Byrne 1991) assumes that subjects attempt to build models

compatible with the premises from which putative conclusions are formed. Invalid conclusions are generally avoided by searching for counter-examples, that is, by attempting to generate models compatible with premises but incompatible with the putative conclusions. Oakhill and Johnson-Laird (1985) argued that where putative conclusions are believable subjects may neglect the third stage of seeking counter-examples. This would lead to precisely the high acceptance of invalid-believable conclusions which is typical of findings in the area (see Table 1). While a kind of selective scrutiny argument itself, the mental model account differs from the proposals of Evans et al. (1983) in assuming that some reasoning always occurs prior to the influence of belief.

A variety of types of evidence have been claimed in favor of the mental models account. Oakhill and Johnson-Laird (1985) and Oakhill, Johnson-Laird, and Garnham (1989) have shown that subjects may be biased in favor of *producing* believable conclusions when given only the premises of the argument, hence showing that the effect is not simply due to the evaluation of presented conclusions. However, Oakhill et al. (1989) also found that subjects may withhold unbelievable conclusions on one-model valid problems, where no counter-examples exist, and are only able to offer an ad hoc account in terms of "conclusion filtering." In fact, there are several sources of evidence demonstrating a negative belief bias, that is, preference for neutral over unbelievable conclusions (Evans and Perry 1990; Evans and Pollard 1990; Newstead, Pollard, Evans, and Allen 1992) which present theoretical problems for both accounts considered here.

A recent paper by Newstead et al. (1992) reports five new experiments which fail to support the original selective scrutiny model and which provide evidence for a modified mental model account. One new finding reported (Experiments 1 and 2) was that little belief bias occurs, and the belief by logic interaction disappears, when the invalid syllogisms used have conclusions which are determinately *false* rather than indeterminate as in the Evans et al. (1983) study. This cannot be explained on the assumption that belief bias precedes an attempt at reasoning. However, the mental model account proposes that initial modeling and formation of a putative conclusion precede the influence of belief. In these cases a believable-invalid conclusion could not survive the initial stage since *no* model of the premises will permit it. Another

finding reported (Experiment 5) was that the belief by logic interaction was removed by elaborated instructions emphasizing logical necessity, which would presumably discourage premature conclusions and stimulate a search for counter-examples. (For discussion of this paper, and a reply, see Oakhill and Garnham 1993; Newstead and Evans 1993).

Is Belief Bias Rational₁?

Now what should we make of these findings in terms of our argument for rationality₁ in human reasoning? These findings do appear to provide evidence of highly irrational reasoning. In the Evans et al. study, for example, subjects were told to base their reasoning only on the information presented and to endorse only conclusions which necessarily followed from the premises. Despite the fact that subjects *can* figure out the logic – as the large effect of validity shows – they were nonetheless quite unable to ignore the believability of the conclusions. Can the belief bias effect be explained within the notion of bounded rationality₁ presented earlier? We believe it can. First, we have to recognize that mechanisms of reasoning have evolved to facilitate the achievement of goals in the real world rather than to solve problems in the psychological laboratory. Second, we have to be sensitive to relevant cognitive constraints.

The first question, then, is whether belief bias effects could result from a normally adaptive process. Both major theoretical accounts considered above involve the notion of selective scrutiny. Only conclusions which are *unbelievable* to the reasoner appear likely to get a full process of logical evaluation. Other invalid conclusions are often accepted unless they are incompatible with the premises or unless elaborated instructions are provided. In general, both believable and even neutral conclusions tend to be accepted without adequate search for counter-examples.

Why would it be adaptive to reason only selectively and more so when the argument goes against rather than for one's beliefs? The maintenance of a large and stable set of beliefs is essential for intelligent behavior, since this forms the basis for any actions which one may take to achieve one's goals. When arguments are encountered which support existing beliefs, the evidence suggests that we do not examine them closely. This is surely rational₁ since (1) it is advantageous to maintain beliefs unless there is good reason to revise them, and (2) the pro-

cessing effort required constantly to question the evidence of current beliefs would be enormous. The situation when confronted with argument or evidence for a statement which contradicts one's beliefs is quite different. To accept such an argument uncritically would be damaging to the individual since this would introduce a contradiction and disrupt the internal consistency of their belief system. Hence, it is quite rational that such arguments should be subjected to the closest possible scrutiny and refuted if at all possible.

A distinct but related phenomenon to belief bias is that of confirmation bias, although some controversy surrounds the evidence claimed for the phenomenon (see Evans 1989; Klayman and Ha 1987). Confirmation bias consists of a tendency to seek out evidence which confirms rather than contradicts current beliefs and thus runs counter to the rational₂ falsification model of science espoused by the philosopher Karl Popper (1959, 1962). The two phenomena together constitute belief-maintaining biases which are often portrayed as evidence of high irrationality in human reasoning. However, Baron (1985) in discussing possible causes of belief-preserving biases offers an argument related to our above comment on belief bias:

“... when beliefs are integrated with each other, so that each provides support (evidence) for the others, a change in one belief might weaken others as well. If we are also motivated to have consistent beliefs, such a change might require reevaluation of other beliefs than the one under attack at the moment. Such reevaluation will require thinking, which has a cost. Thus, revision of a single belief might lead either to inconsistency or to further thinking, both undesirable consequences, although perhaps not equally undesirable for all people. (pp. 165–166)”

The problem with viewing confirmation bias as evidence of irrationality is first that this is based upon rationality₂, and second that it regards any act of confirmation as illogical. Beliefs that hold on most occasions and which maintain consistency with other beliefs may benefit the individual, even though occasional exceptions show them to be strictly false.

Consider the example of falsifying evidence in scientific research. Reading the arguments of some psychologists discussing belief and confirmation biases, you would think that abandonment of a theory was required by a single failed prediction. These psychologists are apparently

presupposing quite a naive Popperian scientific methodology, which has been heavily criticized by philosophers of science in recent years, in large part for rejecting any notion of confirmation or inductive reasoning (Earman 1992; Howson and Urbach 1989). A prediction is usually inferred, not from a theory on its own, but from the theory along with an indefinite number of background beliefs, for example, about the conditions under which the experiment is conducted, and the reliability of the experimental equipment. It is also rare for the prediction to be certain given all these beliefs or hypotheses. For these reasons, it can be far from certain that there is a serious problem at the heart of a previously well-confirmed theory when there has been a failed prediction.

In this section we have offered an interpretation of one of the most reliable biases in the experimental literature on reasoning which is compatible with our notion of rationality₁ in reasoning. We now turn to another area of the experimental literature on deductive reasoning in order to discuss recent work on reasoning with deontic conditionals. This work, we believe, directly demonstrates the decision-making nature of subjects' inferences using laboratory tasks.

Deontic Reasoning

The primary purpose of most of our ordinary reasoning is to help us make good decisions, so that we can have reasonable success in achieving our goals. This point was brought out clearly by Grice (1975), who noted that efficient communication has to be a goal-directed process, in which the participants must infer each other's purposes and then make appropriate decisions about their own speech acts and other actions. Similarly, the purpose of reasoning is best served by drawing inferences from *all* our beliefs, not just from an artificially restricted set of premises, as in most psychological experiments on reasoning.

On this basis, we should also expect people to display rationality₁ in experiments calling for something like ordinary practical reasoning, which is aimed at realistic goals and not at abstract theoretical ones. Striking results of changing the nature of experimental reasoning tasks in this way can be observed in the recent history of work on the Wason selection task. The developments in question have focused selection task research on a type of *deontic* reasoning which is directly and immediately practi-

cal. The object of deontic reasoning is to infer what actions ought to be taken, or may be taken, and it calls for cognitions of probability, utility, and social perspective – aspects of thought which hitherto were the prime concern of research on decision making. Thus in deontic-reasoning research we have a premier case of cross-pollination between the two fields of reasoning and decision making.

The Indicative and Deontic Selection Tasks

As many readers will be aware, a typical selection task experiment involves presenting a conditional sentence of the form *if p then q* with four cards, each of which has a *p* or *not-p* value on one side and a *q* or *not-q* value on the other (see Evans et al. 1993, Chapter 4, for a comprehensive review of work on this problem). In the standard – what we describe as *indicative* – form of the selection task, the conditional is couched in abstract materials (e.g., “If there is an A on one side of a card then there is a 3 on the other”), and the subject is asked to decide which cards would need to be turned over in order to decide *whether the conditional is true or false*. The correct answer is *p* and *not-q* since only the combination of these two values on the same cards could disprove the conditional. However, typically fewer than 10% of intelligent adult subjects give the correct response when the task is presented in this way: Most often they say *p* and *q* or just *p*. In recent times most researchers' attention has been concentrated on facilitating the production of the logically warranted response by changing the content and context in which the problem is presented. Many of these involve a *deontic* version of the task in which subjects decide which cards will tell if a *rule has been followed or violated*, as opposed to deciding whether it is true or false.

For the purposes of the present discussion, the crucial development was the use of a generalized deontic context by Cheng and Holyoak (1985). To explain why the use of such a context has the effect of facilitating the “correct” response, Cheng and Holyoak introduced the theory of *pragmatic reasoning schemas*. It is held that in situations clearly perceived by the reasoner as deontic (in their research, they referred specifically to situations of *permission* and *obligation*, though there are some problems with their definition of these terms; see Manktelow and Over 1991), a set of generalized production rules was activated in which the relation between preconditions and actions was specified. Mapping

these to the specific task content would deliver the appropriate selections.

For example, a version which reliably facilitates performance is that of the drinking age rule (Griggs and Cox 1982). Subjects are asked to imagine that they are police officers checking whether the rule "If a person is drinking beer then that person must be over 19 years of age" has been violated, by inspecting cards which have a beverage on one side and the age of the drinker on the other. Most subjects correctly turn over "beer" (p) and an age under 19 years ($not-q$). This is attributed by Cheng and Holyoak to use of a permission schema in which the rule is mapped to "If you perform an action (*in this case drinking beer*) then you must fulfil a precondition (*in this case being over 19 years of age*)."

This theory has led to an upsurge in research on deontic reasoning and has dominated the explanations of its findings, but it has not gone unchallenged. Its two principal competitors are the theory of mental models (derived from Johnson-Laird and Byrne 1991) and the social contract theory of Cosmides (1989). We shall defer discussion of the former for the moment, and pause briefly on the latter before looking in detail at some of the most recent work. Cosmides' theory has sustained serious criticism, making it no longer tenable in its original form (see, e.g., Cheng and Holyoak 1989; Manktelow and Over 1987, 1991). However, it is of singular importance in one respect: its emphasis on benefits and cost in the explanatory framework. Cosmides' theory holds that the essence of the kinds of deontic thinking explored by reasoning researchers, for example permissions, lies in social exchange; this in turn boils down to an implicit or explicit contract held by its parties, that *if you take a benefit then you pay a cost*. Human life would be impossible without an innate understanding of this contract, says Cosmides, which entails an immediate ability to detect its violation: instances of people taking a benefit without paying a cost, or *cheaters* as she calls them.

Recent Studies of Deontic Reasoning

Recent experimental work has enlarged our understanding of the nature of deontic reasoning, and enabled us to look not only at the particular issue of explaining what goes on in selection tasks of this type, but also at the implications of these findings for theory and for the relation between reasoning and decision making. Let us take these issues in turn.

Gigerenzer and Hug (1992), for example, distinguish between two core components of Cosmides' theory: social contracts and cheating. They found that casting a task in social contract form was not sufficient to produce facilitation of the p , $not-q$ response. This only occurred when a cheating context was specified. When the cheating conditions are clearly set out, this form of deontic reasoning becomes very straightforward, as Light, Girotto, and Legrenzi (1990) found: Children of 12 or younger are adept at such reasoning tasks. Detection of the violation of a clearly specified deontic rule such as a permission (Gigerenzer and Hug 1992; Manktelow and Over 1991), promise (Light et al. 1990), obligation (Gigerenzer and Hug 1992), or warning (Politzer and Nguyen-Xuan 1992) has been demonstrated to be a natural cognitive process by these studies.

Such research has also elucidated the role of social cognition in this form of practical thought. All the studies just cited have pointed out the role of two fundamental parties in deontic reasoning: the one who lays down the rule, and the one whose behavior is its target, termed the *agent* and the *actor*, respectively, by Manktelow and Over (1991). These authors have shown that violations of a rule such as permission can be performed by either party and in more than one way. Take the use of a standard conditional permission rule, *if you do p then you may do q*, which in many contexts pragmatically implies that the only way you get permission to do q is by doing p . Subjects readily understand that, in realistic contexts of this general type, the actor goes wrong by doing q without fulfilling p , while the agent goes wrong by not allowing the actor to do q although p has been fulfilled, or by allowing q without p being fulfilled. Note that these are not all cases of someone being *cheated*, but they are all cases in which someone suffers a cost because of the failure to conform to the rule, or what is pragmatically conveyed by its use, in a realistic context. Permission has, as Gigerenzer and Hug term it, *bilateral* options for violation; some deontic relations are *unilateral* in that they can generally only be violated by the agent (e.g., in the case of promises) or the actor (in the case of obligations).

These observations have forced a reconsideration of the traditional facilitation effect in selection task research, and consequently to an appreciation of the relation between what has always been seen as a reasoning task and its role in explaining decision making, hence to the

relation between rationality₁ and rationality₂, as set out above.

As we saw, the idea of the facilitation effect arises from the original use of the selection task in research on theoretical reasoning, using indicative conditionals, for which a correct response has generally been taken to be to select the *p* and *not-q* cards. The recent studies outlined above have shown that it is routinely possible to elicit high rates of *not-p*, *q* selections in certain well-defined contexts. For instance, Manktelow and Over (1991) used a permission rule, "If you spend more than £100 then you may take a free gift"; subjects were readily cued to select the *not-p*, *q* combination (spent less than £100, took the gift) when the scenario referred to a store giving out more than it should, or customers taking more than they were entitled to (see also Politzer and Nguyen-Xuan 1992, who independently used similar materials and reported similar effects). It is clear then that what is being facilitated here is not something corresponding to the truth conditions of the material conditional.

A Rational₁ Interpretation of Deontic Reasoning

The notion of testing the truth conditions of a conditional does not apply to deontic reasoning at all. In the experiments discussed above, people are not being asked to test the truth of rules, but are being asked to detect violations (a form of action) of rules whose truth status is not in question. This leads to further questions: What counts as a correct response in this case? What counts as a true deontic rule?

The first question leads us to focus again on the relation between reasoning and decision making, and between rationality₁ and rationality₂. As Light et al. (1990) put it, responses in deontic selection tasks should be judged as correct if they lead to the detection of the possible violators, independent of the values that the corresponding cases would have under a formal heading. Detecting violation is an important practical matter. If we could not do this, we would fail to achieve many of our prudential, social, and moral goals.

As for the truth of deontic rules, this gives us reason to part from the schema theories (derived from Cheng and Holyoak, which most current theorists adhere to) on the grounds that the theory of pragmatic reasoning schemas is a non-semantic production rule theory: It contains no component which could specify why a deontic utterance should be made or accepted in the

first place, or when it would be felicitous to do so. We have put forward elsewhere an alternative based on the theory of mental models (see Manktelow and Over 1991; and Over and Manktelow 1993, for details) which addresses this and other points. It is based on the semantic notion of modeling the state of affairs specified by the particular deontic context and content, and the notion of preference between these states.

Suppose that a mother is trying to decide whether to let her son go out to play. She might think that he is likely to get into trouble if he goes out, and in that case, she will prefer him to stay in. She will then announce her decision by saying, "You must stay in," which places her son under an obligation. Another possibility is that she is indifferent to whether he goes out or not, and she might even prefer him to go out (where he will not be under her feet). Expressing a permission, she will consequently say, "You may go out." A slightly more complex case would be one in which she is indifferent to whether her son goes out provided that he satisfies some condition which she has as a goal, say, that of getting his room tidy. She will now utter a conditional permission, that is, a deontic conditional like "If you tidy your room, you may go out."

The mother will consider the above conditional permission true just in case she is indifferent to whether her son goes out, or even prefers her son to go out, given that he tidies his room. If he does do that, he will give his mother something which has utility for her, a tidy room, in exchange for achieving a goal which has utility for him, going out. Notice that this concept of truth for deliberative deontic statements is a subjective one, and indeed depends on the decision theoretic notion of preference, and also that of subjective probability (which we shall discuss below). If the mother foresaw more likely benefit, or less likely cost, in her son staying in than going out after he tidied his room, she would not assert the conditional permission as true. Note also that we are using these terms in a technical sense. To say that a tidy room has more utility for the mother than an untidy one is just to say that she prefers the former to the latter. To say that her son going out is a benefit for the mother, or a cost, is just to say that she prefers the former to the present state of affairs which the son is in, or vice versa.

From the son's perspective, he has to grasp the social context in which he finds himself. His mother has power or authority over him, and can give him benefits or extract costs from

him. She is in a position to make obligation or permission statements which he must take account of if he is to achieve his goals. To do that, he must also understand the essentially pragmatic notion of a violation of a rule. He would generally infer pragmatically, from his mother's utterance of the conditional permission, that the only way he could get permission to go out would be by tidying his room. But the mother might add that the son may go out if he does the washing up (or anything else constructive), and then he might adjust his pragmatic inferences accordingly. Moreover, if the house catches fire, he needs to know that he will not violate his mother's rules, along with her presupposed qualifying conditions and underlying goals to do with his safety, if he rushes out without tidying his room or doing the washing up. In technical terms, his deontic reasoning, at least about violations, has to be nonmonotonic, and be highly sensitive to context, implicated and presupposed information, and the way benefits and costs for himself and his mother change with changing circumstances.

The evidence we have reviewed implies that subjects can identify themselves with a perspective like that of the son's and make rational₁ decisions from it. The subjects, acting as the son, decide to pick just those cards which might reveal a violation by the mother. This violation would be one in which the son suffered a cost because he tidied his room, but his mother did not allow him to attain his goal of going out. It is important for the son to uncover such cases to help him prevent them in the future, by not believing his mother's promises. It could be said that, in this simple case, subjects are acting in a way that would enable them to maximize subjective expected utility from the perspective they adopt. But that does mean that subjects would always act so as to meet such an ideal standard in any deontic reasoning task.

There is, in fact, already some evidence (in Manktelow and Over 1990) that subjects do far less well in a deontic selection task when violating a rule would bring less benefit than conforming to it, rather than a strict loss from a neutral position, such as might result from being punished by an authority. Classical normative decision theory does not distinguish between benefits and costs in a way which would justify this. Some descriptive decision theories, however, do predict special sensitivity to costs, such as the seminal prospect theory of Kahneman and Tversky (1979) with its notion of a reference point, below which one thinks of

oneself as suffering a loss. It can also be argued that, if one's present position is reasonably satisfactory, then being especially sensitive to possible losses is a good, rational₁, satisficing strategy. (See Kahneman and Varey 1991 for recent work on loss aversion, and a discussion of its possible long-term benefits.)

Decision Theory and Rationality

The deontic reasoning we have discussed is practical reasoning, in which we try to infer which actions we ought to perform or may perform. We have suggested that people try to determine whether to accept or assert deontic rules by considering which states of affairs they prefer to others. After doing this, they can use these rules efficiently to infer what they should or may do in appropriate contexts, as these arise in ordinary affairs. This view sees a deep link between deontic reasoning and decision making, in which preference is the basic notion. But as we have also said, classical decision theory lays down the normative SEU principle, according to which rational action is a matter of maximizing expected utility in one's choices, and this should not be the standard of what it is to have rationality₁. We have followed Simon (e.g., 1957, 1983) in rejecting this standard and in speaking instead of bounded rationality. Put in the simplest way, the essential point is (as philosophers say) that *ought* implies *can*; in other words, if we are serious in holding that people ought to conform to some standard, then they should be able to conform to it. But people are often unable to conform to the absolute ideal of classical decision theory, and so it cannot always be the case that they ought to do this.

One particular limitation of classical decision theory we must continue to stress, because this has received so little comment in the psychological literature, is its failure to account for, or take proper account of, people's practical reasoning. Classical decision theory presupposes that people can express their preferences, and that these can be measured in some way, but obviously people's preferences are not always given merely by their basic drives and immediate desires. Preferences are often inferred in sometimes quite complex deontic reasoning, employing perhaps many prudential, social, or moral rules. We must have some account of these inferred preferences in decision making; and yet at the same time, we cannot idealistically assume that people have been able to perform all relevant deontic inferences when they express preferences

after some actual deontic reasoning in the real world.

Depending on the circumstances, we might be able to set a reasonable standard for the number and type of deontic inferences people can be expected to perform, if they have rationality₁. We could not necessarily require them to perform all relevant deontic inferences, from the rules they accept, and so maximize their subjective expected utility, where this is defined by the ideal preferences they would have if they had the time and mental power to perform all these inferences. This is just to say that we could only require some degree of bounded rationality₁ of them.

Another limitation of classical decision making shows in the standard it sets for probability judgments. It requires that these judgments conform to the principles of the abstract mathematical theory of probability: the probability calculus. We do need good probability judgments in practical reasoning. One option is not necessarily better than another because it may lead to the more highly desired outcome or goal; it can all depend on how probable the different outcomes are. There are powerful arguments for holding that probability judgments should ideally conform to the probability calculus (Howson and Urbach 1989). None of us, however, can ensure that we conform to the theory's principles in all cases. This is well illustrated by the fact that the probability calculus requires that all logical truths be assigned a probability of 1, although there is in general no effective way of deciding whether or not a proposition is a logical truth.

The probability calculus also requires that the probability of the conclusion of a valid inference given its premises be 1. But asking people what follows from given premises, which they are in effect to take as certain and definitely not to supplement with anything else they believe, is an unnatural request in itself. People, quite rightly for ordinary decision making, are generally concerned with what follows from their relevant beliefs, and they do not necessarily take even these as certain. For a belief bias effect to limit seriously people's rationality₁ it would have to be the case that people often fail to achieve their ordinary goals because they are too confident, or not confident enough, in the conclusions they infer from their beliefs, whether they think of these as certain or uncertain. Note that the uncertainty of a belief is 1 minus its subjective probability, and that the degree of uncertainty of a conclusion validly inferred from

uncertain beliefs should not exceed the sum of their uncertainties, according to a basic principle of rationality₂ (Adams 1975; Edgington 1992). The research we reviewed above on belief bias effects in deductive reasoning does not show that people often depart from this principle in their actual decision making (though see Tversky and Kahneman 1983 on the conjunction fallacy), nor that if they do in some cases, they often fail to achieve their goals as a result.

So far we have spoken of what people's confidence in the conclusion of a deductive inference should be just given specific premises, which are either to be thought of as certain, or as expressing beliefs which may not be certain. However, degrees of confidence are usually discussed in the body of research on probability judgments and decision making, which unfortunately, as we say, has been seen as distinct from the work on deductive reasoning until recently. In the former body of research, people are said to be overconfident, or underconfident, about some proposition depending on whether the subjective probability they ascribe to it is greater than, or less than, its objective probability, which is usually measured or estimated by the frequency with which events occur in the real world. For example, we may think it highly likely to be sunny on days when it is, in fact, objectively unlikely to be sunny. This difference should show up in a tendency for us to be wrong in our forecasting of sunny days, and we are said to be overconfident that it will be sunny on one of these days. On the other hand, if our subjective confidence that it will be sunny more or less matches the objective probability that it will be, then we are said to be well calibrated on this matter.

Whether people are generally well calibrated obviously has something to do with their rationality, and there is a vigorous debate in progress about the extent to which people are sometimes underconfident and sometimes overconfident, the possible reasons for this, and how far it affects their rationality. (See particularly Gigerenzer, Hoffrage, and Kleinbölting 1991 and Griffin and Tversky 1992.) We can only make some brief points here about this issue and rationality₁.

The abstract principles of the probability calculus do not themselves specify how the subjective and objective notions of probability should be related to each other. This relation has to be covered by some further rule or rules, such as the main one proposed and discussed by a number of philosophers, usually called the principal principle. (For more on this, and the philosophical

issues it raises which we cannot go into here, see Lewis 1981; Howson and Urbach 1989; and Earman 1992.) Suppose we are sure that there is a low (alternatively middling or high) objective probability that it will be sunny on a certain type of day, say, just characterized by the fact that the barometer is falling (steady or rising). Then according to a version of the principal principle, our subjective confidence that it will be sunny on a particular day of just that type should be equally low (middling or high). There are reasons for holding that it is rational₁ to conform to this principle generally, though perhaps not invariably, as we will shortly illustrate. However, the problem with testing whether subjects conform to this principle is, again, that it is difficult to be sure that subjects are restricting themselves to just the information they are strictly given by the experimenters, say, that the day is to be characterized by the fact that the barometer is falling and in no other way. This is particularly a problem if we move away from rather abstract questions about matters distant from real life, such as ones about colored balls in urns, to more realistic ones, to which further information may be relevant, including perhaps what might be pragmatically inferred from the experimental context.

It is very important to note the research which has increasingly found evidence that subjects can sometimes be good at reasoning about objective frequencies (see Cosmides and Tooby 1996; Gigerenzer et al. 1991; Tversky and Kahneman 1983; but note also Griffin & Tversky 1992). This is something that they would have to be fairly competent at in order to have a reasonable chance of achieving some of their goals in ordinary affairs. But it is striking that there is sometimes quite a difference, displayed in this research, between what subjects say about the subjective probability of a single case and about the frequency with which something will happen in cases of that type. We would show this difference if we expressed great confidence that it would be sunny on a particular day, yet were also sure that it rained on most days like that. Thus we would appear to violate the principal principle, and this could limit our ability to achieve some of our ordinary goals. If we observe the frequency with which it rains under certain conditions, but do not adjust our degree of belief appropriately to this, then we could tend to get wet when we want to be dry. We would also be in trouble if we did not match our subjective probability judgments about how trustworthy some-

one was to the frequency with which he broke promises to us.

Our arguments for rationality₁ by no means imply the extremely strong conclusion that people are always well calibrated and conform to the principal principle in ordinary affairs. We would not even make this claim, on simple evolutionary grounds, about people living under primitive conditions. No doubt pregnancy is very risky indeed under such conditions, and so it might be adaptive under those conditions to be *overconfident* about one's chances of safely producing healthy offspring. It is at least as hard to argue that being well calibrated about the risks of pregnancy would have led to greater reproductive success than being overconfident.

However that may be, research so far conducted has not shown that there is a widespread tendency to violate the principal principle in ordinary decision making, nor that when it is sometimes violated there, people invariably fail to achieve their goals as a result. Sometimes being overconfident in the technical sense could help to achieve one's goals, by increasing self-confidence in the ordinary sense and keeping doubts from one's mind. A woman who is overconfident about herself having a healthy baby, even though she knows the objective frequency of complications in pregnancy, may be helped by her positive attitude. Griffin and Tversky (1992) rightly give examples in which overconfidence is more of a cost than a benefit, but then we would not claim that people are never irrational₁ in particular cases, as there are cognitive constraints to take into account. These can exist alongside a general tendency for human beings to achieve a reasonable number of their goals, which they would have to do to survive any length of time, let alone to create complex societies and advanced technologies.

Conclusions

The notion of rationality which really matters to people is rationality₁. People in general do have this to a fair degree, as they do tend to be reasonably good at achieving most of their goals. This is obvious enough, as long as we do not make the mistake of thinking of goals only as grand, distant ends which take special ability or luck to achieve, like becoming a millionaire. We should be impressed enough that people are able to achieve more "mundane" goals, such as all those involved in learning a language, contributing to a cooperative group like a family,

and generally finding one's way in the world. We cannot yet build intelligent machines which can do any of these things; it is much easier to program them to do formal logic. In experimental set-ups, people do sometimes depart from the normative principles of logic, the probability calculus, and decision theory. But this in itself does not demonstrate that they have pervasive biases and are generally irrational₁.

In fact, people sometimes achieve a goal in part because they do *not* try to maximize utility (in the technical sense) or hold coherent and consistent beliefs. With bounded capacities and limited time, people would sometimes miss the chance to achieve a reasonably satisfying goal if they paused to wonder whether their preference relation or their beliefs satisfied abstract normative principles. They can sometimes save precious time by accepting a plausible conclusion without examining closely the logic of its argument, or by being very vague about their preferences.

Of course, to say that people have a reasonable degree of rationality₁ is not to say that this can never be profitably improved. Our natural capacity for practical reasoning originally evolved under very different conditions from some of those in which we find ourselves today. In a technological society, having the means to be extremely precise, for example, about profits and losses can be important. Even quite artificial experiments may reveal bounds on our reasoning abilities which sometimes need to be overcome for achieving certain goals. We should thus study when and how logic, statistics, and decision theory can increase rationality₁ (see Evans 1989). But equally we should remember that normative research, particularly on practical reasoning, is far from at an end. Probably the only way to obtain agreed normative principles for this is to study ever more closely the often highly efficient nature of ordinary goal-directed reasoning.

Section 6: Abduction and Belief Change

Chapter 23: Defeasible Reasoning

JOHN L. POLLOCK

The Inadequacy of Deductive Reasoning

There was a long tradition in philosophy according to which good reasoning had to be deductively valid. However, that tradition began to be questioned in the 1960s, and is now thoroughly discredited. What caused its downfall was the recognition that many familiar kinds of reasoning are not deductively valid, but clearly confer justification on their conclusions. Here are some simple examples:

PERCEPTION

Most of our knowledge of the world derives from some form of perception. But clearly, perception is fallible. For instance, I may believe that the wall is gray on the basis of its looking gray to me. But it may actually be white, and it only looks gray because it is dimly illuminated. In this example, my evidence (the wall's looking gray) makes it reasonable for me to conclude that the wall is gray, but further evidence could force me to retract that conclusion.¹ Such a conclusion is said to be justified *defeasibly*, and the considerations that would make it unjustified are *defeaters*.

INDUCTION

There is one kind of reasoning that few ever supposed to be deductive, but it was often conveniently ignored when claiming that good reasoning had to be deductive. This is inductive reasoning, where we generalize from a restricted sample to an unrestrictedly general conclusion. For example, having observed a number of mammals and noted that they were all warm-blooded, biologists concluded that all mammals are warm-blooded. Hume's concern with induction was just that it is not deductive. He should have taken that as an indication that good reasoning need not be deductive, instead of taking that as a reason for worrying about whether it is reasonable to use induction.

PROBABILISTIC REASONING

We make essential use of probabilities in reasoning about our place in the world. Most of the generalizations that are justified inductively are probabilistic generalizations rather than exceptionless generalizations. For example, I believe that objects usually (with high probability) fall to the ground when released, but I do not believe that this will happen invariably. They might, for example, be hoisted aloft by a tornado. Still, we want to use these generalizations to predict what is going to happen to us. Because things usually fall to the ground when released, I confidently expect my keys to do so when I drop them. I am surely justified in this belief, although it is only based upon a probabilistic generalization. Because it is based on a probabilistic generalization, it is not a deductive consequence of my reasons for holding it. They make the conclusion reasonable, but I might have to retract it in the face of further information. The form of reasoning involved here is sometimes called *the statistical syllogism* (Pollock 1990), and has roughly the following form:

From "This is an *A* and the probability of an *A* being a *B* is high," infer defeasibly, "This is a *B*."

TEMPORAL PROJECTION

Suppose we are standing in a courtyard between two clock towers, and I ask you whether the clocks agree. You look at one, noting that it reads "2:45," and then you turn to the other and note that it reads "2:45," so you report that they do. But note that you are making an assumption. You could not look at the two clocks at the same instant, so you are assuming that the time reported by the first clock did not change dramatically in the short interval it took you to turn and look at the second clock. Of course,

there is no logical guarantee that this is so. Things change.

Our perceptual access to the world is a kind of sampling of bits and pieces at diverse times, and to put the samples together into a coherent picture of the world we must assume that things do not change too rapidly. We have to make a defeasible assumption of stability over times. It might be supposed that we can rely upon induction to discover what properties are stable. We certainly use induction to fine-tune our assumption of stability, but induction cannot provide the origin of that assumption. The difficulty is that to confirm inductively that a property tends to be stable, we must observe that objects possessing it tend to continue to possess it over time, but to do that we must reidentify those objects over time. We do the latter in part in terms of what properties the objects have. For example, if my chair and desk could somehow exchange shapes, locations, colors, and so forth, while I am not watching them, then when I see them next I will reidentify them incorrectly. So the ability to reidentify objects requires that I assume that most of their more salient properties tend to be stable. If I had to confirm that inductively, I would have to be able to reidentify objects without regard to their properties, but that is impossible. Thus a defeasible presumption of stability must be a primitive part of our reasoning about the world.² A principle to the effect that one can reasonably believe that something remains true if it was true earlier is a principle of *temporal projection*.

The preceding examples make it clear that we rely heavily on defeasible reasoning for our everyday cognition about the world. The same considerations that mandate our use of defeasible reasoning make it likely that no sophisticated cognizer operating in a somewhat unpredictable environment could get by without defeasible reasoning. The philosophical problem is to understand how defeasible reasoning works.

A Very Brief History

In philosophy, the study of defeasible reasoning began with Hart's (1948) introduction of the term "defeasible" in the philosophy of law. Chisholm (1957) was the first epistemologist to use the term, taking it from Hart. He was followed by Toulmin (1958), Chisholm (1966), Pollock (1967, 1970, 1971, 1974), Rescher (1977), and then a number of authors. The philosophical work tended to look only casually at the logical structure of defeasible reasoning,

making some simple observations about how it works, and then using it as a tool in analyzing various kinds of philosophically problematic reasoning. Thus, for example, Pollock (1971, 1974) proposed to solve the problem of perception by positing a defeasible reason of the form:

" x looks R to me" is a defeasible reason for me to believe " x is R " (for appropriate R).

Without knowing about the philosophical literature on defeasible reasoning, researchers in artificial intelligence (AI) rediscovered the concept (under the label "nonmonotonic logic") in the early 1980s (Reiter 1980; McCarthy 1980; McDermott and Doyle 1980). They were led to it by their attempts to solve the "frame problem," which I will discuss in detail in the section below "Illustration: The Frame Problem." Because they were interested in implementing reasoning in AI systems, they gave much more attention to the details of how defeasible reasoning works than philosophers had.³ Unfortunately, their lack of philosophical training led AI researchers to produce accounts that were mathematically sophisticated but epistemologically naïve. Their theories could not possibly be right as accounts of human cognition, because they could not accommodate the varieties of defeasible reasoning humans actually employ. Although there is still a burgeoning industry in AI studying nonmonotonic logic, this shortcoming tends to remain to this day. I will give a few examples of this below.

There are still a number of competing views on the nature and structure of defeasible reasoning. What follows will be a (no doubt biased) account presenting my own views on the matter.

Defeasible Reasons and Defeaters

Defeasible reasoning is a form of reasoning. Reasoning proceeds by constructing arguments for conclusions, and the individual inferences making up the arguments are licensed by what we might call *reason schemes*. In philosophy, it is customary to think of arguments as linear sequences of propositions, with each member of the sequence being either a premise or the conclusion of an inference (in accordance with some reason scheme) from earlier propositions in the sequence. However, this representation of arguments is an artifact of the way we write them. In many cases the ordering of the elements of the sequence is irrelevant to the structure of the argument. For instance, consider an argument that proceeds by giving a subargument for

Figure 1. An inference graph.

P and an unrelated subargument for $(P \rightarrow Q)$, and then finishes by inferring Q by modus ponens. We might diagram this argument as in Figure 1. The ordering of the elements of the two subarguments with respect to each other is irrelevant. If we write the argument for Q as a linear sequence of propositions, we must order the elements of the subarguments with respect to each other, thus introducing artificial structure in the representation. For many purposes it is better to represent the argument graphically. Such a graph is an *inference graph*. The compound arrows linking elements of the inference graph represent the application of reason schemes.

In deductive reasoning, the reason schemes employed are deductive inference rules. What distinguishes deductive reasoning from reasoning more generally is that the reasoning is not defeasible. More precisely, given a deductive argument for a conclusion, you cannot rationally deny the conclusion without denying one or more of the premises. In contrast, consider an inductive argument. Suppose we observe a number of swans and they are all white. This gives us a reason for thinking that all swans are white. If we subsequently journey to Australia and observe a black swan, we must retract that conclusion. But notice that this does not give us a reason for retracting any of the premises. It is still reasonable to believe that each of the initially observed swans is white. What distinguishes defeasible arguments from deductive arguments is that *the addition* of information can mandate the retraction of the conclusion of a defeasible argument without mandating the retraction of any of the earlier conclusions from which the retracted conclusion was inferred. By contrast, you cannot retract the conclusion of a deductive argument without also retracting some of the premises from which it was inferred.

REBUTTING DEFEATERS

Information that can mandate the retraction of the conclusion of a defeasible argument constitutes a *defeater* for the argument. There are two kinds of defeaters. The simplest are *rebutting*

defeaters, which attack an argument by attacking its conclusion. In the inductive example concerning white swans, what defeated the argument was the discovery of a black swan, and the reason that was a defeater is that it entails the negation of the conclusion, that is, it entails that not all swans are black. More generally, a rebutting defeater could be any reason for denying the conclusion (deductive or defeasible). For instance, I might be informed by Herbert, an ornithologist, that not all swans are white. People do not always speak truly, so the fact that he tells me this does not entail that it is true that not all swans are white. Nevertheless, because Herbert is an ornithologist, his telling me that gives me a defeasible reason for thinking that not all swans are white, so it is a rebutting defeater.

UNDERCUTTING DEFEATERS

Not all defeaters are rebutting defeaters. Suppose Simon, whom I regard as very reliable, tells me, "Don't believe Herbert. He is incompetent." That Herbert told me that not all swans are white gives me a reason for believing that not all swans are white, but Simon's remarks about Herbert give me a reason for withdrawing my belief, and they do so without either (1) making me doubt that Herbert said what I took him to say or (2) giving me a reason for thinking it false that not all swans are white. Even if Herbert is incompetent, he might have accidentally gotten it right that not all swans are white. Thus Simon's remarks constitute a defeater, but not a rebutting defeater. This is an example of an *undercutting defeater*.

The difference between rebutting defeaters and undercutting defeaters is that rebutting defeaters attack the conclusion of a defeasible inference, while undercutting defeaters attack the defeasible inference itself, without doing so by giving us a reason for thinking it has a false conclusion. We can think of an undercutting defeater as a reason for thinking that it is false that the premises of the inference would not be true unless the conclusion were true. More simply, we can think of it as giving us a reason for believing that (under the present circumstances) the truth of the premises does not guarantee the truth of the conclusion. It will be convenient to symbolize this as "*premises* \otimes *conclusion*."

It is useful to expand our graphical representation of reasoning by including defeat relations. Thus we might represent the preceding example as in Figure 2. Here I have drawn the defeat relations using thick arrows. The rebutting defeater is represented by an arrow from the defeater

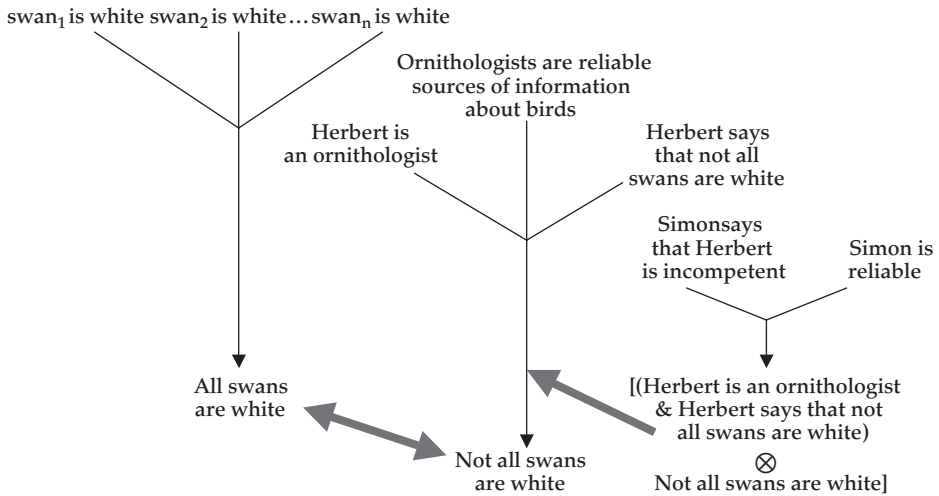

Figure 2. Inference graph with defeat.

to the conclusion it attacks, because a rebutting defeater is a defeater for every defeasible inference having that conclusion. The undercutting defeater is represented by an arrow from the defeater to the inference (represented by a compound arrow) that it attacks. Note that the rebutting defeat is symmetrical, but undercutting defeat is not.

We can usefully distinguish between two concepts of a reason. In the preceding example, “Not all swans are white” is inferred from three premises. If we understand the reliability premise as being about probabilities, this can be seen to be an instance of the aforementioned statistical syllogism. But notice that it would also be natural to report more simply that our reason for thinking that not all swans are white is that Herbert says they aren’t, ignoring the first two premises. That both ways of talking are natural suggests distinguishing between “full reason schemes” and “enthymatic reason schemes.” In enthymatic reason schemes, we drop some of the premises that can be regarded as background information, just as we do in an enthymatic argument. For the purpose of understanding how reasoning works, it is best to avoid appeal to enthymatic reason schemes and express our reason schemes in full detail.

Semantics for Defeasible Reasoning

We can combine all of a cognizer’s reasoning into a single inference graph and regard that as a representation of those aspects of his cognitive state that pertain to reasoning. The hardest problem in a theory of defeasible reasoning is to

give a precise account of how the structure of the cognizer’s inference graph determines what he should believe. Such an account is called a “semantics” for defeasible reasoning, although it is not a semantics in the same sense as, for example, a semantics for first-order logic. If a cognizer reasoned only deductively, it would be easy to provide an account of what he should believe. In that case, a cognizer should believe all and only the conclusions of his arguments (assuming that the premises are somehow initially justified). However, if an agent reasons defeasibly, then the conclusions of some of his arguments may be defeaters for other arguments, and so he should not believe the conclusions of all of them. For example, in Figure 2, the cognizer first concludes “All swans are white.” Then he constructs an argument for a defeater for the first argument, at which point it would no longer be reasonable to believe its conclusion. But then he constructs a third argument supporting a defeater for the second (defeating) argument, and that should reinstate the first argument.

Obviously, the relationships between interacting arguments can be very complex. We want a general account of how it is determined which conclusions should be believed, or to use philosophical parlance, which conclusions are “justified” and which are not. This distinction enforces a further distinction between beliefs and conclusions. When a cognizer constructs an argument, he entertains the conclusion and he entertains the propositions comprising the intervening steps, but he need not believe them. Constructing arguments is one thing. Deciding

which conclusions to accept is another. What we want is a criterion which, when applied to the inference graph, determines which conclusions are defeated and which are not, i.e., a criterion that determines the *defeat statuses* of the conclusions. The conclusions that ought to be believed are those that are undefeated.

One complication is that a conclusion can be supported by multiple arguments. In that case, it is the arguments themselves to which we must first attach defeat statuses. Then a conclusion is undefeated if it is supported by at least one undefeated argument. The only exception to this rule is “initial nodes,” which (from the perspective of the inference graph) are simply “given” as premises. Initial nodes are unsupported by arguments, but are taken to be undefeated. Ultimately, we want to use this machinery to model rational cognition. In that case, all that can be regarded as “given” is perceptual input (construed broadly to include such modes of perception as proprioception, introspection, etc.), in which case it may be inaccurate to take the initial nodes to encode propositions. It is probably better to regard them as encoding percepts.⁴

It is in the computation of defeat statuses that different theories of defeasible reasoning differ. It might seem that this should be simple. The following four principles seem reasonable:

- (1) A conclusion is undefeated (relative to an inference graph) if either it is an initial node or it is supported by at least one undefeated argument in the inference graph.
- (2) An argument is undefeated if every inference in the argument is undefeated.
- (3) If an inference graph contains an undefeated argument supporting a defeater for an inference used in one of its arguments A , then A is defeated.
- (4) If an inference graph contains no undefeated arguments supporting defeaters for inferences used in one of its arguments A , then A is undefeated.

It might be supposed that we can apply these four principles recursively to compute the defeat status of any conclusion. For instance, in Figure 2, by principle (4), the third argument is undefeated because there are no defeating arguments for any of its inferences and hence no undefeated defeating arguments. Then by prin-

Figure 3. Collective defeat.

ciple (3), the second argument is defeated. Then by principle (4), the first argument is undefeated. Finally, by principle (1), the conclusion “All swans are white” is undefeated.

COLLECTIVE DEFEAT

Unfortunately, there are inference graphs that resist such a simple treatment. For example, consider the inference graph of Figure 2 without the third argument. The structure of this case can be diagrammed more simply as in Figure 3, where the dashed arrows indicate defeasible inference. Here we have no arguments lacking defeating arguments, so there is no way for the recursion to get started.

Figure 3 is an example of what is called “collective defeat,” where we have a set of two or more arguments and each argument in the set is defeated by some other argument in the set. What should we believe in such a case? Consider a simple example. Suppose we are in a closed and windowless room, and Jones, whom we regard as reliable, enters the room and tells us it is raining outside. Then we have a reason for believing it is raining. But Jones is followed by Smith, whom we also regard as reliable, and Smith tells us it is not raining. Then we have arguments for both “It is raining” and “It is not raining,” as in Figure 3. What should we believe? It seems clear that in the absence of any other information, we should not form a belief about the weather. We should withhold belief, which is to treat both arguments as defeated. But this means that in cases of collective defeat, an argument is defeated even though its defeating arguments are also defeated.

Cases of collective defeat violate principle (4). For example, in Figure 3, both R and $\sim R$ should be defeated, but neither has an undefeated defeater.

Cases of collective defeat are encountered fairly often. An example of some philosophical interest is the *lottery paradox* (Kyburg 1961). Suppose you hold a ticket in a fair lottery consisting of one million tickets. It occurs to you that the probability of any particular ticket being drawn is one in a million, and so in accordance with the statistical syllogism you can conclude defeasibly that your ticket will not be drawn.

Figure 4. The lottery paradox.

Should you throw it away? Presumably not, because that probability is the same for every ticket in the lottery. Thus you get an equally good argument for each ticket that it will not be drawn. However, you are given that the lottery is fair, which means in part that some ticket will be drawn. So you have an inconsistent set of conclusions, viz., for each ticket n you have the conclusion $\sim D_n$ that it will not be drawn, but you also have the conclusion that some one of them will be drawn. This generates a case of collective defeat. The lottery paradox can be diagrammed initially as in Figure 4, where R is the description of the lottery.

This can be redrawn as a case of collective defeat by noticing that the set of conclusions $\sim D_1, \sim D_2, \dots, \sim D_{1,000,000}, D_1 \vee \dots \vee D_{1,000,000}$ is logically inconsistent. As a result, each subset of the form

$$\sim D_1, \sim D_2, \dots, \sim D_{i-1}, \sim D_{i+1}, \dots, \sim D_{1,000,000}, D_1 \vee \dots \vee D_{1,000,000}$$

entails the negation of the remaining member, that is, entails D_i , so from each such subset of conclusions in the graph we can get an argument for the corresponding D_i , and that is a rebutting defeater for the argument to $\sim D_i$. More simply, pick one ticket. I have reason to think that it will lose. But I also have a reason to think it will win because I have reason to think that all the others will lose, and I know that one has to win. This yields the inference graph of Figure 5. Thus for each conclusion $\sim D_i$ we can derive the rebutting defeater D_i from the other conclusions $\sim D_i$, and hence we have a case of collective defeat.

Accordingly, given a theory of defeasible reasoning that can handle inference graphs with collective defeat, the lottery paradox is resolved by observing that we should not conclude of any ticket that it will not be drawn. (Of course, we can still conclude that it is highly unlikely that it will be drawn, but that yields no inconsistency.)

SELF-DEFEAT

Most theories of defeasible reasoning have some mechanism or other that enables them to get collective defeat right. But there is another kind of case they often have trouble with. This concerns “self-defeating arguments” that support defeaters for themselves. Figure 6 is a simple example of a self-defeating argument. In this example, it seems clear that Q should be defeated. If Q were undefeated, then R would be undefeated, because there is no defeater for the inference from Q to R , and then $(P \otimes Q)$ would be undefeated because it is inferred deductively from R . But if $(P \otimes Q)$ is undefeated, Q must be defeated instead of undefeated. Thus Q has to be regarded as defeated. It seems to follow that R and hence $(P \otimes Q)$ are also defeated. If principle (4) above were correct (we have already seen that it is not), then it would follow that Q is undefeated rather than defeated. This is another example in which principle (4) fails.

Although all standard theories of defeasible reasoning can handle simple cases of collective defeat, many of them have more trouble with self-defeat. For example, Reiter’s (1980) default logic has been quite popular in AI, but it is unable to distinguish between the status of P

Figure 5. The lottery paradox as a case of collective defeat.

Figure 6. A self-defeating argument.

(which ought to be undefeated) and Q, R , and $(P \otimes Q)$ in Figure 6, so it must either rule them all defeated or all undefeated. But either conclusion is unacceptable.⁵

Even if a theory can handle both collective defeat and simple cases of self-defeat, it may not be able to handle combinations of the two. For example, the original semantics that I proposed for defeasible reasoning in Pollock (1986) got all of the above examples right, but it could not handle the example of Figure 7. This results from extending the inference graph for the lottery paradox by noting two things. First, we typically have only a defeasible reason P for believing the description R of the lottery. For example, we may read it in the newspaper. Second, we can combine the arguments for the individual $\sim D_i$ s to obtain an argument for $\sim D_1 \ \& \ \dots \ \& \ \sim D_{1,000,000}$, and that yields an argument for $\sim R$ (because R entails $D_1 \vee \dots \vee D_{1,000,000}$). Thus, the argument from P is self-defeating. I call this “the lottery paradox paradox” (Pollock 1991).

If we distill the self-defeating subargument involving R out of Figure 7, we get the inference graph of Figure 8. This has essentially the same structure as Figure 4, so if we give it the same treatment we should end up concluding that we are not justified in believing R . That is, we should not believe the description of the lottery we get from the newspaper report. But that is clearly wrong — of course we should believe

it. Apparently the other parts of the inference graph change its structure in ways that alter the way the defeat statuses are computed.

The lottery paradox paradox is a counterexample to the semantics for defeasible reasoning that I proposed in Pollock (1986). Other theories also have trouble with it. For example, simple versions of circumscription (McCarthy 1980) pronounce R defeated when it should not be.⁶ However, in Pollock (1995) I proposed a semantics that yields the intuitively correct answers in all of these examples.

My (1995) semantics turns on principles (1)–(4). We cannot apply them recursively to compute defeat statuses because they do not uniquely determine candidate defeat statuses. For example, in Figure 3, there are two different ways of assigning defeat statuses to the conclusions making up the inference graph in such a way that principles (1)–(4) are satisfied. This is diagrammed in Figure 9, where “+” indicates an assignment of “undefeated” and “-” indicates an assignment of “defeated.” The conclusions and arguments that we want to regard as undefeated simpliciter are those that are assigned “+” by all of the ways of assigning defeat statuses consistent with (1)–(4).

The lottery paradox works similarly. For each i , there is a way of assigning defeat statuses according to which $\sim D_i$ is assigned “-,” but for all $j \neq i$, $\sim D_j$ is assigned “+.” Again, the conclusions that are intuitively undefeated are those that are always assigned “+.”

If we turn to the lottery paradox paradox, the same thing holds. There are the same 1,000,000 assignments of defeat statuses, but now for every one of them $\sim D_i \ \& \ \dots \ \& \ \sim D_{1,000,000}$ is assigned “-,” and hence “ $\sim R$ ” is assigned “-” and “ R ” is assigned “+.” Thus, we get the desired result that we are justified in believing the description of the lottery, but we are not justified in believing that any particular ticket will not be drawn.

Figure 7. The lottery paradox paradox.

Figure 8. The self-defeating argument embedded in the lottery paradox paradox.

However, when we turn to the simpler case of self-defeat in Figure 6, things become more complicated. There is no way to assign defeat statuses consistent with principles (1)–(4). By (1), P must be assigned “+,” which is unproblematic. But there is no way to assign a defeat status to Q . Suppose we assign “+.” Then we must assign “+” to R and to $(P \otimes Q)$. Then we would have to assign “-” to Q , contrary to our original assignment. If instead we assign “-” to Q , then we must assign “-” to R and to $(P \otimes Q)$. Then we would have to assign “+” to Q , again contrary to our original assignment. So in this example there can be at most a partial assignment of defeat statuses consistent with (1)–(4). However, it remains true that the intuitively undefeated conclusions are those that are assigned “+” in all partial status assignments that assign statuses to as many conclusions as possible. Let us define:

A *partial status assignment* is an assignment of defeat statuses (“+” or “-”) to a subset of the conclusions and arguments of an inference graph in a manner consistent with principles (1)–(4). A *status assignment* is a maximal partial status assignment, i.e., a partial status assignment that cannot be extended to further conclusions or arguments and remain consistent with principles (1)–(4).

My (1995) proposal was then:

The Defeat Status of an Argument

An argument is undefeated (relative to an inference graph) if every step of the argument is assigned “+” by every status assignment for that inference graph.

It would be natural to propose:

A conclusion is undefeated (relative to an inference graph) if it is assigned “+” by every status assignment for that inference graph.

Indeed, this works in all the preceding examples, but that is only because, in those examples, there are no conclusions supported by multiple arguments.⁷ To see that this does not work in general, consider the case of collective defeat diagrammed in Figure 10. Once again, there are two status assignments. One assigns “+” to R , S , and $(S \vee T)$, and “-” to $\sim R$ and T . The other assigns “-” to R and S and “+” to $\sim R$, T , and $(S \vee T)$. On both assignments, $(S \vee T)$ is assigned “+.” However, there is no argument supporting $(S \vee T)$ all of whose inferences are undefeated relative to both assignments, so there is no undefeated argument supporting $(S \vee T)$. If we regard $(S \vee T)$ as undefeated, then we are denying principle (1), according to which a non-initial node is only undefeated if it is supported by an undefeated argument. However, it seems that principle (1) ought to be true, so instead of the preceding I proposed:

The Defeat Status of a Conclusion

A conclusion is undefeated if it is supported by an undefeated argument.

This is my (1995) semantics. Its justification is that it seems to give the right answer in all those cases in which it is intuitively clear what the right answer is. This semantics has been implemented

Figure 9. Two ways of assigning defeat statuses.

Figure 10. Collective defeat with multiple arguments.

in the OSCAR architecture.⁸ This is an AI system that constitutes an architecture for cognitive agents, and among other things it is a general-purpose defeasible reasoner.

Although this semantics is fairly successful, it leaves at least one important question unaddressed. Reasons have strengths. Not all reasons are equally good, and this should affect the adjudication of defeat statuses. For example, if I regard Jones as significantly more reliable than Smith, then if Jones tells me it is raining and Smith says it is not, it seems I should believe Jones. In other words, this case of collective defeat is resolved by taking account of the different strengths of the arguments for the conflicting conclusions. An adequate semantics for defeasible reasoning must take account of differences in degree of justification. The preceding semantics only works correctly in cases in which all reasons are equally good. In my (1995) I extended the above semantics to deal with reason strengths, but I am now convinced that the (1995) proposal was not correct. I tried again in my (2002), and that semantics or a minor variation of it may be correct, but I have not yet implemented it in OSCAR. There are currently no other proposals in the AI or philosophical literature for how to perform defeasible reasoning with varying degrees of justification.

Defeasible Reasoning versus Bayesian Epistemology

There is another approach to nondeductive belief maintenance. This is *Bayesian epistemology*, which supposes that degrees of justification work like probabilities and hence conflicts can be resolved within the probability calculus. Bayesians propose that updating one's beliefs in the face of new information proceeds by conditioning the probabilities of the beliefs on the

new information. Conditional probabilities are similar to defeasible reasons in that conditioning on additional information can lower the probability. That is, $\text{prob}(P/Q\&R)$ can be lower than $\text{prob}(P/Q)$. So it appears that Bayesian epistemology can handle the same phenomena that gave rise to theories of defeasible reasoning.

There is a huge literature on Bayesian epistemology, but I can only make some brief remarks here.⁹ One of the most important differences between theories of defeasible reasoning and Bayesian approaches is that the former accommodate ordinary reasoning – either deductive or defeasible – as a way of deriving new justified beliefs from previously justified beliefs, but the latter do not. For example, theories of defeasible reasoning agree that if the cognizer is initially justified in believing P and $(P \rightarrow Q)$, and infers Q from those two premises, then in the absence of a reason for disbelieving Q , the cognizer becomes justified in believing Q . (Given a reason for $\sim Q$, the argument might instead require the cognizer to give up one of the premises.) By contrast, Bayesian epistemology makes even deductive reasoning problematic, for reasons I will now explain.

The simplest argument against Bayesian epistemology is that it would make it impossible for a conclusion to be justified on the basis of a deductive argument from multiple uncertain premises. This is because, if degrees of justification work like probabilities, then when you combine premises, the degree of justification decreases. Suppose you have one hundred independent premises, each with a degree of justification of .99. If Bayesian epistemology is correct, then by the probability calculus, the degree of justification of the conjunction will be only .37, so we could never be justified in using these one hundred premises conjointly in drawing a conclusion. But this flies in the face of common sense. For example, consider an opinion pollster surveying people about which of two products they prefer. She surveys one hundred people, collecting from each the verbal expression of an opinion of the form “I prefer x to y .” She summarizes her data by saying, “I surveyed one hundred people, and seventy-nine of them reported preferring A to B .” This conclusion follows deductively from her accumulated data. But each piece of data of the form “Person S reported preferring x to y ” is something she believes with less than certainty – we are supposing she believes it with a degree of justification of .99. Then if degrees of justification work like probabilities, her degree of justification for thinking

that she has surveyed one hundred people and seventy-nine of them reported preferring *A* to *B* would be at most .37, and hence she would not be justified in drawing that conclusion. Surely this is wrong.

Consider another example — counting apples in a barrel. Let us suppose you are a very meticulous counter. You examine each apple carefully as you remove it from the barrel, ascertaining that it is indeed an apple, and you then carefully jot down a mark to count the apple so that when you are finished you can read off the result as a number. Let us suppose you are virtually certain you have not lost count (your degree of justification in that is .999), so the only source of uncertainty is in your judgments that the individual objects counted are apples. Suppose you count n apples, judging each to be an apple with a degree of justification j . If degrees of justification work like probabilities, the probability calculus reveals that your degree of justification for believing that there are at least r ($r \leq n$) apples in the barrel will be

$$\sum_{i=r}^n j^i (1-j)^{n-i} \frac{n!}{i!(n-i)!}.$$

For example, if you count one hundred apples in the barrel, being justified to degree .95 in believing that each object counted is an apple, then your degree of justification for believing that there are one hundred apples in the barrel is only .006. Your degree of justification for believing that there are at least ninety-six apples in the barrel is only .258. You have to drop all the way down to the judgment that there are at least ninety-five apples in the barrel before you get a degree of justification greater than .5. If you want a degree of justification of at least .95 for your judgment of the number of apples in the barrel, the best you can do is conclude that there are at least ninety-one. On this account, you cannot even count apples in a barrel. Similarly, if you have six daughters, and your degree of justification for believing of each that she is indeed one of your daughters is .95, then all you can be justified in believing to degree .95 is that you have at least five daughters. Surely this is ridiculous.

Still, there are philosophers (e.g., Kyburg 1970) who have been willing to bite the bullet and deny that deductive reasoning from justified premises conveys justification to the conclusion. We can make a distinction between two kinds of deductive inference rules. Let us say that a

rule is *probabilistically valid* if it follows from the probability calculus that the conclusion is at least as probable as the least probable premise. For instance, *simplification* and *addition* are probabilistically valid:

Simplification: $(P \& Q) \vdash P$

Addition: $P \vdash (P \vee Q)$.

But not all familiar inference rules are probabilistically valid. For example, it is widely recognized that *adjunction* is not:

Adjunction: $P, Q \vdash (P \& Q)$.

In general, $\text{prob}(P \& Q)$ can have any value between 0 and the minimum of $\text{prob}(P)$ and $\text{prob}(Q)$. Because of this, Kyburg claims that it is a fallacy to reason using adjunction. He calls this fallacy “conjunctivitis.” For those who are persuaded by these considerations, the view would be that we are only allowed to reason “blindly,” without explicitly computing probabilities (or degrees of justification) as we go along, when the rules of inference we use are probabilistically valid. In all other cases, we must compute the probability of the conclusion to verify that it is still sufficiently probable to be believable. Bayesian epistemology is committed to this view. If degrees of justification satisfy the probability calculus, then without computing probabilities we can only be confident that a deductive argument takes us from justified premises to a justified conclusion if all of the inferences are probabilistically valid.

Which deductive inference rules are probabilistically valid? It is easily shown that any valid deductive inference rule proceeding from a single premise is probabilistically valid. By contrast, some rules proceeding from multiple premises are not. For example, *adjunction* is not. Are there others? People are generally amazed to discover that *no* deductive inference rule that proceeds from multiple premises essentially (that is not still valid if you delete an unnecessary premise) is probabilistically valid. They all go the way of adjunction. For instance, *modus ponens* and *modus tollens* are not probabilistically valid. Probabilistic validity is the exception rather than the rule.

The upshot of this is that if Bayesian epistemology is correct, there will be hardly any deductive reasoning from warranted premises that we can do blindly and still be confident that our conclusions are warranted. Blind deductive reasoning can play very little role in epistemic

cognition. Epistemic cognition must instead take the degrees of justification of the premises of an inference and compute a new degree of justification for the conclusion in accordance with the probability calculus.

This might not seem so bad until we realize that it is impossible to do. The difficulty is that the probability calculus does not really enable us to compute most probabilities. In general, all the probability calculus does is impose upper and lower bounds on probabilities. For instance, given degrees of justification for P and Q , there is no way we can compute a degree of justification for $(P \& Q)$ just on the basis of the probability calculus. It is consistent with the probability calculus for the degree of justification of $(P \& Q)$ to be anything from $\text{prob}(P) + \text{prob}(Q) - 1$ (or 0 if $\text{prob}(P) + \text{prob}(Q) - 1 < 0$) to the minimum of the degrees of justification of P and Q individually. There is in general no way to compute $\text{prob}(P \& Q)$ just on the basis of logical form. The value of $\text{prob}(P \& Q)$ is normally a substantive fact about P and Q , and it must be obtained by some method other than mathematical computation in the probability calculus.

These observations lead to a general, and I think insurmountable, difficulty for Bayesian epistemology. Bayesian epistemology claims we must compute degrees of justification as we go along in order to decide whether to accept the conclusions of our reasoning. If conditional degrees of justification conform to the probability calculus, they will generally be idiosyncratic, depending upon the particular propositions involved. That is, they cannot be computed from anything else. If they cannot be computed, they must be stored innately. This, however, creates a combinatorial nightmare. As Gilbert Harman (1973) observed years ago, given a set of just 300 beliefs, the number of probabilities of single beliefs conditional on conjunctions of beliefs in the set is 2^{300} . This is approximately 10^{90} . To appreciate what an immense number this is, a recent estimate of the number of elementary particles in the universe was 10^{78} . So Bayesian epistemology would require the cognizer to store twelve orders of magnitude more primitive probabilities than the number of elementary particles in the universe. This is computationally impossible. Thus Bayesian epistemology would make reasoning impossible.

The upshot of this is that if Bayesian epistemology were correct, we could not acquire new justified beliefs by reasoning from previ-

ously justified beliefs. However, reasoning is an essential part of epistemic cognition. Without reasoning, all we could know is that our current environment looks and feels various ways to us. It is reasoning that allows us to extend this very impoverished perceptual knowledge to a coherent picture of the world. So Bayesian epistemology cannot be correct. Cognition requires a different kind of mechanism for updating beliefs in the face of new information. That is what defeasible reasoning purports to provide.

Reasoning Defeasibly

Above I discussed how to determine what a cognizer ought to believe given what arguments he has constructed. But a theory of rational cognition must also address the question of how the cognizer should go about constructing arguments. In this connection, one can ask how human reasoning works, which is a psychological question, but one can also ask more generally how we can evaluate an arbitrary system of reasoning. For a cognizer that performed only deductive reasoning, we would presumably want to require that the reasoning be consistent, and we would probably want it to be deductively complete in the sense that the system of reasoning is in principle capable of deriving any deductive consequence of the cognizer's beliefs. But for a cognizer that reasons defeasibly, things are more complicated.

There are many systems of automated deductive reasoning in AI. If we focus on reasoners that perform reasoning in the predicate calculus (first-order logic), they are generally sound and complete. In other words, they will produce all and only conclusions that follow deductively from whatever premises we give the system. It is natural to suppose that defeasible reasoners should behave similarly. But what is it for them to behave similarly? We need an analogue of deductive validity for defeasible reasoning.

Let us say that a conclusion is *justified* for a cognizer if it is undefeated relative to the inference graph that encodes all of his reasoning to date. However, for any sophisticated cognizer, reasoning is a nonterminating process. This is true even if the cognizer performs only deductive reasoning in the predicate calculus. However much reasoning the cognizer does, there will always be more that could be done. As a cognizer's inference graph expands, the cognizer may discover not only arguments for new conclusions, but also arguments for defeaters for

earlier conclusions. The result is that a previously undefeated conclusion may become defeated just as a result of the cognizer's performing more reasoning, without any addition to the set of initial nodes from which he is reasoning. This indicates that there are two kinds of defeasibility that we should clearly distinguish. By definition, defeasible reasoning is *synchronically defeasible*, in the sense that the addition of new information (new initial nodes) can lead previously undefeated conclusions to become defeated. Human reasoning is also *diachronically defeasible*, in the sense that performing additional reasoning without adding any new information can change the defeat statuses of conclusions.

A cognizer's inference graph consists of all the reasoning it has so far performed. But we can also consider the idealized inference graph consisting of all the reasoning that could be performed given the cognizer's current initial nodes. Let us say that a proposition (it may not yet be a conclusion) is *warranted* for the cognizer if it is undefeated relative to this idealized inference graph. So warrant is justification in the limit. The set of warranted propositions is, in effect, the target at which defeasible reasoning aims.

Analogous to requiring a deductive reasoner to be sound and complete, we might require a defeasible reasoner to produce all and only warranted conclusions. This is precisely the requirement that has generally been imposed on automated defeasible reasoners in AI. However, for reasons that have been well known since 1980, no defeasible reasoner capable of performing sophisticated reasoning (e.g., reasoning that includes deductive reasoning in the predicate calculus) can satisfy this requirement. It is *mathematically impossible*. I will explain.

For the predicate calculus, it is possible to build an automated reasoner that draws all and only valid conclusions because the set of valid conclusions is *recursively enumerable*. A recursively enumerable set is one for which there is a mechanical procedure (an algorithm) for systematically generating all the members of the set in such a way that no nonmembers are ever generated by the procedure. Proof procedures for the predicate calculus are such procedures, and hence the completeness theorem for the predicate calculus tells us that the set of valid formulas is recursively enumerable. Automated theorem provers for the predicate calculus take advantage of this by implementing such a mechanical procedure.

When we turn to defeasible reasoning, nothing similar is possible. This is because, as Reiter (1980) and Israel (1980) observed, the set of warranted conclusions will not generally be recursively enumerable. Suppose, for instance, that we have a defeasible reasoner that uses a first-order language (i.e., the language contains the quantifiers and connectives of the predicate calculus). Suppose it makes a defeasible inference to a conclusion P . A necessary condition for P to be warranted is that $\sim P$ not be a theorem of the predicate calculus, for if $\sim P$ were a theorem, that would constitute defeat. If the system had to wait until it has determined that P is not defeated before adding it to its set of beliefs, it might have to wait forever. The difficulty is that, by Church's theorem, the set of nontheorems of the predicate calculus is not recursively enumerable. Thus there is no mechanical procedure for verifying that $\sim P$ is not a theorem. If it isn't then no matter what algorithms the reasoner employs, it may never discover that fact, and so it will never be in a position to affirm P .

This is a mathematical constraint on any system of defeasible reasoning. If it waits to affirm a conclusion until it has determined conclusively that the conclusion is undefeated, there will be many warranted conclusions that it will never be in a position to affirm, so it will not produce all warranted conclusions. By contrast, if it does not wait, then it will sometimes get things wrong and affirm conclusions that are justified given the current stage of its reasoning but not warranted.

All automated defeasible reasoners except OSCAR are crippled by this problem. Because they assume that a defeasible reasoner should work like a deductive reasoner, and produce all and only warranted conclusions, they restrict themselves to reasoning in very impoverished languages in which both the set of deductively valid formulas and the set of deductively invalid formulas are recursively enumerable. Technically, these are languages that are *decidable*. Unfortunately, only very weak and inexpressive languages are decidable. Thus with the exception of OSCAR, all automated defeasible reasoners tend to work only in the propositional calculus or some even less expressive subset of it.

Obviously, humans are not so constrained. How do humans avoid this difficulty? They do so by *reasoning defeasibly*. In other words, they draw conclusions with the expectation that they will occasionally have to retract them later. They don't wait for an absolute guarantee of warrant. After all, we draw conclusions in order to help

us decide how to act. But we cannot wait for the end of a nonterminating process before deciding how to act. Decisions have to be based on what we currently believe, on our justified beliefs, not on the ideal set of warranted propositions. Any sophisticated defeasible reasoner must work similarly. OSCAR does the same thing humans do here. That is, OSCAR draws conclusions on the basis of its current reasoning, and when it has to decide how to act it bases its decision on its current beliefs, but as both reasoning and the input of new information proceed, it may have to withdraw some of its beliefs. This means that, occasionally, it will have acted in ways it would not have acted had it had time to do more reasoning. But that does not show that there is something wrong with OSCAR, or that OSCAR is behaving irrationally. It is just a fact of life that cognizers, human or otherwise, will make mistakes as a result of not knowing certain things that would have helped. Some of these mistakes will result from the cognizer not having acquired relevant information perceptually, but other mistakes will result from the cognizer not having time to do enough reasoning. This is just the way cognition works, and it is unrealistic to suppose we could completely avoid either source of mistakes through clever engineering.

Illustration: The Frame Problem

In philosophy, most work on defeasible reasoning has been aimed at using it as a tool for the analysis of philosophically interesting kinds of reasoning — mainly in epistemology but also in the philosophy of law. In AI, on the other hand, the investigation of defeasible reasoning was motivated by the desire to build implemented systems that could solve certain kinds of problems. One problem of interest to both philosophers and AI researchers is the *frame problem*, so I will use it as an illustration of the importance of understanding defeasible reasoning in order to understand how rational cognition works.

What Is the Frame Problem?

There is a great deal of confusion about just what the frame problem is, so I will begin with a brief history. The frame problem arose initially in AI planning theory. Planning theory is concerned with the construction of automated systems that will produce plans for the achievement of specified goals. In order to construct a plan, an agent must be able to predict the outcomes of the var-

ious actions that a plan might prescribe. For this purpose, let us suppose the agent has all the general background knowledge it might need. Consider a very simple planning problem. The agent is standing in the middle of a room, and the light is off. The light switch is by the door. The agent wants the light to be on. The obvious plan for achieving this goal is to walk to the vicinity of the light switch and activate the switch. *We human beings* can see immediately that, barring unforeseen difficulties, this is a good plan for achieving the goal. If an artificial agent is to be able to see this as well, it must be able to infer that the execution of this plan will, barring unforeseen difficulties, achieve the goal. The reasoning required seems easy. First, the switch is observed to be in position *S*. Our background knowledge allows us to infer that if we walk toward position *S*, we will shortly be in that vicinity. Second, our background knowledge allows us to infer that when we are in the vicinity of the switch, we can activate it. Third, it informs us that when we activate the switch, the light will come on. It may seem that this information is all that is required to conclude that if the plan is executed then the light will come on. But, in fact, one more premise is required. We know that the switch is initially in position *S*. However, for the plan to work, we must know that the switch will still be in position *S* when we get there. In other words, we have to know that walking to position *S* does not change the position of the switch. This, of course, is something that we do know, but what this example illustrates is that reasoning about what will change if an action is performed or some other event occurs generally presupposes knowing that various things will not change.

Early attempts in AI to model reasoning about change tried to do so deductively by formulating axioms describing the environment in which the planner was operating and then using those axioms to deduce the outcomes of executing proposed plans. The preceding example illustrates that among the axioms describing the environment there must be both causal axioms about the effects of various actions or events under specified circumstances, and a number of axioms about what does not change when actions are performed or events occur under specified circumstances. The latter axioms were called *frame axioms*.¹⁰ In our simple example, we can just add a frame axiom to the effect that the switch will still be in position *S* if the agent walks to that position, and then the requisite reasoning can be performed. However, in

pursuing this approach, it soon became apparent that more complicated situations required vastly more (and more complicated) frame axioms. A favorite example of early AI researchers was the Blocks World, in which children's building blocks are scattered about and piled on top of each other in various configurations, and the planning problem is to move them around and pile them up in a way that results in the blocks being arranged in some desired order. If we make the world sufficiently simple, then we can indeed axiomatize it and reason about it deductively. But if we imagine a world whose possibilities include all the things that can happen to blocks in the real world, this approach becomes totally impractical. For instance, moving a block does not normally change its color. But it might if, for example, an open can of paint is balanced precariously atop the block. If we try to apply the axiomatic approach to real-world situations, we encounter three problems. First, in most cases we will be unable to even formulate a suitable set of axioms that does justice to the true complexity of the situation. But, second, even if we could, we would find it necessary to construct an immense number of extraordinarily complex frame axioms. And, third, if we then fed these axioms to an automated reasoner and set it the task of deducing the outcomes of a plan, the reasoner would be forced to expend most of its resources reasoning about what does not change rather than what does change, and it would quickly bog down and be unable to draw the desired conclusions about the effects of executing the plan.¹¹

The upshot of this is that in realistically complicated situations, axiomatizing the situation and reasoning about it deductively is made unmanageable by the proliferation and complexity of frame axioms. What became known as the *frame problem* is the problem of reorganizing reasoning about change so that reasoning about nonchanges can be done efficiently.¹²

Unfortunately, some philosophers have confused the frame problem with other rather distantly related problems, and this has confused its discussion in philosophy and cognitive science. For example, Fodor (2001) takes the frame problem to be the general problem of how to reason efficiently against the background of a large database of information. That is indeed a problem, but a solution to it would not tell us how to reason about change.

The frame problem arose in AI, and it has often gone unappreciated that it is equally a

problem for human epistemology. Humans can perform the requisite reasoning, so they instantiate a solution to the frame problem. However, it is not obvious how they do it, any more than it is obvious how they perform inductive reasoning, probabilistic reasoning, or any other epistemologically problematic species of reasoning. Describing such reasoning is a task for epistemology. Furthermore, it seems quite likely that the best way to solve the frame problem for artificial rational agents is to figure out how it is solved in human reasoning and then implement that solution in artificial agents. Thus, the epistemological problem and the AI engineering problem become essentially the same problem.

The frame problem arose in the context of an attempt to reason about persistence and change deductively. That may seem naive in contemporary epistemology, where it is now generally agreed that most of our reasoning is defeasible, but it should be borne in mind that at the time this work was taking place (the late 1960s), philosophy itself was just beginning to appreciate the necessity for nondeductive reasoning, and at that time the predominant view was still that good arguments must be deductively valid. Thirty-five years later, nobody believes that. Some kind of defeasible reasoning is recognized as the norm, with deductive reasoning being the exception. To what extent does the frame problem depend upon its deductivist origins?

This same question occurred to AI researchers. Several authors proposed eliminating frame axioms altogether by reasoning about change defeasibly and adopting some sort of defeasible inference scheme to the effect that it is reasonable to believe that something doesn't change unless you are forced to conclude otherwise.¹³ This is what I called "temporal projection" in Section 1. Implementing temporal projection was the original motivation in AI for research on defeasible reasoning and nonmonotonic logic.¹⁴ Let us consider how temporal projection can be formulated using the system of defeasible reasoning discussed above. Then I will return to its use in the frame problem.

Temporal Projection

In the first section I argued that in order for cognition to work a cognitive agent must have a built-in presumption that the objects tend to have their properties stably. In other words, that

an object has a property at one time gives us a defeasible reason for expecting that it will still have that property at a later time. The built-in epistemic arsenal of a rational agent must include reason-schemes of the following sort for at least some choices of P :

- (1) If $t_0 < t_1$, believing P -at- t_0 is a defeasible reason for the agent to believe P -at- t_1 .

Some such principle as (1) is of crucial importance in enabling an agent to combine the results of different perceptual samplings of the world into unified conclusions about the world. Without this, the agent would be stuck in separate time-slices of the world with no way to bridge the boundaries epistemically.

Principle (1) amounts to a presumption that P 's being true is a stable property of a time. A stable property is one for which the probability is high that if it is possessed at one time, it will continue to be possessed at a later time. Let ρ be the probability that P will hold at time $t + 1$ given that it holds at time t . I will not prove this here, but assuming independence, it follows that the probability that P will hold at time $(t + \Delta t)$ given that it holds at time t is $\frac{1}{2}(2\rho - 1)^{\Delta t} + \frac{1}{2}$. In other words, the strength of the presumption that a stable property will continue to hold over time decays toward .5 as the time interval increases. In a system of defeasible reasoning that accommodates varying degrees of justification, this should be built into the principles of temporal projection by making the strength of the reason a monotonic decreasing function of Δt . However, I will not discuss this further here.

Temporal Projectibility

Principle (1) is not yet an adequate formulation of temporal projection. It takes little reflection to see that there must be some restrictions on what propositions P it applies to. For example, knowing that it is now 3 PM does not give me a defeasible reason for thinking it will still be 3 PM in an hour. Surprisingly, it turns out that certain kinds of logical composition also create problems in connection with Principle (1). For example, we must in general be barred from applying temporal projection to disjunctions. This is illustrated by Figure 11. Let P and Q be unrelated propositions. In the inference-graph of Figure 11, the thin solid arrows symbolize deductive inferences. In this inference graph, the conclusion Q -at- t_2 is undefeated, but this is

Figure 11. Temporal projection with disjunctions.

unreasonable. Q -at- t_2 is inferred from $(P \vee Q)$ -at- t_2 . $(P \vee Q)$ is expected to be true at t_2 only because it was true at t_1 , and it was only true at t_1 because P was true at t_1 . This makes it reasonable to believe $(P \vee Q)$ -at- t_2 only insofar as it is reasonable to believe P -at- t_2 , but the latter is defeated.

Just to have a label for the propositions to which temporal projection can be properly applied, let us say they are *temporally projectible*. The principle of temporal projection can then be formulated as follows:

Temporal Projection

If P is temporally projectible, then believing P -at- t is a defeasible reason for the agent to believe P -at- $(t + \Delta t)$, the strength of the reason being a monotonic decreasing function of Δt .

However, we still need an account of temporal projectibility. That is hard to come by. It seems that the ascriptions of “simple” properties to objects will generally be projectible. For instance, “ x is red” would seem to be temporally projectible. When we turn to logical compounds, it is easily proven that conjunctions of temporally projectible propositions are temporally projectible (Pollock 1998). But, as we have seen, disjunctions of temporally projectible propositions need not be temporally projectible. It follows from these two results that negations of temporally projectible propositions need not be temporally projectible. It is interesting to note that these observations about the “logic” of temporal projectibility are parallel to similar observations about the familiar projectibility constraint required for inductive reasoning (Pollock 1990), although the concepts are different. For one

Figure 12. Conflicting temporal projections.

thing, inductive projectibility pertains to properties, whereas temporal projectibility pertains to propositions. It is, at this time, an unsolved problem just how to characterize the set of temporally projectible propositions.¹⁵

Temporal projection is based on an *a priori* presumption of stability for temporally projectible properties. However, it must be possible to override or modify the presumption by discovering that the probability of *P*'s being true at time $t + 1$ given that *P* is true at time t is not high. This requires the following undercutting defeater:

Probabilistic Defeat for Temporal Projection

“The probability of *P-at-(t + 1)* given *P-at-t* is not high” is an undercutting defeater for temporal projection.

There is a second kind of defeater for temporal projection. Suppose we know that *P* is true at time t_0 but false at a later time t_1 . We want to know whether *P* is true at a still later time t_2 . The presumption should be that it is not. For instance, if my neighbor’s house was white, but he painted it blue yesterday, then I would expect it to be blue tomorrow — not white. However, temporal projection gives us reasons for thinking that it is both white and blue, and these conclusions defeat each other collectively, as in Figure 12.

What is happening here is that temporal projection proceeds on the assumption that if something is true at t_0 then it is true not just at a later time t^* , but throughout the interval from t_0 to t^* . Thus knowing that it is false at some time t between t_0 and t^* should constitute an undercutting defeater for the temporal projection:

Discontinuity Defeat for Temporal Projection

If $t_0 < t < t^*$, “ $\sim P$ -at- t ” is an undercutting defeater for the inference by temporal projection from “*P-at- t_0* ” to “*P-at- t^** .”

Incorporating this defeater into Figure 12 yields Figure 13. Applying the OSCAR semantics to this inference graph, there is just one status assignment, as indicated in the figure. In it, the undercutting defeater is undefeated, and hence “the house is white at t^* ” is defeated, leaving “the house is blue at t^* ” undefeated.

Reasoning about Change

Now let us return to the frame problem and the problem of how to predict changes caused either by our own actions or by extraneous events. To reason about change, we must be able to reason about what does not change, and it was proposed by several authors that the best way to do that is with a defeasible inference scheme to the effect that it is reasonable to believe that something does not change unless you are forced to conclude otherwise. The temporal projection principles defended above can be regarded as a precise formulation of the defeasible inference schemes sought. Unfortunately, these principles do not solve the frame problem. Steve Hanks and Drew McDermott (1986) were the first to observe that even with defeasible principles of persistence, a reasoner will often be unable to determine what changes and what does not. They illustrated this with what has become known as “the Yale shooting problem.” Suppose (simplistically) that there is a causal law dictating that if the trigger is pulled on a loaded gun that is pointed at someone, that person will shortly be dead.

Figure 13. Conflicting temporal projections.

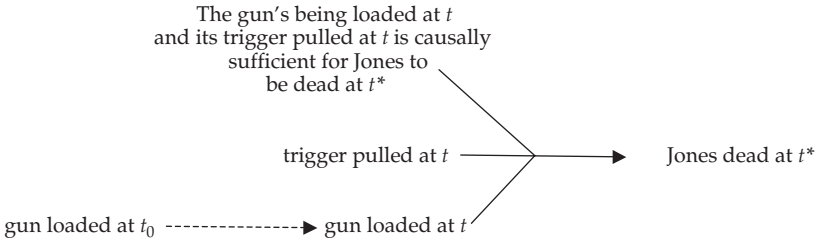

Figure 14. Yale shooting scenario.

Suppose we have a gun that is now loaded. It is then pointed at Jones and the trigger is pulled. It seems we should conclude that Jones will soon be dead. Notice, however, that when firing a gun, you cannot check that it is loaded at the same instant you fire it. You must first check that it is loaded, then point it and pull the trigger. Here you assume that the gun remains loaded until you fire it, and it seems that this is justified by temporal projection. Thus we can reason as in Figure 14.

But as Hanks and McDermott observed, there is a problem. We know that Jones is alive at some time t_0 earlier than t , so it seems we can also use temporal projection to infer that he will still be alive at t^* . Given the causal premise and given that the trigger was pulled at t , it follows that the gun was not loaded at t . This gives us a complicated case of collective defeat, as diagrammed in Figure 15. (I have drawn one set of inference links in gray just to make the graph easier to read.) In terms of the OSCAR semantics, there are two status assignments, one in which "Jones is alive at t^* " is defeated and one in which it is undefeated.

The general form of this problem is common to cases of causal reasoning. We know that some proposition P is true at an initial time t_0 . We

know that action A is performed at a subsequent time t , and we know that if P is still true at t then Q will become true at a later time t^* . We want to infer defeasibly that P will still be true at t , and hence that Q will become true at t^* . This is the intuitively correct conclusion to draw. But temporal projection gives us a reason for thinking that because $\sim Q$ is true initially it will remain true at t^* , and hence P was not true at t after all. The problem is to understand what principles of reasoning enable us to draw the desired conclusion and avoid the collective defeat.

When we reason about causal mechanisms, we think of the world as "unfolding" temporally, and changes only occur when they are forced to occur by what has already happened. In our example, when A is performed, nothing has yet happened to force a change in P , so we conclude defeasibly that P remains true. But given the truth of P , we can then deduce that at a slightly later time, Q will become true. Thus when causal mechanisms force there to be a change, we conclude defeasibly that the change occurs in the later states rather than the earlier states. This seems to be part of what we mean by describing something as a causal mechanism. Causal mechanisms are systems that force changes, where "force" is to be understood in the context of

Figure 15. Yale shooting problem.

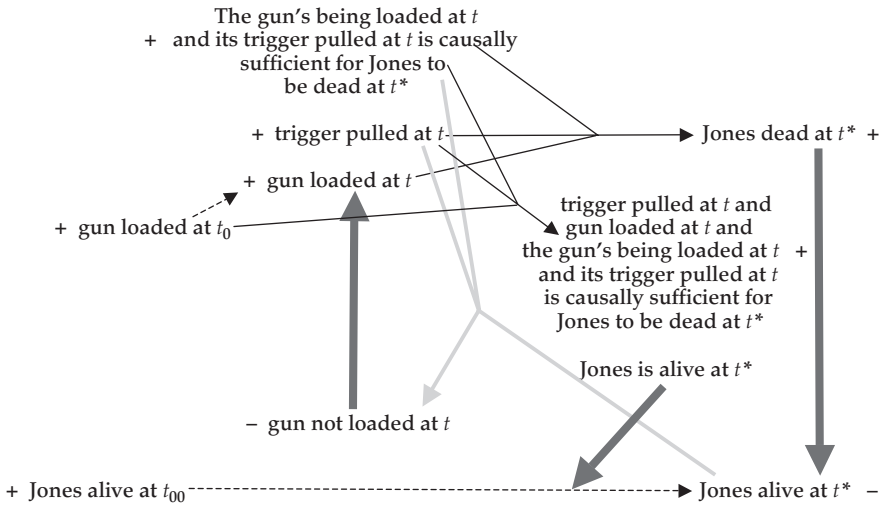

Figure 16. The solved Yale shooting problem.

temporal unfolding.¹⁶ More precisely, when two temporal projections conflict because of a negative causal connection between their conclusions, the projection to the conclusion about the earlier time takes precedence over the later projection. In other words, given the causal connection, the earlier temporal projection provides a defeater for the later one. This can be captured as follows:

Causal Undercutting

If $t_0 < t < t^*$ and $t_{00} < t^*$, “ P -at- t_0 and A -at- t and [P -at- t & A -at- t] is causally sufficient for Q at t^* ” is an undercutting defeater for the inference by temporal projection from “ $\sim Q$ -at- t_{00} ” to “ $\sim Q$ -at- t^* .”

Incorporating this undercutting defeater into Figure 15 gives us Figure 16. If we apply the OSCAR semantics to this inference graph, we find that there is just one status assignment, and in that status assignment the undercutting defeater is undefeated, and hence the temporal projection is defeated, so the conclusion that Jones is dead at t^* is undefeated.

Technically, what makes this solution work is that the undercutting defeater is inferred from the premise of the earlier temporal projection (in this case, “The gun is loaded at t_0 ”), not from the conclusion of that projection. If we redraw the inference graph so that it is inferred instead from the conclusion, we get another case of collective defeat. However, it must be borne in mind that it is the initial temporal projection to which we are giving precedence, and not just its premise. This is supposed to be a way of adjudicating between conflicting temporal projections, so it cannot just

be the premise of the earlier temporal projection that is relevant. This observation can be captured by appealing to the fact that undercutting defeaters are reasons for conclusions of the form $(P \otimes Q)$, and as such they can be defeasible. In the case of causal undercutting, anything that defeats the earlier temporal projection should defeat the application of causal undercutting, thus reinstating the later temporal projection. For example, if we examined the gun at t_0 and determined it was loaded, but then checked again before firing and the second time we looked it was not loaded, this defeats the temporal projection to the conclusion that the gun was loaded when fired. This is what I earlier called “a discontinuity defeater.” In general, any defeater for the earlier temporal projection must also be a defeater for causal undercutting. We have noted two such defeaters, so we should have:

Discontinuity Defeat for Causal Undercutting

If $t_0 < t_1 < t$, “ $\sim P$ -at- t_1 ” is an undercutting defeater for an application of causal undercutting.

Probabilistic Defeat for Causal Undercutting

“The probability of P -at- $(t + 1)$ given P -at- t is not high” is an undercutting defeater for an application of causal undercutting.

Thus, the Yale shooting problem is solved. The same epistemic machinery that solves this problem seems to handle causal reasoning in general. It is not quite right to describe this as a solution to the frame problem, because the frame problem arose on the assumption that all good reasoning is deductive. The frame problem

was the problem of how to handle causal reasoning given that assumption. Once we embrace defeasible reasoning, the original frame problem goes away. There is no reason to think we should be able to handle causal reasoning in a purely deductive way. However, the problem has a residue, namely, that of giving an account of how causal reasoning works. That is the problem I have tried to solve here. The solution has two parts – temporal projection and causal undercutting.

In closing, it is worth noting that this reasoning is easily implemented in OSCAR. I invite the reader to download the OSCAR code from the OSCAR Web site¹⁷ and try it out on other problems.

Conclusions

The assumption that good reasoning must be deductively valid is seen to be wrong when we look carefully at the kinds of reasoning a sophisticated cognizer must be able to do. Defeasible reasoning is the norm, and deductive reasoning is the exception. Defeasible reasoning differs from deductive reasoning in that the reason-schemes employed in defeasible reasoning can have defeaters. A cognizer may produce a number of arguments, some of which defeat others. A semantics for defeasible reasoning aims to tell us how it is determined which of those arguments are defeated and which are undefeated. A cognizer's justified beliefs are then those that are supported by his undefeated arguments. I described the OSCAR semantics for defeasible reasoning, and illustrated its application with a discussion of the frame problem.

Notes

- 1 One might question whether this is really a case of reasoning. See Pollock and Oved (2006) for a more extensive discussion of this example.
- 2 This argument is from Chapter 6 of Pollock (1974).
- 3 I believe that I developed the first formal semantics for defeasible reasoning in 1979, but I did not initially publish it because, being ignorant of AI, I did not think anyone would be interested. That semantics was finally published in Pollock (1986).
- 4 See Pollock (1998) and Pollock and Oved (2006) for a fuller discussion of this.
- 5 Technically, default logic has the consequence that there are no "extensions" for this default theory.
- 6 There are many forms of circumscription, and by using what are essentially ad hoc priori-

tization rules it may be possible to get the right answer in Figure 7. Because the moves required are ad hoc, I don't think this shows anything.

- 7 This observation is due to Makinson and Schlechta (1991).
- 8 The OSCAR architecture is described in my (1995). For up-to-date information on OSCAR, see the OSCAR Web site at <http://oscarhome.soc-sci.arizona.edu/ftp/OSCAR-web-page/OSCAR.html>.
- 9 See Pollock (2006) for a more extensive discussion.
- 10 McCarthy and Hayes (1969).
- 11 On this last point, the reader who lacks experience with automated reasoners will have to take my word, but this is a point about which no AI practitioner would disagree.
- 12 McCarthy and Hayes (1969).
- 13 Sandewall (1972), McDermott (1982), McCarthy (1986).
- 14 For example, see the collection of papers in Ginsberg (1987).
- 15 This problem is equally unsolved for inductive projectibility. A useful survey of literature on inductive projectibility can be found in Stalker (1994).
- 16 This intuition is reminiscent of Shoham's (1987) "logic of chronological ignorance," although unlike Shoham, I propose to capture the intuition without modifying the structure of the system of defeasible reasoning. This is also related to the proposal of Gelfond and Lifschitz (1993) and to the notion of progressing a database discussed in Lin and Reiter (1994, 1995). This same idea underlies my analysis of counterfactual conditionals in Pollock (1979) and (1984).

Chapter 24: Explanatory Coherence

PAUL THAGARD

1. Introduction

Why did the oxygen theory of combustion supersede the phlogiston theory? Why is Darwin's theory of evolution by natural selection superior to creationism? How can a jury in a murder trial decide between conflicting views of what happened? This target article develops a theory of explanatory coherence that applies to the evaluation of competing hypotheses in cases such as these. The theory is implemented in a connectionist computer program with many interesting properties.

The problem of inference to explanatory hypotheses has a long history in philosophy and a much shorter one in psychology and artificial intelligence (AI). Scientists and philosophers have long considered the evaluation of theories on the basis of their explanatory power. In the late nineteenth century, Peirce discussed two forms of inference to explanatory hypotheses: *hypothesis*, which involved the acceptance of hypotheses, and *abduction*, which involved merely the initial formation of hypotheses (Peirce 1931–1958; Thagard 1988a). Researchers in artificial intelligence and some philosophers have used the term “abduction” to refer to both the formation and the evaluation of hypotheses. AI work on this kind of inference has concerned such diverse topics as medical diagnosis (Josephson et al. 1987; Pople 1977; Reggia et al. 1983) and natural language interpretation (Charniak and McDermott 1985; Hobbs et al. 1988). In philosophy, the acceptance of explanatory hypotheses is usually called *inference to the best explanation* (Harman 1973, 1986). In social psychology, attribution theory considers how people in everyday life form hypotheses to explain events (Fiske and

Taylor 1984). Recently, Pennington and Hastie (1986, 1987) have proposed that much of jury decision making can be best understood in terms of explanatory coherence. For example, to gain a conviction of first degree murder, the prosecution must convince the jury that the accused had a preformed intention to kill the victim. Pennington and Hastie argue that whether the jury will believe this depends on the explanatory coherence of the prosecution's story compared to the story presented by the defense.

Actual cases of scientific and legal reasoning suggest a variety of factors that go into determining the explanatory coherence of a hypothesis. How much does the hypothesis explain? Are its explanations economical? Is the hypothesis similar to ones that explain similar phenomena? Is there an explanation of why the hypothesis might be true? In legal reasoning, the question of explaining the hypothesis usually concerns motives: If we are trying to explain the evidence by supposing that the accused murdered the victim, we will find the supposition more plausible if we can think of reasons why the accused was motivated to kill the victim. Finally, on all these dimensions, how does the hypothesis compare against alternative hypotheses?

This paper presents a theory of explanatory coherence that is intended to account for a wide range of explanatory inferences. I shall propose seven principles of explanatory coherence that encompass the considerations just described and that suffice to make judgments of explanatory coherence. Their sufficiency is shown by the implementation of the theory in a connectionist computer program called ECHO that has been applied to more than a dozen complex cases of scientific and legal reasoning. My account of

explanatory coherence thus has three parts: the statement of a theory, the description of an algorithm, and applications to diverse examples that show the feasibility of the algorithm and help to demonstrate the power of the theory (cf. Marr 1982). Finally, I shall discuss the implications of the theory for AI, psychology, and philosophy.

2. A Theory of Explanatory Coherence

2.1. Coherence and Explanation

Before presenting the theory, it will be useful to make some general points about the concepts of coherence and explanation, although it should be made clear that this paper does not purport to give a general account of either concept. The question of the nature of explanation is extremely difficult, and controversial. Philosophers disagree about whether explanation is primarily deductive (Hempel 1965), statistical (Salmon 1970), causal (Salmon 1984), linguistic (Achinstein 1983), or pragmatic (van Fraassen 1980). In AI, explanation is sometimes thought of as deduction (Mitchell et al. 1986) and sometimes as pattern instantiation (Schank 1986). This paper does not pretend to offer a theory of explanation, but is compatible with any of the foregoing accounts (except van Fraassen's, which is intended to make explanation irrelevant to questions of acceptability and truth).

Nor does this paper give a general account of coherence. There are various notions of coherence in the literatures of different fields. We can distinguish at least the following:

Deductive coherence depends on relations of logical consistency and entailment among members of a set of propositions.

Probabilistic coherence depends on a set of propositions having probability assignments consistent with the axioms of probability.

Semantic coherence depends on propositions having similar meanings. Bonjour (1985) provides an interesting survey of philosophical ideas about coherence. Here, I am only offering a theory of *explanatory* coherence.

Explanatory coherence can be understood in several different ways, as

- (a) a relation between two propositions,
- (b) a property of a whole set of related propositions, or
- (c) a property of a single proposition.

I claim that (a) is fundamental, with (b) depending on (a), and (c) depending on (b). That is, explanatory coherence is primarily a relation between two propositions, but we can speak derivatively of the explanatory coherence of a set of propositions as determined by their pairwise coherence, and we can speak derivatively of the explanatory coherence of a single proposition with respect to a set of propositions whose coherence has been established. A major requirement of an account of explanatory coherence is that it shows how it is possible to move from (a) to (b) to (c); algorithms for doing so are presented as part of the computational model described below.

Because the notion of the explanatory coherence of an individual proposition is so derivative and depends on a specification of the set of propositions with which it is supposed to cohere, I shall from now on avoid treating coherence as a property of individual propositions. Instead, we can speak of the *acceptability* of a proposition, which depends on but is detachable from the explanatory coherence of the set of propositions to which it belongs. We should accept propositions that are coherent with our other beliefs, reject propositions that are incoherent with our other beliefs, and be neutral toward propositions that are neither coherent nor incoherent. Acceptability has finer gradations than just acceptance, rejection, and neutrality, however: The greater the coherence of a proposition with other propositions, the greater its acceptability.

In ordinary language, to cohere is to hold together, and explanatory coherence is a holding together because of explanatory relations. We can, accordingly, start with a vague characterization:

Propositions P and Q cohere if there is some explanatory relation between them.

To fill this statement out, we must specify what the explanatory relation might be. I see four possibilities:

- (1) P is part of the explanation of Q.
- (2) Q is part of the explanation of P.
- (3) P and Q are together part of the explanation of some R.
- (4) P and Q are analogous in the explanations they respectively give of some R and S.

This characterization leaves open the possibility that two propositions can cohere for

nonexplanatory reasons: deductive, probabilistic, or semantic. Explanation is thus sufficient but not necessary for coherence. I have taken “explanation” and “explain” as primitives, while asserting that a relation of explanatory coherence holds between P and Q if and only if one or more of (1)–(4) is true. *Incoherence* between two propositions occurs if they contradict each other or if they offer explanations that background knowledge suggests are incompatible.

The psychological relevance of explanatory coherence comes from the following general predictions concerning the acceptance of individual propositions:

If a proposition is highly coherent with the beliefs of a person, then the person will believe the proposition with a high degree of confidence.

If a proposition is incoherent with the beliefs of a person, then the person will not believe the proposition. The applicability of this to several areas of psychological experimentation is discussed in section 9.

2.2. Principles of Explanatory Coherence

I now propose seven principles that establish relations of explanatory coherence and make possible an assessment of the global coherence of an explanatory system S. S consists of propositions P, Q, and $P_1 \dots P_n$. Local coherence is a relation between two propositions. I coin the term “incohere” to mean more than just that two propositions do not cohere: To incohere is to *resist* holding together. The principles are as follows:

Principle 1. Symmetry.

- (a) If P and Q cohere, then Q and P cohere.
- (b) If P and Q incohere, then Q and P incohere.

Principle 2. Explanation.

If $P_1 \dots P_m$ explain Q, then:

- (a) For each P_i in $P_1 \dots P_m$, P_i and Q cohere.
- (b) For each P_i and P_j in $P_1 \dots P_m$, P_i and P_j cohere.
- (c) In (a) and (b), the degree of coherence is inversely proportional to the number of propositions $P_1 \dots P_m$.

Principle 3. Analogy.

- (a) If P_1 explains Q_1 , P_2 explains Q_2 , P_1 is analogous to P_2 , and Q_1 is analogous to

Q_2 , then P_1 and P_2 cohere, and Q_1 and Q_2 cohere.

- (b) If P_1 explains Q_1 , P_2 explains Q_2 , Q_1 is analogous to Q_2 , but P_1 is disanalogous to P_2 , then P_1 and P_2 incohere.

Principle 4. Data Priority.

Propositions that describe the results of observation have a degree of acceptability on their own.

Principle 5. Contradiction.

If P contradicts Q, then P and Q incohere.

Principle 6. Acceptability.

- (a) The acceptability of a proposition P in a system S depends on its coherence with the proposition in S.
- (b) If many results of relevant experimental observations are unexplained, then the acceptability of a proposition P that explains only a few of them is reduced.

Principle 7. System Coherence.

The global explanatory coherence of a system S of propositions is a function of the pairwise local coherence of those propositions.

2.3. Discussion of the Principles

Principle 1, Symmetry, asserts that pairwise coherence and incoherence are symmetric relations, in keeping with the everyday sense of coherence as holding together. The coherence of two propositions is thus very different from the nonsymmetric relations of entailment and conditional probability. Typically, P entails Q without Q entailing P, and the conditional probability of P given Q is different from the probability of Q given P. But if P and Q hold together, so do Q and P. The use of a symmetrical relation has advantages that will become clearer in the discussion of the connectionist implementation below.

Principle 2, Explanation, is by far the most important for assessing explanatory coherence, because it establishes most of the coherence relations. Part (a) is the most obvious: If a hypothesis P is part of the explanation of a piece of evidence Q, then P and Q cohere. Moreover, if a hypothesis P_2 is explained by another hypothesis P_1 , then P_1 and P_2 cohere. Part (a) presupposes that explanation is a more restrictive relation than deductive implication, because otherwise we could prove that any two propositions

cohere; for unless we use a relevance logic (Anderson and Belnap 1975), P_1 and the contradiction P_2 & not- P_2 imply any Q , so it would follow that P_1 coheres with Q . It follows from Principle 2(a), in conjunction with Principle 6, that the more a hypothesis explains, the more coherent and hence acceptable it is. Thus, this principle subsumes the criterion of explanatory breadth (which Whewell 1967 called “consilience”) that I have elsewhere claimed to be the most important for selecting the best explanation (Thagard 1978, 1988a).

Whereas part (a) of Principle 2 says that what explains coheres with what is explained, part (b) states that two propositions cohere if together they provide an explanation. Behind part (b) is the Duhem–Quine idea that the evaluation of a hypothesis depends partly on the other hypotheses with which it furnishes explanations (Duhem 1954; Quine 1961; see Section 10.1). I call two hypotheses that are used together in an explanation “co-hypotheses.” Again I assume that explanation is more restrictive than implication; otherwise it would follow that any proposition that explained something was coherent with every other proposition, because if P_1 implies Q , then so does P_1 & P_2 . But any scientist who maintained at a conference that the theory of general relativity and today’s baseball scores together explain the motion of planets would be laughed off the podium. Principle 2 is intended to apply to explanations and hypotheses actually proposed by scientists.

Part (c) of Principle 2 embodies the claim that if numerous propositions are needed to furnish an explanation, then the coherence of the explaining propositions with each other and with what is explained is thereby diminished. Scientists tend to be skeptical of hypotheses that require myriad *ad hoc* assumptions in their explanations. There is nothing wrong in principle in having explanations that draw on many assumptions, but we should prefer theories that generate explanations using a unified core of hypotheses. I have elsewhere contended that the notion of *simplicity* most appropriate for scientific theory choice is a comparative one preferring theories that make fewer special assumptions (Thagard 1978, 1988a). Principles 2(b) and 2(c) together subsume this criterion. I shall not attempt further to characterize “degree of coherence” here, but the connectionist algorithm described below provides a natural interpretation. Many other notions of simplicity have been proposed (e.g., Foster and Martin 1966; Harman et al. 1988), but

none is so directly relevant to considerations of explanatory coherence as the one embodied in Principle 2.

The third criterion for the best explanation in my earlier account was analogy, and this is subsumed in Principle 3. There is controversy about whether analogy is of more than heuristic use, but scientists such as Darwin have used analogies to defend their theories; his argument for evolution by natural selection is analyzed below. Principle 3(a) does not say simply that any two analogous propositions cohere. There must be an explanatory analogy, with two analogous propositions occurring in explanations of two other propositions that are analogous to each other. Recent computational models of analogical mapping and retrieval show how such correspondences can be noticed (Holyoak and Thagard 1989; Thagard et al. 1989). Principle 3(b) says that when similar phenomena are explained by dissimilar hypotheses, the hypotheses incohere. Although the use of such disanalogies is not as common as the use of analogies, it was important in the reasoning that led Einstein (1952) to the special theory of relativity: He was bothered by asymmetries in the way Maxwell’s electrodynamics treated the case of (1) a magnet in motion and a conductor at rest quite differently from the case of (2) a magnet at rest and a conductor in motion.

Principle 4, Data Priority, stands much in need of elucidation and defense. In saying that a proposition describing the results of observation has a degree of acceptability on its own, I am not suggesting that it is indubitable, but only that it can stand on its own more successfully than can a hypothesis whose sole justification is what it explains. A proposition Q may have some independent acceptability and still end up not accepted, if it is only coherent with propositions that are themselves not acceptable.

From the point of view of explanatory coherence alone, we should not take propositions based on observation as independently acceptable without any explanatory relations to other propositions. As Bonjour (1985) argues, the coherence of such propositions is of a nonexplanatory kind, based on background knowledge that observations of certain sorts are very likely to be true. From past experience, we know that our observations are very likely to be true, so we should believe them unless there is substantial reason not to. Similarly, at a very different level, we have some confidence in the reliability of descriptions of experimental results in carefully refereed scientific journals. Section 10.4 relates

the question of data priority to current philosophical disputes about justification.

Principle 5, Contradiction, is straightforward. By “contradictory” here I mean not just syntactic contradictions like P & not- P , but also semantic contradictions such as “This ball is black all over” and “This ball is white all over.” In scientific cases, contradiction becomes important when incompatible hypotheses compete to explain the same evidence. Not all competing hypotheses incohere, however, because many phenomena have multiple causes. For example, explanations of why someone has certain medical symptoms may involve hypotheses that the patient has various diseases, and it is possible that more than one disease is present. Competing hypotheses incohere if they are contradictory or if they are framed as offering *the* most likely cause of a phenomenon. In the latter case, we get a kind of pragmatic contradictoriness: Two hypotheses may not be syntactically or semantically contradictory, yet scientists will view them as contradictory because of background beliefs suggesting that only one of the hypotheses is acceptable. For example, in the debate over dinosaur extinction (Thagard 1988b), scientists generally treat as contradictory the following hypotheses:

- (1) Dinosaurs became extinct because of a meteorite collision.
- (2) Dinosaurs became extinct because the sea level fell.

Logically, (1) and (2) could both be true, but scientists treat them as conflicting explanations, possibly because there are no explanatory relations between them and their conjunction is unlikely.

The relation “cohere” is not transitive. If P_1 and P_2 together explain Q , while P_1 and P_3 together explain not- Q , then P_1 coheres with both Q and not- Q , which incohere. Such cases do occur in science. Let P_1 be the gas law that volume is proportional to temperature, P_2 a proposition describing the drop in temperature of a particular sample of gas, P_3 a proposition describing the rise in temperature of the sample, and Q a proposition about increases in the sample’s volume. Then P_1 and P_2 together explain a decrease in the volume, while P_1 and P_3 explain an increase.

Principle 6, Acceptability, proposes in part (a) that we can make sense of the overall coherence of a proposition in an explanatory system just from the pairwise coherence relations established by Principles 1–5. If we have

a hypothesis P that coheres with evidence Q by virtue of explaining it, but incoheres with another contradictory hypothesis, should we accept P ? To decide, we cannot merely count the number of propositions with which P coheres and incoheres, because the acceptability of P depends in part on the acceptability of those propositions themselves. We need a dynamic and parallel method of deriving general coherence from particular coherence relations; such a method is provided by the connectionist program described below.

Principle 6(b), reducing the acceptability of a hypothesis when much of the relevant evidence is unexplained by any hypothesis, is intended to handle cases where the best available hypothesis is still not very good, in that it accounts for only a fraction of the available evidence. Consider, for example, a theory in economics that could explain the stock market crashes of 1929 and 1987 but that had nothing to say about myriad other similar economic events. Even if the theory gave the best available account of the two crashes, we would not be willing to elevate it to an accepted part of general economic theory. What does “relevant” mean here? [See BBS multiple book review of Sperber and Wilson’s *Relevance*, BBS 10(4) 1987.] As a first approximation, we can say that a piece of evidence is *directly* relevant to a hypothesis if the evidence is explained by it or by one of its competitors. We can then add that a piece of evidence is relevant if it is directly relevant or if it is similar to evidence that is relevant, where similarity is a matter of dealing with phenomena of the same kind. Thus, a theory of the business cycle that applies to the stock market crashes of 1929 and 1987 should also have something to say about nineteenth-century crashes and major business downturns in the twentieth century.

The final principle, System Coherence, proposes that we can have some global measure of the coherence of a whole system of propositions. Principles 1–5 imply that, other things being equal, a system S will tend to have more global coherence than another if

- (1) S has more data in it;
- (2) S has more internal explanatory links between propositions that cohere because of explanations and analogies; and
- (3) S succeeds in separating coherent subsystems of propositions from conflicting subsystems.

Figure 1. The Necker cube. Either ABCD or EFGH can be perceived as the front.

The connectionist algorithm described below comes with a natural measure of global system coherence. It also indicates how different priorities can be given to the different principles.

3. Connectionist Models

To introduce connectionist techniques, I shall briefly describe the popular example of how a network can be used to understand the Necker cube phenomenon (see, e.g., Feldman and Ballard 1982; Rumelhart et al. 1986). Figure 1 contains a reversing cube: By changing our focus of attention, we are able to see as the front either face ABCD or face EFGH. The cube is perceived holistically, in that we are incapable of seeing corner A at the front without seeing corners B, C, and D at the front as well.

We can easily construct a simple network with the desired holistic property using *units*, crudely analogous to neurons, connected by links. Let Af be a unit that represents the hypothesis that corner A is at the front, while Ab represents the hypothesis that corner A is at the back. Similarly, we construct units Bf, Bb, Cf, Cb, Df, Db, Ef, Eb, Ff, Fb, Gf, Gb, Hf, and Hb. These units are not independent of each other. To signify that A cannot be both at the front and at the back, we construct an *inhibitory* link between the units Af and Ab, with similar links inhibiting Bf and Bb, and so on. Because corners A, B, C, and D go together, we construct *excitatory* links between each pair of Af, Bf, Cf, and Df, and between each pair of Ab, Bb, Cb, and Db. Analogous inhibitory and excitatory links are then set up for E, F, G, and H. In addition, we need inhibitory links between Af and Ef, Bf and Ff, and so on. Part of the resulting network is depicted in Figure 2. I have used solid lines

Figure 2. A connectionist network for interpreting the cube. Af is a unit representing the hypothesis that A is at the front, whereas Ab represents the hypothesis that A is at the back. Solid lines represent excitatory links; dotted lines represent inhibitory links.

to indicate excitatory links, and dotted lines to indicate inhibitory links.

Units can have varying degrees of *activation*. Suppose that our attention is focused on corner A, which we assume to be at the front, so that unit Af is activated. Then by virtue of the excitatory links from Af to Bf, Cf, and Df, these units will be activated. The inhibitory links from Af to Ab and Ef will cause those units to be deactivated. In turn, the excitatory links from Ab to Bb, Cb, and Db will deactivate them. Thus activation will spread through the network until all the units corresponding to the view that A, B, C, and D are at the front are activated, while all the units corresponding to the view that E, F, G, and H are at the front are deactivated.

Goldman has pointed out some of the attractive epistemological properties of this sort of network (Goldman 1986: Ch. 15; see also Thagard 1989). A proposition, represented by a unit, is accepted if it is part of the best competing coalition of units and its rivals are rejected. Uncertainty consists in the absence of a clear-cut winner. Goldman argues that the connectionist view that has units representing propositions settling into either on or off states is more psychologically plausible and epistemologically appealing than the Bayesian picture that assigns probabilities to propositions.

4. ECHO

4.1. The Program

Let us now look at ECHO, a computer program written in Common LISP that is a straightforward application of connectionist algorithms to the problem of explanatory coherence. In ECHO, propositions representing hypotheses and results of observation are represented by units. Whenever Principles 1–5 state that two propositions

cohere, an excitatory link between them is established. If two propositions incohere, an inhibitory link between them is established. In ECHO, these links are symmetric, as Principle 1 suggests: The weight from unit 1 to unit 2 is the same as the weight from unit 2 to unit 1. Principle 2(c) says that the larger the number of propositions used in an explanation, the smaller the degree of coherence between each pair of propositions. ECHO therefore counts the propositions that do the explaining and proportionately lowers the weight of the excitatory links between units representing coherent propositions.

Principle 4, Data Priority, is implemented by links to each data unit from a special evidence unit that always has activation 1, giving each unit some acceptability on its own. When the network is run, activation spreads from the special unit to the data units, and then to the units representing explanatory hypotheses. The extent of data priority – the presumed acceptability of data propositions – depends on the weight of the link between the special unit and the data units. The higher this weight, the more immune the data units become to deactivation by other units. Units that have inhibitory links between them because they represent contradictory hypotheses have to compete with each other for the activation spreading from the data units: The activation of one of these units will tend to suppress the activation of the other. Excitatory links have positive weights; best performance occurs with weights around .05. Inhibitory links have negative weights; best performance occurs with weights around -2 . The activation of units ranges between 1 and -1 ; positive activation can be interpreted as acceptance of the proposition represented by the unit, negative activation as rejection, and activation close to 0 as neutrality. The relation between acceptability and probability is discussed in Section 10.2.

To summarize how ECHO implements the principles of explanatory coherence, we can list key terms from the principles with the corresponding terms from ECHO:

Proposition: Unit

Coherence: Excitatory link, with positive weight

Incoherence: Inhibitory link, with negative weight

Data priority: Excitatory link from special unit

Acceptability: Activation

System coherence: See the function H defined in Section 4.9 below.

The following are some examples of the LISP formulas that constitute ECHO's inputs (I omit LISP quote symbols; see Tables 1–4 for actual input):

1. (EXPLAIN (H1 H2) E1)
2. (EXPLAIN (H1 H2 H3) E2)
3. (ANALOGOUS (H5 H6) (E5 E6))
4. (DATA (E1 E2 E5 E6))
5. (CONTRADICT H1 H4)

Formula 1 says that hypotheses H1 and H2 together explain evidence E1. As suggested by the second principle of explanatory coherence proposed above, formula 1 sets up three excitatory links, between units representing H1 and E1, H2 and E1, and H1 and H2.¹ Formula 2 sets up six such links, between each of the hypotheses and the evidence, and between each pair of hypotheses, but the weight on the links will be less than those established by formula 1, because there are more cohypotheses. In accord with Principle 3(a), Analogy, formula 3 produces excitatory links between H5 and H6, and between E5 and E6, if previous input has established that H5 explains E5 and H6 explains E6. Formula 4 is used to apply Principle 4, Data Priority, setting up explanation-independent excitatory links to each data unit from a special evidence unit. Finally, formula 5 sets up an inhibitory link between the contradictory hypotheses H1 and H4, as prescribed by Principle 5. A full specification of ECHO's inputs and algorithms is provided in the Appendix.

Input to ECHO can optionally reflect the fact that not all data and explanations are of equal merit. For example, a data statement can have the form

(DATA (E1 (E 2.8))).

This formula sets up the standard link from the special unit to E1, but interprets the “.8” as indicating that E2 is not as reliable a piece of evidence as E1. Hence, the weight from the special unit to E2 is only .8 as strong as the weight from the special unit to E1. Similarly, explain statements take an optimal numerical parameter, as in

(EXPLAIN (H1) E 1.9).

The additional parameter, .9, indicates some weakness in the quality of the explanation and results in a lower than standard weight on the excitatory link between H1 and E1. In ECHO's

applications to date, the additional parameters for data and explanation quality have not been used, because it is difficult to establish them objectively from the texts we have been using to generate ECHO's inputs. But it is important that ECHO has the capacity to make use of judgments of data and explanation quality when these are available.

Program runs show that the networks thus established have numerous desirable properties. Other things being equal, activation accrues to units corresponding to hypotheses that explain more, provide simpler explanations, and are analogous to other explanatory hypotheses. The considerations of explanatory breadth, simplicity, and analogy are smoothly integrated. The networks are holistic, in that the activation of every unit can potentially have an effect on every other unit linked to it by a path, however lengthy. Nevertheless, the activation of a unit is directly affected only by those units to which it is linked. Although complexes of coherent propositions are evaluated together, different hypotheses in a complex can finish with different activations, depending on their particular coherence relations. The symmetry of excitatory links means that active units tend to bring up the activation of units with which they are linked, whereas units whose activation sinks below 0 tend to bring down the activation of units to which they are linked. Data units are given priority, but can nevertheless be deactivated if they are linked to units that become deactivated. So long as excitation is not set too high (see Section 12.2), the networks set up by ECHO are stable: In most of them, all units reach asymptotic activation levels after fewer than 100 cycles of updating. The most complex network implemented so far, comparing the explanatory power of Copernicus's heliocentric theory with Ptolemy's geocentric one, requires about 210 cycles before its more than 150 units have all settled. To illustrate ECHO's capabilities, I shall describe some very simple tests that illustrate its ability to handle considerations of explanatory breadth, simplicity, and analogy. Later sections on scientific and legal reasoning provide more complex and realistic examples.

4.2. Explanatory Breadth

We should normally prefer a hypothesis that explains more than alternative hypotheses. If hypothesis H1 explains two pieces of evidence, whereas H2 explains only one, then H1 should be preferred to H2. Here are four formulas

given together to ECHO as input:

(EXPLAIN (H1) E1)
 (EXPLAIN (H1) E2)
 (EXPLAIN (H2) E2)
 (CONTRADICT (H1 H2))
 (DATA (E1 E2))

These formulas generate the network pictured in Figure 3, with excitatory links corresponding to coherence represented by solid lines, and with inhibitory links corresponding to incoherence represented by dotted lines. Activation flows from the special unit, whose activation is clamped at 1, to the evidence units, and then to the hypothesis units, which inhibit each other. Because H1 explains more than its competitor H2, H1 becomes active, settling with activation above 0, while H2 is deactivated, settling with activation below 0. (See Section 4.10 for a discussion of the parameters that affect the runs, and the Appendix for sensitivity analyses.) Notice that although the links in ECHO are symmetric, in keeping with the symmetry of the coherence relation, the flow of activation is not, because evidence units get activation first and then pass it along to what explains them.

ECHO's networks have interesting dynamic properties. What happens if new data come in after the network has settled? When ECHO is given the further information that H2 explains additional data E3, E4, and E5, then the network resettles into a reversed state in which H2 is activated and H1 is deactivated. However, if the additional information is only that H2 explains E2, or only that H2 explains E3, then ECHO does not resettle into a state in which H1 and H2

Figure 3. Explanatory breadth. As in Figure 2, solid lines represent excitatory links, whereas dotted line represents inhibitory links. Evidence units E1 and E2 are linked to the special unit. The result of running this network is that H1 defeats H2.

Figure 4. Being explained. H1 defeats H2 because it is explained by H3.

get equal activation. (It does give H1 and H2 equal activation if the input says that they have equal explanatory power from the start.) Thus ECHO displays a kind of conservatism also seen in human scientists. See the discussion of conservatism in Section 10.4.

4.3. Being Explained

Section 4.2 showed how Principle 2(a) leads ECHO to prefer a hypothesis that explains more than its competitors. The same principle also implies greater coherence, other things being equal, for a hypothesis that is explained. Consider the following input:

- (EXPLAIN (H1) E1)
- (EXPLAIN (H1) E2)
- (EXPLAIN (H2) E1)
- (EXPLAIN (H2) E2)
- (EXPLAIN (H3) H1)
- (CONTRADICT H1 H2)
- (DATA (E1 E2))

Figure 4 depicts the network constructed using this input. Here, and in all subsequent figures, the special evidence unit is not shown. In Figure 4, H1 and H2 have the same explanatory breadth, but ECHO activates H1 and deactivates H2 because H1 is explained by H3. ECHO thus gives more activation to a hypothesis that is explained than to a contradictory one that is not explained. If the above formulas did not include a CONTRADICT statement, then no inhibitory links would be formed, so that all units would asymptote with positive activation. Because of the decay parameter, activation is still less than 1: See the equations in the Appendix.

4.4. Refutation

According to Popper (1959), the hallmark of science is not the acceptance of explanatory theories but the rejection of falsified ones. Take the simplest case where a hypothesis H1 explains (predicts) some piece of “negative evidence” NE1, which contradicts data E1. Then E1 becomes active, deactivating NE1 and hence H1. Such straightforward refutations, however, are rare in science. Scientists do not typically give up a promising theory just because it has some empirical problems, and neither does ECHO. If, in addition to explaining NE1, H1 explains some positive pieces of evidence, E2 and E3, then ECHO does not deactivate it. However, an alternative hypothesis H2 that also explains E2 and E3 is preferred to H1, which loses because of NE1. Rejection in science is usually a complex process involving competing hypotheses, not a simple matter of falsification (Lakatos 1970; Thagard 1988a: Ch. 9; Section 10.1 below).

4.5. Unification

The impact of explanatory breadth, being explained, and refutation all arise from Principle 2(a), which says that hypotheses cohere with what they explain. According to Principle 2(b), cohypotheses that explain together cohere with each other. Thus, if H1 and H2 together explain evidence E, then H1 and H2 are linked. This gives ECHO a preference for unified explanations, ones that use a common set of hypotheses rather than having special hypotheses for each piece of evidence explained. Consider this input, which generates the network shown in Figure 5:

- (EXPLAIN (H1 A1) E1)
- (EXPLAIN (H1 A2) E2)
- (EXPLAIN (H2 A3) E1)
- (EXPLAIN (H2 A3) E2)
- (CONTRADICT H1 H2)
- (DATA (E1 E2))

Figure 5. Unification. H2 defeats H1 because it gives a more unified explanation of the evidence.

Although H1 and H2 both explain E1 and E2, the explanation by H2 is more unified in that it uses A3 in both cases. Hence ECHO forms a stronger link between H2 and A3 than it does between H1 and A1 or A2, so H2 becomes activated and H1 is deactivated. The explanations by H2 are not simpler than those by H1, in the sense of Principle 2(c), because both involve two hypotheses. ECHO's preference for H2 over H1 thus depends on the coherence of H2 with its auxiliary hypothesis and the evidence being greater than the coherence of H1 with its auxiliary hypotheses and the evidence. One might argue that the coherence between cohypotheses should be less than the coherence of a hypothesis with what it explains; ECHO contains a parameter that can allow the weights between cohypothesis units to be less than the weight between a hypothesis unit and an evidence unit.

4.6. Simplicity

According to Principle 2(c), the degree of coherence of a hypothesis with what it explains and with its cohypotheses is inversely proportional to the number of cohypotheses. An example of ECHO's preference for simple hypotheses derives from the input:

(EXPLAIN (H1) E1)
 (EXPLAIN (H2 H3) E1)
 (CONTRADICT H1 H2)
 (DATA (E1))

Here H1 is preferred to H2 and H3 because it accomplishes the explanation with no cohypotheses. The generated network is shown in Figure 6.

Principle 2(c) is important for dealing with *ad hoc* hypotheses that are introduced only to save a hypothesis from refutation. Suppose that H1 is in danger of refutation because it explains negative evidence NE1, which contradicts evidence E1. One might try to save H1 by concocting an auxiliary hypothesis, H2, which together with H1 would explain E1. Such maneuvers are common in science: Nineteenth-century physicists did not abandon Newtonian mechanics because it gave false predictions concerning the motion of Uranus; instead, they hypothesized the existence of another planet, Neptune, to explain the discrepancies. Neptune, of course, was eventually observed, but we need to be able to discount auxiliary hypotheses that do not contribute to any additional explanations. Because the expla-

Figure 6. Simplicity. H1 defeats H2 because it gives a simpler explanation of the evidence.

nation of E1 by H1 and H2 is less simple than the explanation of NE1 by H1, the *ad hoc* maneuver does not succeed in saving H1 from deactivation.

4.7. Analogy

According to Principle 3(a), analogous hypotheses that explain analogous evidence are coherent with each other. Figure 7 shows relations of analogy, derived from the input:

(EXPLAIN (H1) E1)
 (EXPLAIN (H2) E1)
 (EXPLAIN (H3) H3)
 (ANALOGOUS (H2 H3) (E1 E3))
 (CONTRADICT H1 H2)
 (DATA (E1 E3))

The analogical links corresponding to the coherence relations required by Principle 3 are shown by wavy lines. Running this example leads to activation of H2 and deactivation of its rival, H1. Figures 3–7 show consilience, simplicity, and analogy operating independently of each other, but in realistic examples these criteria can all operate simultaneously through activation adjustment. Thus ECHO shows how criteria such as explanatory breadth, simplicity, and analogy can be integrated. My most recent account of inference to the best explanation (Thagard 1988a) included a computational model that

Figure 7. Analogy. The wavy lines indicate excitatory links based on analogies. H2 defeats H1 because the explanation it gives is analogous to the explanation afforded by H3.

Figure 8. Downplaying of evidence. E5 is deactivated, even though it is an evidence unit, because it coheres only with inferior hypotheses.

integrated breadth and simplicity but left open the question of how to tie in analogy. Principle 3 and ECHO show how analogy can participate with consilience and simplicity in contributing explanatory power.

4.8. Evidence

Principle 4 asserts that data get priority by virtue of their independent coherence. But it should nevertheless be possible for a data unit to be deactivated. We see this both in the everyday practice of experimenters, in which it is often necessary to discard some of the data because they are deemed unreliable (Hedges 1987), and in the history of science where evidence for a discarded theory sometimes falls into neglect (Laudan 1976). Figure 8, which derives from the following input, shows how this might happen.

(EXPLAIN (H1) E1)
 (EXPLAIN (H2) E2)
 (EXPLAIN (H1) E3)
 (EXPLAIN (H1) E4)
 (EXPLAIN (H2) E2)
 (EXPLAIN (H2) E5)
 (EXPLAIN (H3) E3)
 (EXPLAIN (H3) E5)
 (EXPLAIN (H4) E4)
 (EXPLAIN (H4) E5)
 (CONTRADICT H1 H2)
 (CONTRADICT H1 H3)
 (CONTRADICT H1 H4)

These inputs lead to the deactivation of E5, dragged down by the deactivation of the inferior hypotheses H3, H4, and H5. Because E5 coheres only with propositions that are themselves unac-

ceptable, it becomes unacceptable too. Because H1 has four excitatory links, it easily deactivates the other three hypotheses, and their negative activation brings down the initially positive activation of E5 into the negative range.

Principle 6(b) also concerns evidence, undermining the acceptability of hypotheses that explain only a small part of the relevant data. Accordingly, ECHO automatically increases the value of a decay parameter in proportion to the ratio of unexplained evidence to explained evidence (see Appendix). A hypothesis that explains only a fraction of the relevant evidence will thus decay toward the beginning activation level of 0 rather than become activated.

4.9. Acceptability and System Coherence

If ECHO is taken as an algorithmic implementation of the first five principles of explanatory coherence, then it validates Principle 6, Acceptability, for it shows that holistic judgments of the acceptability of a proposition can be based solely on pairwise relations of coherence. A unit achieves a stable activation level merely by considering the activation of units to which it is linked and the weights on those links. Asymptotic activation values greater than 0 signify acceptance of the proposition represented by the unit, whereas negative values signify rejection.

ECHO also validates Principle 7, System Coherence, because we can borrow from connectionist models a measure H of the global coherence of a whole system of propositions at time t :

$$H(t) = \sum_i \sum_j w_{ij} a_i(t) a_j(t). \quad (1)$$

In this equation, w_{ij} is the weight from unit i to unit j , and $a_i(t)$ is the activation of unit i at time t . This measure or its inverse has been variously called the “goodness,” “energy,” or “harmony” of the network (Rumelhart et al. 1986, vol. 2, p. 13). For historical reasons, I prefer a variant of the last term with the alternative spelling “harmony” (Harman 1973). Thus ECHO stands for “Explanatory Coherence by Harmony Optimization.”

Equation 1 says that to calculate the harmony of the network, we consider each pair of units a_i and a_j that are linked with weight w_{ij} . Harmony increases, for example, when two units with high activation have a link between them with high weight, or when a unit with high activation and a unit with negative activation have between

them a link with negative weight. In ECHO the harmany of a system of propositions increases, other things being equal, with increases in the number of data units, the number of links, and the number of cycles to update activations to bring them more in line with the weights.

4.10. Parameters

The simulations just described depend on program parameters that give ECHO numerous degrees of freedom, some of which are epistemologically interesting. In the example in Section 4.2 (Figure 3), the relation between excitatory weights and inhibitory weights is crucial. If inhibition is low compared to excitation, then ECHO will activate both H1 and H2, because the excitation that H2 gets from E1 will overcome the inhibition it gets from H1. Let the *tolerance* of the system be the absolute value of the ratio of excitatory weight to inhibitory weight. With high tolerance, the system will entertain competing hypotheses. With low tolerance, winning hypotheses deactivate the losers. Typically, ECHO is run with excitatory weights set at .05 and inhibition at $-.2$, so tolerance is .25. If tolerance is high, ECHO can settle into a state where two contradictory hypotheses are both activated. ECHO performs well using a wide range of parameters (see the sensitivity analyses in the Appendix).

Other parameters establish the relative importance of simplicity and analogy. If H1 explains E1 by itself, then the excitatory link between H1 and E1 has the default weight .05. But if H1 and H2 together explain E1, then the weight of the links is set at the default value divided by 2, the number of cohypotheses, leaving it at .025. If we want to change the importance of simplicity as incorporated in Principle 2(c), however, then we can raise the number of cohypotheses to an exponent that represents the *simplicity impact* of the system. Equation 3 for doing this is given in the algorithm section of the Appendix. The greater the simplicity impact, the more weights will be diminished by having more cohypotheses. Similarly, the weights established by analogy can be affected by a factor representing *analogy impact*. If this is 1, then the links connecting analogous hypotheses are just as strong as those set up by simple explanations, and analogy can have a very large effect. If, on the other hand, analogy impact is set at 0, then analogy has no effect.

Another important parameter of the system is decay rate, represented by θ (see equation 4 in

the Appendix). We can term this the *skepticism* of the system, because the higher it is, the more excitation from data will be needed to activate hypotheses. If skepticism is very high, then *no* hypotheses will be activated. Whereas tolerance reflects ECHO's view of contradictory hypotheses, skepticism determines its treatment of all hypotheses. Principle 6(b) can be interpreted as saying that if there is much unexplained evidence, then ECHO's skepticism level is raised.

Finally, we can vary the priority of the data by adjusting the weights to the data units from the special unit. *Data excitation* is a value from 0 to 1 that provides these weights. To reflect the scientific practice of not treating all data equally seriously, it is also possible to set the weights and initial activations for each data unit separately. If data excitation is set low, then, contrary to Section 4.2, new evidence for a rejected hypothesis will not lead to its adoption. If data excitation is high, then, contrary to Section 4.8, evidence that supports only a bad hypothesis will not be thrown out.

With so many degrees of freedom, which are typical of connectionist models, one might question the value of simulations, as it might seem that any desired behavior whatsoever could be obtained. However, if a fixed set of default parameters applies to a large range of cases, then the arbitrariness is much diminished. In *all* the computer runs reported in this paper, ECHO has had excitation at .05, inhibition at $-.2$ (so tolerance is .25), data excitation at .1, decay (skepticism) at .05, simplicity impact at 1, and analogy impact at 1. As reported in the Appendix in the section on sensitivity analyses, there is nothing special about the default values of the parameters: ECHO works over a wide range of values. In a full simulation of a scientist's cognitive processes, we could imagine better values being *learned*. Many connectionist models do not take weights as given, but instead adjust them as the result of experience. Similarly, we can imagine that part of a scientist's training entails learning how seriously to take data, analogy, simplicity, and so on. Most scientists get their training not merely by reading and experimenting on their own but also by working closely with scientists already established in their field; hence, a scientist can pick up the relevant values from advisors. In ECHO they are set by the programmer, but it should be possible to extend the program to allow training from examples.

The examples described in this section are trivial and show merely that ECHO has some desired properties. I shall now show that ECHO

Table 1: Input Propositions for Lavoisier (1862) Example

<i>Evidence</i>	
(proposition 'E1	"In combustion, heat and light are given off.")
(proposition 'E2	"Inflammability is transmittable from one body to another.")
(proposition 'E3	"Combustion only occurs in the presence of pure air.")
(proposition 'E4	"Increase in weight of a burned body is exactly equal to weight of air absorbed.")
(proposition 'E5	"Metals undergo calcination.")
(proposition 'E6	"In calcination, bodies increase weight.")
(proposition 'E7	"In calcination, volume of air diminishes.")
(proposition 'E8	"In reduction, effervescence appears.")
<i>Oxygen hypotheses</i>	
(proposition 'OH1	"Pure air contains oxygen principle.")
(proposition 'OH2	"Pure air contains matter of fire and heat.")
(proposition 'OH3	"In combustion, oxygen from the air combines with the burning body.")
(proposition 'OH4	"Oxygen has weight.")
(proposition 'OH5	"In calcination, metals add oxygen to become calxes.")
(proposition 'OH6	"In reduction, oxygen is given off.")
<i>Phlogiston hypotheses</i>	
(proposition 'PH1	"Combustible bodies contain phlogiston.")
(proposition 'PH2	"Combustible bodies contain matter of heat.")
(proposition 'PH3	"In combustion, phlogiston is given off.")
(proposition 'PH4	"Phlogiston can pass from one body to another.")
(proposition 'PH5	"Metals contain phlogiston.")
(proposition 'PH6	"In calcination, phlogiston is given off.")

can handle some much more substantial examples from the history of science and from recent legal deliberations.

5. Applications of ECHO to Scientific Reasoning

Theories in the philosophy of science, including computational ones, should be evaluated with respect to important cases from the history of science. To show the historical application of the theory of explanatory coherence, I shall discuss two important cases of arguments concerning the best explanation: Lavoisier's argument for his oxygen theory against the phlogiston theory, and Darwin's argument for evolution by natural selection. ECHO has also been applied to the following:

- Contemporary debates about why the dinosaurs became extinct (Thagard 1988b);
- Arguments by Wegener and his critics for and against continental drift (Thagard and Nowak 1988; 1990);
- Psychological experiments on how beginning students learn physics (Ranney and Thagard 1988); and
- Copernicus's case against Ptolemaic astronomy (Nowak and Thagard 1992).

Additional applications are currently under development.

5.1. Lavoisier

In the middle of the eighteenth century, the dominant theory in chemistry was the phlogiston theory of Stahl, which provided explanations of important phenomena of combustion, respiration, and calcination (what we would now call oxidation). According to the phlogiston theory, combustion takes place when phlogiston in burning bodies is given off. In the 1770s, Lavoisier developed the alternative theory that combustion takes place when burning bodies combine with oxygen from the air (for an outline of the conceptual development of his theory, see Thagard 1990). More than ten years after he first suspected the inadequacy of the phlogiston theory, Lavoisier mounted a full-blown attack on it in a paper called "Réflexions sur le Phlogistique" (Lavoisier 1862).

Tables 1 and 2 present the input given to ECHO to represent Lavoisier's argument in his 1783 polemic against phlogiston. Table 1 shows the eight propositions used to represent the evidence to be explained and the twelve used to represent the competing theories. The evidence concerns different properties of combustion and calcination, while there are two sets

of hypotheses representing the oxygen and phlogiston theories, respectively. These propositions do not capture Lavoisier's argument completely but do recapitulate its major points. (In a slightly more complicated simulation not presented here, I have encoded the attempt by the phlogiston theory to explain the increase in weight in combustion and calcination by the supposition that phlogiston has negative weight; Lavoisier argues that this supposition renders the phlogiston theory internally contradictory, because phlogiston theorists sometimes assumed that phlogiston has positive weight.)

Table 2 shows the part of the input that sets up the network used to make a judgment of explanatory coherence. The "explain" statements are based directly on Lavoisier's own assertions about what is explained by the phlogiston theory and the oxygen theory. The "contradict" statements reflect my judgment of which of the oxygen hypotheses conflict directly with which of the phlogiston hypotheses.

These explanations and contradictions generate the network partially portrayed in Figure 9. Excitatory links, indicating that two propositions cohere, are represented by solid lines. Inhibitory links are represented by dotted lines. All the oxygen hypotheses are arranged along the top line and all the phlogiston hypotheses along the bottom, with the evidence in the middle. Omitted from the figure for the sake of legibility are the excitatory links among the hypotheses of the two theories and the links between the evi-

Figure 9. Network representing Lavoisier's (1862) argument. E1–E8 are evidence units. OH1–OH6 are units representing hypotheses of the oxygen theory; PH1–PH6 represent the phlogiston hypotheses. Solid lines are excitatory links; dotted lines are inhibitory.

dence units and the special unit. In addition to its displayed links to evidence, OH1 has excitatory links to OH2, OH3, OH4, OH5, and OH6. The link between OH1 and OH3 is particularly strong, because these two hypotheses participate in three explanations together. Figure 10, produced by a graphics program that runs with ECHO, displays the links to OH3, with excitatory links shown by thick lines and the inhibitory link with PH3 shown by a thin line. The numbers on the lines indicate the weights of the links rounded to three decimal places: In accord with Principle 2(c), weights are different from the default weight of .05 whenever multiple hypotheses are used in an explanation. If the hypotheses participate in only one explanation, then the weight between them is equal to the default excitation divided by the number of hypotheses; but weights are additive, so that the weight is increased if two hypotheses participate in more than one explanation. For example, the link between OH3 and E1 has the weight .017 (.0166666 rounded), because the explanation of E1 by OH3 required two additional hypotheses. The weight between OH3 and OH1 is .058 (.025 + .0166666 + .0166666), because the two of them alone explain E3, and together they explain E1 and E4 along with a third hypothesis in each case. OH1 and OH3 are thus

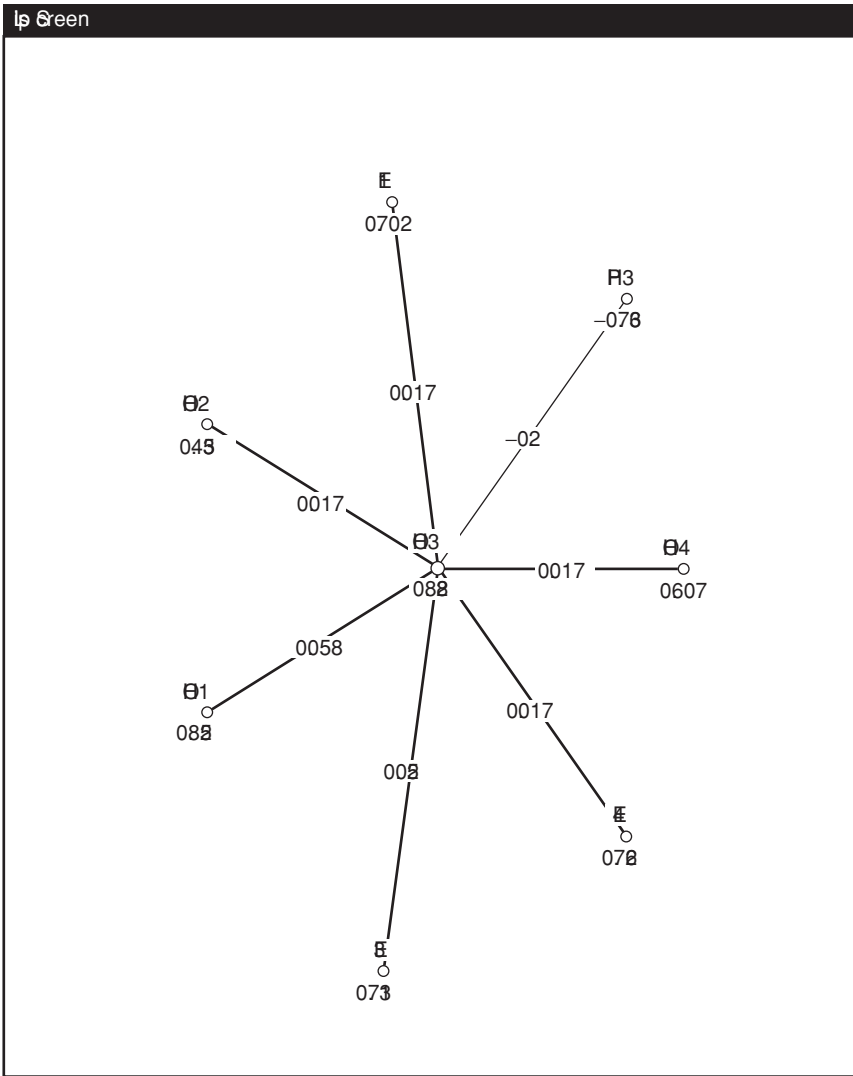

Figure 10. Connectivity of oxygen theory unit OH3. The numbers under the units are their activation values after the unit has settled. Thick lines indicate excitatory links; thin line indicates inhibitory link. Numbers on the lines indicate the weights on the links.

highly coherent with each other by virtue of being used together in multiple explanations.

The numbers beneath the names in Figure 10 indicate the final activation of the named units, rounded to three decimal places. When ECHO runs this network, starting with all hypotheses at activation .01, it quickly favors the oxygen hypotheses, giving them activations greater than 0. In contrast, all the phlogiston hypotheses become deactivated. The activation history of the propositions is shown in Figure 11, which charts activation as a function of the number of cycles of updating. Figure 11 shows graphs,

produced automatically during the run of the program, of the activations of all the units over the 107 cycles it takes them to reach asymptote. In each graph, the horizontal line indicates the starting activation of 0 and the y axis shows activation values ranging between 1 and -1. Notice that the oxygen hypotheses OH1–OH6 rise steadily to their asymptotic activations, while PH3 and PH6, which directly contradict oxygen hypotheses, sink to activation levels well below 0. The other phlogiston hypotheses that are not directly contradicted by oxygen hypotheses start out with positive activation but are

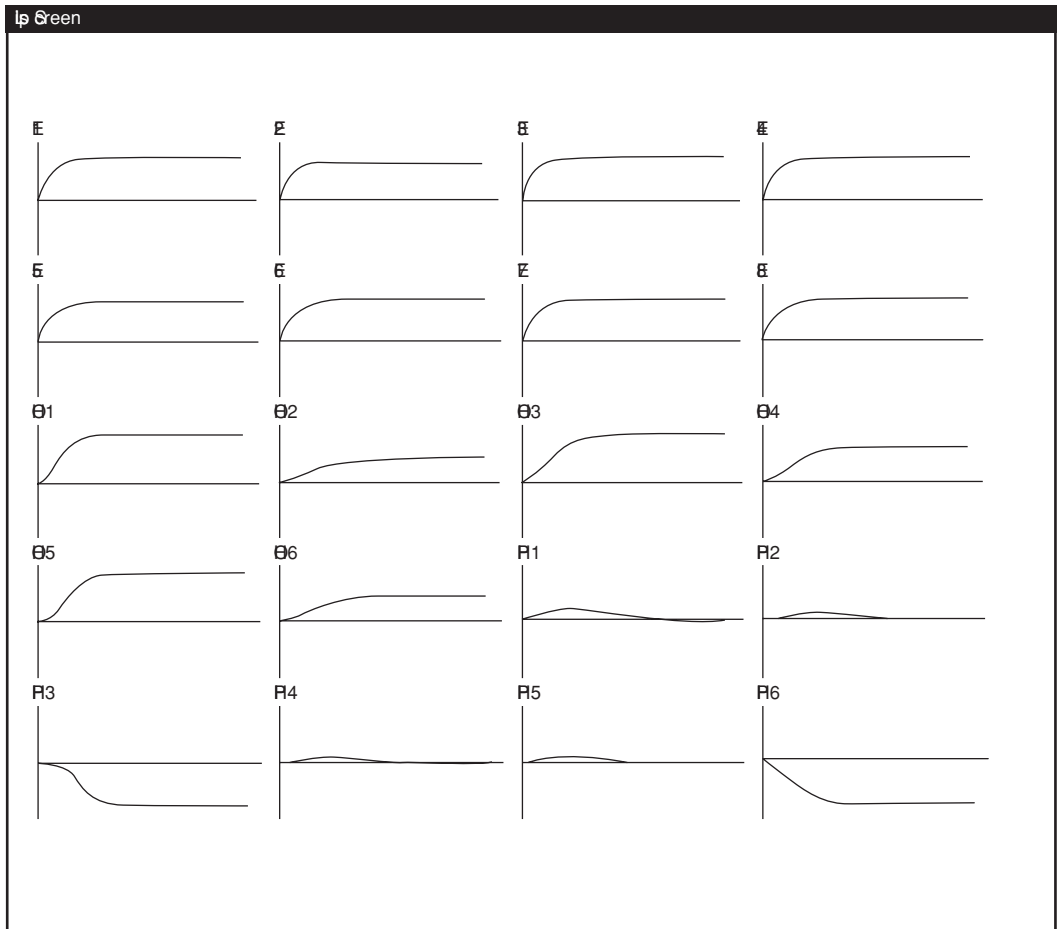

Figure 11. Activation history of Lavoisier (1862) network. Each graph shows the activation of a unit over 107 cycles of updating, on a scale of -1 to 1 , with the horizontal line indicating the initial activation of 0 .

dragged down toward 0 through their links with their deactivated cohypotheses. Thus the phlogiston theory fails as a whole.

This run of ECHO is biased toward the oxygen theory because it was based on an analysis of Lavoisier's argument. We would get a different network if ECHO were used to model critics of Lavoisier such as Kirwan (1789/1968), who defended a variant of the phlogiston theory. By the late 1790s, the vast majority of chemists and physicists, including Kirwan, had accepted Lavoisier's arguments and rejected the phlogiston theory, a turnaround contrary to the suggestion of Kuhn (1970) that scientific revolutions occur only when proponents of an old paradigm die off.

Lavoisier's argument represents a relatively simple application of ECHO, showing two sets of hypotheses competing to explain the evi-

dence. But more complex explanatory relations can also be important. Sometimes a hypothesis that explains the evidence is itself explained by another hypothesis. Depending on the warrant for the higher-level hypothesis, this extra explanatory layer can increase acceptability: A hypothesis gains from being explained as well as by explaining the evidence. The Lavoisier example does not exhibit this kind of coherence, because neither Lavoisier nor the phlogiston theorists attempted to explain their hypotheses using higher-level hypotheses; nor does the example display the role that analogy can play in explanatory coherence.

5.2. Darwin

Both these aspects – coherence based on being explained and on analogy – were important in

Table 3: Explanations and Contradictions for Darwin (1962) Example

<i>Darwin's evidence</i>	
(proposition 'E1	"The fossil record contains few transitional forms.")

(proposition 'E6	"Once extinct, species do not reappear.")
(proposition 'E7	"Forms of life change almost simultaneously around the world.")
(proposition 'E8	"Extinct species are similar to each other and to living forms.")
(proposition 'E9	"Barriers separate similar species.")
(proposition 'E10	"Related species are concentrated in the same areas.")
(proposition 'E11	"Oceanic islands have few inhabitants, often of peculiar species.")
(proposition 'E12	"Species show systematic affinities.")
(proposition 'E13	"Different species share similar morphology.")
(proposition 'E14	"The embryos of different species are similar.")
(proposition 'E15	"Animals have rudimentary and atrophied organs.")
<i>Darwin's main hypotheses</i>	
(proposition 'DH1	"Organic beings are in a struggle for existence.")
(proposition 'DH2	"Organic beings undergo natural selection.")
(proposition 'DH3	"Species of organic beings have evolved.")
<i>Darwin's auxiliary hypotheses</i>	
(proposition 'DH4	"The geological record is very imperfect.")
(proposition 'DH5	"There are transitional forms of complex organs.")
(proposition 'DH6	"Mental qualities vary and are inherited.")
<i>Darwin's facts</i>	
(proposition 'DF1	"Domestic animals undergo variation.")
(proposition 'DF2	"Breeders select desired features of animals.")
(proposition 'DF3	"Domestic varieties are developed.")
(proposition 'DF4	"Organic beings in nature undergo variation.")
(proposition 'DF5	"Organic beings increase in population at a high rate.")
(proposition 'DF6	"The sustenance available to organic beings does not increase at a high rate.")
(proposition 'DF7	"Embryos of different domestic varieties are similar.")
<i>Creationist hypothesis</i>	
(proposition 'CH1	"Species were separately created by God.")

Darwin's argument for his theory of evolution by natural selection (Darwin 1962). His two most important hypotheses were:

DH2 – Organic beings undergo natural selection.

DH3 – Species of organic beings have evolved.

These hypotheses together enabled him to explain a host of facts, from the geographical distribution of similar species to the existence of vestigial organs. Darwin's argument was explicitly comparative: There are numerous places in the *Origin* where he points to phenomena that his theory explains but that are inexplicable on the generally accepted rival hypothesis that species were separately created by God.

Darwin's two main hypotheses were not simply cohypotheses, however, for he also used

DH2 to explain DH3! That is, natural selection explains why species evolve: If populations of animals vary, and natural selection picks out those with features well adapted to particular environments, then new species will arise. Moreover, he offers a Malthusian explanation for why natural selection occurs as the result of the geometrical rate of population growth contrasted with the arithmetical rate of increase in land and food. Thus Malthusian principles explain why natural selection takes place, which explains why evolution occurs, and natural selection and evolution together explain a host of facts better than the competing creation hypothesis does.

The full picture is even more complicated than this, for Darwin frequently cites the analogy between artificial and natural selection as

evidence for his theory. He contends that just as farmers are able to develop new breeds of domesticated animals, so natural selection has produced new species. He uses this analogy not simply to defend natural selection, but also to help in the explanations of the evidence: Particular explanations using natural selection incorporate the analogy with artificial selection. Finally, to complete the picture of explanatory coherence that the Darwin example offers, we must consider the alternative theological explanations that were accepted by even the best scientists before Darwin proposed his theory.

Analysis of *On the origin of species* suggests the 15 evidence statements shown in Table 3. Statements E1-E4 occur in Darwin's discussion of objections to his theory; the others are from the later chapters where he argues positively for his theory. Table 3 also shows Darwin's main hypotheses. DH2 and DH3 are the core of the theory of evolution by natural selection, providing explanations of its main evidence, E5-E15. DH4-DH6 are auxiliary hypotheses that Darwin uses in resisting objections based on E1-E3. He considers the objection concerning the absence of transitional forms to be particularly serious, but explains it away by saying that the geological record is so imperfect that we should not expect to find fossil evidence of the many intermediate species his theory requires. Darwin's explanations also use a variety of facts he defends with empirical arguments that would complicate the current picture too much to present here. Hence, I will treat them (DF1-DF7) simply as pieces of evidence that do not need explanatory support. The creationist opposition frequently mentioned by Darwin is represented by the single hypothesis that species were separately created by God.

Table 4 shows the explanation and contradiction statements that ECHO uses to set up its network, which is partially displayed in Figure 12. Notice the hierarchy of explanations, with the high rate of population increase explaining the struggle for existence, which explains natural selection, which explains evolution. Natural selection and evolution together explain many pieces of evidence. The final component of Darwin's argument is the analogy between natural and artificial selection. The wavy lines represent excitatory links based on analogy. Just as breeders' actions explain the development of domestic varieties, so natural selection explains the evolution of species. At another level, Darwin sees an embryological analogy. The embryos of different

domestic varieties are quite similar to each other, which is explained by the fact that breeders do not select for properties of embryos. Similarly, nature does not select for most properties of embryos, which explains the many similarities between embryos of different species.

Darwin's discussion of objections suggests that he thought creationism could naturally explain the absence of transitional forms and the existence of complex organs and instincts. Darwin's argument was challenged in many ways, but based on his own view of the relevant explanatory relations, at least, the theory of evolution by natural selection is far more coherent

Figure 12. Network representing Darwin's (1962) argument. E1–E15 are evidence units. DH2 represents natural selection, and DH3 represents evolution of species. These defeat CH1, which represents the hypothesis that species were independently created. Solid lines are excitatory links; dotted line is inhibitory.

than the creation hypothesis. Creationists, of course, would marshal different arguments.

For clarity, Figure 12 omits the links from DH2 to all the evidence propositions besides E5, and the links from DH2 and DH3 to DH4, DH5, and DH6. Figure 13 shows the actual connectivity of DH3. Running ECHO to adjust the network to maximize harmony produces the expected result: Darwin's hypotheses are all activated, whereas the creation hypothesis is deactivated. In particular, the hypothesis DH3 – that species evolved – reaches an asymptote at .921, while the creation hypothesis, CH1, declines to $-.491$. DH3 accrues activation in three ways. It gains activation from above, from being explained by natural selection, which is derived from the struggle for existence, and from below, by virtue of the many pieces of evidence

it helps to explain. In addition, it receives activation by virtue of the sideways, analogy-based links with explanations using artificial selection. Figure 14 graphs the activation histories of most of the units over the 70 cycles it takes them to settle. Note that the creationist hypothesis, CH1, initially gets activation by virtue of what it explains, but is driven down by the rise of DH3, which contradicts it.

The Lavoisier and Darwin examples show that ECHO can handle very complex examples of actual scientific reasoning. One might object that in basing ECHO analyses on written texts, I have been modeling the rhetoric of the scientists, not their cognitive processes. Presumably, however, there is some correlation between what we write and what we think. ECHO could be equally well applied to explanatory relations

Figure 13. Connectivity of unit DH3 in the Darwin network. The numbers under the units are their activation values after the unit has settled. Thick lines indicate excitatory links; thin line indicates inhibitory link. Numbers on the lines indicate the weights on the links.

that were asserted in the heat of verbal debate among scientists. Ranney and Thagard (1988) describe ECHO's simulation of naive subjects learning physics, where the inputs to ECHO were based on verbal protocols.

6. Applications of ECHO to Legal Reasoning

Explanatory coherence is also important for some kinds of legal reasoning. Most discussions of legal reasoning concern either deductive inference, in which legal principles, rules, or statutes are applied to particular cases, or analogical inference, in which past cases are used as prece-

denents to suggest a decision in a current case (Carter 1984; Gardner 1987; Golding 1984). Recently, however, some attention has been paid to the role of explanatory inferences in legal reasoning (Hanan 1987; Pennington and Hastie 1986, 1987). These researchers are concerned primarily with inferences made by juries about factual, rather than legal, questions. In murder trials, for example, juries can be called upon to infer what happened, choosing between contradictory accounts provided by the prosecution and the defense. To get a conviction on a first-degree murder charge, the prosecution must show (1) that the accused killed the victim and (2) that the accused did so with a previously

Figure 14. Activation history of the Darwin network. Each graph shows the activation of a unit over 49 cycles of updating, on a scale of -1 to 1 , with the horizontal line indicating the initial activation of 0 .

formed purpose in mind. The first proposition must account for much of the evidence; the second provides one possible explanation of the first. The defense may try to defend alternative hypotheses, such as that someone else killed the victim or that the accused acted in self-defense and therefore is innocent, or that the accused acted in the heat of the moment and is therefore guilty only of manslaughter. The defense need not provide an alternative explanation of the killing, but may undermine the explanatory coherence of the prosecution's account by providing alternative interpretations of key testimony. For example, in the Peyer murder trial discussed below, the defense tried to discredit two impor-

tant witnesses for the prosecution who had come forward just before the trial (a year after the killing) by saying that they were merely seeking publicity and had not seen what they claimed.

In terms of my theory of explanatory coherence and ECHO, we can think of the prosecution and defense as advocating incompatible ways of explaining the evidence. But, as in scientific reasoning, explanatory inference in the legal domain is not simply a matter of counting which of two hypotheses explains the most pieces of evidence. More complicated organizations of hypotheses and evidence will often arise. The hypothesis that the accused intended to kill the victim will be more plausible if we can

Table 5: Input Propositions for Chambers Case

Evidence

(proposition 'E0	"L died.")

Source: Data gathered from daily reports in the *New York Times* over a three-month period in 1988; see also Taubman (1988).

explain why the accused had it in for the victim, say, because of a previous altercation. Analogy can also play a role: Pennington and Hastie (1986, p. 254) report that jurors sometimes evaluate the plausibility of explanations by considering how *they* would act in analogous situations. For example, a juror might reason, "If the victim had done to me what he did to the accused, then I would be angry and would want to get back at him, so maybe the accused did intend to kill the victim." Explanatory inferences can also be relevant to evaluating the testimony of a witness. If a witness who was a good friend of the accused says they were together at the time of the murder, the jury has to decide whether

the best explanation of the witness's utterance is that (1) the witness really believed it or (2) the witness was lying to protect the accused.

The plausibility of a theory of explanatory coherence for legal reasoning depends on its application to real cases. ECHO has been used to model reasoning in two recent murder trials: the "preppy" murder trial in which Robert Chambers was accused of murdering Jennifer Levin in New York City and the San Diego trial in which Craig Peyer was accused of murdering Cara Knott. In both cases, there were no witnesses to the killing, so the juries had to infer on the basis of circumstantial evidence what actually happened.

6.1. Chambers

On August 26, 1986, Robert Chambers, by his own admission, killed Jennifer Levin in Central Park after the two had left a bar together. He maintained, however, that the killing was accidental, occurring when he struck her by reflex when she hurt him during rough sex. The prosecution maintained, in contrast, that he had killed her intentionally during a violent struggle. The

trial took place in the first three months of 1988 and was extensively reported in the press. The following ECHO analysis is based on daily reports in the *New York Times* that described the major testimony and arguments. This information is, of course, not nearly as complete as that presented in the courtroom itself, but it suffices for displaying the structure of a very complex explanatory inference (see also Taubman 1988).

The input to ECHO is shown in Tables 5 and 6. G1–G7 are hypotheses used by the prosecution to argue for Chambers's guilt, whereas I1–I8 present a very different explanatory account that supports his innocence. Figure 15 shows part of the network produced by this input, with excitatory links shown by solid lines and inhibitory ones shown by dotted lines (NE4 and NE9 are omitted to relieve crowding). The evidence propositions E0–E16 are indicated by number alone. Notice the layers of explanations: I3 explains I4, which explains I1, which explains E4. The prosecution's case does a better job of explaining the physical evidence using hypotheses concerning a struggle and a strangling. I have included two units, G6 and G7, to represent the question of Chambers's intent, which is crucial for deciding whether he is guilty of second-degree murder (he intended to kill her) or manslaughter (he intended merely to hurt her).

Running the network produces a clear win for G1, the main hypothesis implying Chambers's guilt. Figure 16 shows the links to G1 and the asymptotic activation of the units linked to it. Figure 17 displays the activation histories of all the units over 80 cycles. In the actual trial, the jury never got a chance to finish deciding the second-degree murder charge because a manslaughter plea-bargain was arranged during their deliberations. One important aspect that is not directly displayed in this simulation is the notion of determining guilt "beyond a reasonable doubt." Perhaps hypotheses concerning innocence should receive special activation so that hypotheses concerning guilt have to be very well supported to overcome them. Alternatively, we could require a high tolerance level so that guilt hypotheses would only be able to deactivate innocence hypotheses that were markedly inferior.

6.2. Peyer

Let us now consider another recent trial, where the evidence was less conclusive. Cara Knott was killed on December 27, 1986, and Craig Peyer,

Figure 15. Network representing the Chambers trial. 1–16 are evidence units. G1–G7 represent hypotheses concerning Chambers’s guilt; I1–I8 represent his innocence. Solid lines are excitatory links; dotted lines are inhibitory.

a veteran California Highway Patrolman, was accused. Twenty-two women, young and attractive like the victim, testified that they had been pulled over by Peyer for extended personal conversations near the stretch of road where Knott’s body was found. The trial in San Diego ended February 27, 1988, and ECHO analysis is based on very extensive coverage (two full pages) that appeared the next day in the *San Diego Union* and the *San Diego Tribune*.

Tables 7 and 8 show the inputs to ECHO representing the evidence, hypotheses, and explanatory and contradictory statements in the Peyer trial. As in the Chambers representation, the G propositions are hypotheses concerning Peyer’s guilt, whereas the I propositions concern his innocence. The prosecution can be understood as arguing that the hypothesis that Peyer killed Knott is the best explanation of the evidence, whereas the defense contends that the evidence does not support that claim beyond a reasonable doubt. Figure 18 shows the network ECHO sets up using the input given to it. Figure 19 shows

the connectivity of the unit G1 along with the asymptotic activation of units linked to it, and Figure 20 graphs the activation histories of most of the units, omitting E1 and E2 for lack of space.

Peyer’s trial ended in a hung jury, with seven jurors arguing for conviction on the second-degree murder charge and five arguing against it; the case is being retried. Figure 20 shows that ECHO finds more explanatory coherence in the guilt hypotheses than in the innocence hypotheses, although the activation of some of the I units shows that, in part, the defense had a more convincing case. Why, then, were some jurors reluctant to convict? It could, in part, be the question of establishing guilt beyond a reasonable doubt. The sensitivity analyses reported in the Appendix (see Table 11) show that ECHO rejects the hypothesis of Peyer’s innocence much less strongly than it rejects the hypothesis of Chambers’s innocence. With greater tolerance accruing from somewhat higher excitation or lower inhibition, the unit representing Peyer’s innocence is not deactivated.

Figure 16. Connectivity of the unit G1, representing the claim that Chambers strangled Levin. The numbers under the units are their activation values after the unit has settled. Thick lines indicate excitatory links; thin lines indicate inhibitory links. Numbers on the lines indicate the weights on the links.

It is also possible that matters extraneous to explanatory coherence were playing the key role in convincing some of the jurors against conviction. One juror was quoted as saying that a California Highway Patrolman with 13 years of service could never have committed a murder. This line of reasoning is represented partially by I8, which in the above simulation is swamped by G1, but a juror could give E17 (Peyer's spotless record) such a high priority that I8 could defeat G1. The simulation here is not claimed to handle all the factors that doubtless go into real jurors' decisions: "I could tell he was lying because he

had shifty eyes," "The defense lawyer was such a nice man," "If he wasn't guilty of this, he was guilty of something else just as bad," and so on. But ECHO successfully handles a large part of the evidence and hypotheses in these two complex cases of legal reasoning.

7. Limitations of ECHO

It is important to appreciate what ECHO cannot do as well as what it can. The major current limitation of ECHO is that the input propositions, explanation statements, and contradiction

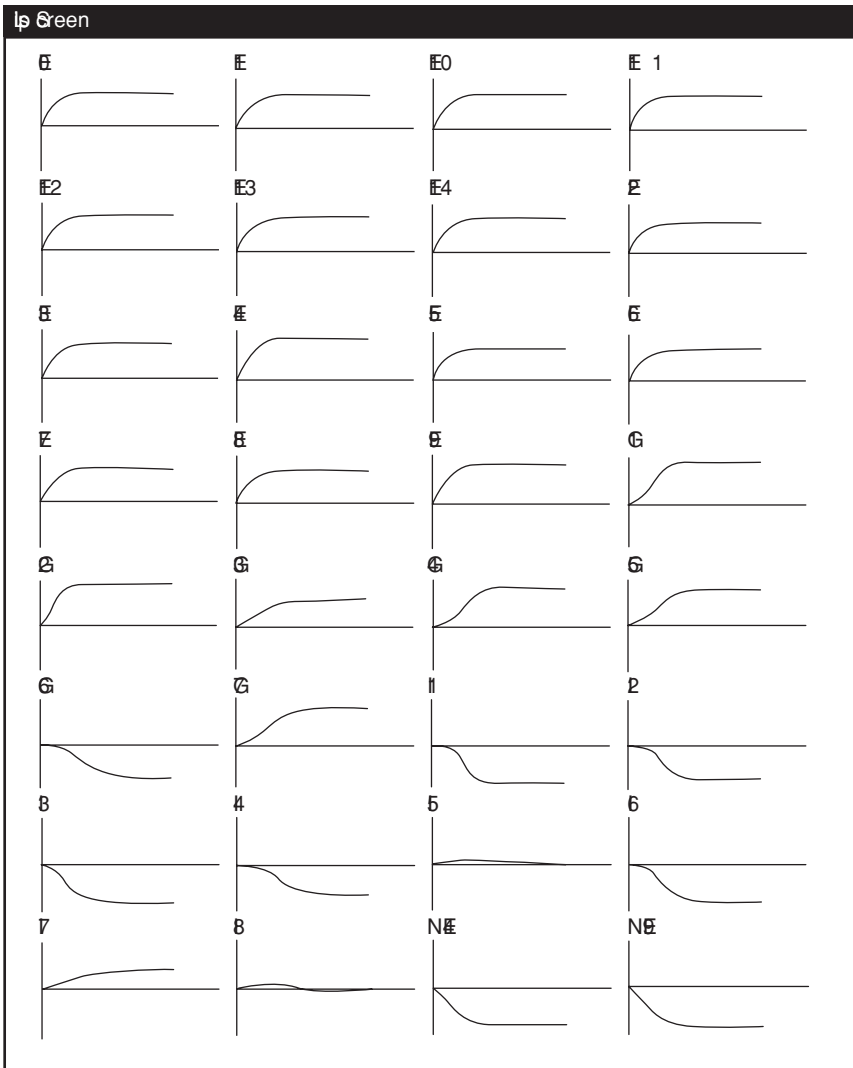

Figure 17. Activation history of the Chambers network. Each graph shows the activation of a unit over 59 cycles of updating, on a scale of -1 to 1 , with the horizontal line indicating the initial activation of 0 .

statements are constructed by the programmer. How arbitrary are these encodings? Several different people have successfully done ECHO analyses, on more than a dozen disparate cases. In all four of the examples presented in this paper, virtually no adjustment of input was required to produce the described runs. We have not yet done the experiment of having several people analyze the same case and assessing the inter-coder reliability, however. We can nevertheless maintain that the representations are not arbitrary thought experiments, because they are derived from scientific texts, newspaper reports of trials, and subject protocols.

ECHO's scope is not universal: Not every case of reasoning can be analyzed for ECHO's application. In doing our analyses, we try to restrict the EXPLAIN statements to cases where there is a causal relation. A research assistant attempted to use ECHO to analyze arguments in this journal for and against parapsychology (Rao and Palmer 1987; Alcock 1987), but concluded that ECHO was not appropriate. This debate largely concerns the reliability of parapsychological experiments, and ECHO is not a data analyzer. ECHO would be appropriate for this case only if there were a general parapsychological theory whose explanatory coherence could be evaluated. The

general conclusion of Rao and Palmer is that parapsychological experiments are not explainable with current science, but that conclusion is not in itself an explanation of the experiments.

From a logical point of view, the analysis of explanatory relations is easily trivialized. The explanations of E1 and E2 by hypotheses H1 and H2 together can be collapsed logically by conjoining E1 and E2 into E3, and H1 and H2 into H3, so that we are left with only the boring explanation of E3 by H3. Fortunately, in real disputes in law and the history of science,

such trivializations do not occur. We can easily get the appropriate level of detail by attending to the claims that scientists and lawyers make about the explanatory power of their theories. Lavoisier and the phlogiston theorists operated at roughly the same level of detail. In analyzing texts to assess explanatory coherence, I recommend the following maxim:

Detail Maxim.

In analyzing the propositions and explanatory relations relevant to evaluating competing

theories, go into as much detail as is needed to distinguish the explanatory claims of the theories from each other, and be careful to analyze all theories at the *same* level of detail.

Following this maxim removes much of the apparent arbitrariness inherent in trying to adjudicate among theories.

Ideally, we would want to automate the production of the input to ECHO. This could be done either in a natural language system capable of detecting explanatory arguments (cf. Cohen

1983) or, more easily, in an integrated system of scientific reasoning that formed explanatory hypotheses which could then be passed to ECHO for evaluation. PI (which is short for “processes of induction” and is pronounced “pie”) is a crude version of such a system (Thagard 1988a). In PI, it is possible to represent hypotheses like those in the scientific examples discussed above using rules. One of Lavoisier's principles might be translated into the rule:

If x is combustible and x combines with oxygen, then x burns.

Like other rule-based systems, PI can use such rules to make inferences. Given a set of such rules, PI can be set the task of explaining other rules representing the evidence. While PI runs, it is possible to keep track of which rules were used in explaining which pieces of evidence. Thus explanation from this computational point of view is a process of derivation that can be inspected to determine what was actually used in deriving what. Tracing back to which hypotheses were used in deriving which evidence could generate the EXPLAIN formulas that are input for ECHO. Because PI does not have the rules of inference that permit logicians to concoct nonexplanatory deductions – for example, to infer (A or B) from A – we can identify what hypotheses played a role in explaining what pieces of evidence. Putting together all the rules to make up Lavoisier's theory and furnish explanations is a daunting task, because his writings and my summary for ECHO omit much background knowledge that would have to be dredged up and included if the derivations were to look complete. But AI models of problem solving and learning such as PI provide at least a glimpse of how explanations can be noticed. Falkenhainer and Rajamoney (1988) describe a system that combines hypothesis formation by analogy with hypothesis evaluation by experimental design, so eventually it should be possible to integrate ECHO with a system that generates explanations and provides its input automatically.

ECHO is a very natural way of implementing the proposed theory of explanatory coherence, but one might argue for the construction of a nonconnectionist coherence model. Perhaps it could be based on simple rules such as the following:

- (1) If a proposition is a piece of evidence, then accept it.

Figure 18. Network representing the Peyer trial. 1–17 are evidence units. G1–G8 represent hypotheses concerning Peyer’s guilt; 11–18 concern his innocence. Solid lines are excitatory links; dotted lines are inhibitory.

- (2) If a proposition contradicts an accepted proposition, then reject it.
- (3) Of two contradictory hypotheses, accept the one that coheres (by virtue of explanatory and analogical relations) with more accepted propositions and has fewer co-hypotheses.
- (4) If a proposition does not contradict any other propositions, accept it if it coheres with more accepted propositions than rejected ones.

Analysis suggests that an implementation of such rules could be a fair approximation to ECHO for many cases, but would lack several advantages that derive from ECHO’s connectionist algorithms. First, rules such as (1) and (2) are much too categorical. ECHO is capable of rejecting a piece of evidence if it coheres only with a very inferior theory (Section 4.8), just as scientists sometimes throw out data. Similarly, a hypothesis should not be rejected just because it makes a false prediction, because additional assumptions may enable it to explain the evidence and explain away the negative result. Second, the rule-based implementation would be very sensitive to the order of application of rules, requir-

ing that the four rules stated above be applied in approximately the order given. Moreover, if a hypothesis is contradicted by two other propositions, it will be important to evaluate the other propositions first so that together they can count against the given hypothesis, otherwise it might be accepted and then knock them out one at a time. ECHO’s parallelism enables it to evaluate all propositions simultaneously, so these undesirable order effects do not arise. Third, rules (3) and (4) above should not operate in isolation from one another: In our simulation of Wegener’s argument for continental drift (Thagard and Nowak 1988), units representing the views that Wegener rejects become deactivated because of a *combination* of being contradicted and being coherent with rejected propositions. Fourth, the rule-based system’s use of the binary categories of acceptance and rejection will prevent it from having the sensitivity of ECHO in indicating *degrees* of acceptance and rejection by degrees of activation. Fifth, the rule-based system does not come with a metric for system coherence (Section 4.9). Thus, although ECHO is not the only possible means for computing coherence, its connectionist algorithms give it many natural advantages over alternative approaches.

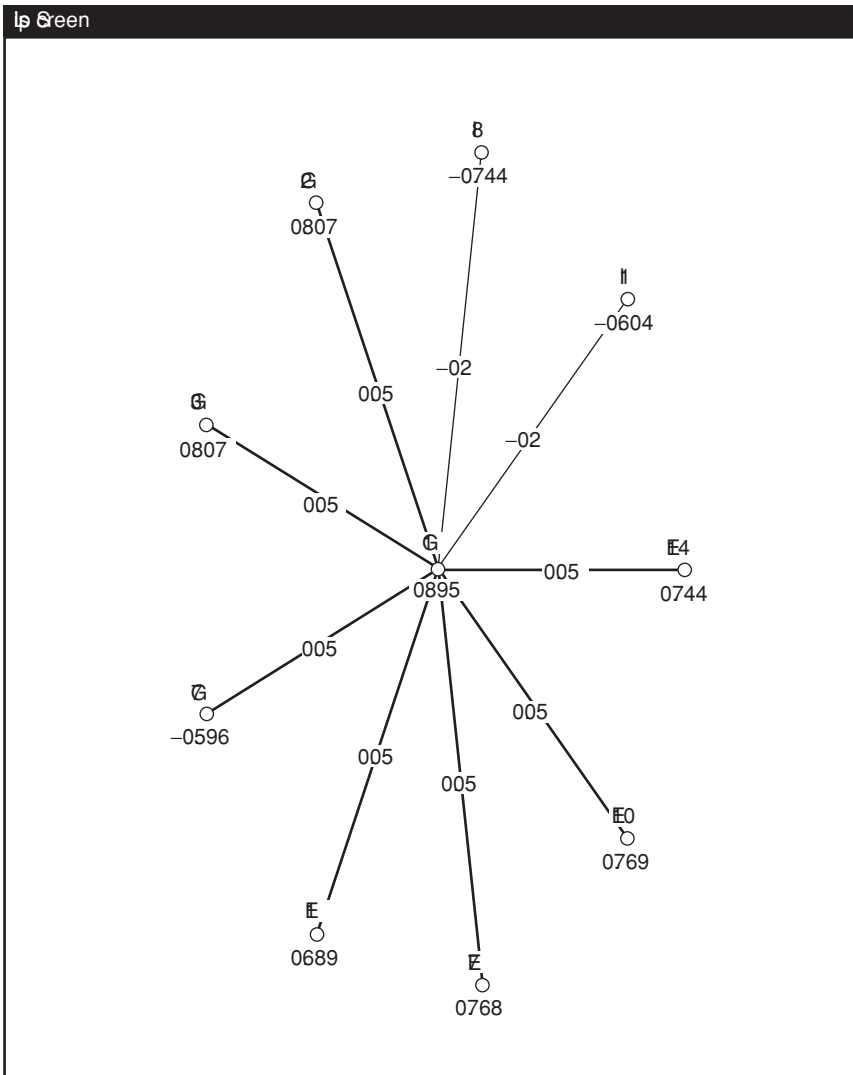

Figure 19. Connectivity of the unit G1, representing Peyer's guilt. The numbers under the units are their activation values after the unit has settled. Thick lines indicate excitatory links; thin lines indicate inhibitory links. Numbers on the lines indicate the weights on the links.

Finally, as an implementation of a theory of explanatory coherence, ECHO is only as good as the principles in that theory. The seven principles of explanatory coherence seem now to be complete enough to characterize a wide range of cases of hypothesis evaluation, but they are themselves hypotheses and therefore subject to revision.

8. Implications for Artificial Intelligence

The theory of explanatory coherence and its implementation in ECHO have implications for

research in the areas of artificial intelligence, cognitive psychology, and philosophy. Like the evaluation of scientific theories, the evaluation of philosophical and computational theories is a comparative matter. While discussing the computational, psychological, and philosophical significance of the approach proposed here, I shall compare it with similar research in these fields.

8.1. Connectionism

Very recently, other researchers have also suggested connectionist models for the evaluation of

Figure 20. Activation history of the Peyer network. Each graph shows the activation of a unit over 54 cycles of updating, on a scale of -1 to 1 , with the horizontal line indicating the initial activation of 0 .

explanatory hypotheses. Peng and Reggia (1989) describe a connectionist model for diagnostic problem solving. Theoretically, it differs from my proposal mostly in that it does not use constraints involving simplicity (in the sense indicated by Principle 2[c]), analogy, and the desirability of a hypothesis being explained as well as explaining. Their implementation differs from ECHO most strikingly in that it does not use inhibitory links between units representing incompatible hypotheses, but instead has nodes competing for activation from the output of a source node. Goel et al. (1988) propose an architecture that chooses the best explanation by con-

sidering explanatory coverage of data, number of hypotheses, and prior plausibility of hypotheses. ECHO uses the first two of these criteria, but not the third, because in the domains to which it has been applied, plausibility appears to be determined by explanatory coherence alone.

Parallel constraint satisfaction models somewhat similar to ECHO have been proposed for other phenomena: analogical mapping (Holyoak and Thagard 1989), analog retrieval (Thagard et al. 1989), discourse processing (Kintsch 1988), and word pronunciation retrieval (Lehnert 1987). (See also surveys by Feldman and Ballard 1982 and Rumelhart et al. 1986.) These

systems differ from Boltzmann machines and back-propagation networks (Rumelhart et al. 1986) in that they do not adjust weights while the network is running, only activations.

ECHO's connectionist character may prompt immediate boos or cheers from different partisan quarters. Currently, debate rages in cognitive science concerning competing methodologies. We can distinguish at least the following approaches to understanding the nature of mind and intelligence:

- (1) Straight neuroscience, studying neurons or sections of the brain
- (2) Computational models of actual neurons in the brain
- (3) Connectionist models using distributed representations, so that a concept or hypothesis is a pattern of activation over multiple units
- (4) Connectionist models using localist representations, in which a single unit represents a concept or proposition
- (5) Traditional artificial intelligence models using data structures such as frames and production rules
- (6) Psychological experiments
- (7) Mathematical analysis
- (8) Theoretical speculation

ECHO falls into (4), but I reject as *methodological imperialism* the opinion that other approaches are not worth pursuing as well. In the current neonatal state of cognitive science, restrictions on ways to study the mind are clearly premature. By pursuing all eight strategies, we can hope to learn more about how to investigate the nature of mind. As suggested by my juxtaposition of PI and ECHO in Section 7, I see no great incompatibility between connectionist systems and traditional symbolic AI. Much is to be gained from developing hybrid systems that exploit the strengths of both research programs (Hendler 1987; Lehnert 1987).

Despite ECHO's parallelism, and use of a vague neural metaphor of connections, I have not listed neural plausibility as one of its advantages, because current knowledge does not allow any sensible mapping from nodes of ECHO representing propositions to anything in the brain. For the same reason, I have not used the term "neural net." Parallelism has its advantages independent of the brain analogy (Thagard 1986).

8.2. Probabilistic Networks

The account of explanatory coherence I have given bears some similarity to Pearl's (1986, 1987) work on belief networks. Pearl also represents propositions as nodes linked by inferential dependencies and uses a parallel algorithm to update numerical values assigned to the nodes. The major difference between ECHO and Pearl's networks, however, is that he construes numerical values as the *probabilities* of the propositions, and weights between nodes as conditional probabilities. Thus, in contrast to links established by coherence relations, Pearl's links are asymmetric, because in general the probability of P given Q is not equal to the probability of Q given P.

Although Pearl's probabilistic approach appears promising for domains such as medical diagnosis where we can empirically obtain frequencies of co-occurrence of diseases and symptoms and thus generate reasonable conditional probabilities, it does not seem applicable to the cases of explanatory coherence I have been considering. What, for example, is the conditional probability of burned objects gaining in weight given the hypothesis that oxygen is combined with them? It would be 1 if the hypothesis entailed the evidence, but it does so only with the aid of the additional hypothesis that oxygen has weight, and some unstated background assumption about conservation of weight. To calculate the conditional probability, then, we need to be able to calculate the conjunctive probability that oxygen has weight and that oxygen combines with burning objects, but these propositions are dependent to an unknown degree. Moreover, what is the probability that the evidence is correct? In contrast to the difficulty of assigning probabilities to these propositions, the coherence relations established by my principles are easily seen directly in arguments used by scientists in their published writings. When frequencies are available because of empirical studies, probabilistic belief networks can be much more finely tuned than my coherence networks, but they are ill-suited for the kinds of nonstatistical theory evaluation that abounds in much of science and everyday life.

One clear advantage to the probabilistic approach is that the properties of probabilities are naturally understood using the axioms of probability and their natural interpretation in terms of games of chance. Acceptability, as indicated in ECHO by activation levels, has no such precise interpretation. (See Section 10.2 for

further discussion of probability versus acceptability.)

8.3. *Explanation-Based Learning*

In machine learning, a rapidly growing part of AI, the term “explanation-based” is used to distinguish cases of knowledge-intensive learning from cases of simple learning from examples (see, for example, DeJong and Mooney 1986). Rajamoney and DeJong (1988) discuss the problem of “multiple explanations” and describe a program that does simulated experiments to select an explanatory account. This program is Popperian in spirit, in that the experiments concerning electricity and heat flow serve to refute all but one of the competing hypotheses. (Science is rarely so neat; see Sections 4.4 and 10.4.) Systems that deal with more complex theories than those occurring in Rajamoney and DeJong’s system will need a more comparative method of choosing among multiple explanations such as that found in ECHO.

Recently, there has been growing attention in AI to “abduction,” construed as the construction and selection of competing explanatory hypotheses. (Peirce applied “abduction” only to hypothesis formation, but the term is used in many quarters to apply to hypothesis evaluation as well.) Abduction has been investigated in the domains of medical diagnosis (Josephson et al. 1987; Pople 1977; Reggia et al. 1983), natural language understanding (Hobbs et al. 1988), and folk psychology (O’Rorke et al. 1988). My account shares with these models the aim of finding the most comprehensive explanation, but it differs in both theory and implementation. The biggest theoretical difference is that my principles of explanatory coherence also favor hypotheses that are explained and fare well on considerations of simplicity and analogy. Leake (1988) describes a program for evaluating individual explanations, a problem different from selecting a hypothesis on the basis of how well it explains a wide range of evidence.

9. Implications for Psychology

The theory of explanatory coherence described here is intended to describe approximately the way people reason concerning explanatory hypotheses (see Section 10.5 for further discussion of the descriptive *and* normative character of the theory). The psychological relevance of explanatory coherence is evident in at least three important areas of psychological research: attri-

bution theory, discourse processing, and conceptual change. After sketching how explanatory coherence is germane to these topics, I shall illustrate the testability of the ECHO model.

9.1. *Attribution*

Because the inferences that people make about themselves and others generally depend on causal theories, social psychology is a very rich domain for a theory of explanatory coherence, and *attribution theory* has been a major focus of research for several decades. Research on attribution “deals with how the social perceiver uses information in the social environment to yield causal explanations for events” (Fiske and Taylor 1984, p. 21). Much of the theorizing about attribution can be understood in terms of explanatory coherence. For example, we can interpret the *correspondent inference theory* of Jones and Davis (1965) as saying that we accept hypotheses about the dispositional attributes of other people on the basis of the hypotheses providing coherent explanations of their behavior. Jones and Davis’s discussion of the *analysis of noncommon effects* can be understood as saying that we infer that someone has one of a set of intentions because that intention explains some aspects of their behavior that the other intentions do not. Our inferences about other people’s dispositions will also depend on the available alternative explanations of their behavior, such as coercion, social desirability, social role, and prior expectations. Explanatory coherence theory does not address the question of how people form these kinds of hypotheses, but it does show how people can select from among the hypotheses they have formed. I conjecture that if cases of attributional inferences were analyzed in sufficient detail to bring out the relevant data and hypotheses, preferences for situational or dispositional explanations would follow from the nature of the explanatory networks.

As we saw in the preppy murder trial, jurors often have to infer the intentions of witnesses and of the accused. Pennington and Hastie (1986, 1987) have interpreted the results of their experiments on juror decision making by hypothesizing that jurors make judgments based on considerations of explanatory coherence; their cases look ripe for ECHO analysis. Of course, ECHO does not model all the kinds of reasoning involved in these experiments. In particular, it does not model how the jurors process the statements about evidence and combine them into explanatory stories. But it does give an account

of how jurors choose between stories on the basis of their explanatory coherence.

9.2. *Discourse Processing*

The problem of recognizing intention in utterances can be understood in terms of explanatory coherence.² Clark and Lucy (1975) advocated a stage model of comprehension, according to which a literal meaning for an utterance is calculated before any nonliteral meanings are considered. In contrast, Gibbs (1984) and others have argued that hearers are able to understand that “Can you pass the salt?” is a request, without first interpreting it as a question. In explanatory coherence terms, we can think of competing hypotheses – that the utterance is a request and that it is a question – as simultaneously being evaluated with respect to what they explain and how they themselves are explained. To take an extreme example, the utterance might even be construed as an insult if it was expressed in a nasty tone of voice and if we had reason to believe that the utterer wanted to be insulting. Parallel evaluation of the different explanations of the utterance results in an appropriate interpretation of it.

Trabasso et al. (1984) have argued that causal cohesiveness is very important for story comprehension. They analyze stories in terms of networks of causally related propositions that are similar to ECHO’s explanatory networks except that there are no links indicating contradictions. Comprehension differs from theory evaluation in lacking easily identified alternatives competing for acceptance. Still, it is possible that some mechanism similar to ECHO’s way of activating a subset of mutually coherent propositions may be involved in reaching a satisfactory understanding of a story. Text comprehension obviously involves many processes besides inferences about causal or explanatory coherence, but ECHO-like operation may nevertheless contribute to the necessary task of appreciating the causal cohesiveness of a story.

9.3. *Belief Revision and Conceptual Change*

Ranney and Thagard (1988) describe the use of ECHO to model the inferences made by naive subjects learning elementary physics by using feedback provided on a computer display (Ranney 1987). Subjects were asked to predict the motion of several projectiles and then to explain these predictions. Analyses of verbal

protocol data indicate that subjects sometimes underwent dramatic belief revisions while offering predictions or receiving empirical feedback. ECHO was applied to two particularly interesting cases of belief revision with propositions and explanatory relations based on the verbal protocols. The simulations captured well the dynamics of belief change as new evidence was added to shift the explanatory coherence of the set of propositions.

The theory of explanatory coherence sketched here has the capacity to explain major conceptual changes such as those that have been hypothesized to occur in scientific revolutions (Kuhn 1970; Thagard, 1990) and in children (Carey 1985). Because ECHO evaluates a whole network of hypotheses simultaneously, it is capable, when new data are added, of shifting from a state in which one set of hypotheses is accepted to a state in which an opposing set is accepted. This shift is analogous to the Gestalt switch described in Section 3, except that scientists rarely shift back to a rejected view. Developmental psychologists have speculated about the existence of some kind of “transition mechanism” that could shift a child forward from a primitive conceptual scheme to an advanced one. We currently have insufficient experimental data and theoretical understanding to know whether knowledge development in children has the somewhat precipitous nature attributed to scientific revolutions, but if children do undergo dramatic changes in conceptual systems because they have acquired a more coherent way of understanding their worlds, then ECHO may be very useful for modeling the transition.

9.4. *Testability*

So far, my discussion of the psychological relevance of ECHO has been merely suggestive, showing that explanatory coherence judgments may be plausibly considered to contribute to important kinds of inferential behavior. A defense of ECHO as a psychological model, however, will require controlled experiments that provide a much finer-grained evaluation of the theory of explanatory coherence. Fortunately, there appears to be great potential for testing explanatory coherence theory and the ECHO model by comparing the performance of human subjects with ECHO-based predictions about qualitative and quantitative features of the acceptance and rejection of hypotheses. Michael Ranney and I are planning several studies in which subjects will be given textual descriptions of scientific and

legal debates. We want to determine whether, when ECHO is run with inputs derived from subjects' own analyses of debates, the analyses predict their conclusions. We also want to determine whether manipulating textual descriptions of evidence, explanations, and contradictory hypotheses will affect the confidence that subjects have in different hypotheses in a way that resembles how manipulations affect ECHO's activation levels. It will also be interesting to find out whether important transitional points in the amount of evidence and explanation that tend to tip ECHO's activations over to new sets of accepted beliefs correspond to major shifts in subjects' beliefs at the same points. Such transitions, in both subjects and ECHO, are described in Ranney and Thagard (1988).

The methodology here is to use ECHO to test the psychological validity of the theory of explanatory coherence embodied in the seven principles in Section 2.2. These principles in themselves are too general to have direct experimental consequences, but their implementation in ECHO makes possible very detailed predictions about the conclusions people will reach and the relative degree of confidence they will have in those conclusions. Merely proposing experiments does not, of course, show the psychological validity of the theory or the model, but it does show their joint testability. The theory of explanatory coherence presented in this paper has been well explored computationally, but I hope the above section shows that it is also suggestive psychologically.

10. Implications for Philosophy

In philosophy, a theory of explanatory coherence is potentially relevant to metaphysics, epistemology, and the philosophy of science. In metaphysics, a coherence theory of truth, according to which a proposition is said to be true if it is part of a fully coherent set, has been advocated by idealist philosophers such as Bradley and Rescher (Bradley 1914; Rescher 1973; see also Cohen 1978). In epistemology, the view that justified reasoning involves the best total explanatory account has been urged by Harman (1973, 1986) and contested by Goldman (1986) and Lehrer (1974). The theory of explanatory coherence in this paper is not aimed primarily at questions of truth or justification, but rather at the philosophy of science and of law, illuminating the kinds of reasoning used to justify the acceptance and rejection of scientific and legal hypotheses. The account of explanatory coher-

ence offered here is as compatible with a correspondence theory of truth – according to which the truth of a proposition depends on its relation to an independent reality – as it is with a theory that attempts to define truth in terms of coherence.

10.1. Holism

A major concern in epistemology and philosophy of science concerns whether inference is holistic. According to Quine (1961, p. 41), “our statements about the external world face the tribunal of sense experience not individually but only as a corporate body.” In a similar vein, Harman (1973, p. 159) writes that “inductive inference must be assessed with respect to everything one believes.” Behind these holistic views is the antifoundationalist assumption that it is impossible to provide isolated justifications for isolated parts of our system of beliefs. Quine's position is based on his rejection of the analytic–synthetic distinction and on the view of Duhem (1954) that deducing an observation statement from a hypothesis always involves a complex of other hypotheses, so that no hypothesis can be evaluated in isolation. Because predictions are usually obtained from sets of hypotheses, observations that contradict the predictions do not provide grounds for rejecting any particular hypothesis, only for concluding that there is at least one false hypothesis. Harman argues that reasoning is inference to the best explanation, which includes both inference to hypotheses that explain the evidence and inference to what is explained. Inferential holism is therefore suggested by the following considerations:

- (1) Hypotheses cannot be refuted and confirmed in isolation.
- (2) Hypothesis evaluation must take into account the total sum of relevant evidence.
- (3) The acceptability of a proposition is a function not only of what it explains but also of its being explained.

Unfortunately, holism brings many problems with it. Hegel (1967, p. 81) said that “the true is the whole,” but he insisted that it should not be taken to be a crude, undifferentiated whole. If sets of hypotheses must be evaluated together, and everything is potentially relevant to everything else, how can we make a reasonable judgment about which hypotheses to maintain and which to reject? Kuhn's (1970) influential account of theory change as shifts in whole

paradigms has been taken by some to imply that there is no rationality in science. Fodor (1983) has concluded from Quinean holism not only that philosophers have failed to provide a reasonable account of scientific confirmation, but even that cognitive science is unlikely ever to provide an account of such central psychological processes as hypothesis selection and problem solving (see Holland et al. 1986: Ch. 11, for a rebuttal).

My theory of explanatory coherence and its implementation in ECHO are holistic in that the acceptability of a hypothesis potentially depends on its relation to a whole complex of hypotheses and data. But there is nothing mystical about how ECHO uses pairwise relations of local coherence to come up with global coherence judgments. Although evidence units can be deactivated, just as data are sometimes ignored in scientific practice, the evidence principle gives some priority to the results of observation.

Although ECHO does not exhibit simplistic Popperian falsification, it need not succumb to the various strategies that can be used to save a hypothesis from refutation. The strongest direct evidence *against* a hypothesis is pointing out that it has implications that contradict what has been observed. One way of saving the hypothesis from an objection of this sort is to use an auxiliary hypothesis to explain away the negative evidence. Section 4.6 showed how simplicity considerations can prevent this strategem from working. Another way of saving a hypothesis in the face of negative evidence is to modify its cohypotheses. As Duhem and Quine pointed out, if H1 and H2 together imply some NE1 that contradicts a datum E1, then logic alone does not tell whether to reject H1, H2, or both. In ECHO, which hypotheses are deactivated depends on other relations of explanatory coherence. If H1 contributes to fewer explanations than H2, or if H1 contradicts another highly explanatory hypothesis, H3, then H1 will be more likely to be deactivated than H2.

Although ECHO makes it possible for a set of hypotheses to be accepted or rejected as a whole, it also admits the possibility of more piecemeal revision. Perrin (1988, p. 115) reports that the conversion of phlogiston theorists to the oxygen theory sometimes took several years, with the converts gradually accepting more and more of Lavoisier's views. ECHO's networks such as the oxygen-phlogiston one shown in Figure 9 do not connect everything to everything else. Explanatory relations may produce relatively isolated packets of coherent hypotheses and evidence;

these may sometimes be accepted or rejected independent of the larger theory.

10.2. Probability

My account of theory evaluation contrasts sharply with probabilistic accounts of confirmation that have been influential in philosophy since Carnap (1950). Salmon (1966), for example, advocates the use of Bayes's theorem for theory evaluation, which, if $P(H,E)$ stands for the probability of H given E, can be written as:

$$P(H, E) = \frac{P(H)P(E, H)}{P(E)} \quad (2)$$

Consider what would be involved in trying to apply this to Lavoisier's argument against the phlogiston theory. We would have to take each hypothesis separately and calculate its probability given the evidence, but it is totally obscure how this could be done. Subjective probabilities understood as degrees of belief make sense in contexts where we can imagine people betting on expected outcomes, but scientific theory evaluation is not such a context. How could we take into account that alternative explanations are also being offered by the phlogiston theory? The issue is simplified somewhat if we consider only likelihood ratios for the oxygen and phlogiston theories – that is, the ratio of $P(E, \text{oxygen})$ to $P(E, \text{phlogiston})$ – but we still have the problem of dealing with the probability of the conjunction of a number of oxygen hypotheses whose degree of dependence is indeterminate. As I argued in Section 8.2, probabilities have marginal relevance to qualitative explanatory inferences in science and law.

My account of coherence based on explanation contrasts markedly with probabilistic accounts. A set of propositions, S, is probabilistically coherent if there is a real-valued function that gives an assignment of values to the propositions consistent with the axioms of probability (Levi 1980). This constraint is very different from the ones governing explanatory coherence that ECHO shows to be sufficient for accepting and rejecting hypotheses. The real numbers that are degrees of activation of propositions in ECHO are clearly not probabilities, because they range from 1 to -1 , like the certainty factors in the AI expert system MYCIN (Buchanan and Shortliffe 1984). Note that two contradictory propositions can both have activation greater than 0, if neither is substantially more coherent with the evidence than the other.

Probabilities, ranging from 0 to 1, are often interpreted as degrees of belief, but this interpretation obscures the natural distinction between acceptance and rejection, belief and disbelief. I do not just have low confidence in the proposition that the configuration of the stars and planets at birth affects human personality; I reject it as false. One advantage of probability theory, however, is that it provides rules for calculating the probabilities of conjunctions and disjunctions. In contrast, the acceptability (in my sense) of “P and Q” and “P or Q” is not defined, because such composite propositions do not, in general, figure in explanations. One can concoct cases of disjunctive explanations (“He said he was flying in from either New York or Philadelphia, and the weather is very bad in both places, so that explains why he’s delayed”), but I have never encountered one in a scientific or legal context. Explanations depending on conjunctions of copenhypotheses are common, but ECHO has no need to calculate the acceptability of “P and Q,” because relations of explanatory coherence tell you all you need to know about P and Q individually. The apparent advantage of probability theory is much weakened in practice by the fact that the calculation of conjunctive and disjunctive probabilities requires knowledge of the extent to which the two propositions are independent of each other. Such information is easily gained when one is dealing with games of chance and in other cases where frequencies are available, but it is hard to come by in cases of scientific and legal reasoning: For Lavoisier, what was the conditional probability of OH1 (pure air contains oxygen principle) given OH2 (pure air contains matter of fire and heat)?

10.3. Confirmation Theory

My view of theory evaluation based on explanatory coherence can also be contrasted with confirmation theory, according to which a hypothesis is confirmed by observed instances (Glymour 1980; Hempel 1965). The cases I discussed in detail in this paper are typical, I would argue, of the general practice in scientific argumentation that theories are not justified on the basis of particular observations that can be derived from them. Rather, observations are collected together into generalizations. These generalizations are sometimes rough, describing mere tendencies. In this process, particular observations can be tossed out as faulty or irrelevant. Theory evaluation starts with the explanation of the generalizations, not with particular observations.

Lavoisier, for example, did not defend his theory by pointing to particular confirming observations such as his measurements indicating that a sample of burned phosphorus gained weight on a particular day in 1772. Rather, his central claim in defense of his theory is that it explains why objects in general gain weight when burned. Qualitative confirmation theory also does not in itself suggest how simplicity, analogy, competition, and being explained can play a role in theory evaluation.

10.4. Explanationism and Conservatism

Now let me turn to a brief discussion of philosophical views that are much closer to my account of explanatory coherence. My discussion of hypotheses is compatible with the “explanationism” of Harman (1986) and Lycan (1988). Unlike them, however, I am not trying to give a general account of epistemic justification: I hold that there are other legitimate forms of inference besides inference to the best explanation. The principle of data priority assumes that results of observation start with a degree of acceptability that derives from their having been achieved by methods that lead reliably to true beliefs. This justification is closer to the “reliabilism” of Goldman (1986), a position which has problems, however, in justifying the acceptance of hypotheses (Thagard, 1989). My own view of justification is that explanation and truth are *both* epistemic goals that need to be taken into account as part of a larger process of justifying inferential strategies (Thagard 1988a: Ch. 7).

The other major difference I have with Harman and Lycan is that they both advocate *conservatism* as a supplement to considerations of explanatory coherence. Harman says we should try to maximize explanatory coherence while minimizing change. I view conservatism as a *consequence* of explanatory coherence, not as a separate factor in brief revision. In ECHO, we get a kind of conservatism about new evidence, as I showed in Section 4.2. For ECHO, new evidence that does not cohere with what has been accepted is not treated equally with old evidence. In addition to conservatism about new evidence, there is a kind of conceptual conservatism inherent in any cognitive system: If an alternative theory requires a network of concepts which differs from my own, then I cannot evaluate the new system until I have effortfully acquired that system of concepts (Thagard 1990). Hence, an existing set of views

will be conservatively favored until the alternative is fully developed.

The conservatism favored by Harman and Lycan seems most plausible, not for actual scientific cases, but for imagined ones in which a trivial variant of an accepted theory appears as an alternative. Suppose H1 gets high activation as the best explanation of E1 and E2, and then H2 is proposed to explain them both. If H1 and H2 are contradictory, then ECHO readjusts activation so that H1 and H2 are virtually at the same level. What if H2 is just a trivial variant of H1? Then H2 does not really contradict H1, so they can both be highly active without any problem. One might worry that the system will quickly be cluttered with trivial variants, but in a full computational system, that would be taken care of by having pragmatic constraints on what hypotheses are generated (Holland et al. 1986).

As a final comparison, consider the complementary views on explanatory unification of Kitcher (1981). He describes how powerful theories such as Darwin's and Newton's provide unification by applying similar *patterns* of explanation to various phenomena. That this should contribute to explanatory coherence is a consequence of my theory, for if H1, H2, and H3 are all used to explain the evidence, we get the result not just that each coheres with the evidence, but also that they cohere with each other. Moreover, degrees of coherence are cumulative, so that the more two hypotheses participate in explaining different pieces of evidence, the more they cohere with each other. (See the simple example in Section 4.5.)

The major philosophical weakness of my account of explanatory coherence concerns the nature of explanation. This paper has bypassed the crucial question of what explanation is. Fortunately, to apply the principles of explanatory coherence and to generate input for ECHO, it is not necessary to have an exact analysis of the nature of explanation. We can take for granted the explanatory relations described by scientists such as Lavoisier and Darwin, or we can get an approximation using a computational system such as PI, as described in Section 7. For an outline of what a computational account of explanation might look like, see Thagard (1988a: Ch. 3).

10.5. *The Descriptive and the Normative*

Philosophy differs from psychology primarily in its concern with normative matters – how people *ought* to reason rather than how they

do reason. For some philosophers, any analysis that smacks of psychology has disqualified itself as epistemology. From this perspective, one faces the dichotomy: Is my theory of explanatory coherence normative or is it merely descriptive? In accord with Goldman (1986) and Harman (1986), I reject this rigid dichotomy, maintaining that descriptive matters are highly relevant to normative issues (see Thagard 1988a: Ch. 7). The seven principles of explanatory coherence are intended to capture both what people generally do and what they ought to do. By no means do they constitute a full theory of rationality. There are undoubtedly cases where people deviate from explanatory coherence – for example, preferring a hypothesis because it makes them happy rather than because of the evidence for it (Kunda 1987). Racial or other types of prejudice may prevent jurors from taking a piece of evidence seriously. Various other biases (Nisbett and Ross 1980) may intrude to throw off considerations of explanatory coherence. Much psychological experimentation and modeling is needed to show when people's reasoning can be accounted for in terms of explanatory coherence and when it is affected by other factors. This work can go hand in hand with refinements in the normative aspects of the theory.

11. Conclusion

I conclude with a brief survey of the chief accomplishments of the theory of explanatory coherence offered here.

First, it fits directly with the actual arguments of scientists such as Lavoisier and Darwin who explicitly discuss what competing theories explain. There is no need to postulate probabilities or contrive deductive relations. The theory and ECHO have engendered a far more detailed analysis of these arguments than is typically given by proponents of other accounts. Using the same principles, it applies to important cases of legal reasoning as well.

Second, unlike most accounts of theory evaluation, this view based on explanatory coherence is inherently comparative. If two hypotheses contradict each other, they incohere, so the subsystems of propositions to which they belong will compete with each other. As ECHO shows, successful subsystems of hypotheses and evidence can emerge gracefully from local judgments of explanatory coherence.

Third, the theory of explanatory coherence permits a smooth integration of diverse criteria such as explanatory breadth, simplicity, and

analogy. ECHO's connectionist algorithm shows the computability of coherence relations. The success of the program is best attributed to the usefulness of connectionist architectures for achieving parallel constraint satisfaction, and to the fact that the problem inherent in inference to the best explanation is the need to satisfy multiple constraints simultaneously. Not all computational problems are best approached this way, but parallel constraint satisfaction has proven to be very powerful for other problems as well – for example, analogical mapping (Holyoak and Thagard 1989).

Finally, my theory surmounts the problem of holism. The principles of explanatory coherence establish pairwise relations of coherence between propositions in an explanatory system. Thanks to ECHO, we know that there is an efficient algorithm for adjusting a system of propositions to turn coherence relations into judgments of acceptability. The algorithm allows every proposition to influence every other one, because there is typically a path of links between any two units, but the influences are set up systematically to reflect explanatory relations. Theory assessment is done as a whole, but a theory does not have to be rejected or accepted as a whole. Those hypotheses that participate in many explanations will be much more coherent with the evidence, and with each other, and will therefore be harder to reject. More peripheral hypotheses may be deactivated even if the rest of the theory they are linked to wins. We thus get a holistic account of inference that can nevertheless differentiate between strong and weak hypotheses. Although our hypotheses face evidence only as a corporate body, evidence and relations of explanatory coherence suffice to separate good hypotheses from bad.

12. Appendix

Technical Details of ECHO

For those interested in a more technical description of how ECHO works, this appendix outlines its principle algorithms and describes sensitivity analyses that have been done to determine the effects of the various parameters on ECHO's performance.

12.1. ALGORITHMS

As I described in Section 4.1, ECHO takes as input PROPOSITION, EXPLAIN, CONTRADICT, and DATA statements. The basic data structures in ECHO are LISP atoms that imple-

Table 9: Algorithms for Processing Input to ECHO

-
1. Input: (PROPOSITION NAME SENTENCE)
Create a unit called NAME and an index for it.
Store SENTENCE with NAME.
 2. Input: (EXPLAIN LIST-OF-PROPOSITIONS PROPOSITION)
Make excitatory links^a between each member of LIST-OF-PROPOSITIONS and PROPOSITIONS.
Make excitatory links^a between each pair of LIST-OF-PROPOSITIONS.
Record what explains what.
 3. Input: (CONTRADICT PROPOSITION-1 PROPOSITION-2)
Make an inhibitory link between PROPOSITION-1 and PROPOSITION-2.
 4. Input: (DATA LIST-OF-PROPOSITIONS)
For each member of LIST-OF-PROPOSITIONS, create an excitatory link from the special evidence unit with the weight equal to the data excitation parameter, unless the member is itself a list of the form (PROPOSITION WEIGHT). In this case, the weight of the excitatory link between the special unit and PROPOSITION is WEIGHT.
If there are unexplained data propositions, increase the decay rate parameter by multiplying it by the ratio of the total number of evidence propositions to the number of explained evidence propositions.
-

^a The weights on these links are determined by equation 3 given in the text. Weights are additive: If more than one EXPLAIN statement creates a link between two proposition units, then the weight on the link is the sum of the weights suggested by both statements.

ment units with property lists that contain information about connections and the weights of the links between units. Table 9 describes the effects of the four main kinds of input statements. All are very straightforward, although the EXPLAIN statements require a calculation of the weights on the excitatory links. The equation for this is:

$$\text{weight}(P, Q) = \text{default weight} / (\text{number of cohypotheses of } P)^{(\text{simplicity impact})} \quad (3)$$

Here simplicity impact is an exponent, so that increasing it lowers the weight even more, putting a still greater penalty on the use of multiple assumptions in an explanation. In practice, however, I have not found any examples where it was interesting to set simplicity impact at a value other than 1.

Table 10: Algorithms for Network Operation

-
1. Running the network:
 - Set all unit activations to an initial starting value (typically .01), except that the special evidence unit is clamped at 1.
 - Update activations in accordance with (2) below.
 - If no unit has changed activation more than a specified amount (usually .001), or if a specified number of cycles of updating have occurred, then stop.
 - Print out the activation values of all units.
 2. Synchronous activation updating at each cycle:
 - For each unit u , calculate the new activation u in accord with equations 3 and 4 in the text, considering the old activation of each unit u' linked to u .
 - Set the activation of u to the new activation.
-

After input has been used to set up the network, the network is run in cycles that synchronously update all the units. The basic algorithm for this is shown in Table 10. For each unit j , the activation a_j , ranging from -1 to 1 , is a continuous function of the activation of all the units linked to it, with each unit's contribution depending on the weight w_{ij} of the link from unit i to unit j . The activation of a unit j is updated using the following equation:

$$a_j(t+1) = a_j(t)(1 - \theta) + \begin{cases} net_j(max - a_j(t)) & \text{if } net_j > 0 \\ net_j(a_j(t) - min) & \text{otherwise} \end{cases} \quad (4)$$

Here θ is a decay parameter that decrements each unit at every cycle, min is minimum activation (-1), max is maximum activation (1), and net_j is the net input to a unit. This is defined by

$$net_j = \sum_i w_{ij} a_i(t) \quad (5)$$

Repeated updating cycles result in some units becoming activated (getting activation > 0) while others become deactivated (activation < 0).

12.2. SENSITIVITY ANALYSES

Multiple connected localist networks sometimes exhibit instability, failing to settle into stable activation patterns because complexes of mutually excitatory units produce activation oscillations. As Figures 11, 14, 17, and 20 suggest, ECHO's networks are generally stable, usually requiring fewer than 100 units of updating for all units to reach asymptotic levels. Pearl (1987) devotes considerable effort to rearranging probabilistic networks so that they will be singly connected and hence stable. Fortunately, the networks set up by ECHO in accord with the theory of explanatory coherence do not require any alteration to settle into stable activations. Whereas a probabilistic network may need links specifying the conditional probabilities of p given q , q given r , r given s , and s given p , such cyclic paths rarely arise in ECHO because the "explain" relation sets up hierarchies of units rather than cycles. ECHO undergoes activation oscillations only when the excitation parameter is high relative to inhibition, for example, in the Chambers case, if excitation has a value of .17 instead of .05. ECHO is efficient: In each of the four major examples, a complete run, including network creation and settling, takes less than a minute of cpu time on a Sun 3/75 workstation. Because networks with hundreds more units and thousands more links than ECHO's networks have run successfully in ACME, a similar program that does analogical mapping (Holyoak & Thagard, 1989), I see no problem in scaling ECHO up to run on much larger examples.

Table 11 shows, for each major example, the size of the networks created and the number of cycles of activation updating it takes for them to settle using the default parameter values of .05 for excitation, -2 for inhibition, .1 for data excitation, and .05 for decay. Experiments have shown that ECHO exhibits the behavior described in the text over a wide range of values for these parameters. For example, in the Lavoisier example, no important differences in the results occur if the decay, excitation, inhibition, and

Table 11: Network Information for Four Major Examples

	Units	Links	Cycles to Settle	Excitation Ceiling	Inhibition Floor
Lavoisier	20	49	107	.13	-.18
Darwin	29	70	49	.06	-.16
Chambers	34	59	63	.17	-.07
Peyer	34	54	78	.08	-.13

data excitation parameters are all halved or doubled. In general, lowering positive parameters and making inhibition closer to 0 tends to prolong settling time. Increasing decay tends to flatten the activation curves, both positive and negative, keeping them closer to 0. Increasing data excitation leads evidence units to have higher asymptotic activation. Varying excitation and inhibition systematically reveals that there is a critical value for each. If excitation is high relative to inhibition, then the system shows much "tolerance" and does not deactivate inferior hypotheses. Table 11 lists excitation ceilings and inhibition floors for the four major examples. The excitation ceilings are the maximum values that excitation can have without activating units representing inferior hypotheses; inhibition here is constant at the default value of $-.2$. The excitation values at which networks become unstable are well above these ceilings. The inhibition floors are the minimum values that inhibition must have without failing to deactivate units representing inferior hypotheses; excitation here is constant at the default value of $.05$. The excitation ceiling and the inhibition floor indicate the most important respects in which quantitative parameter changes in ECHO have qualitative effects. Keep in mind that the excitation ceilings and inhibition floors listed in Table 11 are based on a fixed value for, respectively, inhibition and excitation. Varying these values will produce different floors and ceilings, so that the range of possible parameter values is much larger than Table 11 portrays.

Notes

- 1 From here on, I shall be less careful about distinguishing between units and the propositions they represent.
- 2 I owe this suggestion to Daniel Kimberg.

Chapter 25: Belief Revision

HANS ROTT

1. Introduction

The terms “belief revision” and “belief change” refer to the change of a system of beliefs or opinions in response to new information, in particular to information that is inconsistent with this system. In the 1960s and 1970s, works of Isaac Levi, William Harper, and Brian Ellis prepared the ground for systematic studies of belief change processes. In the 1980s, a seminal research paradigm of belief revision was established by Carlos Alchourrón, Peter Gärdenfors, and David Makinson (also known as “AGM”) who discovered a common structure in the logic of normative systems and of the logic of counterfactual conditionals – areas which turned out to be structurally related and were merged into the field of belief change (also known as “theory change”). The AGM paradigm is a classic by now that has in many ways been extended and revised. Still almost all new theories that are being proposed today define themselves in relation to the basic ideas of AGM.

Belief revision theories are different from descriptive psychological investigations or investigations of theory dynamics as conducted in the philosophy of science in that they provide abstract logical postulates for rational revision processes, as well as construction recipes for belief changes on the basis of certain revision-guiding structures. At present, research in belief revision is an interdisciplinary undertaking in logic, philosophy, computer science, and, to a lesser extent, in economics and cognitive science. Belief revision theories are often assigned to the field of “knowledge representation” in computer science, and are presented as theories about “knowledge change,” but this terminology is misleading because knowledge has to be true and justified, and neither truth nor justification are topics discussed at any depth in

the belief revision literature. In terms originating with Plato, belief revision theories deal with the dynamics of *doxastic* rather than epistemic states.

The problem of belief revision is best illustrated by an example. Suppose you believe that

- (1) David is excellent in teaching. t
- (2) David has a paper in the p
Journal of Philosophy.
- (3) If David has a paper in the $p \rightarrow r$
Journal of Philosophy he is
excellent in research.
- (4) If David is excellent in $r \wedge t \rightarrow j$
research and teaching, he will
get the job.

Like any person capable of good reasoning, you conclude from these premises that

- (5) David will get the job. j

From the point of view of belief revision theories, it is not necessary that you actually perform the requisite reasoning and draw this conclusion in such a way that (5) becomes an occurrent belief. It is sufficient that you can be *ascribed* the belief that j , or that you are *committed* to believing j on the basis of premises (1) to (4). Now suppose that at a certain point you learn, from a perfectly reliable source, that David has not in fact got the job. This is a surprise to you that manifests itself in a contradiction between the new information $\neg j$ and your old premises (1) to (4). Thinking about the matter, you realize that given your initial premises, logic in a way compelled you to believe j . Since you have now found out that j is not true after all and you want to add $\neg j$ to your stock of beliefs, there are only two options. Either your logical reasoning that delivered the

conclusion j was faulty, or (at least) one of the premises (1)–(4) was wrong. The answer typically given by belief revision theories is that classical logic is correct. So, assuming you want to accept the new piece of information $\neg j$, logic enforces that you give up (at least) one of the premises. Logic, however, is completely silent about *which* of the premises to give up. Something else has to step in that provides you with guidance how to proceed. The theme of belief revision theories is to find out what this “something else” is, and how it helps you to resolve such problems in the transformation of belief states or doxastic states.¹

In order to accommodate the new information $\neg j$ and to avoid that your beliefs become inconsistent, you need to *revise* your belief base. Some of the original premises must be *retracted*. In general one does not want to give up all of one’s beliefs, since this would mean an unnecessary loss of valuable information, but when giving up the belief j , you have to decide which of the reasons for holding j to retain and which to retract. You have to *choose* between retracting $r \wedge t \rightarrow j$, $t, p \rightarrow r$, or p . For instance, you may come to decide that you were too optimistic in endorsing $r \wedge t \rightarrow j$. Excellent research and teaching may not be sufficient to secure David a job.

The process of belief revision is nontrivial precisely because purely logical considerations alone do not tell us which of the beliefs to give up. What makes the task more difficult is that beliefs have logical consequences. When giving up a belief one has to decide as well which of its consequences to retain and which to retract. For example, one of the logical consequences of $r \wedge t \rightarrow j$ is

If David is excellent in research and teaching and fluent in Italian, he will get the job. $r \wedge t \wedge i \rightarrow j$

Should you keep this or some similar beliefs, if you decide to retract $r \wedge t \rightarrow j$ in the situation just described? How is the answer to this question to be decided?

2. The Representation of Belief

Any theory of the formation and transformation of belief states consists of (1) a static part describing the belief states that a person can be in and (2) a dynamic part describing how belief states change in response to external input. The static picture constrains the dynamic picture.

Any mechanism for belief revision is sensitive to the formalism chosen for the representation of belief states. We need to be precise about the items we are talking about before we can say how these items are to be changed, so we need to decide how to represent beliefs (what a person believes) and belief states (the mental states that believers are in).

The models we shall consider are all qualitative in the sense that they do not make use of any numbers. In qualitative theories, belief states don’t carry numerical information, and reasoners accept new incoming information without numerical qualification. No numbers represent degrees of “certainty,” “security,” “plausibility,” and so on, and belief is always plain belief, so these models tend to be rather crude. In quantitative theories, by contrast, reasoners do not, or in any case do not have to, accept new information *simpliciter*, but can accept them with a certain degree of certainty or plausibility.²

The best known quantitative modeling of belief is the probabilistic one. But there are other numerical methods of belief change using so-called *qualitative (“Baconian”) probabilities or ranking functions* (Rescher 1976; Cohen 1977; Spohn 1988; Dubois and Prade 1988; Goldszmidt and Pearl 1992; all foreshadowed by Shackle 1949). Quantitative approaches are more expressive than qualitative methods. They provide representations of degrees of belief and, using arithmetic operations, of independence relations between beliefs. This additional expressive power of quantitative approaches is a substantial advantage, but it cannot be denied that there is a price to be paid for it: Often it is not clear where the numbers come from and what they are supposed to mean. While in probability theory numerical values are often considered to be explicable in terms of betting quotients, the precise meaning of the numbers in ranking functions remains largely unelucidated. Moreover, real as opposed to ideally rational persons are notoriously bad at reasoning with probabilities, so while working with numbers helps us to come to terms with many challenging modeling tasks, it is based on parameters the meaning of which is not fully understood and puts very heavy demands on a person’s reasoning capabilities.

Belief revision theories have traditionally been *sentential* or *propositional* in the sense that beliefs are represented as sentences or propositions (with sentential structure). One must first fix an appropriate *language* in which to formulate the beliefs. Belief revision theories typically work with a language L closed under

applications of the Boolean operators of negation, conjunction, disjunction, and implication. We will use lowercase letters p, q , and so on as atomic sentences from L , and capital letters A, B, C , etc., as variables standing for sentences in L .

A sentence A expresses a given proposition if and only if A is true in exactly that set of possible worlds that represents this proposition. Aside from technical details, possible worlds models for belief change are very similar to linguistic models of belief change, since the latter usually stipulate that different sentences that are logically equivalent should be treated alike. We will neglect technical problems concerning possibly indefinable infinite sets of possible worlds in this article.

In modern epistemology there is an important contrast between foundationalist and coherentist theories of the justification of belief. Although belief revision theories developed independently from philosophical discussions surrounding the concept of knowledge, this contrast is mirrored in belief revision theories. Foundationalists in belief revision assume that there is a set of foundational beliefs that are somehow given (*data* in the literal sense of the Latin word) and may be thought of as directly, non-inferentially justified. All other beliefs are justified only in so far as they can be derived in a noncircular (well-founded) way from the stock of foundational beliefs. In more formal terms, such theories presume that there is a belief base H of distinguished sentences. Foundationalists in epistemology typically take simple perceptual beliefs as foundational and sometimes claim that they are infallible. Foundationalists in belief revision leave it completely open what the foundationalist beliefs are about, whether they are true or even infallibly true.

Any arbitrary set H of sentences in L can serve as a *belief base*. No restrictions whatsoever are imposed by belief revision theories on the structure or contents of *basic beliefs*. The elements of a belief base do not have to be true, let alone infallibly true. Basic beliefs are just given, they are *data* in the literal sense of the Latin word.

In the introductory example we began by focusing on a small set of basic beliefs, but then we saw that we have to take care of all their logical consequences as well. The basic beliefs are conceived as being directly justified, but there are other beliefs that arise as consequences from more basic beliefs and have no independent standing. Hence, another factor to be decided in a formal modeling of belief states is what logic governs the language that is used for expressing

the beliefs. Let Cn be a *logic* or *consequence operation* that assigns to any set H of sentences the set $Cn(H)$ of all logical consequences of H . It is commonly assumed that Cn includes classical propositional logic, and is in general quite close to it.³

We call H a *base* for the belief set K if and only if $K = Cn(H)$. *Belief sets* are sets K of sentences in L that are closed under Cn , i.e., for which $K = Cn(K)$. Belief sets are *theories* in the logician's sense. The interpretation of such a belief set is that it contains all the sentences that are accepted by a person in a given belief state. If A is an element of K , then A is *accepted* in K . If the negation $\neg A$ is an element of K , then A is *rejected* in K . Of course, in general there are also sentences A that are neither accepted nor rejected, but on which the reasoner suspends judgment. In such a case, neither A nor $\neg A$ is in K (cf. Quine and Ullian 1978: 12, on the distinction between disbelief and nonbelief). A belief set can thus be seen as a theory that is a partial description of the world.

A belief derived from a belief base is justified by those elements of the base that are used in the derivation of the belief in question.⁴ As already mentioned, modelings using belief bases may be regarded as belonging to the epistemological *foundations theories*, according to which propositions should not be accepted as beliefs unless they are positively justified. In foundations theories, reasoners must keep track of the justifications for their beliefs. In contrast, *coherence theories* hold that one track of the pedigrees of one's beliefs. The focus is instead on the logical or inferential structure of the beliefs – what matters for the rationality of a belief is how it coheres with the other beliefs that are accepted in the current state, and ultimately how all of one's beliefs fit together. For the coherentist, there is no designated set of basic beliefs. All beliefs depend in some way on there being certain other beliefs that support them.

Which model is the better one as a representation of doxastic states, that using belief bases or that using full belief sets? There is no general answer to this question. As models of explicit (active, occurrent) belief, bases are psychologically more realistic since they are usually finite entities. On the other hand, changes of belief sets rather than bases represent what an ideal reasoner would do when forced to reorganize his beliefs. Belief set dynamics offers a competence model that helps us to understand what people ought to do ideally if they were not bounded by limited logical or computational

reasoning capabilities. It is sometimes said that the requirement of logical closure is too extreme an idealization to merit serious consideration. But there are interpretations that make good sense of it: A belief set may be taken to represent the set of beliefs *ascribed* to a reasoner, or the set of beliefs a reasoner *is committed* to.

Another important point is neutral with respect to the particular kind of representation one chooses for beliefs and belief states: Any systematic theory of belief revision should obey the following *Principle of Categorical Matching* (Gärdenfors and Rott 1995):

(PCM) The representation of a belief state after a belief change has taken place should be of the same format as the representation of the belief state before the change.

In the early belief revision theories of the 1980s, belief sets tended to be identified with belief states, but as we shall see from Section 7 on, richer and more elaborate entities were introduced as representations of belief states later in the development of the research paradigm initiated by AGM.

3. Kinds of Belief Change

We saw that if belief states are represented by sets of sentences, there can only be three “degrees of belief.” A sentence can be accepted, rejected, or neither (then it is a nonbelief, on which the reasoner suspends judgment). We distinguish two basic types of belief change: A sentence A can be *inserted* into a belief set (turned into a belief) or *deleted* from a belief set (turned into a nonbelief). In established terminology, the former is called a *revision* by A , denoted $K * A$, and the latter a *contraction* with respect to A , denoted $K \dot{-} A$.

The term “revision” is actually used in three different senses in the literature: In its widest meaning, “belief revision” is synonymous with “belief change” and refers to any operation of transforming belief states. In a second, narrower meaning, “revision” refers to the problem of introducing a new piece of information (expressed by a sentence A) into a belief state, irrespective of the sentence’s status in the prior belief state. In its third and narrowest meaning, “revision” refers to the special case where the new information is inconsistent with the prior belief set, that is, where a disbelief is turned into a belief. Such *belief-contravening revisions* are usually taken to be much more interest-

ing than the consistent case in which revisions (in the second sense) are usually identified with expansions. An *expansion* $K + A$ of a belief set K by a new piece of information A is simply formed by set-theoretic addition and subsequent logical closure: $K + A = Cn(K \cup \{A\})$. An expansion thus defined is closed under logical consequences, and it is consistent as long as A is consistent with K . However, according to the classical rule of *Ex falso quodlibet*, a single inconsistency entails any arbitrary sentence, so the expansion operation is useless for the belief-contravening case. There is only one inconsistent set closed under Cn if Cn is a standard consequence operation, and this is the set of *all* sentences in the language. Gärdenfors once called this set “epistemic hell.” If a reasoner wants to preserve the consistency of his or her belief set, the inclusion of a belief-contravening piece of information requires choices for retractions that cannot be made on the basis of set theory and logic alone. We shall use the term “revision” in its second meaning in what follows.

Expansion is defined solely in logical and set theoretical terms. It is not possible to give a similarly explicit definition of revisions and contractions. The specific problems of belief revision were illustrated in our introductory example. From a logical point of view, we had several ways of constructing the revision when accommodating $\neg j$. There is no purely logical reason for making one choice rather than another among the sentences to be retracted. One has to rely on additional information concerning these sentences. What is needed is a well-defined method for constructing the revision by new information that takes into account a number of coherence constraints (see Section 4). Such a method is represented formally by a *revision function* $*$ associated with a belief set K that takes sentences A and returns as values the revised belief sets $K * A$.⁵

The contraction process faces parallel problems. Let us return to our initial example and consider the belief set K containing the sentences $t, p, p \rightarrow r, t \wedge r \rightarrow j$ together with all their logical consequences (among which is j). Suppose that we want to contract K with respect to j . Of course, j must be deleted from K when forming $K \dot{-} j$, but at least one of the sentences $t, p, p \rightarrow r$, or $t \wedge r \rightarrow j$ must be given up as well in order to be able to maintain deductive closure. Again there is no purely logical reason for making one choice rather than another. Deleting j from our belief set poses quite the same problems as adding $\neg j$ to it.

We have now formed an idea that the problem of belief revision (by $\neg j$) is closely related to the problem of belief contraction (with respect to j). In parallel with revision functions one can introduce the concept of a *contraction function* $\dot{-}$ associated with a belief set K that takes sentences A and returns as values the contracted belief sets $K\dot{-}A$. While for belief-contravening revision the problem of maintaining consistency is most palpable, in belief contraction there is no problem with consistency: Shrinking one's set of beliefs can never introduce an inconsistency. Instead the problem of logical closure makes itself felt rather acutely. Just removing the target sentence from a belief set is not enough; one has to make sure that this sentence cannot be re-derived from other sentences that have remained in the belief set. The common denominator to the questions raised by revision and contraction is that a corpus of beliefs is not viewed merely as a collection of atomic items, but rather as a collection of sentences from which other sentences can be derived. The interaction between an updated "database" and its derived consequences is the ultimate source of the problem of belief change. In Section 6, we shall give a more formal presentation showing how closely the problems of revision and contraction are related.

4. Coherence Constraints for Belief Revision

Rational believers should be coherent – both coherent in their beliefs at a given point of time and coherent in the ways they change their beliefs. We can distinguish three quite different interpretations of this general maxim of coherence:

- a static notion of coherence encoding the idea of a reflective equilibrium
- a dynamic notion of coherence entailing a principle of minimal change
- a dispositional notion of coherence characterizing stable preferences across different potential belief changes

The static notion of coherence refers to the set or system of beliefs held by (or ascribed to) a person at a certain point of time.⁶ A minimal notion of coherence is consistency. Since one of two contradictory sentences is bound to be false and we aim at truth in our beliefs, we will want to avoid holding contradictory beliefs. Consistency is perhaps *the* major driving force of belief revision theories.⁷ A more demanding idea of static

coherence is that the set of beliefs should be logically closed, that is, form a belief set in the technical sense introduced above. Consistency and closure both refer to the logic Cn that governs the language used by the reasoner.

The dynamic notion of coherence refers to a sequence of doxastic states, where the transition from a state to its successor state is brought about by a single application of some belief change operation. Dynamic coherence says that the whole sequence should somehow "make sense." There should not be too many and too drastic disruptions. If the sequence were too erratic, we would have problems to ascribe any meaning to the individual stages. As a kind of corollary for pairs of successive belief states, consider the changes occasioned by some new piece of input perturbing as it were the static coherence of the prior state. In such cases, dynamic coherence requires that the changes be as small as permitted by the input. The information captured in the prior beliefs should not be abandoned beyond necessity. Dynamic coherence implies a principle of conservatism or, in different terms, of informational economy, minimal change, minimum mutilation (Quine) or cognitive inertia.

The notion of dispositional coherence refers to various potential transitions from a given doxastic state to possible successor states. It compares the believer's disposition to respond to different inputs, in particular to pieces of information of related syntactic structure or logical strength. As we shall see, a typical constraint relates the change by a conjunction to the changes by the conjoined sentences taken one by one. In the introductory example, we found that the problem of revision involves a choice which of the previous beliefs (whether basic or derived) to retract. Since logic alone is silent about this matter, an important methodological problem of belief revision is to isolate extralogical factors that determine the relevant choices. It has turned out that dispositional coherence in belief revision is closely related to the coherence of choices as studied in rational choice theory. Constraints for rational choices have been brought to bear on the choices involved in syntactic or semantic constructions for belief revision processes, and were shown to be 'translatable' into rationality postulates for belief revision (Lindström 1991; Rott 1993, 2001; Schlechta 1997; Lehmann 2001).

While static coherence is basically a logical notion, dynamic and dispositional coherence are notions relating to two different concepts of

economic behavior.⁸ The dynamic notion says that the amount of information lost in a belief change should be kept minimal. This principle has been advertised as one of the principal driving forces of belief revision theories by many researchers. It is, however, controversial whether this is an accurate description of the ideas that the formalisms developed in belief revision theory actually encode (Rott 2000). Dispositional coherence can be interpreted as referring to the sort of rational choice as captured in the theories championed by leading economists Paul Samuelson, Kenneth Arrow, Amartya Sen, and others.

5. Different Modes of Belief Change

Foundations and coherence theories of belief (Section 2) have different implications for what should count as rational *changes* of belief systems. According to the foundations theory, belief revision should see to it that all beliefs that do not have a satisfactory justification any more are given up, while propositions that have become justified are added to the stock of beliefs. Harman (1986: 39) suggests the following principle:

Principle of Negative Undermining. One should stop believing *A* whenever one does not associate one's belief in *A* with an adequate justification (either intrinsic or extrinsic). (Variable renamed)

Thus, if a belief state is revised so that a certain belief is lost, all beliefs that depend on it for their justification should be given up in the revised state, too. According to the coherence theory, in contrast, belief revision should primarily see to it that the requirements of coherence are obeyed. The following general principle that is again due to Harman is characteristic of coherentism:

Principle of Positive Undermining. One should stop believing *A* whenever one positively believes one's reasons for believing *A* are no good. (Variable renamed)

Coherentists think that there is no *Letztbegründung* and that all justification is ultimately coherence-based. Coherence tends to keep beliefs in place, so there must be some positive reason for giving up a sentence, not just a loss of justification.

Evidently, foundations and coherence theories of belief revision are based on conflicting ideas of what constitutes a rational change of belief. Without taking sides in this matter, let us keep in mind that it is an important methodological decision how to conceptualize the relation

between the basic (or explicit) beliefs and the beliefs that can be inferred from these (derived or implicit beliefs). One has to decide whether the former should be given a privileged status in comparison to "merely" derived beliefs, or whether the pedigree of a belief should be considered irrelevant for its fate in processes of belief revision.

From the standpoint of a foundationalist epistemology, every belief set *K* (or every more complex belief state) is regarded as generated from a belief base *H* which is associated with the belief set. The belief set *K* is labeled as it were with its pedigree *H*. Belief sets are less structured than belief bases, and the correspondence between belief sets and belief bases is one-many. Two different bases *H* and *H'* may well generate the same belief set *K*, so presumably the result of a revision of *K* by *A* is different depending on whether *K* is generated from *H* or *H'*. Instead of defining revision and contraction functions on belief sets, foundationalists suggest that these functions should operate on the bases of belief sets (or of belief states), or at least with essential reference to their bases. Such functions are called *base revisions* and *base contractions*, respectively. It is then plausible to assume that a revision of a belief set *K* is derived from a revision of its belief base *H*, followed by a process of drawing inferences from the (revised) belief base:

$$K * A = \text{Inf}(H * A)$$

Here *H * A* and *K * A* denote the revisions of the base and theory, respectively, by the new information *A*. *Inf* stands for some inference operation, which may be a standard consequence operation *Cn* but may also be of a much more sophisticated, perhaps paraconsistent and non-monotonic kind.⁹ In this model, the belief base *H* is not taken to be a mere axiomatization of the theory *K*. *H* carries important information in its syntactic structure (and, possibly, in a prioritization of its elements¹⁰) that plays a crucial role in potential or actual revisions of *K*. For instance, two sentences *A* and *B* taken together have the same logical power as the conjunction *A ∧ B*. But if *A* and *B* are individual elements of a belief base, the withdrawal of *A* will not result in a withdrawal of *B*, whereas if the belief base instead contains the conjunction *A ∧ B*, *A* cannot be canceled without canceling *B*. In the term "*Inf*(*H * A*)," the asterisk "*" stands for a *revision operation* on the base level, "*Inf*" for a *reflection operation* taking the reasoner from the base level to the theory level.

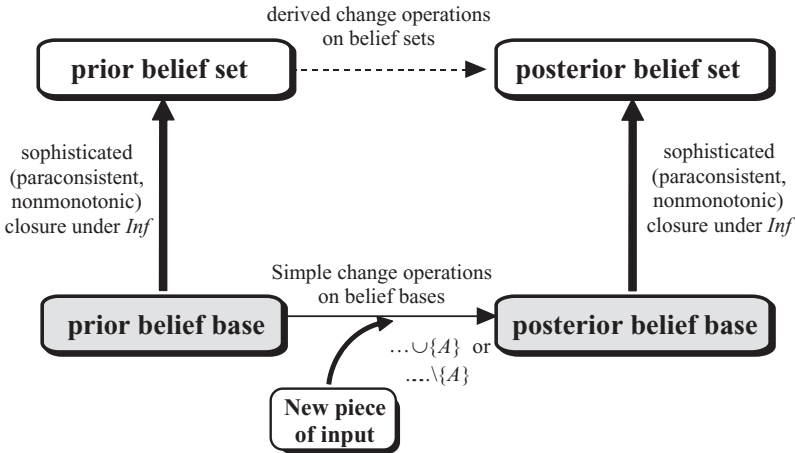

Figure 1. The immediate mode of belief revision (foundationalist perspective).

We are now in a position to distinguish two essentially different modes of performing belief changes that are suggested by the foundationalism–coherentism distinction. As foundational theories regard belief sets as generated from basic beliefs, they suggest a *direct* or *immediate* mode of belief change. In this mode, elements of belief bases are just inserted and deleted, without respect for any coherence constraints. The trivial change operations of insertion and deletion are subsequently followed by a sophisticated reflection process in which the reasoner draws inferences from the revised belief base (see Fig. 1). In a sense, the immediate mode reduces the dynamics of belief to the statics of inference relations: Revision is simple, reflection is difficult.

In contrast, the coherence view of belief states makes sense only if completed by a *logic-constrained* mode of revision. In this mode, the static or logical coherence constraints are taken as constraints controlling the very process of belief change, so that the change operations

themselves will become definitely nontrivial. In reward for these pains, the method may make use of a standard propositional logic as the inference operation (roughly, $Inf = Cn$). The reflection process reduces to the closing of the posterior set of beliefs under logical consequences. Whereas immediate belief change operates on belief bases that are not required to be logically closed, logic-constrained belief change operates on the level of belief sets, that is, on statically coherent theories (see Fig. 2). In this mode of belief change, revision is difficult, reflection is simple. This idea is most prominently instantiated by the original AGM model.¹¹

Roughly speaking, immediate belief change allows the reasoner to forget the old belief *set* (or the old belief *state*) while logic-constrained belief change allows him or her to forget the old inputs (and also the old belief base).

In general, one can say that there is a trade-off here: The more challenging the task of drawing inferences from the belief base (the task of reflection, without external input) is, the easier

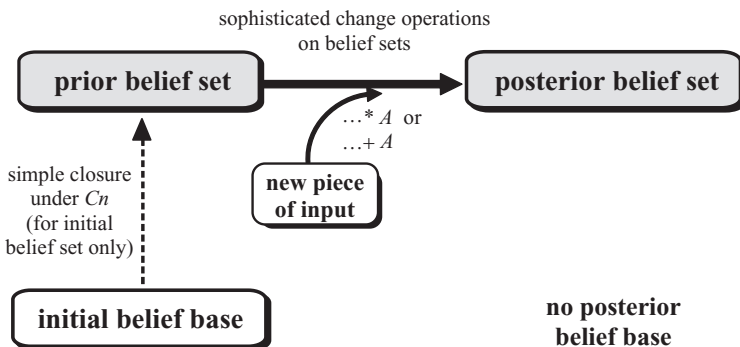

Figure 2. The logic-constrained mode of belief revision (coherentist perspective).

is the task of accommodating the input (the task of revision, of the transformation of the set of beliefs in response to some input). If one uses classical logic in the transition from a belief base to the belief set, the revision process has to take over the task of maintaining consistency. However, if some sort of paraconsistent inference operation is used in the transition from belief base to the theory, the revision process may well be allowed to introduce some “local” inconsistencies into the belief base.

6. Two Strategies for Characterizing Rational Changes of Belief

We have been dealing with very general considerations so far. When tackling belief revision in more concrete detail, two general strategies are viable. First, one can set out to make a list of desiderata that an appropriate belief revision function should fulfill. Our standards for revision and contraction functions can be laid down in various *rationality postulates*, which are typically given in the form of set-theoretic relationships. Second, one will ultimately want to present *explicit constructions* for rational changes of belief. The solution to the problem of belief revision will not be complete unless we know how to define and compute appropriate revision and contraction functions for a given belief state. We shall see that the classic constructions of belief change all make essential use of doxastic preference relations (or similar structures usable for making the necessary choices).

6.1. The Postulates Strategy

In their seminal paper, Alchourrón, Gärdenfors, and Makinson (1985) proposed a set of general *postulates* (now usually called the *AGM postulates*) for the rational revision of belief sets:

- (*1) $K * A$ is closed under C_n (closure)
- (*2) $A \in K * A$ (success)
- (*3) $K * A \subseteq K + A$ (expansion 1)
- (*4) If $\neg A \notin K$, then $K + A \subseteq K * A$ (expansion 2)
- (*5) If A is consistent, so is $K * A$ (consistency)
- (*6) If $C_n(A) = C_n(B)$, then $K * A = K * B$ (extensionality)
- (*7) $K * (A \wedge B) \subseteq (K * A) + B$ (conjunction 1)

- (*8) If $\neg B \notin K * A$, then $(K * A) + B \subseteq K * (A \wedge B)$ (conjunction 2 or rational monotonicity)

We have already commented on the ideas behind closure (*1), success (*2) and consistency (*5). Extensionality (*6) says that it is the content of a new piece of information that matters, not its syntactic surface structure. The expansion postulates (*3) and (*4) jointly say that in the case where the new piece of information A is consistent with the belief set K , the revision is formed by set-theoretically adding A and then taking the logical closure. These are the only AGM postulates encoding the idea of minimal change. The conjunction postulates (*7) and (*8) compare revisions of K by a conjunction $A \wedge B$ with revisions by the first conjunct A . They state that whenever B is consistent with $K * A$, $K * (A \wedge B)$ can be identified with the expansion of $K * A$ by B .

Isaac Levi advanced the thesis that any rational belief revision occasioned by a new piece of information A is decomposable into two successive steps, namely, an elimination of the negation of A (a *contraction* with respect to $\neg A$), followed by an expansion by A (which produces no inconsistency, thanks to the previous contraction step). This suggestion, which is in accordance with the intuitive discussion of our introductory example, has become known as the *Levi identity*:

$$(L) \quad K * A = (K \dot{-} \neg A) + A$$

Many authors have endorsed this suggestion and sought to reduce the problem of belief revision to the problem of withdrawing a belief from a belief set. They focused on postulates and methods of constructing belief contractions. But there is also an equation-defining contraction in terms of revision. This is the so-called *Harper identity*, which is in a rather precise sense the converse for the Levi identity:

$$(H) \quad K \dot{-} A = K \cap K * \neg A$$

The contraction of a belief set K with respect to A is thus defined as that part of K that would survive K 's revision by $\neg A$. Given the equations (L) and (H), the following set of *AGM postulates* for the rational contraction of belief sets has turned out to be equivalent to the set of postulates for belief revision:

- ($\dot{-}$ 1) $K \dot{-} A$ is closed under C_n (closure)
- ($\dot{-}$ 2) $K \dot{-} A \subseteq K$ (inclusion)

- (\div -3) If $A \notin K$, then $K \div A = K$ (*vacuity*)
 (\div -4) If $A \notin Cn(\emptyset)$, then $A \notin K \div A$ (*success*)
 (\div -5) $K \subseteq (K \div A) + A$ (*recovery*)
 (\div -6) If $Cn(A) = Cn(B)$, then $K \div A = K \div B$ (*extensionality*)
 (\div -7) $K \div A \cap K \div B \subseteq K \div (A \wedge B)$ (*conjunction 1*)
 (\div -8) If $A \notin K \div (A \wedge B)$, then $K \div (A \wedge B) \subseteq K \div A$ (*conjunction 2*)

Postulate (\div -1) requires that the contraction of a belief set results in a belief set again. (\div -2) says that a contraction produces a subset of the original belief set, and (\div -3) says that this is a proper subset only if the sentence to be contracted is actually contained in the original set. The success postulate (\div -4) requires that the sentence A to be eliminated is in fact excluded from the contracted belief set, unless A is a logical truth. The recovery postulate (\div -5) says that one can undo contractions in the sense that contracting by A and subsequently adding A back again does not lose any prior beliefs. (\div -6) states that it is the content of the sentence to be withdrawn that matters, not its syntactic surface structure. The conjunction postulates (\div -7) and (\div -8) compare contractions of K with respect to a conjunction $A \wedge B$ with contractions with respect to the conjuncts A and B . They state that any sentence that is contained both in the contraction of K with respect to A and in the contraction of K with respect to B is contained in the contraction of K with respect to $A \wedge B$. As a kind of converse, if the contraction with respect to $A \wedge B$ eliminates A , then any sentence contained in the contraction with respect to $A \wedge B$ is also contained in the contraction with respect to A . The idea of postulates (\div -7) and (\div -8) can be understood if one calls to mind that eliminating $A \wedge B$ in effect means eliminating A or eliminating B (or eliminating both).

The first six AGM postulates for revisions and contractions have been called the *basic* postulates, the last two *supplementary* postulates. It seems fair to say, however, that much of the power of, and of the interest in, AGM belief revision theory is due just to the latter pair of postulates. As we shall see in the next section, they entail that belief change operations are (or can be construed as being) guided by some well-behaved doxastic preference relation. In many contexts, however, postulates (*7) and (*8), and

correspondingly postulates (\div -7) and (\div -8), have turned out to be too strong. Interesting weakenings, for example, are the following:

- (*7c) If $B \in K * A$, then $K * (A \wedge B) \subseteq K * A$ (*cut*)
 (*8c) If $B \in K * A$, then $K * A \subseteq K * (A \wedge B)$ (*cautious monotonicity*)
 (\div -7c) If $B \in K \div (A \wedge B)$, then $K \div A \subseteq K \div (A \wedge B)$
 (\div -8c) If $B \in K \div (A \wedge B)$, then $K \div (A \wedge B) \subseteq K \div A$

The “c” in the names of these conditions means “cumulative,” due to the fact that there are corresponding postulates for nonmonotonic logics that are characteristic of *cumulative reasoning* (cf. Section 9.3). Given the basic postulates, (*7c) and (*8c) taken together are equivalent to the following condition:

- (*R) If $A \in K * B$ and $B \in K * A$, then $K * A = K * B$ (*reciprocity or Stalnaker property*)

The reciprocity condition says that if each of two sentences is believed after revision of K by the other, then these sentences lead to identical revisions of the belief set K . The corresponding condition for belief contractions is somewhat less intuitive:

- (\div -R) If $A \rightarrow B \in K \div B$ and $B \rightarrow A \in K \div A$, then $K \div A = K \div B$

6.2. The Constructive Strategy

Logical postulates are not sufficient to determine a particular revision or contraction of K with respect to some proposition A , and this is just as it should be. For instance, if a person wants to contract successfully the belief set $K = Cn(\{p, p \rightarrow q\})$ with respect to q , he or she has to make a choice whether to give up p or to give up $p \rightarrow q$, and it is not a matter of logic or rationality which of these possibilities is to be preferred. The construction of contractions and revisions has to draw on extralogical factors such as a preference relation over the elements of K or over (some of) the subsets of K . In some constructions, the syntactic structure of the base for K is itself taken to encode such preferences (Lewis 1981; Nebel 1989, 1992). Since the 1990s, most researchers have assumed that these extralogical factors belong to, or can

even be identified with, the reasoner's doxastic state. It may also be argued that external, objective criteria (like objective probability, informational content, truthlikeness, objective similarity between possible worlds) should play the key role in fixing such revision-guiding structures.¹² The crucial difference is that for models based on some objective standard, there is only one rational way to revise a given belief set in response to an input, while for subjectivists two persons with identical belief sets may well decide to choose different revisions in the face of the same input, and this is precisely because their personal belief states are different.

In the classic AGM paradigm of the 1980s, three standard methods were developed for the construction of the contraction $K \dot{-} A$ of a belief set K with respect to a sentence A .¹³ The first method defines $K \dot{-} A$ as the intersection of the "best" maximal subsets of K not implying A , where what is best is determined by a doxastic preference relation (*partial meet contraction*). This method was later shown to be intimately related to a semantic modeling using possible worlds (Grove 1988, after Lewis 1973). Here $K \dot{-} A$ is defined as the set of sentences in K that are true in all maximally "plausible" worlds that do not satisfy A , where what is most plausible is determined by a system of spheres of possible worlds centered around the worlds satisfying K .¹⁴ The second method keeps in $K \dot{-} A$ precisely those propositions of K that are "safe" in all minimal subsets of K that imply A , where again what is safe is determined by a doxastic preference relation (*safe contraction*). The third method keeps in $K \dot{-} A$, roughly speaking, those propositions that are doxastically "well-entrenched," where entrenchment relations are yet another kind of doxastic preferences (*entrenchment-based contraction*). Importantly, the doxastic preference relations used in each of these constructions are independent of the particular sentence to be contracted.

Having presented both postulates and constructions for belief change functions, it is natural to ask whether the two strategies can be connected in an enlightening way. The answer is "yes." Assuming that doxastic preferences meet a number of formal requirements (including transitivity and completeness), AGM and their followers were able to prove various *representation theorems* to the effect that a contraction operation for a belief set K satisfies the AGM postulates for contraction if and only if it can be (re-)constructed by any of the standard construction recipes. Revisions are taken care of with the help

of the Levi identity. As a corollary, the three standard methods are thereby proven equivalent. This is an indirect method of proving equivalence, but there are also direct mappings linking the various sorts of doxastic preference relations used in partial meet contraction, safety relations, and entrenchment relations in such a way that preference relations mapped onto one another lead to the same belief change functions.¹⁵

The concept of entrenchment is particularly interesting because it has several quite diverse interpretations. Suppose that a belief set K is generated from a preordered belief base H , i.e., that $K = Cn(H)$, and there is a reflexive and transitive preference relation (i.e., a preorder) \leq on H specifying the importance or certainty of the basic beliefs. Then an element A of K can be called more entrenched than another element B of K if there is a subset of H implying A the \leq -weakest element of which is \leq -stronger than the \leq -weakest element of any subset of H that implies B . This is a *positive* concept of entrenchment, saying intuitively that there is a more certain way of obtaining A than of obtaining B . But an alternative concept makes equally good sense. The idea is that an element A of K can be called more entrenched than another element B of K if for every subset H_1 of H not implying A there is another subset H_2 of H not implying B which is "better" than H_1 in the following sense: There is an element of H lost in H_1 but not in H_2 which is \leq -stronger than any element of H lost in H_2 but not in H_1 . This is a *negative* concept of entrenchment, saying intuitively that there are less costly ways of getting rid of B than there are ways of getting rid of A . It can be shown that negative entrenchment is a refinement of positive entrenchment. Negative entrenchment introduces incomparabilities, while all beliefs are comparable in terms of the less discriminating positive entrenchment relation. Yet another, much more general but less constructive interpretation is to consider entrenchment as a *revealed preference relation* that can be abstracted from binary choices between beliefs: A is more entrenched in K than B if the contraction of K with respect to $A \wedge B$ (which, as noted earlier, comes down to the contraction of K with respect to at least one of A and B) contains A but does not contain B . Clearly, this idea is reconstructive rather than constructive, since it presumes that a method of belief contraction is already given. But it captures the meaning of the term "entrenchment" very well, and it does not presuppose that the belief set K is generated from a particular (prioritized) belief base H .

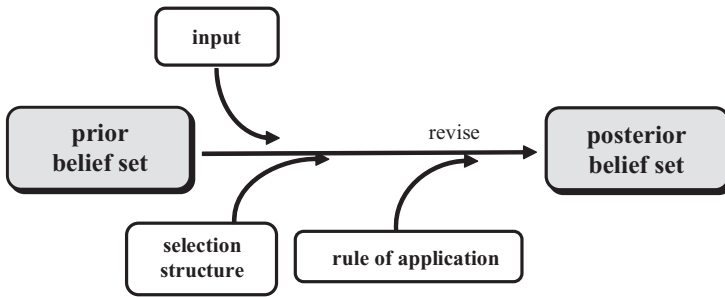

Figure 3. Elements of AGM-style theories of belief change.

While the idea of informational economy has played a rather modest role in AGM-style theorizing of belief revision, economical ideas have always formed an essential part of belief revision theories through the systematic study of the structure and application of preference relations to cognitive choice problems. Varying (usually weakening) the formal requirements for the relevant preference relations results in variations (usually weakenings) of the seventh and eighth AGM postulates. As already mentioned, the full set of AGM postulates is rather strong. Some natural relaxations of the requirements for preference relations (including the renunciation of completeness) lead to the postulates (*7c) and (*8c) mentioned in the last section. One can indeed show that insights gained in rational choice theory over the last four or five decades can be applied in quite a straightforward way to choice problems involved in belief change processes – choices concerning least plausible sentences or concerning most plausible possible worlds (Rott 2001). Seen from this perspective, the problem of belief revision is just an instantiation of the general problem of rational choice, with some additional constraints set up by the background logic C_n . While the formation and transformation of belief sets or theories would usually be classed as a problem of theoretical reason, the making of choices belongs to the realm of practical reason. The observation that from a purely formal point of view, the former falls under the latter is indeed a surprising result. However, the interpretation of this observation is far from clear. Should we take the use of choice functions as indicating that believers are free to decide to believe or not to believe a proposition according to their preferences (*doxastic voluntarism*)? Are they free to adopt the doxastic preferences as they wish? Or are such choices predetermined in a way similar to the choices of chess computers that are bound

to make the moves they evaluate as best in a perfectly deterministic and mechanical way? We have to leave these questions open here, but it is worth pointing out that only part of the problem of belief change, namely, the dispositional coherence part of the classic AGM theory, is within the reach of rational choice theory. As we shall see in Sections 8 and 9, this theory needs itself to be extended and revised in various ways. Rational choice theory cannot be brought to bear, for instance, on the problem of iterated belief change that goes well beyond AGM.

7. An Abstract View of the Elements of Belief Change

The problem of iterated belief change requires us to take a more abstract point of view. Belief change theories deal with the transformation of belief states (doxastic states) in response to incoming information. We have seen that we need more than just logical and set-theoretical means to tackle this task. In the beginning of belief revision theory as represented by the classic AGM framework, the following elements were involved in a single transition episode (see Fig. 3):

- a prior belief set
- a piece of input
- a selection structure
- a rule of how to apply the selection structure
- a posterior belief set

The belief state of a person was identified by AGM (more implicitly than explicitly) with his or her belief set, and accordingly, the revision functions operated on the belief sets. The selection structure, typically some preference relation or choice function, was *used*, but it never took center stage as an object of the discussion. This theory was formally beautiful, but it

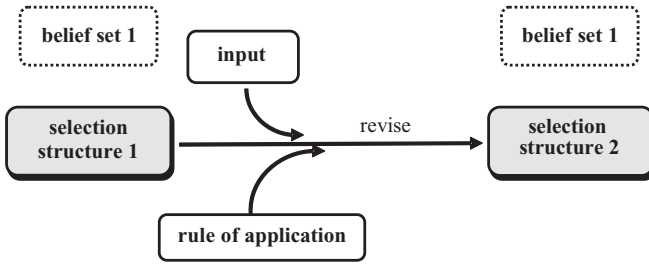

Figure 4. Elements of theories of iterated belief change.

remained silent about the question where the selection structure comes from. It was unclear whether the selection structure was conceived as an objective feature of the world, to be understood either on a priori or on empirical grounds, or whether it formed part of the reasoner's subjective belief state.¹⁶ Support for the latter interpretation can be found in the fact that it was often assumed that the selection structure somehow "fits" the belief set. To see what is meant by that, one must know that for each selection structure there is a consistent belief set that can be retrieved from it. In the possible worlds modeling, for instance, the belief set of a person is determined by the set of sentences satisfied in all maximally plausible worlds according to the person's system of spheres. In the entrenchment modeling, it is determined as the set of sentences that are more than minimally entrenched according to his or her doxastic preferences. If a person's beliefs are exactly the ones associated with the person's doxastic preferences, the latter *fit* his or her belief set.

A few years after the AGM program had been started, changes of *belief bases* were suggested as an alternative, possibly more realistic model for human belief change (Nebel 1989, 1992; Fuhrmann 1991; Hansson 1991). It is important to see that belief bases can function as selection structures. First, the belief set can be retrieved from the belief base, by processing the latter with the help of a more or less sophisticated inference operation (we mentioned non-standard, paraconsistent, and nonmonotonic logics). Second, the relevant change functions operate on the belief base level rather than on the belief set level (cf. Section 5). Third, belief bases may themselves come with a preference relation, often called the prioritization of the elements of the base, and in such cases one needs to devise inference processes that respect and exploit the priorities as well as the syntactic structures of the basic beliefs. Depending on the inference oper-

ation applied, generating a belief set from the belief base can be, but need not be, a highly demanding task.

With the benefit of hindsight, one can interpret theories of belief base change as suggesting that belief bases should be regarded as more adequate representations of belief states than belief sets. Bases possess more structure than belief sets. The insight that belief states are more than just belief sets, however, gained wide currency only when the problem of *iteration* was attacked systematically in the 1990s. In order to be prepared for repeated belief changes, a reasoner needs not only a revised belief set after each step in the sequence, but also a new revision-guiding selection structure. Two ways of solving this problem are possible. One can either take the concept of belief state as primitive (Darwiche and Pearl 1997) and *assign* a belief set and a selection structure to a given belief state, or one can take the view that belief states can be *identified* with, or simply *are*, selection structures. This, I think, is the view implicit in most works on iterated belief revision, and the picture that emerges is shown in Fig. 4.

Here revision functions do not operate on the belief sets any more, but on selection structures, and this is what makes iterations possible in the first place. From such structures, we have already seen, belief sets can readily be retrieved. Preference relations are the paradigmatic selection structures. A variety of change functions on preference relations have been proposed in the literature (more on this in Section 8).

Recently, a further generalization of this picture has been developed in the field of *belief merging* (also known as *belief fusion*). The inputs of qualitative belief change processes have quite long been thought of as purely propositional in nature. But there is no reason to restrict inputs to such a format. Inputs may be much more finely structured than that. In fact, the input can even be a full selection structure, so that the prior

Figure 5. Elements of theories of belief merging for two reasoners.

belief state and the input have precisely the same format. This kind of input can most naturally be taken to be the belief state of another reasoner. The picture that surfaces for the two-person case is shown in Fig. 5.

Having gone that far, it is a small step to the merging of the belief states of any (finite) number of reasoners. Ordinary revision by a propositional input can in this model be mimicked by the merging with a very coarse-grained selection structure (e.g., by a system of spheres of possible worlds, or an entrenchment relation, with only two or three levels). The idea of belief merging is an important advancement of the theory of belief revision.

8. Iterated Changes of Belief

There is an almost universal consensus about how to use selection structures in one-step belief revision. If these structures satisfy the formal properties required by AGM, then the solution to the problem of belief change in response to a single piece of input is the AGM solution.¹⁷ Iterated belief change, or equivalently, the change of selection-structures, however, exhibits substantial ambiguities (Darwiche and Pearl 1994, 1997). Even within the narrow confines of the technical framework of classic revision (no numbers, only propositional inputs), there are quite a few models that have been proposed.¹⁸ I shall focus on four particularly important ones, taking the terminology from Rott (2003b). These models usually confirm the application of the AGM postulates to one-step belief change, but they also have at least one additional rule taking care of iterations.

The first method uses one and the same selection structure for all possible belief sets (the

method is surveyed in Areces and Becher 2001). As this selection structure in general does not fit the reasoner's current belief set, it cannot represent his or her belief state, but is *external* to it. In contrast, the other three methods may be interpreted as identifying the belief state with the selection structure. The second method is *radical* in that the input is given uncompromising priority over the previous beliefs; any world or situation that does not satisfy the input is considered maximally implausible after the revision (Seegerberg 1998; Friedman and Halpern 1999). The third method, in contrast to the second one, is maximally *conservative*; the selection structure is changed so that the input just gets accepted, but the changes made are absolutely minimal, and as a consequence the newly acquired information is very easily lost in further belief changes (Boutilier 1993, 1996). The fourth method is *moderate* in that it opts for an intermediate way between the second and the third methods; it recommends giving high priority to the incoming information, but it does not wipe out all plausibility distinctions between worlds or situations not complying with it (Nayak 1994; Nayak, Pagnucco, and Peppas 2003).

Each of these methods can be axiomatically characterized by a single axiom taking care of the iteration case. In the following axioms, the belief set *K* should be taken to be a fixed starting point.¹⁹

*External revision (invariable selection structure with associated belief set F)*²⁰

$$(K * A) * B = \begin{cases} (K * A) + B & \text{if } B \text{ is consistent} \\ & \text{with } K * A \\ F * B & \text{otherwise} \end{cases}$$

Radical reversion

$$(K * A) * B = K * (A \wedge B)$$

Conservative revision

$$(K * A) * B = \begin{cases} (K * A) + B & \text{if } B \text{ is consistent} \\ & \text{with } K * A \\ K * B & \text{otherwise} \end{cases}$$

Moderate revision

$$(K * A) * B = \begin{cases} K * (A \wedge B) & \text{if } B \text{ is consistent} \\ & \text{with } A \\ K * B & \text{otherwise} \end{cases}$$

All of these methods are well-defined independently of the presence of the seventh and eighth AGM axioms, that is, whether the reasoner's dispositions for one-step belief change are coherent or not (Rott 2003b). The belief set resulting from any finite number of revision steps can be generated inductively by repeated applications of the respective axiom. We can see that according to each method, two revision steps can be reduced to one-step revision, usually by means of some characteristic case distinction.²¹ Radical revision is the only method that has no case distinction, and it leads to the inconsistent belief set as soon as the incoming information happens to be contradictory.²² The lower lines of the other three methods indicate that earlier evidence is prone to be forgotten if inconsistencies with later evidence arise. Moderate revision appears to be the most reasonable method, because it forgets A only if B is inconsistent with A , and an inconsistency of B with A is much less likely to arise than an inconsistency of B with the full belief set $K * A$.

Summing up, we have seen that there are a number of competing models for iterated belief change, each of which appears to be adequate for some purposes. But it is not difficult to come up with examples showing that each of these methods has its drawbacks. At the time of writing, no one has put forward a *methodology* that would tell us when to use which method or combination of methods.²³ Which of all these methods makes sense for which kinds of applications or contexts? And the same questions that we asked about the selection structures a few pages ago, can now be raised about the rules for changing selection structures: Where do they come from? Should we think of them as forming a part of the reasoner's belief state, of another compartment of the reasoner's mind, or are they external, subject to objective criteria and constraints? How do

we, and how should we, go about selecting the rules for changing selection structures?

9. Further Developments

9.1. Variants and Extensions of Belief Revision

The field of belief revision has widened considerably since the time of the classic AGM model. There have been numerous interesting developments of which we briefly mention only three and present a fourth one in slightly more detail. All of these extensions capture AGM-style belief revision as a limiting case; none of them is reducible to the classic AGM belief change theory.

Multiple revisions are occasioned by sets of sentences that have to be accepted or to be withdrawn simultaneously (Fuhrmann and Hansson 1994; Zhang and Foo 2001). In *nonprioritized belief revision*, reasoners do not invariably incorporate the new information, but first decide in the light of (a designated part of) his or her current belief state whether or not a belief change should take place at all (Hansson 1997; Chopra, Ghose, and Meyer 2003). *Two-dimensional belief revision* is a method that changes beliefs in response to imperatives of the form "Accept A with a degree of plausibility that at least equals that of B " (Cantwell 1997; Fermé and Rott 2004; Rott 2007). Put differently, one can say that this belief change operation takes two arguments, an *input sentence* A and a *reference sentence* B , or that the input is of the form " $B \leq A$." This method of changing belief states has both characteristics of belief revision (with respect to the input sentence) and characteristics of belief contraction (with respect to the reference sentence). Two-dimensional belief revision is much more flexible than the methods of iterated belief revision mentioned in Section 8. For instance, beliefs can be *lowered* and non-beliefs can be *raised* in doxastic status while still remaining beliefs and non-beliefs, respectively.

9.2. Updates

An important distinction arising already on the level of ordinary one-step belief change is marked by Katsuno and Mendelzon's (1992) terminological distinction between *revisions* and *updates*. Revisions are prompted by new information about a ("static") world that has not changed, while updates are prompted by

information about changes in the (“dynamic”) world. The difference comes out best by a possible worlds representation of the case where the new piece of information A is consistent with the belief set K . Revisions by A make a person eliminate from the set of worlds he or she deems possible those worlds that do not satisfy A . If you learn that David is the head of the department, with the understanding that this has been the case for a while, then you just cut off all possible worlds in which someone else is head of the department (this was already recommended by AGM). In contrast, if you learn that David is head of the department with the understanding that he has just been appointed head of the department, then you keep all your possible worlds and continue as it were every single one of them by letting David become head of the department there. So an update by A makes a person consider, for each world he or she deems possible, how the world would develop if A were brought about in this world. A formal mark of such updates is that they violate postulate (*4) and instead satisfy the following monotonicity condition

(*Ml) If $K_1 \subseteq K_2$, then $K_1 * A \subseteq K_2 * A$. (*-monotonicity
left)

(*Ml) is a paradigmatic nontheorem of classic AGM-style belief revision (see Gärdenfors 1988: Ch. 7).

9.3. Default Inferences as Expectation Revision

Given the information that Tweety is a bird (A), your belief set will typically include that Tweety can fly, but given the information that Tweety is a penguin (B), which of course implies that Tweety is a bird, you will *not* believe that Tweety can fly (but instead believe that Tweety cannot fly). Thus belief revision theories characteristically fail to validate the following monotonicity principle

(*Mr) If $A \in Cn(B)$, then $K * A \subseteq K * B$. (*-monotonicity
right)

The fact that belief revision theories violate (*Mr) indicates that they can serve to model patterns of *defeasible* or *nonmonotonic reasoning*. It has been one of the most important insights of logic-based AI research of the past twenty-five years that for the basic inference patterns used in commonsense reasoning, an extension of the set of premises not only *gains*, but often *loses*

some conclusions that were drawn on the basis of the smaller premise set (Ginsberg 1987; Gabbay, Hogger, and Robinson 1994). You lose your belief in Tweety’s ability to fly after gaining the new information that Tweety is a penguin. If you don’t know that a particular bird doesn’t fly, you take it that it flies. Everyday reasoning thus does not conform to (all) the rules of classical logic. The *argument from ignorance* or *appeal to ignorance* that has traditionally been dismissed as fallacious turns out to be, if judiciously employed, a useful and powerful scheme of ordinary reasoning. Inference operations *Inf* allowing for such nonmonotonic phenomena violate the following central rule of ordinary (Tarskian) logics

(M) If $H \subseteq H'$, then $Inf(H) \subseteq Inf(H')$. (Inf-monotonicity)

Makinson and Gärdenfors (1991) and Gärdenfors and Makinson (1994) proposed that the set of defeasible consequences $Inf(H)$ of a finite set of premises $H = \{A_1, \dots, A_n\}$ should be regarded as the theory that results from the revision of some set of *background assumptions, defaults, or expectations* E by the conjunction of the premise set H . They suggested the following identity

(I) $Inf(H) = E*(A_1 \wedge \dots \wedge A_n)$

For the inference relation *Inf* thus defined, adding information can defeat previously drawn conclusions, as we see when we enlarge the singleton premise set containing only ‘Tweety is a bird’ (A_1) with the sentence ‘Tweety is a penguin’ (A_2). Given our expectations, the input A_1 makes us conclude that Tweety can fly, whereas the input A_2 (which, given our background theory, is equivalent with $A_1 \wedge A_2$) will make us draw the opposite conclusion.

Defeasible or nonmonotonic inference operations are quite irregular as compared to Tarskian logics. The failure of (M) is indeed incisive. However, commonsense reasoning nevertheless appears to leave intact quite a number of important classical inference patterns (Gabbay 1985; Kraus, Lehmann, and Magidor 1990; Makinson 1994, 2005). In the following, we identify finite premise sets with the conjunction of their elements and apply *Inf* to single sentences only. An inference relation is called *cumulative* if it satisfies the following six conditions:

Reflexivity $A \in Inf(A)$

Left Logical Equivalence If $Cn(A) = Cn(B)$, then $Inf(A) = Inf(B)$

<i>Right Weakening</i>	If $B \in \text{Inf}(A)$ and $C \in \text{Cn}(B)$, then $C \in \text{Inf}(A)$
<i>And</i>	If $B \in \text{Inf}(A)$ and $C \in \text{Inf}(A)$, then $B \wedge C \in \text{Inf}(A)$
<i>Cut</i>	If $B \in \text{Inf}(A)$, then $\text{Inf}(A \wedge B) \subseteq \text{Inf}(A)$
<i>Cautious Monotonicity</i>	If $B \in \text{Inf}(A)$, then $\text{Inf}(A) \subseteq$ $\text{Inf}(A \wedge B)$

A cumulative inference relation Inf is *preferential* if it also satisfies the rule Or; it is *rational*, if it in addition satisfies Or and Rational Monotonicity:

<i>Or</i>	$\text{Inf}(A) \cap \text{Inf}(B) \subseteq \text{Inf}(A \vee B)$
<i>Rational Monotonicity</i>	If $\neg B \notin \text{Inf}(A)$, then $\text{Inf}(A) \subseteq$ $\text{Inf}(A \wedge B)$

Makinson and Gärdenfors proved the following results. If a revision function $*$ satisfies the AGM postulates (*1)–(*8), then the inference operation Inf generated by equation (I) has all the properties required of a rational inference relation. And conversely, for any rational inference operation Inf , there is a set E and a revision function $*$ satisfying (*1)–(*8) such that Inf can be represented by equation (I). Similar correspondence theorems were shown for cumulative reasoning and the set consisting of (*1)–(*6) plus (*7c) and (*8c), and also for preferential reasoning and the set (*1)–(*7) plus (*8c). The expectation set E implicit in an inference operation Inf can be defined as $\text{Inf}(\text{TAUT})$, where TAUT is an arbitrary tautology. Results such as these suggest that belief change and defeasible reasoning are just “two sides of the same coin” (Gärdenfors).

9.4. Belief Merging

Arguably the most important of the recent developments is the field of *belief merging* or *belief fusion* that is concerned with the rational aggregation of two or more belief states (Baral et al. 1991, 1992; Revesz 1993, 1997; Nayak 1994; Liberatore and Schaerf 1997; Konieczny and Pino-Pérez 1998, 2002). In many versions, negotiation procedures or aggregation processes similar to those known from social choice theory find application in belief merging.

As our prime example, we present the axioms for *merging with integrity constraints* introduced by Konieczny and Pino-Pérez (2002). Following these authors, we use a finitary language, so that a belief set K can be represented by a single sen-

tence, viz., the conjunction of representatives of the equivalence classes of K under Cn . With a slight abuse of notation, we identify belief sets with the sentences representing them in the following. Let K_i be the belief set of reasoner i . A *belief profile* P is a multiset of (finitary) belief sets $[K_1, \dots, K_n]$.²⁴

While belief merging should be thought of as primarily combining belief states of several agents, room is also made for propositional “inputs” in the original AGM sense. This is what Konieczny and Pino-Pérez call “constraints,” with the formal idea that any resulting belief set must contain the specified constraint. This is an analogue to the AGM postulate of “success.” Now we are ready for the official definition. An operator $*$ taking pairs consisting of a belief profile and a single sentence (representing an “integrity constraint” or, in our terminology, an “input”²⁵) and returning belief sets is an operator of merging with constraints if and only if it satisfies the following postulates:

- (KP0) $A \in [K_1, \dots, K_n]*A$
- (KP1) If A is consistent, so is $[K_1, \dots, K_n]*A$
- (KP2) If K_1, \dots, K_n are jointly consistent with A , then $[K_1, \dots, K_n]*A = \text{Cn}(K_1 \wedge \dots \wedge K_n \wedge A)$
- (KP3) If $[K_1, \dots, K_n]$ and $[K'_1, \dots, K'_n]$ are member-wise equivalent under Cn and if $\text{Cn}(A) = \text{Cn}(A')$, then $[K_1, \dots, K_n]*A = [K'_1, \dots, K'_n]*A'$.
- (KP4) If $A \in K \cap K'$ and $[K, K']*A$ is consistent with K , then $[K, K']*A$ is also consistent with K' .
- (KP5) $[K_1, \dots, K_n, K'_1, \dots, K'_m]*A \subseteq \text{Cn}([K_1, \dots, K_n]*A \cup [K'_1, \dots, K'_m]*A)$
- (KP6) If $[K_1, \dots, K_n]*A$ is consistent with $[K'_1, \dots, K'_m]*A$, then $[K_1, \dots, K_n]*A \subseteq [K_1, \dots, K_n, K'_1, \dots, K'_m]*A$
- (KP7) $[K_1, \dots, K_n]*(A \wedge B) \subseteq ([K_1, \dots, K_n]*A) + B$
- (KP8) If $[K_1, \dots, K_n]*A$ is consistent with B , then $([K_1, \dots, K_n]*A) + B \subseteq [K_1, \dots, K_n]*(A \wedge B)$

Intuitively, $[K_1, \dots, K_n]*A$ is the belief set that results from merging the beliefs of n reasoners under the constraint that A be accepted. Belief merging is an important generalization of

the classic belief revision paradigm. An *AGM-style revision* is obtained from it by taking $n = 1$. An operator of *pure merging* (without “input” or “integrity constraint”) can be defined by fixing a tautology as input. Postulates (KP1)–(KP3), (KP7), and (KP8) are easily recognized as counterparts to AGM postulates. Merging proper is dealt with by postulates (KP4)–(KP6). Postulate (KP4) is a fairness condition saying that if the constraint is satisfied by the belief sets of two players, the merging of both belief sets should not result in a belief set consistent with one but inconsistent with the other. Postulates (KP5) and (KP6) say, roughly, that if the constraint is fixed and no intermediate inconsistency arises, the merging of a belief profile of size $n + m$ can be achieved by merging subprofiles of size n and size m separately, and then taking the union of the two results and closing under logical consequences. Konieczny and Pino-Pérez show that the merging postulates can be modified or supplemented in a wide variety of interesting ways. They also provide a constructive approach by giving appropriate representation theorems for the basic as well as the modified and supplemented models.²⁶

10. Concluding Remarks

After a quarter of a century’s work, the field of belief revision is well established today. Some may say that the magic that dwells in each beginning has vanished, but a sizable bulk of knowledge has been accumulated, and important new developments have been initiated, particularly in iterated belief change and belief merging. Research in belief revision originally started out in philosophy and is now most actively pursued in computer science, but it is still an essentially interdisciplinary undertaking. On the one hand, for instance, there are difficult technical problems best addressed by mathematicians; on the other hand, psychologists have become interested because they are looking for clear-cut models of some interesting cognitive processes. There are certainly countless exciting things to explore. One of the tasks ahead is to develop a methodology for when to apply which of the many models on offer. Belief revision theory should be useful after all. Another task is to close the gap between idealized models of perfectly rational reasoners and the actual facts about the limited computational and logical capacities of human beings. Whether we view it from a normative or an empirical perspective, the formation and transformation of beliefs is a problem that raises

its head just about everywhere, and it will stay with us as an object of scientific theorizing for a long time to come.

Acknowledgments

I would like to thank Jonathan Adler, Guido Löhrer, Patrick Peindl, Matthias Söllner, and, in particular, Ralf Busse for valuable comments on an earlier version of this paper.

Notes

- 1 The terms “belief state” and “doxastic state” are used as synonyms throughout this paper.
- 2 In probability theory, plain conditionalization (which assigns probability 1 to new evidence) may be replaced by Jeffrey conditionalization with a certain parameter α which specifies the posterior probability of the new evidence at any arbitrary value between 0 and 1 (cf. Jeffrey 1965): $P_{A,\alpha}(B) = \alpha \cdot (P(A \wedge B)/P(A)) + (1 - \alpha) \cdot (P(\neg A \wedge B)/P(\neg A))$. In Spohn’s (1988) model of ordinal conditional functions (now often called “ranking functions,” Goldszmidt and Pearl 1992), beliefs are fully accepted, but inputs are accompanied by a value α of certainty as well: $\kappa_{A,\alpha}(B) = \min\{\kappa(A \wedge B) - \kappa(A), \alpha + \kappa(\neg A \wedge B) - \kappa(\neg A)\}$. Note that in these theories the input proposition *can* and *must* be qualified by a number that specifies the new proposition’s degree of certainty or plausibility.
- 3 More precisely, the logic C_n is usually supposed to be *Tarskian*, that is, reflexive ($H \subseteq C_n(H)$), monotonic (if $H \subseteq H'$, then $C_n(H) \subseteq C_n(H')$), idempotent ($C_n(C_n(H)) \subseteq C_n(H)$), and compact (if $A \in C_n(H)$, then $A \in C_n(H')$ for some finite $H' \subseteq H$).
- 4 Being derived from a belief base through the application of C_n is only a very crude notion of justification. For more interesting ideas about justification in belief change, see Haas (2005).
- 5 Many authors present revision functions as two-place functions taking a pair of a belief set and a sentence and returning a new belief set. This way of putting things appears misleading to me, since one and the same belief set may be associated with different belief revision strategies, so $*$ as acting on pairs (K, A) cannot be function in the K argument. This issue is a delicate one. For more details, see Rott (1999).
- 6 The term “static” is not meant to deny that the drawing of inferences is a process that takes time. I use the term here just to indicate that no input coming from the external world disturbs the belief state. Changes of the latter kind are “dynamic” phenomena in my terminology.
- 7 The consistency requirement can be seen as marking off the enterprise of belief revision from that of paraconsistent logic, which shares the aim

- of explicating rational deliberation in the face of contradictory information. A logic or inference operation is paraconsistent if it does not satisfy the classical rule of *Ex falso quodlibet*, that is, if not everything is derivable from a classically inconsistent set of premises (Priest, Routley, and Norman 1989).
- 8 See Rott (2003a). An important way of deriving recipes for belief revision from decision-theoretic principles has been vigorously advocated by Isaac Levi (1991, 2004).
 - 9 For paraconsistency, see footnote 7; for non-monotonicity, see Section 9.3.
 - 10 A prioritization of a belief base is a preorder, that is, a transitive and connected relation, that reflects the priorities, or the degrees of importance, of the elements of the base.
 - 11 I have been neglecting here an important mode located 'between' the direct mode and the logic-constrained mode. The change operation may be applied on belief bases and respect consistency, that is, the first half of static coherence, while ignoring the second half, closure. In this mode, revision is difficult and reflection may be performed with the simple logic $Inf = Cn$ (for a comprehensive and detailed treatment of various ways to implement this mode, see Hansson 1999). Thus the dichotomy between foundationalism and coherentism is not identical with that between the immediate and the direct mode. The foundationalist approach (change operations on belief bases rather than theories) is compatible with both the immediate mode and the logic-constrained mode. The coherence approach makes sense only if combined with the logic-constrained mode of belief revision.
 - 12 See for instance Schlechta (1991), Hansson (1991), Katsuno and Mendelzon (1991), and Konieczny and Pino-Pérez (2002). In computer science, the most common way of measuring distances between possible worlds (or models) is to set-theoretically compare or to count the atoms on which two worlds differ (the so-called Hamming distance). This concept of distance is independent of the belief state of the reasoner. Clearly, such ideas do not achieve full objectivity, since distances thus conceived are dependent on the language used to describe the world.
 - 13 For more detailed overviews, see Gärdenfors (1988), Gärdenfors and Rott (1995), and Hansson (1999).
 - 14 A system of spheres of possible worlds is equivalent to a complete preorder on the set of possible worlds – yet another closely related semantic modeling influential in belief revision theory (Katsuno and Mendelzon 1991).
 - 15 For further discussion of the two strategies cf. Makinson (1985). More material about a great variety of representation theorems can be found in Gärdenfors (1988), Hansson (1999), Bochman (2001), and Rott (2001).
 - 16 We shall soon encounter the surprising idea that a selection structure may also be (part of) the input.
 - 17 Even though the AGM solution was more or less universally acclaimed, there were some significant discussions concerning most notably "updates" (see Section 9.2) and "withdrawals" (Pagnucco and Rott 1999; Levi 2004) of belief.
 - 18 See Konieczny and Pino-Pérez (2000), Rott (2003b), and von Ditmarsch (2005).
 - 19 Alternatively, the symbol K may be taken to stand, by abuse of notation, for a full belief *state* rather than a belief *set*. Compare Darwiche and Pearl (1997).
 - 20 We should emphasize here that not all methods that may justly be called "external" validate this axiom scheme. Methods based on global (i.e., belief-state independent) similarities or distances between possible worlds are external, but their logical behavior is very different (more complicated and more interesting) in that they do take the current belief set into account in the case of a belief-contravening revision step. See Lehmann, Magidor, and Schlechta (2001).
 - 21 This is true on the level of *belief sets*, but not on the level of *belief states* (selection structures).
 - 22 There is a slightly less radical version of this operation that puts $(K*A)*B = K*(A\wedge B)$ if B is consistent with A , and $(K*A)*B = Cn(B)$ otherwise.
 - 23 Notice that we need to provide for a mix of methods anyway, since in repeated belief changes reasoners are likely to encounter problems of contraction as well as revision.
 - 24 Multisets are collections of objects at a level of abstraction between sets and sequences. The number of occurrences of the members in a multiset matters, but their order doesn't. For example, $[K, K, K']$ is identical with $[K, K', K]$, but different from $[K, K']$. In order to ensure continuity with our presentation, I have adapted Konieczny and Pino-Pérez's terminology. We call belief set what they call belief base, and we call belief profile what they call belief set. I have also adapted the notation of Konieczny and Pino-Pérez for easy comprehension in the context of this paper. Where they write $\Delta_A(P)$, I write $[K_1, \dots, K_n]*A$.
 - 25 Here the cautionary remark of footnote 5 does not apply because Konieczny and Pino-Pérez deliberately employ similarity relations that are external to the reasoner's belief states.
 - 26 Konieczny and Pino-Pérez make use of a preorder semantics in the style of Katsuno-Mendelzon; cf. footnote 14.

Chapter 26: *Belief, Doubt, and Evidentialism*

ISAAC LEVI

The Main Task of Epistemology: Justifying Changes in Full Belief

I would bet my bottom dollar that William Henry Seward was Secretary of State in the Cabinets of Presidents Abraham Lincoln and Andrew Johnson. I am equally confident that while holding that office under Johnson he negotiated the purchase of Alaska by the United States of America from Russia. I am sure that the purchase was in 1867 give or take a year or so. (I am fairly confident that the year was 1867 but not absolutely certain.) However, I am absolutely certain that Seward had his permanent residence in Auburn, New York, for most of his life.

Confident assertion of matters of fact strikes many as out of place. Epistemic modesty requires that I refrain from expressions of absolute certainty not only about the date of the purchase of Alaska but concerning all the other claims made in the previous paragraph.

A public claim of absolute certainty even when one is sincere in the claim is not the way to win friends and influence people. But champions of epistemic modesty are concerned with more than conversational etiquette or political correctness. Not only should we avoid *expressing* absolute certainty, we should not *be* absolutely certain about questions of fact.

Many philosophers would concede that we should all be certain about the truth of the theses of logic and, perhaps, concerning other theses lurking in the cores of our conceptual frameworks. Questions of logic ought to be non-controversial although even the principle of non-contradiction has been challenged. But disagreements over issues of fact are different. Some may disagree with my convictions about Seward. Others may never have heard of Seward or the alleged folly of purchasing Alaska. And others

may never have heard of Auburn, New York. There may, for all I know, be someone who is familiar with Seward's achievements but who is convinced that Seward is alive or who at least surmises that he still lives. What entitles anyone to absolute certainty that Seward lived in Auburn in the face of the circumstance that for one reason or another others doubt this?

The question concedes that seeking to justify one's convictions to those who already share them is as pointless as preaching to the converted. It presupposes, however, that to be entitled to absolute certainty, one should be in a position to justify one's convictions to others when they disagree. The presupposition is absurd on its face.

What is required of X in order for X to justify X's conviction that *h* to Y? One possibility is that X is obliged to show that X acquired X's full belief that *h* from previously held beliefs in a justifiable manner. But why should X be required to display the pedigree of X's conviction to Y in order to be entitled to absolute certainty that *h*? Even if Y acknowledges that X successfully justified adding belief that *h* to X's original belief state, Y may not recognize that as a legitimate reason to withdraw dissent from X's belief that *h* and be justified in thinking so. The disagreement between X and Y might persist.

Let the demand on X be to show that Y is justified in modifying Y's beliefs so as to come into accord with X's beliefs. No doubt we often seek to resolve our disagreements with others. If I try to convince someone else to become certain that Seward lived in Auburn, I might try to justify my view to that person by appealing to premises that my interlocutor endorses and new information the interlocutor acknowledges to be reliable (perhaps a respected history of the Republican Party).

Nonetheless, I am not obliged to convince everyone who disagrees with me upon demand. To be required to do so would be an excessive form of intellectual tyranny. No dictate of reason demands it of me. No special epistemological obligation calls for it.

Sometimes, of course, I do have a duty to justify my opinions to those who disagree with me. A wide variety of personal, moral, political, economic considerations may require my undertaking joint ventures with others. In the context of such collaborations, I may owe it to others to justify some of my convictions to them. But the notion that I am under some obligation to justify my views to others whenever the request for such justification is made is not supportable by any moral, political, or other value commitment I am prepared to accept.

Even when I think it desirable to justify my convictions to others, I do not need to justify my current full beliefs to myself. Asking whether I am entitled to be absolutely certain that Seward lived in Auburn given that I fully believe this to be so is incoherent. For me to ask is for me to seek information I already have. To ask is to acknowledge as a serious possibility that Seward did not live in Auburn when I have already ruled out that logical possibility as a serious possibility.¹

Of course, I may not have ruled out this logical possibility. In that case, I do not fully believe that Seward lived in Auburn. In such a condition of doubt, my concern would be whether I can justify to myself *changing* from a position of suspense as to the location of Seward's permanent residence to full belief. But such justification aims at warranting a change in my state of full belief. It does not aim at warranting any of my current beliefs (i.e., it does not seek to justify any of the consequences of my initial state of full belief).

There do, however, appear to be counterinstances to this claim. For example, someone may ask me whether Seward lived near Lake Owasco, and I might express some doubt even though I am on record that Auburn is a small city on Lake Owasco in upstate New York. According to the argument I have given, the doubt I express presupposes that I fail to believe that Seward lived near Lake Owasco. So when someone points out to me that the truth of this proposition is a logical consequence of what I already believe, the demonstration justifies me in coming to believe that proposition. Yet, it may well be argued that I already do believe the proposition so that the justification is a justification of a current belief.

Moreover, the situation illustrates the possibility of doubting current full beliefs.

The counterinstance is specious. I am, in the example, *committed* to fully believing all the implications of my full beliefs; but the obstacles to logical omniscience preclude my fulfilling my commitments. We should distinguish between believing that Seward lived near Lake Owasco as a doxastic commitment and believing that Seward lived near Owasco as a fulfillment of that commitment. I may have the doxastic commitment and fail to fulfill it.

The doubt I express may be due to my failure to put two and two together – that is, to recognize the logical consequences of my full beliefs. This failure may be a symptom of computational incompetence or it may be a failure to recognize that I believe both that Seward lived in Auburn and that Auburn is a small city near Lake Owasco in upstate New York. Either way, the doubt in this case is a symptom of my failure to fulfill my doxastic commitments. I am committed to ruling out as impossible the logical possibility that Seward did not live near Lake Owasco. That is to say I am committed to fully believing that Seward did live near Owasco, and deducing this latter claim from the full beliefs I explicitly avow shows this to be so. In this sense, justifying current full beliefs may be saved from utter absurdity. The justification is not of my current doxastic commitment that Seward lived near Lake Owasco. It is rather a justification for some verbal, behavioral, or psychological affirmation on the grounds that it fulfills the doxastic commitment. Such justification interprets verbal, behavioral, or psychological activities as fulfilling doxastic commitments successfully. The kind of justification of core relevance to epistemology ought to be justification of change in doxastic commitment. Psychology ought to be focused on the extent to which agents fulfill such commitments.²

I call inquirer X's state K of doxastic commitment at a given time t, X's *state of full belief* at t. K belongs to a set K of *potential states of full belief*. The elements of K are states that at t X could have been in or could entertain being in. X's conceptual framework at t is constituted by the set of such potential states and constitutes a Boolean algebra (closed under meets and joins of sets of arbitrary cardinality up to the cardinality of the set K). Such an algebra K induces a partial ordering on the potential states from the strongest potential state to weaker ones. This partial ordering is a consequence relation. Potential state K' is a consequence of potential state K

if and only if K is stronger than or relieves doubt more than K' .

The set of consequences of K is the set of full beliefs to which an agent in state K is committed (Levi 1991: Ch. 1). Thus a state of full belief K is representable by the set of full beliefs to which the agent in that state is committed. Agent X in state K is committed to judging each member of this belief set true and the complements of the members of this set false. K is X 's standard for judging truth.

Each potential state K in K divides the elements of K into those that have the complement K^c of K as consequence and those that do not. Elements of the first set are seriously impossible according to K and the other set is the set of serious possibilities. In this formal sense, each potential state K in K is capable of serving as a *standard for serious possibility*.³ A potential state K is X 's standard for serious possibility at a given time if and only if at t , X is committed to judging all and only those elements of K to be seriously impossible that are impossible according to K and the remainder to be seriously possible.

If X is in state K , X is committed to dividing K into three parts: those potential states whose complements are impossible according to K , those potential states that are impossible according to K , and those potential states that are serious possibilities and whose complements are serious possibilities.

The first set is the set of full beliefs, and the second is the set fully believed to be false. The potential states in the third category are held in suspense. X is uncertain as to their truth or falsity and may make fine-grained distinctions among these potential states with respect to how certain or uncertain X is.

Consider, for example, judgments of subjective probability. The inquiring agent X is committed to assigning credal probabilities to all potential states in K no matter what state K of full belief X is in. However, the consequences of K (the full beliefs) are all assigned credal probability 1 and their complements credal probability 0. No fine graining occurs. The potential states that are serious possibilities according to K and their complements are assigned credal probabilities ranging from 0 to 1 inclusive.⁴

It is clear that inquirers who adopt states of credal probability judgment are committed to standards for serious possibility and, hence, to states of full belief.

The same is true of inquirers who register some sort of uncertainty by measures of degrees of disbelief (potential surprise) and belief satis-

fying the formalism invented by G. L. S. Shackle (1949, 1962) and reinvented by many others (for example, L. J. Cohen 1977 when he introduced "Baconian probability"). According to this formalism, a member of the third category (those potential states that are serious possibilities according to K and whose complements are also serious possibilities and are potential answers to a given question) carry a degree of belief equal to the degree of disbelief in their negation. The degree of belief in a conjunction is the minimum of the degree of belief in a conjunct. Given a set of exclusive and exhaustive potential states according to K each consistent with K , at least one of the complements carries a 0 degree of belief and all complements may do so. Full beliefs carry a maximum degree of belief and their complements carry a maximum degree of disbelief (we assume that there is a maximum that we stipulate to be 1).

We often claim that an inquirer is justified in adding belief that h to the initial state of full belief K , if the degree of belief that h according to K is sufficiently high. There has been a widespread tendency to think that "degree of belief" here means "credal probability" – even though this view leads to changing to inconsistent belief states. I have argued in many places that satisficing notions of degree of belief ought to satisfy Shackle's requirements that avoid such predicaments.⁵

Degrees of belief and disbelief as evaluated using Shackle measures presupposes, like probabilistic degrees of belief, a distinction between serious possibility and impossibility and, hence, a standard for serious possibility or state of full belief and thus a set of full beliefs to which the inquirer is committed at time t . Moreover, the use of such measures of belief and disbelief as satisficing measures presupposes that states of full belief may be changed legitimately by "expansion" through adding potential states consistent with K that carry sufficiently high degrees of belief.

In sum, states of full belief as standards for serious possibility are presupposed by judgments of uncertainty of the sort represented by states of credal probability judgment, by judgments of degree of belief and disbelief in the satisficing Shackle sense and, indeed, by many other candidate ways of representing uncertainty.

In addition, the use of some of these measures (e.g. satisficing measures) presupposes that states of full belief or standards for serious possibility are subject to legitimate modification through inquiry. The notion that we can

dispense with full belief or absolute certainty except for logical, *a priori*, or conceptual truth is quite unwarranted.

To the contrary, the main preoccupation of epistemology ought to be with giving an account of prescriptions for X's justifying changes in X's state of full belief to X. The question of justifying X's current beliefs to others or to X ought to be ignored.

Evidentialism

Jonathan Adler (2002) shares with me the view that we are often warranted in coming to full belief and that full belief is corrigible. We also agree that if X fully believes that *h*, X is committed to judging that *h* is true.

Adler insists, however, that there must be a "link" between the "belief's claim of truth" and the "condition of the truth of the belief." That link is the "evidence" for X's belief that *h*.

According to Adler, X must have evidence for X's belief that *h* simultaneously with X's full belief. Otherwise, the link that entitles X to judge that *h* is true is absent. Need for such a link is a "crucial premise of any argument for evidentialism" (2002, p. 5). Evidentialism is the following view: "Our degree of belief must match our degree of evidential support since only the evidence can secure the claim to truth of belief" (2002, p. 2), and to fully believe that *p*, one must have adequate reasons that *p* (2002, p. 5).

To my way of thinking, evidentialism concerning degrees of belief and full belief are both incoherent. The remainder of this essay will be given over to elaborating on the untenability of both types of evidentialism.

Evidentialism Concerning Degrees of Belief

If Adler's crucial premise of any argument for evidentialism is to be entertained, full belief that *h* and degree of belief that *h* must both have truth conditions and so be true or false. Moreover, full belief that *h* and degree of belief that *h* must be true or false in a sense in which it can matter to the inquirer whether the inquirer's beliefs and degrees of belief are true or false.

I take it that avoiding false full beliefs is a desideratum that rational inquirers may pursue. I myself think that this desideratum should be a mandatory constituent of the goals of efforts to change full beliefs. It is enough for our purposes to take for granted that full beliefs are true or false in a sense that can matter to the inquirer.

Degrees of belief are a different matter. If X believes that *h* to degree *r* short of absolute certainty, X is committed to judging that *h* might be true and *h* might be false. That is to say, X makes that judgment in a context where the truth of *h* hangs in suspense.

X may well be *entertaining* the question as to whether *h* is true or false, but X is not judging that *h* is true or that *h* is false. So X cannot make a false judgment as to whether *h* is true or false, and he cannot make a true one either.

For example, I am in doubt as to how far Skaneateles is from Auburn. I have some confidence that it is about seven miles distant from the center of Auburn but not complete confidence. Suppose it is ten miles distant. Since I did not judge it true that the distance was seven miles, I cannot be charged with error.

Ramsey insisted that the axioms of the calculus of probabilities could not be a "logic of truth" for probability because probability judgments (as judgments of degree of belief or partial belief) lack truth-values (Ramsey 1991). Savage offered a decisive argument for maintaining that one could not assign credal probabilities other than 0 or 1 to credal probabilities and, in this sense, could not be "unsure" about credal probabilities (Savage 1954). So either credal probability judgments would have to be logical or conceptually necessary truths or lack truth-values. The former alternative is untenable. Even if there were a standard method for assigning degrees of credal probability given the available evidence, X's degree of probabilistic belief that Michael Bloomberg will be elected to a second term as Mayor of New York being equal to some value *r* is not a necessary truth. The handwriting is on the wall.

Perhaps, degrees of belief are not such "Pascalian" probabilities but are "Baconian" as Cohen maintained where Baconian probabilities are Shackle's degrees of belief. Savage's argument is thus evaded. Even so, the conclusion stands. According to Shackle-based degrees of belief, the higher the degree of boldness required for adding *h* to one's stock of full beliefs, the lower the degree of belief prior to adding *h*. The degree of boldness is itself an expression of the trade-off between the credal probability that *h* and the value of the information provided by full belief that *h* (Levi 1967: Ch. 8, 1984, 1996: 6.6, 6.7, 6.9, 2004: 3.6). Neither of the components in this trade-off carries a truth-value, nor does the weighing of the components in the trade-off. The judgment that the degree of belief that *h* has reached a given threshold is made prior to

changing one's state of full belief when h is judged to be possibly false. That judgment lacks a truth-value just as the judgment that the credal probability that h is such and such regardless of the truth-value of h itself.

The two leading candidates for attitudes characterized as degrees of belief – degrees of credal or belief probability and degrees of belief in the sense of Shackle – characterize attitudes that are neither true nor false in a sense in which it makes sense to be concerned to avoid false belief in fixing such beliefs.

Thus, even though Adler thinks that the easiest part of the case for evidentialism concerns degrees of belief, there is no claim of truth in such cases. There are no truth conditions for such judgments. Hence, there is no need for a "link" between a nonexistent claim and a nonexistent truth condition. Adler has failed to make his case even in the easiest part.

Yet, I think we would be overhasty to dismiss evidentialism in the spirit if not the letter of Adler's thesis. As Adler himself seems to acknowledge, there could be reasons for belief that are not evidential in his sense because they are not reasons for the truth of the belief. Agents may have reason to believe various claims because doing so promotes their emotional stability, and they are good reasons, let us suppose, for the promotion of such stability. Adler would insist, however, that they are not relevant to the truth-value of the claims in question. If our concern is exclusively with forming true beliefs, emotional stability is no reason for belief. Only reasons that promote the quest for true beliefs qualify as evidence. Perhaps, evidentialism is supportable by an appeal to the aims of efforts to fix beliefs rather than to some missing links between truth claims that are often nonexistent and correspondingly dubious truth conditions.

Judgments of credal probability or belief probability are used to evaluate the expected values of gambles where payoffs depend on which of a set of rival hypotheses is true. Credal probability is well adapted to articulate assessments of risk of error in fixing belief. If we are concerned to minimize risk of error, assessments of risk of error should be controlled by evidence – that is, by X 's stock of full beliefs without suggesting that the evidence supply a link between a claim of truth and a truth condition.

To put the demand more formally, we may require X to be committed to a method of assigning credal states to potential states of full belief in K representable by a function $C: K \rightarrow B$ from

K to the set B of potential credal states where a credal state determined by consistent potential state K is itself representable by a set B of conditional probability functions $p(y/x)$ where x is consistent with K .

In the past it has been widely taken for granted that the set B is a singleton so that credal probability judgments are numerically determinate. Carnap called the function C a confirmation function (1950) or, when emphasizing that it represented the commitment of an agent, a credibility function (1960). I call it a confirmational commitment (Levi 1980). Carnap among many others thought that there ought to be a standard confirmational commitment to which all agents ought to subscribe. He thought it ought to be numerically determinate. I think that confirmational commitments, like states of full belief, are subject to reasoned change. I also think that the revisability of confirmational commitments calls for abandonment of the view that the credal state B determined by the state of full belief K (Levi 1974, 1980, 1984: Ch. 11) should be a singleton. I shall not elaborate on this issue here.

Those who favor a standard confirmational commitment advocate a fairly strong form of evidentialism even if they do not always feel obliged to establish a "link" between claims of truth and truth conditions. As already indicated, this form of evidentialism seems as unacceptable as one that seeks the sort of "link" required by Adler.

There remains the weaker version of evidentialism with respect to degree of belief construed as degree of credal probability. According to this version, credal probability judgments may be indeterminate and confirmational commitments revisable. This form of evidentialism seems tolerable.

Full Belief as a Simplifying Device

Adler also claims that full belief, as a matter of conceptual necessity, ought to be determined by evidence or by "reasons" for the truth of the target beliefs. It is incoherent, according to Adler, for X to declare, "p but I lack evidence that p." He thinks he can parlay an alleged consensus among those who reflect on this point into a case for "evidentialism."⁶

Full belief that h , according to Adler (2002), ends inquiry as to its truth. On this we agree, but according to Adler, it thereby conserves resources and time (p. 232). In a footnote, Adler writes: "Because full belief reflects a demand on us to economize, betting behavior poorly

captures the logic of full belief" (p. 325). Full belief, so it appears, is made necessary because various social, psychological, and physical constraints preclude expression of complex views in terms of degrees of belief. You must express your views often in terms of full beliefs.

The unavoidability is never a barrier to responding to reasons. One can try to negotiate the constraints. One must express one's opinions, but if one's views are very complex, one seeks forums that tolerate more expansive and nuanced argument. My claim is that one cannot regularly opt out when one does not find such sophisticated forums. The strength of this "cannot" is the strength of demands on us to participate in many social, intellectual practices, and of our impotence to shape them. (Adler 2002: 215)

Full belief is necessitated, according to Adler, by the need to express opinions of some complexity in contexts where relatively little sophistication is tolerated. We must avoid the impression of being "flip floppers" like John Kerry if we want to get elected President. If I understand Adler correctly, X has adequate evidence to fully believe that h only if X's evidence warrants a degree of belief that h that is sufficiently high. By degree of belief, Adler appears not to mean credal or subjective probability. According to Adler's discussion of the paradoxes of the preface and the lottery, high credal probability is not sufficient to warrant full belief (Adler 2002: Ch. 7). I conjecture on purely circumstantial evidence that he thinks of the degree of belief as something like Cohen's Baconian probability or, with greater historical accuracy, Shackle's measure of degree of belief.

To my way of thinking, full belief is no mere concession to coarse-grained thinking. Anyone who is fortunate enough to formulate nuanced views in a forum that tolerates complexity and invokes judgments of subjective probability (whether numerically determinate or not), degrees of confidence exhibiting the structures introduced originally by G. L. S. Shackle or other such modes of assessment *presupposes* a distinction between serious possibility and impossibility and, as a consequence, embraces a state of full belief.

If X is not so fortunate and is obliged to formulate views in a more coarse-grained manner, X's coarse-grained judgment that p may express belief that p in some qualitative sense distinct from full belief. Insofar as the belief that p that is based on "adequate evidence" (that is, on suffi-

ciently strong evidence) is a coarse-grained simplification of the degree of belief appropriate to that degree of evidential support, the serious possibility $\sim p$ acknowledged by the standard for serious possibility K is not ruled out. The qualitative sense of belief may correspond to mere belief as conceived in Levi (1967) or plain belief as in Spohn (1988). It is not to be confused with full belief.

Perhaps, the evidence in the initial state of full belief warrants changing the standard for serious possibility so that $\sim p$ is ruled out as a serious possibility. Then X is committed to a new state of full belief whether X reasons with the booboisie or with the sophisticated. There is nothing coarse-grained or simplifying about it.

Full Belief and Modified Evidentialism

Full belief is thus quite commonplace just as Adler maintains. But X's current state of full belief (i.e., X's standard for serious possibility) is not justified by reasons for its truth as Adler's evidentialism maintains. There is no serious possibility according to X's first personal point of view that X's state of full belief contains error. There is no room for doubt concerning its truth in the sense where doubting that h is equivalent to suspending judgment between h and $\sim h$. Where there is no doubt in this sense, there is no point in marshaling reasons for believing that h .⁷

X should, so I claim, require justification for ceasing to doubt that h given that X initially doubts it and for coming to doubt it given that X fully believes that h . So it might be thought that there is room for a modification of Adler's evidentialism in these cases. Justification of change in state of full belief or standard for serious possibility is, according to the modified evidentialism, justification for the change based exclusively on the initial state of full belief (which constitutes the evidence available to the inquirer prior to the change).

Even this modified evidentialism will not work. In cases where doubt in the sense of suspense is present, justifying coming to full belief that h (expanding K so that h is a consequence) by appeal to reasons or evidence does not secure a link between the claim that h is true and truth conditions for the claim. Matters are even worse in cases of ceasing to fully believe that h (contracting K so that h is no longer a consequence).

In inquiry, so I think the common feature of the diverse goals of efforts to remove doubts in various inquiries ought to be to avoid error and to

acquire valuable new information. The goal here is constituted as the aggregation of two distinct desiderata: Coming to full belief that the information is true relieves doubt present according to K . It also incurs a risk of error as judged according to K . In order to justify expanding the initial state of full belief K by adding h and its consequences and thus coming to full belief that h , it is necessary to show that the information thereby obtained (the relief from doubt thus achieved) compensates for the risk of error incurred *as evaluated relative to the initial state of full belief K when $\sim h$ is judged a serious possibility.*

From X 's point of view prior to expansion by adding h , the truth conditions for h can be specified by X 's state of full belief K . That is to say, in seeking to avoid error, X is seeking to avoid adding a false belief by adding h to K , and this will happen if and only if the truth conditions for h on the assumption that K and its consequences are true fail to be satisfied. In this sense, K is the "link" between the claim that h is true in the sense of the coming to full belief that h and the truth conditions for h . Otherwise, I am not sure what Adler means by such a link. In this sense, the "evidence" as link is just K and its consequences.

On this construal, the risk of error incurred by adding h to K may reasonably be taken to mean credal probability of error. If the credal probability that h is determined by K as it would be if X endorsed a confirmational commitment specifying for each consistent K in K the credal state X should adopt, we might say that the evidence determines the risk of error. Hence if the sole reason for adding h to K were the risk of error incurred, the reason would satisfy Adler's evidentialist requirements as I understand them.

But X 's reason for expanding K by adding h is not determined by the risk of error alone. As James rightly pointed out in criticizing Clifford (and as Popper reminded us)⁸, focusing exclusively on risk of error argues for refusing to expand K at all. One needs, in addition, an incentive to risk error. In inquiry, that incentive is to relieve doubt by acquiring information of value. Now the value of information or relief from doubt is *not* determined by K alone – that is, by the link between the claim that h and the truth conditions for h .

Assessments of informational value are subject to some constraints. Stronger potential states of full belief carry more informational value than weaker ones. Hence, in seeking valuable information, inquirer X should never assess the *infor-*

mational value of a weaker potential state as greater than that of a stronger one. Sometimes the additional information carried by a stronger answer to a question is not worth anything given the demands of the question so the stronger may carry the same informational value as the weaker one. But insofar as the inquirer is concerned to maximize informational value, the inquirer should never rank a weaker potential answer over a stronger one.

Subject to this *weak positive monotonicity* constraint, there may be many ways to extend the partial ordering with respect to strength to obtain a weak ordering with respect to informational value. Considerations of simplicity, explanatory and predictive power, and other allegedly scientific or epistemic virtues are often invoked in order to complete the ordering. Whether these modes of assessment are or are not free of appeal to moral, political, economic, aesthetic, or religious values and whether or not other ways of completing the ordering that are more explicit in invoking such nonscientific or epistemic values are invoked, as long as positive weak monotonicity (and some other restrictions) is observed, the evaluation may serve as an assessment of informational value representing the incentive for risking error (Levi 2004: 80–86).

Given the assessment of risk of error and the assessment of informational value, the evaluation of *expected epistemic utility* of potential answers to a question is represented by a trade-off or balance between risk of error and informational value. The more the balance in favor of informational value, the bolder and less cautious the inquirer X . The best of the available answers is one that is optimal according to this evaluation of expected epistemic utility. The reason for adopting that answer is that it is the best and its optimality is a function of two components: risk of error and informational value as balanced by the boldness exercised by the inquirer.

The answer that is recommended is the expansion of K by adding some potential state of full belief or "doxastic proposition" that h and its consequences. The answer can also be characterized as the set of doxastic propositions that are warranted at a sufficiently low degree of boldness or sufficiently high degree of Baconian probability or degree of belief. To this extent, the reasons for fully believing the members of the set appear to have the properties that I think Adler intends them to have, but the evidence in the initial state K of full belief alone does not qualify as the reasons.

Thus, X may have a reason for expanding K by adding h , but the reason is not evidence for h in what I take to be Adler's sense. To be sure, one component of X's reason may be evidence in Adler's sense, but Adler is simply mistaken in maintaining that, all things considered, the reason for coming to believe that h is the reason for the truth of h . One dimension (risk of error) of the reason for coming to such belief is relevant to the truth of h . However, there is another dimension (informational value) that is not relevant in this way.

In this discussion, I have focused on reasons for expanding K. Recall, however, that K is a state of doxastic commitment. If h expresses a potential state that is a consequence of K, one might say that K is a reason for h in something akin to Adler's sense of a link between the coming to believe that h and its truth conditions. In this sense, deductive or logical reasons may be alleged to be reasons in Adler's sense, but, of course, they are not reasons for changing doxastic commitments.

Crucial Experiments and Tacit Confirmation

Adler may or may not be prepared to endorse my distinction between doxastic commitment and doxastic performance (I suspect not); but he does appear to think that he is demanding evidence for coming to believe and current belief that is not merely deductive and, hence, is, on my account, reason for changing doxastic commitment.

His most explicit discussion of this matter surfaces in his discussion of empirical support by tacit confirmation for background belief (Adler 2002: 6.2). According to the famous argument of Duhem, there is no crucial experiment for a hypothesis H. Suppose an allegedly crucial experiment is run and it yields datum e . If H&A entails e , where A is a set of so called "auxiliary assumptions," e confirms H if e is true. $\sim e$ disconfirms H and, indeed, falsifies it. Duhem and Quine insist that this is wrong. The experiment is not crucial in the way described because, in the face of $\sim e$, A could be disconfirmed or falsified just as much as H. As Adler reports, it is now claimed that if $\sim e$ obtains, either H or A is disconfirmed.

Adler insists, however, that if this is so, then when e is true, *both* H and A are confirmed – H explicitly and A tacitly.

Adler is right to complain about the asymmetry in the treatment of auxiliary assump-

tions in confirmation and disconfirmation in the Duhem–Quine account. He is wrong in the way he seeks to address the asymmetry. There are three cases to consider.

Case 1: The initial state of full belief K implies A. Both H and $\sim H$ are consistent with K and, hence, serious possibilities. X conducts a test of the conjecture that H is true. If e is observed, H is confirmed. Since A is already fully believed, its truth is settled. There is no question about confirming or testing it. A is neither tacitly confirmed nor disconfirmed by e . If $\sim e$ is observed, H is falsified. Once more the truth of A is settled. Once more there is neither tacit confirmation nor disconfirmation for A. The asymmetry between H and A in this case is entirely legitimate. X is absolutely certain that A is true whereas H is a hypothesis subject to test. *Pace* Duhem, in such a situation, the test is a crucial experiment.

Case 2: Both H and A are hypotheses as is their conjunction H&A. All three potential states of full belief might be false according to X in state K. If e is observed, H&A gains confirmation. If $\sim e$ is observed, H&A is falsified. Neither H nor A is falsified. Neither H nor A alone is confirmed either explicitly or tacitly by e . H&A is confirmed. (I am using what I take to be Adler's standards for confirmation here.)

Case 3: Both H and A are implied by the initial state K. No experiment is run to test them since there is no point in doing so. However, an experiment is run for some other purpose (e.g., classroom demonstration) that yields e if H&A is true. Thus, Michelson's initial application of the interferometer was to establish that the velocity of the earth in the Ether could be measured. Michelson was not attempting to test the claim that the Ether existed, the classical mechanics, or electrodynamics. There can be no increase in confirmation for H&A since it is settled. Suppose $\sim e$ is observed. This constitutes an example of inadvertent expansion into inconsistency. (Thus, Michelson was committed to the view that his measurements would not yield a null result. Inadvertent expansion into inconsistency is as Gärdenfors put it, expansion into "epistemic hell." X must beat a retreat. See Levi 1991: 4.1 and 4.8; Olsson 2003; Levi 2003).

In retreating from inconsistency, X may call H&A into question by removing it from the full beliefs, may call e into question, or may do both. (All of the above were seriously pursued investigations after Michelson's initial null results).

Removing H&A while retaining e amounts, so I have proposed elsewhere, to contracting the

original *K* (before inconsistency) by removing *H&A* and then expanding the result by adding *e*.

Calling *e* into question is (roughly) equivalent to remaining with *K*.

Doing both is (roughly) equivalent to contracting the original *K* by removing *H&A*.

I have urged elsewhere that one should assess the losses of valuable information incurred by the first two. If one incurs a greater loss in informational value than the other, the one that minimizes such loss should be chosen. If they both incur equal loss or if they are noncomparable, the contraction calling both *H&A* and *e* into question should be chosen.

These appraisals require a determination of the best contraction removing *H&A* from *K*. In particular, should *H* alone be removed, *A* alone, or both? Making these assessments calls for distinguishing between full beliefs relative to *K* with respect of vulnerability to being given up (degree of incorrigibility or degree of entrenchment). I contend that since both *A* and *H* are maximally certain, there can be no difference between them either in probabilistic or Shackle degree of belief. They are both maximally and absolutely certain. The difference in vulnerability to being given up depends exclusively on loss of informational value, and this has nothing to do with conditions of truth or evidential support in what seems to be Adler's official understanding of evidential support.

Without going into details, I suggest that if the first two options incur substantially equal losses in informational value, the third option should be deployed. Otherwise adopt one of the other options depending on which incurs the smallest loss in informational value.

To complete the third case, suppose that either the first or third option is deployed. *H&A* must then cease being fully believed. Which should be given up: *H*, *A*, or both? Once more the decisive factor is loss of informational value.

Now the important point to emphasize here relevant to Adler's discussion is that nowhere is there anything like tacit confirmation. Only conjectures subject to real and living doubt can be subject to confirmation and disconfirmation by testing. Full beliefs are always absolutely certain and perfectly free of all doubt.

Nonetheless, distinctions can be made between full beliefs in a state of full belief *K*. In removing *H&A* from *K+e* in Case 3, even though *H* and *A* are both equally and maximally certain according to *K*, they could differ with respect to the loss of informational value one or the other would incur in contraction, and it is

loss of informational value that controls the relative vulnerability of these items to removal in contracting *H&A*.

Change of state of full belief in contraction, as in expansion, may be justified by reasons, but, as in the case of expansion, the reasons cannot be evidential reasons in Adler's sense. The relative losses of informational value *H* and *A* have little bearing on their truth-values as judged according to state of full belief *K* from which they are to be removed. According to *K*, both *H* and *A* are absolutely certainly true. In this respect, there is nothing to differentiate them from one another.

I have argued elsewhere (Levi 1991, 2004) that the evaluation of candidate contractions from *K* removing some doxastic proposition *h* ought to minimize *damped* informational value where such assessment of informational value obeys not only weak positive monotonicity but also constraints imposing the formal structure of Shackle measures on such appraisals. However, what, according to Shackle's intention was a degree of belief no longer is comes with this interpretation. It is now construed as an assessment of loss of informational value.

The two uses cannot, however, be identified. Shackle measures as degrees of belief are a function of two components, probability of truth and informational value in an undamped sense. Shackle measures, as measures of loss of informational value, are a function of undamped informational value where undamped informational value is converted to damped informational in a certain way. Probability of truth plays no role.

Many authors who have deployed Shackle-type measures (e.g., Gärdenfors and Makinson 1993; Spohn 1988) have recognized both uses of such measures but have sought to integrate them into a single measure. These authors want to avoid, however, changes in standards for serious possibility – or, at least, so it appears to me. Spohn, in particular, is quite clear that there should be no change in states of full belief. All changes in belief in a qualitative sense are changes in "plain" belief. *X* plainly believes that *h* if and only if *X* believes that *h* to some positive degree (in the Shackle sense). Plain belief is not the standard for serious possibility, which on Spohn's account does not change. Items that are consequences of the state of plain belief can differ from one another with respect to the degree of belief one has in their truth, and these differences will have a bearing, according to Spohn, on the vulnerability of these items to being given up under pressure.

There ought to be no dispute as to whether there is an intelligible notion of plain belief. When engaged in an inquiry aimed at determining how *K* ought to be expanded in order to answer a given question, the plain beliefs turn out to be the doxastic propositions that should be added if the inquirer is maximally bold. Of course, this characterization is one that Spohn could not endorse as giving important use to plain belief since it focuses on the topic of changing standards for serious possibility – something on which Spohn looks askance. My point is merely to note that for those who recognize the importance of justifying changes in states of full belief, plain belief can be acknowledged as intelligible and potentially useful.

Is Full Belief Compatible with Doubt?

Adler apparently does not want to follow the approach favored by Spohn. He does seem to think that full beliefs are modifiable. He wants to insist that full beliefs are judged as certain as certain can be. On these points he and I are on the same side in opposition to Mill. And it appears that in this respect, *all* full beliefs endorsed by *X* at time *t* are on the same footing.

Adler, however, wants to insist, in agreement with Mill, on the *fallibility* of belief and here Adler means full belief (2002: 256). Now my terminological practice has been to take fallibility of belief to mean possibility of falsehood. I claim that from *X*'s point of view, there is no serious possibility that *X*'s full beliefs are false. I have called this view “epistemological infallibilism” or infallibilism of the present. I do not think that Adler differs from me on this score. He uses “fallibilism” to mean something different from what I mean.

One possible meaning could be what I have called “corrigibilism” or vulnerability to being modified either by expansion or contraction. In the case of vulnerability to contraction, I have acknowledged that distinctions may be drawn between full beliefs or certainties with respect to losses of valuable information incurred by giving them as reflected in degrees of entrenchment or incorrigibility. This acknowledgment of corrigibilism, however, will not suffice, however, to justify giving a hearing to dissenting opinions. For one needs in addition to show that one is indeed justified in contracting one's state of full belief to give a hearing to the dissent. This is in my view often feasible, but the reasons that justify are not evidence in Adler's sense.

Now Adler wants to follow Mill in defending the giving of a hearing to dissenting views. He wants to do so even when we are absolutely certain that they are false. But he does not want to admit that what is absolutely certain might be false. So he draws a distinction between certainty (and probability), on the one hand, and confidence, on the other. We may be absolutely certain that *h* but less than maximally confident that *h*. We may have doubts. We can thus acknowledge a kind of fallibility. We can distinguish between certainties with respect to levels of confidence or doubtworthiness.

Adler is emphatic that this recognition of fallibility or presence of doubt that *h* is not evidence or reason to give up full belief that *h*. In contrast to my view, he does seem to think that sometimes inquirers have evidential reasons for contracting states of full belief. Insofar as I understand him, Adler thinks that in the case where *X* observes $\sim e$ when already fully believing that *H*&*A*, *H*&*A* has to be given up for evidential reasons. This is far from obvious both in scientific practice and according to common sense. Even if *e* is retained but *H*&*A* abandoned (which is not going to be always the appropriate recommendation), I fail to see how reason for this recommendation has anything to do with the truth or probability of truth of anything.

Even conceding this to him, Adler is silent as to how *H*&*A* is to be given up. Should *H* alone be given up? Should *A* alone be abandoned? Should *X* cease to be certain of both? Above all, do the reasons that support one recommendation rather than the other constitute evidence related to truth conditions for truth claims? The remarks made by Adler related to these matters fail to sustain his evidentialist position. For example, sometimes *X* should give up a proposition because, if the costs of error (or the value of being correct) are altered, the standards for adequate evidence for full belief are altered. Not only do I disagree with views that insist that one should give up full beliefs because the pedigree of their acquisition has been jeopardized, but even from Adler's point of view, the kind of reason he is talking about cannot be evidential. The account of contraction based on loss of informational value incurred in contraction furnishes a systematic response to these questions. Of course, it abandons evidentialism.

In any case, Adler insists that the presence of reasonable doubt or the acknowledgment of fallibility provides no evidential reasons for contraction. I am not interested in a word battle

concerning what “fallible” and “doubt” mean although I remain perfectly content with my own usage. What is critical here is what function the fallibility of full belief and compatibility of full belief and doubt serves in deliberation and inquiry according to Adler’s view.

It appears that the important function is that it allows X, who is absolutely certain that h , to engage in serious critical reflection as to whether h is true or false while certain that h . It requires X to give a hearing to the dissenter who proclaims $\sim h$ just as Mill seems to suggest. This stance is explicitly directed at claims I have made to the effect that, in order to subject a proposition h to critical scrutiny and test, it should cease being a certainty or settled assumption and become a hypothesis (p. 280). And in a discussion of Berlin’s treatment of Mill’s argument (Levi 1997: Ch. 12), I insisted that according to a dissenter the respect of giving a serious hearing to the dissenter’s view calls for opening up one’s mind or contraction. Such a contraction needs to be justified. That is to say, the dissenter’s view needs to earn the hearing.

Adler mounts an intricate and, to my way of thinking, unconvincing argument in support of his view that full belief and doubt are compatible. He begins by taking note of the paradox of ideal evidence arguments purporting to show that we need, in addition to the probability on the evidence, some indicator of how confident we are in the evidential backing for the probability judgment. (Ideas of this sort have been discussed by many authors, including Peirce and Keynes.) Probability is not full belief as Adler acknowledges, but Adler seeks to piggyback on the weight of argument versus balance of argument contrast found in Keynes to support his view that full beliefs come with varying levels of confidence. Adler then invokes the idea that full belief is, nonetheless, fallible – an idea that he makes intelligible by insisting that full belief is compatible with doubt – and a model of why base rates may be neglected and a few examples that he invokes as an intuition pump – one that does not touch me but which it would take much too long a time to discuss in detail.

I confess that my own usage of fallibilism is only one of many usages that could be derived from plain speech. But if full belief is the standard for serious possibility, doubt is incompatible with full belief. Adler seems to agree that full belief is the standard for serious possibility. Yet doubt is not ruled out. I think here that Adler

has stretched the meaning of doubt beyond anything that presystematic practice warrants, but whether I am right or wrong, as long as full belief is the standard for serious possibility, X cannot coherently subject h to critical scrutiny and test to check on the truth value of h unless X regards both h and $\sim h$ as serious possibilities. If initially X fully believes that h , X needs to contract.

Can X examine reasons for ceasing to fully believe that h where X already fully believes that h ? Sometimes X may suppose that some proposition g is true *for the sake of the argument* and explore the ramifications of such a supposition for explaining some phenomenon. Given the initial state K, g is incompatible with h so that the supposition is belief contravening. The suppositional reflection yields the result that g has considerable virtue as an explanatory proposition. This does not itself alter X’s full belief that g is false. However, recognition of this explanatory virtue could be a good reason (albeit not an evidential reason) to contract K in order to give g a hearing by conducting tests that, if successful, would render a verdict between h and g . That is to say, the nonevidential reason is a reason for coming to doubt that h is true not in the for-the-sake-of-the-argument fantasy but genuinely.

I have focused on the nonevidential status of reasons for contraction in these last remarks because the main burden of Adler’s remarkable claims about belief and doubt seem to be addressed to sustaining evidentialism in the context of contraction, but evidentialism fares no better in the context of expansion than in the context of contraction as I have also argued. To resist evidentialism, however, is not to resist avoidance of error (and, hence, truth) as a desideratum in inquiry. It is to resist the thesis that it is the sole desideratum.

Finally, to maintain that the goals with respect to which changes in belief are justified are multidimensional and appeal not only to considerations of truth-value and risk of error but also to nonevidential considerations does not imply that the goals of inquiry are reducible to practical, moral, economic, political, aesthetic goals and values. The quest for knowledge ought, in my view, to promote the realization of certain special kinds of goals – in brief, the acquisition of new, error-free, and valuable information. Practical, moral, economic, political, aesthetic, and so goals often contribute to the determination of the value of information acquired. Neither avoidance of error, nor the acquisition of new, valuable information, nor the balance between

the two is reducible to practical values in the vulgar sense just indicated. All of this is achievable without advocating evidentialism in Adler's conceptual sense or in any other.

Notes

- 1 Of course, the question asked must be posed as a sincere demand for information. It cannot be an invitation to a "paper doubt" of the sort that Peirce charged Descartes with posing. Had I initially been absolutely certain that Seward lived in Auburn and subsequently asked the question, I would have changed from certainty to doubt. The doubt would qualify as a paper doubt if I had not been justified in ceasing to be certain that Seward lived in Auburn.
- 2 Both epistemology and psychology thus have ineliminably normative components. They differ in the tasks they undertake to perform. We should avoid psychologizing epistemology or epistemologizing psychology by conflating the two tasks. See Levi 1991: Ch. 2, 1997: Ch. 1, and 2002 for further discussion of the commitment-performance distinction.
- 3 In Levi 1980: I.2 (and in publications dating back to the early 1970s), I took X's state of knowledge to be X's standard for serious possibility. I continue to think that the most useful definition of "X knows that *h*" is that X fully and truly believes that *h*. From X's current point of view, X's current state of knowledge and current state of full belief coincide. In later publications, I began speaking of state of certainty or full belief in order to avoid becoming engaged in tedious word battles. Analyzing the verb "to know" ought not to preoccupy epistemology. Accounting for conditions under which changes in states of full belief are and are not justified should.
- 4 Potential states that are serious possibilities according to *K* may be assigned 0 probability. Thus judgments of credal probability alone cannot distinguish between serious possibility and impossibility in those cases. The standard for serious possibility must be invoked. One might consider invoking judgments of conditional credal probability to do the job. $p(x/y) = r$ where *r* is some standard real value presupposes that *y* is consistent with *K* and thus a serious possibility according to *K*. That is to say, this is so when conditional probability is taken as primitive rather than unconditional probability and the multiplication theorem is taken as axiomatic. This is the practice of H. Jeffreys (1957, 1961), B. de Finetti (1972), Dubins (1975: 96), and I. Levi (1980), all of whom avoid assuming countable additivity. One might seek to derive the standard for serious possibility from the agent's state of credal probability judgment (credal state) by determining the set of elements of *K* that must be in the domain of definition of the permissible probability function of the credal state. An effort to do this based on an idea of van Fraassen's is developed by H. Arló Costa (2001).
- 5 For recent statements of this view, see Levi 1996: Ch. 8, 2002. Earlier statements are found in Levi 1966, 1967, and 1984: Ch. 14, where a comparison with L. J. Cohen's conception of Baconian probability in Cohen 1977 is undertaken.
- 6 When I sincerely assert that *p*, I am expressing my full belief that *p*. There is no serious possibility that $\sim p$. No evidence I currently have can support what is already settled. No evidence I currently have could undermine it. Of course, my full belief that *p* could be counted as evidence I have that *p*, but it is not evidence in the sense that evidence is used to settle what is unsettled. In that sense, to declare that I lack evidence for my full belief is pointless. Hence, the declaration is strange but not paradoxical. It is surely not inconsistent. Adler compares "*p* but I lack evidence that *p*" to the more familiar saying and disbelieving paradox of G. E. Moore "*p* but I do not believe it" (Adler, 2002: Ch. 1.2 and Ch. 7.2). He claims that the Moore sentence is "heard" as inconsistent even though it is perfectly consistent. He argues that what is inconsistent is the claim that I know both that *p* but I do not believe that *p*. If the Moorean sentence were inconsistent, its negation " $p \supset I$ believe that *p*" would be necessarily true. This is absurd. I may claim that whatever I fully believe is true but not the converse. What Adler has shown via his transparency assumption is that I cannot coherently believe or know " $p \supset I$ believe that *p*" to be false. But I can coherently fail to believe it to be true. It is judged negatively but not positively valid in doxastic logic. (See Levi 1997: Ch. 3, Sec. 7 for more on this point.) Even if one conceded (as I do not) that "*p* but I lack evidence for *p*" is conceptually incoherent, it would not follow that one should embrace " $p \supset I$ have evidence for *p*." Still if Adler were right about the analogy with the saying and disbelieving case, agent X would be incoherent if X believed one extralogical *p* true and also believed that X lacked evidence for it. Adler seems enthusiastically convinced he is right. It seems clear to me that he is mistaken. Indeed, for reasons explained above, if I fully believe that *p*, I cannot coherently claim to have evidence for *p* in the sense that evidence settles the unsettled. I might marshal reasons why you should come to believe that *p* or why I was justified in coming to believe that *p* in the first place, but I am not incoherent if I lack reasons of this kind even if I have no real and living doubt as to the truth of *p*.
- 7 Doubt that *h* sometimes means failure to believe – that is, either suspense or belief that

$\sim h$, and sometimes it may mean full belief that h is false. The presence of doubt in either of these senses is not sufficient to motivate inquiry. If the agent fails to be in suspense (fails to be uncertain) as to whether h is true or false, either the agent fully believes that h or fully believes that $\sim h$. There is no real and living doubt motivating efforts to eliminate the doubt by finding reasons to come to full belief that h or full belief that $\sim h$. The presence of doubt as I shall use understand it is in the sense of suspense.

Chapter 27: Reflections on Conscious Reflection: Mechanisms of Impairment by Reasons Analysis

JAMIN HALBERSTADT AND TIMOTHY D. WILSON

Western culture has an ambivalent relationship with rationality, displaying a reverence for reasoning, objective evidence, and science, accompanied by a strong suspicion of them. Individuals respect logic and rationality, but often only when there are consistent with their intuition, and a common lay belief is that some, even most, judgments are best made on the basis of one's "gut feelings."

Is analytic thought good or bad? Perhaps not surprisingly, the answer lies in the theoretical expanse between these extremes. Researchers have become increasingly interested in this expanse, concluding that people are right to trust their intuitions under (at least) some circumstances. Studies of nonconscious judgments, automatic evaluations, and functional heuristics, for example, all show that people can and do make good decisions based on quick, unanalyzed responses (Bargh and Chartrand 1999; Damasio 1994; Dijksterhuis 2004; Gigerenzer 2000; LeDoux 1996; Wilson 2002). But it is also clear that people should not always trust their intuitions, which can be contaminated by unwanted or invalid information, often in ways in which people are unaware, as shown by research on the misuse of heuristics, biased information processing, and automatic prejudice (Devine 1989; Gilovich, Griffin, and Kahneman 2002; Greenwald and Banaji 1995; Nisbett and Ross 1980; Tversky and Kahneman 1974; Wilson and Brekke 1994).

In this chapter, we explore how conscious reflection has been operationalized and studied in the context of both preferences (e.g., for a particular sports team) and predictions (e.g., of whether that sports team will win its next game). In both cases conscious reflection makes judg-

ments worse, at least under some circumstances. But while substantial progress has been made in explaining the effects of reflection on preferences, how reflection reduces the accuracy of judgments relative to objective criteria poses an important theoretical puzzle. In the second half of the chapter, we speculate about a novel solution to this puzzle, reporting data to suggest that when people engage in conscious reflection they make relatively poor use of subjective experience, which can be a surprisingly valid cue to many objective decision criteria. Our proposal has implications for the integration of research on conscious reflection, as well as practical implications for when intuition can be trusted.

Effects of Conscious Reflection on Attitudes

Wilson and his colleagues have established that analyzing the reasons for one's attitude can change it (see Wilson, Dunn, Kraft, and Lisle 1989 for a review). In one study typical of the paradigm, college students evaluated two types of posters: reproductions of Impressionist paintings and contemporary, humorous posters, such as a photograph of a kitten perched on a rope with the caption, "Gimme a Break" (Wilson, Lisle, Schooler, Hodges, Klaaren, and LaFleur 1993). Half of the participants were asked to write down, privately and anonymously, why they felt the way they did about each poster, whereas control participants completed a filler task. Everyone then rated their liking for each poster and chose one poster to take home.

Control participants showed a strong preference for the Impressionist posters, giving these the highest ratings and overwhelmingly choosing

one of them to take home. The people who analyzed reasons (hereafter "reasoners"), however, found it easiest to verbalize negative features of the Impressionist posters and positive features of the humorous ones. For example, many people focused on the colors of the Impressionist paintings, which were not entirely pleasing (e.g., "The green part in the middle of the Monet seems dull and dreary"). The reasons they found easiest to verbalize about the humorous posters were more positive (e.g., "I like the bright blue background, and I like the kitten's patchworky colors"). And, they based their preferences and choices on their reasons: They gave the humorous posters more positive ratings than did control participants, and they were significantly more likely to choose one of these posters to take home. The same reasons-based attitude change has been demonstrated with numerous other attitude objects, including soft drinks (Wilson and Dunn 1986), strawberry jams (Wilson and Schooler 1991), political candidates (Wilson, Kraft, and Dunn 1989), and romantic partners (Wilson and Kraft 1993). Such effects are not due to cognitive load or interference associated with the reasoning process, because participants who reason about *other* topics (such as their college major) fail to show attitude change. Nor do they appear to be the result of demand characteristics or self-presentational concerns (see Wilson et al. 1989 for a discussion of these issues).

Just because reasoners changed their attitudes, of course, does not necessarily mean that their attitudes were inferior in any way. One might even argue that a reasoned attitude is likely to be more stable or predictive of later behavior. However, research suggests that attitude change caused by analyzing reasons is unlikely to be particularly long-lasting. (Indeed, it would be rather surprising if a permanent change in people's attitudes could be brought about simply by asking them to explain why they felt the way they did.) After the passage of time, the reasons people brought to mind are less likely to be accessible in memory, and people are likely to revert to their chronic attitudes, those that come to mind without any conscious reflection.

One consequence of the temporary nature of reasons-induced attitude change is that attitudes expressed right after analyzing reasons will be worse predictors of people's later behavior than are unanalyzed reasons (Millar and Tesser 1986; Wilson, Bybee, Dunn, Hyman, and Rotondo 1984; for a review, see Wilson et al. 1989). A

second is that people will be prone to regret choices they make immediately after analyzing reasons, because their attitudes later revert to their chronic, unanalyzed preferences. Wilson et al. (1993) found support for this prediction in the poster study discussed earlier. They telephoned participants a few weeks after the study and asked them several questions about their current liking for the poster they chose to take home (e.g., how much they liked it, whether they still had it, whether they had hung it up on their wall). As predicted, people who analyzed reasons were less pleased with their choice of poster than people who did not.

It has also been proposed that reasoners' attitudes are not only relatively poor predictors of behavior and judgment satisfaction, but also that they are in some sense objectively inferior to nonreasoned ones. Wilson and Schooler (1991: Study 1), for example, compared participants' preferences for five brands of strawberry jam to the preferences of trained sensory experts. As predicted, people who first analyzed the reasons for their preferences reported attitudes that corresponded less with expert opinion than people who did not analyze reasons. Wilson and Schooler (1991: Study 2) similarly showed that attitudes toward psychology courses were impaired relative to a different type of expert – students who had actually taken the courses (a finding replicated by Halberstadt and Green 2004). And in perhaps the most face-valid demonstration of attitudinal impairment, Halberstadt and Green (2004) found that reasoners' evaluations of Olympic dives corresponded less well to the scores the dives received by the Olympic judges.

Halberstadt and Levine (1999) even demonstrated reasons-based impairment of judgments relative to an indisputably objective criterion for accuracy, the factual outcome of basketball games. In that study two samples of self-described "basketball experts" (students at Indiana University) predicted the outcomes of eight games prior to the third ("Sweet Sixteen") round of the National Collegiate Athletic Association (NCAA) Division I basketball tournament. Half of the participants, before making their predictions, listed reasons why they thought each team would do well or poorly in the tournament; the other half were told explicitly not to analyze their reasons and to make their judgments based on their "first instinct." As predicted (yet nevertheless surprisingly given the legendary unpredictability of the NCAA tournament), reasoners'

predictions were less accurate than nonreasoners', in terms of the proportion of outcomes correctly predicted, expert opinion (the Las Vegas betting lines), and the margin of victory of those games (see also Reifman, Larrick, Crandall, and Fein 1996).

Mechanisms of Reasons-Based Interference

In the research on attitudinal analysis, thinking about reasons is believed to lead to a change in the information on which people base their attitudes, a process we refer to as "information shift." Specifically, thinking about reasons triggers three processes that lead to attitude change. First, when queried about the reasons for their attitude people construct their reasons online, either because they never knew the actual causes of their attitudes (Bargh and Chartrand 1999; Nisbett and Wilson 1977b; Wegner 2002; Wilson 2002), or because they once knew but later forgot. Indeed, research shows that there is often little relationship between people's memory for the attributes of a stimulus and their evaluation of that stimulus. That is, people often form evaluations online as they encode information about a stimulus, but are unable to recall exactly what attributes of the stimulus influenced their judgment (Hastie and Park 1986). In any case, we believe that, when asked to give reasons, people engage in a constructive process, whereby they infer their reasons, based on what sounds plausible, what is accessible in memory, and what is easy to verbalize (Gazzaniga and LeDoux 1978; Hirstein 2005; Nisbett and Wilson 1977b). When people in the Wilson et al. (1993) study generated reasons for why they liked or disliked the posters, for example, it is unlikely that they were fully aware of the exact reasons for their preferences, causing them to construct reasons.

Second, the reasons people generate often imply a somewhat different attitude than the one people held before they thought about reasons. It might seem that people would attempt to justify their initial attitude, focusing only on reasons that are consistent with it. If people are not completely aware of why they love their spouse, for example, it seems unlikely that they would generate a list of reasons why they dislike him or her. We acknowledge that such a justification process can occur, whereby reasons that are consistent with an attitude are more accessible than reasons that are inconsistent with it. Our point is that there is room for slippage, whereby

the valence of reasons that are accessible, plausible, and easy to verbalize do not completely match the valence of people's initial attitude. People may not generate reasons why they hate their spouse, but if they just had an argument about whose turn it was to cook dinner, some negative thoughts might be accessible and find their way into their reasons.

Reasons also can have a different valence than people's attitude because of cultural teachings about why people feel the way they do. In Western cultures, there is a bias toward giving rational attributes of the attitude object as reasons for liking or disliking it, even when attitudes are caused by other factors. In the hundreds of reasons we have coded over the years, by far the majority of them are of this type, such as, "We get along well because we have common friends and enjoy many of the same activities," "I like this puzzle because it had a logical answer," "I don't like this painting because the flowers look like they're dying." In contrast, there is ample evidence that attitudes are often caused by factors other than rational cognitions about the attributes of the attitude object, such as mere exposure (Zajonc 1968), classical conditioning (Cacioppo, Marshall-Goodell, Tassinari, and Petty 1992; Staats and Staats 1958), operant conditioning (Insko and Cialdini 1971), halo effects (Nisbett and Wilson 1977a), and attitudes stemming from people's core values such as their religious beliefs or the beliefs of their parents (Ellsworth and Ross 1983; Herek 1986; Rokeach 1973; Sears 1983). When people in our studies are asked to think about reasons, they rarely mention such factors.

Several studies have found support for the idea that people's reasons do not entirely match their initial attitudes. In these studies people report their attitudes at Time 1, and then, at some later time, they think about why they feel the way they do about the attitude object. Typically, we find that the correlation between the valence of people's reasons and their initial attitude is significant, which is consistent with the idea that people do not bring to mind reasons that radically conflict with their initial attitude. The correlations are sufficiently low, however, to suggest that people often generate reasons that do not completely match the valence of their initial attitudes. For example, Wilson and Kraft (1993) asked people involved in steady dating relationships to rate how happy they were with their relationship. Then, on four separate occasions, people wrote down why their

relationship was going the way it was. The correlation between the valence of the reasons people listed and their initial attitudes ranged from $-.03$ to $.24$, with an average of $.10$.

The third part of the information shift account is that people adopt the attitude implied by their reasons, much like a self-perception effect (Bem 1972), in part because they are unaware of their unawareness about the causes of their attitudes. They believe that the reasons they generate are accurate, a phenomenon that Wilson (2002) called the illusion of authenticity. For example, in our studies, almost no one has said, "I don't know" when asked for their reasons, even when they were assured that no one would ever look at what they wrote. Thus, people seem to have a fair degree of confidence that they know at least some of the reasons for their feelings – despite evidence that such reasons can be inaccurate.

Evidence for this part of the process has been obtained in studies in which researchers subtly influenced the kinds of reasons people would generate (Salancik 1974; Seligman, Fazio, and Zanna 1980). Seligman et al., for example, asked participants involved in romantic relationships one of two questions about why they were dating their partner. "I go out with this person *because I...*" or, "I go out with this person *in order to...*" The former question was designed to elicit reasons that were primarily internal (i.e., having to do with one's own feelings and commitment), while the latter question was designed to elicit reasons that were primarily external (i.e., having to do with factors other than love and commitment, such as the desire to impress one's friends). As predicted, participants seemed not to have realized that they had generated a biased set of reasons and adopted the attitude implied by their reasons. That is, subjects who answered the "because I" question reported significantly more love and expressed more of an intention to marry their partners than did subjects who answered the "in order to" question. Similarly, participants in reasons analysis studies often come up with biased samples of reasons, even without help from wily experimenters, and base their attitudes on these reasons. Consistent with this conclusion, the reasons that participants generate typically have a somewhat different valence than their initial attitude (as noted earlier), and the attitude they report after generating reasons is highly correlated with their reasons. For example, Wilson and Schooler (1991) found a corre-

lation of $.92$ between the valence of people's reasons and their subsequent attitudes toward the posters.

More direct evidence for the hypothesis that people infer their attitudes from their reasons was obtained by Wilson, Hodges, and LaFleur (1995), who manipulated the valence of reasons that were accessible to people when they analyzed reasons. Participants read a list of positive, negative, and neutral behaviors that were performed by a target person and formed an initial impression of her. To manipulate whether the positive or negative behaviors were most accessible in memory, the researchers showed participants either the positive or negative behaviors again (participants expected to see all the behaviors again but the slide projector "malfunctioned" after only the positive or negative ones were repeated). After a delay, half of the participants listed reasons why they liked or disliked the target person, whereas half did not. All participants then rated how much they liked her.

The accessibility manipulation was successful; when the positive behaviors were repeated people were most likely to recall these behaviors, and when the negative behaviors were repeated people were most likely to recall these behaviors. Importantly, when people did *not* analyze reasons, the memory manipulation had no effect on their liking for the target person. Because people had already formed an impression of the target, showing them either the positive or negative behaviors did not change these impressions. When people analyzed the reasons for their impressions, however, they were influenced by the memory manipulation. Consistent with our hypothesis that people infer their attitudes from their reasons, subjects in the reasons condition reported significantly more liking for the target person when positive behaviors had been repeated than when negative behaviors had been repeated (see Figure 1).

These results are compatible with self-perception theory (Bem 1972), which argues that people often infer their attitudes from their behavior, but also extend the theory into new terrain. According to self-perception theory people infer their attitudes from external behavior that is observable by other people. In fact, a central tenet of the theory is that people are often in a functionally identical position to outside observers in knowing how they feel, because both actors and observers infer attitudes from the actor's overt behavior. Wilson et al. found

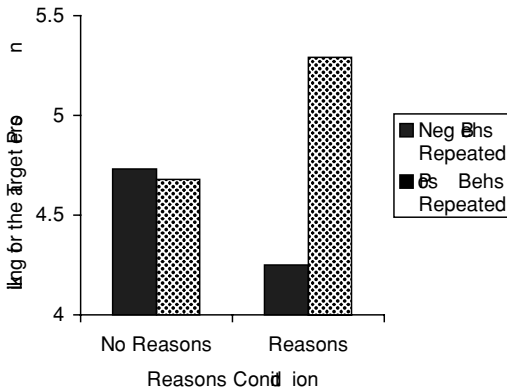

Figure 1. Liking for the target person: Study 1. The higher the rating, the greater the reported liking. From: Wilson T. D. (1995) *Journal of Personality and Social Psychology*, 69(1), 16–28.

that people also inferred their attitudes from *internal* cues, namely the nature of the thoughts that were accessible when they analyzed reasons – a self-perception process whereby people are not in a functionally identical position as outside observers, because they are inferring their attitudes from privileged information (their reasons).

Research on analyzing reasons also suggests that any situational factors that enhance the salience of particular reasons are likely to influence analyzed attitudes. This conclusion has particularly important implications for decision making in groups, where other people may provide novel reasons or enhance the plausibility of existing reasons for an individual's attitude. Such a mechanism, in different theoretical terms, has in fact been implicated in the group polarization effect, in which group members contribute confirmatory but unique information that pushes the group toward more extreme attitudes and decisions (Burnstein and Vinokur 1977). Thus, when the social setting serves to enhance the salience of reasons unrepresentative of individuals' attitudes, they may precipitate attitude change, at least when individuals are in an analytic frame of mind.

The Puzzle of the Quality of Objective Judgments

Although the information shift account of reasons analysis – a sometimes-unfortunate conjunction of memory- and based processing a biased subset of available information – provides a plausible mechanism of attitude change *per se*, it may not provide a complete explanation of all

reasoning phenomena, particularly the impairment of objective judgment quality and predictive accuracy. Specifically, it is not clear why information that is accessible, plausible, and easy to verbalize should happen to be less reliable than the information used under normal (non-reasoning) conditions. For the information shift account to explain impairment in basketball predictions, for example, it must account for why the reasons made hyperaccessible by analytic thought are worse cues than those used by people who do not analyze reasons. There is reason to believe, we suggest, that people naturally use cues and heuristics that often lead to accurate judgments, and that analyzing reasons reduces their use of these cues.

Affect Heuristics

We speculate that subjective feeling states, including both generalized affective experiences such as familiarity and fluency, as well as discrete emotional responses such as anger and fear, can serve as simple but highly predictive cues of even complex predictions and decisions. Gigerenzer, Todd et al. (1999), for example, have argued that many judgments can be approximated surprisingly well using stimulus recognition, that is, by simply choosing an alternative that is recognized over one that is not. This strategy, which Gigerenzer et al. (1999) call the “recognition heuristic” is effective when the criterion on which the stimuli are being judged covaries with the likelihood of stimulus exposure. For example, Goldstein and Gigerenzer (2002) asked Americans and Germans to judge the larger of pairs of German cities. By choosing the cities they recognized, the American participants performed better on this task than did German students, despite having less knowledge about the cities (the converse effect was found for judgments of American cities). Choosing recognized cities worked in this specific domain because, it turns out, the larger a city is, the more likely it is to be recognized, and only American students, who recognized some but not all of the cities, had this heuristic at their disposal.

More generally, whenever stimulus familiarity, which is the basis of recognition judgments, covaries via any mechanism with a criterion of interest, the former can in principle be used to directly and accurately infer the latter. Consider, for example, how we might reinterpret Halberstadt and Levine's (1999) basketball data in terms of a “familiarity heuristic.” Although

familiarity data were unfortunately not collected in that study, several proxies for familiarity can be used to explore the plausibility of an affective interference account. For example, the recency with which a team had appeared in the NCAA tournament should be related both to the subjective familiarity of a team (via extensive media coverage of the tournament), as well as to performance in the tournament in immediately subsequent years. Halberstadt and Catty (2005) discovered that if, for games in which only one team had appeared in the previous year's tournament, a person always bet on that team, and guessed on the remaining games, he could achieve 68.8 percent accuracy, approximately equal to nonreasoners' performance (70.4% vs. reasoners' 65.2%) in Halberstadt and Levine's original study. Similarly, Ayton and Onkal (1997, cited in Goldstein and Gigerenzer 2002) found that Turkish participants predicted the correct outcomes of British soccer matches 63 percent of the time by relying on their recognition of British cities (after which the soccer teams are named), a performance which almost equaled that of British participants (66%) who knew far more about the teams.

Furthermore, although familiarity has been extensively researched and linked to a number of important social psychological judgments (and errors), such as fame (Jacoby, Kelley, Brown, and Jasechko 1989), attractiveness (Halberstadt and Rhodes 2000; Halberstadt, Rhodes, and Catty 2003), liking (Zajonc 1968), and prototypicality (Franks and Bransford 1971; Gordon and Holyoak 1983; Halberstadt et al. 2003), in principle, any feeling state could become associated with any objective state of the world. Damasio's (1994) "somatic marker" hypothesis in fact explicitly assumes that valuable outcomes are associated with measurable physiological tags, which are used unconsciously to make good decisions in normal individuals. In a provocative illustration of the use and importance of somatic markers, Bechara, Damasio, Tranel, and Damasio (1997) found that normal participants chose the more advantageous of two bets, and showed corresponding physiological responses, before they could explicitly state the reasons for their choice. Participants with damage to their ventromedial prefrontal cortex (where emotional responses are stored and linked to declarative knowledge) showed neither anticipatory responses nor the adaptive decisions, even after they were able to state the differences between the bets. In general, prefrontal damage has been associated with impaired decision making and moral rea-

soning, in theory because individuals with this damage cannot access the somatic information that points toward adaptive responses. A number of other researchers have also proposed that positive emotional responses are used to infer judgments either directly or in the context of other cognitions. (e.g., Forgas 1995; Halberstadt and Badland 2005; Martin, Ward, Achee, and Wyer 1993; Monin 2003; Schwarz and Clore 1983, Slovic, Finucane, Peters, and MacGregor 2002).

Relatedly, perceptual and cognitive fluency – the ease with which a stimulus can be perceived and categorized – can potentially serve as a valid proxy for a variety of judgments. Winkielman and his colleagues have demonstrated a relationship between processing ease and positive affect, due either to the inherently positive nature of the feeling of successful comprehension and categorization, or due to the association that fluency has with positive cognitive assessments, such as the judgment that a stimulus is safe. Manipulations that facilitate stimulus processing, such as preceding the presentation of a stimulus with its outline (Reber, Winkielman, and Schwarz 1998) or a category-related priming word (2003, cited in Reber, Schwarz, and Winkielman 2004) increase liking judgments for the stimulus, as well as psychophysiological expressions of positive affect (2001). At the same time, fluency has been linked to a number of important social judgments, such as artistic pleasure (Leder, Belke, Oeberst, and Augustin 2004; Reber et al. 2004) and prototypicality (Winkielman, Halberstadt, Fazendeiro, and Catty, 2006). Reber et al. (2004), for example, argue that many of the features of "beautiful" stimuli (clarity, simplicity, good form, familiarity, etc.) are empirically or theoretically associated with fluency. Indeed, Halberstadt and Hooton (in press) recently found that the speed with which a painting can be identified as a particular artist's work predicts liking for the painting.

Other, more discrete and basic emotional responses could also serve as valid cues to social judgments, such as of trustworthiness, safety, and threat. Just as behavioural implications of a stimulus (its "affordances") can theoretically be extracted directly from the rich information present in natural environmental covariation (MacArthur and Baron 1983), at least some social judgments may be inherent in the judgment targets themselves, and conveyed via reliable covariation with the particular feeling states they elicit. Thus, to the extent

Figure 2. Examples of violent offenders used in Halberstadt and Ngu (2005).

trustworthy people make us feel trusting, safe people make us feel safe, and unhappy people make us feel unhappy, we can accurately estimate these objective social realities directly from the corresponding feeling states. In a recent study in our laboratory, for example, participants were presented with a series of actual police “mug shots” of men, half of whom had been arrested for violent crimes (e.g., murder and serious assault) and the other half for non-violent crimes (e.g., drunk driving and drug possession). Examples appear in Figure 2. Participants judged both the likelihood that each man was a violent offender (a task they can normally perform above chance; Memon, Vrij, and Bull 2003; Ruffman, personal communication 2005), as well as how threatened each man made them *feel*. Participants judged the violent offenders both as more violent and as more threatening than the nonviolent offenders and, more intriguingly, the latter judgments predicted (Halberstadt and Ngu, 2005) over 90 percent of the variance in the former. Although preliminary, these results suggest that social perceivers could rely on the natural correlation between their feelings and a person’s dangerousness to assess the objective risk of a social interaction.

People’s ability to exploit the correlations between feeling states and the stimuli that elicit them may partially account for the accuracy of “thin slice” judgments of personality (Ambady and Rosenthal 1992, 1993). Ambady and Rosenthal (1992), for example, found that undergraduates’ ratings of teachers on fourteen dimensions of competency, such as empathy and supportiveness, correlated well with their “real” competen-

cies (i.e., student ratings at the end of the term), even when the former were based on silent video clips as short as 2s. What makes this finding so surprising, of course, is that it seems unlikely that teachers will display behavior representative or predictive of their performance in a short video clip, and indeed the researchers ruled out a number of simple nonverbal behaviours, such as head nodding and fidgeting, as judgment cues. However, even 2s slices of behavior can produce brief emotional responses in the perceiver, and if these responses correlate with the competency dimensions judged by others, the responses can be used to make direct and accurate inferences.

Reasoning and Affect Heuristics

Thus, affect heuristics – domain-specific relationships between feeling states and objective states of the world – can be a powerful and direct means of making accurate judgments. Such a mechanism is further implicated in reasons analysis effects because, we argue, reasoners are less likely than nonreasoners to access and use their subjective experiences appropriately. As already noted, historically the vast majority of information brought to mind by reasoners has been “cognitive,” that is, rational arguments that do not invoke or reference affective experiences. One possible explanation of this bias involves relatively trivial semantic and conversational norms: People report cognitive reasons because they believe that the term “reasons” refers to such. Indeed “reason” means both “explanation” and “the human capacity for logic and rational

thought," so it is plausible that people generally limit their "reasons" to those that can be logically and rationally justified. Even if people accept the validity of noncognitive reasons, cultural norms, particularly in the context of a scientific experiment, may prevent them from verbalizing those reasons. As noted, Western culture scorns decision-making based on illogical or emotional arguments, so individuals may be reluctant to report such factors when queried, or may themselves view them as implausible causes of their judgments.

Even if reasoners are willing to offer their subjective experiences as causes of their judgments, they may be unable to do so, for several reasons. First, such experiences may simply be too difficult to put into words. Although humans do have an enormous vocabulary of terms for their feeling states, this is not to say that they can precisely and accurately map those terms on to their own experience. Melcher and Schooler (1996), for example, argued that limitations on individuals' knowledge and language use could account for impaired memory following verbalization (a manipulation closely related to reasons analysis). The researchers found that participants with moderate knowledge of wine, whose vocabulary was inadequate relative to their perceptual and aesthetic experiences, who described the taste of wines remembered them less well than controls who did not verbalize. Importantly, such "verbal overshadowing" did not occur in either wine experts or wine novices, both of whose language and experience are likely to be more equally matched. Thus, both inadequate introspective ability to distinguish subjective experiences, as well as limited language to represent those experiences, are likely to limit reports of emotional responses in analyses of judgments.

Complicating matters further is that analytic thought, and reasons analysis in particular, is effortful, and effort itself is associated with affect. Research on "cognitive fluency," the effort involved in apprehending and categorizing a stimulus, demonstrates the relationship between processing ease (usually operationalized as forced choice categorization speed) and positive affect.

Although there are no studies examining the effort associated with reasons analysis per se, related studies on the subjective experience of retrieval (e.g., Schwarz 1998; Winkielman and Schwarz 2001) illustrate the informational value and use of processing ease in judgment. Winkiel-

man and Schwarz (2001), for example, manipulated the difficulty of retrieving childhood memories (by asking participants to recall either four or twelve such memories), as well as the meaning of that difficulty (by suggesting that either positive or negative events tend to be forgotten). Participants believing in positive amnesia judged their childhood as more happy after the difficult task of recalling twelve events, than after the easy task of recalling four events. The reverse was true for participants believing in negative amnesia. Similarly, participants who find the experience of reasons analysis difficult or unpleasant are liable to use that subjective information in conjunction with their other beliefs to formulate a judgment. Indeed research on "need for cognition," the individual difference variable associated with reasons analysis, assumes that analytic processing is inherently effortful, but not necessarily unpleasant (items on the Need for Cognition scale include "Thinking is not my idea of fun" as well as "I prefer my life to be filled with puzzles that I must solve"). In any case it is clear that the cognitive effort involved in reasons analysis will produce affect that could obscure the detection of other judgment-relevant subjective responses.

Finally, reasoners may be impaired at identifying emotional responses in particular because, even with the proper skills and language, language and reasoning may be cognitively or neurologically incompatible with emotion perception. Recent research and theorizing (e.g., Halberstadt 2003, 2005; Schooler 2002) suggests that verbal processes may be incompatible with "configural" stimuli – stimuli that are processed as nondecomposable wholes rather than individual parts. Schooler and his colleagues have repeatedly shown that verbalization impairs recognition memory for configural stimuli, including faces (e.g., Dodson, Johnson, and Schooler 1997; Fallshore and Schooler 1995; Schooler and Engstler-Schooler 1990), facial expressions (Halberstadt 2005), colors (Schooler and Engstler-Schooler 1990), voices (Perfect, Hunt, and Harris 2002), wines (Melcher and Schooler 1995), music (Houser, Fiore, and Schooler 1996), and visual forms (Brandimonte, Schooler, and Gabbino 1997). These and other findings have led to the suggestion that language use produces a shift away from configural processing, speculatively related to the disparate brain regions controlling the two, which impairs the encoding and retrieval of configural stimuli (Schooler 2002).

Therefore, the featural processing shift associated with explicit analysis will interfere with the perception of a multidimensional feeling state if it is normally fused as a unitary subjective experience.

Empirical Studies

Thus, affect heuristics can in principle provide an account of reasons-based judgment impairment by assuming that quality is sometimes strongly predicted by the perceiver's subjective experience, and that subjective experience is in turn less likely to be used effectively in analytic conditions. To test the plausibility of this account empirically, Halberstadt and Catty (2005) examined reasoned judgments in a new domain, music popularity, for which they believed a high-valid affect heuristic – subjective familiarity – would be available. That is, a song's objective popularity (as quantified by its position on a national "top singles" list compiled based on sales and airplay) is likely to be strongly predicted by its subjective familiarity, in this case via the overwhelming media exposure popular songs receive. To test this assumption, Halberstadt and Catty asked participants to judge their subjective familiarity with songs that had appeared in either a high or low position on the New Zealand Top Singles List, emphasizing that they should assess their subjective *feeling* of familiarity, as opposed to whether they believed they had heard the songs before. As predicted, the more familiar a song felt, the more popular it had actually been ($r = .79$), and the more popular it was judged to be ($r = .73$).

Thus, subjective feelings of familiarity are a strongly predictive cue to the objective criterion of music popularity. However if, as argued above, reasons analysis interferes with either the assessment or use of this subjective experience, then it should decrease the correlation between familiarity and popularity judgments and, depending on just how good a cue familiarity is relative to other, more cognitive factors, it should decrease the accuracy of judgments. As an initial test of this hypothesis, Halberstadt and Catty asked participants to judge the more popular of pairs of songs that differed in their objective popularity. Ostensibly to help them with their decision making, half of the participants, while listening to short excerpts from each song, were told to "think about and analyze *why* one song might have been more or less popu-

lar than the other" (emphasis in original instructions), and to type into the computer at least two of those reasons. As in the pretest, subjective familiarity (measured later in the experiment) was associated with both perceived and actual popularity. Preliminary analyses indicated that participants chose the more familiar song of a pair as the more popular one 83 percent of the time and, because familiarity and popularity are indeed related, their choice was correct 76 percent of the time. Unexpectedly, however, reasons did not differ from controls on either of these measures.

Further analysis of the data, however, revealed an important moderating variable. Although familiarity was predictive of popularity overall, it was not equally predictive for every participant. For whatever reasons – perhaps exposure to or liking for pop music – participants' "familiarity validity" (effectively, a participant's theoretical accuracy assuming consistent use of the familiarity heuristic) ranged from .43 to .92 (chance accuracy = .5). In other words, familiarity was useless for some participants and a near-perfect cue for others. As illustrated in Figure 3, reasoning impaired familiarity use and judgment accuracy only for participants with relatively high familiarity validity. Thus, the hypothesis that reasoning interferes with the use of affect heuristics was confirmed, but with an important, and (in retrospect) obvious, caveat: such impairment is only evidenced when subjective experience is indeed a good cue to judgment. When reasoning decreases use of a subjective feeling that was poorly predictive of the judgment criterion, the judgment is likely to remain unchanged, or even to improve, depending on value of the alternative information used. That is, when other cues exist that are highly predictive of the criterion, then reasoning could be beneficial by decreasing reliance on the (less valid) subjective information. Thus the affect heuristics account acknowledges that reasoning is sometimes beneficial, and in principle provides an algorithm for predicting when it will be: specifically, when subjective responses are both heavily weighted in a particular (nonanalyzed) judgment, and at the same time poorly predictive of its criterion.

Of course being essentially correlational, this study on its own is insufficient to show that participants chose the more familiar songs *because* they were familiar. Familiar songs may have differed from unfamiliar songs along other dimensions that could have served as cues to accurate

Figure 3. Percent of correct popularity judgments as a function of reasoning condition and cue validity.

judgments. In another study, however, Halberstadt and Catty (in press) manipulated the familiarity of a new set of “songs” (actually brief, novel bass solos downloaded from the Internet) by presenting some of them earlier in the study. Again, participants judged which of two solos was more popular (according to a supposed Internet rating system). Each pair of solos consisted of one familiar (i.e., previously heard) solo and one unfamiliar (never before heard) solo. And again, results indicated that participants who first analyzed and recorded the reasons for their judgments before making them were less likely to choose previously encountered solos as more popular.

Halberstadt and Catty’s studies thus provide the first direct evidence for changes in the use of subjective experience following analytic thought, and thereby a plausible link between reasons analysis and objective decision quality. Participants who analyzed their reasons were less likely to choose subjectively familiar songs as more popular. Unfortunately, the state of the world was such that, at least for many participants, the subjectively familiar songs *were* more popular, and their inability or unwillingness to rely on their feelings of familiarity impaired their judgments.

When Will Reasoning Impair Judgment?

In sum, we have speculated that some judgments can and will be made using affect heuristics – that is, using feeling states that are directly predictive of the criterion of interest – and in these cases reasons analysis can produce objectively worse judgments by interfering with the use of the critical feeling states. We consider this account to be an extension of the information shift account offered for reasons-based attitude change. The latter proposes that reasoners frequently bring to mind information that is not representative of the real reasons for their attitude. The temporarily changed attitudes that result can be nonetheless damaging when subjectively poor (i.e., dissatisfying) decisions are made under their influence, but it is not clear why either the attitudes or the judgments should be worse relative to objective quality criteria. The affect heuristics account fills this theoretical gap by suggesting that people often make quick unanalyzed judgments on the basis of valid subjective responses and proposing several mechanisms by which analytic thought will particularly underweight such information. Together, the two accounts provide a more complete picture of the process of analytic impairment, and

suggest different conditions under which analytic thought will be most risky. We explore some of these conditions next.

VALIDITY

Whether analyzing reasons impairs objective judgments depends on whether the affective heuristic is a valid cue to the decision criterion. If it is not strongly predictive of the criterion, or is less predictive than the information brought to mind and used during reasons analysis, then its disruption will have either no effect or will improve judgment. Furthermore, even when valid information is accessible, reasoners may fail to use it if it seems implausible. The same is true of the information shift account: If the actual causes of attitudes are implausible, then people who analyze reasons will overlook these factors and focus on other reasons, often resulting in attitude change.

EXPERTISE

Expertise is a particularly interesting variable because there are suggestions of contradictory effects in the literatures on attitudes and judgment. A number of studies on attitude change and attitude-behavior consistency have concluded that experts are relatively immune to the effects of reasons analysis. For example, Wilson, Kraft, and Dunn (1989: Study 2) found that reasoning only changed attitudes toward political candidates among participants who were relatively unfamiliar with them. Knowledge had a similar moderating effect in Wilson et al.'s (1993) poster study discussed earlier, as well as in several other studies (see Table 1). By contrast, Halberstadt and Levine (1999), who explicitly recruited knowledgeable participants for their study, proposed that their effects might be more pronounced among experts.

This apparent contradiction, however, may be due to confounding two different kinds of expertise. One sense of expertise involves simply having more knowledge about a judgment domain, including facts about the decision options as well as about one's own responses to them. However, another dimension of expertise is the ability to use one's knowledge effectively. Although we believe that expertise in both senses will buffer an individual against the biasing effects of reasons analysis, the fact that they can emerge independently complicates any simple relationship between expertise and judgment, and requires that we consider their effects in turn.

The bulk of research on reasons analysis has treated expertise as factual knowledge. A number of studies have found that people who are knowledgeable about a topic are less susceptible to attitude change after analyzing reasons. For example, Wilson et al. (1989: Study 2) asked college students to rate their attitudes toward several candidates for president, early in the 1988 U.S. presidential race (before the major parties selected their candidates). Participants also rated how familiar they were with the candidates. Several weeks later they took part in an ostensibly unrelated laboratory experiment, in which half of the participants listed their reasons, privately and anonymously, as to why they liked or disliked six of the candidates. The other participants completed a filler task. All participants then rated their attitudes toward the candidates again. The standard effect of analyzing reasons was found among people who were relatively unknowledgeable: People who analyzed reasons changed their attitudes significantly more than those who did not. However, analyzing reasons had no significant effects on the attitudes of knowledgeable people. Knowledge had a similar moderating effect in the Wilson et al. (1993) poster study discussed earlier, as well as in several other studies (see Table 1).

There are a variety of possibilities as to why knowledgeable people are immune to reasons-based attitude change. Knowledgeable people may simply have stronger attitudes that are less likely to change in response to any manipulation, including introspecting about reasons. We suspect, however, that the answer lies in the conditions we have discussed that must be met for analyzing reasons to change people's attitudes: People have to bring to mind reasons that are of a different valence than their initial attitude, and they have to infer that these reasons reflect their current attitude. Do knowledgeable people bring to mind reasons that are more consistent with their attitudes, do they prevent themselves from basing their attitudes on their reasons, or both? To answer this question, we examined the reasons that knowledgeable and unknowledgeable people gave in the studies listed in Table 1. There was no evidence that knowledgeable people were less likely to base their attitudes on their reasons. Averaging across the five studies, the correlation between reasons and subsequently reported attitudes was no lower among knowledgeable than unknowledgeable people; in fact, it was slightly (albeit nonsignificantly)

Table 1: Studies Finding That Knowledge Moderates the Effects of Analyzing Reasons on Attitudes

<i>Study</i>	<i>Attitude Object</i>	<i>Measure of Expertise/Knowledge</i>	<i>Results</i>
Wilson et al. (1984: Study 3)	Dating relationships	Length of relationship	Analyzing reasons lowered attitude-behavior consistency for low knowledge group, no effects in high knowledge group.
Wilson, Kraft, and Dunn (1989: Study 1)	Candidates for 1984 U.S. presidential election	Knowledge test	Analyzing reasons lowered attitude-behavior consistency for low knowledge group, no effects in high knowledge group.
Wilson, Kraft, and Dunn (1989: Study 2)	Candidates for 1988 U.S. presidential election	Self-reported familiarity with the candidates	Analyzing reasons produced attitude change in low knowledge group, not in high knowledge group.
Wilson et al. (1993)	Art posters	Number of art courses taken in high school and college	Analyzing reasons produced (a) attitude change and (b) reduced satisfaction with choice of poster in low knowledge but not high knowledge group.
Erber, Hodges, and Wilson (1995)	Ronald Reagan	Self-reported knowledge	Analyzing reasons more likely to produce attitude change among people low in knowledge (trend).

higher among knowledgeable people, $M = .87$ versus $.75$.

In contrast, knowledgeable people were less likely to bring to mind reasons that conflicted with their initial attitude. In two of the studies listed in Table 1, people's initial attitudes were measured before they analyzed reasons attitudes (Erber, Hodges, and Wilson 1995; Wilson et al. 1989: Study 1), and the correlation between these initial attitudes and the valence of the reasons they subsequently listed were higher among knowledgeable people. Averaging across studies, the correlation between reasons and initial attitudes was $.87$ among knowledgeable people and $.65$ among unknowledgeable people, $z = 2.34$, $p < .05$. Thus, knowledgeable people appear to be immune to the effects of analyzing reasons because they are less likely to generate reasons that conflict with their initial attitudes.

We should note that the reason for this difference is not entirely clear. There are at least two possibilities: First, knowledgeable people might have so much experience with the attitude object that they know more why they feel the way they do, whereas unknowledgeable people may be less aware of their reasons and

thus generate plausible-sounding causes, some of which are of a different valence than their initial attitude. Or, knowledgeable people may be no more aware of the actual causes of their attitudes than unknowledgeable people, but might be more likely to generate reasons that are consistent with their initial attitude. They might, for example, have more of a vested interest in their attitude (Crano 1995), or a better developed schema or knowledge-structure (Lusk and Judd 1988), leading to the construction of reasons that conform to their attitudes. In support of this latter possibility, we found that the reasons reported by knowledgeable people were of greater evaluative consistency than the reasons reported by unknowledgeable people. That is, in the five studies in Table 1, knowledgeable people were significantly more likely to report reasons of a consistent valence, whereas unknowledgeable people were more likely to report a mixture of positive and negative reasons (see Lusk and Judd 1988 for a similar result). The more knowledgeable people become about a topic the more they might organize their knowledge around a consistent evaluation, such that when they think about reasons, they focus on reasons that are consistent with this evaluation.

The second dimension of expertise, the ability to use one's knowledge effectively, also may moderate the effects of analyzing reasons. From the perspective of the information shift account, experts might be better able to identify the real reasons underlying their attitude, thereby avoiding the first condition necessary for introspection to cause attitude change (bringing to mind inaccurate or incomplete reasons). More intriguingly, experts might be able to recognize when the reasons they generate are not representative of their feelings, thereby avoiding the second condition necessary for introspection to cause attitude change (the inference that one's reasons reflect one's attitude). The latter is similar to Salthouse's (1991) conception of expertise as the circumvention of limitations on human information processing. "Experts" and "novices" alike would be unable to identify all of the causes of their attitudes via introspection, but only experts would recognize this limitation and overcome it by short-circuiting the self-perception process (inferring one's attitude from one's reasons) that normally occurs. Similarly, from the perspective of the affect heuristics account, experts may have learned to identify and use particular feeling states and the covariations between their feeling states and judgment criteria. In fact, participants in Halberstadt and Catty's research showed some proficiency in using their feeling states strategically; participants whose subjective familiarity was more weakly predictive of popularity were less likely to use familiarity to make their judgments. Because familiarity validity and use are theoretically independent, this difference suggests that participants may have moderated their use of familiarity to maximize its effectiveness (although any strategic use of familiarity was unconscious; a follow-up study revealed that participants had no explicit knowledge of the validity of their subjective cues).

Some social psychological theories have posited a general tendency to focus on oneself and to recognize one's abilities, traits, and feelings. Self-awareness theory (Carver and Scheier 1981; Duval and Wicklund 1972) argues that people cannot simultaneously focus inward on themselves and outward on the environment, and thus alternate between these two types of "awarenesses." Furthermore, the theory argues that there are individual differences in the amount of time people spend focusing on themselves (Fenigstein, Scheier, and Buss 1975). Some people are chronically high in "private self-

consciousness," in that they are more likely to endorse questionnaire items such as, "I reflect about myself a lot" (Fenigstein et al. 1975: 524). Furthermore, there is some evidence that people high in private self-consciousness make more accurate reports about their traits and abilities (e.g., Scheier, Buss, and Buss 1978).

It might seem that people high in private self-consciousness would also be more accurate at detecting the reasons for their attitudes, due to repeated practice. We are, however, dubious about such claims. Our hunch is that detecting the reasons for our feelings and attitudes is not a skill that improves with practice (Wilson 2002). The human mind seems to be constructed in such a way that a great deal of information processing occurs outside of awareness, and trying to improve the accuracy of introspection about reasons may be as difficult as trying to improve the accuracy of introspection about the digestive system. Some evidence consistent with this view can be found in the use of introspection as a method by early experimental psychologists such as Titchener and Wundt. Accurate introspection about the contents of the mind required practice, they reasoned; it was a skill that could be obtained. According to Boring (1953), Wundt gave his participants ten thousand practice trials before they were considered to be "good" introspectionists. And yet, even with this amazing amount of practice, the introspectionist method failed, largely because of the failure of one person's introspections to reliably match another's.

We have examined the question of individual differences in the accuracy of introspection in some of our studies, by including a few relevant personality measures. In the Wilson et al. (1993) poster study, for example, many of our participants had completed the Fenigstein et al. (1975) self-consciousness inventory during an earlier mass testing session. We examined whether any of the components of this measure – private self-consciousness, public self-consciousness, and social anxiety – moderated the effects of analyzing reasons, and found that they did not. In another study (Hodges and Wilson 1994), scores were available on another measure that might reflect expertise in introspection, Leary, Shepperd, McNeil, Jenkins, and Barnes's (1986) construct of "objectivism." This measure assesses the extent to which people base their judgments and decisions on introspections about empirical information versus subjective and intuitive considerations (e.g., one item states, "After I make a decision, it is often difficult

for me to give logical reasons for it"; Leary et al. 1986: 34). Interestingly, this measure had no significant moderating effects on the tendency for analyzing reasons to change people's attitudes.

We do not mean to suggest that there are no individual differences that moderate the effects of analyzing reasons. There are other reasonable candidates that we have not examined, such as Cacioppo and Petty's (1982) measure of the need for cognition and Hansell, Mechanic, and Brondolo's (1986) measure of introspectiveness. Another possible individual difference is the extent to which people are able to deduce the reasons for their attitudes from observations of their own behavior. Even if people do not have direct access to their reasons, they can sometimes infer reasons from careful observations of the co-occurrence of their preferences and the conditions that precede them (Wilson and Stone 1985). For example, after many observations a person might accurately infer that he or she prefers romantic partners who are independent and nurturing, even if this person was previously unaware of these influences. Conceivably there are individuals who are better at this sort of deduction than others.

Summary and Conclusions

Several lines of research have implicated analytic thought in attitude change, attitude-behavior inconsistency, subjectively poorer attitude judgments and behavioral predictions, and impairment of objectively verifiable judgments. Previous research and theory have produced a plausible model of thought-induced attitude change, what we termed the "information shift account," in which reasoners overweight salient, plausible, and easily verbalized information, to the exclusion of other factors on which their "real" attitude is based. On its own, however, this account is less plausible as an explanation of how reasons analysis can produce objectively worse judgments.

In this chapter, we have reviewed research on information shift and proposed a supplementary account to bridge the gap between reasoning-driven biases in information accessibility and judgment quality. In many domains, quality outcomes are associated with subjective experiences – particularly familiarity and positive affect, but potentially more specific and basic emotional responses as well – either as evolved psychological mechanisms or as fortu-

itous environmental covariations. In these cases, people can and do rely primarily or exclusively on their subjective feeling states as heuristics for quality judgments, and analyzing reasons can impair judgment by obscuring the nature or magnitude of the critical feeling states.

Chapter 28: Belief Change as Propositional Update

RENÉE ELIO AND FRANCIS JEFFRY PELLETIER

Introduction

Suppose you need to send an express courier package to a colleague who is away at a conference. You believe that whenever she is in New York City and the New York Rangers are playing a home game, she stays at the Westin Mid-Manhattan Hotel. You also believe that she is in New York City this weekend and that the Rangers are playing this weekend as well. You call up the Westin Mid-Manhattan Hotel and you find out that she isn't there. Something doesn't fit. What do you believe now? Well, assuming that you accept the hotel's word that she isn't there, there are various (logically consistent) ways to reconcile the contradiction between what you used to believe and this new information. First, you could believe that she is in New York City and that the Rangers are indeed playing, but disbelieve the conditional that says whenever both of these are true, then she stays at the Westin Mid-Manhattan Hotel. Alternatively, you could continue to believe the conditional, but decide that either she isn't in New York this weekend or that the Rangers aren't playing a home game (or possibly both). Which do you choose as your new set of beliefs?

Belief change – the process by which a rational agent makes the transition from one belief state to another – is an important component for most intelligent activity done by epistemic agents, both human and artificial. When such agents learn new things about the world, they sometimes come to recognize that new information extends or conflicts with their existing belief state. In the latter case, rational reasoners would identify which of the old and new beliefs clash to create the inconsistency, decide whether in

fact to accept the new information, and, if that is the choice, to eliminate certain old beliefs in favor of the new information. Alternatively, new information may not create any inconsistency with old information at all. In this case, the reasoner can simply add the new information to the current set of beliefs, along with whatever additional consequences this might entail.

Although this is an intuitively attractive picture, the principles behind belief-state change are neither well-understood nor agreed-upon. Belief revision has been studied from a formal perspective in the artificial intelligence (AI) and philosophy literatures and from an empirical perspective in the psychology and management-science literatures. One of the practical motivations for AI's concern with belief revision, as portrayed in our opening scenario, is the development of knowledge bases as a kind of intelligent database: one enters information into the knowledge base and the knowledge base itself constructs and stores the consequences of this information – a process which is non-monotonic in nature (i.e., accepted consequences of previously believed information may be abandoned). More generally, the current belief state of any artificial agent may be contradicted either when the world itself changes (an aspect of the so-called frame problem) or when an agent's knowledge about a static world simply increases. Katsuno and Mendelson (1991) distinguish between these two cases, calling the former belief *update* and latter belief *revision*. Although much of the AI belief revision work focuses on formalizing competence theories of update and revision, prescriptive principles for how artificial agents “should” resolve conflict in

the belief revision case – where there is a need to contract the set of accepted propositions in order to resolve a recognized contradiction – are far from settled. From the perspective of human reasoning, we see an important interplay between issues of belief revision and deductive reasoning, particularly in terms of the kind of representational assumptions made about how a belief state should be modeled. But while human performance on classical deductive problems has been extensively studied, both Rips (1994, p. 299) and Harman (1986, p. 7) have noted the need for descriptive data and theories on how people resolve inconsistency when new information about a static world is presented. The studies we present in this article are concerned exactly with this issue.

We make two simplifications in our portrayal of belief revision and the paradigm we used to investigate it. The first concerns what we refer to as “beliefs.” Here, beliefs are sentences that people are told to accept as true, in the context of resolving some (subsequent) contradiction arising from new information that is provided. Now, being told to accept something as true is not necessarily the same as believing it to be true. The contradictions we introduce in our paradigm are not probes into a person’s preexisting belief system (e.g., as in social cognition investigations of attitude change; see Petty, Priester, & Wegener, 1994) or of a person’s hypotheses that are acquired over time via direct interactions with the world. The second simplification we make is treating beliefs as propositions that are believed either to be true or to be false (or, sometimes, that have a belief status of “uncertain”). This idealization characterizes the perspective of AI researchers who are interested in showing how classical deductive reasoning is related to belief revision. We will call this perspective “classical belief revision,” to distinguish it from other frameworks, including one direction in formal studies of defeasible reasoning, that map statistical or probabilistic information about a proposition into a degrees of belief in that proposition (Kyburg, 1983, 1994; Pearl, 1988; Pollock, 1990; Bacchus, Grove, Halpern, & Koller, 1992). Both classical belief revision and defeasible reasoning are concerned with non-monotonicity and it is possible to view belief revision as driving defeasible reasoning or vice versa (Gärdenfors, 1990a; Makinson & Gärdenfors, 1991).

This alternative formalization of beliefs and belief change in terms of probabilistic or statistical information have analogies in certain empirical investigations as well. A primary concern in the management-science literature, for example,

is to understand what factors influence a shift in the degree of belief in a particular proposition of interest. These factors include information framing (e.g., Ashton & Ashton, 1990; Shields, Solomon, & Waller, 1987) and agreement with prior beliefs and expectations (e.g., Koehler, 1993). Carlson and Dulany (1988) have proposed a model of belief revision about causal hypotheses from circumstantial evidence, in which the level of certainty in a causal hypothesis depends in part on the level of certainty the reasoner ascribes to circumstantial evidence supporting it. In Thagard’s (1989) computer model of explanatory coherence, propositions have levels of activation that roughly correspond to acceptance levels; such a model has been applied to accounts of scientific reasoning and to belief revision as evidenced in protocols of subjects performing elementary physics (Ranney & Thagard, 1988).

Notwithstanding these alternative ways to conceptualize belief states, we believe that the issues investigated under our simplifications are relevant to these other perspectives. Belief revision as a deliberate act by an agent must be driven by something, and that driving force must include the detection of a conflict (defined logically or otherwise) within the belief state. The problem of explicitly “expunging” or contracting of beliefs, after having noticed a conflict, has been acknowledged within some degree-of-belief frameworks (e.g., Kyburg, 1983, 1994). As soon as one attempts to define notions like “acceptance” or “full commitment to” within a degrees-of-belief framework, for the purpose of making a decision or taking an action, then new information can introduce conflict with existing accepted information. Hence, the issue still remains as to which prior belief or assumption an agent continues to believe (or to increase the degree of belief in) and which the agent decides to abandon (or decrease the degree of belief in).¹

Belief revision has also been studied as something that does not occur when it “should.” That is, there is considerable evidence indicating that people are in general very reluctant to change their current belief sets in the face of evidence that indicates those beliefs are unjustified; and that they are much more likely to reject, ignore, or reinterpret the new information which conflicts with their current beliefs rather than attempt to add it to their beliefs and make the necessary adjustments (Edwards, 1968; Einhorn & Hogarth, 1978; Ross & Lepper, 1980; Lepper, Ross, & Lau, 1986; Hoenkamp, 1988). Although it is true that there are occasions in which people fail to revise their beliefs or refuse

to accept new information, and there are theories offered as accounts of that reluctance, our starting point in these investigations assumes that any inertia against changing a belief set has been overcome.

Given our simplifications for the representation of belief states, the specific issue that concerns us can be easily stated. It is the question of which belief(s) out of some initial set is (are) abandoned when new, contradictory information must be integrated. The matters we consider in this study relate to certain formal notions that have been central to (what we have called) the classical AI belief revision perspective. These notions are epistemic entrenchment (whether some forms or types of information are less readily abandoned to resolve contradiction) and minimal change. It is not possible to consider these ideas without considering the fundamental choice that theories make in modeling a belief state either as a set of formulae or as a set of models. The implications of choosing one framework or another are crucial to operationalizing ideas like epistemic entrenchment. We review these two alternative positions on modeling belief states, and their relation to theories of human deduction, in the next section.

On Modeling Belief States and Deduction

Classical Models of Belief Revision

Alchourrón, Gärdenfors, and Makinson (1985; henceforth, “AGM”) proposed a set of “rationality postulates” as a competence specification of what rational belief change should be. Many of these ideas are intrinsically important to thinking about human belief revision as we are studying it here, so we borrow some key distinctions from that literature in setting the stage for our studies.

There are two predominant camps in how belief states are modeled within what we earlier defined as the classical belief revision community: “syntactic-based theories” *v.* “model-based theories.” The majority of the work in either of these camps follow the idealizations we outlined above: that beliefs are propositional in nature, that the status of a belief is “believed true,” “believed false,” or “uncertain,” and that logical inconsistency is to be avoided within the agent’s chosen belief state.

The difference between the syntactic and model approaches can be seen by example. Consider what might be in a belief state of an agent told: *All of Kim’s cars are made in the US; this (some particular) car is made in Ger-*

many. The syntax-based theories take the position that what is stored in the agent’s belief state are the two *formulas* mentioned (plus whatever background information the agent already had... also stored as a set of formulas). Since beliefs are just formulas, doing a logical inference amounts to performing some further mental activity on these formulas. This further activity would generate a *different* belief state from the initial one. And so there is no guarantee that the agent will perform *any* logical inferencing to generate new beliefs. For instance, there is no guarantee that this agent will use the background information it may have that Germany is a different country than the US and that cars made in the one are not made in the other to infer that this car is not made in the US. Even if it does perform this inference, there is no guarantee that it will make the further inference that the car is not owned by Kim. In this conception, two beliefs are different when and only when they are expressed by two syntactically distinct formulas.

In contrast to this, the model-based theories identify a belief state with a *model* – an interpretation of the world which would make a group of beliefs be true. In the above example of Kim’s cars, a model-based theory would identify the agent’s belief state with those models of the world in which all of Kim’s cars are made in the US and where furthermore some particular car is made in Germany. Assuming the agent’s background beliefs include that Germany is a different country than the US and that cars made in the one are not made in the other, the set of background models that can accommodate such situations in the world are merged with those describing the two stated beliefs and the output is a model (or models) in which Kim’s cars are made in the US, and this car is made in Germany, and hence this car is not made in the US, and hence this car is not owned by Kim. All this sort of “inferencing” is done already in the very *description* of the belief state. The fact that the belief state is a model of the world described by the sentences guarantees that all logical consequences of these sentences will be represented, for otherwise it couldn’t be a model of those sentences.

One common way of putting the difference is to say that the syntax-based approach is committed only to *explicit beliefs* as defining a belief state, whereas a model-based approach is committed to defining a belief state in terms not only of explicit beliefs but also of the implicit beliefs that are entailed by the explicit ones.

Both approaches involve a certain amount of theoretical idealization. Under the model-based view, the very definition of an agent's belief state already embodies finding the models that perfectly suit it, and this in effect means that all the logical conclusions of any explicit beliefs are included. Within the syntactic framework, there is an assumption that only "obvious" or "minimal" conclusions are drawn, but how these are recognized as such goes unspecified. Secondly, it is not clear how syntactic-based theories detect arbitrary logical contradictions beyond ones that can be immediately spotted by a syntactic pattern-match, such as " p and $\sim p$," since beliefs are represented as strings of symbols and not models of the world being described.²

A third conception of belief states – which could be seen as an intermediate stance between the syntactic and the model-based approaches – might be called a "theory-based" theory of beliefs. Here a belief state is identified with a *theory*, which is taken to be a set of sentences, as the syntactic-based theories hold. However, this set is the infinite set of all the logical consequences of the explicit beliefs.³ This is the approach advocated in the original work done by AGM (1985). It too is obviously an idealization, for taken to the extreme, it would require a person's mind (or an agent's memory) to be infinite in order to hold a belief. Although theory-based theories are like syntax-based theories in containing formulas (and unlike model-based theories in this regard), they differ from syntax-based theories in obeying a principle called "The Irrelevance of Syntax": if two formulas are logically equivalent, then adding one of them to a belief state will yield the same result as adding the other, since the set of their logical consequences is the same. This principle is obeyed by both the theory-based and the model-based theories, and has been vigorously defended (AGM, 1985; Dalal, 1986; Yates 1990; Katsuno & Mendelson, 1991) on the grounds that all that is relevant to belief change is how the world is, or would be, if the beliefs were true.

Many of the concepts and distinctions mentioned above as characterizing classical AI belief revision also apply to other belief revision frameworks. Computational frameworks in which propositions are represented as nodes in some kind of belief network (e.g., Pearl, 1988; Thagard, 1989) are syntactic, because any semantic contradiction between two nodes is merely reflected by the names of the links chosen to join the nodes in the network. Methods proposed by Halpern (1990) and Bacchus et al. (1992) for

deriving degrees of belief from statistical information are model-based approaches: the degree of belief in a sentence stems from the probability of the set of worlds in which the sentence is true. Kyburg's theory of rational belief (1983, 1994), in which levels of acceptance are also derived from probabilities, falls into what we have called the "theory theory" category. He models beliefs as a set of (first-order logic) sentences but then requires the set to obey the irrelevance of syntax principle: if two sentences have the same truth value in belief set, then their probabilities are also equivalent within that set. So we see that, although the classical belief revision approach comes from a milieu where performance criteria are not explicitly considered, the sorts of distinctions made within these classical belief revision frameworks can elucidate the representational assumptions of other approaches as well.

Performance Theories of Human Deduction

Harman (1986) has argued that the principles guiding belief revision are not the rules of deductive logic. Certainly, any principles that can dictate which of several different belief state changes to select are outside the scope of deductive inference rules. Any characterization of belief revision must first make some commitment to how a belief state is represented; as the formal theories we outlined above illustrate, making (or not making) inferences is crucial to how the belief revision process is to be conceptualized. Certainly, the ability to recognize inconsistency is a necessary step towards deliberate belief revision, and that step may involve some aspects of what has been studied and modeled as deductive reasoning. Hence, it seems that theories about how people draw inferences from propositional knowledge will be crucially related to the transition from one belief state to another, if only because those inferences may define the content of the belief states themselves.

Generally speaking, the theories of human deductive reasoning have split along a dimension that is similar to, but not identical with, the syntactic v. model-theoretic distinction in AI. On the one hand, mental-model theories of the type proposed by Johnson-Laird and colleagues (Johnson-Laird, Byrne, & Schaeken, 1992; Johnson-Laird & Byrne, 1991) hold that a person reasons from particular semantic interpretations (models) of sentences such as $p \rightarrow q$ and either p or q .⁴ In this framework, a reasoner identifies or validates a particular conclusion by manipulating and comparing these models.

On the other hand, proof-theoretic approaches (Rips, 1983 1994; Braine & O'Brian, 1991) propose that people possess general inference rules and follow a kind of natural deduction strategy to derive conclusions from a set of premises. Like the different kinds of belief revision theories in AI, these different psychological accounts of human deduction offer distinct representational assumptions about the constituent parts that are said to define a belief state. But unlike the AI belief revision theories, psychological theories must make a commitment to a plausible process account of how a person generates and operates upon these different representations.

Neither mental-model nor proof-theoretic accounts of deduction were initially developed for belief revision as we have portrayed it here; nor have there been, as yet, extensions designed to accommodate aspects of this phenomenon. However, we consider some of their basic assumptions in the discussion of our tasks and results, and so here we briefly summarize the mental-models framework proposed by Johnson-Laird and colleagues and the proof-theoretic model proposed by Rips (1994).

If we apply a state-space abstraction to mental models frameworks and to proof-theoretic frameworks, the main distinction between proof theoretic and model-based theories of human deduction can be summarized as differences in what defines a state and what constitutes the operators that make transitions from one state to another. In a proof-theoretic system like the one proposed by Rips (1994), a state is a partial proof and the operators are a set of inference rules (a subset of the classical logic inference rules). These operators extend a proof (and hence move the system from one state to the next) by following a natural deduction-like strategy, with heuristics that order their application within this general control strategy. The goal can be viewed as a state (or a path to a state) which includes a given conclusion as an outcome of a proof (hence validating it) or includes a statement not already specified in the problem's premises (drawing a new conclusion). In the mental-models theory, a state contains one or more interpretations of the sentence set, i.e., tokens with specific truth values that correspond to some situation in the world. Operators retrieve models of sentences and move the system to new states that constitute candidate models of the world. More specifically, the mental models framework assumes there are particular models that are initially associated with particular sentence forms (conditionals, disjuncts, and so forth), with other mod-

els of these forms sometimes held in abeyance until there is a need to consider them. A conclusion is any truth condition that is not explicitly stated in the sentence set, but which must hold given a consistent interpretation of the sentence set. Hence, the goal state can be seen as one in which such a truth condition is identified. Thus, the proof-theoretic theory of human deduction can be seen as a search for alternative inference rules to apply to a sentence set in order to extend a proof, whereas the mental-models theory can be seen as a search for alternative interpretations of a sentence set, from which a novel truth condition can be identified or validated.

It is important to be clear not only about the similarities but also about the differences between the classical, competence belief-revision theories and the psychological performance theories of human deduction. What the mental-models theory shares with the formal model-based belief revision theories is the essential idea that the states being operated upon are models. These models capture the meaning of the connectives as a function of the possible truth values for individual atomic parts that the connectives combine. However, there are three key differences between these two types of model theories. First, although the irrelevance-of-syntax principle is a distinguishing feature of formal models of belief revision in AI, it does not distinguish between mental-models and proof-theoretic models of human deductive reasoning, both of which offer alternative accounts of the pervasive finding that syntactic form does influence how people reason about problems that are otherwise logically equivalent. Second, in the mental-models theory, the models of $p \rightarrow q$ are generated in a serial, as-needed basis, depending on whether a conclusion is revealed or validated by the initial interpretation (and it is the order in which such models are generated that plays in the mental model's account of the effect of syntactic form on deductive reasoning). The AI model-based belief revision frameworks do not make any such process assumptions, except in their idealization that all models are available as the belief state. Third, the mental-models framework may be considered closer to what we have called the "theory theory" classical belief-revision framework, than to the pure model framework, because separate models of each sentence are produced and operated upon.

What a psychological proof-theoretic framework of deduction shares with its formal AI syntactic-based counterparts is a commitment

to apply deductively sound inference rules to sentences. But unlike the syntactic-based competence theories of belief revision, psychological proof-theoretic models of deduction do not presume that a person has a representation of every deductive rule of inference and they may presume there is some heuristic ordering of the available rules; these differences are relevant to how a proof-theoretic perspective models the relative difficulties that people have with certain forms of deductive problems. Further, some of the undesirable aspects of syntactic competence models, such as uncontrolled deductive closure in searching for contradictions, are avoided in proof-theoretic performance models (e.g., Rips, 1994) by explicitly positing that the reasoner's current goals and subgoals are what direct and control the application of inference rules.

Minimal Change and Epistemic Entrenchment

A basic assumption behind most AI theories of belief revision (e.g., the AGM postulates) and some philosophical accounts (e.g., Harman, 1986) is that an agent should maintain as much as possible of the earlier belief state while nonetheless accommodating the new information. But it is not completely clear what such a minimal change is. First, there is the problem in defining a metric for computing amounts of change. Often, this relies on counting the number of propositions whose truth value would change in one kind of revision versus another. The revision that leaves the belief state "closest" to the original one is to be preferred. But as we next illustrate, how such a definition of closeness works depends on whether one takes a syntactic or model-based approach.

As an example of the differences that can evolve, consider our earlier story about your New York-visiting colleague. Let n stand for she-is-in-New-York, r stand for Rangers-are-playing, and w stand for she-stays-at-the-Westin. Symbolically, your initial beliefs were $[n \ \& \ r \ \rightarrow \ w, n, r]$, from which you deduced w . But then you found out $\sim w$. In a model-based approach, the unique model describing your initial belief set (unique, at least, if we attend only to $n, r,$ and w) is: n is true, r is true, w is true. Then you discover that the model is incorrect because w is false. The minimal change you could make is merely to alter w 's truth value, and so your resulting belief states is: n is true, r is true, w is false. In a syntax-based approach, you would instead keep track of the ways that as many as possible of the

three initial sentences remain true when you add $\sim w$ to them. There are three such ways: $S_1 = [n \ \& \ r \ \rightarrow \ w, n, \sim r, \sim w]$, $S_2 = [n \ \& \ r \ \rightarrow \ w, \sim n, r, \sim w]$, $S_3 = [\sim(n \ \& \ r \ \rightarrow \ w), n, r, \sim w]$.⁵ Now consider what common sentences follow from each of $S_1, S_2,$ and $S_3,$ and the answer is that the consequences of $[\sim w, n \vee r]$ will describe them. Note that this is different from the version given as a model-theoretic solution. In the syntactic case, only one of n and r need remain true, whereas in the model-based belief revision version, both need to remain true.

The notion of "epistemic entrenchment" in the belief revision literature (Gärdenfors, 1984, 1988; Gärdenfors & Makinson, 1988; Willard & Yuan, 1990; Nebel, 1991) has been introduced as a way to impose a preference ordering on the possible changes. Formally, epistemic entrenchment is a total pre-ordering relation on all the sentences of the language, and this ordering obeys certain postulates within the AGM framework. Less formally, epistemic entrenchment can be viewed as deeming some sentences as "more useful" in that they have greater explanatory power and hence are more deserving of entrenchment than other sentences; and in cases where there are multiple ways of minimizing a change to a new belief state, these priority schemes will dictate which way is chosen. Now, the general issue of whether some types of knowledge (e.g., sensory observations v reasoned conclusions) should be a priori more epistemically privileged than other types of knowledge has occupied much of philosophy throughout its history. One particular, more modest, contrast is between what might be called statements about data v statements about higher-order regularities. From one perspective, it can seem that conditional statements should enjoy a greater entrenchment in the face of conflicting evidence because they either express semantic constraints about the world or express an important predictive regularity that might be the result of some long-standing and reliable inductive process. As an example of this sort of perspective, one can point to scientific theorizing that is based on statistical analysis, where one rejects "outlying" data as unimportant, if other regularities characterize most of the remaining data. In doing so, we give priority to the regularity over (some of) the data. Certain approaches to database consistency (e.g., Elmasri & Navathe, 1994, pp. 143–151) and some syntactic theories of belief revision (e.g., Foo & Rao, 1988; Willard & Yuan, 1990) advocate the entrenchment of the conditional form $p \rightarrow q$ over non-conditional

(ground) forms. For database consistency, a relation like $p \rightarrow q$ can be said to represent a semantic integrity constraint, as in “If x is y ’s manager, then x ’s salary is higher than y ’s salary.” For classical belief revision theories, the intuition driving the idea of entrenching $p \rightarrow q$ over other types of sentences is not because material implication per se is important, but because “lawlike relations” are often expressed in sentences of this form. For example, Foo and Rao (1988) assign the highest epistemic entrenchment to physical laws, which may be especially effective in reasoning about how a dynamic world can change (e.g., the belief update, rather than revision, problem).

But there is another perspective that would propose exactly the opposite intuitions about entrenchment: what should have priority are observations, data, or direct evidence. These are the types of statements which are fundamental and about which we can be most certain. Any kind of semantic regularities expressed in conditional form are merely hypotheses or data-summarizing statements that should be abandoned (or at least suspected) when inferences predicted from them are not upheld by direct evidence. This sentiment for data priority seems plausible in the context of hypothesis evaluation (e.g., Thagard, 1989) as it did to some involved in the “logical construction of the world” (e.g., Russell, 1918; Wittgenstein, 1922).

In sum, we note that these alternative intuitions about entrenching conditionals ν . nonconditionals are more or less readily accommodated, depending on the representation of belief states. It is easy to use the form of a sentence as a trigger for entrenchment principles, if one has a syntactic stance; but if a reasoner works with models of the world, then this sort of entrenchment is not as easily supported (unless sentences are individually modeled and knowledge of “form” is somehow retained). By first understanding the principles that actually guide belief revision in people, we are in a better position to formulate what kinds of representations would enable those principles to operate in a cognitive system.

Overview of Experiments

So far, we have touched upon a number of broad theoretical issues that bear on belief revision, at least when this is characterized as a deliberate decision to remove some proposition(s) that had been accepted as true, in order to resolve a contradiction noted in the belief set. Although our longer-term interest is to better understand

what plausible principles might define epistemic entrenchment, our immediate interest in the present studies was first to acquire some baseline data on what belief revision choices people make in relatively content-free tasks and to tie these results to models of deduction. To do this, we consider the simple task of choosing to abandon a conditional sentence ν . a non-conditional, ground sentence as a way to resolve a logical contradiction. This decision corresponds to the example dilemma we presented at the start of this article. The initial belief state, defined by a conditional and a ground sentence, can be expanded by the application of a deductive inference rule. In our paradigm, it is this resulting inferred belief that is subsequently contradicted. Because we know that human deduction is influenced by the particular form of the inference rule used (cf. Evans, Newstead, & Byrne, 1993), we are secondarily interested in whether the inference rule used in defining the initial belief set impacts a subsequent belief revision rule. While these particular experiments are not designed to discriminate between proof theoretic or mental-models theories of deduction, such evidence is relevant to expanding either of these performance models of human reasoning to embrace aspects of resolving contradiction. The final two studies examine more directly various of the alternative model-theoretic definitions of minimal change, and investigate whether minimal change – by any of these definitions – is a principle for human belief revision. This organization notwithstanding, we note that these issues – the syntactic versus model-theoretic distinction, epistemic entrenchment, and minimal change – are tightly interwoven and each experiment bears on each of them in some way.

Entrenchment of Conditionals

In the first three experiments we report, we used two problem types that differed in whether the initial belief state included a conclusion drawn by the application of a modus ponens inference rule or by the application of a modus tollens inference rule. Modus ponens is the inference rule that from *If p then q* , and furthermore p , then infer q . The modus ponens belief set consisted of a conditional, a ground sentence that was the conditional’s antecedent, and the derived consequent. Modus tollens is the rule that from *If p then q* , and furthermore $\sim q$, infer $\sim p$. The initial modus tollens belief set consisted of a conditional, a ground sentence that was the negation of its consequent, and the derived negation of the

Table 1: Definitions of Initial Belief States and Revision Alternatives for Experiment 1's Problem Set

<i>Problem Type</i>		<i>Revision Alternatives</i>
Modus Ponens		
Initial SS:	$p \rightarrow q, p, q$	1. $p \rightarrow q, \sim p, \sim q$
Expansion:	$\sim q$	2. $\sim(p \rightarrow q), \sim q, ?p$
		3. $\sim(p \rightarrow q) p, \sim q$
Modus Tollens		
Initial SS:	$p \rightarrow q, \sim q, \sim p$	1. $p \rightarrow q, p, q$
Expansion:	p	2. $\sim(p \rightarrow q), p, ?q$
		3. $\sim(p \rightarrow q), p, ?q$

Note. SS means sentence set. Expansion means the expansion information. ? means uncertain.

antecedent. We introduced contradiction with the initial belief state by providing new information – the expansion information – which contradicted whatever the derived conclusion was. In the modus ponens case, the expansion was $\sim q$. In the modus tollens case, the expansion was p .⁶

We defined belief-change problems, using these well-studied problem types, both to provide a baseline for understanding the role of syntactic form in belief-change problems, and to make contact with existing data and theories about human performance on these classic deductive forms in a different problem context. If a conditional enjoys some kind of entrenchment by virtue of its syntactic form, people should prefer a revision that retained the conditional but reversed the truth status of the ground sentence that permitted the (subsequently contradicted) inferred sentence. A related question is whether this belief revision choice is made differently, depending on whether the belief state consisted of a modus ponens or modus tollens inference. From an AI model-theoretic viewpoint, modus ponens and modus tollens are just two different sides of the same coin: they differ only in their syntactic expression. Classical AI model-theoretic approaches would consider a revision that denied the conditional to be a more minimal change.⁷ From a psychological viewpoint, it is well documented (e.g., see the survey by Evans, Newstead, & Byrne, 1993) that people find making a modus tollens inference more difficult than making a modus ponens inference. In this work, we did not want this feature of reasoning to come into play. Therefore, we provided the inferences explicitly in defining the initial belief set, and then asked whether the deductive rule used to derive them affects the belief revision choice.

The existing literature on human reasoning performance also indicates an influence of domain-specific content on the kinds of inferences that people are able or likely to draw. To account for these effect, theories have proposed the use of abstract reasoning schemas (Cheng & Holyoak, 1989; Cheng, Holyoak, Nisbett, & Oliver, 1993) and a reasoning by analogy approach (Cox & Griggs, 1982). For these initial investigations of belief-revision choices, we were not interested in investigating the direct applicability of these theoretical distinctions to the issue of belief-revision, but rather considered the general empirical findings that people reason differently with familiar topics than they sometimes do when given problems involving abstract symbols and terms. If belief revision is viewed less as a decision task driven by notions like minimal change and more as a problem of creating consistent explanations of past and current data, then we might expect the pattern of revision choices to be different when the problem content is more “real-worldly” than abstract. So, these experiments used both abstract problems (containing letters and nonsense syllables to stand for antecedents and consequents) and equivalent versions using natural language formats.

Experiment 1

Method

PROBLEM SET

Table 1 gives the schematic versions of the two problem types used in this experiment. Each problem consisted of an initial sentence set, expansion information, and then three alternative revision choices. The initial sentence set was labeled “the well-established knowledge at time 1.” The expansion information was

introduced with the phrase, "By time 2, knowledge had increased to include the following."⁸ Each revision alternative was called a "theory" and consisted of statements labeled "Believe," "Disbelieve," or "Undecided About." A theory could have statements of all these types, or of just some of these types. The task for subjects was to choose one of the alternative revision theories as their preferred belief state change.

For the modus ponens and modus tollens problems, the original sentence set included a conditional of the form $p \rightarrow q$ and either the antecedent p or the negated consequent $\sim q$, respectively. In both cases, the derived inferences were included in the initial set (q for modus ponens, $\sim p$ for modus tollens). The expansion information for both problems contradicted the derived inference and this was explicitly noted to subjects in the presentation of the problem. Revision choices 1 and 3 offered two different logically consistent ways to reconcile this: deny the conditional (choice 3) or retain the conditional but reverse the truth status of the ground sentence that permitted the inference (choice 1). Revision choice 2 was included to provide a choice that was non-minimal by almost any standard: it included the expansion information, denied the conditional, and labeled the ground sentence that permitted the inference to be made as "uncertain" (signified by a ? in Table 1). Note that all revision alternatives indicated that the expansion information must be believed.

Problems had one of two presentation forms: a symbolic form, using letters and nonsense syllables, and a science-fiction form. An "outer space exploration" cover story was used to introduce the science-fiction forms. Here is an example of how a modus tollens problem appeared in the science fiction condition:

On Monday, you know the following are true:

If an ancient ruin has a protective force field, then it is inhabited by the aliens called Pylons.

The tallest ancient ruin is not inhabited by Pylons.

Therefore, the tallest ancient ruin does not have a protective force field.

On Tuesday, you then learn:

The tallest ancient ruin does have a protective force field.

The Tuesday information conflicts with what was known to be true on Monday. Which of

the following do you think should be believed at this point?

A corresponding symbol version of this problem was: *If Lex's have a P, then they also have an R. Max is a Lex that has a P. Therefore, Max has an R. The expansion information was Max does not have an R.*

DESIGN

All subjects solved both modus ponens and modus tollens problem types. Presentation form (symbolic *v.* science-fiction) was a between-subjects factor. The science-fiction cover stories used several different clauses to instantiate the problems. The clauses used for each problem type are shown in Appendix A.

SUBJECTS

One-hundred twenty subjects from the University of Alberta Psychology Department subject pool participated in the study. Equal numbers of subjects were randomly assigned to the symbol and science fiction conditions.

PROCEDURE

The modus ponens and modus tollens belief problems appeared as part of a larger set of belief revision problems. The order of revision alternatives for each problem was counterbalanced across subjects. Below are excerpts from the instructions, to clarify how we presented this task to our subjects:

... The first part of the problem gives an initial set of knowledge that was true and well-established at time 1 (that is, some point in time). There were no mistakes at that time. The second part of the problem presents additional knowledge about the world that has come to light at time 2 (some later time). This knowledge is also true and well-established. ... The world is still the same but what has happened is that knowledge about the world has increased. ... After the additional knowledge is presented, the problem gives two or more possible "theories" that reconcile the initial knowledge and the additional knowledge. ... Your task is to consider the time 1 and time 2 knowledge, and then select the theory that you think is the best way to reconcile all the knowledge.

Results

Each subject contributed one revision-type choice for each of the two problem types. This

Table 2: Percentage of Subjects Choosing Each Revision Alternative, Experiment 1

Revision Alternative	Problem Type					
	Modus Ponens			Modus Tollens		
	Symbol	SciFi	Mean	Symbol	SciFi	Mean
1. disbelieve ground sentence	.25	.14	.20	.33	.17	.25
2. disbelieve conditional, uncertain about ground sentence	.38	.29	.34	.38	.54	.46
3. disbelieve conditional	.37	.58	.48	.28	.29	.29

gives us frequency data for how often each revision choice was selected, as a function of two variables: problem form (modus ponens *v.* modus tollens) and presentation form (science-fiction *v.* symbolic). Table 2 presents this data as the percentages of subjects choosing a particular revision choice.

From the schematic versions of the problems in Table 1, it is clear that the three belief revision alternatives for the modus ponens (MP) and modus tollens (MT) problems have a certain symmetry, even though the actual details of each revision are necessarily different. In Table 2's presentation of the data, we re-label these revision alternatives in a more general form that reflects this symmetry. For both problem types, revision choice 1 retains the conditional but reverses the truth status for the ground sentence that was the other initial belief. (For the MP problem, the expansion was $\sim q$, so p was the initial ground sentence. For the MT problem, the expansion mentioned p ; so $\sim q$ was the initial ground sentence.) In revision choice 2, the conditional is disbelieved and the ground sentence is uncertain. Under revision choice 3, the conditional is disbelieved and the ground sentence retains whatever truth value it had initially.

In general, subjects preferred revisions in which the $p \rightarrow q$ rule was disbelieved (revisions 2 and 3). Collapsing across presentation condition, the clearest difference between the MP and MT belief-change problems concerned which of these two rule-denial revisions subjects preferred: on MP problems, the preferred belief change saw subjects preferring simply to disbelieve only the rule; on MT problems, the preferred revision was to disbelieve the rule and to regard the initial ground sentence, $\sim q$, as uncertain.

To analyze this frequency data, one could create a set of two-way tables for each level of each variable of interest to assess whether the distribution of frequencies is different, and com-

pute a chi-square test of independence for each sub-table; however, this does not provide estimates of the effects of variables on each other. Loglinear models are useful for uncovering the relationships between a dependent variable and multiple independent variables for frequency data. A likelihood-ratio chi-square can be used to test how well a particular model's prediction of cell frequencies matches the observed cell frequencies.

We can first ask whether the three revision alternatives were selected with equal probability, when collapsed across all conditions. The observed percentages of 22.2%, 39.9%, and 37.9% for revision choices 1, 2, and 3, respectively, were significantly different from the expected percentages ($\chi^2 = 13.27$, $df = 2$, $p = .001$). By examining the residuals, we can identify patterns of deviation from the model. The two deviations in this case were the percentage of revision 1 and revision 2 choices.

To test whether revision choice is independent of problem type and presentation mode, we fit a model that included simple main effects for each factor, but no interaction terms. The chi-square value indicates that such an independence model does not fit the data well ($\chi^2 = 15.33$, $p = .004$, $df = 4$). Models that included only one interaction term for revision by problem type, or only one for revision by presentation mode, were also poor fits to the observed data ($\chi^2 = 12.02$ and 10.52 , respectively, df 's = 4, p 's < .05). The simplest model whose predicted frequencies were not significantly different from observed frequencies included both a revision by problem type and a revision by presentation-mode interaction term ($\chi^2 = 3.18$, $df = 2$, $p = .203$).⁹

The means in Table 2 indicate that the pattern of difference between MP and MT choices is primarily due to differences in responses on the science-fiction problems. Fifty-eight percent of the science-fiction condition subjects chose to

Table 3: Percentage of Subjects Choosing Each Response Alternatives, Experiment 2

<i>Revision Choice</i>	<i>Problem</i>	
	<i>Modus Ponens</i>	<i>Modus Tollens</i>
1. disbelieve ground sentence	.23	.26
2. disbelieve conditional; ground sentence uncertain	.12	.16
3. disbelieve conditional	.35	.12
4. disbelieve both conditional and ground sentence	.14	.02
5. both conditional and ground sentence uncertain	.16	.44

disbelieve $p \rightarrow q$ on modus ponens belief states, while only 29% did so in the modus tollens case. The most frequently chosen revision (54%) for a science fiction MT belief-revision was a non-minimal change: disbelieving $p \rightarrow q$ and changing q 's initial truth status from false to uncertain. Only 29% of the subjects choose this revision on the modus ponens belief state.

Experiment 2

In Experiment 1, subjects may have been evaluating merely whether each revision option was logically consistent, independently of what the initial sentence set and expansion information was. Only two of the revisions alternatives offered minimal-changes to the initial sentence set, and this might have accounted for the close pattern of responses between symbolic-form MT and MP problems. Asking subjects to generate, rather than select, a revision would most directly address this possibility, but for these studies, we decided to retain the selection paradigm and to increase the alternatives. For Experiment 2, we included an extra non-minimal change revision and a revision in which the sentences were logically inconsistent.

Method

PROBLEM SET AND DESIGN

Table 3 presents the response alternatives for the modus ponens and modus tollens problems used in Experiment 2. The first three response choices were the same as those used in Experiment 1. The fourth choice denies both the rule and changes the original truth status of the initial ground sentence. This is a non-minimal change and results in an inconsistent set of sentences as well. The fifth revision choice labels both the conditional and the ground sentences from the initial belief set as uncertain. These changes too are non-minimal, but the final belief set is logically consistent.

Subjects and Procedure

Forty-three subjects participated as part of a course requirement for an introductory psychology course. All subjects solved both MP and MT problems, as part of a larger set of belief-revision problems. Only symbolic forms of the problems were used in this follow-up experiment. The instructions were the same as those used for Experiment 1.

Results

The percentage of subjects choosing each revision choice are also given in Table 3. There is some consistency in the patterns of responses across both Experiments 1 and 2. The frequency of revisions in which the initial ground sentence's truth value was changed (revision choice 1) was still relatively low (about 25%) on both problem types, as we had found in Experiment 1. About 33% of the subjects opted simply to disbelieve the conditional (revision 3) on the MP problem (as they had in Experiment 1). However, on the MT problem, changing both the conditional and the initial ground sentence to uncertain (revision 5) accounted for most of the choices. A chi-square computed on the revision-choice by problem-type frequency table confirmed there was a different pattern of revision choices for these modus ponens and modus tollens problems ($\chi^2 = 15.33$, $df = 4$, $p = .004$).

Experiment 3

In the first experiments, we explicitly included the derived consequences in the modus ponens and modus tollens problems. In Experiment 3, we tested whether or not this inclusion of consequences as explicit elements of the initial belief set (versus allowing the subjects to draw their own conclusions) would affect revision choice. Consider, for example, problem type 1 in Table 4. This problem's initial belief set supports

Table 4: Templates for Experiment 3 Problem Types

Problem Type 1	
Initial Sentence Set	$m \ \& \ d \rightarrow g, m, d$ [Therefore, g]
Expansion	$\sim g$
Revision Alternatives	1. $\sim[m \ \& \ d \rightarrow g], m, d$ 2. $m \ \& \ d \rightarrow g, (\sim m \ \& \ d)$ or $(m \ \& \ \sim d)$ or $(\sim m \ \& \ \sim d)$
Problem Type 2	
Initial Sentence Set	$c \rightarrow h, h \rightarrow m, c.$ [Therefore, h and m]
Expansion	$\sim h$
Revision Alternatives	1. $h \rightarrow m, \sim[c \rightarrow h], c, ?m$ 2. $h \rightarrow m, c \rightarrow h, \sim c, ?m$ 3. $h \rightarrow m, \sim[c \rightarrow h], c, m$ 4. $h \rightarrow m, c \rightarrow h, \sim c, m$

Note. Bracketed consequences appeared in the initial sentence set for “consequences given” condition and were omitted in the “no consequences given” condition. All response choices included the expansion sentence as part of the revision description. See text for percentages of subjects choosing each option.

a simple modus ponens inference from a conditional $m \ \& \ d \rightarrow g$ and the ground sentences m and d to generate the conclusion g . As in the previous experiments, there were two logically consistent ways to reconcile the $\sim g$ expansion information: deny the conditional or deny one or more of the ground sentences that comprise the conditional’s antecedent. The two revision choices reflect these two choices. Alternative 1 disbelieves the conditional and retains belief in the ground sentences; alternative 2 retains belief in the conditional and calls into question one or both of the ground sentences.

Whether or not the initial sentence set includes derived consequences can have more profound implications when the initial belief set supports a chain of inferences. Consider problem type 2 in Table 4, in which the initial belief state is $[c \rightarrow h, h \rightarrow m; c]$ and the expansion information is $[\sim h]$. One conclusion supported in the initial belief set is h . And this is in conflict with the expansion information. There are two ways to resolve this conflict: deny the conditional $c \rightarrow h$, arriving at the final belief set of $[c, h \rightarrow m, \sim h]$. Or deny c and retain the conditional $c \rightarrow h$, to obtain, the revised belief set $[c \rightarrow h, h \rightarrow m, \sim c, \sim h]$. Note that m cannot be inferred from either of these two revised belief states, but note also that it was a consequence of the initial belief set. Should we continue to believe in m ? We can do that only if we believed in m in the first place, that is, if we drew m as a logical consequence of the first set of sentences. Otherwise, its status would be uncertain – neither believed nor disbelieved. Belief revision alternatives were

provided for both these possibilities, and this was investigated both in the case where logical consequences of beliefs were explicitly included in the initial belief set (as in Experiments 1 and 2) and also without explicit inclusion.

A second factor we considered in this follow-up was whether the conditional sentences in the initial belief set were propositional sentences or were universally quantified sentences. The belief revision problem hinges on the reconciliation of conflicting information, but how that reconciliation proceeds may depend on whether it contradicts what is believed about a class (hence, is a factor relevant to predicate logic), versus what is believed about an individual (and hence is a feature of propositional logic). Therefore, we manipulated whether the initial belief set was specified by universally quantified sentences or propositional sentences for each of the problems studied in Experiment 3.

Method

PROBLEM SET AND DESIGN

The schematic versions of the two problem types given in Table 4 were used to create eight different problems. Two factors were crossed for both problem types 1 and 2. The first factor was whether the minimal logical consequences of the initial sentence set were explicitly given as part of the initial belief set. In Table 4, the bracketed ground sentences were either explicitly listed as part of the initial belief set in the consequences-given condition or were omitted in the no-consequences given condition.

The second factor, sentence-form, was whether the belief set was based only on propositional sentences, or concerned sentences about universally quantified arguments. Thus, one propositional form of a conditional was *If Carol is in Chicago, then she stays at the Hilton Hotel*, while the universally quantified form was *Whenever any manager from your company is in Chicago, s/he stays at the Hilton Hotel*. The associated ground sentences in each case referenced a particular individual. For the propositional example, the sentence instantiating the antecedent was *You know that Carol is in Chicago*. For the universally quantified condition, it was *You know that Carol, one of the company managers, is in Chicago*.

For problem type 1, the revision choices were either to disbelieve the conditional (revision alternative 1) or to disbelieve one or both of the initial ground sentences (revision alternative 2). The same distinction holds for problem type 2, which had four revision alternatives: alternatives 1 and 3 involved denying the conditional $c \rightarrow h$, while revision choices 2 and 4 retained the conditional and instead changed c to $\sim c$. The other key distinction in problem type 2's revision alternatives concerned the status of m , which was the chained inference that the initial belief set supports. Revision choices 1 and 2 labeled m as uncertain; revision alternatives choices 3 and 4 retained m as a belief.

All of the problems were presented in natural language formats. The following text illustrates how Problem Type 1 appeared in the consequences given – propositional condition:

Suppose you are reviewing the procedures for the Photography Club at a nearby university, and you know that the following principle holds:

If the Photography Club receives funding from student fees and it also charges membership dues, then it admits non-student members.

You further know that the Photography Club does receive funding from student fees. It also charges membership dues. So you conclude it admits non-student members.

You ask the Photography Club for a copy of its by-laws and you discover

The Photography Club does not admit non-student members – all members must be registered students.

SUBJECTS AND PROCEDURE

Thirty-five University of Alberta students served as subjects, to fulfill a course requirement for experiment participation. Problems were presented in booklet form, which included other belief-revision problems as fillers. All subjects solved all four versions of both problem types 1 and 2: no consequence – propositional, consequences given – propositional, no consequences – quantified, consequences given – quantified. There were six pseudo – random orders for the problems within the booklet; within each order, the four versions of any given problem were separated by at least two other problems of a different type. The order of response alternatives for each problem was also randomized.

Results

For problem type 1, revision choice 1 (disbelieving the conditional; see Table 4) accounted for 82% of the revision choices. This is consistent with the pattern of choices in Experiment 1's results on science-fiction problems, and this preference to disbelieve the conditional was not affected by whether or not the modus tollens inference was explicitly listed in the initial sentence set nor by the use of propositional v . universally quantified sentences. In terms of the first factor, we note that people generally find modus ponens an easy inference to make, and these results confirm that the general preference to disbelieve the conditional does not rest on whether the contradicted inference is explicitly provided. Concerning propositional v . universally quantified sentences, we observe that it is difficult to construct if $p \rightarrow q$ sentences that are not, somehow, interpretable as universally quantified over time. Thus, even sentences like *If Carol is in Chicago, then Carol is at the Hilton*, may be interpreted as *For all times when Carol is in Chicago, . . .* There seems to be little in the line of systematic, empirical study of the effect of propositional v . single quantifier v . multiple quantifier logic upon people's reasoning (although both Rips, 1994, Chaps. 6 and 7, and Johnson-Laird & Byrne, 1991, Chaps. 6 and 7, address this issue in their respective computational frameworks). Nonetheless, it seems clearly to be an important issue for studies that place an emphasis upon recognition of contradictions, since the impact of contradictory information upon "rules" is different in these different realms.

There was also no impact of either the consequences-given or the sentence-form factor on the patterns of revision choices for problem type 2, in which the initial belief set contained an intermediate conclusion h and then a chained conclusion m , that depended on h , and where expansion information contradicted h . The percentage of revision choice 1 (denying the conditional $c \rightarrow h$) accounted for 52% of the choices; choice 2 (denying the ground sentence c) accounted for 29% of the choices. In both these cases, the status of m , the chained inference that depended on h , was labeled uncertain. Revision alternatives 3 and 4, which were analogous to alternatives 1 and 2 except that they retained belief in m , accounted for 14% and 5%, respectively, of the remaining choices. The preference to change m 's truth status from true to uncertain rather than retain it as true is interesting: it is an additional change to the initial belief state beyond what is necessary to resolve the contradiction. Perhaps people's revision strategy is guided more by the recognition that a belief depends on another than upon minimizing the number of truth values that change from one state to the next.

Discussion

In Experiments 1–3, we aimed to identify what kinds of revision choices subjects would make in symbolic and non-symbolic types of problems, with the former providing some kind of baseline for whether a conditional statement enjoys some level of entrenchment merely as a function of its syntactic form. Our second concern was to assess whether belief revision choices were affected by the composition of an initial belief set, i.e., whether it was defined through the use of the conditional in a modus ponens or modus tollens inference. This offers us a bridge between belief revision (as a task of making a deliberate change in what is to be “believed” in the face of contradictory information) and the data and theories on deductive reasoning.

There was no evidence that people preferred to entrench the conditional on these tasks. In the choices we gave subjects, there was one way to continue to believe the conditional and two ways to disbelieve it. If people were equally likely to retain the conditional as they were to abandon it, we might expect 50% of the choices falling into the keep-the-conditional revision, with the two ways to disbelieve it each garnering 25% of the choices. On the symbolic problems in

Experiments 1 and 2, the frequency of retaining the conditional after the expansion information was only about 25% on both modus ponens and modus tollens problems; it was even lower on the natural language problems.

Although subjects' preference was to abandon belief in the conditional, the way in which this occurred on modus ponens and modus tollens problems was slightly different. On modus ponens problems, subjects disbelieved the conditional but continued to believe the ground sentence as it was specified in the initial belief set. On modus tollens problems, subjects tended towards more “uncertainty” in the new belief state: either denying the conditional and deciding the ground sentence was uncertain (Experiment 1) or labeling both as uncertain when that was an option (Experiment 2). These tendencies on modus tollens problems could be interpreted as conservative revision decisions, since neither the initial conditional nor the initial ground sentence is explicitly denied; on the other hand, they correspond to maximal changes because the truth values of both initial beliefs are altered. We leave further discussion of entrenchment issues to the “General Discussion.”

It is natural at this point to consider the relationship between this belief-change task and standard deduction, and to ask whether this task and its results can be understood as a deduction task in some other guise. In next sections, we present two reasons we think it is not. First, we consider the task demands and results for the modus ponens and modus tollens belief revision problems, and then briefly outline results we have obtained on belief expansion problems that did not involve a contradiction.

The Task Demands of the Modus Ponens and Modus Tollens Belief-Revision Problems

We can neutrally rephrase the modus ponens belief-change problem that subjects faced as “Make sense of $[p \rightarrow q, p, q] + [\sim q]$,” where the first sentence set represents the initial belief set and the second signifies the expansion information. Since subjects had to accept the expansion information, what we call the modus ponens problem thus becomes “Make sense of $[p \rightarrow q, p, \sim q]$, such that $\sim q$ is retained.” Similarly, the modus tollens problem is “Make sense of $[p \rightarrow q, \sim q, p]$, such that p is retained.” Because these two problems are semantically equivalent, the forms in the set of propositions to be considered

are the same and the models of these sentence sets are the same. The difference lies only in the nature of the derivation in the initial sentence set, and the corresponding constraint on what must be retained after the revision.

What we have called the modus ponens belief revision problem could be construed as a modus tollens deduction problem, if subjects consider only the conditional in combination with the expansion information: "Given [$p \rightarrow q$] + [$\sim q$], what can I derive?" The invited modus tollens inference is $\sim p$. If they derived this, they could at least consider retaining the conditional and changing p to $\sim p$ in their belief-state change. The trouble that modus tollens inferences present for people could in this way explain the observed prevalence of abandoning the conditional on modus ponens belief revision problems to achieve a consistent belief set.

Applying this same perspective on the task to the modus tollens problem, we would see the modus tollens belief revision problem becoming an modus ponens deduction problem, if only the conditional and the expansion information are considered: "Given [$p \rightarrow q$] + [p], what can I derive?" People have little difficulty with modus ponens and under this analysis, it would be an "easy inference" to conclude q , and so be led to reverse the truth status of $\sim q$ as the belief change. But the majority of subjects did not do this – on these problems as well, they disbelieved the conditional. Therefore, it does not seem that our general pattern of disbelieving the conditional in belief revision can be reduced to, and accounted for by the nature of the difficulties in making certain types of standard deductive inferences.

It is possible that subjects did not accept the modus tollens belief set as consistent in the first place. (People have difficulty both in generating modus tollens inferences and in validating them when they are provided [*cf.* Evans, Newstead, & Byrne, 1993, p. 36].) So perhaps this could be used to account for why there was high percentage of "everything but the expansion information is uncertain" revisions on modus tollens problems in Experiment 2. However, this does not account for why, on these modus tollens problems, subjects would not simply focus on both the conditional and the expansion information, and then draw an modus ponens inference – that would lead to reversing the truth status of the initial ground sentence, as opposed to what they in fact did.

Deductive Reasoning and Belief-State Expansions

The second reason we believe these tasks are not reducible to equivalent deductive reasoning problem stems from results we obtained on other belief-state expansion problems, in the expansion information did not contradict the initial belief set (Elio & Pelletier, 1994). These problems used two different but logically equivalent forms of a biconditional: (p if and only if q) and ($(p \ \& \ q) \vee (\sim p \ \& \ \sim q)$). The expansion information was sometimes p and at other times $\sim p$. Unlike the belief revision problems, these problems have a deductively "correct" answer: given $p \rightarrow q$ (in either form) as an initial belief, with the sentence p as the expansion, it logically follows that q should be asserted and made part of the belief state. (And if $\sim q$ is the expansion, then $\sim p$ should be believed). If we view the biconditional-plus-expansion information problems as biconditional modus ponens (or biconditional modus tollens) problems, then we would expect that subjects presented with our biconditional and disjunctive belief expansion problems should behave like the subjects given biconditional and disjunctive deductive problems in other studies. Yet we found that subjects asserted q on the p if and only if q form of our biconditionals much less frequently (about 72%) than typically reported for these problems presented as standard deduction tasks (e.g., 98% accuracy in Johnson-Laird et al., 1992). And fully 56% of subjects given the biconditional in disjunctive form followed by the belief expansion p did not augment their belief set with q , when the problem was presented with a science-fiction cover story. Instead, they decided q was uncertain and that the biconditional itself was uncertain or unbelievable.

In sum, we believe that the task of belief revision, even in the relatively constrained way we have defined it here, does not simply unpack into deductive reasoning, particularly when natural-language formats are used for the problem. That is, subjects may not integrate information arriving across time (e.g., learning "later" that p holds true) into a belief set in the same way as information known to be true at the same time ("From *If p is now true, then q is also true*, and furthermore *p is now true*, what follows?"). It may be that the belief revision task invites the reasoner to make certain assumptions about evidence that is not explicitly included in the initial or subsequent information; it may also be

that couching the task as changes in beliefs invites a more conservative strategy than what characterizes people's choices on formal logic problems.

On Models of Belief States and Deduction

The experiments we designed do not speak to whether belief states are best modeled as sets of sentences or sets of models. However, we can observe the following. First, AI competence models are typically not concerned with human performance, yet they sometimes appeal to human rationality to justify their particular perspective. For example, a syntax-based competence model proponent may point to the fact that a model-based perspective involves an infinite number of models, when taken to the extreme, and because that is so clearly beyond the capability of human cognition, such modeling cannot be appropriate. That syntax-proponent might also observe that a model-theoretic competence framework could never model differences in human reasoning with modus ponens and modus tollens, since modus ponens and modus tollens are indistinguishable from the perspective of formal model theories. Further, our finding that people seem to prefer to abandon the conditional is problematic for model-theoretic frameworks, unless they retain some mapping between each sentence and the model which that sentence generates. But there are also difficulties for a syntactic-based perspective. A model-theoretic proponent might say that it is only via models of the actual world that the meaning of the sentences has any reality. And it is unclear that the syntactic form of sentences per se should be a primary tag for guiding belief revision decisions. Indeed, our finding that people were more willing to abandon the conditional on natural language problems than on symbolic problems suggests that there are other, non-syntactic considerations at play that may serve as pragmatic belief revision principles. We return to this issue in the "General Discussion."

The belief revision results we obtained do not speak directly to performance theories of human deduction, but there are some important observations we can make here as well. First, the Johnson-Laird mental models framework could possibly accommodate the general preference to deny the conditional, by the preference ordering it puts on models that different types of sentences generate. The mental model of $p \rightarrow q$

is " $[p \ q] \dots$," where $[p \ q]$ represents the initial explicit model, in which both p and q are true, and the ellipsis " \dots " represents that there are additional models of this sentence (corresponding to possible models in which p is not true; Johnson-Laird, Byrne, and Schaeken, 1992). For our modus ponens problem, the initial sentence set is $p \rightarrow q$, p , and $\therefore q$. Let C indicate models of the conditional, and S to indicate models of ground sentences in the initial belief set. Hence, the initial modus ponens model set would be C: $[p \ q] \dots$, S: $[p]$, S: $[q]$, respectively. Note that the models for the ground sentences are consistent with what the mental models theory proposes as the initial explicit model for the conditional. The modus ponens expansion information is $\sim q$ and we denote its model as E: $[\sim q]$. Suppose a subject compares the expansion model E: $[\sim q]$, which must be retained in any revision, to each of the models from the initial set. The expansion model would eliminate the model S: $[q]$, be silent on the model S: $[p]$, and eliminate the model C: $[p \ q]$ of the conditional. By this process, the preferred revision choice should be to deny this model of the conditional and the retain the ground sentence p . In fact, this choice accounted for 75% of the modus ponens revisions in Experiment 1 and about 60% in Experiment 2. By the same general reasoning, the mental-models approach would find itself predicting a preponderance of conditional denials for modus tollens problems. While we did find this is true in general, there would have to be some further account for people's greater tendency to decide the conditionals are uncertain (rather than false) on modus tollens problems than on modus ponens problems.

From a proof-theoretic perspective, Rips (1994, pp. 58–62) directly considers the problem of belief revision as the issue of which of several premises to abandon in the face of contradiction, acknowledging that deduction rules cannot alone "solve" the belief revision problem. He discusses a multi-layer approach, in which the principles governing belief revision decisions are themselves "logic-based processing rules" that co-exist with the deduction rules that he proposes as components of reasoning and problem-solving. Thus, a proof-theoretic approach might be extended to deal with our belief revision results by having an explicit higher-level rule that, when contradiction is recognized, indicates the action of disbelieving a conditional form when it is one of the premises. But even

without an appeal to this approach, it is possible to consider a proof-theoretic account of our results, as we did for the mental-models perspective, using Rips' (1994) framework. Recall again the above perspective that portrayed the modus ponens belief-revision problem as boiling down to "Given $[p \rightarrow q, p] + [\sim q]$ and the constraint that $\sim q$ must be retained as a belief, what can you prove?" One can imagine that a subject formulates two competing sets of premises. One set is $[p \rightarrow q, \sim q]$, to which a modus tollens rule could apply. But there is no direct modus tollens rule in Rips' theory (the modus tollens inference is accomplished through the application of two other inference rules), thus accounting for the notion that modus tollens proof for $\sim p$ is difficult and may halt. On the other hand, there is a readily available inference rule (so-called and introduction) that can apply to the other combination of premises $[p, \sim q]$ to yield $[p \text{ and } \sim q]$. From this perspective, subjects might reach a state that they can more easily recognize as valid and that may be why they prefer a revision in which these sentences are retained and the conditional is disbelieved. On the modus tollens problem, we can characterize the belief revision dilemma as "Given $[p \rightarrow q, \sim q] + [p]$ and the constraint that p must be retained, what can you prove?" The modus ponens rule is readily available according to Rips' theory, and so the premise combination $[p \rightarrow q, p]$ easily yields q . Just as easily, the other combination of premises $[\sim q, p]$ yields $[p \text{ and } \sim q]$. The greater tendency to prefer revisions that label the conditional (and the ground sentence) "uncertain" in the modus tollens belief-revision case relative to the modus ponens belief-revision case may reflect subjects' ability to prove something from both combinations of premises (as we have stated them) and their appreciation that they have no reason to prefer the premises of one proof over the other in these simple problems.

Our goal in considering how two contrasting perspectives of deductive reasoning might accommodate our results was not to support one over the other. The accounts we sketched above are offered as speculations on how each perspective might be extended into the realm of belief revision, given their representation and processing assumptions about deductive reasoning. Such extensions are an important component for an integrated theory of reasoning and required much more consideration than we have briefly allowed here.

Models and Minimal Change

As we noted earlier, one of the desiderata of the classical AI belief-revision perspective is that an agent should make a minimal change to its initial belief set, when resolving any conflict that results from new information. Within a syntactic approach, the definition of change is computed from the number of formulas retained from one belief state to another, there are not many different ways to compute this number, since the formulas are fixed. The primary issue is whether or not the set of formula is closed, i.e., includes all consequences of the initially specified set of sentences. When the set of formulas is not closed, making a formula become part of the explicit belief set is regarded as more of a change than having it be in the implicit beliefs.

Within a model-theoretic approach, it turns out there is more than one way to compute what a minimal change might be, even for the simplest problems. In this section, we present the gist of some alternative computational definitions of minimal change. None of these approaches were devised as psychological models of how humans might manipulate alternative models in the face of conflicting information. And while the ways the algorithms that compute minimal change might not be psychologically plausible, the final change that each one deems minimal often corresponds to an intuitively reasonable way of integrating both the old and new belief information. We provide simple algorithmic interpretations of each of these minimal change definitions in Table 5 and highlight the functional effects of computing minimal change according to one algorithm or another.

A straightforward way to quantify the degree of change is to count the number of propositions whose truth values change if one model (e.g., expansion information) is integrated with another model (e.g., the initial belief set). The tricky part comes when there is more than one model of the initial belief set, or of the expansion information, or both. Clearly, there will be more than one possible interpretation for a sentence set whenever there is an explicit uncertainty. By explicit uncertainty, we mean a belief sentence that directly mentions that the truth status of some proposition is either true or false. Hence, in the sentence set $(p, q \vee \sim q)$, q is explicitly uncertain, so there are two models of this sentence set: $[p \sim q]$, $[p q]$. Suppose, however, that the initial sentence set were "Either p and q are true at the same time, or they are false at the

Table 5: Algorithms for Minimal Change

Algorithm

Algorithm D

- D1 For each model of the expansion information do
- D1.1 For each model of the initial belief set do
 - Find and save the differences.
 - D1.2 From the set of differences, identify the smallest change. Put this smallest change and the expansion model responsible for it on the candidate stack.
- D2 From the candidate stack, chose as the new belief state the expansion model that is responsible for the smallest of all the minimal changes saved from D1.2. If there is more than one, use their disjunction

Algorithm W

- W1 For each model of the belief set do
- W1.1 For each model of expansion do
 - Find and save the propositions that must change
 - W1.2 Retain just the minimal set of propositions that must change for this pairing of an belief set model and an expansion model
- W2 Take the union of all proposition sets identified in W1.2 and remove them from the initial belief set
- W3 Identify the set of remaining KB propositions with known (certain) truth values. If this set is empty, then the new belief set is the expansion information. Otherwise, the new belief set is the conjunction of the old KB propositions with the expansion information

Algorithm B

- B1 For each model of the initial belief set do
- B1.1 For each model of the expansion do
 - Find the differences and save them
 - B1.2 From the set of differences, identify the minimal change and put the expansion model responsible for it on the candidate stack
- B2 Combine all models of expansion information on the candidate stack to determine the new belief state.

Algorithm S

- S1 For each model of the initial belief set
 - For each model of the expansion, stack the differences between them.
- S2 From the set of differences, eliminate non-minimal changes
- S3 Combine all models of expansion information on the candidate stack to determine the new belief state.

same time” and that the expansion information is “ p is false, q is true, and furthermore r is true.” The initial belief state has two models, $[p q]$, $[\sim p \sim q]$, and both p and q are explicitly uncertain. The proposition r was not in either of the initial models of the world. But clearly, its truth status (along with every other possible sentence) in the initial belief set was, in hindsight, uncertain. This is what we call implicit uncertainty, and all the algorithms in Table 5 construct different models of the initial belief set to accommodate the implicit uncertainty about r just as if it were explicitly uncertain in the first place. Thus, the computations for minimal change for this problem would begin with these models of the initial belief set $[p q \sim r]$, $[p q r]$, $[\sim p \sim q \sim r]$, and $[\sim p \sim q \sim r]$. As we shall see in the first example below, this same approach of creating extra mod-

els also applies when a sentence that is present in the initial belief set is not mentioned the expansion information.

One approach to determining a minimal change is to choose a model of the expansion sentences that is the minimal distance from some model of the initial belief set. Suppose an initial belief is “Either p , q , r , s are all true at the same time, or they are all false at the same time.” So there are two different models of this initial belief: $[p q r s]$ and $[\sim p \sim q \sim r \sim s]$. Expansion information such as “ p is true s is false, and r is false” contradicts this initial belief state and furthermore does not mention anything about q . There are then two models of the expansion, one in which q is true $[p q \sim r \sim s]$ and one in which it is false $[p \sim q \sim r \sim s]$. The latter model of the expansion is “close” to the second model

(disjunct) of the initial belief set and is indeed "closer" than either expansion model is to the first model of the initial belief set. By this reasoning, a new belief state that represents a minimal change on the initial state is $[p \sim q \sim r \sim s]$. This is the gist of the minimal change approach proposed by Dalal (1988) and summarized as Algorithm D in Table 5. More formally, Dalal's revision of a belief set by an expansion sentence is a set of minimal models where (a) each member of this set satisfies the expansion information, and (b) there is no other model of the initial belief set that also satisfies the expansion information and differs from any model of initial belief set by fewer atoms than the set of minimal models. The revision results in the set of all these minimal models. Thus, Dalal's algorithm settles on one model of the expansion information, if possible, and in doing so, can be viewed as retroactively settling on one particular model of the initial belief set.

An alternative intuition would hold that: only informative (non-tautological) initial beliefs can be used to choose among multiple interpretations of the expansion information, if they exist. This is one way to interpret an algorithm proposed by Weber (1986). Simply put, Weber's algorithm first identifies the initially believed sentences that must take on whatever truth values are specified for them in the expansion. For the same example in the preceding paragraph, this set would contain the sentences p , r , and s , because they each have a specific value they are required to take, according to the new information. These sentences are then eliminated from the initial belief set to identify what (if any) informative sentences propositions might be retained from the initial belief set. Subtracting p , r , and s from the initial belief set $\{[pqr], [\sim p \sim q \sim r \sim s]\}$ leaves $[q \vee \sim q]$, which is a tautology, and by Weber's algorithm, leaves no (informative) proposition. (Had there been some other sentence which was in both of the initial models, it would have then been assigned to the revised belief state.) The algorithm then conjoins these two components: the truth values of p , r , and s as determined by the expansion information $[p \sim r \sim s]$ and whatever can be retained with certainty from the initial belief set, which here is the empty model $[\]$. Whereas Dalal's revision for this problem would be $[p \sim r \sim s \sim q]$, Weber's minimal revision would be $[p \sim r \sim s]$, with q implicitly uncertain by virtue of its absence from the model. A simple algorithm that corresponds to this approach is given as Algorithm W in Table 5.

Borgida (1985) proposes an algorithm that is similar to Dalal's, but produces what might be considered a more conservative belief-state change. Essentially, each expansion model is compared to each initial belief-set model: the expansion model that produces a minimal change for a particular initial-belief interpretation is remembered. All these expansions that are minimal with respect to some model of the initial belief set are then used to define the new belief set. An algorithm that captures this approach is given as Algorithm B in Table 5. Consider a case where there is more than one interpretation of the initial belief set. If $[pqr \sim s]$ is the initial belief set, and $[\sim p \sim q \sim r \sim s]$ and $[\sim p \sim q \sim r \sim s]$ are two models of the expansion information, then two models of the initial belief set are considered: the first contains r and second contains $\sim r$. Both interpretations of the expansion information define a minimal change with one of the interpretations of the initial belief set (the first expansion disjunct with the first interpretation of the belief set, and the second expansion disjunct with the second interpretation of the belief set). Thus, both $[\sim p \sim q \sim r \sim s]$ and $[\sim p \sim q \sim r \sim s]$ are on the stack after step B1.2. Since neither of these is minimal with respect to the other, the final belief set consists of guaranteed truth values for those propositions on which the interpretations agree and uncertain truth values for propositions on which they disagree, yielding a final belief state of $[\sim p \sim q \{r \sim s \vee \sim r s\}]$. Algorithm B differs from Algorithm D in that each model of the initial belief set identifies, in Algorithm B, what model of the expansion information would result in a minimal change (by number of propositions changed). Once one of the expansion models is identified as minimal with respect to a particular model of the initial belief set, there is no further check of whether one change is more or less minimal than some other combination of initial-belief interpretation and expansion-interpretation (as Algorithm D does on step D2). This can be viewed as a more conservative belief-state change, because there isn't the possibility of settling on one particular model of the initial belief state.

Satoh (1988) proposed belief revision operator that is a less-restricted version of Borgida's revision operator, when applied to the propositional case. The feature that makes it less restricted is illustrated in Algorithm S, which is identical to Algorithm B, except that step B1.2 in Algorithm B occurs outside the first control loop as step S2 in Algorithm S. Functionally, this difference means that there is no pruning

of non-minimal changes with respect to a particular belief-set model (as on Step 1.2 in Algorithm B). Instead, the entire set is saved until step S2, which removes any change that subsumes another change. After S2, all changes that remain are minimal. Step S3 then finds a model of the expansion that is consistent with the minimal set of necessary changes. Put more intuitively, this algorithm crosses all interpretations of the initial belief set and all interpretations of the expansion set to create the model set from which a minimal change is computed. The functional effect is that, when there is just one model of the initial belief set, that model may “choose” the closest interpretation of the expansion information; when there is just a single version of the expansion information, that model may “choose” among alternative models of the initial information. Only the latter may occur under the Borgida algorithm.

We are not interested so much in the means by which these alternative model-based revision frameworks define minimal change, as we are in the way they capture alternative intuitions about manipulating multiple models. In Algorithm D, the way that minimal change is computed can have the effect of “selecting” one of multiple interpretations of the initial belief set. The effect of Algorithm B is to retain multiple models in the new belief set when there are multiple models of the expansion information. Algorithm S will compute a new belief state with multiple models, when multiple models exist in both the initial and expansion information; but it can use a single model of either to produce a single model of the new belief set. Finally, Algorithm W uses the expansion information to define what can be believed with certainty; other belief-set sentences not mentioned in the expansion information may decide between multiple interpretations of the expansion information, but only if their truth value was known with certainty in the first place (i.e., was true in every model or false in every model of the initial belief state).

There are plausible elements in each of these approaches for principles that might dictate how people deal with multiple interpretations of information when resolving inconsistencies. Our interest was whether which, if any of them, corresponded to how people integrate multiple models in a belief revision task. As the reader might surmise, for any particular problem, some or all of the methods could yield the same final belief set. It is possible, however, to define a set of problems for which a pattern of

responses would distinguish among these alternative approaches. We developed such a problem set to obtain data on whether people follow a minimal change principle, as defined by any of these approaches. The revision problems were very simple: there were either one or two models of the initial belief set and either one or two models of the expansion information. The problem sets were designed to distinguish among the four model-based minimal change frameworks described above.

Experiment 4

Method

PROBLEM SET

Table 6 gives the problem set used for Experiments 4 and 5. The first five problems in this table were used only in Experiment 4; problem 6 was added for Experiment 5. For economy of space, we write sentence letters adjacent to one another to mean ‘and’. Thus, the problem 1 notation $(pqrs) \vee (\sim p \sim q \sim r \sim s)$ means “Either p , q , r , and s are each true at the same time or else they are each false at the same time.”

The subscripts for the revision choices in Table 6 correspond to the particular model-theoretic definition of minimal change: D for Algorithm D , W for Algorithm W , and so forth. Experiment 4 offered subjects two revision choices for Problems 1–5 (of Table 6); these each corresponded to one or more of the four definitions of minimal change we outlined in the previous section. It can be seen that each of the four algorithms selects a different set of answers across these five problems: Algorithm D selects answers $\langle 1, 1, 1, 1, 1 \rangle$ for its five answers; Algorithm B selects answers $\langle 2, 2, 2, 1, 1 \rangle$; Algorithm S selects answers $\langle 2, 2, 1, 1, 2 \rangle$; and Algorithm W selects answers $\langle 2, 2, 2, 2, 2 \rangle$.

DESIGN

Problem type was a within-subjects factor; all subjects solved all five problems. As in Experiment 1, presentation form (symbolic *v.* science-fiction stories) was manipulated as a between-subjects factor. Appendix B shows how the initial-belief sentences and the expansion sentences were phrased in the symbolic condition; the revision alternatives were phrased in a similar manner. Different letters were used in each of the problems that the subjects actually solved. The five different science-fiction cover stories were paired with the problems in six different ways.

Table 6: Problems and Percentage of Subjects Choosing Each Revision Alternative, Experiments 4 and 5

Problem	Revision Alternative	Experiment		
		4	5	
1	Initial: (pqrs) or ($\sim p \sim q \sim r \sim s$)	1. $p \sim q \sim r \sim s_{D}$.06	.07
	Expansion: $p \sim r \sim s$	2. $p \sim r \sim s ?q_{B, S, W}$ 3. $p \ q \ \sim r \ \sim s$ 4. $p \ ?q \ ?r \ ?s$.94	.58 .05 .30
2	Initial: (pqrs) or ($\sim p \sim q \sim r \sim s$)	1. $p \sim q \sim r \sim s_{D}$.11	.07
	Expansion: ($\sim p \sim qrs$) or ($p \sim q \sim r \sim s$)	2. ($\sim p \sim qrs$) or ($p \sim q \sim r \sim s$) _{B, S, W} 3. $\sim p \sim q \ r \ s$ 4. $\sim q \ ?p \ ?r \ ?s$.89	.21 .35 .37
3	Initial: $pq \sim s$	1. $\sim p \sim q \ r \ \sim s_{D, S, W}$.22	.20
	Expansion: ($\sim p \sim q$) & [($r \sim s$) or ($\sim rs$)]	2. ($\sim p \sim q$) & [($r \sim s$) or ($\sim rs$)] _B 3. $\sim p \sim q \ \sim r \ s$ 4. $\sim p \sim q \ ?r \ ?s$.78	.43 .0 .37
4	Initial: pq	1. p or q , not both _{D, B, S}	.12	.07

6	Initial: $\sim p \sim q \sim r$	1. $p \ \sim q \ \sim r_{D, B}$.07
	Expansion: ($\sim pqr$) or ($p \sim q \sim r$)	2. ($\sim p \ q \ r$) or ($p \ \sim q \ \sim r$) _{S, W} 3. $\sim p \ q \ r$ 4. $?p \ ?q \ ?r$.30 .23 .40

Note. 'Initial' means initial sentence set, 'Expansion' means expansion information.

SUBJECTS AND PROCEDURE

The same 120 subjects who participated in Experiment 1 provided the data presented here as Experiment 4. Sixty subjects were assigned to the symbolic condition and sixty were assigned to the science-fiction condition. Equal numbers of subjects received the six different assignments of science-fiction cover stories to problems. No science-fiction cover story appeared more than once in any subject's problem booklet. Other details about the procedure and instructions were as described for Experiment 1.

Results

Unlike the modus ponens and modus tollens belief revision problems, there was no significant effect for the symbolic versus science-fiction manipulation on these problems. Table 6 presents the percentage of subjects choosing each possible revision choice, collapsed across presentation condition. The only planned com-

parisons concerning these data were within-problem differences, i.e., whether one revision choice was preferred significantly more often than another. Within each problem, there is a clear preference for one revision over the other: subjects chose revisions that most closely matched the form of the expansion information. We also tabulated the number of subjects whose response pattern across problems matched the particular pattern associated with each revision algorithm described in Table 5. Virtually no subjects matched a particular response pattern for all five problems.

Experiment 5

A concern about these data is that subjects were not following any particular model of change at all, but simply using the expansion sentence to define the new belief set. This could mean that they viewed the problem as an update, rather than a revision, problem (i.e., the world has

moved to a new state defined by the expansion and there is no reason to maintain anything from the initial belief state), or it could mean that they were simply not engaged in the task. Since the same subjects generated distinct problem-specific patterns of responses in Experiment 1, we do not believe the latter possibility holds.

In Experiment 5, we included two additional response alternatives for each problem in order to test whether subjects continued just to adopt the expansion information (which might be the simplest interpretation of the results). Revision choice 3 was a non-minimal change model that was consistent with some interpretation of the expansion information. Revision choice 4 included only those sentences whose truth values were not contradicted within the expansion information or between some model of the initial sentences and the expansion. Basically, revision choice 4 offered the minimal number of sentences that could be known with certainty and made all other conflicts between truth values become “uncertain.”

We also added Problem 6, which was isomorphic in form to Problem 5, except that the initial belief set consisted of all negated sentences rather than of all positive sentences. If subjects have a bias for models that consist primarily of non-negated sentences, then they should prefer such “positive” models regardless of whether they are minimal change models. Problems 5 and 6 differed only in whether the sentences in the initial set were all true or all false. Note the symmetry between revision choices 1 and 3 for these problems: the revision $[\sim pqr]$, with one negated sentence, is a minimal change model for Problem 5 but a non-minimal change model for Problem 6. Conversely, $[p\sim q\sim r]$ is the minimal change model for Problem 6 and a non-minimal change model for Problem 5. If subjects are biased towards revisions that maximize non-negated sentences, then there should be an interaction between the form of the initial belief set and the revision selected. Finally, we stressed in the instructions that both the initial and subsequent information should be considered before determining what should or should not be believed, just in case subjects believed that the expansion information should replace the initial belief set.

Method

Forty-three subjects solved problems 1–6 from Table 6 in random order. Since Experiment 4 had shown no effect for symbolic *v.* science-fiction

presentation, the problems were presented in symbolic form only and the response alternatives appeared in different random orders for each subject.

Results and Discussion

The percentages of subjects choosing each revision choice in Experiment 5 are given in Table 6. As in Experiment 4, Experiment 5’s subjects did not consistently obey any particular pattern of minimal change. First, it is striking that revision choice 1 was never the most preferred revision – it is the syntactically simplest way of specifying a model that accommodates the expansion sentence and corresponds to Algorithm D, which has an intuitively simple notion of minimal change. The second feature of the results concerns the relative percentages of revision 2 (in which the new belief state is simply the adoption of the new information) and revision 4. While revision choice 2 was the clear preference in Experiment 4, it was no longer the clear favorite here. Generally speaking, if subjects were given the option of tagging certain sentences as “uncertain” (revision 4), they gravitated to this choice over a revision that more precisely (and more accurately) specifies the uncertainty as multiple models (revision 2). One conjecture is that subjects elect to use revision 4 as short-hand way of expressing the uncertainty entailed in having multiple models of the world. That is, they may see “*p* and *q* are both uncertain” as equivalent to $(p\sim q) \vee (\sim pq)$, although, of course, it is not. It is unclear whether subjects appreciate the ‘loss of information’ inherent in such a presumption of equivalence.

Problems 5 and 6 were of particular interest, because they differed only in whether the initial belief set consisted of positive or negated sentences; the expansion information was the same. The set of revision alternatives was also identical. As with the other problems, the most preferred revision choice (about 40%) was to declare all sentences uncertain, when their truth value differed in two different models of the expansion information (and subjects did not merely adopt the multiple model described by the expansion information as the new belief state, as they had in Experiment 4). However, if we restrict our attention just to the percentage of revision 1 and revision 3 choices in these problems, we see that about the same number of subjects (20%) chose the revision $\sim pqr$ when it served as minimal change revision 1 for problem 5 and also when it was the non-minimal

revision 2 for Problem 6. Conversely, only 7% of the subjects chose $p \sim q \sim r$ when it was the non-minimal revision 1 for Problem 5, but also only 7% chose it when it was (the minimal change) revision 3 for Problem 5. A chi-square computed on the response-choice by problem type (Problem 5 *v.* Problem 6) frequency table was marginally significant ($\chi^2 = 7.52$, $df = 3$, $p = .057$). These results suggest that there may be a bias against revisions that have more negated beliefs than non-negated beliefs in them. There is some suggestion of this in problem 2 as well, in which 35% of the subjects choose a non-minimal change revision (revision 3) than either of the two minimal change revisions (revisions 1 and 2). Such a finding itself is certainly consistent with body of evidence indicating that reasoning about negated sentences pose more difficulties for subjects (see, e.g., Evans, Newstead & Byrne, 1993, on “negated conclusions”); hence, people may prefer to entertain models of situations that contain fewer negations, when possible. This possibility of a bias against models with negations needs further, systematic study. In sum, Experiments 4 and 5 suggest that subjects are not following any single model-based minimal change metric and do not integrate the expansion information wholeheartedly. Despite the availability of choices that could be selected via a matching procedure between disjuncts appearing in the initial and new information (revision 1 across all problems), our subjects seem to prefer belief states that consist of single models and models with non-negated beliefs, when possible.

General Discussion

We can summarize the main findings from this study as follows. First, to resolve the inconsistency that new information creates with an existing belief set that consists of ground sentences (p , q) and conditional sentences ($p \rightarrow q$), the preferred revision was to disbelieve the conditional rather than alter the truth status of the ground sentence. This preference was even stronger on problems using science-fiction or familiar topic cover stories than it was using symbolic formulas. Second, there were some differences in revision choices depending on whether the initial belief set was constructed by using a modus tollens or modus ponens inference. Subjects more often changed the truth status of the initial ground sentence (and the conditional, when there was that option) to “uncertain” on the modus tollens problems than they did on

the modus ponens problems. Third, we observed that the patterns of revision choices on the simple problems we investigated does not depend on whether or not the (modus ponens) inference was explicitly listed in the initial belief set or whether subjects were left to perform the inference themselves. Fourth, we note that the patterns of revision did not change when the initial belief state was constructed from purely propositional reasoning or used universally quantified inferences. Fifth, we discovered that when an implied conclusion of the initial belief set itself gives rise to yet another conclusion, and when the first of these conclusions is contradicted by the expansion information, then the status of the second conclusion is regarded as “uncertain.”

Finally, we investigated alternative model-theoretic definitions of minimal change. We found that subjects did not adhere to any of these particular prescriptions, some of which (e.g., Algorithm D) can be construed as a fairly straightforward matching strategy between a model in the initial information and a model of the expansion information. Even when the initial belief state had only one model, subjects did not use it to chose among alternative models of (uncertain) expansion information; and even when there was only a single model of expansion information, subjects did not use this to chose among alternative models of an (uncertain) initial belief state. And while a disjunction of multiple models can specify how the truth value of one sentence co-varies with another's, our subjects did not prefer such multiple-model specifications of a belief state as a way to represent uncertainty. They instead chose single-model revisions that retained only those sentences that had an unambiguous truth value across the initial and expansion information, and labeled all other sentences as uncertain (even though this results in a loss of information). There is a possibility as well that people prefer revisions that contain positive rather than negated sentences; this requires further study. In the remainder of this section, we consider these results for notions of epistemic entrenchment and minimal change.

On Epistemic Entrenchment

The rationale behind a notion like epistemic entrenchment is that, practically, an agent may need to choose among alternative ways to change its beliefs, and intuitively, there will be better reasons to chose one kind of change over another. These better reasons are realized as a

preference to retain or discard some types of knowledge over another; the issue is what those epistemically based principles of entrenchment are or ought to be. As we noted in the introduction, some theorists have argued that conditional statements like $p \rightarrow q$ may warrant, a priori, a higher degree of entrenchment than some other sentence types, not because there is something to be preferred about material implications, but because that form often signals “law-like” or predictive relations that have explanatory power. And law-like relations, because of their explanatory power, should be retained over other types of knowledge when computing a new belief state.

We did not find evidence for this kind of entrenchment as a descriptive principle of human belief revision in the tasks we studied. In general, the frequency of continuing to believe the conditional was lower than what might be expected by chance, and lower still on natural language problems. Finding that belief-revision choices changed when the problems involved non-abstract topics is not surprising, for there are many results in the deductive problem solving literature indicating that real-world scenarios influence deductive inferences, serving either to elicit, according to some theories, general pragmatic reasoning schemas (e.g., Cheng & Holyoak, 1989) or, according to other interpretations, specific analogous cases (Cox & Griggs, 1982). On the other hand, there was no domain-specific knowledge subjects could bring to bear about a science-fiction world. Indeed, the clauses used to make science-fiction sentences are not unlike those used by Cheng and Nisbett (1993) as “arbitrary” stimuli to investigate causal interpretations of conditionals. Nonetheless it is clear that subjects revised and expanded non-symbolic belief sets differently than they did symbolic belief sets.

Subjects may have interpreted the science-fiction conditional relations as predictive, or possibly causal, relations. The instructions that set up the science-fiction problems enjoined subject to imagine that information about an alien world was being relayed from an scientific investigative team. This may have prompted a theory-formation perspective, based on the assumption that even alien worlds are governed by regularities. The generation of, and belief in, these regularities depends on observations. The initial belief set had such a regularity in it (the conditional), plus a “direct observation” sentence. When the expansion information indicated that the inference from these two was contradicted,

the “denial” of the conditional is one way of asserting that the regularity it expresses, as specified, does not hold, *in this particular case*. Cheng and Nisbett (1993) found that a causal interpretation of *if p, then q* invokes assumptions of contingency, namely, that the probability of *q*'s occurrence is greater in the presence of *p* than in the absence of *p*. Subjects may have viewed the (contradictory) expansion information in the modus ponens and modus tollens problems as calling this contingency into question. Such a perspective only makes sense when the problems are not manipulations of arbitrary symbols, and is consistent with our finding a higher rate of rule denials on non-abstract problems than on symbolic problems.

When ground statements of *p* and *q* are viewed as observations about some world, $p \rightarrow q$ can be interpreted as a theory, or summarizing statement, about how the truth values of these observations are related. This is, essentially, a model-theoretic viewpoint: an expression such as $p \rightarrow q$ is shorthand for how the truth values of *p* and *q* occur in the world. Taking this understanding of conditionals, the preference of our subjects to deny the conditional as a way of resolving contradiction can be interpreted as a preference to retain the truth value of “data” (the ground sentences) and deny the particular interdependence that is asserted to hold between them. This seems rational from an empiricist viewpoint: the “regularities” are nothing more than a way of summarizing the data. So, for a through-and-through empiricist, it is not even consistent to uphold a “law” in the face of recalcitrant data. Such a perspective puts a different light on the observation that people did not make the “easy” modus ponens inference from the expansion information combined with a modus tollens belief set: to have opted for this revision would have required changing the truth values of observational data. While doing so may be a plausible alternative when problems involve meaningless symbols, it may not seem rational alternative when working with information that is interpretable as observational data.

The idea that data enjoy a priority over regularities has been offered as a belief revision principle in other frameworks (Thagard, 1989; Harman, 1986) particularly when regularities are (merely) hypotheses under consideration to explain or systematize observed facts. There is a natural role, then, for induction mechanisms in specifying the process of belief revision, once the conditional “regularity” is chosen

by the agent as suspect. We note that the classical AI belief revision community presents the belief revision problem as denying previously believed sentences, including conditionals. But replacing $p \rightarrow q$ with $(p \ \& \ r) \rightarrow q$ or $(p \ \& \ \sim s) \rightarrow q$ are equally good ways to deny $p \rightarrow q$. In such a case, the conditional regularity can either be “patched” or demoted to the status of default rule (“Most of the time, $p \rightarrow q$, except when r holds”). In our view, this method of denying a conditional as belief revision choice seems to be preferable to merely lowering a degree of belief in the conditional, for the latter leaves the agent is no wiser about when to apply such a rule, only wiser that it should be less confident about the rule. This approach is being pursued in some classical approaches to belief revision (e.g., Ghose, Hadjinian, Sattar, You, & Goebel, 1993) and in explanation-based learning approaches to theory revision in the machine learning community, where the inability of a domain theory to explain some data causes changes to the domain theory rules (Ourston & Mooney, 1990; Richards & Mooney, 1995).

While some aspects of the belief revision process can be viewed as inductive processes searching for a better account of some data, we note that such a perspective itself does provide principles for guiding such a process when there are alternative ways to reconcile a contradiction. Specifically, we don’t *always* believe the data at the expense of a regularity or contingency that we currently believe holds in the world. As we noted in the introduction, there are intuitions opposite to those that would deny or change a regularity to accommodate data: Kyburg’s (1983) belief framework includes a place for both measurement error and the knowledge that some types of observations are more prone to error than others. Thagard (1989) offers an explanatory coherence metric by which data can be discounted, if they cohere with hypotheses which themselves are poor accounts of a larger data set. Carlson and Dulany’s (1988) model of reasoning with circumstantial evidence includes parameters for degrees of subjective belief in the evidence. So the broader questions for epistemic entrenchment might be to ask what kinds of data and what kinds of regularities are more differentially entrenched in the face of contradiction than others.

On our simple belief revision tasks, we found some baseline results that suggest a tendency to abandon the conditional. But it has long been recognized by researchers in both linguistics and human deduction that the *if p then q* form is used

to express a broad range of different types of information, e.g., scientific laws, statistical relationships, causal relations, promises, and intentions (“If it doesn’t rain tomorrow, we will play golf”). More recent studies (Elio, 1997), using both the revision-choice task described here as well as a degree-of-belief rating task, have found that different types of knowledge expressed in conditional form—e.g., causal relations, promises, and definitions—appear differentially entrenched in the face of contradictory evidence. Elio (1997) discusses these results within a possible-worlds framework, in which epistemic entrenchment is not a guide for, but rather a descriptor of, the belief revision outcome. This possible-worlds interpretation also ties certain features of the belief-revision task investigated here to probabilistic aspects of deductive reasoning, in which the reasoner may not accord full belief in the premises from which some conclusion is based (e.g., George, 1995; Stevenson & Over, 1995).

On Multiple Models and Minimal Change

One clear result we obtained is that people retain uncertainty in their revised belief states – they did not use single models of the new information to choose among alternative interpretations of the initial information, or conversely, in the tasks we gave them (e.g., they did not follow Algorithm D). Further, they tended to select revisions that include more uncertainty than is logically defensible, opting for “ p is uncertain and so is q ” as often or more frequently than “ p is true and q is false, or else p is false and q is true.” It seems clear that people could recognize (were it pointed out to them) that the former is less informative than the latter about possible combinations of p and q ’s truth values, but our subjects chose it anyway. One way to view the results we obtained is to say that many of our subjects preferred revisions which were not minimal with respect to what was changed, but were instead minimal with respect to what they believed to hold true without doubt when both the initial and expansion information were considered jointly. It certainly seems more difficult to work with a “world” specification like $\{[\sim p \sim q \ r \ s] \text{ or } [p \sim q \sim r \sim s]\}$ than it is with one that says “ q is false and I’m not sure about anything else,” even though (from a logical point of view) the former specification contains much more information than the latter.

What we learned from our initial investigations on minimal change problems may have less

to do with the metrics of minimal change and more to do with issues of how people manipulate multiple models of the world. Rips' (1989) work on the knights-and-knaves problem also highlights the difficulty that people have in exploring and keeping track of multiple models. In that task, the supposition that one character is a liar defines one model, being a truth-teller defines another model, and each of these might in turn branch into other models. Even working such a problem out on paper presented difficulties for subjects, Rips reported. Yet in real life, we can certainly reason about vastly different hypothetical worlds that could be viewed as being equivalent to disjunctions of complex sentence sets. Unlike the arbitrary problems given to our subjects or even the knights-and-knaves problems, alternative hypothetical worlds about real-world topics may have some "explanatory glue" that holds together the particular contingencies, and no others, among the truth values of the independent beliefs. The question is whether for more real-world situations, are people better able to retain and integrate the interdependencies among truth values in multiple models?

Alternative Representations of Belief States

Representing a belief state as a set of sentences or even as a set of models is a simplification. We believe that number of important issues arise from this simple conceptualization and this study offers data on some of those issues. We noted alternative approaches to modeling belief states in the introduction, specifically those that use probabilistic information and degrees of belief. But there are two other perspectives that have long been considered from a philosophical viewpoint: the foundationalist view and the coherentist view. The foundationalist view (Swain, 1979; Moser, 1985, 1989; Alston, 1993) distinguishes between beliefs that are accepted without justification and those that depend on the prior acceptance of others. Such a distinction is used in truth-maintenance systems (e.g., Doyle, 1979; deKleer, 1986) for keeping track of dependencies among beliefs and to prefer the retraction of the latter ("assumptions") over the former ("premises") when contradictions are caused by new information. Pollock's (1987) defeasible reasoning theory defines a wider class of distinctions (e.g., "warrants" and "undercutters") and such distinctions can also be used to define normative foundationalist models of belief revision. The coherentist view (Quine

& Ullian, 1978; BonJour, 1985; Harman, 1986) does not consider some beliefs as more fundamental than others, but rather emphasizes the extent to which an entire set of beliefs "coheres." One set of beliefs can be preferable to another if it has a higher coherence, however defined. Thagard's (1989) theory of explanatory coherence is an instance of this perspective and operational definitions of coherence can, in such a framework, be a means of implementing belief revision principles (Thagard, 1992). Pollock (1979) gives a whole range of epistemological theories that span the spectrum between foundationalist and coherentist.

It has been argued (e.g., Harman, 1986; Gärdenfors, 1990b; Doyle, 1992; Nebel, 1992) that the original AGM account of belief revision, as well as model-based versions of it, are coherentist in nature. Harman and Gärdenfors go so far as to say that a foundationalist approach to belief revision (as advocated, e.g., by Doyle, 1979; Fuhrmann, 1991; Nebel, 1991) is at odds with observed psychological behavior, particularly concerning people's ability to recall the initial justifications for their current beliefs. More marshaling of this and other experimental evidence (including the type we have reported in this article) could be a reasonable first step towards an experimentally justified account of how human belief structures are organized; and with this is perhaps an account of how belief structures of non-human agents could best be constructed.

Finally, we note that it remains a difficult matter to examine "real beliefs" and their revision in the laboratory (as opposed to the task of choosing among sentences to be accepted as true); the paradigm of direct experimentation with some micro-world, which has been used to study theory development, is one direction that can prove fruitful (e.g., Ranney & Thagard, 1988). However, conceptualizing a belief state merely as a set of beliefs can still afford, we think, some insight into the pragmatic considerations people make in resolving contradiction.

Future Work

There are many issues raised in these investigations that warrant further study; we have touched upon some of them throughout our discussions. The possibility of bias against changing negated beliefs to non-negated ones, or in preferring revisions with non-negated sentences, needs systematic study. We used a selection paradigm throughout this study and it is important to

establish whether similar results hold when subjects generate their new belief state. A more difficult issue is whether there are different patterns of belief revision depending on whether the belief set is one a person induces themselves or whether it is given to them. In the former case, one can speculate that a person has expended some cognitive effort to derive a belief, and a by-product of that effort may create the kind of coherentist structure that is more resistant to the abandonment of some beliefs in the face of contradictory information. This kind of perspective can be applied to an early study by Wason (1977) on self-contradiction. He found that subjects given the selection task were quite reluctant to change their conclusions about how to validate a rule, even when they were shown that such conclusions were contradicted by the facts of the task. Yet on a different sort of task, he found that subjects can recognize and correct invalid inferences about the form of a rule they are actively trying to identify from a data set, when the data set leads them to valid inferences that contradict the invalid ones they make. If recognizing a contradiction depends on the demands that a task imposes on a reasoner, then this might elucidate how premises are formulated and how inferences are validated; in the belief revision scenarios we used in this study, the contradiction occurs not because of the reasoner's inferencing process, but because additional information about the world indicates that one of initially accepted premises must be suspect. The recognition and resolution of contradiction is impor-

tant to general theories of human reasoning that employ deduction, induction, and belief revision. How general performance models of deductive and inductive reasoning can embrace belief revision decisions is an important open issue.

Appendix A: Clauses Used for Science-Fiction Stimuli, Experiment 1

Subjects received one of the three possible science-fiction versions of the modus ponens and modus tollens rules, given below. Each version was used equally often across subjects.

Modus Ponens Rules

If a Partiplod hibernates during the day, then it is a meat eater.

If a cave has a Pheek in it, then that cave has underground water.

If a ping burrows underground, then it has a hard protective shell.

Modus Tollens Rules

If Gargons live on the planet's moon, then Gargons favor interplanetary cooperation.

If an ancient ruin has a force field surrounding it, then it is inhabited by aliens called Pylons.

If a Gael has cambrian ears (sensitive to high-frequency sounds), then that Gael also has tentacles.

Appendix B: Phrasing of Problems in the Symbolic Condition for Experiments 4 and 5

<i>Problem</i>	<i>Initial Belief Set</i>	<i>Expansion</i>
1	Either A, B, C, and D are all true, or none of them are true.	A is true. C is true. C is false.
2	Either A, B, C, and D are all true, or none of them are true.	B is false. Exactly one of these is true, but no one knows for sure which one: <ul style="list-style-type: none"> • A is true, and C and D are both false. • A is false, and C and D are both true.
3	A is true. B is true. D is true.	A is false. B is false. Either C is true or D is true, but not both of them.
4	A is true. B is true.	At least one of A and B is false, and possibly both of them are.
5	A is true. B is true. C is true.	Either A is false and B and C are both true, or A is true and B and C are both false. No one knows for sure which it is.
6	A is false. B is false. C is false.	Either A is true and B and C are both false, or A is false and B and C are both true. No one knows for sure which it is.

Notes

- 1 We note, however, that not all proponents of probabilistic frameworks concur that acceptance is a required notion. Cheeseman (1988) and Doyle (1989), for example, argue that acceptance is really a mixture of two distinct components: the theory of degree of belief together with a theory of action. The latter theory uses degrees of belief plus a theory of utility to produce a notion of deciding to act in a particular circumstance. Jeffrey (1965) also proposes a framework that avoids an acceptance-based account of belief.
- 2 Most syntax-based approaches put into their definitions of belief revision that the set of all logical consequences is computed for the original belief state in order to determine the contradictions. But only changes to this original "base" belief set are considered in constructing the new belief state. One intuition behind this variety of belief revision is that certain beliefs (the ones in the "base") are more fundamental than other beliefs, and any change in belief states should be made to the implicit beliefs first and only to the base if absolutely required. This view has relations to the foundationalist conception of belief states that we return to in our general discussion.
- 3 Some works, e.g., Fagin, Ullman, and Vardi (1986), use the term "theory" to include both what we call a syntax-based approach and what we call a theory-based approach. When they want to distinguish the two, they call the latter a "closed theory."
- 4 We aim to carefully distinguish our remarks about model-theoretic competence frameworks, as proposed by what we have been calling the classical AI belief revision community, from remarks concerning model-theoretic performance frameworks of human deduction, such as the mental-models theory. It is proper to talk of "models" in the context of either framework. Context will normally convey which framework we intend, but we use the terms "formal AI models" or "mental models" when it is necessary.
- 5 The explicit inclusion of $\sim r$ in S_1 and $\sim n$ in S_2 is, by some accounts, an extra inference step beyond what is necessary to incorporate $\sim u$, since they could be considered as implicit beliefs rather than explicit beliefs; this could be accommodated simply by dropping any mention of r and n from S_1 and S_2 , respectively.
- 6 The actual problems used in these first experiments were really quantified versions of modus ponens and modus tollens. Our modus ponens problem type is more accurately paraphrased as: *For any x , if p holds of x , then q holds of x , and furthermore p holds of a , we can infer q holds of a .* Similar remarks can be made for our modus tollens.
- 7 The reason is this. In a model approach, the initial belief state is the model [p is true, q is true]. When this is revised with $\sim q$, thereby forcing the change from q 's being true to q 's being false in the model, we are left with the model [p is true, q is false]. Such a model has zero changes, other than the one forced by the expansion information; and in this model $p \rightarrow q$ is false. In order to make this conditional be true, a change to the model that was not otherwise forced by the revision information would be required, to make p be false. (Similar remarks hold for the modus tollens case.) Thus model theories of belief revision will deny the conditional in such problems.
- 8 We used the term "knowledge" rather than "belief" in instructions to subjects, because we wanted them to accord full acceptance to them prior to considering how they might resolve subsequent contradiction. The use of "knowledge" here, as something that could subsequently change in truth value, is nonstandard from a philosophical perspective, although common in the AI community. Although these instructions may have appeared inconsistent to a subject sensitive to such subtle distinctions, subsequent studies in which we called the initial belief set as "things believed to be true" have not impacted the type of results we report here.
- 9 The loglinear model for this data is $\ln(F_{ijk}) = \mu + \lambda\rho_i + \lambda pres_j + \lambda prob_k + \lambda\rho_i pres_j + \lambda\rho_i prob_k + \lambda pres_j prob_k$ where F_{ijk} is the observed frequency in the cell, $\lambda\rho_i$ is the effect of the i th response alternative, $\lambda pres_j$ is the effect of the j th presentation-form category, $\lambda prob_k$ is the effect of the k th problem-type category, and the remaining terms are two-way interactions among these. The equivalent "logit" model, in which response is identified as the dependent variable, has terms for response, response by presentation mode, and response by problem type; it yields identical chi-square values. Loglinear and logit procedures from SPSS version 5.0 were used for these analyses. Chi-squares computed on several two-way frequency tables are consistent with the loglinear analyses and the conclusions presented in the text. The effect of symbol v science-fiction presentation approached significance on both MP and on MT problems, when chi-squares were computed for separate two-dimensional frequency tables ($\chi^2 = 5.65$ and 4.87, $p = .059$ and $.087$, $df = 2$ in both cases).

Section 7: Causal and Counterfactual Reasoning

Chapter 29: Causal Thinking

LANCE J. RIPS¹

One damn thing leads to another. I forget to open the garage door this morning, back my car into the door, and splinter it. The actions we perform cause other events – my backing up causes the splintering. But events of other kinds – non-actions – have their effects, too. With no help from me, last night’s storm caused a branch to fall from a tree, putting a hole in my roof.

Much as we might like to forget them, we often keep track of events like these and the causes that unite them. Although we might not have predicted these events, we can remember and reconstruct part of the causal sequences after they occur. In retelling the events of last summer, for example, we tend to relate the events in forward causal order, starting, say, at the beginning of our trip to Virginia in May and proceeding chronologically. If we want to mention other kinds of events from the same period, such as our summer work experiences, we may start again at the beginning of the summer, moving along the events in a parallel causal stream (Barsalou 1988). We also remember fictional stories in terms of the causal changes that compose their main plot line, remembering less about events falling on deadend side plots (Trabasso and Sperry 1985). We sometimes attribute causal powers to concrete objects as well as to events, but we can understand this sort of talk as an abbreviation for event causation. If Fred caused the glass to break that’s because one of Fred’s actions – maybe his dropping it – caused the breaking. I’ll take event causation as basic in this article on the strength of such paraphrases.

We remember causes and effects for event types as well as for event tokens. Ramming heavy objects into more fragile ones typically causes the fragile items damage; repeating phone numbers four or five times typically causes us to remember them for awhile. Negotiating routine events (e.g., Schank and Abelson 1977), con-

structing explanations (e.g., Lewis 1986), and making predictions all require memory for causal relations among event categories. Causal generalities underlie our concepts of natural kinds, like daisies and diamonds (e.g., Ahn and Kim 2000; Barton and Komatsu 1989; Gelman and Wellman 1991; Keil 1989; Rehder and Hastie 2001; Rips 1989, 2001) and support our concepts of artifacts like pianos or prisms. Our knowledge of how beliefs and desires cause actions in other people props up our own social activities (e.g., Wellman 1990).

The importance of causality is no news. Neither are the psychological facts that we attribute causes to events, remember the causes later, and reason about them – although, as usual, controversy surrounds the details of these mental activities. Recently, though, psychologists seem to be converging on a framework for causal knowledge, prompted by earlier work in computer science and philosophy. Rhetorical pressure seems to be rising to new levels among cognitive psychologists working in this area: For example, “until recently no one has been able to frame the problem [of causality]; the discussion of causality was largely based on a framework developed in the eighteenth century. But that’s changed. Great new ideas about how to represent causal systems and how to learn and reason about them have been developed by philosophers, statisticians, and computer scientists” (Sloman 2005: vii). And at a psychological level, “we argue that these kinds of representations [of children’s knowledge of causal structure] and learning mechanisms can be perspicuously understood in terms of the normative mathematical formalism of directed graphical causal models, more commonly known as Bayes nets. . . . This formalism provides a natural way of representing causal structure, and it provides powerful tools for accurate

prediction and effective intervention" (Gopnik et al. 2004: 4).

It's a little unfair to catch these authors in mid rhetorical flight. But the claims for these formalisms do provoke questions about how far they take us beyond the simple conclusions I've already mentioned. Kids and adults learn, remember, and apply causal facts. As a card-carrying CP (i.e., cognitive psychology) member, I believe that kids and adults therefore mentally represent these facts. But what's new here that further illuminates cognitive theorizing? Here's the gloomy picture: The new methods are at heart data-analytic procedures for summarizing or approximating a bunch of correlations. In this respect, they're a bit like factor analysis and a whole lot like structural equation modeling. (If you think it surprising that psychologists should seize on a statistical procedure as a model for ordinary causal thinking, consider that another prominent theory in this area is Kelley's [1967] ANOVA model; see the section on *Causation from Correlation*, and Gigerenzer 1991.) The idea that people use these methods to induce and represent causality flies in the face of evidence suggesting that people aren't much good at normatively correct statistical computations of this sort (e.g., Tversky and Kahneman 1980). Offhand, it's much more likely that what people have are fragmentary and error-prone representations of what causes what.

The rosier picture is the one about "great new ideas."

The jury is still out, and I won't be resolving this issue here. But sorting out the claims for the new causal representations highlights some important questions about the nature of causal thinking.

How Are Causal Relations Given to Us?

Here's a sketch of how a CD player works (according to Macaulay 1988): A motor rotates a spindle that rotates the CD. As the CD turns, a laser sends a beam of light through a set of mirrors and lenses onto the CD's surface. The light beam lands on a track composed of reflecting and nonreflecting segments that have been burned onto the CD. The reflecting segments bounce the light beam back to a photodiode that registers a digital "on" signal; the nonreflecting segments don't bounce the light back and represent an "off" signal. The pattern of digital signals

is then converted into a stereo electrical signal for playback.

You could remember this information in something like the form I just gave you – an unexciting little narrative about CD players. But the new psychological approach to causal knowledge favors directed graphs like Figure 1 as mental representations – "causal maps" of the environment (Gopnik et al. 2004). This graph contains nodes that stand for event types (e.g., the CD player's motor rotating or not rotating, the CD turning or not turning) and directed links that stand for causal connections between these events (the motor rotating causes the CD's turning; the laser producing a beam and the mirror-lens assembly focusing the beam jointly cause the beam to hit the CD's surface). Of course, no one disputes the fact that people can remember some of the information these diagrams embody. Although people can be overconfident about their knowledge of mechanical devices like this one (Rozenblit and Keil 2002), they're nevertheless capable of learning, say, that the CD player's motor causes the CD to turn. What's not so clear is how they acquire this cause-effect information, how they put the component facts together, and how they make inferences from such facts. In this section, we'll consider the acquisition problem, deferring issues of representation and inference till the second part of this chapter.

Causation in Perception

You're not likely to get much of the information in Figure 1 by passively observing a CD player, unless you already know about the nature of similar devices. But sometimes you do get an impression of cause from seeing objects move. Repeated sightings of an event of type E_1 followed by an event of type E_2 may provide evidence that E_1 causes E_2 . Rather weak evidence, but evidence nonetheless. When we later see an example of the same sequence, we can infer the causal link. But psychologists sometimes claim there is a more intimate perception of cause in which an observer directly experiences one event causing another.

PERCEPTUAL STUDIES

In a famous series of demonstrations, Michotte (1963) rigged a display in which a square appeared to move toward a second square and to stop abruptly when they touched. If the second square then began to move within a fixed

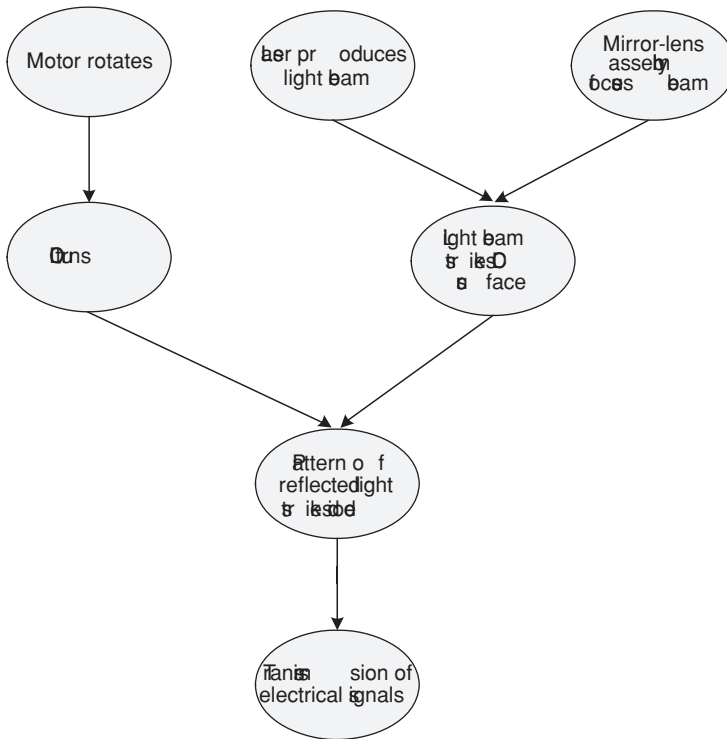

Figure 1. A directed graph representing the operation of a CD player, based on text by Macaulay (1988).

interval of the touching and at a speed similar to that of the first square, observers reported the first square causing the second to move, *launching* it.

Michotte's extensive experiments aimed to isolate the purely perceptual conditions that produce this immediate impression of causality, but there's a paradoxical quality to his efforts. The first square in the display doesn't actually cause the second to move. The displays showed 2-D projections of simple geometrical forms whose movements could be carefully controlled behind the scenes. (In those days before lab computers, Michotte engagingly created his displays using striped disks rotating behind slits or using pairs of moving slide projectors.) The goal was therefore not to determine when people correctly detect causal relations in their environment but instead to uncover the cues that lead them to report causality.² Michotte himself discusses a number of situations in which people report one event causing another, even though the interaction is physically unlikely or impossible. In one such case, a square A moves at 30 cm/s and comes into contact with another square B, which is already moving at 15 cm/s. If

A comes to a halt and B moves off at a *slower* pace than before (7.5 cm/s), observers report a causal effect. "Such cases are particularly interesting in that they show that causal impressions arise as soon as the psychological conditions of structural organization are fulfilled, and indeed that they can arise even in situations where we know from past experience that a causal impression is a downright impossibility" (Michotte 1963: 71). Michotte's project attempted to explain these causal impressions in noncausal terms: His descriptions of the crucial stimulus conditions don't presuppose one object causally influencing another. He believed that people's impression of causality arises as their perceptual systems try to resolve a conflict (e.g., in the launching event) between the initial view of the first square moving and the second square stationary and the final view of the first square stationary and the second moving. The resolution is to see the movement of the first object extending to the second, which Michotte called "ampliation of the movement" (which, I hope, sounds better in French).

Michotte (1963: 351–352) believed that this resolution "enables us to understand why, when

such a structure is established, participants can communicate adequately what they perceive only by saying that they *see* the [initially moving] object make the second go forward." Why? The obvious answer would be that this perceptual situation is one that real objects produce when they undergo causal interactions. The resolution that takes place in the experimental displays reminds the observers, perhaps unconsciously, of what happens when they view causal comings and goings in the ordinary environment, and they therefore interpret it the same way. But this answer is one Michotte rejects, since he consistently denies that the launching effect is due to acquired knowledge. This is why physically impossible cases, like the one described in the previous paragraph, are important to him: They seem to rule out the possibility that observers are making an inference to causality based on experience.

The easiest way to understand Michotte's theory (though not in terms he used) is as the claim that people have a built-in causality detector that is triggered by the conditions he attempted to describe. Since the detector is presumably innate, its operations don't depend on learning from previous experience. Moreover, the detector responds reliably but not perfectly. Toads dart at insects in their visual fields but can be tricked into darting at moving black-on-white or white-on-black spots, according to the old ethology chestnut (e.g., Ewert 1974). In the same way, whenever the movement of an object "extends" to a second, people receive the impression of causality, whether or not the first object actually causes the second to move.

But this approach, like some moving spots, is hard to swallow. Although Michotte stressed that observers spontaneously report the events in causal language – for example, that "the first square pushed the second" – the impression of causality doesn't seem as immediate or automatic as typical perceptual illusions. We can't help but see the apparent difference in line length in the Muller-Lyer illusion or the apparently bent lines in the Poggendorf and Hering figures (see, e.g., Gregory 1978, for illustrations of these). And toads, so far as we know, can't help unleash their tongues at moving specks. But Michotte's demonstrations allow more interpretative leeway.

Suppose Michotte was right that people possess an innate detector of some sort that's broad enough to be triggered by the displays his participants report as causal. The detector, of course, produces false positive responses to some dis-

plays that are in fact noncausal (e.g., Michotte's displays), and it produces false negative or non-responses to some causal ones (e.g., reflections of electromagnetic rays in an invisible part of the spectrum). So what the detector detects is not (all or only) causal interactions but perhaps something more like abrupt transitions or discontinuities in the speed of two visible objects at the point at which they meet. This would include both the normal launching cases and the causally unlikely or impossible ones, such as slowing on impact. Nor do we ultimately take the output of the detector as indicating the presence of a causal interaction. In the case of Michotte's demos, for example, we conclude that no real causal interaction takes place between the squares, at least when we become aware of what's going on behind the smoke and mirrors. The issue of whether we *see* causality in the displays, then, is whether there's an intermediate stage between the detector and our ultimate judgment, a stage that is both relevantly perceptual and also carries with it a causal verdict. Because these two requirements pull in opposite directions, the claim that we can see causality is unstable.

Here's an analogy that may help highlight the issue. People viewing a cartoon car, like the ones in the Disney film *Cars*, immediately "see" the cartoon as a car (and report it as a car), despite the fact that it is physically impossible for cars to talk, to possess eyes and mouths, and to move in the flexible way that cartoon cars do. Although I don't recommend it, you could probably spend your career pinning down the parameter space (e.g., length-to-width ratios) within which this impression of carness occurs. But there isn't enough evolutionary time since the invention of cars in the 19th century for us to have evolved innate car detectors. The fact that we immediately recognize cartoons as cars even when they possess physically impossible properties can't be evidence for innate car perception. Michotte's evidence seems no stronger as support for innate cause detection. Although it's an empirical issue, I'm willing to bet that the impression of carness generated by the cartoon cars is at least as robust as the impression of causality generated by launching displays.

Causality is an inherently abstract relation – one that holds not only between moving physical objects but also between subatomic particles, galaxies, and lots in the middle – and this abstractness makes it difficult to come up with a plausible theory that would have us perceiving it directly, as opposed to inferring it from

more concrete perceived information.³ There's no clear way to defeat the idea that "when we consider these objects with the utmost attention, we find only that the one body approaches the other; and the motion of it precedes that of the other without any sensible interval" (Hume 1739/1967: 77).

DISSOCIATION BETWEEN PERCEIVED AND INFERRED CAUSALITY

More recent evidence suggests that people's judgments about perceived causality are independent of some of the inferences they make about cause. Investigators have taken these dissociations to suggest that Michotte (1963) was right that perceived causality is an innate module. One such study (Roser, Fugelsang, Dunbar, Corballis, and Gazzaniga 2005) employed two split-brain patients, presenting causal tasks to the patients' right or left hemispheres. In one task, the patients saw Michotte-type launching events that varied in the spatial gap between the two objects at the moment the second object began to move and, also, the time-delay between the point at which the first object stopped and the second object began moving. Both spatial gaps and time delays tend to weaken the impression of perceived causality in normal participants. And so they did in the split-brain patients, but with an important qualification. The patients had to choose whether the first object appeared to cause the second to move or whether the second object moved on its own, and their positive "cause" judgments were more frequent when there was no delay and no gap. This difference appeared, however, only when the patients' right hemisphere processed the display. Left-hemisphere processing showed no difference between conditions. A second task asked the same split-brain patients to solve a problem in which they had to use the statistical co-occurrence between visually presented events to decide which of two switches caused a light to come on. Patients were more often correct in this task when the displays presented the information to their left hemispheres than when they presented it to their right hemispheres.

Split-brain patients may process causal information in atypical ways, but investigators have found similar dissociations with normal participants. Schlottmann and Shanks (1992, Experiment 2) varied the temporal gap within launching events (as in Roser et al. 2005) and also the contingency that existed across trials between whether the first object moved and whether the second object moved. On some

series of trials, the first object's moving was necessary and sufficient for the second object to move; on others, the second object could move independently of the first. Participants made two types of judgments on separate trials within these series: how convincing a particular collision appeared and whether the collisions were necessary for the second object to move. Schlottmann and Shanks found an effect of delay but no effect of contingency on judgments of the display's convincingness. Judgments of necessity, however, showed a big effect of contingency and a much smaller effect of delay.

These dissociations suggest – what should become clear in the course of this chapter – that causal thinking is not of one piece. Some causal judgments depend vitally on detailed perceptual processing, while others depend more heavily on schemas, rules, probabilities, and other higher-order factors. What's not so clear is whether the dissociations also clinch the case for a perceptual causality detector. The right hemispheres of Roser et al.'s (2005) split-brain patients could assess the quality of launching events even though they were unable to evaluate the impact of statistical independencies. But this leaves a lot of room for the influence of other sorts of inference or association on judgments about launching. Suppose, for example, that launching judgments depend on whether observers are reminded of real-world interactions of similar objects. Unless the right hemisphere is unable to process these reminders, inference could still influence decisions about launchings. Similarly, Schlottmann and Shanks's (1992) finding shows that observers can ignore long-run probabilities in assessing the convincingness of a particular collision, but not that they ignore prior knowledge of analogous physical interactions.

STUDIES OF INFANTS

Developmental studies might also yield evidence relevant to Michotte's claim, since if the ability to recognize cause is innate, we should find infants able to discriminate causal from non-causal situations. The evidence here suggests that by about six or seven months, infants are surprised by events that violate certain causal regularities (Kotovskiy and Baillargeon 2000; Leslie 1984; Leslie and Keeble 1987; Oakes 1994). In one such study, for example, Kotovskiy and Baillargeon first showed seven-month-olds static displays containing a cylinder and a toy bug, either with a thin barrier separating them (no-contact

Figure 2. Familiarization and test conditions from Kotovsky and Baillargeon (2000).

condition) or with a partial barrier that did not separate them (contact condition). Figure 2 displays these two conditions at the left and right, respectively. A screen then hid the position that contained the barrier or partial barrier. In the experiment's test phase, the infants saw the cylinder roll down a ramp and go behind the screen, as shown at the bottom of Figure 2. The screen hid what would be the point of impact, but if the bug moved as if the cylinder had struck it, the infants looked longer in the no-contact than in the contact condition. If the bug failed to move, infants showed the opposite pattern of looking.

At seven months,⁴ then, infants appear to discriminate some cases in which simple launching events will and won't occur, but should we take this as evidence for innate perception of causality? Unfortunately, there seems to be no evidence that would allow us to compare directly the class of interactions that Michotte's participants report as causal with the class that infants react to. It would be useful to know, in particular, whether the "impossible" displays that Michotte's observers report as causal are also ones to which infants give special attention. What we do know, however, is that infants take longer than seven months to recognize causal interactions even slightly more complex than simple launching. For example, at seven months

they fail to understand situations in which one object causes another to move in a path other than dead ahead, situations that adults report as causal (Oakes, 1994).

If the classes of interactions that adults and infants perceive as causal are not coextensive, this weakens the evidence for innate, modular perception of causality. You could maintain that the perceptual impression of causality changes with experience from an innate starting point of very simple causal percepts, such as dead on launchings, but this opens the door to objections to the very idea of directly perceiving cause. If learning can influence what we see as a causal interaction, then it seems likely that top-down factors – beliefs and expectations – can affect these impressions. Perhaps the learning in question is extremely local and low level. But if not – if observers' impressions of cause change because of general learning mechanisms – then this suggests that the impressions are a matter of inference rather than direct perception. Much the same can be said about evidence that seven-month-olds' reaction to launching events depends on whether the objects are animate or inanimate (Kotovsky and Baillargeon 2000). The animacy distinction presumably depends on higher-level factors, not just on the spatiotemporal parameters Michotte isolated (see Saxe and Carey 2006 for a review).

Of course, uncertainty about the evidence for direct perception of causality needn't affect the claim that the concept of causality is innate (see the section on causal primitives later in this chapter). Children may have such a concept but be initially unsure exactly what sorts of perceptual data provide evidence it applies. Moreover, nonperceptual, as well as perceptual, data may trigger such a concept; in fact, most theories of causality in psychology have avoided tying cause to specifically perceptual information. These theories take seriously the other aspect of Hume's (1739/1967) view, trying to account for judgments of causality in terms of our experience of the co-occurrence of events. Does recent research shed any light on this possibility?

Causation from Correlation

Even if we can literally perceive causality in some situations, we have to resort to indirect methods in others. A careful look at a CD player's innards can't disclose the causal link between the reflected pattern of light and the transmission of sound signals at the bottom of Figure 1. We may see the reflected light and hear the resulting sound, but we don't have perceptual access to the connection between them. Similarly, we can't see atmospheric pressure influencing the boiling point of a liquid or a virus producing a flu symptom or other people's beliefs motivating their actions. Experiments in science would be unnecessary if all we had to do to isolate a causal mechanism is look.

Scientists, of course, aren't the only ones in need of hidden causal facts. We need to predict how others will behave if we want to enlist them in moving a sofa. We need to know what buttons to press if we want to make a cell phone call or record an opera broadcast or adjust the drying cycle to keep from scorching our socks. We need to know which foods are likely to trigger our allergy, which windows are best for which plants, which greetings will produce another greeting versus a stunned silence or a slap in the face. We can sometimes rely on experts to tell us about the hidden causes. Allergists are often good on allergies, botanists on plants, and Miss Manners on manners. But sometimes we have to proceed on our own, and the question is how ordinary people cope with the task of recognizing causal relationships when they can't look them up. The answer that psychologists have usually given to this question is that people operate from bottom up, observing the temporal co-occurrence

of events and making an inductive inference to a causal connection. They might passively register the presence or absence of a potential cause and its effects or they may actively intervene, pressing some buttons to see what happens. In either case, they decide whether a cause-effect link is present on the basis of these results. This section considers the more passive route to discovering causes, and the next section looks at the more active one.

CAUSE, CONTRAST, CORRELATION

If we suspect event type C causes event type E, we should expect to find E present when C is present and E absent when C is absent. This correlation might not be inevitable even if C really is a cause of E. Perhaps E has an alternative cause C'; so E could appear without C. Or perhaps C is only a contributing cause, requiring C'' in order to produce E; then C could appear without E. But if we can sidestep these possibilities or are willing to define *cause* in a way that eliminates them, then a correlation between C and E may provide evidence of a causal relation. Codifying this idea, Mill (1874) proposed a series of well-known rules or canons for isolating the cause (or effect) of a phenomenon. The best known of these canons are the method of agreement and the method of difference. Suppose you're looking for the cause of event type E. To proceed by the method of agreement, you should find a set of situations in which E occurs. If cause C also occurs in all these situations but no other potential cause does, then C causes E. To use the method of difference, which Mill regarded as more definitive, you should find two situations that hold constant all but one potential cause, C, of E. If E is present when C is present, and E is absent when C is absent, then C causes E.

Psychologists have mostly followed Mill's canons in their textbooks and courses on scientific methods.⁵ If you're a victim of one of those courses, you won't find it surprising that psychological theories of how nonscientists go about determining cause-effect relations reflect the same notions:

The inference as to where to locate the dispositional properties responsible for the effect is made by interpreting the raw data . . . in the context of subsidiary information from experiment-like variations of conditions. A naïve version of J. S. Mills' method of difference provides the basic analytic tool. The effect is attributed to that condition which is present when the effect is present and which

Table 1: Two Contrasts for Assessing the Presence of a Causal Relation

a.

	<i>This Occasion</i>		<i>Other Occasions</i>	
	<i>Calvin</i>	<i>Other People</i>	<i>Calvin</i>	<i>Other People</i>
tango	1	0	1	0
other dances	1	0	1	0

b.

	<i>This Occasion</i>		<i>Other Occasions</i>	
	<i>Calvin</i>	<i>Other People</i>	<i>Calvin</i>	<i>Other People</i>
tango	1	1	1	1
other dances	0	0	0	0

1's indicate that a person likes a particular dance on a given occasion; 0's indicate not liking to dance.

is absent when the effect is absent. (Kelley 1967: 194)

As an example (similar to one from Cheng and Novick 1990), suppose you know that Calvin danced the tango last Thursday. To find out the cause of this event, you need to examine potential causes that the outcome suggests: Maybe it was a disposition of Calvin's, maybe it was the tango, maybe it was something about this particular occasion. To figure out which of these potential causes was at work, you mentally design a study in which the three causes are factors. The design will look something like what's in Table 1. The 1's in the cells stand for somebody dancing on a particular occasion, and the 0's stand not dancing. If the pattern of data looks like what's in Table 1a, we have an effect for the person but no effects for either the occasion or the type of dance; so we might conclude that the reason Calvin danced the tango on this occasion is that he just likes dancing. By contrast, if the data come out in the form of Table 1b, where Calvin and others don't do other kinds of dancing, but everyone dances the tango, we might conclude that it was the tango that caused Calvin's dancing.

Kelley's (1967) ANOVA (analysis of variance) theory aimed to explain how individuals determine whether their reaction to an external object is due to the object itself (e.g., the tango) or to their own subjective response, and the theory focused on people, objects, times, and "modalities" (different ways of interacting with the entity) as potential factors. Cheng and Novick (1990, 1992) advocated a somewhat

more flexible approach in which people choose to consider a set of potential factors on pragmatic grounds: "Contrasts are assumed to be computed for attended dimensions that are present in the event to be explained" (1990: 551). According to this theory, people also determine causation relative to a particular sample of situations, a "focal set," rather than to a universal set. Within these situations, people calculate causal effectiveness in terms of the difference between the probability of the effect when the potential cause is present and the probability of the effect when the same potential cause is absent:

$$(1) \quad \Delta P = \text{Prob}(\text{effect} | \text{factor}) - \text{Prob}(\text{effect} | \sim \text{factor}),$$

where $\text{Prob}(\text{effect} | \text{factor})$ is the conditional probability of the effect given the presence of the potential causal factor and $\text{Prob}(\text{effect} | \sim \text{factor})$ is the conditional probability of the effect given the absence of the same factor. When this difference, ΔP , is positive, the factor is a contributory cause of the effect; when it's negative, the factor is an inhibitory cause; and when it's zero, the factor is not a cause. Cheng and Novick also distinguish causes (contributory or inhibitory) from "enabling conditions" – factors whose ΔP is undefined within the focal set of situations (because they are constantly present or constantly absent) but that have nonzero ΔP in some other focal set.

We can illustrate some of these distinctions in the Table 1 results. In Table 1a, $\Delta P = 1$ for Calvin versus other people, but 0 for the object and occasions factors. So something about

Calvin is a contributory cause of his dancing the tango at that time, and the tango and the occasion are noncauses. In the Table 1b data, the object (dance) factor has a ΔP of 1, whereas the person and occasion factors have ΔP 's of 0; so the tango causes the event. Reversing the 0's and 1's in Table 1b, so that Calvin and others never dance the tango but always dance other dances, will produce a ΔP of -1 . In this case, the tango is an inhibitory cause. A factor – perhaps, music – that is present in all the situations in the focal set considered here would be an enabling condition if it turned out to have a positive ΔP in a larger sample of situations in which it was present in some and absent in others. The results in Table 1 are all-or-none, but the ΔP measure obviously generalizes to situations in which the effect can occur within each cell sometimes but not always.

Related notions about cause derive from work on associative learning. Creatures learning that, say, a shock often follows a tone are remembering contingency information about the tone and shock (or the pain or fear that the shock creates – sorry, animal lovers, but these aren't my experiments). A number of researchers have proposed that this primitive form of association might provide the basis for humans' causal judgments (e.g., Shanks and Dickinson 1987; Wasserman, Kao, Van Hamme, Katagiri, and Young 1996). Data and models for such learning suggest that this process may be more complex than a simple calculation of ΔP over all trials. In particular, the associative strength between a specific cue (e.g., tone) and an unconditioned stimulus (shock) depends on the associative strength of other cues (lights, shapes, colors, etc.) that happen to be in play. The associative strength for a particular cue is smaller, for example, if the environment already contains stronger cues for the same effect. If these associative theories are correct models for judgments about a specific potential cause, then such judgments should depend on interactions with other potential causes, not just on "main effect" differences like those of the ANOVA model or ΔP . Evidence for these interactions in causal judgments appears in a number of studies (e.g., Chapman and Robbins 1990; Shanks and Dickinson 1987).⁶ However, ΔP -based theories can handle some of these results if participants compute ΔP while holding other confounded factors constant (a conditional ΔP , see Cheng 1997; Spellman 1996). Also, under certain conditions (e.g., only one potential cause present), associative theories sometime reduce to ΔP (Chapman and Robbins 1990; Cheng 1997).⁷ Because both associative and statistical

models make use of the same bottom-up frequency information, we consider them together here (see the section on Power for more on interactions).

LOTS OF CORRELATIONS

The same textbooks on methodology that extol Mill's canons of causal inference also insist that a correlation between two variables can't prove that one causes the other. Because Mill's methods, the ANOVA theory, ΔP , associative theories, and their variants all work along correlational lines, how can they provide convincing evidence for causation?⁸ If these methods yield a positive result, there's always the possibility that some unknown factor confounds the relation between the identified cause and its effect. Maybe Calvin's love of dancing didn't cause his dancing the tango Thursday, but instead the cause was his girlfriend's insistence that he dance every dance on every occasion (in the Table 1a example). If these methods yield a negative result for some putative cause, there's always the possibility that some unknown factor is suppressing the first. The tango's special allure might surface if Calvin and his girlfriend hadn't crowded other couples off the dance floor. If we can't identify a cause (due to possible confounding) and we can't eliminate a potential cause (because of possible suppression), how can we make any progress with these correlational methods? Of course, the ANOVA theory and the ΔP theory (unlike Mill's methods) are intended as models of ordinary people's causal reckoning, and ordinary people may not consider confoundings or suppressors. Superstitious behavior may attest to their unconcern about spurious causes and noncauses, as might the need for the textbook warnings about these weak inferences. Even children, however, can reject confoundings under favorable conditions (Gopnik et al. 2004; Koslowski 1996: Ch. 6). So we seem to need an explanation for how people can go beyond correlation in their search for causes.

Although a single contrast or correlation between factors may not be convincing evidence, multiple correlations may sometimes reveal more about the causal set up. To see why this is so, let's go back to the CD diagram in Figure 1. Both the rotating motor and the laser beam influence the final transmission of electrical signals. So we would expect both the rotation of the motor and the presence of the laser beam to be correlated with the transmission. The correlation between the motor and the light beam, however, should be zero, provided no further

factors outside the diagram influence both of them. (If there is a power switch, for example, that controls both the motor and the laser, then, of course, there will be such a correlation. So imagine there are separate controls for present purposes.) Similarly, the diagram predicts that if we can hold constant the state of some of the variables in Figure 1, the correlation among other variables should go to zero. For instance, although there should be a correlation between whether the CD is rotating and transmission of signals, we should be able to break the correlation by observing only those situations in which the intermediate variable, the light striking the diode is constant. For instance, when light is not striking the diode, there should be no correlation between the rotating and the transmission. The causal relations among the different parts of the diagram put restrictions on what is correlated with what. Working backward from the pattern of correlations, then, we may be able to discern which causal relations are consistent with these correlations and which are not. For example, the presence of a correlation between the rotation and the light beam would be a reason to think that the causal arrows in Figure 1 are incorrect. Statistical techniques like path analysis and structural equation modeling exploit systems of correlations in this way to test theories about the causal connections (e.g., Asher 1983; Klem 1995; Loehlin 1992).

There are limits to these methods, however, that are similar to those we noted in connection with single correlations (Cliff 1983). In the first place, there may still be confounding causes that are not among the factors considered in the analysis. In the setup of Figure 1, for example, we should observe a correlation between the light striking the diode and the transmission of signals, but there is no guarantee, based on correlations alone, that this is due to the direct effect of the diode on the signals (as the figure suggests). Rather, the correlation could be due to the effect of some third, confounding variable on both the diode and the signal. The same is obviously true for the rest of the direct connections that appear in the graph. Each direct connection is subject to exactly the same uncertainty about confoundings that we faced with single correlations. Second, the pattern of correlations can drastically underdetermine the causal structure. Consider, for example, a completely arbitrary set of correlations among four variables A, B, C, and D. The causal connections in Figure 3a (i.e., A has a direct causal effect on B, C, and D; B has a direct effect on C and D; and C has

a direct effect on D) will be perfectly consistent with those correlations, whatever they happen to be. For example, a path analysis based on these connections will *exactly* predict the arbitrary correlations. Moreover, so will any of the other twenty-three models in which the position of the variables in this structure is permuted – for instance, the one in Figure 3b in which D directly causes C, B, and A; C directly causes B and A; and B directly causes A. These are *fully recursive* models in path-analysis terminology, and they always fit the data perfectly. Additional information beyond the correlations would be necessary to discriminate among these sets of possible causal connections (Klem 1995; see also Pearl 2000 for a discussion of Markov equivalent causal structures).

CAUSAL MECHANISMS AND SCHEMAS

To compound these difficulties for the bottom-up, correlation-to-causation approach, the causal environment typically contains an enormous number of factors that could produce a given effect. Calvin, the tango, or the occasion may produce events that cause his dancing the tango on Thursday, but these factors are cover terms that contain many different potential causes: They serve as causal superordinate categories. Not all of Calvin's dispositions would plausibly cause him to dance, but this still leaves a seemingly unlimited number to choose from. Is the cause his showmanship, his athleticism, his musical talents, his religious fervor, his distaste of being a wallflower, his fear of letting down his girlfriend, . . . ? Moreover, we needn't stop at people, objects, and occasions, as we've already noted. Maybe it's his girlfriend's demands, maybe it's bribery by the DJ, maybe it's cosmic rays, maybe it's his therapist's hypnotic suggestion, maybe it's a disease (like St. Vitus dance), and so on. Since there is no end to the possibilities, there is no way to determine for each of them whether it is the cause, making a purely bottom-up approach completely hopeless.

We should again distinguish the plight of the scientist from the task of describing laypeople's causal search. Laypeople may take into account only a handful of potential causes and test each for a correlation with the effect. Although such a procedure might not be normatively correct, it may nevertheless be the recipe people follow in everyday life. But even if people use correlations over a restricted set of factors, an explanation of their causal reasoning would then also have to include an account at how they arrive at the restricted set. The factors they test are the factors

Figure 3. A hypothetical causal model for four variables in original form (a) and permuted form (b).

they attend to, of course, but what determines what they attend to? People's causal thinking often aims at explaining some phenomenon, where what needs explaining may be a function of what seems unusual or abnormal within a specific context (Einhorn and Hogarth 1986; Hilton 1988; Kahneman and Miller 1986). The explanation process itself depends on broadly pragmatic factors, such as the explainers' interest or point of view, the contrast class of explanations they have in mind, the intended audience for the explanation, and the availability of evidence, among others (Brem and Rips 2000; Hilton 1990; Lewis 1986; van Fraassen 1980). The same goes for determining "the cause" of a phenomenon, which is a disguised way of asking for the main cause or most important cause.

Evidence supports the notion that people's search for causes relies on information other than correlation. Ahn, Kalish, Medin, and Gelman (1995) asked participants what kinds of evidence they needed to determine the cause of an event like the one about Calvin. (Ahn et al. used some of the stimulus materials from Cheng and Novick 1990.) For example, participants had to write down questions that they would like to have answered in order to figure out the cause of (in this case) Calvin's *not* dancing the tango on this occasion. Ahn et al. predicted that if the participants were following the ANOVA or Cheng-Novick ΔP theory, they should be seeking information that fills out the rest of the design matrix in Table 1 – the kind of information they could use to compute experimental contrasts or ΔP . Did other people dance the tango? Did Calvin dance other kinds of dances?

Did Calvin dance the tango on other occasions? And so forth. What Ahn et al. found, though, is that participants asked these sorts of questions only about 10 percent of the time. Instead, participants asked what Ahn et al. call "hypothesis-testing" questions, which were about specific explanatory factors not explicitly mentioned in the description of the event. Participants asked whether Calvin had a sore foot or whether he ever learned the tango, and about similar sorts of common-sense causal factors. These hypothesis-testing questions showed up on approximately 65 percent of trials. Ahn et al. concluded that when people try to explain an event, they look for some sort of mechanism or process that could plausibly cause it. They have a set of these potential mechanisms available in memory, and they trot them out when they're trying to discover a cause.

People may also infer correlational information from their causal beliefs rather than the other way round. Psychologists have known since Chapman and Chapman's (1967; Chapman 1967) initial work on illusory correlations that causal expectancies can affect estimates of correlations (for reviews, see Alloy and Tabachnik 1984; Busemeyer 1991; Nisbett and Ross 1980). For example, both clinicians and laypeople overestimate the correlation between diagnostic categories (e.g., paranoia) and certain test results (e.g., unusual eye shapes in patients' drawings). This is probably because the judges' causal theories dictate a relation between the category and the result – paranoia causes patients to be especially aware of the way people look at them or of their own glances at others – since the true correlation is negligible.

Similarly, Tversky and Kahneman's (1980) experiments on causal schemas show that causal theories can dictate estimates of conditional probabilities. Participants in one experiment were asked to choose among the following options:

Which of the following events is more probable?

- (a) That a girl has blue eyes if her mother has blue eyes.
- (b) That a mother has blue eyes if her daughter has blue eyes.
- (c) The two events are equally probable.

The converse conditional probabilities in (a) and (b) are necessarily equal, according to Bayes Theorem, provided that the (marginal or unconditional) probability of being a blue-eyed mother is the same as being a blue-eyed daughter. (A follow-up experiment verified that most participants think this equality holds.) The results showed that 45 percent of participants correctly chose option (c). The remaining participants, however, chose (a) much more often than (b): 42 percent versus 13 percent. According to Tversky and Kahneman's interpretation, these judgments are biased by the belief that it's the mother who is causally responsible for the daughter's eye color rather than the reverse. This causal asymmetry induces an incorrect impression of an asymmetry in the conditional probabilities.

Finally, Waldmann and his colleagues have shown that people's judgment about a cause can depend on causal background beliefs, even when correlational information is constant (Waldmann 1996). Consider, for example, the fictitious data in Table 2, which exhibits the relation between whether certain fruit has been irradiated and the fruit's quality in two samples, A and B. Summed over the samples, the quality of fruit is positively related to irradiation; ΔP is positive when irradiation is the factor and quality the effect. Within each sample, however, the effect reverses. Both ΔP 's are negative when calculated within sample, as shown in the bottom row of the table. This situation is an example of what's known as *Simpson's paradox*: When the number of cases in the cells is unequal, the size and even the direction of contingency statistics can depend on how the population is partitioned.⁹ In Table 2, people should judge irradiation to be positively related to quality if they base their decision on the entire sample, but should make

Table 2: Contingency Information from Waldmann and Hagmayer (2001)

	Sample A	Sample B	Total
Irradiated	16/36	0/4	16/40
Not irradiated	3/4	5/36	8/40
ΔP	-.31	-.14	+.20

The first two rows indicate what fraction of a group of fruit was good as a function of whether the fruit was irradiated or not and whether it was from sample A or sample B. The top number in each fraction is the number of good fruit and the bottom number is the total number tested in that condition. Bottom row shows ΔP [i.e., $\text{Prob}(\text{Good} | \text{Irradiation}) - \text{Prob}(\text{Good} | \text{No Irradiation})$] for the entire population and for each sample separately.

the opposite judgment if they attend to samples A and B separately. Waldmann and Hagmayer (2001: Experiment 1) manipulated participants' assumptions about the causal import of the sample by informing them in one condition that sample A consisted of one type of tropical fruit and sample B consisted of a different type. In a second condition, participants learned that A and B were samples randomly assigned to two different investigators. Participants in both conditions, however, saw the same list of 80 cases (distributed as in Table 2) that identified the sample (A or B) and, for each piece of fruit, its treatment (irradiated or not) and its outcome (good or bad quality). All participants then rated how strongly irradiation affected the fruits' quality. Although correlational information was constant for the two conditions, participants rated irradiation as negatively affecting quality when the samples were causally relevant (types of fruit) but positively affecting quality when the samples were irrelevant (different investigators).

Given these findings, there is little chance that people construct judgments of cause from bottom up, except under the most antiseptic conditions. Naturally, this doesn't mean that contingencies, associations, and correlations are irrelevant to people's assessment of cause, but the role they play must be a piece of a much larger picture.

POWER

As a step toward a more theory-based view of cause, we might analyze observed contingencies as due to two components: the mere

presence or absence of the cause and the tendency or power of this cause to produce the effect (Cheng 1997; Novick and Cheng 2004). The cause can't bring about the effect, of course, unless it's present. But even if it is present, the cause may be co-opted by other causes or may be too weak to produce the effect in question. Ordinarily, we can observe whether or not the cause is present, at least in the types of experiments we have been discussing, but the cause's power is unobservable. In this vein, Novick and Cheng (2004: 455) claim that "previous accounts, however, are *purely covariational* in that they do not consider the possible existence of unobservable causal structures to arrive at their output. In contrast, our theory explicitly incorporates into its inference procedure the possible existence of *distal* causal structures: Structures in the world that exist independently of one's observations" (emphasis in the original). On this theory, you can detect the nature of these distal structures only under special circumstances. When these special assumptions are met, the distal causal power isn't exactly an ANOVA contrast or ΔP , but it looks much like a normalized ΔP .

To derive the power of a cause C , suppose first that C is present in the environment. Then the effect, E , will occur in two cases: (a) C produces E (with probability p_c), or (b) other alternative causes, collectively designated A , occur in the same environment and produce E (with probability $\text{Prob}(A|C) \cdot p_a$). Thus, the probability of E when C is present is:

$$(2) \quad \text{Prob}(E|C) = p_c + \text{Prob}(A|C) \cdot p_a - p_c \cdot \text{Prob}(A|C) \cdot p_a.$$

The final term in (2) (after the minus sign) ensures that we count only once the case in which C and A both produce E . When C is absent, only the alternative causes A can bring about E . So the probability of E given that C is not present is:

$$(3) \quad \text{Prob}(E|\sim C) = \text{Prob}(A|\sim C) \cdot p_a.$$

Substituting these expressions in Equation (1), above, we get:

$$(4) \quad \Delta P = [p_c + \text{Prob}(A|C) \cdot p_a - p_c \cdot \text{Prob}(A|C) \cdot p_a] - [\text{Prob}(A|\sim C) \cdot p_a].$$

Solving (4) for p_c yields the following expression for the causal power of C :

$$(5) \quad p_c = \frac{\Delta P - [\text{Prob}(A|C) - \text{Prob}(A|\sim C)]p_a}{1 - \text{Prob}(A|C)p_a}.$$

In the special case in which causes A and C occur independently (so that $\text{Prob}(A|C) =$

$\text{Prob}(A|\sim C) = \text{Prob}(A)$), then Equation (5) reduces to:

$$(6) \quad p_c = \frac{\Delta P}{1 - \text{Prob}(A)p_a} \\ = \frac{\Delta P}{1 - \text{Prob}(E|\sim C)}$$

The last expression follows since, by Equation (3), $\text{Prob}(E|\sim C)$ is equal to $\text{Prob}(A) \cdot p_a$ when A and C are independent. The interpretation of (6) may be clearer if you recall that ΔP is itself equal to $\text{Prob}(E|C) - \text{Prob}(E|\sim C)$. In other words, p_c is roughly the amount that C contributes to producing E relative to the maximal amount that it could contribute. Thus, p_c , unlike ΔP , is immune to ceiling effects – situations in which E already occurs frequently in the absence of C – except in the extreme case in which $\text{Prob}(E|\sim C) = 1$, where p_c is undefined. (To see this, suppose $\text{Prob}(E|C) = .95$ and $\text{Prob}(E|\sim C) = .90$. Then $\Delta P = .05$, a seemingly small effect for C because both $\text{Prob}(E|C)$ and $\text{Prob}(E|\sim C)$ are high. But $p_c = .50$, a much larger effect because of the correction.) The formulas in (5) and (6) define contributory causal power, but analogous ones are available for inhibitory causal power (see Cheng 1997).

Does the power statistic, p_c , correspond to people's concept of a distal cause, as Novick and Cheng (2004) claim? Why shouldn't we consider it just another estimate of the likelihood that a particular cause will produce an effect – ΔP corrected for ceiling effects? The Cheng-Novick set-up portrays causation as a two-step affair. If we want to predict whether C causes E , we need to know both the likelihood that C is present and also the likelihood that C will produce E . But granting this framework, we may have some options in interpreting the latter likelihood. One issue might be whether people think that "distal power" is a probabilistic matter, as Luhmann and Ahn (2005) argue. Setting aside subatomic physics, which is outside the ken of ordinary thinking about ordinary causal interactions, people may believe that causal power is an all-or-none affair: Something either is a cause or isn't; it's not a cause with power .3 or .6. Of course, there might be reasons why a potential cause doesn't run its course, such as the failure of intermediate steps. For example, a drunk driver might have caused an accident if his car hadn't been equipped with antilock brakes. But do we want to say that the causal power of the drunk driving was some number between 0 and 1?¹⁰ There are also cases in which a

potential cause doesn't succeed in producing its effect for reasons that we simply don't know. If we're in the dark about why a cause doesn't always produce an effect, we might want to attach a probability to it. As Cheng and Novick (2005: 703) acknowledge, "A probabilistic causal power need not indicate any violation of the power PC assumptions even for a reasoner who believes in causal determinism. . . . A probabilistic causal power might instead reflect the reasoner's imperfect representation of this cause." But this isn't consistent with Novick and Cheng's distal causal power idea. Our lack of knowledge isn't an intermediate degree of distal causal power: It's a proximal matter of our beliefs. Probabilistic beliefs about causes aren't beliefs about probabilistic causes.

Novick and Cheng are likely right that people believe that there are causes in the world and that these causes have power to produce certain effects. What's in question is whether you can model these powers as probabilities in a way that doesn't sacrifice basic intuitions about causality, which for ordinary events might be necessarily all-or-none (Luhmann and Ahn 2005) and inherently mechanistic ("intrinsically generative," in White's 2005 terms). It is possible for power proponents to retreat to the position that causal power describes an idealized, normatively correct measure that actual causal judgments merely approach. After all, distal causal powers, like distal properties and objects, are the sorts of things we infer rather than directly apprehend. However, the causal power formulas in (5) and (6), and their variants for inhibitory and interactive cases, don't necessarily yield normatively correct estimates. Like other measures of causal effectiveness – main effect contrasts, ΔP , path analysis coefficients, and similar measures estimated directly from co-occurrence data – the power formulas don't always yield a normatively correct result. Glymour observes (2001: 87) that there "is an obvious reason why [the power method] will not be reliable: unobserved common causes. We have seen that the estimation methods [for generative and preventive powers] are generally insufficient when there are unobserved common causes at work, and often we have no idea before we begin inquiry whether such factors are operating." If we already know the structure of the causal environment, we can safely use power-like calculations to estimate the strength of particular pathways, and in this context, power may be a normative ideal. But this presupposes some way other than power to arrive at the correct structure.

Causation from Intervention

We're finally in a position to return to the claims at the beginning of this article about "great new ideas" for representing causation. One of these ideas is the use of multiple correlations or contingencies, as in the path-analysis theories we glimpsed in the previous section. Perhaps people represent a causal system as a graph connecting causes to effects, along the lines of Figures 1 and 3. These graphs embody statistical relations – the pattern of conditional probabilities among the depicted events – that put constraints on what can be a cause of what effect. At a psychological level, we might encode this pattern of contingencies and then find the best graph – or at least a good graph – that fits them. The resulting structure is our subjective theory or causal model of the reigning causal forces. You could complain that this isn't exactly a new idea, deriving as it does from data-analytic work by Wright in the 1920s (see Wright 1960 for a recap; see also Simon 1953). But perhaps it's an innovation to take such diagrams seriously as mental representations, mental causal maps. Further elaborations may constitute genuine advances. Let's see what these could be.

We noted that graphical representations of multiple-correlation systems are open to problems of confounding and underdetermination. The very same pattern of correlations and partial correlations can be equally consistent with very different causal graphs, as the Figure 3 example illustrates. Faced with this kind of causal indeterminacy, though, scientists don't always throw up their hands. They can sometimes bring experiments to bear in selecting among the alternative causal possibilities. In the case of Figure 3, for example, imagine an experiment in which a scientist explicitly manipulates factor A to change its value. You'd expect this experiment also to change the value of B in the set up of Figure 3a but not in that of Figure 3b. Intuitively, this is because manipulating a factor can have only forward influence on its effects, not backward influence on its causes. So intervention can discriminate the two causal frameworks. Of course, we can sometimes make the same discovery without getting our hands dirty if we know the time at which the factors change their values, since causes don't follow their effects in time. In the world of Figure 3a, observing a change in A should be followed by observing a change in B, but this is not the case in Figure 3b.

Manipulating factors, however, has an advantage that goes beyond merely clarifying temporal

relationships. By changing the value of a factor, we can often remove the influence of other factors that typically covary with it, isolating the former from confoundings. If we're interested, for example, in whether listening to Mozart improves students' math scores, we could randomly assign one set of students to listen to fifteen minutes of Mozart and another to fifteen minutes of silence before a math test. In doing so, we're removing the influence of intelligence, social class, and other background factors that could affect both a tendency to listen to Mozart and to do well on math tests. In the graph of Figure 3a, suppose factor A is the social class of students' families, B is intelligence, C is listening to Mozart, and D is test performance. Then the manipulation just described deletes the links from social class and intelligence to Mozart listening. In the experiment we're contemplating, students with more intelligence are no more likely to listen to Mozart than those with low intelligence. If we still find an effect of listening on test scores, this can assure us that Mozart listening affects the scores apart from the influence of the two background variables. This advantage for manipulating is due at least in part to the fact that intervention places additional constraints on the statistical relations among the variables (Pearl 2000). If we manipulate Mozart listening as just described, we're essentially creating a new graphical structure – Figure 3a minus the arrows from social class and intelligence to Mozart listening – and we're demanding that the correlations change in a way that conforms to this remodeling.

Recent evidence suggests that adults, children, and even rats are sometimes aware of the benefits of explicitly manipulating variables in learning a causal structure (Blaisdell, Sawa, Leising, and Waldmann 2006; Gopnik et al. 2004; Lagnado and Sloman 2005; Steyvers, Tenenbaum, Wagenmakers, and Blum 2003). For example, Gopnik et al. (2004) report an experiment in which four-year-olds observed a stage containing two "puppets" (simple rods with differently colored balls attached). The experimenter could move the puppets in two ways: either out of the view of the children (by reaching under the stage) or in their view (by pulling them up and down). The experimenter told the children that one of the puppets was special in that this puppet could make the other move. The children's task was to decide which was special – say, the yellow or the green one. Children first saw the yellow and green puppets moving together as the result of the exper-

imenter's concealed action. They then observed the experimenter explicitly pulling up the yellow puppet while the green puppet remained stationary. Under these conditions, 78 percent of the children could identify the green puppet as the special one. Because a child saw the experimenter manipulate the yellow puppet without any effect on the green one, he or she could reason that the yellow puppet couldn't have been responsible for their initial joint movement and, thus, that the green puppet must be the cause. Purely association-based or correlation-based theories have trouble accounting for results like these, since such models don't distinguish between event changes that result from interventions and those that result from noninterventions.

In more complex situations (and with college-age participants), however, the advantage for interventions is not as clear-cut (Lagnado and Sloman 2005; Steyvers et al. 2003). According to Lagnado and Sloman, any benefit for intervention in their experiments seems due to the simple temporal consequences mentioned earlier (that interventions must precede their effects) rather than to the statistical independencies that interventions create. Steyvers et al. (2003: Experiment 2) presented ten observational trials about a three-variable system. They then allowed participants a single intervention, followed by an additional ten trials based on that intervention. (No explicit temporal information was available during the observation or intervention trials.) Participants' ability to identify the correct causal structure increased from 18 percent before intervention to 34 percent after (chance was 5.6 percent); however, ideal use of the intervention in this experiment should have led to 100 percent accuracy.¹¹ This suggests that when the environment is simple (as in Gopnik et al. 2004) and people know there are only a small number of potential causal alternatives (e.g., X causes Y vs. Y causes X), they can use facts about interventions to test which alternative is correct. When the number of alternatives is larger, hypothesis testing isn't as easy, and the participants are less able to use the difference between observations and interventions to determine the causal arrangement. Investigators have also looked at participants' ability to use a previously learned causal structure to make predictions based on observations or interventions, and we will consider the results of these experiments in the section on reasoning later in this article. The present point is that the intervention/observation difference is not

very robust when people must go from data to causal structure.

Perhaps one reason why people don't always pick up on interventions is that – as every experimentalist knows – interventions don't guarantee freedom from confounding. The literature on causal nets sometimes suggests that intervening entails only removing causal connections – links from the immediate causes of the variable that's being manipulated (i.e., the independent variable). But manipulations typically insert a new cause into the situation that substitutes for the old one in controlling the independent variable, and sometimes the new cause comes along with extraneous connections of its own. Take the example of the Mozart effect. Randomizing participants to conditions removes the influence of intelligence and other participant-centered factors. But placing participants in a control group that has to experience fifteen minutes of silence may have an aversive effect that could lower test scores to a greater extent than would merely not listening to Mozart (see Schellenberg 2005). Figuring out the right manipulation isn't always an easy matter. Ambiguity about the possible effects of an intervention may lead participants to back off from using such cues during causal learning. Of course, you can define "intervention" as a manipulation that does not affect any variable other than the one intervened on (Gopnik et al. 2004; Hausman and Woodward 1999), but this is not much help to the working scientist or layperson, who often doesn't have advance knowledge of possible side effects of the manipulation.¹²

Reasoning from Causal Theories

We've just looked at the possibility that people discover causal relations by noticing the patterning of events in their surroundings. That method is problematic for both theoretical and empirical reasons. Theoretically, there is no limit on the number or complexity of potential causal relationships, and correlation is often unable to decide among these rival causal set ups. Empirically, there is no compelling evidence that people have hard-wired cause detectors, so people probably don't automatically derive causal facts from event perception. Moreover, our ability to infer cause from event co-occurrence seems to rely heavily on higher-level beliefs about what sorts of events can cause others, on beliefs about how events interact mechanistically, and on pragmatic pressures concerning what needs

to be explained. To make matters worse, knowledge about cause sometimes colors our knowledge about co-occurrence frequency or correlation.

The classic alternative strategy for deriving causal knowledge is a form of inference to the best explanation (Harman 1965). We can start with theories about the potential causes of some phenomenon and then check to see which theory best predicts the data. The theory that provides the best fit is the one that gives the right causal picture. Of course, this form of inference doesn't give us certainty about our causal conclusions, since it depends on the range of alternatives we've considered, on the validity of the tests we've performed, and on the goodness of the data we've collected. But *no* method yields certainty about such matters. What could give us a better idea about correct causal relations than the best explanation that exploits them? This approach reserves a place for observational data, but the place is at the receiving end of a causal theory rather than at its source.

This top-down strategy, however, yields a host of further psychological problems. We still need to know the source of our theories or hypotheses if they don't arise purely from observation. We also need to consider how people use causal theories to make the sorts of predictions that hypothesis testing depends on. In this last respect, the causal schemas or Bayes nets that we looked at earlier can be helpful. We noted that people don't always accurately construct such schemes from data, even when they're allowed to manipulate relevant variables. Nevertheless, once people settle on such a representation, it may guide them to conclusions that correctly follow.

Representing Causal Information: Causal Principles and Causal Theories

If we don't get causal information from innate perceptual cause detectors or from pure associative/correlational information, what's left?

CAUSAL PRIMITIVES

According to one top-down theory of causality, we have, perhaps innately, certain primitive causal concepts or principles that we bring to bear on the events we observe or talk about, primitives that lend the events a causal interpretation. Perhaps there is a single primitive causal relation, *cause*(x, y), that we combine with other concepts to produce more complex and specific

causal descriptions (e.g., Dowty 1979; McCawley 1968; Parsons 1990). Thus, we might mentally represent the sentence in (7a) as (7b):

- (7) a. John paints a picture
 b. cause (John paints, become (a picture exists))

Or perhaps there are several primitive causal relations or subtypes that vary in ways that distinguish among causing, enabling, and preventing, among others (e.g., Jackendoff 1990; Schank and Riesbeck 1981; Talmy 1988; Wolff, Klettke, Ventura, and Song 2005; see also Tufte 2006 for related conclusions about causal graphs).

I suggested earlier that there was no strong evidence to support the view that people have innate cause detectors in perception, but this is consistent with the possibility of innate causal concepts. The difficulty for the perceptual view is that scenes that are supposed to trigger causal impressions automatically can usually be interpreted noncausally. But this Humean way of thinking about the perceptual demonstrations is exactly what we should expect if our interpretation of the scenes depends on how we apply our causal concepts. Having an innate concept of cause doesn't mean that external stimuli can force us to apply it. But having an innate (perceptual) cause detector – an input module in Fodor's (1983) sense – presumably does.

Of course, the existence of these concepts doesn't mean that perceptual or contingency information plays no role in our judgments about causality, and it doesn't mean that babies appear on the scene already knowing everything about causation that adults do. Percepts and contingencies can provide evidence about what we should investigate to uncover possible causal connections; however, they don't ordinarily provide a direct route to such connections. Similarly, having a causal concept may be necessary in understanding causal systems, but exactly what causes what in a particular physical setting often requires further learning. Knowing that events can be connected causally doesn't automatically tell us, for example, how chemical reactions take place or how astronomical objects interact; it simply gives us one of the ingredients or building blocks. Infants may have some domain-specific theories in areas such as psychology (Carey 1985), biology (Atran 1998), or physics (Spelke, Breinlinger, Macomber, and Jacobson 1992) that provide more specific information about causal relations in these areas, but

even initial theories obviously undergo elaborations with experience and schooling, perhaps quite radical ones.

The existence of conceptually primitive causal concepts goes along with the idea that babies come equipped with the notions that events have causes, that the causes precede their effects, and that the causes bring about the effects in a mechanistic way. Bullock, Gelman, and Baillargeon (1982) propose principles along these lines – their Determinism, Priority, and Mechanism principles – and they suggest that children's and adults' later understanding of cause builds on these principles by adding information both about specific types of causal relations and about which environmental cues are most important when events interact. Preschoolers do not understand that rainbows are caused by scattering light, but they know that rainbows have some preceding mechanistic cause or other.

CAUSAL SCHEMAS

Many cognitive theories suggest that people maintain unified representations of causal systems. If the system is the CD player in Figure 1, then memory for this information would include the individual causal relations (corresponding to the arrows in the figure) together with some larger structure that specifies how they fit together. Some theories represent the structure in terms of propositions, as in (7b), with further embedding for more complex situations (e.g., Gentner 1983); other theories employ more diagrammatic representations, similar to Figure 1 itself. The unified representations in either case may speed search for the included facts, make the included information less susceptible to interference, and highlight certain inferences. Of course, a commitment to a unified representation still leaves room for some flexibility in the representation's abstractness and completeness. It's possible that causal schemas are relatively sparse, even for familiar causal systems (Rozenblit and Keil 2002), and they may sometimes amount to little more than top-level heuristics, such as "more effort yields more results" (diSessa 2000).

As cognitive representations, causal schemas don't necessarily carry explicit information about the statistical relations among the included events. It seems possible that people could possess a schema similar to that of Figure 1 and still fail to notice the implications it has for statistical dependencies and independencies,

such as the ones we considered earlier (see the section *Causation from Correlation*). What sets Bayes nets apart from other causal schemas in psychology is their tight connection to statistical matters. Bayes nets depend essentially for their construction on a property called the (Parental) Markov condition (Pearl 2000; Spirtes, Glymour, and Scheines 2000). This is the principle that conditioning on the states of the immediate causes (the “parents”) of a variable renders that variable statistically independent of all other variables in the net, except for those it causes (its “descendants”). Because the Markov principle is what determines whether a Bayes net contains or omits a link, the plausibility of Bayes nets as a psychological representation depends on the Markov condition. In the case of the CD player in Figure 1, holding constant whether the light strikes the diode will make the transmission of electrical signals independent of the rest of the variables in the figure. In the next section, we examine the empirical status of this assumption: Do people who know the causal connections in a system obey the Markov principle? In the meantime, we consider some theoretical issues that surround Bayes nets as cognitive schemas.

CAUSAL BAYESIAN NETWORKS AND FUNCTIONAL CAUSAL MODELS AS CAUSAL SCHEMAS

Although psychologists commonly cite Pearl (2000) as a source for the theory of Bayes nets, they gloss over the fact that Pearl presents three different versions of the theory that provide successively more complex accounts of causality. These versions of Bayes nets seem to correspond to stages in the theory’s evolution, with later versions placing more constraints on the representation. What Pearl refers to as “Bayesian networks” are directed graphs of variables and links that respect the Markov principle we just reviewed. What Bayesian networks depict are the pattern of statistical dependencies and independencies among a set of variables. If a set of variables X is statistically independent of another set Y given Z , then the graph displays these independencies (the graph is a *D-map* in Pearl’s 1988 terminology). Conversely, if the graph displays X as independent of Y given Z , then the probability distribution contains this independency (the graph is an *I-map*). For reasons mentioned in connection with Figure 3, however, Bayesian networks do “not necessarily imply causation” (Pearl 2000: 21), since several different networks can be equally consistent with the pattern of statistical dependencies and independencies in a data set.

To overcome this indeterminacy problem, Pearl moves to a reformulated representation called “causal Bayesian networks.” These networks have the same form as ordinary Bayes nets. They are still directed acyclic graphs (i.e., ones with no loops from a variable to itself), such as those in Figures 1 and 3. But causal Bayesian networks also embody constraints about interventions. These networks are answerable not just to the statistical dependencies inherent in the full graph of variables and links, but also to the statistical dependencies in the subgraphs you get when you manipulate or intervene on the variables. Within this theory, intervening on a variable means severing the connections from its parent variables and setting its value to a constant. For example, we could intervene on the “CD turns” variable in Figure 1 by disconnecting the CD holder from the motor and manually rotating it. Causal Bayes networks help eliminate the indeterminacy problem by requiring the representation to reflect all the new statistical relations that these interventions imply.

In the last part of Chapter 1 and in Chapter 7 of his book, Pearl (2000) moves to a third kind of representation: “functional causal models.” At first glance, there doesn’t seem to be much difference between causal Bayesian networks and functional causal models, and this might make Pearl’s claims about the latter models surprising. Functional causal models are given by a set of equations of a particular type that have the form in (8):

$$(8) \quad x_i = f_i(pa_i, u_i), \quad i = 1, 2, \dots, n.$$

Each of these equations specifies the value of one of the variables x_i on the basis of the immediate (parent) causes of that variable, pa_i , and an additional set of variables representing other unknown factors, u_i , that also affect x_i . In the case of Figure 1, for example, we can think of the node labeled CD turns as having the value 0 if the CD is not turning and 1 if it is turning. That is, $x_{CD} = 0$ means the CD is not turning and $x_{CD} = 1$ means that it is. This value will be determined by a function like that in (8), f_{CD} , that will depend on the value of the parent variable (whether the motor is turning) and of a variable u_{CD} (not shown in Figure 1) representing other unknown factors. Pearl considers a special case of this representation, called “Markovian causal models,” in which the graph is acyclic and the u terms are independent of each other, and he proves that Markovian causal models are consistent with exactly the same joint probability distributions as the corresponding causal Bayes

nets. "In all probabilistic applications of Bayesian networks . . . we can use an equivalent functional model as specified in [(8)], and we can regard functional models as just another way of encoding joint distribution functions" (Pearl 2000: 31).

So what's the advantage to functional causal models that we didn't already have with causal Bayesian nets? (From now on, let's call these "causal models" and "causal nets" for short.) We noticed in discussing causal nets that the definition of these nets was given, not in terms of causal mechanisms, but in terms of probabilities. A causal net is just a Bayesian network that captures additional probability distributions, namely, the ones we get by intervening on variables. With (Markovian) causal models, we are starting in the opposite direction, beginning with functions that completely determine the states of the variables rather than beginning with probabilities. This seems consistent with the lessons of the first half of this article. As Pearl (2000: 31) puts it, ". . . agents who choose to organize their knowledge using Markovian causal models can make reliable assertions about conditional independence relations without assessing numerical probabilities – a common ability among humanoids and a useful feature for inference." Everything operates in a deterministic way in causal models, with any uncertainty confined to our lack of knowledge about the values of the u_i 's. Moreover, the system's equations in (8) are not just arbitrary functions that happen to give the correct x_i values for cases we've observed. They reflect the actual causal determinants of the system, with pa_i and u_i being the true causes of x_i .

Pearl is explicit about the fact that an important benefit of causal models over causal networks is that the models deal correctly with counterfactual conditionals – statements of the form "If X had happened, then Y would have happened," like *If Fred had taken the trouble to fix his brakes, he wouldn't have had an accident*. It's been recognized at least since Goodman (1955) that there's a close connection between counterfactuals and causation. The truth of many counterfactual conditionals seems to depend on causal laws that dictate the behavior of events. These laws hold not just in our current state of affairs, but also in alternative states that differ from ours but still obey the laws in question. It's reasonable to think that the sentence about Fred is true or false because of the causal laws governing mechanical devices like brakes. If causal schemas are records of our understanding of causal laws, then they should enable us

to make judgments about counterfactual conditionals. Pearl is clearly right that if causal models support counterfactuals, then this gives them a leg up on ordinary causal nets. But in order to do this, the functions in (8) have to mirror these causal laws and must be constant over all causally possible situations. Pearl outlines a specific procedure that is supposed to answer counterfactual questions ("Would Y have happened if X had happened?") using causal models, and we'll look at the psychological plausibility of this hypothesis in more detail in discussing causal reasoning. It's clear, though, that knowledge of causal laws (from the f_i 's) and knowledge of the input states of the system (from the u_i 's) ought to give us what we need to simulate how the system will work in all the eventualities it represents, including counterfactual ones.

The direction of explanation that Pearl's analysis takes is from causality (as given by the causal functions in (8)) to counterfactuals. At first glance, though, the opposite strategy may also seem possible. Some philosophical analyses of causation – prominently, David Lewis's (1973) – interpret causation in terms of counterfactuals. If event e would not have happened had c not happened, then e causally depends on c, according to this analysis. Psychologists have occasionally followed this lead, deciding whether one event in a story causes a second according to whether people are willing to say that the second would not have happened if the first hadn't happened (Trabasso and van den Broek 1985). Lewis's theory of counterfactuals, however, depends on similarity among possible worlds, where similarity can, in turn, depend on causal laws. The counterfactual "If c had not happened then e would not have happened" is true just in case there is a world in which neither c nor e happens that is closer to the actual world than any world where c doesn't happen but e does. And whether one world is closer to the actual world than another depends at least in part on whether the causal laws of the actual world are preserved in the alternative. Lewis didn't intend his analysis to eliminate causal laws but to provide a new way of exploiting them in dealing with relations between individual events.¹³ So even if we adopt Lewis's theory, we still need the causal principles that the f_i 's embody (see the papers in Collins, Hall, and Paul 2004 for more recent work on the counterfactual analysis of cause).

Another possible complaint about causal models as psychological representations is that they don't come with enough structure to

explain how people are able to learn them (Tenenbaum, Griffiths, and Niyogi, in press). In figuring out how a device like a CD player works, we don't start out considering all potential networks that connect the key events or variables in the system. Instead, we take seriously only those networks that conform to our prior knowledge of what general classes of events can be causes for others. Because lasers are unlikely to turn motors, we don't waste time testing (or at least we give low weight to) causal models that incorporate such a link. According to Tenenbaum et al., people use higher-level theories to determine which network structures are possible, and this restricts the space of hypotheses they take into account. This objection seems right, since we do sometimes possess high-level knowledge (e.g., that diseases cause symptoms or that beliefs and desires cause actions) that shapes lower-level theories. Moreover, higher-level knowledge about causal laws seems necessary, given the restrictions on the f_i functions that we've just discussed. But even in Tenenbaum et al.'s more elaborate hierarchy, causal models are at center-stage, mediating higher-level theory and data. This leaves us with an empirical issue: Assuming the causal models are possible psychological representations, how well do they explain people's ability to reason from their causal beliefs?

Causal Reasoning

The phrase *causal reasoning* could potentially apply to nearly any type of causal thinking, including the types of causal attribution that we considered in the first part of this chapter. The issue there was how we reason *to* causal beliefs from data or other noncausal sources. Our considerations so far suggest that there may be relatively little reliable reasoning of this sort without a healthy dose of top-down causal information already in place. But how well are we able to exploit this top-down information? Once we know a batch of causal relations, how do we use them in drawing further conclusions?

CAUSAL INTERPRETATIONS OF INDICATIVE CONDITIONALS

Cognitive psychology has tip-toed up to the issue of how people reason from causal beliefs. A number of experiments have attempted to demonstrate that inferences from conditional sentences – ones of the form *If p then q* – can depend on whether the content of the conditionals suggests a causal relation (e.g., Cum-

mins, Lubart, Alksnis, and Rist 1991; Staudenmayer 1975; Thompson 1994). The conditionals in these experiments are indicatives, such as *If the car is out of gas, then it stalls*, rather than the counterfactual (or subjunctive) conditionals mentioned in the previous section (*If X had happened, then Y would have happened*). Because indicatives are less obviously tied to causal relationships than counterfactuals, people may reason with such conditionals in a way that does not depend on causal content.

What the results of these studies show, however, is that causal content affects people's inferences. For example, Thompson (1994) compared arguments like the ones in (9) to see how likely her participants were to say that the conclusion logically followed:

- (9) a. If butter is heated, then it melts.
The butter has melted.
Was the butter heated?
b. If the car is out of gas, then it stalls.
The car has stalled.
Is the car out of gas?

Arguments (9a) and (9b) share the same form in that both have the structure: *If p then q; q; p?* So if participants attend only to this form in deciding about the arguments, they should respond in the same way to each. However, people's beliefs about cars include the fact that running out of gas is just one thing that could cause a car to stall, whereas their beliefs about butter include the fact that heating butter is virtually the only way to get it to melt. If people lean on these beliefs in determining whether the conclusions logically follow, they should be more likely to endorse the argument in (9a) than the one in (9b), and indeed they do. The difference in acceptance rates is about forty percentage points. It is possible to argue about the role played by causal information versus more abstract logical information in experiments like these, and other aspects of the data show that participants aren't simply throwing away the *if...then* format in favor of their causal beliefs. For our purposes, however, the question is what such experiments can tell us about the nature of those causal principles.

Thompson (1994) and others view these results as due to people's knowledge of necessary and sufficient conditions (see also Ahn and Graham 1999). Heating butter is both necessary and sufficient for its melting, whereas running out of gas is sufficient but not necessary for a car stalling. Thus, given that the butter was melted, it was probably heated; but given the car has

stalled, it may not be out of gas. The same point is sometimes made in terms of “alternative” causes or “additional” causes (e.g., Byrne 1989; Byrne, Espino, and Santamaria 1999; Cummins et al. 1991; De Neys, Schaeken, and d’Ydewalle 2003; Markovits 1984). An alternative cause is one that, independently of the stated cause (e.g., running out of gas), is able to bring about the effect, and an additional cause is one that must be conjoined with the stated cause in order for the effect to occur. The explanation of the difference between (9a) and (9b) is therefore that participants know of no alternative causes for the conditional in (9a) that would block the inference, but they do know of alternatives for the conditional in (9b) – perhaps an overheated engine or a broken fuel pump. Giving participants further premises or reminders that explicitly mention alternative or additional causes also affects the conclusions they’re willing to draw (Byrne 1989; Byrne et al. 1999; De Neys et al. 2003; Hilton, Jaspars, and Clarke 1990).

The more general framing in terms of necessary and sufficient conditions, though, raises the issue of whether the experiments are tapping reasoning with specifically causal relations or with more abstract knowledge. Some of the same experiments cited earlier (Ahn and Graham 1999; Thompson 1994) demonstrate similar effects with conditionals that are about non-causal relations (e.g., conditional permissions such as *If the licensing board grants them a license, then a restaurant is allowed to sell liquor*). Likewise, you can interpret the results as due to participants’ use of conditional probabilities (Evans and Over 2004; Oaksford and Chater 2003). According to Oaksford and Chater (2003), for example, people’s response to the question in (9a) depends on the conditional probability that butter is heated given that it is melted, and the response to (9b) reflects the conditional probability that the car is out of gas given that it has stalled. Since the first of these is likely to be greater than the second, participants should tend to answer “yes” more often for (9a) than (9b). According to both the necessity/sufficiency and the probabilistic theories, people’s beliefs about causation informs the way they represent these problems, but their reasoning is carried out over representations that don’t distinguish causes from other relations.

REASONING WITH CAUSAL VERSUS INDICATIVE CONDITIONAL STATEMENTS

We may be able to get a more direct view of how people reason about causes by look-

ing at experiments that give participants statements containing the word *cause* or its derivatives. A number of studies have found that people make different inferences from statements of the form *p causes q* (or *q causally depends on p*) than from ones of the form *If p then q* (Rips 1983; Sloman and Lagnado 2005; Staudenmayer 1975). For example, Staudenmayer (1975) observed that participants were more likely to interpret explicit causal statements as implying a two-way, if-and-only-if, connection. For example, *Turning the switch on causes the light to go on* was more likely than *If the switch is turned on then the light goes on* to entail that the light goes on if and only if the switch is turned on. Many causal setups, however, don’t lend themselves to such an interpretation. *My turning on the switch causes the light to go on* is a case in point, since the light’s going on could be caused by someone else’s turning. Staudenmayer included examples like these, in which the cause is not necessary for the effect. But if causal statements don’t force an if-and-only-if interpretation, why the difference between causals and conditionals in the results? It seems possible that *cause* allows more freedom of interpretation than *if*. Although a two-way interpretation is possible for both *if* and *cause* in some situations (for pragmatic or other reasons), people may be more cautious about adopting it in the case of *if*.

In another respect, however, *cause* is more selective than *if*. Consider the arguments in (10):

- (10) a. If the gear turns then the light flashes.
The bell rings.
Therefore, if the gear turns then both the light flashes and the bell rings.
- b. The light flashing causally depends on the gear turning.
The bell rings.
Therefore, both the light flashing and the bell ringing causally depend on the gear turning.

The conclusion of (10a) seems to follow, since the conditionals are understood as statements about an existing state of affairs. The gear’s turning means that the light will flash, and since the turning presumably won’t affect the bell’s ringing, then if the turning occurs, so will the flashing and the ringing. Argument (10a) is valid in classical propositional logic, reading *if* as the truth functional connective “ \supset ” and *and* as “&.” There are many reasons to question whether natural language *if* is equivalent to \supset (see Bennett 2003 for a thorough review); but even if we treat

the *if*'s in (10a) as expressing probabilistic or default relations – for example, that the conditional probability of the flashing is high given the turning, or that the turning occurs when the flashing does, all else being equal – the inference in (10a) still seems a strong one. Not so (10b). Intuitively, the conclusion asserts a causal connection between the gear's turning and the bell's ringing that goes beyond anything asserted in (10b)'s premises. In line with this impression, I found that, although 60.2 percent of participants agreed that the conclusion of arguments like (10a) had to be true whenever the premises were true, only 31.0 percent agreed to the conclusion of items like (10b) (Rips 1983). (The relatively low overall percentage of responses is probably due to the fact that the full data set included several arguments with more complex structures than that of (10).)

These differences between *cause* and *if* reflect fundamental differences in their meaning. There are disputes about the correct formal semantics for conditional sentences (see Bennett 2003). But it is plausible to think that people evaluate them by temporarily supposing that the *if*-part (antecedent) of the sentence is true and then assessing the *then*-part (consequent) in that supposed situation (Ramsey 1929/1990; Stalnaker 1968).¹⁴ In these terms, *if* relates the current situation to a similar one (or similar ones) in which the antecedent holds. Conditionals can thus depend on circumstances that may not be a direct effect of the antecedent but simply carry over from the actual situation to the supposed one. This explains why we tend to judge that the conclusion of (10a) follows: Although the gear's turning doesn't cause the bell's ringing, nevertheless, the ringing occurs in the situation in which the gear turns. *Cause*, however, is not a sentence connective, but a predicate that connects terms for events. In order to create parallel structures between conditionals and causals in these experiments, investigators have to rephrase the antecedent and consequent as nominals (e.g., *the gear turns* in (10a) becomes *the gear turning* in (10b)), but the nominals still refer to events. Whether a causal sentence is true depends on exactly how these events are connected and not on what other circumstances may happen to hold in a situation in which the cause takes place. In this respect, causal sentences depend on the specifics of the cause-effect relation, just as ordinary predicates like *kiss* or *kick* do. Whether *John kisses Mary* is true depends on whether the appropriate relation holds between John and Mary, and whether the

gear's turning causes both the light's flashing and the bell's ringing likewise depends on whether the right causal connection holds between these events. The conclusion of (10b) fails to follow from the premises, since the premises entail no such connection.

This point about the difference between conditionals and causals may be an obvious one, but analyses of *cause* can sometimes obscure it. For example, some formal treatments of action, like McCarthy and Hayes's (1969) situation calculus, represent these actions (a type of cause) as a function from a situation that obtains before the action to one that obtains after it. But although we may be able to think of both *if* and *cause* as types of functions, the truth of a causal depends more intimately on the way in which the resulting state of affairs is brought about. We judge that "if *c* occurs then *e* occurs" on the basis of whether *e* holds in the situations that we get by supposing *c* is true, but this is not enough to support the assertion that "*c* causes *e*." Similarly, there are causal modal logics (e.g., Burks 1977) that represent the causal necessity or possibility of conditionals. Such logics, for example, can symbolize sentences of the type "It is causally necessary that if *c* occurs then *e* occurs," with the interpretation that "If *c* occurs then *e* occurs" in all possible worlds that retain the actual world's causal laws. However, causally necessary conditionals aren't equivalent to causals. It is causally necessary that if $5 + 7 = 12$ then $5 + 8 = 13$, since $5 + 7 = 12$ and $5 + 8 = 13$ are true in all possible worlds, including the causally necessary ones. But $5 + 7 = 12$ doesn't cause $5 + 8 = 13$ (or anything else, for that matter), since arithmetic facts don't have causal properties.

The experiments just mentioned provide evidence that people distinguish causal sentences from indicative conditional ones, even when the conditionals have causal content. The experiments have less to say, however, about the nature of causal reasoning itself. We'd like to know in more detail how accurately people recognize inferences that follow directly from causal relations. Two possibilities present themselves, both based on our earlier discussion of causal models. First, people who know the causal facts about a system should follow the causal Markov principle in estimating probabilities of the events these models encode. Second, people's predictions about the system's behavior should respect differences between interventions and observations. We'll see that although the evidence for the first of these predictions is weak, evidence for the second is more robust.

REASONING FROM CAUSAL MODELS: THE
CAUSAL MARKOV PRINCIPLE

We've seen that Bayesian causal models (Pearl 2000) provide an explicit representation of cause-effect relations, and they include normative constraints that should govern causal reasoning. In particular, causal models obey the causal Markov principle, which provides their structural basis and mirrors statistical dependencies. We can therefore get a closer look at causal reasoning by teaching people causal connections that compose such a model and checking whether they follow the Markov principle in drawing inferences from it.

In a pioneering study of this kind, Rehder and Burnett (2005) taught participants explicit causal relations about fictional categories, such as Lake Victoria shrimp or Neptune computers. For example, participants might be told that Victoria shrimp tend to have a high quantity of ACh neurotransmitter, a long-lasting flight response, an accelerated sleep cycle, and a high body weight. The participants learned that about 75 percent of category members have each of these features. They also learned the causal relations among these features, both verbally and in an explicit diagram. For example, these participants might learn the "common cause" pattern in Figure 4a, in which high levels of ACh neurotransmitter in Lake Victoria shrimp cause a long-lasting flight response, an accelerated sleep cycle, and a high body weight. Rehder and Burnett then tested the participants by giving them descriptions of a category member with an unknown feature and asking them to rate how likely the category member was to have that feature. How likely is it, for instance, that a Victoria shrimp with high ACh, a long flight response, but no accelerated sleep cycle, also has high body weight?

The interesting predictions concern the causal Markov condition: Conditioning on the states of the parent variables renders a child variable statistically independent of all other variables, except its descendants. In the case of the Figure 4a example, if we know whether a Lake Victoria shrimp has high (or low) ACh, then the values of the lower-level features – flight response and body weight, for example – will be statistically independent of each other. If we're trying to predict whether a shrimp has high body weight, it should matter a lot whether it has high or low ACh levels. But as long as we know its ACh level, we needn't worry about whether it has any of the sister features (a long flight response or an accelerated sleep cycle), since

these are not descendants of body weight. It shouldn't matter how many of these sister features the shrimp has, given that it has high (low) ACh.

What Rehder and Burnett (2005) found, however, is that participants systematically violated the Markov principle. Participants' estimates of the probability that a Lake Victoria shrimp has high body weight correctly depended on whether they were told it had high levels of ACh. But these estimates also increased if the shrimp had a long flight response and an accelerated sleep cycle, even when participants knew the state of the ACh level. (See Rehder 2006; Waldmann and Hagmayer 2005: Experiment 3, for evidence of similar violations in the case of causal systems other than categories.) Rehder and Burnett's participants had learned the common-cause structure in Figure 4a, which depicts the causal model, and the Markov principle is the central ingredient in defining the model. So why do participants flagrantly disregard the principle?

Rehder and Burnett propose that participants were indeed using causal nets, but nets with a configuration that differed from the one they learned. According to this theory, the participants were assuming that there is an additional hidden node representing the category member's underlying mechanisms. The network in Figure 4b illustrates this structure, containing the new hidden mechanism node with direct connections to all the observed nodes. According to Rehder and Burnett (2005: 37), "to the extent that an exemplar has most or all of the category's characteristic features, it also will be considered a *well functioning* category member. That is, the many characteristic features are taken as a sign that the exemplar's underlying causal mechanisms functioned (and/or are continuing to function) properly or normally for members of that kind. And if the exemplar's underlying mechanisms are operating normally, then they are likely to have produced a characteristic value on the unobserved dimension." Because participants obviously aren't told the state of the hidden mechanism, the sister nodes at the bottom of the figure are no longer statistically independent. Thus, participants' tendency to rely on these sister nodes no longer violates the Markov principle. Rehder and Burnett show in further experiments that this hidden-mechanism theory also predicts the results from experiments using different network structures – for example, a net consisting of a single chain of variables and a "common effect" net with multiple causes

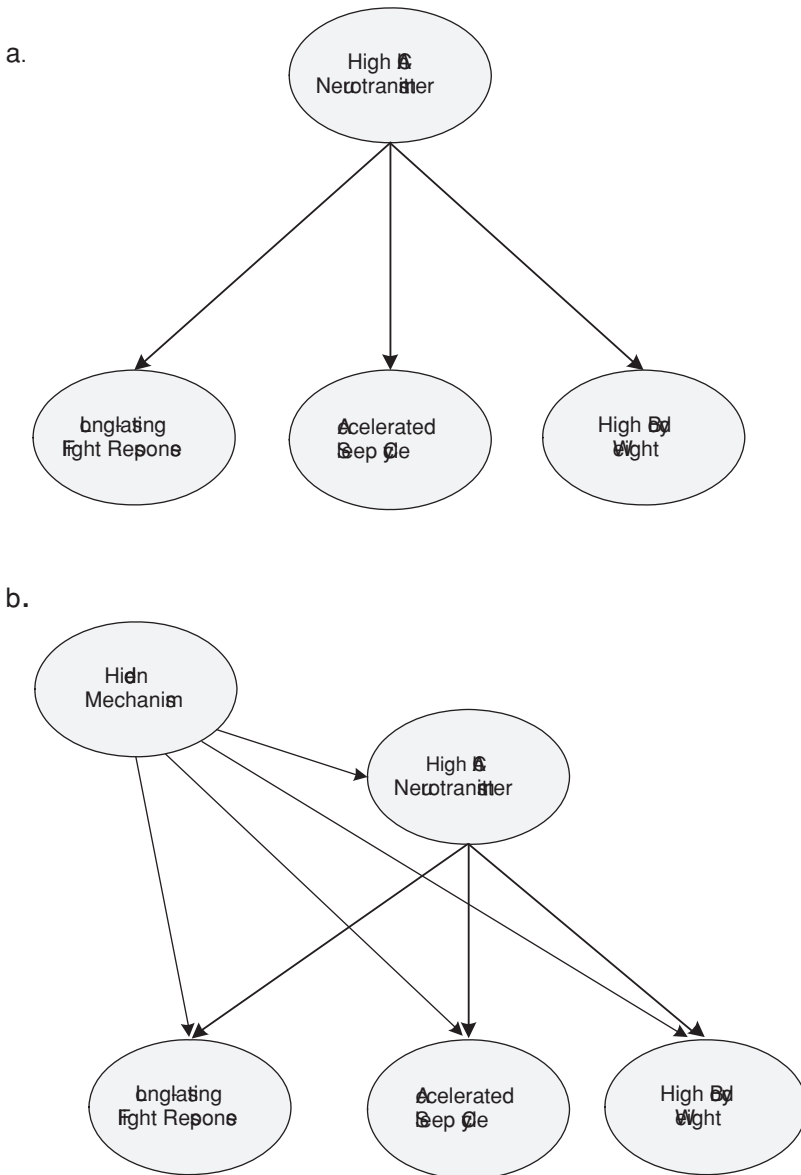

Figure 4. An example of the common cause condition from Rehder and Burnett (2005: Experiment 1). (a) The network participants learned, and (b) a possible alternative network to explain the empirical findings.

for a single effect. For the latter networks, the underlying mechanism idea seems quite plausible, and the theory is consistent with models of causal centrality and psychological essentialism (e.g., Ahn et al. 1995). Participants may suspect that a natural kind or complex artifact is likely to have some central cause or causes that hold the object together, an assumption that's in line with essentialist theories of categories (e.g., Gelman 2003; Medin and Ortony 1989). As Hausman

and Woodward (1999) note, applications of the causal Markov principle have to ensure that all relevant variables are included in the model, that the causal system is analyzed at the right level, and that the included variables are not logically or definitionally related.

For common cause structures such as Figure 4a, however, why would participants go to the trouble of positing an extra hidden mechanism when they already have an explicit

common cause? Rehder and Burnett (2005: Experiment 2) also found the same pattern of results – violations of the Markov constraint – when participants were taught a common cause structure like Figure 4a for a nonsense category, daxes, whose features were arbitrarily labeled A, B, C, and D. Even if hidden mechanisms are reasonable for shrimp and computers, where you might suppose there are underlying causes in addition to those taught in the experiment, it is harder to understand why you would posit them for an obviously fictitious category. Why would participants believe there are hidden mechanisms governing well-functioning daxes? You would at least expect some decrease in the non-independence effect when the category gives participants less reason to suppose that an underlying mechanism is at work. But there doesn't seem to be much, if any, difference in the extent of the violations for daxes versus known kinds and artifacts. Although it's possible that participants were positing hidden mechanisms, a simpler alternative might be that they were reasoning in a more primitive way. Perhaps they were assuming that the dominant values of a category's features tend to cluster together, without worry too much about the exact causal set up. Participants may have been short-cutting the Bayes net circuitry, relying instead on the belief that the more typical Lake Victoria shrimp features an item has, the more likely it is to have other Lake Victoria shrimp features. Ditto for daxes. Participants weren't completely ignoring the causal structure, since they recognized the role of direct causes. But they may have given little thought to implications for the indirectly connected variables.

REASONING FROM CAUSAL MODELS: OBSERVATION VERSUS INTERVENTION

In discussing whether people are able to infer causal nets from data (see *Causation from Intervention*), we found only limited support for the idea that people can exploit interventions in order to figure out the correct causal system. Although people use interventions within very simple systems, their ability to do so seems to fall off rapidly with even moderately complex networks. This difficulty may reflect general information-processing limits, since the number of possible causal nets (acyclic directed graphs) increases exponentially with the number of variables (see Rips and Conrad 1989). A more sensitive test of people's understanding of the intervention/observation difference is simply to

give people the relevant causal relations and see whether they can predict the effects of intervening on a variable versus observing its values.

Two series of experiments provide support for sensitivity to interventions. Sloman and Lagnado (2005: Experiment 6, p. 26) gave one group of participants the problem in (11):

- (11) All rocket ships have two components, A and B. Movement of Component A causes Component B to move. In other words, if A, then B. Both are moving. Suppose Component B were prevented from moving, would Component A still be moving?

A second group received the same problem, except that the final question was changed to *Suppose Component B were observed not to be moving, would Component A still be moving?* If an external process explicitly manipulates a variable – in this case, prevents Component B from moving – the internal causal connections to that variable are no longer in force, and we can't reliably use them to predict the state of the cause (Component A). By contrast, if normal internal causes are intact – if B is merely observed not to be moving – then the state of the effect provides diagnostic information about the cause. In line with this difference, 85 percent of participants responded "yes" to the intervention question, but only 22 percent did so for the observation question. A slightly more complicated problem, involving a chain of three variables instead of two, produced a similar difference between intervention questions and observation questions (Sloman and Lagnado 2005: Experiment 2). Waldmann and Hagmayer (2005: Experiment 1) also found an observation/intervention difference, using more complex five-variable systems that they presented to participants in both verbal and graphical formats.

It may seem odd, at first glance, that causal nets (or models) make correct empirical predictions in the case of the intervention/observation difference but largely incorrect predictions in the case of the causal Markov principle. This divergence might be due to differences between studies, but in fact, both results have appeared within the same experiment (Waldmann and Hagmayer 2005: Experiment 3). On second thought, though, there is no reason why these principles should necessarily hang together. We associate both the observation/intervention distinction and the Markov principle with causal nets because causal modelers have given clear formal treatments for both. And the Markov

principle, in particular, does seem tightly connected to causal nets because of the role it plays in their construction. But causal nets aren't the only way to formulate knowledge about interventions. The basic idea that you can't use the state of a manipulated variable to make inferences about its normal causes may simply be a piece of commonsense knowledge that's independent of the specific representation it gets in causal nets and models.¹⁵ Evidence for correct understanding of interventions is support for correct causal reasoning but not necessarily support for causal nets.

REASONING FROM CAUSAL MODELS:
COUNTERFACTUALS AND CAUSE

There's one more piece of the causal net puzzle we need to consider. We've noticed substantive differences, both theoretical and empirical, between indicative conditional sentences and related causal sentences, as in (10a) and (10b). We've also noticed a much closer conceptual link between counterfactual conditionals and causals (see *Causal Bayesian Networks and Functional Causal Models as Causal Schemas*). Pearl's (2000) move from causal nets to causal models, in particular, was due to the fact that causal models give a better formulation of counterfactual questions. Causal models, but not causal nets, can tell us whether a different effect would have occurred if a cause had taken a value other than its actual one. Do causal models correctly predict people's reasoning with counterfactuals?

To handle counterfactual statements within the causal-model framework, we need a set of structural equations, like those in (8), that specify the state of each variable in terms of the state of both its parents and of uncorrelated background factors or error terms. In the simplest possible case, consider a two-variable system, such as that in (11). We can assume for the sake of this example that the all variables are dichotomous, either on or off, which we will code as 1 or 0. We can then specify the f functions like this:

$$(12) \quad \begin{array}{l} \text{a. } f_A(u_A) = u_A \\ \text{b. } f_B(A, u_B) = A * u_B, \end{array}$$

where A is the variable for Component A, and B for Component B. In other words, Component A will operate ($A = 1$) provided that the error variable, u_A , has the value 1, and Component B will operate ($B = 1$) provided both that its error variable, u_B , is 1 and that Component A is operating as well.

To determine the answer to a counterfactual question in this case – for example, *Suppose Com-*

ponent B were not operating, would Component A still operate? – we follow a series of three steps, according to Pearl (2000: Theorem 7.1.7): We first update the probability of the background u variables, given the current evidence about the actual state of affairs. If we assume that the two components are operating in the actual state, as in (11), then $u_A = u_B = 1$. Second, we modify the causal model for an intervention on the event mentioned in the antecedent of the counterfactual. For the sample question just mentioned, we modify Component B in the usual way by orphaning B from its parent A and setting its value to a constant, while also keeping the u variables constant. This entails changing the equation in (12b) to:

$$(12) \quad \text{b'}. f_B(u_B) = 0,$$

since the antecedent states that Component B is not operating. Finally, to determine whether Component A would still operate, we compute its probability (i.e., the value of f_A) in the modified model, using the updated probabilities of the background variables. Since we have $u_A = 1$, the equation in (12a) gives us a positive answer.

According to the causal model framework, the answer to our sample counterfactual question should be exactly the same as what we would get if the question had directly mentioned the manipulation of Component B. For example, we should also get a "yes" to the question: *Suppose Component B were prevented from operating, would Component A still operate?* This question is also counterfactual and differs from the first one only in making the intervention explicit. Sloman and Lagnado's (2005) Experiment 5 directly compared answers to straight counterfactuals and prevention counterfactuals, but found a reliable difference between them (68% of participants answered "yes" to the straight counterfactual and 89% "yes" to the prevention counterfactual). A similar difference appeared for scenarios describing a slightly more complicated three-variable system (Sloman and Lagnado 2005: Experiment 2). One group of participants rated the answer to a straight counterfactual (e.g., *What is the probability that A would have happened if B had not happened?*), while a second group rated an explicit prevention counterfactual (*Someone intervened directly on B, preventing it from happening. What is the probability that A would have happened?*). The average probability rating for the straight counterfactual was 3.2 on a 1–5 response scale (1 = very low, 5 = very high probability), whereas the average was 3.9 for the prevention version. Although

Sloman and Lagnado don't compare these means statistically, they do report that the first was not significantly higher than the scale midpoint (3.0), whereas the second was significantly higher than the midpoint.

Because counterfactuals were the main reason for introducing causal models (as an alternative to causal nets), it's important to see why these predictions fail. It is possible that participants are behaving in nonnormative ways in the experiments just cited, but we should also consider the possibility that the procedure itself gives an incorrect account of how counterfactuals should be understood. One thing that seems clear is that Pearl's (2000) procedure can't evaluate all reasonable counterfactuals. As he points out, the procedure is useless with "backtracking" counterfactuals that hypothesize what would have happened prior to a supposed event. For example, Sentence (13) posits an event – getting an F in a course – and gives an earlier event as a probable cause:

- (13) If Fred had gotten an F in Theoretical Billiards in June, then it would have had to have been the case that he had forgotten to do his homework during the entire month of May.

Backtracking counterfactuals are sometimes clumsy to express because of tense shifts and modality, but there is no reason to think they are incoherent or uninformative. However, we would be unable to understand or evaluate backtracking counterfactuals if we had to sever the effect from its normal parent causes, since it's precisely the cause that is in question. Backtracking counterfactuals take the proposition expressed in the antecedent of the counterfactual as diagnostic of the proposition in the consequent.

Perhaps we should follow Pearl (2000) in setting aside backtracking counterfactuals and taking his procedure as a proposal about forward counterfactuals only. However, even forward counterfactuals may depend on how the hypothetical cause was brought about. Imagine that Fred's F could have been the result of two possible causes: his failure to do his homework or negligence on the part of his instructor. Then our evaluation of the truth of the forward counterfactual in (14) will depend on which of these causes we believe is the correct one:

- (14) If Fred had gotten an F in the course, his instructor would have been disciplined.

As it actually happened, Fred finished his homework, his instructor was diligent, and Fred got a C. If we hold background variables constant, snip the relevant causal connections (between Fred's homework and his grade and between the instructor's behavior and his grade), and then set the grade to F, how do we determine whether the counterfactual is true or false? Intuitively, our judgment about the sentence would seem to depend on the likelihood that Fred did his homework. On one hand, if he's a marginal student, then the cause of his F is probably his own doing, and it's unlikely that the instructor will be disciplined. On the other hand, if Fred is a model student, then it may be more likely that the cause of the F was the instructor's negligence. The problem is that cutting the connection between the state of Fred's homework and his course grade renders the probability of these variables independent, and this means that the probability that his instructor will be disciplined is also independent of the homework.

The motive for cutting causal ties to the past is clear. In a deterministic system, such as those conforming to (8), no change to the actual event can occur without some alteration to its causes. To envision Fred receiving an F rather than a C, we have to envision a world in which some of the causes that produced his grade are no longer in force. We must also construct this alteration leaving as much as possible of the causal fabric of the world intact, since arbitrary changes to preceding causes give us no way to determine whether a counterfactual sentence is true or false. But although some minimal break with the past is necessary, it isn't always correct to make this break by causally isolating the event mentioned in the antecedent of the counterfactual. As the examples in (13) and (14) show, we may have to trace back to some of the causes of the antecedent event in order to see which of them is most likely to have produced the alteration. Determining which of the preceding causes must be changed may depend on which is most mutable (Kahneman and Miller 1986), as well as which is powerful enough to bring about the new effect.¹⁶

These reflections may help explain the differences between straight counterfactuals and prevention counterfactuals in Sloman and Lagnado's (2005) experiments. Prevention counterfactuals require explicit manipulation of the event that the antecedent of the conditionals describes. The scenario in (11) suggests that if someone had prevented Component B from operating, the intervention occurred directly at

B (perhaps by disrupting its internal mechanism). But the straight counterfactual (i.e., *Suppose Component B were not operating, would Component A still operate?*) allows more room for interpretation. We're free to imagine different ways for B to have stopped operating, some of which might plausibly involve the failure of A. Although it might seem that a world in which both A and B fail is causally more distant from the actual workaday world than one in which only B fails, this depends on details that the scenario in (11) does not supply. Stopping B by direct action on B may be more disruptive than stopping B by stopping A. There is simply no way to tell. This ambiguity is related to one we have met before in our study of causal models (in the section *Causation from Intervention*). We noted that intervening on an event means more than removing an old cause. It also entails substituting a new cause, and the way in which the intervener does this can have important consequences for what follows in the world of the intervention. The present point is that if all we know is that some event has changed from the actual situation to a counterfactual one, we have an even larger choice of mechanisms for understanding that change.

The difficulty with Pearl's (2000) account of counterfactuals doesn't mean we necessarily have to give up causal models. There may be other theories of counterfactuals based on causal schemas that provide better approaches to cases such as (13)–(14).¹⁷ Nevertheless, people's representations of causal models are necessarily incomplete depictions of event interactions, since any event has a causal history stretching back over enormous temporal distances. We can indicate our ignorance about these prehistories by including explicit representations of uncertainty, such as Pearl's *u* variables. But part of our causal reasoning consists in filling in some of these missing pieces, for example, in considering what sort of disturbance or manipulation could have brought about a hypothetical event. Severing preexisting connections in a model often won't be enough to explain these circumstances, since they may involve bringing in new mechanisms that we hadn't previously represented as parts of the model.

Concluding Comments

Causal theorizing must be essential, both in everyday thinking and scientific endeavors, but it is unclear how people accomplish it. The

implication of the first part of this paper is that we probably don't do such thinking by strictly bottom-up observation. We can interpret simple displays of colliding geometric shapes as instances of pushings, pullings, and other causal events. Similarly, we can interpret other swarming movements of geometrical shapes as instances of actions – for example, chasings, catchings, and fightings, as Heider and Simmel (1944) demonstrated. But we can also take a more analytical attitude to these displays, interpreting these movements as no more than approachings, touchings, and departings with no implication that one shape caused the other to move. There is no evidence to suggest that the causal interpretations are hardwired or impenetrable in the way standard perceptual illusions often are. The evidence is consistent with the idea that we see these demos as causal, but probably only in the way that we see certain visual arrays as cows or toasters. This suggestion is reinforced by the fact that, although seven-month-old infants may register some of these animations as special, others that adults report as causal are not distinctive for these infants. Of course, doubts about innate perceptual causality detectors needn't extend to doubts about innate causal concepts, but it seems likely that causal concepts, innate or learned, must have sources that aren't purely perceptual.

Are the sources of causality co-occurrence frequencies? Here there are both empirical and conceptual difficulties. On the empirical side, people are obviously limited in which potential causes they can test using frequency-based methods, and there is no theory of how they search through the space of these causes. Moreover, even when an experimenter tells participants about the relevant candidates and provides the relevant frequencies, the participants appear guided by prior hypotheses in their evaluation of the data. Theoretically, the frequency-based or correlation-based methods – main effect contrasts, ΔP , conditional ΔP , Rescorla-Wagner strength, power, and path coefficients – all give incorrect answers in certain causal environments, especially when there are hidden confounding factors. Explicit manipulation or intervention can remove some of the ambiguities by eliminating the confoundings, just as in scientific experiments, but current research suggests that people are often unable to make use of such information, except in very simple settings. The empirical results are generally in line with the conclusions of Waldmann (1996) and others that

people pursue knowledge of cause in a largely top-down fashion. The theoretical results are in line with the conclusion that this might be the correct way for them to pursue it.

A top-down approach implies that people begin with hypotheses when they assess or reason about cause. But this leaves plenty of room for variation. Causal hypotheses could be anything from fragmented bits of information about a system to highly integrated and consistent theories. It's clear that people can reason with causal information and that this reasoning differs (sometimes appropriately) from what they do with similar indicative conditionals. It also seems likely that people's causal knowledge of a situation is not entirely isolated into units at the grain of individual atomic propositions (e.g., Rumelhart 1975). It is very unclear, though, what else we can say about such representations.

Bayes nets present one way of representing causal information in schematic form, and these nets provide many advantages in understanding causal situations, especially in the context of data-mining and analysis. They provide a way to factor a situation into statistically independent parts, and they therefore clarify the kinds of conclusions that we can draw from specific observations and experiments. In particular, they delimit the cases in which traditional statistical methods, such as regression or factor analysis, are likely to lead to the right results. Should we also take Bayes nets to be the mental representations that people ordinarily use to store causal facts in memory? Bayes nets go beyond a vague commitment to causal schemas in this respect, since they embody strong assumptions about the relation between the causal links in the model and statistical regularities, and they generate predictions about how people could reason about interventions and counterfactuals. They may well be consistent with the way people learn about new causal situations, though they may require additional constraints or heuristics to achieve this. In simple cases that include a small number of variables, they produce correct predictions for both children's and adults' reasoning. There seems little doubt, for example, that people observe the distinction between observation and intervention that Bayes nets embody.

On the other side of the balance, there is very little evidence that people observe the causal Markov condition, the key ingredient in Bayes net's construction. All versions of Bayes nets tie the presence and absence of causal links to the presence and absence of statistical depen-

dencies in the data. But participants' reasoning with causal information doesn't always agree with predictions based on these dependencies. Although we can interpret the results of these experiments on the assumption that the participants are reasoning with Bayes nets that are different from the ones they are taught, there is currently little positive evidence that the Markov principle constrains people's causal reasoning. And without the Markov principle, we're back to a position not much different from ideas about cognitive schemas, models, scripts, frames, or theories that preceded Bayes nets.

Bayes nets are also oddly inarticulate as cognitive representations. Proponents of Bayes nets have generally been uninterested in the way in which people express causal regularities, presumably because people's talk about cause is filtered through pragmatic channels, obscuring their underlying beliefs. But, although this can be true, it's also the case that people's causal reasoning depends on whether a cause or set of causes is necessary or sufficient, as the literature on causal conditionals attests. Likewise, reasoning depends on the differences between independent ("alternative") and interactive ("additional") causes. While we can derive information of this sort from the underlying conditional probabilities that Bayes nets capture, we can't get them from the graphs themselves. Two arrows running into an effect could equally represent two independent, individually sufficient causes of that effect or two causes that are only jointly sufficient. The same is true for contributory versus inhibitory causes. In addition, people make a wealth of adverbial distinctions in the way that causation comes about. They distinguish, for example, between pushings, shovings, and thrustings in ways that don't seem recoverable from the bare networks or even from their underlying conditional probabilities or functional equations. These limits on expressibility may not be fundamental ones, but they do lessen the appeal of Bayes nets as cognitive maps of our causal environment.

To accord with the facts about human causal thinking, we need a representation that's less nerdy – less tied to statistical dependencies and more discursive. This doesn't mean that we should jettison Bayes nets' insights, especially insights into the differences between intervention and observation. But it does suggest that we should be looking for a representation that better highlights people's talents in describing and

reasoning about causation and downplays ties to purely quantitative phenomena.

Notes

- 1 I'm grateful to Jonathan Adler, Russell Burnett, Douglas Medin, Brian Scholl, and to undergraduate and graduate students in courses on causal reasoning at Northwestern for comments on this paper.
- 2 Michotte (1963) is inconsistent on how to understand these reports. On the one hand, he emphasizes the phenomenal character of the observers' experiences: "Now the responses in these conditions given by the subjects always relate, of course, to the physical 'world'... But the physical 'world' in question here is no longer the world of physical *science*, as revealed by measuring instruments; it is *the world of things*, as it *appears to the subject* on simple inspection, his 'phenomenal world', disclosed in this case by the indications which he gives as a human 'recording instrument'. Thus, when he says that A 'pulls B' or 'pushes B', he is referring to an event occurring in a world which appears as external to him, an event of which he thinks himself simply a witness and which he is merely describing" (p. 306). But one page later, on the other hand, Michotte retreats to a position in which statements about what an observer sees are no more than abbreviations for what the observer reports: "Throughout this book there often occur expressions such as 'what the subject sees', or 'the impression received by the subject', and so on. These expressions are clearly only abbreviations, and are used to make the text less cumbersome. They in fact refer to the subjects' verbal responses and they therefore mean 'what the subject says or asserts that he sees' or 'that of which the subject says or asserts that he has an impression', and so on" (p. 307, note 5, emphasis in the original in both these passages).
- 3 Fodor (2003: Ch. 3) argues that even if observers directly perceive an event in the display, it's likely to be a lower-level one like square x pushing another y (which is indeed what observers report, according to Michotte) rather than square x causing y to move. There's no reason to think, according to Fodor, that perceiving an event like a pushing entails perceiving the causing. Although x *pushes* y may imply x *causes* y to *move*, we may get the causing from the pushing by inference rather than by direct perception. This distinction may seem unimportant to investigators, who may be satisfied that at least one type of causal interaction (pushing or launching) is directly perceived, but it is a reminder that the conclusions about direct perception have limited scope.
- 4 There is some debate about the exact age at which infants are first able to perceive causal interactions as such. See Cohen and Oakes (1993) for the view that infants don't fully grasp the launching interactions as causal until seven to ten months. The exact age, however, is not crucial for the issues addressed here, though the extent to which infants' recognition of causal interactions changes with experience is important. What's of interest in the present context is that infants appear to recognize oblique launching events later than linear ones.
- 5 For example, according to a methodology textbook by Pelham and Blanton (2003), "Most researchers who wish to understand causality rely heavily on the framework proposed by the 19th-century philosopher John Stuart Mill" (p. 63). Similarly, Cook and Campbell (1979) note, "A careful reading of chapters 3 through 7 will reveal how often a modified form of Mill's canons is used to rule out identified threats to valid inference" (p. 19). Or, in more detail, "The conditions necessary for arriving at explanations were set forth in the nineteenth century by the philosopher John Stuart Mill. . . . Mill argued that causation can be inferred if some result, X , follows an event, A , if X and A vary together and if it can be shown that event A produces result X . For these conditions to be met, what Mill called the **joint method of agreement and difference** must be used. In the joint method, if A occurs then so will X , and if A does not occur, then neither will X " (Elmes, Kantowitz, and Roediger 1999: 103, emphasis in the original). The joint method is the third of Mill's canons, which he regarded as superior to the method of agreement but inferior to the method of difference.
- 6 There is also a normative problem with ΔP (as Cheng 1997 argues). Since ΔP does not take into account the presence of other causes, it can yield a misleading index of the strength of any particular cause. For example, if other causes usually bring about the effect, then ΔP for the target cause will be systematically too small. In general, measures of causal strength run into normative difficulties by ignoring the structure of the causal system (e.g., the possible presence of confounding factors). Glymour (2001) shows that this problem affects not only ΔP but also conditional ΔP , Rescorla-Wagner strength, power, multiple regression coefficients, and others.
- 7 Chapman and Robbins (1990) and Cheng (1997) prove that under simplifying assumptions Rescorla and Wagner's (1972) theory of associative conditioning reduces to ΔP . (In general, however, the equivalence does *not* hold; see Glymour 2001 citing earlier work by Danks.) A prominent member of my own faculty once declared that no graduate student from our cognitive program should get a Ph.D. without

having studied the Rescorla-Wagner model. So here's the idea: Suppose that a creature is learning a relation between a set of conditioned stimuli C_1, C_2, \dots, C_n (e.g., lights, tones, etc.) and an unconditioned stimulus U_j (e.g., shock). Then the change to the associative strength, ΔV_i , of a particular stimulus C_i on any trial is a function of the difference between the asymptotic level of strength that's possible for the unconditioned stimulus and the sum of associative strengths for all the conditioned stimuli:

$$\Delta V_i = \alpha_i \beta_j (\lambda_j - \sum V_k),$$

where α_i is the salience of cue C_i , β_j is the learning rate for U_j ($0 \leq \alpha, \beta \leq 1$), λ_j is the asymptotic level of strength possible for U_j , and the sum is over all cues in C_1, C_2, \dots, C_n present on the trial. The asymptote λ will have a high value (> 0) when the unconditioned stimulus is present and a low value (perhaps 0) when it is absent on a trial. No change occurs to the strength of C_i if it is not present on a trial ($\Delta V_i = 0$). The important thing to notice is that the change in strength for an individual cue depends on the strength of all others present. See Shanks and Dickinson (1987) for a discussion of the Rescorla-Wagner theory and other learning models as applied to causal judgments.

- 8 Psychologists tend to see ANOVA methods as superior to correlational ones in isolating the cause of some phenomenon. But as far as the statistics goes, there's no important difference between them, since ANOVA is a special case of multiple correlation/regression. The perceived difference between them is due to the fact that psychologists use ANOVA to analyze designed experiments but use correlations to analyze observational ones. Manipulation does have advantages over passive observation for reasons discussed in the following section.
- 9 "Simpson's paradox" is not a true paradox but an algebraic consequence of the fact that the difference between each of two proportions $a/b - c/d$ and $e/f - g/h$ can be positive (negative) while the aggregate difference $(a + e)/(b + f) - (c + g)/(d + h)$ can be negative (positive), as the numbers in Table 2 illustrate. Simpson (1951: 240) pointed out that this leaves "considerable scope for paradox and error" in how we interpret the two-way interaction between the remaining factors (i.e., the two that don't define the partition between a-d and e-h). For example, should we say that irradiation is positively or negatively related to the quality of fruit in Table 2?
- 10 These cases also may violate assumptions necessary in deriving p_c and, if so, lie outside the domain of the power theory (see Luhmann and Ahn 2005).
- 11 It's also difficult to tell how much of the improvement after interventions in Stevyers et al. (2003) is due to the extra trials rather than to the interventions themselves. That is, part of participants' increased ability to identify the correct causal structure may have been the result of a larger amount of data and not to interventions per se.
- 12 A variation on an example of Sloman's (2005: 57–59) illustrates the same ambiguity. Suppose peptic ulcers result either from bacterial infections of a certain sort or from taking too many aspirin and similar drugs. Peptic ulcers, in turn, cause burning pains in the gut. In this situation, we may be able to intervene on someone's ulcer by administering a drug – Grandma's special formula, in Sloman's example – that cures the ulcer and thereby relieves the pain. But what should we conclude about whether the bacteria or the aspirin continue to be present after the intervention? The natural thing to say is that this depends on how Grandma's formula works. If it acts as a kind of barrier that protects the stomach lining, then perhaps the presence of the bacteria or the aspirin is unchanged. But if it works by destroying the bacteria and neutralizing the aspirin, then, of course, neither will exist after the intervention. Sloman is careful to stipulate that Grandma's special formula "goes directly to the ulcer, by-passing all normal causal pathways, and heals it every time." But how often do we know in the case of actual interventions that they route around all normal causal channels? Isn't the more usual case one where the intervention disrupts some causal paths but not others and where it may be unclear how far upstream in the causal chain the intervention takes place?
- 13 The old way involved deducing causal relations between individual events from general "covering" laws plus particular statements of fact (see Hempel 1965).
- 14 Of course, a suppositional theory needs to be worked out more carefully than can be done here. In particular, the supposition can't be such as to block all modus tollens arguments that entail the falsity of the conditional's antecedent. For a recent attempt to construct such a theory, see Evans and Over (2004).
- 15 This isn't to say there is no relation between the causal Markov condition and the idea of intervention. Hausman and Woodward (1999: 553) argue that "the independent disruptability of each mechanism turns out to be the flip side of the probabilistic independence of each variable conditional on its direct causes from everything other than its effects." But their argument requires a number of strong assumptions (each variable in the Bayes net must have unobserved causes and these unobserved causes can affect only one variable) that may not always be true of the representations people have of causal systems. See Cartwright (2001) for a

- general critique of the causal Markov condition, and Cartwright (2002) for a specific critique of Hausman and Woodward's "flip side" claim.
- 16 Morteza Dehghani and Rumen Iliev have suggested factors like these in conversation.
- 17 In one promising account, Hiddleston (2005) proposes a causal network theory of counterfactuals that improves on Pearl (2000). Given a causal network with variables A and C , we can evaluate the truth of the counterfactual *If $A = a$ then $C = c$* by considering all minimally different assignments of values to variables in the network such that $A = a$. If $C = c$ is true in all these minimal assignments, then so is *If $A = a$ then $C = c$* . As assignment is minimally different, roughly speaking, if (a) it has as few variables as possible whose value is different from that in the actual situation but all of whose parents have the same values, and (b) among the variables that are not effects of A , it has as many variables as possible whose values are the same as in the actual situation and all of whose parents are also the same. As Hiddleston notes, this theory allows for backtracking counterfactuals such as (13). It is unclear, however, whether this theory can capture people's intuitions about the truth of (13)–(14) and their kin. Assume a model in which turning in homework and instructor diligence are both causes of getting a grade and in which instructor diligence and the grade cause discipline of the instructor. Then there are at least two minimal models of (13)–(14) in which Fred gets an F: In one of them, Fred does his homework, the instructor is negligent, Fred gets an F, and the instructor is disciplined. In the other, Fred forgets his homework, the instructor is diligent, Fred gets an F, and the instructor is not disciplined. Since Fred does his homework in one of these models but not in the other, (13) is false, according to the theory. Similarly, for (14). As already noted, however, people's judgment of (13)–(14) may depend on how easily they can imagine the change to Fred's grade being brought about by lack of homework versus instructor negligence.

Chapter 30: Causation

DAVID LEWIS

Hume defined causation twice over. He wrote “we may define a cause to be *an object followed by another, and where all the objects, similar to the first, are followed by objects similar to the second.* Or, in other words, *where, if the first object had not been, the second never had existed.*”¹

Descendants of Hume’s first definition still dominate the philosophy of causation: a causal succession is supposed to be a succession that instantiates a regularity. To be sure, there have been improvements. Nowadays we try to distinguish the regularities that count – the “causal laws” – from mere accidental regularities of succession. We subsume causes and effects under regularities by means of descriptions they satisfy, not by overall similarity. And we allow a cause to be only one indispensable part, not the whole, of the total situation that is followed by the effect in accordance with a law. In present-day regularity analyses, a cause is defined (roughly) as any member of any minimal set of actual conditions that are jointly sufficient, given the laws, for the existence of the effect.

More precisely, let C be the proposition that c exists (or occurs) and let E be the proposition that e exists. Then c causes e , according to a typical regularity analysis,² iff (1) C and E are true; and (2) for some nonempty set \mathcal{L} of true law-propositions and some set \mathcal{F} of true propositions of particular fact, \mathcal{L} and \mathcal{F} jointly imply $C \supset E$, although \mathcal{L} and \mathcal{F} jointly do not imply E and \mathcal{F} alone does not imply $C \supset E$.³

Much needs doing, and much has been done, to turn definitions like this one into defensible analyses. Many problems have been overcome. Others remain: in particular, regularity analyses tend to confuse causation itself with various

other causal relations. If c belongs to a minimal set of conditions jointly sufficient for e , given the laws, then c may well be a genuine cause of e . But c might rather be an effect of e : one which could not, given the laws and some of the actual circumstances, have occurred otherwise than by being caused by e . Or c might be an epiphenomenon of the causal history of e : a more or less inefficacious effect of some genuine cause of e . Or c might be a preempted potential cause of e : something that did not cause e , but that would have done so in the absence of whatever really did cause e .

It remains to be seen whether any regularity analysis can succeed in distinguishing genuine causes from effects, epiphenomena, and preempted potential causes – and whether it can succeed without falling victim to worse problems, without piling on the epicycles, and without departing from the fundamental idea that causation is instantiation of regularities. I have no proof that regularity analyses are beyond repair, nor any space to review the repairs that have been tried. Suffice it to say that the prospects look dark. I think it is time to give up and try something else.

A promising alternative is not far to seek. Hume’s “other words” – that if the cause had not been, the effect never had existed – are no mere restatement of his first definition. They propose something altogether different: a counterfactual analysis of causation.

The proposal has not been well received. True, we do know that causation has something or other to do with counterfactuals. We think of a cause as something that makes a difference, and the difference it makes must be a difference from

what would have happened without it. Had it been absent, its effects – some of them, at least, and usually all – would have been absent as well. Yet it is one thing to mention these platitudes now and again, and another thing to rest an analysis on them. That has not seemed worthwhile.⁴ We have learned all too well that counterfactuals are ill understood, wherefore it did not seem that much understanding could be gained by using them to analyze causation or anything else. Pending a better understanding of counterfactuals, moreover, we had no way to fight seeming counterexamples to a counterfactual analysis.

But counterfactuals need not remain ill understood, I claim, unless we cling to false preconceptions about what it would be like to understand them. Must an adequate understanding make no reference to unactualized possibilities? Must it assign sharply determinate truth conditions? Must it connect counterfactuals rigidly to covering laws? Then none will be forthcoming. So much the worse for those standards of adequacy. Why not take counterfactuals at face value: as statements about possible alternatives to the actual situation, somewhat vaguely specified, in which the actual laws may or may not remain intact? There are now several such treatments of counterfactuals, differing only in details.⁵ If they are right, then sound foundations have been laid for analyses that use counterfactuals.

In this chapter, I shall state a counterfactual analysis, not very different from Hume's second definition, of some sorts of causation. Then I shall try to show how this analysis works to distinguish genuine causes from effects, epiphenomena, and preempted potential causes.

My discussion will be incomplete in at least four ways. Explicit preliminary settings-aside may prevent confusion.

1. I shall confine myself to causation among *events*, in the everyday sense of the word: flashes, battles, conversations, impacts, strolls, deaths, touchdowns, falls, kisses, and the like. Not that events are the only things that can cause or be caused; but I have no full list of the others, and no good umbrella-term to cover them all.
2. My analysis is meant to apply to causation in particular cases. It is not an analysis of causal generalizations. Presumably those are quantified statements involving causation among particular events (or non-

events), but it turns out not to be easy to match up the causal generalizations of natural language with the available quantified forms. A sentence of the form "*C*-events cause *E*-events," for instance, can mean any of

- (a) For some *c* in *C* and some *e* in *E*, *c* causes *e*.
- (b) For every *e* in *E*, there is some *c* in *C* such that *c* causes *e*.
- (c) For every *c* in *C*, there is some *e* in *E* such that *c* causes *e*, not to mention further ambiguities. Worse still, 'Only *C*-events cause *E*-events' ought to mean
- (d) For every *c*, if there is some *e* in *E* such that *c* causes *e*, then *c* is in *C*.

if 'only' has its usual-meaning. But no; it unambiguously means (b) instead! These problems are not about causation, but about our idioms of quantification.

3. We sometimes single out one among all the causes of some event and call it "the" cause, as if there were no others. Or we single out a few as the "causes," calling the rest mere "causal factors" or "causal conditions." Or we speak of the "decisive" or "real" or "principal" cause. We may select the abnormal or extraordinary causes, or those under human control, or those we deem good or bad, or just those we want to talk about. I have nothing to say about these principles of invidious discrimination.⁶ I am concerned with the prior question of what it is to be one of the causes (unselectively speaking). My analysis is meant to capture a broad and nondiscriminatory concept of causation.
4. I shall be content, for now, if I can give an analysis of causation that works properly under determinism. By determinism I do not mean any thesis of universal causation, or universal predictability-in-principle, but rather this: the prevailing laws of nature are such that there do not exist any two possible worlds which are exactly alike up to some time, which differ thereafter, and in which those laws are never violated. Perhaps by ignoring indeterminism, I squander the most striking advantage of a counterfactual analysis over a regularity analysis: that it allows undetermined events to be caused.⁷ I fear, however, that my present analysis cannot yet

cope with all varieties of causation under indeterminism. The needed repair would take us too far into disputed questions about the foundations of probability.

Comparative Similarity

To begin, I take as primitive a relation of *comparative overall* similarity among possible worlds. We may say that one world is *closer to actuality* than another if the first resembles our actual world more than the second does, taking account of all the respects of similarity and difference and balancing them off one against another.

(More generally, an arbitrary world w can play the role of our actual world. In speaking of our actual world without knowing just which world is ours, I am in effect generalizing over all worlds. We really need a three-place relation: world w_1 is closer to world w than world w_2 is. I shall henceforth leave this generality tacit.)

I have not said just how to balance the respects of comparison against each other, so I have not said just what our relation of comparative similarity is to be. Not for nothing did I call it primitive. But I have said what *sort* of relation it is, and we are familiar with relations of that sort. We do make judgments of comparative overall similarity – of people, for instance – by balancing off many respects of similarity and difference. Often our mutual expectations about the weighting factors are definite and accurate enough to permit communication. I shall have more to say later about the way the balance must go in particular cases to make my analysis work. But the vagueness of overall similarity will not be entirely resolved. Nor should it be. The vagueness of similarity does infect causation, and no correct analysis can deny it.

The respects of similarity and difference that enter into the overall similarity of worlds are many and varied. In particular, similarities in matters of particular fact trade off against similarities of law. The prevailing laws of nature are important to the character of a world; so similarities of law are weighty. Weighty, but not sacred. We should not take it for granted that a world that conforms perfectly to our actual laws is *ipso facto* closer to actuality than any world where those laws are violated in any way at all. It depends on the nature and extent of the violation, on the place of the violated laws in the total system of laws of nature, and on the countervailing similarities and differences in other respects. Likewise, similarities or differences of particular fact may be more or less weighty, depending

on their nature and extent. Comprehensive and exact similarities of particular fact throughout large spatiotemporal regions seem to have special weight. It may be worth a small miracle to prolong or expand a region of perfect match.

Our relation of comparative similarity should meet two formal constraints. (1) It should be a weak ordering of the worlds: an ordering in which ties are permitted, but any two worlds are comparable. (2) Our actual world should be closest to actuality; resembling itself more than any other world resembles it. We do *not* impose the further constraint that for any set A of worlds there is a unique closest A -world, or even a set of A -worlds tied for closest. Why not an infinite sequence of closer and closer A -worlds, but no closest?

Counterfactuals and Counterfactual Dependence

Given any two propositions A and C , we have their *counterfactual* $A \square \rightarrow C$: the proposition that if A were true, then C would also be true. The operation $\square \rightarrow$ is defined by a rule of truth, as follows. $A \square \rightarrow C$ is true (at a world w) iff either (1) there are no possible A -worlds (in which case $A \square \rightarrow C$ is *vacuous*), or (2) some A -world where C holds is closer (to w) than is any A -world where C does not hold. In other words, a counterfactual is nonvacuously true iff it takes less of a departure from actuality to make the consequent true along with the antecedent than it does to make the antecedent true without the consequent.

We did not assume that there must always be one or more closest A -worlds. But if there are, we can simplify: $A \square \rightarrow C$ is nonvacuously true iff C holds at all the closest A -worlds.

We have not presupposed that A is false. If A is true, then our actual world is the closest A -world, so $A \square \rightarrow C$ is true iff C is. Hence $A \square \rightarrow C$ implies the material conditional $A \supset C$; and A and C jointly imply $A \square \rightarrow C$.

Let A_1, A_2, \dots be a family of possible propositions, no two of which are compossible; let C_1, C_2, \dots be another such family (of equal size). Then if all the counterfactuals $A_1 \square \rightarrow C_1, A_2 \square \rightarrow C_2, \dots$ between corresponding propositions in the two families are true, we shall say that the C 's *depend counterfactually* on the A 's. We can say it like this in ordinary language: whether C_1 or C_2 or \dots depends (counterfactually) on whether A_1 or A_2 or \dots .

Counterfactual dependence between large families of alternatives is characteristic of

processes of measurement, perception, or control. Let R_1, R_2, \dots be propositions specifying the alternative readings of a certain barometer at a certain time. Let P_1, P_2, \dots specify the corresponding pressures of the surrounding air. Then, if the barometer is working properly to measure the pressure, the R 's must depend counterfactually on the P 's. As we say it: the reading depends on the pressure. Likewise, if I am seeing at a certain time, then my visual impressions must depend counterfactually, over a wide range of alternative possibilities, on the scene before my eyes. And if I am in control over what happens in some respect, then there must be a double counterfactual dependence, again over some fairly wide range of alternatives. The outcome depends on what I do, and that in turn depends on which outcome I want.⁸

Causal Dependence among Events

If a family C_1, C_2, \dots depends counterfactually on a family A_1, A_2, \dots in the sense just explained, we will ordinarily be willing to speak also of causal dependence. We say, for instance, that the barometer reading depends causally on the pressure, that my visual impressions depend causally on the scene before my eyes, or that the outcome of something under my control depends causally on what I do. But there are exceptions. Let G_1, G_2, \dots be alternative possible laws of gravitation, differing in the value of some numerical constant. Let M_1, M_2, \dots be suitable alternative laws of planetary motion. Then the M 's may depend counterfactually on the G 's, but we would not call this dependence causal. Such exceptions as this, however, do not involve any sort of dependence among distinct particular events. The hope remains that causal dependence among events, at least, may be analyzed simply as counterfactual dependence.

We have spoken thus far of counterfactual dependence among propositions, not among events. Whatever particular events may be, presumably they are not propositions. But that is no problem, since they can at least be paired with propositions. To any possible event e , there corresponds the proposition $O(e)$ that holds at all and only those worlds where e occurs. This $O(e)$ is the proposition that e occurs.⁹ (If no two events occur at exactly the same worlds – if, that is, there are no absolutely necessary connections between distinct events – we may add that this correspondence of events and propositions is one to one.) Counterfactual dependence among events is simply counterfac-

tual dependence among the corresponding propositions.

Let c_1, c_2, \dots and e_1, e_2, \dots be distinct possible events such that no two of the c 's and no two of the e 's are compossible. Then I say that the family e_1, e_2, \dots of events *depends causally* on the family c_1, c_2, \dots iff the family $O(e_1), O(e_2), \dots$ of propositions depends counterfactually on the family $O(c_1), O(c_2), \dots$. As we say it: whether e_1 or e_2 or \dots occurs depends on whether c_1 or c_2 or \dots occurs.

We can also define a relation of dependence among single events rather than families. Let c and e be two distinct possible particular events. Then e *depends causally* on c iff the family $O(e), \sim O(e)$ depends counterfactually on the family $O(c), \sim O(c)$. As we say it: whether e occurs or not depends on whether c occurs or not. The dependence consists in the truth of two counterfactuals: $O(c) \square \rightarrow O(e)$ and $\sim O(c) \square \rightarrow \sim O(e)$. There are two cases. If c and e do not actually occur, then the second counterfactual is automatically true because its antecedent and consequent are true: so e depends causally on c iff the first counterfactual holds. That is, iff e would have occurred if c had occurred. But if c and e are actual events, then it is the first counterfactual that is automatically true. Then e depends causally on c iff, if c had not been, e never had existed. I take Hume's second definition as my definition not of causation itself, but of causal dependence among actual events.

Causation

Causal dependence among actual events implies causation. If c and e are two actual events such that e would not have occurred without c , then c is a cause of e . But I reject the converse. Causation must always be transitive; causal dependence may not be; so there can be causation without causal dependence. Let c, d , and e be three actual events such that d would not have occurred without c and e would not have occurred without d . Then c is a cause of e even if e would still have occurred (otherwise caused) without c .

We extend causal dependence to a transitive relation in the usual way. Let c, d, e, \dots be a finite sequence of actual particular events such that d depends causally on c , e on d , and so on throughout. Then this sequence is a *causal chain*. Finally, one event is a *cause* of another iff there exists a causal chain leading from the first to the second. This completes my counterfactual analysis of causation.

Counterfactual versus Nomic Dependence

It is essential to distinguish counterfactual and causal dependence from what I shall call *nomic dependence*. The family C_1, C_2, \dots of propositions depends nomicly on the family A_1, A_2, \dots iff there are a nonempty set \mathcal{L} of true law-propositions and a set \mathcal{F} of true propositions of particular fact such that \mathcal{L} and \mathcal{F} jointly imply (but \mathcal{F} alone does not imply) all the material conditionals $A_1 \supset C_1, A_2 \supset C_2, \dots$ between the corresponding propositions in the two families. (Recall that these same material conditionals are implied by the counterfactuals that would comprise a counterfactual dependence.) We shall say also that the nomic dependence holds *in virtue of the premise sets* \mathcal{L} and \mathcal{F} .

Nomic and counterfactual dependence are related as follows. Say that a proposition B is *counterfactually independent* of the family A_1, A_2, \dots of alternatives iff B would hold no matter which of the A 's were true – that is, iff the counterfactuals $A_1 \Box \rightarrow B, A_2 \Box \rightarrow B, \dots$ all hold. If the C 's depend nomicly on the A 's in virtue of the premise sets \mathcal{L} and \mathcal{F} and if in addition (all members of) \mathcal{L} and \mathcal{F} are counterfactually independent of the A 's, then it follows that the C 's depend counterfactually on the A 's. In that case, we may regard the nomic dependence in virtue of \mathcal{L} and \mathcal{F} as explaining the counterfactual dependence. Often, perhaps always, counterfactual dependences may be thus explained. But the requirement of counterfactual independence is indispensable. Unless \mathcal{L} and \mathcal{F} meet that requirement, nomic dependence in virtue of \mathcal{L} and \mathcal{F} does not imply counterfactual dependence, and, if there is counterfactual dependence anyway, does not explain it.

Nomic dependence is reversible, in the following sense. If the family C_1, C_2, \dots depends nomicly on the family A_1, A_2, \dots in virtue of \mathcal{L} and \mathcal{F} , then also A_1, A_2, \dots depends nomicly on the family AC_1, AC_2, \dots , in virtue of \mathcal{L} and \mathcal{F} , where A is the disjunction $A_1 \vee A_2 \vee \dots$. Is counterfactual dependence likewise reversible? That does not follow. For, even if \mathcal{L} and \mathcal{F} are independent of A_1, A_2, \dots and hence establish the counterfactual dependence of the C 's on the A 's, still they may fail to be independent of AC_1, AC_2, \dots , and hence may fail to establish the reverse counterfactual dependence of the A 's on the AC 's. Irreversible counterfactual dependence is shown below: @ is our actual world, the dots are the other worlds, and distance on the page represents similarity “distance.”

The counterfactuals $A_1 \Box \rightarrow C_1, A_2 \Box \rightarrow C_2$, and $A_3 \Box \rightarrow C_3$ hold at the actual world; wherefore the C 's depend on the A 's. But we do not have the reverse dependence of the A 's on the AC 's, since instead of the needed $AC_2 \Box \rightarrow A_2$ and $AC_3 \Box \rightarrow A_3$ we have $AC_2 \Box \rightarrow A_1$ and $AC_3 \Box \rightarrow A_1$.

Just such irreversibility is commonplace. The barometer reading depends counterfactually on the pressure – that is as clear-cut as counterfactuals ever get – but does the pressure depend counterfactually on the reading? If the reading had been higher, would the pressure have been higher? Or would the barometer have been malfunctioning? The second sounds better: a higher reading would have been an incorrect reading. To be sure, there are actual laws and circumstances that imply and explain the actual accuracy of the barometer, but these are no more sacred than the actual laws and circumstances that imply and explain the actual pressure. Less sacred, in fact. When something must give way to permit a higher reading, we find it less of a departure from actuality to hold the pressure fixed and sacrifice the accuracy, rather than vice versa. It is not hard to see why. The barometer, being more localized and more delicate than the weather, is more vulnerable to slight departures from actuality.¹⁰

We can now explain why regularity analyses of causation (among events, under determinism) work as well as they do. Suppose that event c causes event e according to the sample regularity analysis that I gave at the beginning of this chapter, in virtue of premise sets \mathcal{L} and \mathcal{F} . It follows that \mathcal{L}, \mathcal{F} , and $\sim O(c)$ jointly do not imply $O(e)$. Strengthen this: suppose further that they do imply $\sim O(e)$. If so, the family $O(e), \sim O(e)$, depends nomicly on the family $O(c), \sim O(c)$ in virtue of \mathcal{L} and \mathcal{F} . Add one more supposition: that \mathcal{L} and \mathcal{F} are counterfactually independent of $O(c), \sim O(c)$. Then it follows according to my counterfactual analysis that e depends counterfactually and causally on c , and hence that c causes e . If I am right, the regularity analysis gives conditions that are almost but not quite sufficient for explicable causal dependence. That is not quite the same thing as causation; but causation without causal dependence is scarce, and if there is inexplicable causal dependence we are (understandably!) unaware of it.¹¹

Effects and Epiphenomena

I return now to the problems I raised against regularity analyses, hoping to show that my counterfactual analysis can overcome them.

The *problem of effects*, as it confronts a counterfactual analysis, is as follows. Suppose that c causes a subsequent event e , and that e does not also cause c . (I do not rule out closed causal loops a priori, but this case is not to be one.) Suppose further that, given the laws and some of the actual circumstances, c could not have failed to cause e . It seems to follow that if the effect e had not occurred, then its cause c would not have occurred. We have a spurious reverse causal dependence of c on e , contradicting our supposition that e did not cause c .

The *problem of epiphenomena*, for a counterfactual analysis, is similar. Suppose that e is an epiphenomenal effect of a genuine cause c of an effect f . That is, c causes first e and then f , but e does not cause f . Suppose further that, given the laws and some of the actual circumstances, c could not have failed to cause e ; and that, given the laws and others of the circumstances, f could not have been caused otherwise than by c . It seems to follow that if the epiphenomenon e had not occurred, then its cause c would not have occurred and the further effect f of that same cause would not have occurred either. We have a spurious causal dependence of f on e , contradicting our supposition that e did not cause f .

One might be tempted to solve the problem of effects by brute force: insert into the analysis a stipulation that a cause must always precede its effect (and perhaps a parallel stipulation for causal dependence). I reject this solution. (1) It is worthless against the closely related problem of epiphenomena, since the epiphenomenon e does precede its spurious effect f . (2) It rejects a priori certain legitimate physical hypotheses that posit backward or simultaneous causation. (3) It trivializes any theory that seeks to define the forward direction of time as the predominant direction of causation.

The proper solution to both problems, I think, is flatly to deny the counterfactuals that cause the trouble. If e had been absent, it is not that c would have been absent (and with it f , in the second case). Rather, c would have occurred just as it did but would have failed to cause e . It is less of a departure from actuality to get rid of e by holding c fixed and giving up some or other of the laws and circumstances in virtue of which c could not have failed to cause e , rather

than to hold those laws and circumstances fixed and get rid of e by going back and abolishing its cause c . (In the second case, it would of course be pointless not to hold f fixed along with c .) The causal dependence of e on c is the same sort of irreversible counterfactual dependence that we have considered already.

To get rid of an actual event e with the least overall departure from actuality, it will normally be best not to diverge at all from the actual course of events until just before the time of e . The longer we wait, the more we prolong the spatiotemporal region of perfect match between our actual world and the selected alternative. Why diverge sooner rather than later? Not to avoid violations of laws of nature. Under determinism *any* divergence, soon or late, requires some violation of the actual laws. If the laws were held sacred, there would be no way to get rid of e without changing all of the past; and nothing guarantees that the change could be kept negligible except in the recent past. That would mean that if the present were ever so slightly different, then all of the past would have been different – which is absurd. So the laws are not sacred. Violation of laws is a matter of degree. Until we get up to the time immediately before e is to occur, there is no general reason why a later divergence to avert e should need a more severe violation than an earlier one. Perhaps there are special reasons in special cases – but then these may be cases of backward causal dependence.

Preemption

Suppose that c_1 occurs and causes e ; and that c_2 also occurs and does not cause e , but would have caused e if c_1 had been absent. Thus c_2 is a potential alternate cause of e , but is preempted by the actual cause c_1 . We may say that c_1 and c_2 overdetermine e , but they do so asymmetrically.¹² In virtue of what difference does c_1 but not c_2 cause e ?

As far as causal dependence goes, there is no difference: e depends neither on c_1 nor on c_2 . If either one had not occurred, the other would have sufficed to cause e . So the difference must be that, thanks to c_1 , there is no causal chain from c_2 to e ; whereas there is a causal chain of two or more steps from c_1 to e . Assume for simplicity that two steps are enough. Then e depends causally on some intermediate event d , and d in turn depends on c_1 . Causal dependence is here intransitive: c_1 causes e via d even though e would still have occurred without c_1 .

So far, so good. It remains only to deal with the objection that e does *not* depend causally on d , because if d had been absent then c_1 would have been absent and c_2 , no longer preempted, would have caused e . We may reply by denying the claim that if d had been absent then c_1 would have been absent. That is the very same sort of spurious reverse dependence of cause on effect that we have just rejected in simpler cases. I rather claim that if d had been absent, c_1 would somehow have failed to cause d . But c_1 would still have been there to interfere with c_2 , so e would not have occurred.

Notes

- 1 *An Enquiry concerning Human Understanding*, Section VII.
- 2 Not one that has been proposed by any actual author in just this form, so far as I know.
- 3 I identify a *proposition*, as is becoming usual, with the set of possible worlds where it is true. It is not a linguistic entity. Truth-functional operations on propositions are the appropriate Boolean operations on sets of worlds; logical relations among propositions are relations of inclusion, overlap, etc. among sets. A sentence of a language *expresses* a proposition iff the sentence and the proposition are true at exactly the same worlds. No ordinary language will provide sentences to express all propositions; there will not be enough sentences to go around.
- 4 One exception: Aardon Lyon, "Causality," *British Journal for Philosophy of Science*, XVIII, 1 (May 1967): 1–20.
- 5 See, for instance, Robert Stalnaker, "A Theory of Conditionals," in Nicholas Rescher, ed., *Studies in Logical Theory* (Oxford: Blackwell, 1968); and my *Counterfactuals* (Oxford: Blackwell, 1973).
- 6 Except that Morton G. White's discussion of causal selection, in *Foundations of Historical Knowledge* (New York: Harper & Row, 1965), pp. 105–181, would meet my needs, despite the fact that it is based on a regularity analysis.
- 7 That this ought to be allowed is argued in G. E. M. Anscombe, *Causality and Determination: An Inaugural Lecture* (Cambridge: University Press, 1971); and in Fred Dretske and Aaron Snyder, "Causal Irregularity," *Philosophy of Science*, XXXIX, 1 (March 1972): 69–71.
- 8 Analyses in terms of counterfactual dependence are found in two papers of Alvin I. Goldman: "Toward a Theory of Social Power," *Philosophical Studies*, XXIII (1972): 221–268; and "Discrimination and Perceptual Knowledge," presented at the 1972 Chapel Hill Colloquium.
- 9 Beware: if we refer to a particular event e by means of some description that e satisfies, then we must take care not to confuse $O(e)$, the proposition that e itself occurs, with the different proposition that some event or other occurs which satisfies the description. It is a contingent matter, in general, what events satisfy what descriptions. Let e be the death of Socrates – the death he actually died, to be distinguished from all the different deaths he might have died instead. Suppose that Socrates had fled, only to be eaten by a lion. Then e would not have occurred, and $O(e)$ would have been false; but a different event would have satisfied the description 'the death of Socrates' that I used to refer to e . Or suppose that Socrates had lived and died just as he actually did, and afterward was resurrected and killed again and resurrected again, and finally became immortal. Then no event would have satisfied the description. (Even if the temporary deaths are real deaths, neither of the two can be *the* death.) But e would have occurred, and $O(e)$ would have been true. Call a description of an event e *rigid* iff (1) nothing but e could possibly satisfy it, and (2) e could not possibly occur without satisfy it. I have claimed that even such commonplace descriptions as 'the death of Socrates' are nonrigid, and in fact I think that rigid descriptions of events are hard to find. That would be a problem for anyone who needed to associate with every possible event e a sentence $\phi(e)$ true at all and only those worlds where e occurs. But we need no such sentences – only propositions, which may or may not have expressions in our language.
- 10 Granted, there are contexts or changes of wording that would incline us the other way. For some reason, "If the reading had been higher, that would have been because the pressure was higher" invites my assent more than "If the reading had been higher, the pressure would have been higher." The counterfactuals from readings to pressures are much less clear-cut than those from pressures to readings. But it is enough that some legitimate resolutions of vagueness give an irreversible dependence of readings on pressures. Those are the resolutions we want at present, even if they are not favored in all contexts.
- 11 I am not here proposing a repaired regularity analysis. The repaired analysis would gratuitously rule out inexplicable causal dependence, which seems bad. Nor would it be squarely in the tradition of regularity analyses any more. Too much else would have been added.
- 12 I shall not discuss symmetrical cases of overdetermination, in which two overdetermining factors have equal claim to count as causes. For me these are useless as test cases because I lack firm naive opinions about them.

Chapter 31: Propensities and Counterfactuals: The Loser That Almost Won

DANIEL KAHNEMAN AND CAROL A. VAREY

The question of how people think of things that could have happened but did not has attracted increasing interest among psychologists in recent years (J. T. Johnson, 1986; Kahneman & Miller, 1986; Kahneman & Tversky, 1982a; Landman, 1987; D. T. Miller, Turnbull, & MacFarland, 1990; Wells & Gavanski, 1989; Wells, Taylor, & Turtle, 1987). As philosophers have long known, the study of counterfactuals cannot be separated from a conception of causality, and an understanding of causality requires a conception of possibility and conditional probability. Counterfactual assertions rest on causal beliefs, and causal attributions invoke counterfactual beliefs, for example, about what would have happened in the absence of a putative cause. Some counterfactual assertions assign degrees of probability or plausibility to unrealized outcomes, many causal beliefs are probabilistic, and judgments of probability often draw on impressions of causal tendencies or propensities. The present article is concerned with a psychological analysis of this nexus of issues.

Our study began with an attempt to understand the psychology of assertions of the form “X almost happened,” which we call *close counterfactuals*. An important characteristic of such assertions is that they are not expressed as a conditional with a specified antecedent, as counterfactual conditionals are. The close counterfactual does not invoke an alternative possible world, but states a fact about the history of this world – namely, that things were close to turning out differently than they did.

Our approach combines some elementary phenomenological observations and an equally elementary linguistic inquiry into the conditions under which close counterfactual assertions are appropriate. The genre is not unknown in psychology: Heider (1958) and Schank and Abelson (1977), in particular, have successfully carried out ambitious exercises in this vein. Studies of what people mean when they say that “John went to the restaurant” or when they use the words *can* and *try* have contributed significantly to an understanding of how people think about events and actions. In this article, we examine the use of the word *almost* in a speculative attempt to explore how people think about counterfactuals, probability, and causation.¹ The present analysis is restricted to cases in which “X almost happened” implies that X could have happened. We ignore figurative uses of *almost* in which it is used to denote “coming close” without implication of possibility, as in “at that bend the train almost touches the embankment.” We also restrict our discussion of *almost* to cases in which either the actual outcome or the close counterfactual is an achievement (see Lyons, 1977; G. A. Miller & Johnson-Laird, 1976; Vendler, 1967) – a change of state that occurs at a particular moment, usually as the culmination of a longer causal episode. We analyze the beliefs that a speaker expresses by the assertion that an individual almost died, or almost missed a deadline, and examine what such beliefs imply to us about the cognitive representation of uncertain events and of causal propensities.

Reproduced with permission from Kahneman, D., and Varey, C. A. (1990) Propensities and counterfactuals: The loser that almost won. *Journal of Personality and Social Psychology*, 59, 1101–1110.

This article develops the following ideas: (a) Counterfactuals, causes, and (some) probabilities are treated as facts about the world, not as constructions of the mind. (b) The absence of perfect hindsight indicates that people attribute inherent uncertainty to causal systems – what happened is not treated as necessary or inevitable. (c) The perception and representation of causal episodes is organized around possible outcomes of the episode. (d) Probabilities of outcomes can be assessed on the basis of advance knowledge (dispositions) or of cues gained from the causal episode itself (propensities). The distinction is critical to the use of *almost*, which requires the attribution of a strong propensity to the counterfactual outcome. (e) Cues to propensity are the temporal or causal proximity of the focal outcome and indications of rapid progress through a causal script. (f) A general schema of causal forces competing over time is applicable to many achievement contexts. (g) There are characteristic differences between a psychological and a philosophical approach to the analysis of probability, causality, and counterfactuals.

The Counterfactual Stance

The statement “*X almost happened*” implies several ancillary beliefs. It commits the speaker to the belief that another observer with the same information would agree with the counterfactual assertion, as would be the case with public, objective facts. The close counterfactual also implies that *X* could have happened, denying the necessity or inevitability of what actually happened and implicitly denying the deterministic character of the situation. We examine these beliefs in the following sections.

Objective Reference

By definition, counterfactual statements refer to events that did not, in fact, occur. However, there is a compelling intuition that some counterfactuals are treated as having an objective character, not as mere mental constructions. Refuting the possible-worlds analysis of counterfactuals, Goodman (1983) put the point strongly: “We have come to think of the actual as one among many possible worlds. We need to repaint that picture. All possible worlds lie within the actual one” (p. 57). In ascribing objective status to counterfactuals, we intend to contrast the attitude toward these objects of thought from the attitude toward imaginings, fantasies, and desires, which are normally tagged as subjective

(M. K. Johnson, 1988). The discrimination of what actually happened from what almost did is, of course, essential in the monitoring of reality – the counterfactual event is not perceived as real, but it is not treated as subjective. The “fact” is that the outcome truly is close, or is not close, independently of anyone’s beliefs.

The distinction between beliefs that have objective or subjective status recalls an earlier discussion of alternative cognitive representations of probability (Kahneman & Tversky, 1982b). Two main interpretations of that notion were identified, which respectively assign it subjective or objective status. In the subjective interpretation, which is standard in Bayesian philosophy, a probability judgment describes the subject’s degree of belief in a proposition. “The probability that the Nile is longer than the Amazon is *p*” is usually understood as describing the speaker’s beliefs, not as a fact about these rivers. The attribution of subjective status to a belief is often marked by the possessive pronoun: “My probability that the Nile is longer than the Amazon . . .” is more natural than “the probability that the Nile . . .” In contrast, the probability that a thumbtack will land on its point if tossed and the probability that Team A will defeat Team B are normally understood as descriptions of the causal dispositions of the thumbtack or of the competing teams. A speaker who wishes to indicate a subjective interpretation of probability will use the possessive pronoun: “My probability that Team A will win is . . .” acknowledges the possibility of valid alternatives, a stance that is not usually adopted in factual statements.

The two types of representation of uncertainty are most clearly distinguished when the uncertainty is removed. The possessive pronoun is then obligatory if the probability has subjective status. “The probability that the Nile is longer than the Amazon was . . .” is simply anomalous. In contrast, it is reasonable to maintain that the probability that the thumbtack would land on its point was .55 even when it is known that it did not do so on a particular instance. More interestingly, the statement that “the probability that Team A would win was high . . .” is acceptable even if that team is known to have lost. The statement of past probability need not refer to anyone’s beliefs at the time of the episode. The statement could be made, for example, by a speaker who learned, after the game had ended, that a player of Team B had undertaken to throw the game if he had an opportunity to do so. As this example illustrates, current knowledge of the relevant causal factors

may allow a speaker to say retrospectively that an event that did not take place had high probability – and as a special and rather extreme case to assert that the event almost occurred.

Although in this article we often appeal to the reader's intuitions in the expectation that they match ours, we also tested some of our conclusions by collecting judgments of appropriateness from native speakers of English. Subjects were recruited on the Berkeley campus by a poster offering students a small payment in return for a completed questionnaire. Respondents were given instructions and several questions as illustrated by the examples below.

In the following questions you are asked to rate statements on a scale from "appropriate" to "very peculiar." One or more statements are presented for each question. You are to rate whether the statement in italics is appropriate, given the information in the rest of the question.

1. *Tom almost died* but in fact he was never in real danger.

Appropriate	Somewhat	Very
7%	peculiar 27%	peculiar 66%
		($n = 29$) ²

2. *Everyone thought Phil almost died* but in fact he was never in real danger.

Appropriate 69%	Very peculiar 10%
	($n = 29$)

3. The autopsy showed that when he was a child, Sid had suffered from a rare childhood disease. The pathologist said that if the disease had lasted a few days longer, it would have killed him. No one knew about it at the time; they thought he had a mild case of measles. *Sid almost died as a child from that rare disease.*

Appropriate 61%	Very peculiar 0%
	($n = 18$)

These examples illustrate that the close counterfactual has the status of a historical fact. As is generally true when such facts are asserted, everything known to the speaker at the time of the utterance can be relevant, but the beliefs of observers of the actual event are not. As shown by Example 2, the objective status of close counterfactuals allows them to be believed erroneously. Indeed, counterfactuals can be faked. Professional wrestlers on television have perfected the art of appearing almost to kill one another, but they avoided regulation by

demonstrating that their occupation is actually quite safe.

Like counterfactuals and (some) probabilities, causal attributions are also treated as objective facts about the world. This is true of causality directly observed, as in the perception of a collision and in Michotte's (1946) demonstrations of launching. It is also true of the more abstract causes that are judged to raise the (objective) probabilities of events or, in some contexts, render them inevitable (Mackie, 1974). The counterfactual assertion that an effect would not have occurred in the absence of the cause, the *sine qua non* condition of necessity, has the same objective character.

Inherent Uncertainty

The frequent mentions of counterfactual possibilities in everyday discourse demonstrate a prevailing intuition that things could have been different, and in some cases almost were. This intuition commits the speaker to a particular set of beliefs about causality. Specifically, X is neither necessary nor inevitable if it can properly be said that Y almost happened instead of it. Naive intuitions are evidently not dominated by a pervasive belief in strict determinism. Kwart (1986) reached a similar conclusion in his discussion of counterfactual conditionals.

There is an intriguing tension between the intuition that things could have been otherwise and the well-known hindsight effect, in which the inevitability of events that actually took place tends to be exaggerated. The evidence is compelling that retrospective assessments of the probability of events are affected by knowledge of whether or not these events have taken place (Fischhoff, 1975, 1982). The term *creeping determinism* has been used in this context. Two distinct forms of hindsight effects are associated, respectively, with subjective and objective interpretations of probability. The most common test of hindsight effects requires the retrieval of a past state of belief: "What was your probability at the end of 1988 that the Berlin Wall would be opened within a year?" A hindsight bias is revealed in such questions by a tendency to exaggerate the past subjective probabilities of whatever is now known to be true. An example of an objective hindsight question could be "In the light of current knowledge, what was the probability in 1988 that the Berlin Wall would be opened within a year?" A discrepancy between prospective and retrospective probabilities is

typically observed in tests of objective as well as subjective hindsight (Fischhoff, 1975).

Unlike the subjective case, hindsight with an objective interpretation of probability is not necessarily a mistake. It is entirely reasonable for an observer to make inferences about a causal system from the knowledge that it produced a particular outcome. Indeed, what is most puzzling in this context is the limited extent of creeping determinism in retrospective evaluations of outcomes.

Of course, not all causal systems are uncertain. As illustrated by most people's attitudes toward the mechanical and electronic devices that surround them, a belief in strict determinism does not require much understanding of how the system works; it cannot be ignorance about the causal system that precludes determinism about close counterfactuals. It is an important fact about causal reasoning that a sense of the necessity of consequences is often absent. In particular, there is no sense of necessity or inevitability in considering games of chance, many contests and competitions, some physical systems (e.g., weather and chance devices), or intentional actions.

The Representation of Causal Episodes

The idea that perceived goals serve to organize the representation of action and imbue events with meaning was articulated by Heider (1958), and is at the core of the more recent treatments of scripts and story grammars (Black & Bower, 1979; Kintsch & van Dijk, 1978; Rumelhart, 1977; Schank, 1975; Trabasso, Secco, & van den Broek, 1984) and treatments of decision making and causal reasoning that rely on a story-based account (Pennington & Hastie, 1988; Read, 1987). Our conception of causal episodes generalizes this idea to achievements. The class of achievements contains the outcomes of intentional action but is much richer: Dying from a disease, a river overflowing its bank, and the Dow-Jones index rising 1,000 points in a year are all achievements. Many achievements are associated with particular causal scripts. The representation of an episode as an instantiation of a causal script is therefore organized in terms of its possible *focal outcomes*, and attention to different achievements will alter the representation. The storm that could fill the reservoirs could also ruin the cherry crop, and its representation will be different if attention is directed to one of these outcomes rather than the other.

To illustrate the function of focal outcomes, we introduce a thought experiment to which we shall repeatedly return. Imagine observing a sequence of red and blue balls as they are drawn from an urn, or the representation of such a process on a computer screen. Note the potent effects of an intention to watch for a particular outcome, such as the color that is most frequent after eleven draws, or an excess of four red balls or six blue balls – whichever happens first. Although these focal outcomes are not goals, they serve the same function in organizing the impression of the sequence. Most important, watching the same sequence with different outcomes in mind alters the experience. Although our thought experiment involves real-time observation and uncertainty, neither of these elements is essential: A designated outcome will affect the interpretation of a story, and the effect is not reduced when thinking of an episode whose outcome is already known.

The probability of the focal outcome may fluctuate in the course of a causal episode. Changes of probability are always involved in close counterfactuals: Perhaps the most compelling intuition about the statement "X almost happened" is that the probability of X must have been quite high at some point before it dropped – all the way to zero if another outcome eventually terminated the episode.³

There are several reasons for probability changing in the course of an episode. We turn again to the urn example to illustrate two types of probability change. If there was initial uncertainty about the composition of the urn, beliefs about the urn will change to accommodate observed events – by Bayes's rule for an ideal observer – and the probability of the focal outcome will change accordingly. In addition, the actual probability of the focal outcome also changes *because* of the intervening events. Every red ball drawn makes it more probable that the aggregate outcome will be an excess of red over blue balls. The probability of the focal outcomes will change, more or less regularly and perhaps with large fluctuations, until a decisive event brings about an outcome that terminates the episode. Note that this situation can support a close counterfactual: It is easy to imagine a sequence of draws of which it can appropriately be said that the focal outcome almost occurred (red almost won), or almost did not.

The same types of changes of probability will also be found in observing (or hearing about) a storm that could cause a flood or a couple deciding on a joint future. The events that constitute

the episode reveal the strength of an underlying causal process, and also contribute to bring about or retard the outcome. They also indicate possible changes in the causal system – changes that could be modeled by an urn whose composition is modified after each draw, perhaps in response to the draw.

Propensities and Dispositions

The discussion so far has been in terms of “objective” probabilities – in the chance example these are probabilities that could be computed precisely, given some initial beliefs about the composition of the urn. It is evident from this example that an account of *almost* in terms of probability has some appeal: The probability of the counterfactual outcome must have been high at some point. It turns out, however, that an account that relies exclusively on objective probabilities will not work. Some aspects of the puzzle to be solved are illustrated by the following examples:

4. Mark tried to register for the chess tournament. Because of a problem in mailing the form he missed the registration deadline by one day. Mark is a much stronger player than all the participants in the tournament. *Mark almost won the tournament.*

Appropriate 0% Very peculiar 97%
(*n* = 33)

5. At the end of a long game of chance, John could have won the whole pot if a die that he rolled showed a six. The die that he rolled was loaded to show six 80% of the time. John rolled it and it showed a two. *The die almost showed six.*

Appropriate 0% Very peculiar 77%
(*n* = 31)

6. At the end of a long game of chance, John could have won the whole pot if a die that he rolled showed a six. The die that he rolled was loaded to show six 80% of the time. John rolled it and it showed a two. *John almost won the whole pot.*

Appropriate 43% Very peculiar 20%
(*n* = 31)

The close counterfactual is decisively rejected in Examples 4 and 5 but not in Example 6, although the prior probability of the focal outcome was high in all cases. Before it was rolled, the probability of the die showing six was .80

in Examples 5 and 6, and the prior probability of Mark winning the tournament was also high, though unspecified. Despite this, the intuition that *almost* is inappropriate in the first two examples is so strong that they seem almost absurd. A strong belief in the counterfactual conditional “Mark would have won if he had played” is not sufficient to support the close counterfactual “Mark almost won,” even if it is also accepted that he almost played in the tournament. Why is this the case? And what else is required for the close counterfactual to be appropriate?

The answer to the first question is that the close counterfactual is never appropriate if it is only supported by indications of likelihood or causal force that were available before the onset of the relevant causal episode. Achievements, such as winning a tournament, getting married, or a die showing six, are associated with causal scripts that usually have a definite starting point: when play begins, when the couple start dating, when the die is rolled. Probabilities can be assigned to possible outcomes of a causal process before it is initiated: Mark may be a rated player, the couple could appear severely mismatched, the die could be loaded. We shall refer to the cognitive representation of such prior probabilities as the (perceived) *disposition* of a causal system to yield particular outcomes. Examples 4 and 5 show that dispositions, however strong, do not suffice to support the assertion of a close counterfactual.

A close counterfactual must be supported by the evidence of event cues, as these accumulate in the course of the causal episode. We use the term *propensity* for what is learned about the probability of an outcome from observing event cues or from hearing about them. Mark had a disposition to win his chess tournament and probably would have won it if he had registered, but the causal episode for his victory never began, and there was therefore no opportunity to establish a propensity for that outcome. The standard example of propensity in a chance event is the cinematic cliché of the roulette wheel that slows down as it approaches a critical number, slows down even more, leans against the spring, then finally trips it and stops on a neighboring number. To be described as almost showing six, a die must display a propensity to stop its roll in that position.

The contrasting responses to Examples 5 and 6 illustrate the need to distinguish propensity from probability. We suppose that our respondents would have assigned a probability of .8 both to the die showing six and to John winning

the whole pot. However, the propensities of the two outcomes clearly differ. Example 6 illustrates a common structure in which one achievement (the die showing six) is nested inside another (John winning the pot). Because the focal outcome of winning the pot invokes a more inclusive causal episode that had begun long before the critical play, John can be said to have had a propensity to win, even if it is not established that the die had a propensity to show six. Thus, although the two statements have the same probability before the throw, the differential effects of propensity and disposition allow "John almost won" to be appropriate although "the die almost showed six" is not.

We should now review the rather subtle relations among the concepts of disposition, propensity, and probability, as they are used in this article. Disposition has been defined as the cognitive representation of the probability of a focal outcome, before the beginning of the relevant causal episode. A disposition can be assessed either prospectively or in hindsight, depending on whether or not the outcome is known. Disposition is a psychological construct, not a logical or mathematical one, and in view of what is known about intuitive judgment there is little reason to expect dispositions to obey the standard axioms of probability (Kahneman, Slovic, & Tversky, 1982). Dispositions represent knowledge about the particular causal system that will (or will not) produce the focal outcome of current concern. Dispositions are inferred from the base rates of outcomes previously produced by that system (Mark has won most of his tournaments) or from structural knowledge that supports causal inferences (the die was loaded in a particular fashion). Thus, the concept of disposition has causal as well as statistical implications.

Our concept of propensity is even more imbued with causal content. Event cues reveal the causal system in action. They indicate advance toward the focal outcome, or regression away from it. They suggest changes in the momentary state of the causal system – changes that may be real or illusory, as when a player is seen to have a "hot hand" (Gilovich, Vallone, & Tversky, 1985). Perhaps most important, propensities depend on the proximity of the outcome, on the possibility of quickly achieving a decisive advance to it. In sharp contrast to probability, the propensities for all competing outcomes of a process may be low early in a causal episode, and more than one propensity can be high at once when the end is close. These ideas are elaborated in subsequent sections.

Our main interest in the remainder of this article is to use close counterfactuals to learn about propensity. We consider propensity to be a dimension of the experience and cognitive representation of events, just as pitch is a dimension of auditory experience. There should be no presuppositions about the determinants of propensity; in particular, propensity could reflect causality as well as probability, just as pitch depends on both the frequency and the intensity of sound. To anchor this speculative analysis in observables, we assume that the appropriateness of *almost*, in its literal meaning, provides a usable indication of high propensity.

Disposition Neglect

Dispositions and propensities are differentially susceptible to revision in hindsight. Consider two cases in which the observer of the last lap of a footrace might assign a high probability of victory to a particular runner: (a) a runner who is in contention and is known to have a strong finish, or (b) a runner who has been catching up rapidly with the leader. The real-time expectations are equally strong in both cases, we assume, but they are based on different cues – dispositional knowledge in (a) and event cues in (b). Now imagine that the two runners both fail to win, by the same amount: The first did not show a strong finish and the second never quite caught up. Note that it will not do to say of the runner who usually has a strong finish that he or she almost won the race with a strong finish, if in fact he or she showed no evidence of talent on that particular occasion. The close counterfactual that the loser almost won is more applicable to (a) than to (b), although a counterfactual conditional could be appropriate in (a). The general hypothesis is that dispositional expectations that are not confirmed by event cues become irrelevant in hindsight.

The differential weighting of event cues and dispositional expectations in retrospective judgments will be called *disposition neglect*; the effect bears an intriguing resemblance to the relative neglect of base-rate information that has been observed in some prospective judgments. For example, the judged probability that a short personality sketch describes a lawyer rather than an engineer is not much affected by the proportion of engineers and lawyers in the sample from which it was drawn. The information about the individual case largely supersedes the information about the base rate instead of combining with it according to Bayes's rule (Kahneman &

Tversky, 1973). Similarly, Ajzen (1977) found that people predicting exam success for a student based their predictions on a descriptive sketch and gave little weight to the information that the student was drawn at random from a set selected by a researcher to include 75% failures. As Ajzen observed, however, the neglected base rate in these examples is merely statistical. There is no causal connection between the composition of the student sample and the factors that would make a particular student succeed or fail. The situation changes when such a causal connection is provided: The information that 75% of students taking the test failed it leads readily to the inference that the test was a difficult one, and the information has much more impact on the judgment of the probable success of an individual (Ajzen, 1977). There have been other demonstrations of the general principle that causally relevant base-rate information will not be neglected (Gigerenzer, Hell, & Blank, 1988; Tversky & Kahneman, 1980, 1982; see also Bar-Hillel, 1990, for a discussion of these issues).

Ajzen's (1977) experiment demonstrated that dispositional information tends to dominate statistical base rates, and that dispositional information from two sources (the difficulty of the exam and the student's ability) tends to be integrated. A variation of this experiment would demonstrate disposition neglect: Evidence that a student is extremely able does not support the inference that the student almost passed an exam that he failed, nor does the knowledge that a test was very hard support the conclusion that a student who passed almost failed it. In assessing close counterfactuals, event cues dominate causal base rates and other dispositional information.

The neglect of statistical base rates leads to violations of Bayes's rule in prospective judgments. The neglect of dispositional expectations in hindsight is not necessarily an error, but the psychology of the two effects may well reflect a single general principle. In both cases, the data that bear most directly on the causal forces at work in the individual case have the greatest impact.

Correlates of Propensity

In this section, we develop the concept of propensity by examining two of its close correlates: shrinking distance and increasing impact. The force of distance and motion in the close counterfactual is evident in the near syn-

onymy of "X almost happened," "X nearly happened," and "X was close to happening." These expressions invoke a rich metaphor in which an extended causal process is represented as movement in space (e.g., see the "source-path-goal" kinesthetic image schema analyzed in Lakoff, 1987; the various "journey" metaphors in Lakoff & Johnson, 1980; and the force and space images in Talmy, 1981, 1983). This metaphor imposes a metric of causal distance between situations and suggests the closest approach to an outcome as a measure of its propensity. The second correlate of increasing propensity is an escalation in the apparent causal significance of events as the outcome is approached.

Causal Proximity

The present analysis has emphasized causal processes that extend over time, but close counterfactuals can be asserted on the basis of a measure of proximity or similarity even when the process is instantaneous. For example, the statement "The house was almost struck by lightning" is appropriate when lightning struck nearby. The actual outcome is the only event cue in such cases, and it induces a gradient of propensity in its spatial and temporal vicinity. From the fact that lightning struck in a particular place at a particular time, a propensity is inferred to strike in neighboring places, and at about the same time. Similarly, it is appropriate to say that Tom almost got six sixes in rolling dice if he got five sixes and a two. Indeed, it would be even more appropriate to say that Tom almost got six sixes if he rolled five sixes and a five.

Scripts for achievements often specify a series of landmarks that provide a provisional metric of proximity to the outcome. Getting a wedding license, for example, is one of the last landmarks in the script for marriage. It will usually be appropriate to say of a couple that came that far but did not marry that they almost got married. However, although high propensity for an outcome can be inferred from the near completion of the script for that outcome, such inferences are tentative and dependent on default assumptions about the causal system. Thus, it is not correct to say of a tethered mountain climber who falls that he or she "almost fell to the bottom of the cliff," or even was close to doing so, although the script for a fall to the bottom was almost completely satisfied. Nor will it be correct to say that Tom almost rolled six sixes if one of the dice has been altered to make that outcome impossible. The propensity for a counterfactual

outcome cannot be reduced to a superficial assessment of the similarity of the actual episode to the completed script for that outcome.

Intentions can contribute to an impression of propensity. For example, it is more appropriate to say that the escaping murderer was almost killed by a shot that went six inches above his or her head if the shot was intended to kill than if it was intended to warn. Intentions do not suffice, however, when there are significant obstacles to be overcome. For an individual to "consider doing X" is sometimes sufficient to support the inference that the individual "almost did X," but not always. Selected examples follow:

7. Martin considered getting married to Meg. *Martin almost married Meg.*

Appropriate 14%	Very peculiar 34%
(n = 29)	

8. Neil considered not getting married to Amanda. *Neil almost didn't marry Amanda.*

Appropriate 62%	Very peculiar 19%
(n = 32)	

9. Fred considered stealing his child's savings. *Fred almost stole his child's savings.*

Appropriate 30%	Very peculiar 15%
(n = 75)	

10. Ned considered breaking into a bank vault. *Ned almost broke into a bank vault.*

Appropriate 18%	Very peculiar 44%
(n = 75)	

Mere consideration of a marriage is not sufficient (at least in this culture) to support the assertion that the marriage almost took place. The situation is somewhat different in Example 8, because either party (again in this culture) has the power single-handedly to put a stop to plans to marry. Responses to Examples 9 and 10 show that subjects are sensitive to the fact that much more remains to be done, beyond mere consideration, for the project of breaking into a bank vault than for stealing one's child's savings.

Decisiveness

Many outcomes are produced by a conjunction of events, all contributing to making the outcome necessary. It is useful to distinguish two privileged roles of events in multiple causation: *Critical events* are those that initiate a causal

episode, potentiate subsequent causal events, or both; *decisive events* are those that rule out all alternatives, and ensure (or almost ensure) a particular outcome. The special role of critical events that initiate coherent causal episodes has been confirmed in studies of blame (J. T. Johnson, Ogawa, Delforge, & Early, 1989) and studies or mental simulations that "undo" outcomes (Wells et al., 1987). The person who starts a quarrel will get much of the blame for its consequences. However, the decisive and irreversible events that terminate causal episodes are also important, especially when the events in the causal sequence are not themselves causally related (D. T. Miller & Gunasegaram, 1990). Hart and Honore (1959) proposed that a cause is found by "tracing back" from the effect to the nearest plausible candidate in the causal chain. They also discussed the legal doctrine of the last clear chance: The last person who had a good chance to avoid harm is alone held responsible (see also Wells & Gavanski, 1989). The responsible individual is the one whose actions cannot be reversed by anyone else. The same intuition shows up in the context of blackjack; many players believe that the player on the seventh box, who receives cards immediately prior to the dealer's draw that all players are trying to beat, determines the outcomes for all players (Keren & Wagenaar, 1985). By the time the cards are dealt, the sequence of cards is fixed, though unknown, and the seventh player, by refusal or acceptance of a card, decisively determines its allocation.

It is instructive to analyze decisiveness in terms of probability. Consider an urn game that ends whenever the excess of balls of one color reaches a critical value. Suppose the prior probability of red being the "winning" color is high, because there are more red than blue balls in the urn. Now imagine another scenario, which involves a balanced urn and a majority of red balls in early draws. When the objective probabilities of a red victory are matched in these two scenarios, the probabilities of two more specific events will be higher in the case favored by event cues: (a) the probability of the outcome occurring *soon*, and (b) the probability that the current lead will be preserved until the end of the game. We suggest that impressions of propensity are related to the probability of the next favorable event being decisive, and of current progress not being reversed before the outcome is reached.

The intuition that causal impact increases in the course of the episode is especially compelling when the episode terminates at a fixed time. Obviously, the probability that a team that

leads by a touchdown will win the ball game must increase as time remaining to play diminishes. A score that changes the lead is accordingly perceived as more likely to be decisive if it comes late rather than early in the game. Correspondingly, the close counterfactual is most compelling if the propensity for the unrealized outcome peaked late in the causal episode. An early event may support a counterfactual such as “Team A could have won if Fred had not missed that touchdown in the first quarter,” but the description “Team A almost won” is much more convincing if the missed touchdown happened in the closing minutes of the game.

Propensities for all outcomes will be weak in the early phases of a causal episode, if no decisive advantage can be gained at that time. Early in a football game, neither team has a strong propensity to win, although one of them may have a strong disposition to do so. Later on, propensities to win will be attributed to a team to the extent that it already has, or appears on its way to achieving, a lead that is likely to be maintained to the end. Toward the end of the game, a team with a large lead has an overwhelming propensity to win, and both teams have a significant propensity if the game is close. On the usual interpretation of probability, of course, the sums of the probabilities of victory for the two teams (barring ties) should add to one at all stages of the game. A formal representation of propensities should incorporate the attribute of noncomplementarity, which is admissible in some nonstandard models of probability (Shafer, 1976).

Competitive Causation

The psychological concept of propensity that was introduced in the preceding section has a dual meaning as a probabilistic and as a causal notion. We have interpreted propensity as an intuitive assessment of the current probability of the focal outcome based on event cues, and also as an assessment of the current probability of particular cases of the focal outcome – for example, the event of this outcome occurring soon. But the term *propensity* was chosen because it also denotes a direct expression of causal force – *Webster's Dictionary* defines propensity as “an urgent and often intense natural inclination.” Urgency and intensity are not part of the meaning of probability in theoretical discourse. We suggest, however, that these dynamic features are important aspects of the cognitive representation of many causal processes, including, in

particular, the processes that have achievements as outcomes.

The probabilistic and the causal aspects of propensity suggest different representations of the relation between the alternative outcomes of a causal process. In the language of probability, this relation is expressed by complementarity: Changes in the probability of the focal outcome are mirrored by compensating changes in the aggregate probability of other outcomes. In the language of causal dynamics, the relation between alternative outcomes is best described as competition and conflict. The competition metaphor is evident in many phrases chosen to describe episodes and their outcomes (e.g., “They had to admit defeat and gave up hope of beating the deadline” or “The Harvard job offer won out”). A competitive model of causation is particularly appealing for close counterfactuals, where the strongest propensity is associated first with one outcome, then with another – suggesting a shifting balance between variable opposing forces.

A schema of competing and interacting propensities is most obviously applicable to athletic contests, from which several of our examples have been drawn, but is not restricted to these situations. Displays of the chance games that we have discussed invite a competitive interpretation, much as the figures in the famous Heider and Simmel (1944) animation evoke impressions of intentionality and meaningful interaction. We propose the general hypothesis that the competitive schema is commonly evoked by situations in which the focal outcome is an achievement. These include such varied cases as the making of a difficult individual decision, the vicissitudes of a couple that may or may not break up or get married, the struggle of a firm threatened with bankruptcy, the story of a life-threatening illness, the construction of a building under time constraints, and the wrecking of a building by a tropical storm. Each of these situations is defined by one or more focal achievements. Causal episodes that produce such achievements, or fail to produce them, are naturally described as a struggle of conflicting and variable forces favoring alternative outcomes, or in some cases as a struggle between a single variable force and a series of obstacles.

The notion of conflict between opposing forces is not new to psychological analyses of causality, at least in the context of explaining action. Lewin (1936) introduced motion in a force field as a model of action under conflict. His theory influenced Heider's subsequent

analysis of the naive theory of action, in which action is the resultant of the effective personal force and the effective environmental force (Heider, 1958). Both models explain action as a vectorial combination of forces. Lewin's famous theory of conflict also incorporated a dynamic element: The forces acting on the individual change predictably as the individual moves toward sources of attraction or away from aversive states. In general, however, applications of force field analysis have been static. There has been little emphasis on time or on the possibility of causal forces interacting and changing in the course of an event.

A model of competing propensities would extend Lewinian force field analysis in several ways. First, the concept of focal achievement applies to outcomes that are not goals, such as someone dying from a disease, and to situations that do not involve intentions at all, such as a storm destroying a building. Second, the focus of the competitive model is on extended causal episodes. Third, the competitive model attributes inherent uncertainty to causal systems and describes causal episodes in terms of propensities that may change and interact.

Psychology – or Philosophy?

The present study occupies a somewhat uncomfortable middle ground between psychology and philosophy. We have attempted to identify the conditions under which a particular class of counterfactual assertions would be considered true, or appropriate, and we have introduced a notion of propensity to account for these observations. The questions we addressed are similar to those modern philosophers often raise: Philosophical analyses of counterfactuals, for example, focus on the truth conditions or assertability conditions for counterfactual conditionals. Furthermore, some elements of the method are similar: Persuasive philosophical arguments commonly draw on compelling examples that evoke strong shared intuitions. Although the final product of philosophical analysis often has the form of a formal deductive system, induction from intuitions about particular examples is clearly an important part of philosophical endeavor. However, there are important differences between the aims and assumptions of the two disciplines. Philosophers try to understand causality, probability, or counterfactual conditionals, whereas psychologists try to understand how people think about these topics. These different aims have important consequences in

the attitude toward logical consistency: Understanding a matter involves imposing a consistent logical structure on it, but the study of human thinking should neither assume nor impose consistency on its subject matter.

There is a large and interesting philosophical literature on counterfactuals (e.g., Adams, 1976; Goodman, 1954; Lewis, 1973, 1979; Nute, 1980; Pollock, 1976; Skyrms, 1980; Stalnaker, 1968).⁴ After developing our notions of causal episodes and changing propensities, we encountered similar ideas in Kvart's treatment of counterfactuals and in his later work on causality (Kvart, 1986, 1989). Kvart (1986) described the truth conditions for counterfactual conditionals on the basis of causal processes diverging from actual historical processes at a particular point in time. He introduced a notion of causal paths, explicated by reference to conditional probabilities changing over time. Kvart also emphasized that the commonsense view of the world is non-deterministic, involving a concept of an open future. As might be expected in a philosophical analysis, Kvart treated counterfactuals as objects of thought, not as constructions of the mind. He also had recourse to formal notions of probability and to formal constraints on causal paths, which we have avoided.

Psychologists have drawn most heavily on the tools and concepts of logical and philosophical analysis in studies of deductive reasoning (Braine, 1978; Johnson-Laird, 1983; Rips, 1990). The costs of such borrowing could be high in studies of causality, probability, and counterfactuals. The intensity of current philosophical debate regarding these topics suggests the existence of compelling but mutually inconsistent intuitions. The concepts that have been developed in attempts to resolve these inconsistencies are sometimes quite remote from the naive categories of thought with which psychologists are concerned. Just as an understanding of naive physics may benefit more from acquaintance with Aristotelian physics than with the modern variety, psychological studies of causality, probability, and counterfactuals may do well to avoid exaggerated dependence on the categories of modern philosophical thought.

The dominant approach to causality in psychology, perhaps reflecting a similar dominance in philosophy, treats causation as a particular relationship of dependency between events – expressed by necessary or sufficient conditions or by increased conditional probabilities (Einhorn & Hogarth, 1986; Kelley, 1967; Mackie, 1974). There is another view, however, which treats

causality as a directly perceived link between events or as an emergent property of a patterned sequence of events. The main sources of this approach to causality in psychology are still the classic works by Michotte (1946) and Heider and Simmel (1944), which, respectively, explored variations on the themes of spatiotemporal contiguity and of schemas of intentional action. Ducasse (1969) has developed a philosophical analysis that draws on similar intuitions. The notion of propensity that has been presented here belongs to this tradition of research in causality.

In our use of the term, the representation of propensity is inherently causal, and inherently predictive, much like the perception of an object in motion (Freyd & Finke, 1984). Our emphasis on event cues to propensity deliberately straddled the standard distinction between causes and effects as well as the distinction between causal force and probability. Is there a justification for a concept that blurs accepted distinctions between important categories of thought? There may be. We have described propensity as a perceived attribute with objective reference, much like the perceived length of a line or the perceived distance of an object. Even in the case of lengths and distances, the crude correspondence of the dimensions of percepts to the dimensions of physical description of the world does not guarantee correspondence of the geometries that describe the space people perceive and the space in which they move. The more general point is that the mental representations of events and their relations may not correspond to any logical analysis of causality or probability, and that intuitions about these matters may not be internally consistent. The student of lay intuitions faces a problem that is familiar to cultural anthropologists: How does one make sense of a system of thought without imposing alien categories on it?

Notes

- 1 The importance of the word *almost* as an indication of cognitively and emotionally relevant alternatives to outcomes that actually materialized was pointed out by Heider (1958, pp. 141–144), who drew attention to an instructive passage in Henry Fielding's *Tom Jones* (1749/1975, Vol. 2, p. 691); see also Hofstadter (1979, pp. 634–643).
- 2 The number in parentheses refers to the number of respondents answering the question. In later examples, results will only be reported for the two extreme categories of response.

- 3 Kwart (1986) has offered a treatment for a broad class of counterfactual conditionals in which causality is explicated by probabilities that change over time.
- 4 Skyrms (1980) has a treatment of counterfactual conditionals that relies on what he calls "prior propensities." However, the meaning of his term more closely resembles our usage of dispositions.

Section 8: Argumentation

Chapter 32: The Layout of Arguments

STEPHEN EDELSTON TOULMIN

An argument is like an organism. It has both a gross, anatomical structure and a finer, as-it-were physiological one. When set out explicitly in all its detail, it may occupy a number of printed pages or take perhaps a quarter of an hour to deliver; and within this time or space one can distinguish the main phases marking the progress of the argument from the initial statement of an unsettled problem to the final presentation of a conclusion. These main phases will each of them occupy some minutes or paragraphs, and represent the chief anatomical units of the argument – its ‘organs’, so to speak. But within each paragraph, when one gets down to the level of individual sentences, a finer structure can be recognised, and this is the structure with which logicians have mainly concerned themselves. It is at this physiological level that the idea of logical form has been introduced, and here that the validity of our arguments has ultimately to be established or refuted.

The time has come to change the focus of our inquiry, and to concentrate on this finer level. Yet we cannot afford to forget what we have learned by our study of the grosser anatomy of arguments, for here as with organisms the detailed physiology proves most intelligible when expounded against a background of coarser anatomical distinctions. Physiological processes are interesting not least for the part they play in maintaining the functions of the major organs in which they take place; and micro-arguments (as one may christen them) need to be looked at from time to time with one eye on the macro-arguments in which they figure; since the precise manner in which we phrase them and set them out, to mention only

the least important thing, may be affected by the role they have to play in the larger context.

In the inquiry which follows, we shall be studying the operation of arguments sentence by sentence, in order to see how their validity or invalidity is connected with the manner of laying them out, and what relevance this connection has to the traditional notion of ‘logical form’. Certainly the same argument may be set out in quite a number of different forms, and some of these patterns of analysis will be more candid than others – some of them, that is, will show the validity or invalidity of an argument more clearly than others, and make more explicit the grounds it relies on and the bearing of these on the conclusion. How, then, should we lay an argument out, if we want to show the sources of its validity? And in what sense does the acceptability or unacceptability of arguments depend upon their ‘formal’ merits and defects?

We have before us two rival models, one mathematical, the other jurisprudential. Is the logical form of a valid argument something quasi-geometrical, comparable to the shape of a triangle or the parallelism of two straight lines? Or alternatively, is it something procedural: is a formally valid argument one *in proper form*, as lawyers would say, rather than one laid out in a tidy and simple *geometrical* form? Or does the notion of logical form somehow combine both these aspects, so that to lay an argument out in proper form necessarily requires the adoption of a particular geometrical layout? If this last answer is the right one, it at once creates a further problem for us: to see how and why proper procedure demands the adoption of simple geometrical shape, and how that shape guarantees in

its turn the validity of our procedures. Supposing valid arguments can be cast in a geometrically tidy form, how does this help to make them any the more cogent?

These are the problems to be studied in the present inquiry. If we can see our way to unravelling them, their solution will be of some importance – particularly for a proper understanding of logic. But to begin with we must go cautiously, and steer clear of the philosophical issues on which we shall hope later to throw some light, concentrating for the moment on questions of a most prosaic and straightforward kind. Keeping our eyes on the categories of applied logic – on the practical business of argumentation, that is, and the notions it requires us to employ – we must ask what features a logically candid layout of arguments will need to have. The establishment of conclusions raises a number of issues of different sorts, and a practical layout will make allowance for these differences: our first question is – what are these issues, and how can we do justice to them all in subjecting our arguments to rational assessment?

Two last remarks may be made by way of introduction, the first of them simply adding one more question to our agenda. Ever since Aristotle it has been customary, when analysing the micro-structure of arguments, to set them out in a very simple manner: they have been presented three propositions at a time, ‘minor premiss; major premiss; *so* conclusion’. The question now arises, whether this standard form is sufficiently elaborate or candid. Simplicity is of course a merit, but may it not in this case have been bought too dearly? Can we properly classify all the elements in our arguments under the three headings, ‘major premiss’, ‘minor premiss’, and ‘conclusion’, or are these categories misleadingly few in number? Is there even enough similarity between major and minor premisses for them usefully to be yoked together by the single name of ‘premiss’?

Light is thrown on these questions by the analogy with jurisprudence. This would naturally lead us to adopt a layout of greater complexity than has been customary, for the questions we are asking here are, once again, more general versions of questions already familiar in jurisprudence, and in that more specialised field a whole battery of distinctions has grown up. ‘What different sorts of propositions’, a legal philosopher will ask, ‘are uttered in the course of a law-case, and in what different ways can such propositions bear on the soundness of a legal claim?’ This has always been and still is a central question for

the student of jurisprudence, and we soon find that the nature of a legal process can be properly understood only if we draw a large number of distinctions. Legal utterances have many distinct functions. Statements of claim, evidence of identification, testimony about events in dispute, interpretations of a statute or discussions of its validity, claims to exemption from the application of a law, pleas in extenuation, verdicts, sentences: all these different classes of proposition have their parts to play in the legal process, and the differences between them are in practice far from trifling. When we turn from the special case of the law to consider rational arguments in general, we are faced at once by the question whether these must not be analysed in terms of an equally complex set of categories. If we are to set our arguments out with complete logical candour, and understand properly the nature of ‘the logical process’, surely we shall need to employ a pattern of argument no less sophisticated than is required in the law.

The Pattern of an Argument: Data and Warrants

‘What, then, is involved in establishing conclusions by the production of arguments?’ Can we, by considering this question in a general form, build up from scratch a pattern of analysis which will do justice to all the distinctions which proper procedure forces upon us? That is the problem facing us.

Let it be supposed that we make an assertion, and commit ourselves thereby to the claim which any assertion necessarily involves. If this claim is challenged, we must be able to establish it – that is, make it good, and show that it was justifiable. How is this to be done? Unless the assertion was made quite wildly and irresponsibly, we shall normally have some facts to which we can point in its support: if the claim is challenged, it is up to us to appeal to these facts, and present them as the foundation upon which our claim is based. Of course we may not get the challenger even to agree about the correctness of these facts, and in that case we have to clear his objection out of the way by a preliminary argument: only when this prior issue or ‘lemma’, as geometers would call it, has been dealt with, are we in a position to return to the original argument. But this complication we need only mention: supposing the lemma to have been disposed of, our question is how to set the original argument out most fully and explicitly. ‘Harry’s hair is not black’, we assert. What have we got to go on? we are asked.

Our personal knowledge that it is in fact red: that is our datum, the ground which we produce as support for the original assertion. Petersen, we may say, will not be a Roman Catholic: why? We base our claim on the knowledge that he is a Swede, which makes it very unlikely that he will be a Roman Catholic. Wilkinson, asserts the prosecutor in Court, has committed an offence against the Road Traffic Acts: in support of this claim, two policemen are prepared to testify that they timed him driving at 45 m.p.h. in a built-up area. In each case, an original assertion is supported by producing other facts bearing on it.

We already have, therefore, one distinction to start with: between the *claim* or conclusion whose merits we are seeking to establish (C) and the facts we appeal to as a foundation for the claim – what I shall refer to as our *data* (D). If our challenger's question is, 'What have you got to go on?', producing the data or information on which the claim is based may serve to answer him; but this is only one of the ways in which our conclusion may be challenged. Even after we have produced our data, we may find ourselves being asked further questions of another kind. We may now be required not to add more factual information to that which we have already provided, but rather to indicate the bearing on our conclusion of the data already produced. Colloquially, the question may now be, not 'What have you got to go on?', but 'How do you get there?'. To present a particular set of data as the basis for some specified conclusion commits us to a certain *step*; and the question is now one about the nature and justification of this step.

Supposing we encounter this fresh challenge, we must bring forward not further data, for about these the same query may immediately be raised again, but propositions of a rather different kind: rules, principles, inference-licences or what you will, instead of additional items of information. Our task is no longer to strengthen the ground on which our argument is constructed, but is rather to show that, taking these data as a starting point, the step to the original claim or conclusion is an appropriate and legitimate one. At this point, therefore, what are needed are general, hypothetical statements, which can act as bridges, and authorise the sort of step to which our particular argument commits us. These may normally be written very briefly (in the form 'If D, then C'); but, for candour's sake, they can profitably be expanded, and made more explicit: 'Data such as D entitle one to draw conclusions, or make claims, such as C',

or alternatively 'Given data D, one may take it that C.'

Propositions of this kind I shall call *warrants* (W); to distinguish them from both conclusions and data. (These 'warrants', it will be observed, correspond to the practical standards or canons of argument referred to in our earlier essays.) To pursue our previous examples: the knowledge that Harry's hair is red, entitles us to set aside any suggestion that it is black, on account of the warrant, 'If anything is red, it will not also be black.' (The very triviality of this warrant is connected with the fact that we are concerned here as much with a counter-assertion as with an argument.) The fact that Petersen is a Swede is directly relevant to the question of his religious denomination for, as we should probably put it, 'A Swede can be taken almost certainly not to be a Roman Catholic.' (The step involved here is not trivial, so the warrant is not self-authenticating.) Likewise in the third case: our warrant will now be some such statement as that 'A man who is proved to have driven at more than 30 m.p.h. in a built-up area can be found to have committed an offence against the Road Traffic Acts.'

The question will at once be asked, how absolute is this distinction between data, on the one hand, and warrants, on the other. Will it always be clear whether a man who challenges an assertion is calling for the production of his adversary's data, or for the warrants authorising his steps? Can one, in other words, draw any sharp distinction between the force of the two questions, 'What have you got to go on?' and 'How do you get there?'. By grammatical tests alone, the distinction may appear far from absolute, and the same English sentence may serve a double function: it may be uttered, that is, in one situation to convey a piece of information, in another to authorise a step in an argument, and even perhaps in some contexts to do both these things at once. (All these possibilities will be illustrated before too long.) For the moment, the important thing is not to be too cut-and-dried in our treatment of the subject, nor to commit ourselves in advance to a rigid terminology. At any rate we shall find it possible in *some* situations to distinguish clearly two different logical functions; and the nature of this distinction is hinted at if one contrasts the two sentences, 'Whenever A, one *has found* that B' and 'Whenever A, one *may take* it that B.'

We now have the terms we need to compose the first skeleton of a pattern for analysing arguments. We may symbolise the relation between

the data and the claim in support of which they are produced by an arrow, and indicate the authority for taking the step from one to the other by writing the warrant immediately below the arrow:

Or, to give an example:

As this pattern makes clear, the explicit appeal in this argument goes directly back from the claim to the data relied on as foundation: the warrant is, in a sense, incidental and explanatory, its task being simply to register explicitly the legitimacy of the step involved and to refer it back to the larger class of steps whose legitimacy is being presupposed.

This is one of the reasons for distinguishing between data and warrants: data are appealed to explicitly, warrants implicitly. In addition, one may remark that warrants are general, certifying the soundness of *all* arguments of the appropriate type, and have accordingly to be established in quite a different way from the facts we produce as data. This distinction, between data and warrants, is similar to the distinction drawn in the law-courts between questions of fact and questions of law, and the legal distinction is indeed a special case of the more general one – we may argue, for instance, that a man whom we know to have been born in Bermuda is presumably a British subject, simply because the relevant laws give us a warrant to draw this conclusion.

One more general point in passing: unless, in any particular field of argument, we are prepared to work with warrants of *some* kind, it will become impossible in that field to subject arguments to rational assessment. The data we cite if a claim is challenged depend on the warrants we are prepared to operate with in that field, and the warrants to which we commit ourselves are implicit in the particular steps from data to claims we are prepared to take and to admit. But supposing a man rejects all warrants whatever authorising (say) steps from data

about the present and past to conclusions about the future, then for him rational prediction will become impossible; and many philosophers have in fact denied the possibility of rational prediction just because they thought they could discredit equally the claims of all past-to-future warrants.

The skeleton of a pattern which we have obtained so far is only a beginning. Further questions may now arise, to which we must pay attention. Warrants are of different kinds, and may confer different degrees of force on the conclusions they justify. Some warrants authorise us to accept a claim unequivocally, given the appropriate data – these warrants entitle us in suitable cases to qualify our conclusion with the adverb ‘necessarily’; others authorise us to make the step from data to conclusion either tentatively, or else subject to conditions, exceptions, or qualifications – in these cases other modal qualifiers, such as ‘probably’ and ‘presumably’, are in place. It may not be sufficient, therefore, simply to specify our data, warrant and claim: we may need to add some explicit reference to the degree of force which our data confer on our claim in virtue of our warrant. In a word, we may have to put in a *qualifier*. Again, it is often necessary in the law-courts, not just to appeal to a given statute or common-law doctrine, but to discuss explicitly the extent to which this particular law fits the case under consideration, whether it must inevitably be applied in this particular case, or whether special facts may make the case an exception to the rule or one in which the law can be applied only subject to certain qualifications.

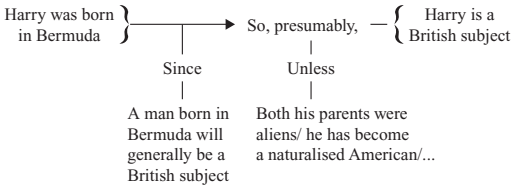

If we are to take account of these features of our argument also, our pattern will become more complex. Modal qualifiers (Q) and conditions of exception or rebuttal (R) are distinct both from data and from warrants, and need to be given separate places in our layout. Just as a warrant (W) is itself neither a datum (D) nor a claim (C), since it implies in itself something about both D and C – namely, that the step from the one to the other is legitimate; so, in turn, Q and R are themselves distinct from W, since they comment implicitly on the bearing of W on this step – qualifiers (Q) indicating the strength conferred by the warrant on this step, conditions of rebuttal (R) indicating circumstances in which the general authority of the warrant would have to be set aside. To mark these further distinctions, we may write the qualifier (Q) immediately beside the conclusion which it qualifies (C), and the exceptional conditions which might

be capable of defeating or rebutting the warranted conclusion (R) immediately below the qualifier.

To illustrate: our claim that Harry is a British subject may normally be defended by appeal to the information that he was born in Bermuda, for this datum lends support to our conclusion on account of the warrants implicit in the British Nationality Acts; but the argument is not by itself conclusive in the absence of assurances about his parentage and about his not having changed his nationality since birth. What our information does do is to establish that the conclusion holds good 'presumably', and subject to the appropriate provisos. The argument now assumes the form:

i.e.

We must remark, in addition, on two further distinctions. The first is that between a statement of a warrant, and statements about its applicability – between 'A man born in Bermuda will be British', and 'This presumption holds good provided his parents were not both aliens, etc.' The distinction is relevant not only to the law of the land, but also for an understanding of scientific laws or 'laws of nature': it is important, indeed, in all cases where the application of a law may be subject to exceptions, or where a warrant can be supported by pointing to a general correlation only, and not to an absolutely invariable one. We can distinguish also two purposes which may be served by the production of additional facts: these can serve as further data, or they can be cited to confirm or rebut the applicability of a warrant. Thus, the fact that Harry was born in Bermuda and the fact that his parents were not aliens are both of them directly relevant to the question of his present nationality; but they are relevant in different ways. The one fact is a datum, which by itself establishes a presumption of British nationality; the other fact, by setting aside one possible rebuttal, tends to confirm the presumption thereby created.

One particular problem about applicability we shall have to discuss more fully later: when we set out a piece of applied mathematics, in which some system of mathematical relations is used to throw light on a question of (say) physics, the correctness of the calculations will be one thing, their appropriateness to the problem in hand may be quite another. So the question 'Is this calculation mathematically impeccable?' may be a very different one from the question 'Is this the relevant calculation?' Here too, the applicability of a particular warrant is one question: the result we shall get from applying the warrant is another matter, and in asking about the *correctness* of the result we may have to inquire into both these things independently.

The Pattern of an Argument: Backing Our Warrants

One last distinction, which we have already touched on in passing, must be discussed at some length. In addition to the question whether or on what conditions a warrant is applicable in a *particular* case, we may be asked why *in general* this warrant should be accepted as having authority. In defending a claim, that is, we may produce our data, our warrant, and the relevant qualifications and conditions, and yet find that we have still not satisfied our challenger; for he may be dubious not only about this particular argument but about the more general question whether the warrant (W) is acceptable at all. Presuming the general acceptability of this warrant (he may allow) our argument would no doubt be impeccable – if D-ish facts really do suffice as backing for C-ish claims, all well and good. But does not that warrant in its turn rest on something else? Challenging a particular claim may in this way lead on to challenging, more generally, the legitimacy of a whole range of arguments. 'You presume that a man born in Bermuda can be taken to be a British subject,' he may say, 'but why do you think that?' Standing behind our warrants, as this example reminds us, there will normally be other assurances, without which the warrants themselves would possess neither authority nor currency – these other things we may refer to as the *backing* (B) of the warrants. This 'backing' of our warrants is something which we shall have to scrutinise very carefully: its precise relations to our data, claims, warrants, and conditions of rebuttal deserve some clarification, for confusion at this point can lead to trouble later.

We shall have to notice particularly how the sort of backing called for by our warrants varies

from one field of argument to another. The *form* of argument we employ in different fields

need not vary very much as between fields. ‘A whale will be a mammal’, ‘A Bermudan will be a Briton’, ‘A Saudi Arabian will be a Muslim’: here are three different warrants to which we might appeal in the course of a practical argument, each of which can justify the same sort of straightforward step from a datum to a conclusion. We might add for variety examples of even more diverse sorts, taken from moral, mathematical or psychological fields. But the moment we start asking about the *backing* which a warrant relies on in each field, great differences begin to appear: the kind of backing we must point to if we are to establish its authority will change greatly as we move from one field of argument to another. ‘A whale will be (i.e. *is classifiable as*) a mammal’, ‘A Bermudan will be (*in the eyes of the law*) a Briton’, ‘A Saudi Arabian will be (*found to be*) a Muslim’ – the words in parentheses indicate what these differences are. One warrant is defended by relating it to a system of taxonomical classification, another by appealing to the statutes governing the nationality of people born in the British colonies, the third by referring to the statistics which record how religious beliefs are distributed among people of different nationalities. We can for the moment leave open the more contentious question, how we establish our warrants in the fields of morals, mathematics and psychology: for the moment all we are trying to show is the *variability* or *field dependence* of the backing needed to establish our warrants.

We can make room for this additional element in our argument pattern by writing it below the bare statement of the warrant for which it serves as backing (B):

This form may not be final, but it will be complex enough for the purpose of our present discussions. To take a particular example: in support of the claim (C) that Harry is a British

subject, we appeal to the datum (D) that he was born in Bermuda, and the warrant can then be stated in the form, ‘A man born in Bermuda may be taken to be a British subject’: since, however, questions of nationality are always subject to qualifications and conditions, we shall have to insert a qualifying ‘presumably’ (Q) in front of the conclusion, and note the possibility that our conclusion may be rebutted in case (R) it turns out that both his parents were aliens or he has since become a naturalised American. Finally, in case the warrant itself is challenged, its backing can be put in: this will record the terms and the dates of enactment of the Acts of Parliament and other legal provisions governing the nationality of persons born in the British colonies. The result will be an argument set out as follows:

In what ways does the backing of warrants differ from the other elements in our arguments? To begin with the differences between B and W: statements of warrants, we saw, are hypothetical, bridgelike statements, but the backing for warrants can be expressed in the form of categorical statements of fact quite as well as can the data appealed to in direct support of our conclusions. So long as our statements reflect these functional differences explicitly, there is no danger of confusing the backing (B) for a warrant with the warrant itself (W): such confusions arise only when these differences are disguised by our forms of expression. In our present example, at any rate, there need be no difficulty. The fact that the relevant statutes have been validly passed into law, and contain the provisions they do, can be ascertained simply by going to the records of the parliamentary proceedings concerned and to the relevant volumes in the books of statute law: the resulting discovery, that such-and-such a statute enacted on such-and-such a date contains a provision specifying that people born in the British colonies of suitable parentage shall be entitled to British citizenship, is a straightforward statement of fact. On the other hand, the warrant which we apply *in virtue of* the statute

containing this provision is logically of a very different character – ‘If a man was born in a British colony, he *may be presumed to be* British.’ Though the facts about the statute may provide all the backing required by this warrant, the explicit statement of the warrant itself is more than a repetition of these facts: it is a general *moral* of a practical character, about the ways in which we can safely argue in view of these facts.

We can also distinguish backing (B) from data (D). Though the data we appeal to in an argument and the backing lending authority to our warrants may alike be stated as straightforward matters-of-fact, the roles which these statements play in our argument are decidedly different. Data of some kind must be produced, if there is to be an argument there at all: a bare conclusion, without any data produced in its support, is no argument. But the backing of the warrants we invoke need not be made explicit – at any rate to begin with: the warrants may be conceded without challenge, and their backing left understood. Indeed, if we demanded the credentials of all warrants at sight and never let one pass unchallenged, argument could scarcely begin. Jones puts forward an argument invoking warrant W_1 , and Smith challenges that warrant; Jones is obliged, as a lemma, to produce another argument in the hope of establishing the acceptability of the first warrant, but in the course of this lemma employs a second warrant W_2 ; Smith challenges the credentials of this second warrant in turn; and so the game goes on.

Some warrants must be accepted provisionally without further challenge, if argument is to be open to us in the field in question: we should not even know what sort of data were of the slightest relevance to a conclusion, if we had not at least a provisional idea of the warrants acceptable in the situation confronting us. The existence of considerations such as would establish the acceptability of the most reliable warrants is something we are entitled to take for granted.

Finally, a word about the ways in which B differs from Q and R: these are too obvious to need expanding upon, since the grounds for regarding a warrant as generally acceptable are clearly one thing, the force which the warrant lends to a conclusion another, and the sorts of exceptional circumstance which may in particular cases rebut the presumptions the warrant creates a third. They correspond, in our example, to the three statements, (i) that the statutes about British nationality *have in fact* been validly passed into law, and say this: . . . , (ii) that Harry *may be presumed* to be a British subject, and (iii)

that Harry, having recently become a naturalised American, *is no longer covered* by these statutes.

One incidental point should be made, about the interpretation to be put upon the symbols in our pattern of argument: this may throw light on a slightly puzzling example which we came across when discussing Kneale’s views on probability. Consider the arrow joining D and C. It may seem natural to suggest at first that this arrow should be read as ‘so’ in one direction and as ‘because’ in the other. Other interpretations are however possible. As we saw earlier, the step from the information that Jones has Bright’s Disease to the conclusion that he cannot be expected to live to eighty does not reverse perfectly: we find it natural enough to say, ‘Jones cannot be expected to live to eighty, *because* he has Bright’s Disease’, but the fuller statement, ‘Jones cannot be expected to live to eighty, *because* the probability of his living that long is low, *because* he has Bright’s Disease’, strikes us as cumbrous and artificial, for it puts in an extra step which is trivial and unnecessary. On the other hand, we do not mind saying, ‘Jones has Bright’s Disease, *so* the chances of his living to eighty are slight, *so* he cannot be expected to live that long’, for the last clause is (so to speak) an *inter alia* clause – it states one of the many particular morals one can draw from the middle clause, which tells us his general expectation of life.

So also in our present case: reading along the arrow from right to left or from left to right we can normally say both ‘C, because D’ and ‘D, so C’. But it may sometimes happen that some more general conclusion than C may be warranted, given D: where this is so, we shall often find it natural to write, not only ‘D, so C’, but also ‘D, so C’, so C’, C’ being the more general conclusion warranted in view of data D, from which in turn we infer *inter alia* that C. Where this is the case, our ‘so’ and ‘because’ are no longer reversible: if we now read the argument backwards the statement we get – ‘C, because C’, because D’ – is again more cumbrous than the situation really requires.

Ambiguities in the Syllogism

The time has come to compare the distinctions we have found of practical importance in the layout and criticism of arguments with those which have traditionally been made in books, on the theory of logic: let us start by seeing how our present distinctions apply to the syllogism or syllogistic argument. For the purposes of our

present argument we can confine our attention to one of the many forms of syllogism – that represented by the time-honoured example:

Socrates is a man;
All men are mortal;
So Socrates is mortal.

This type of syllogism has certain special features. The first premiss is ‘singular’ and refers to a particular individual, while the second premiss alone is ‘universal’. Aristotle himself was, of course, much concerned with syllogisms in which both the premisses were universal, since to his mind many of the arguments within scientific theory must be expected to be of this sort. But we are interested primarily in arguments by which general propositions are applied to justify particular conclusions about individuals; so this initial limitation will be convenient. Many of the conclusions we reach will, in any case, have an obvious application – *mutatis mutandis* – to syllogisms of other types. We can begin by asking the question ‘What corresponds in the syllogism to our distinction between data, warrant, and backing?’ If we press this question, we shall find that the apparently innocent forms used in syllogistic arguments turn out to have a hidden complexity. This internal complexity is comparable with that we observed in the case of modally-qualified conclusions: here, as before, we shall be obliged to disentangle two distinct things – the force of universal premisses, when regarded as warrants, and the backing on which they depend for their authority.

In order to bring these points clearly to light, let us keep in view not only the two universal premisses on which logicians normally concentrate – ‘All A’s are B’s’ and ‘No A’s are B’s’ – but also two other forms of statement which we probably have just as much occasion to use in practice – ‘Almost all A’s are B’s’ and ‘Scarcely any A’s are B’s.’ The internal complexity of such statements can be illustrated first, and most clearly, in the latter cases.

Consider, for instance, the statement, ‘Scarcely any Swedes are Roman Catholics.’ This statement can have two distinct aspects: both of them are liable to be operative at once when the statement figures in an argument, but they can nevertheless be distinguished. To begin with, it may serve as a simple statistical report: in that case, it can equally well be written in the fuller form, ‘The proportion of Swedes who are Roman Catholics is less than (say) 2%’ – to which we may add a parenthetical reference

to the source of our information, ‘(According to the tables in *Whittaker’s Almanac*)’. Alternatively, the same statement may serve as a genuine inference-warrant: in that case, it will be natural to expand it rather differently, so as to obtain the more candid statement, ‘A Swede can be taken almost certainly not to be a Roman Catholic.’

So long as we look at the single sentence ‘Scarcely any Swedes are Roman Catholics’ by itself, this distinction may appear trifling enough: but if we apply it to the analysis of an argument in which this appears as one premiss, we obtain results of some significance. So let us construct an argument of quasi-syllogistic form, in which this statement figures in the position of a ‘major premiss’. This argument could be, for instance, the following:

Petersen is a Swede;
Scarcely any Swedes are Roman Catholics;
So, almost certainly, Petersen is not a Roman Catholic.

The conclusion of this argument is only tentative, but in other respects the argument is exactly like a syllogism.

As we have seen, the second of these statements can be expanded in each of two ways, so that it becomes either, ‘The proportion of Swedes who are Roman Catholics is less than 2%’, or else, ‘A Swede can be taken almost certainly not to be a Roman Catholic.’ Let us now see what happens if we substitute each of these two expanded versions in turn for the second of our three original statements. In one case we obtain the argument:

Petersen is a Swede;
A Swede can be taken almost certainly not to be a Roman Catholic;
So, almost certainly, Petersen is not a Roman Catholic.

Here the successive lines correspond in our terminology to the statement of a datum (D), a warrant (W), and a conclusion (C). On the other hand, if we make the alternative substitution, we obtain:

Petersen is a Swede;
The proportion of Roman Catholic Swedes is less than 2%;
So, almost certainly, Petersen is not a Roman Catholic.

In this case we again have the same datum and conclusion, but the second line now states the backing (B) for the warrant (W), which is itself left unstated.

For tidiness' sake, we may now be tempted to abbreviate these two expanded versions. If we do so, we can obtain respectively the two arguments:

(D) Petersen is a Swede;

(W) A Swede is almost certainly not a Roman Catholic;

So, (C) Petersen is almost certainly not a Roman Catholic:

and,

(D) Petersen is a Swede;

(B) The proportion of Roman Catholic Swedes is minute;

So, (C) Petersen is almost certainly not a Roman Catholic.

The relevance of our distinction to the traditional conception of 'formal validity' should already be becoming apparent, and we shall return to the subject shortly.

Turning to the form 'No A's are B's' (e.g. 'No Swedes are Roman Catholics'), we can make a similar distinction. This form of statement also can be employed in two alternative ways, either as a statistical report, or as an inference-warrant. It can serve simply to report a statistician's discovery – say, that the proportion of Roman Catholic Swedes is in fact zero; or alternatively it can serve to justify the drawing of conclusions in argument, becoming equivalent to the explicit statement, 'A Swede can be taken certainly not to be a Roman Catholic.' Corresponding interpretations are again open to us if we look at an argument which includes our sample statement as the universal premiss. Consider the argument:

Petersen is a Swede;

No Swedes are Roman Catholics;

So, certainly, Petersen is not a Roman Catholic.

This can be understood in two ways: we may write it in the form:

Petersen is a Swede;

The proportion of Roman Catholic Swedes is zero;

So, certainly, Petersen is not a Roman Catholic,

or alternatively in the form:

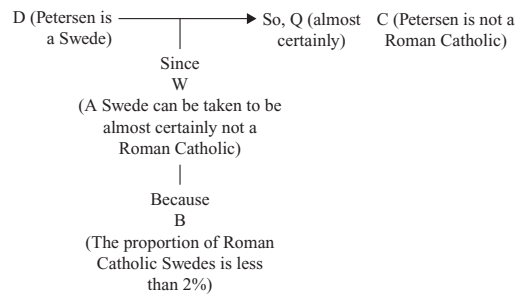

Petersen is a Swede;

A Swede is certainly not a Roman Catholic;

So, certainly, Petersen is not a Roman Catholic.

Here again the first formulation amounts, in our terminology, to putting the argument in the form 'D, B, so C'; while the second formulation is equivalent to putting it in the form 'D, W, so C'. So, whether we are concerned with a 'scarcely any...' argument or a 'no...' argument, the customary form of expression will tend in either case to conceal from us the distinction between an inference-warrant and its backing. The same will be true in the case of 'all' and 'nearly all': there, too, the distinction between saying 'Every, or nearly every single A has been found to be a B' and saying 'An A can be taken, certainly or almost certainly, to be a B' is concealed by the over-simple form of words 'All A's are B's.' A crucial difference in practical function can in this way pass unmarked and unnoticed.

Our own more complex pattern of analysis, by contrast, avoids this defect. It leaves no room for ambiguity: entirely separate places are left in the pattern for a warrant and for the backing upon which its authority depends. For instance, our 'scarcely any...' argument will have to be set out in the following way:

Corresponding transcriptions will be needed for arguments of the other three types.

When we are theorising about the syllogism, in which a central part is played by propositions of the forms 'All A's are B's' and 'No A's are B's', it will accordingly be as well to bear this distinction in mind. The form of statement 'All A's are B's' is as it stands deceptively simple: it may have in use both the force of a warrant and the factual content of its backing, two aspects which we can bring out by expanding it in different ways. Sometimes it may be used, standing alone, in only one of these two ways at once;

but often enough, especially in arguments, we make the single statement do both jobs at once and gloss over, for brevity's sake, the transition from backing to warrant – from the factual information we are presupposing to the inference-licence which that information justifies us in employing. The practical economy of this habit may be obvious; but for philosophical purposes it leaves the effective structure of our arguments insufficiently candid.

There is a clear parallel between the complexity of 'all...' statements and that of modal statements. As before, the *force* of the statements is invariant for all fields of argument. When we consider this aspect of the statements, the form 'All A's are B's' may always be replaced by the form 'An A can certainly be taken to be a B': this will be true regardless of the field, holding good equally of 'All Swedes are Roman Catholics', 'All those born in British colonies are entitled to British citizenship', 'All whales are mammals', and 'All lying is reprehensible' – in each case, the general statement will serve as a warrant authorising an argument of precisely the same form, $D \rightarrow C$, whether the step goes from 'Harry was born in Bermuda' to 'Harry is a British citizen' or from 'Wilkinson told a lie' to 'Wilkinson acted reprehensibly.' Nor should there be any mystery about the nature of the step from D to C, since the whole *force* of the general statement 'All A's are B's', as so understood, is to authorise just this sort of step.

By contrast, the kind of *grounds* or *backing* supporting a warrant of this form will depend on the field of argument: here the parallel with modal statements is maintained. From this point of view, the important thing is the factual content, not the force of 'all...' statements. Though a warrant of the form 'An A can certainly be taken to be a B' must hold good in any field in virtue of *some* facts, the actual sort of facts in virtue of which any warrant will have currency and authority will vary according to the field of argument within which that warrant operates; so, when we expand the simple form 'All A's are B's' in order to make explicit the nature of the backing it is used to express, the expansion we must make will also depend upon the field with which we are concerned. In one case, the statement will become 'The proportion of A's found to be B's is 100%'; in another, 'A's are ruled by statute to count unconditionally as B's'; in a third, 'The class of B's includes taxonomically the entire class of A's'; and in a fourth, 'The practice of doing A leads to the following intolerable consequences, etc.' Yet, despite

the striking differences between them, all these elaborate propositions are expressed on occasion in the compact and simple form 'All A's are B's.'

Similar distinctions can be made in the case of the forms, 'Nearly all A's are B's', 'Scarcely any A's are B's', and 'No A's are B's.' Used to express warrants, these differ from 'All A's are B's' in only one respect, that where before we wrote 'certainly' we must now write 'almost certainly', 'almost certainly not' or 'certainly not'. Likewise, when we are using them to state not warrants but backing: in a statistical case we shall simply have to replace '100%' by (say) 'at least 95%', 'less than 5%' or 'zero'; in the case of a statute replace 'unconditionally' by 'unless exceptional conditions hold', 'only in exceptional circumstances' or 'in no circumstances whatever'; and in a taxonomical case replace 'the entirety of the class of A's' by 'all but a small sub-class...', 'only a small subclass...' or 'no part of...'. Once we have filled out the skeletal forms 'all...' and 'no...' in this way, the field-dependence of the backing for our warrants is as clear as it could be.

The Notion of 'Universal Premisses'

The full implications of the distinction between force and backing, as applied to propositions of the form 'All A's are B's', will become clear only after one further distinction has been introduced – that between 'analytic' and 'substantial' arguments. This cannot be done immediately, so for the moment all we can do is to hint at ways in which the traditional way of setting out arguments – in the form of two premisses followed by a conclusion – may be misleading.

Most obviously, this pattern of analysis is liable to create an exaggerated appearance of uniformity as between arguments in different fields, but what is probably as important is its power of disguising also the great differences between the things traditionally classed together as 'premisses'. Consider again examples of our standard type, in which a particular conclusion is justified by appeal to a particular datum about an individual – the singular, minor premiss – taken together with a general piece of information serving as warrant and/or backing – the universal, major premiss. So long as we interpret universal premisses as expressing not warrants but their backing, both major and minor premisses are at any rate categorical and factual: in this respect, the information that not a single Swede is recorded as being a Roman Catholic is on a par

with the information that Karl Henrik Petersen is a Swede. Even so, the different roles played in practical argument by one's data and by the backing for one's warrants make it rather unfortunate to label them alike 'premisses'. But supposing we adopt the alternative interpretation of our major premisses, treating them instead as warrants, the differences between major and minor premisses are even more striking. A 'singular premiss' expresses a piece of information *from* which we are drawing a conclusion, a 'universal premiss' now expresses, not a piece of information at all, but a guarantee *in accordance with* which we can safely take the step from our datum to our conclusion. Such a guarantee, for all its backing, will be neither factual nor categorical but rather hypothetical and permissive. Once again, the two-fold distinction between 'premisses' and 'conclusion' appears insufficiently complex and, to do justice to the situation, one needs to adopt in its place at least the fourfold distinction between 'datum', 'conclusion', 'warrant' and 'backing'.

One way in which the distinction between the various possible interpretations of the 'universal premiss' may prove important to logicians can be illustrated by referring to an old logical puzzle. The question has often been debated, whether the form of statement 'All A's are B's' has or has not any existential implications: whether, that is, its use commits one to the belief that some A's do exist. Statements of the form 'Some A's are B's' have given rise to no such difficulty, for the use of this latter form always implies the existence of some A's, but the form 'All A's are B's' seems to be more ambiguous. It has been argued, for instance, that such a statement as 'All club-footed men have difficulty in walking' need not be taken as implying the existence of any club-footed men: this is a general truth, it is said, which would remain equally true even though, for once in a while, there were no living men having club feet, and it would not suddenly cease to be true that club-footedness made walking difficult just because the last club-footed man had been freed of his deformity by a skilful surgeon. Yet this leaves us uncomfortable: has our assertion then no existential force? Surely, we feel, club-footed men must at any rate *have* existed if we are to be able to make this assertion at all?

This conundrum illustrates very well the weaknesses of the term 'universal premiss'. Suppose that we rely on the traditional mode of analysis of arguments:

Jack is club-footed;

All club-footed men have difficulty in walking;

So, Jack has difficulty in walking.

For so long as we do, the present difficulty will be liable to recur, since this pattern of analysis leaves it unclear whether the general statement 'All . . .' is to be construed as a permissive inference warrant or as a factual report of our observations. Is it to be construed as meaning 'A club-footed man will (i.e. may be expected to) have difficulty in walking', or as meaning 'Every club-footed man of whom we have records had (i.e. was found to have) difficulty in walking'? We are not bound, except by long habit, to employ the form 'All A's are B's', with all the ambiguities it involves. We are at liberty to scrap it in favour of forms of expression which are more explicit, even if more cumbersome; and if we make this change, the problem about existential implications will simply no longer trouble us. The statement 'Every club-footed man of whom we have records . . .' implies, of course, that there have been at any rate *some* club-footed men, since otherwise we should have no records to refer to; while the warrant 'A club-footed man will have difficulty in walking', equally of course, leaves the existential question open. We can truthfully say that club-footedness would be a handicap to any pedestrian, even if we knew that at this moment everyone was lying on his back and nobody was so deformed. We are therefore not compelled to answer as it stands the question whether 'All A's are B's' has existential implications: certainly we can refuse a clear Yes or No. Some of the statements which logicians represent in this rather crude form do have such implications; others do not. No entirely general answer can be given to the question, for what determines whether there are or are not existential implications in any particular case is not the form of statement itself, but rather the practical use to which this form is put on that occasion.

Can we say then that the form 'All A's are B's' has existential implications when used to express the backing of a warrant, but not when used to express the warrant itself? Even this way of putting the point turns out to be too neat. For the other thing which excessive reliance on the form 'All A's are B's' tends to conceal from us is the different sorts of backing which our general beliefs may require, and these differences are relevant here. No doubt the statement that every club-footed man of whom we have any record found his deformity a handicap in

walking, which we have here cited as backing, implies that there have been some such people; but we can back the same warrant by appeal to considerations of other kinds as well, e.g. by arguments explaining from anatomical principles in what way club-footedness may be expected to lead to disability – just how this shape of foot will prove a handicap. In these theoretical terms we could discuss the disabilities which would result from any kind of deformity we cared to imagine, including ones which nobody is known ever to have had: this sort of backing accordingly leaves the existential question open.

Again, if we consider warrants of other types, we find plenty of cases in which the backing for a warrant has, as it stands, no existential implication. This may be true, for instance, in the case of warrants backed by statutory provisions: legislation may refer to persons or situations which have yet to be – for instance, to all married women who will reach the age of 70 after 1 January 1984 – or alternatively to classes of persons none of whom may ever exist, such as men found guilty on separate occasions of ten different murders. Statutes referring to people of these types can provide backing for inference-warrants entitling us to take all kinds of steps in argument, without either the warrants or their backing implying anything about the existence of such people at all. To sum up: if we pay closer attention to the differences between warrants and backing, and between different sorts of backing for one and the same warrant, and between the backing for warrants of different sorts, and if we refuse to focus our attention hypnotically on the traditional form ‘All A’s are B’s’, we can not only come to see *that* sometimes ‘All A’s are B’s’, does have existential implications and sometimes not, but furthermore begin to understand *why* this should be so.

Once one has become accustomed to expanding statements of the form ‘All A’s are B’s’, and replacing them, as occasion requires, by explicit warrants or explicit statements of backing, one will find it a puzzle that logicians have been wedded to this form of statement for so long. The reasons for this will concern us in a later essay: for the moment, we may remark that they have done so only at the expense of impoverishing our language and disregarding a large number of clues to the proper solutions of their conundrums. For the form ‘All A’s are B’s’ occurs in practical argument much less than one would suppose from logic textbooks: indeed, a great deal of effort has to be expended in order to

train students in ways of rephrasing in this special form the idiomatic statements to which they are already accustomed, thereby making these idiomatic utterances apparently amenable to traditional syllogistic analysis. There is no need, in complaining of this, to argue that idiom is sacrosanct, or provides by itself understanding of a kind we could not have had before. Nevertheless, in our normal ways of expressing ourselves, one will find many points of idiom which can serve as very definite clues, and are capable in this case of leading us in the right direction.

Where the logician has in the past cramped all general statements into his predetermined form, practical speech has habitually employed a dozen different forms – ‘Every single A is a B’, ‘Each A is a B’, ‘An A will be a B’, ‘A’s are generally B’s’ and ‘The A is a B’ being only a selection. By contrasting these idioms, instead of ignoring them or insisting that they all fall into line, logicians would long ago have been led on to the distinctions we have found crucial. The contrast between ‘Every A’ and ‘Not a single A’, on the one hand, and ‘Any A’ or ‘An A’, on the other, points one immediately towards the distinction between statistical reports and the warrants for which they can be the backing. The differences between warrants in different fields are also reflected in idiom. A biologist would hardly ever utter the words ‘All whales are mammals’; though sentences such as ‘Whales are mammals’ or ‘The whale is a mammal’ might quite naturally come from his lips or his pen. Warrants are one thing, backing another; backing by enumerative observation is one thing, backing by taxonomic classification another; and our choices of idiom, though perhaps subtle, reflect these differences fairly exactly.

Even in so remote a field as philosophical ethics, some hoary problems have been generated in just this way. Practice forces us to recognise that general ethical truths can aspire at best to hold good in the absence of effective counter-claims: conflicts of duty are an inescapable feature of the moral life. Where logic demands the form ‘*All* lying is reprehensible’ or ‘*All* promise-keeping is right’, idiom therefore replies ‘Lying is reprehensible’ and ‘Promisekeeping is right.’ The logician’s ‘all’ imports unfortunate expectations, which in practice are bound on occasion to be disappointed. Even the most general warrants in ethical arguments are yet liable in unusual situations to suffer exceptions, and so at strongest can authorise only presumptive conclusions. If we insist on the ‘all’, conflicts of duties land us in

paradox, and much of moral theory is concerned with getting us out of this morass. Few people insist on trying to put into practice the consequences of insisting on the extra 'all', for to do so one must resort to desperate measures: it can be done only by adopting an eccentric moral position, such as absolute pacifism, in which one principle and one alone is admitted to be genuinely universal, and this principle is defended through thick and thin, in the face of all the conflicts and counter-claims which would normally qualify its application. The road from nice points about logic and idiom to the most difficult problems of conduct is not, after all, such a long one.

The Notion of Formal Validity

The chief morals of this study of practical argument will be our concern in the final pair of essays. But there is one topic – the one from which this present essay began – about which we are already in a position to say something: namely, the idea of 'logical form', and the doctrines which attempt to explain the validity of arguments in terms of this notion of form. It is sometimes argued, for instance, that the validity of syllogistic arguments is a consequence of the fact that the conclusions of these arguments are simply 'formal transformations' of their premisses. If the information we start from, as expressed in the major and minor premisses, leads to the conclusion it does by a valid inference, that (it is said) is because the conclusion results simply from shuffling the parts of the premisses and rearranging them in a new pattern. In drawing the inference, we re-order the given elements, and the formal relations between these elements as they appear, first in the premisses and then in the conclusion, somehow or other assure for us the validity of the inference which we make.

How does this doctrine look, if we now make our central distinction between the two aspects of the statement-form 'All A's are B's'? Consider an argument of the form:

X is an A;

All A's are B's;

So X is a B.

If we expand the universal premiss of this argument as a warrant, it becomes 'Any A can certainly be taken to be a B' or, more briefly, 'An A is certainly a B.' Substituting this in the argument, we obtain:

X is an A;

An A is certainly a B;

So X is certainly a B.

When the argument is put in this way, the parts of the conclusion are manifestly the same as the parts of the premisses, and the conclusion can be obtained simply by shuffling the parts of the premisses and rearranging them. If that is what is meant by saying that the argument has the appropriate 'logical form', and that it is valid on account of that fact, then this may be said to be a 'formally valid' argument. Yet one thing must be noticed straight away: provided that the correct warrant is employed, any argument can be expressed in the form 'Data; warrant; so conclusion' and so become formally valid. By suitable choice of phrasing, that is, any such argument can be so expressed that its validity is apparent simply from its form: this is true equally, whatever the field of the argument – it makes no difference if the universal premiss is 'All multiples of 2 are even', 'All lies are reprehensible' or 'All whales are mammals.' Any such premiss can be written as an unconditional warrant, 'An A is certainly a B', and used in a formally valid inference; or, to put the point less misleadingly, can be used in an inference which is so set out that its validity becomes formally manifest.

On the other hand, if we substitute the backing for the warrant, i.e. interpret the universal premiss in the other way, there will no longer be any room for applying the idea of formal validity to our argument. An argument of the form 'Data; backing; so conclusion' may, for practical purposes, be entirely in order. We should accept without hesitation the argument:

Petersen is a Swede;

The recorded proportion of Roman Catholic Swedes is zero;

So, certainly, Petersen is not a Roman Catholic.

But there can no longer be any pretence that the soundness of this argument is a consequence of any formal properties of its constituent expressions. Apart from anything else, the elements of the conclusion and premisses are not the same: the step therefore involves more than shuffling and re-ordering. For that matter, of course, the validity of the (D; W; so C) argument was not really a *consequence* of its formal properties either, but at any rate in that case one could state the argument in a particularly tidy form. Now this can no longer be done: a (D; B; so C)

argument will not be formally valid. Once we bring into the open the backing on which (in the last resort) the soundness of our arguments depends, the suggestion that validity is to be explained in terms of 'formal properties', in any geometrical sense, loses its plausibility.

This discussion of formal validity can throw some light on another point of idiom: one in which the customary usage of arguers again parts company with logical tradition. The point arises in the following way. Suppose we contrast what may be called 'warrant-using' arguments with 'warrant-establishing' ones. The first class will include, among others, all those in which a single datum is relied on to establish a conclusion by appeal to some warrant whose acceptability is being taken for granted – examples are 'Harry was born in Bermuda, so presumably (people born in the colonies being entitled to British citizenship) Harry is a British citizen', 'Jack told a lie, so presumably (lying being generally reprehensible) Jack behaved in a reprehensible way', and 'Petersen is a Swede, so presumably (scarcely any Swedes being Roman Catholics) Petersen is not a Roman Catholic'. Warrant-establishing arguments will be, by contrast, such arguments as one might find in a scientific paper, in which the acceptability of a novel warrant is made clear by applying it successively in a number of cases in which both 'data' and 'conclusion' have been independently verified. In this type of argument the warrant, not the conclusion, is novel, and so on trial.

Professor Gilbert Ryle has compared the steps involved in these two types of argument with, respectively, the taking of a journey along a railway already built and the building of a fresh railway: he has argued persuasively that only the first class of arguments should be referred to as 'inferences', on the ground that the essential element of innovation in the latter class cannot be made the subject of rules and that the notion of inference essentially involves the possibility of 'rules of inference'.

The point of idiom to be noticed here is this: that the distinction we have marked by the unwieldy terms 'warrant-using' and 'warrant-establishing' is commonly indicated in practice by the word 'deductive', its affiliates and their opposites. Outside the study the family of words, 'deduce', 'deductive', and 'deduction', is applied to arguments from many fields; all that is required is that these arguments shall be warrant-using ones, applying established warrants to fresh data to derive new conclusions. It makes no difference to the propriety of these

terms that the step from D to C will in some cases involve a transition of logical type – that it is, for instance, a step from information about the past to a prediction about the future.

Sherlock Holmes, at any rate, never hesitated to say that he had *deduced*, e.g., that a man was recently in East Sussex from the colour and texture of the fragments of soil he left upon the study carpet; and in this he spoke like a character from real life. An astronomer would say, equally readily, that he had *deduced* when a future eclipse would occur from the present and past positions and motions of the heavenly bodies involved. As Ryle implies, the meaning of the word 'deduce' is effectively the same as that of 'infer'; so that, wherever there are established warrants or set procedures of computation by which to pass from data to a conclusion, there we may properly speak of 'deductions'. A regular prediction, made in accordance with the standard equations of stellar dynamics, is in this sense an unquestionable deduction; and so long as Sherlock Holmes also is capable of producing sound, well-backed warrants to justify his steps, we can allow that he too has been making deductions – unless one has just been reading a textbook of formal logic. The protestations of another sleuth that Sherlock Holmes was in error, in taking for deductions arguments which were really inductive, will strike one as hollow and mistaken.

The other side of this coin is also worth a glance: namely, the way in which the word 'induction' can be used to refer to warrant-establishing arguments. Sir Isaac Newton, for instance, regularly speaks of 'rendering a proposition general by induction': by this he turns out to mean 'using our observations of regularities and correlations as the backing for a novel warrant'. We begin, he explains, by establishing that a particular relation holds in a certain number of cases, and then, 'rendering it general by induction', we continue to apply it to fresh examples for so long as we can successfully do so: if we get into trouble as a result, he says, we are to find ways of rendering the general statement 'liable to exceptions', i.e. to discover the special circumstances in which the presumptions established by the warrant are liable to rebuttal. A general statement in physical theory, as Newton reminds us, must be construed not as a statistical report about the behaviour of a very large number of objects, but rather as an open warrant or principle of computation: it is established by testing it in sample situations where both data and conclusion are independently

known, then rendered general by induction, and finally applied as a rule of deduction in fresh situations to derive novel conclusions from our data.

In many treatises on formal logic, on the other hand, the term deduction is reserved for arguments in which the data and backing positively entail the conclusion – in which, that is to say, to state all the data and backing and yet to deny the conclusion would land one in a positive inconsistency or contradiction. This is, of course, an ideal of deduction which no astronomer's prediction could hope to approach; and if that is what formal logicians are going to demand of any 'deduction', it is no wonder they are unwilling to call such computations by that name. Yet the astronomers are unwilling to change their habits: they have been calling their elaborate mathematical demonstrations 'deductions' for a very long time, and they use the term to mark a perfectly genuine and consistent distinction.

What are we to make of this conflict of usage? Ought we to allow any argument to count as a deduction which applies an established warrant, or must we demand in addition that it should be backed by a positive entailment? This question we are not yet ready to determine. All we can do at the moment is register the fact that at this point customary idiom outside the study tends to deviate from the professional usage of logicians. As we shall see, this particular deviation is only one aspect of a larger one, which will concern us throughout a large part of our fourth essay and whose nature will become clearer when we have studied one final distinction. To that distinction, between 'analytic' and 'substantial' arguments, we must now turn.

Analytic and Substantial Arguments

This distinction is best approached by way of a preamble. We remarked some way back that an argument expressed in the form 'Datum; warrant; so conclusion' can be set out in a formally valid manner, regardless of the field to which it belongs; but this could never be done, it appeared, for arguments of the form 'Datum; backing for warrant; so conclusion'. To return to our stock example: if we are given information about Harry's birthplace, we may be able to draw a conclusion about his nationality, and defend it with a formally valid argument of the form (D; W; so C). But the warrant we apply in this formally valid argument rests in turn for its authority on facts about the enactment and pro-

visions of certain statutes, and we can therefore write out the argument in the alternative form (D; B; so C), i.e.:

Harry was born in Bermuda;

The relevant statutes ($W_1 \dots$) provide that people born in the colonies of British parents are entitled to British citizenship;

So, presumably, Harry is a British citizen.

When we choose this form, there is no question of claiming that the validity of the argument is evident simply from the formal relations between the three statements in it. Stating the backing for our warrant in such a case inevitably involves mentioning Acts of Parliament and the like, and these references destroy the formal elegance of the argument. In other fields, too, explicitly mentioning the backing for our warrant – whether this takes the form of statistical reports, appeals to the results of experiments, or references to taxonomical systems – will prevent us from writing the argument so that its validity shall be manifest from its formal properties alone.

As a general rule, therefore, we can set out in a formally valid manner arguments of the form 'D; W; so C' alone: arguments of the form 'D; B; so C' cannot be so expressed. There is, however, one rather special class of arguments which appears at first sight to break this general rule, and these we shall in due course christen *analytic* arguments. As an illustration we may take the following:

Anne is one of Jack's sisters;

All Jack's sisters have red hair;

So, Anne has red hair.

Arguments of this type have had a special place in the history of logic, and we shall have to pay close attention to them: it has not always been recognised how rare, in practice, arguments having their special characteristics are.

As a first move, let us expand this argument as we have already done those of other types. Writing the major premiss as a statement of backing, we obtain:

Anne is one of Jack's sisters;

Each one of Jack's sisters has (been checked individually to have) red hair;

So, Anne has red hair.

Alternatively, writing warrant in place of backing, we have:

Anne is one of Jack's sisters;

Any sister of Jack's will (i.e. may be taken to) have red hair;

So, Anne has red hair.

This argument is exceptional in the following respect. If each one of the girls has been checked individually to have red hair, then Anne's hair-colour has been specifically checked in the process. In this case, accordingly, the backing of our warrant includes explicitly the information which we are presenting as our conclusion: indeed, one might very well replace the word 'so' before the conclusion by the phrase 'in other words', or 'that is to say'. In such a case, to accept the datum and the backing is *thereby* to accept implicitly the conclusion also; if we string datum, backing and conclusion together to form a single sentence, we end up with an actual tautology – 'Anne is one of Jack's sisters and each one of Jack's sisters has red hair *and also* Anne has red hair.' So, for once, not only the (D; W; so C) argument but also the (D; B; so C) argument can – it appears – be stated in a formally valid manner.

Most of the arguments we have practical occasion to make use of are, one need hardly say, not of this type. We make claims about the future, and back them by reference to our experience of how things have gone in the past; we make assertions about a man's feelings, or about his legal status, and back them by references to his utterances and gestures, or to his place of birth and to the statutes about nationality; we adopt moral positions, and pass aesthetic judgements, and declare support for scientific theories or political causes, in each case producing as grounds for our conclusion statements of quite other logical types than the conclusion itself. Whenever we do any of these things, there can be no question of the conclusion's being regarded as a mere restatement in other words of something already stated implicitly in the datum and the backing: though the argument may be formally valid when expressed in the form 'Datum; warrant; so conclusion', the step we take in passing to the conclusion from the information we have to rely on – datum and backing together – is a substantial one. In most of our arguments, therefore, the statement obtained by writing 'Datum; backing; *and also* conclusion' will be far from a tautology – obvi-

ous it may be, where the legitimacy of the step involved is transparent, but tautological it will not.

In what follows, I shall call arguments of these two types respectively *substantial* and *analytic*. An argument from D to C will be called analytic if and only if the backing for the warrant authorising it includes, explicitly or implicitly, the information conveyed in the conclusion itself. Where this is so, the statement 'D, B, and also C' will, as a rule, be tautological. (This rule is, however, subject to some exceptions which we shall study shortly.) Where the backing for the warrant does not contain the information conveyed in the conclusion, the statement 'D, B, and also C' will never be a tautology, and the argument will be a substantial one.

The need for some distinction of this general sort is obvious enough, and certain aspects of it have forced themselves on the attention of logicians, yet its implications have never been consistently worked out. This task has been neglected for at least two reasons. To begin with, the internal complexity of statements of the form 'All A's are B's' helps to conceal the full difference between analytic and substantial arguments. Unless we go to the trouble of expanding these statements, so that it becomes manifest whether they are to be understood as stating warrants or the backing for warrants, we overlook the great variety of arguments susceptible of presentation in the traditional syllogistic form: we have to bring out the distinction between backing and warrant explicitly in any particular case if we are to be certain what sort of argument we are concerned with on that occasion. In the second place, it has not been recognised how exceptional genuinely analytic arguments are, and how difficult it is to produce an argument which will be analytic past all question: if logicians had recognised these facts, they might have been less ready to treat analytic arguments as a model which other types of argument were to emulate.

Even our chosen example, about the colour of Anne's hair, may easily slip out of the analytic into the substantial class. If the backing for our step from datum, 'Anne is Jack's sister', to conclusion, 'Anne has red hair', is just the information that each of Jack's sisters has *in the past* been observed to have red hair, then – one might argue – the argument is a substantial one even as it stands. After all, dyeing is not unknown. So ought we not to rewrite the argument in such a way as to bring out its substantial character

openly? On this interpretation the argument will become:

Datum – Anne is one of Jack’s sisters;

Backing – All Jack’s sisters have previously been observed to have red hair;

Conclusion – So, presumably, Anne now has red hair.

The warrant relied on, for which the backing is here stated, will be of the form, ‘Any sister of Jack’s may be taken to have red hair’: for the reasons given, this warrant can be regarded as establishing no more than a presumption:

It seems, then, that I can defend my conclusion about Anne’s hair with an unquestionably analytic argument only if at this very moment I have all of Jack’s sisters in sight, and so can back my warrant with the assurance that every one of Jack’s sisters has red hair at this moment. But, in such a situation, what need is there of an *argument* to establish the colour of Anne’s hair? And of what relevance is the other sisters’ hair-colour? The thing to do now is use one’s eyes, not hunt up a chain of reasoning. If the purpose of an argument is to establish conclusions about which we are not entirely confident by relating them back to other information about which we have greater assurance, it begins to be a little doubtful whether any genuine, practical argument could ever be properly analytic.

Mathematical arguments alone seem entirely safe: given the assurance that every sequence of six or more integers between 1 and 100 contains at least one prime number, and also the information that none of the numbers from 62 up to 66 is a prime, I can thankfully conclude that the number 67 is a prime; and that is an argument whose validity neither time nor the flux of change can call in question. This unique character of mathematical arguments is significant. Pure mathematics is possibly the only intellectual activity whose problems and solutions are ‘above time’. A mathematical problem is not a quandary; its solution has no time-limit; it involves no steps of substance. As a model argument for formal logi-

cians to analyse, it may be seducingly elegant, but it could hardly be less representative.

The Peculiarities of Analytic Arguments

For the rest of this essay, two chief tasks remain. First, we must clarify a little further the special characteristics of analytic arguments: after that, we must contrast the distinction between analytic and substantial arguments with three other distinctions whose importance we have already seen:

- (i) that between formally valid arguments and those which are not formally valid,
- (ii) that between warrant-using and warrant-establishing arguments,
- (iii) that between arguments leading to necessary conclusions and those leading only to probable conclusions.

As to the nature of analytic arguments themselves, two things need to be discussed. To begin with we must ask upon what foundation arguments of this type ultimately depend for their validity: after that, we must go on to reconsider the criteria provisionally suggested for distinguishing analytic arguments from others – for the ‘tautology test’ turns out, after all, to involve unsuspected difficulties.

To see how the first question arises, one should first recall how much less sharply than usual, in the case of analytic arguments, we can distinguish between data and warrant-backing – between the information we argue *from*, and the information which lends authority to the warrants we argue *in accordance with*: so far as it concerns the conclusion that Anne has red hair, the information that Anne is Jack’s sister has, at first sight, the same sort of bearing as the information that every one of Jack’s sisters has red hair. This similarity may lead us to construe both pieces of information as data, and if we do so the question may be raised, ‘What warrant authorises us to pass from these two premisses jointly to the required conclusion?’ Surely we cannot get from *any* set of data to a conclusion without *some* warrant; so what warrant can we produce to justify our inference in this case? This is the problem, and we can tackle it in only two ways: either we must accept the question, and produce a warrant, or alternatively we must reject the question in the form in which it stands, and insist on sending it back for rephrasing. (It is arguable, for instance, that we have a perfectly good warrant for passing from the *first* datum

to the conclusion, and that the 'second piece of information is the backing for that warrant.) For the moment, however, let us consider this problem in the form in which it arises here.

The first thing to notice about this problem is the fact that it is completely general. So long as one is arguing only from Anne's being Jack's sister to her having red hair, the question what warrant authorises our inference is a *particular* question, relevant only to this argument and a few others; but if one asks, what warrant authorises us to pass from the information *both* that Anne is Jack's sister *and* that every single one of Jack's sisters has red hair to the conclusion that Anne has red hair, that question is nowhere near so restricted a question, since it can arise in exactly the same form for all arguments of this type, whatever their explicit subject-matter. The answer to be given must therefore be equally general, and stated in such a way as to apply equally to all such arguments. What warrant, then, are we to say does authorise this particular step? The attempts to answer this question satisfactorily have been prolonged and inconclusive, and we cannot follow them through here: several different principles of a wholly general character have been put forward as the implied warrant for steps of this kind – the 'Principle of the Syllogism', the 'Dictum de Omni et Nullo', and others. But, quite apart from the respective merits of their rival answers, philosophers have not even been agreed about *how* such general principles really authorise us to argue as we do. What sort of a statement is (say) the Principle of the Syllogism? – that is the first question needing attention.

There is a temptation to say that any principle validating all syllogisms alike must be understood as a statement about the meanings of our words – an implicit analysis of such pre-eminently logical words as 'all' and 'some'. One consequence of this view, which we shall scrutinise in essay IV of *The Uses of Argument*, has been the growth of a rather limited doctrine about the nature and scope of logic. If the only principles of inference properly so-called are statements about the meanings of our words, then (some have argued) it is misleading to apply the title of inferring-rules to other sorts of general statement also, which are concerned with matters of substance and not simply with the meanings of our words: as a result, the whole notion of inference-warrants, as set out in this essay, has been pushed aside as confused.

Now we may agree that there is not an exact parallel between the Principle of the Syllogism

and those other sorts of argument-governing rules we have given the name of 'warrant', and yet feel that this conclusion goes too far. Without questioning at the moment the need for some Principle of the Syllogism, we may yet object to its being called a statement *about* the meanings of our words: why should we not see in it, rather, a warrant of a kind that holds good *in virtue of* the meanings of our words? This is an improvement on the previous formulation in at least one respect, for it leaves us free to say that other warrants – those we argue in accordance with outside the analytic field – hold good in virtue of other sorts of consideration. Legal principles hold good in virtue of statutory enactments and judicial precedents, the scientist's laws of nature in virtue of the experiments and observations by which they were established, and so on. In all fields, the force of our warrants is to authorise the step from certain types of data to certain types of conclusions, but, after all we have seen about the field-dependence of the criteria we employ in the practical business of argument, it is only natural to expect that inference-warrants in different fields should need establishing by quite different sorts of procedure.

Accordingly, there seems room for an accommodation – for us to accept the Principle of the Syllogism as the warrant of all analytic syllogisms, while retaining other kinds of general statement as warrants for arguments of other types. Yet there remains something paradoxical about admitting the need for a Principle of the Syllogism at all. With arguments of all other kinds, a man who is given the data and the conclusion and who understands perfectly well what he is told may yet need to have explained to him the authority for the step from one to the other. 'I understand what your evidence is, and I understand what conclusion you draw from it,' he may say, 'but I don't see *how* you get there.' The task of the warrant is to meet his need: in order to satisfy him we have to explain what is our warrant, and if necessary show on what backing it depends, and until we have done this it is still open to him to challenge our argument. With analytic arguments, on the other hand, this sort of situation is hardly conceivable: one is tempted to say of analytic arguments (as of analytic statements) that anyone who understands them must acknowledge their legitimacy. If a man does not see the legitimacy of an analytic step in any particular case, we shall not help him much by proffering him any principle so general as the Principle of the Syllogism.

The suggestion that this principle really does a job for us, by serving as the warrant for all syllogistic arguments, is therefore implausible. Certainly, if it is to be regarded as a warrant, it is a warrant which requires no backing: this much is conceded by Aristotle in the fourth book of the *Metaphysics*, where he goes out of his way to reject any demand that the law of non-contradiction should be *proved* – he recognises that no backing we could produce would add anything to the strength of the principle, and that all we need do in its defence is to challenge a critic to produce a meaningful objection to it.

Let us therefore try following the alternative course: let us reject the request for a warrant to lend authority to all analytic syllogisms, insisting instead that one premiss of every such syllogism provides all the warrant we need. The information that *every* one of Jack's sisters has red hair, we may say, serves as backing for the warrant that *any* of his sisters may be taken to have hair of that colour, and it is this limited warrant which takes us from our initial information about Anne's being Jack's sister to the conclusion about her hair-colour: 'that's just analytic!' Our task is now to define more carefully what exactly here is 'just analytic', and to work out clearer tests than we have stated so far for recognising whether an argument is an analytic or a substantial one.

Three different tests suggest themselves, and their merits we must now consider. First, there is the *tautology* test: in an analytic syllogism with an 'all' in the major premiss, the data and backing positively entail the conclusion, so that we can write 'D, B, or *in other words* C', confident that in stating the conclusion we shall simply be repeating something already stated in the backing. The question is whether this is true of *all* analytic arguments: I shall argue that it is not. Secondly, there is the *verification* test: must verifying the backing implicitly relied on in an argument *ipso facto* involve checking the truth of the conclusion? This does not universally lead to the same result as the first test, and will prove to be a more satisfactory criterion. Finally, there is the test of *self-evidence*: once a man has had data, backing and conclusion explained to him, can he still raise genuine questions about the validity of the argument? This might at first seem to amount to the same as the first test but, as we shall see, it corresponds in practice more nearly to the second.

One type of example can be mentioned straight away in which the tautology criterion

leads to difficulties. This is the 'quasi-syllogism', discussed earlier, in which the universal quantifiers 'all' and 'no' are replaced by the more restrictive ones 'nearly all' and 'scarcely any'. As an instance, we may take the argument:

Petersen is a Swede;

Scarcely any Swedes are Roman Catholics;

So, almost certainly, Petersen is not a Roman Catholic.

This argument differs from the corresponding 'no' argument –

Petersen is a Swede;

No Swedes are Roman Catholics;

So, certainly, Petersen is not a Roman Catholic –

only in relying on a weaker warrant and so ending in a more tentative conclusion. (Written explicitly as warrants the universal premisses are, respectively, 'A Swede can almost certainly be taken not to be a Roman Catholic' and 'A Swede can certainly be taken not to be a Roman Catholic'.)

The validity of the argument is in each case manifest, and by the test of self-evidence both should be classed as analytic arguments. If we imagine a man to challenge the 'scarcely any' argument, and to demand further backing to show its validity, his request will be no more intelligible than it would be in the case of the 'no' argument: he might ask in the first case to have the *conclusion* more firmly grounded, seeing that so long as we know only that scarcely any Swedes are Roman Catholics the possibility of any particular Swede's being of that persuasion is not ruled out past all question, but the *validity* of both arguments is surely not open to doubt. If he fails to see the force of either argument, there is little more we can do for him; and if he presents the same data and warrant-backing in support of the negated conclusion, the result will in either case be not just implausible but incomprehensible:

Petersen is a Swede;

The proportion of Roman Catholic Swedes is less than 5%/zero;

So, almost certainly/certainly, Petersen *is* a Roman Catholic.

By the test of self-evidence, then, the 'scarcely any' and 'nearly all' arguments have as much right to be classed as analytic as have the 'all' and 'no' arguments.

But if we allow this parallel, how far do our other tests for recognising analytic arguments fit? In checking the backing for our warrant, we asked, would we *ipso facto* check the conclusion of our arguments? (This we called the verification test.) Alternatively, if we wrote down our data and backing, and added the words 'and also C' – C being our conclusion – would the result be a tautology? Traditional syllogisms satisfy all our criteria equally well. Checking exhaustively that the proportion of Roman Catholic Swedes is zero of course involves checking what Petersen's religion is; while in addition the statement, 'Petersen is a Swede, and the proportion of Roman Catholic Swedes is zero, and also Petersen is not a Roman Catholic', can reasonably be called tautological. But when we look at quasi-syllogisms, we find the tautology test no longer applicable.

The verification test still fits the new cases, though it applies in a slightly Pickwickian manner: in checking exhaustively that the proportion of Roman Catholic Swedes was (say) less than 5% we should *ipso facto* check what Petersen's religion was – whether it was actually Roman Catholicism or not. On the other hand, the statement, 'Petersen is a Swede and the proportion of Roman Catholic Swedes is less than 5%, and also Petersen is not a Roman Catholic', is no longer tautological: it is, rather, genuinely informative, since the conclusion locates Petersen definitely in the 95% majority. Even if we insert the modal qualifier 'almost certainly' in the conclusion, the resulting statement is not tautological either – 'Petersen is a Swede, the proportion of Roman Catholic Swedes is less than 5%, and also, almost certainly, Petersen is not a Roman Catholic.'

As a result, when we look for a general criterion to mark off analytic arguments from others, the verification test will enable us to classify quasi-syllogisms along with traditional syllogisms in a way the tautology test will not. We shall therefore class an argument as analytic if, and only if, it satisfies that criterion – if, that is, checking the backing of the warrant involves *ipso facto* checking the truth or falsity of the conclusion – and we shall do this whether a knowledge of the full backing would in fact verify the conclusion or falsify it.

At this point, two comments are needed about Petersen's case. Once we do have access to the complete backing, we shall of course no longer be entitled to rely simply on the bare percentage of the statistician's tables and our original argument will no longer be in place.

We must base our argument about the likelihood of Petersen's being a Roman Catholic on *all* the relevant information we can get: if we in fact possess the detailed census returns, the only proper procedure is to look Petersen up by name, and find out the answer for certain. Secondly, the statement, 'Petersen is a Swede and the proportion of Roman Catholic Swedes is very low, and Petersen is almost certainly not a Roman Catholic', *would* be entirely tautological if one could properly *define* 'certainty' and 'probability' directly in terms of proportions and frequency. But to do this, as we saw, would mean ignoring the practical function of the term 'probability' and its cognates as modal qualifiers. It would also lead to paradox: as things stand, a man can say with perfect propriety, 'Petersen is a Swede and the proportion of Roman Catholic Swedes is very low, and yet Petersen is almost certainly a Roman Catholic' – he will be entitled to say this, for instance, if he knows something further about Petersen which places him very probably in the Roman Catholic minority – whereas, if the original statement were a tautology, this new statement would be bound to be a self-contradiction.

One cannot, then, characterise analytic arguments as arguments in which the statement 'D, B and also C' is a tautology: in some cases at least, this criterion fails to serve our purposes. This helps to explain one further philosophical doctrine – that even analytic syllogisms are not valid in virtue of the meanings of words alone, and that failure to understand such an argument is a sign, not of linguistic incompetence, but rather of a 'defect of reason'. Suppose we tell a man that Petersen is a Swede, and that the proportion of Roman Catholic Swedes is either zero or very low; 'so', we conclude, 'Petersen is certainly – or almost certainly – not a Roman Catholic'. He fails to follow us: what then are we to say about him? If the tautology test were adequate, this would show that he did not really understand the meanings of all the words we had employed: if we give up the tautology view, this explanation is no longer open to us. Now we must say, rather, that he is blind to, i.e. fails to see the force of, the argument. Indeed what else can we say? This is not an explanation: it is a bare statement of the fact. He just does not follow the step, and the ability to follow such arguments is, surely, one of the *basic* rational competences.

This observation can throw some light on the true status of the Principle of the Syllogism. That principle, I suggested, enters logic when the second premiss of an analytic syllogism is

misinterpreted as stating a datum instead of a warrant or its backing, and the argument is thereupon (apparently) left without any authorising warrant. The Principle of the Syllogism is then held out to us as somehow showing the *ultimate* foundation for the validity of *all* syllogistic arguments.

When considering arguments in other fields, we may again find ourselves going through this same sequence of steps. Suppose we begin by mistaking the backing of our warrant for an additional set of data; having done this, we shall appear to be arguing straight from data to conclusion, without our step's having any authority; and this lack will be found to affect, not just one, but every argument in the field concerned. To fill these fresh gaps, further completely general principles will now need to be invoked: one basic principle to lie behind all scientific predictions, another to lie behind all properly grounded moral judgements, and so on. (This is a topic which we need mention here only in passing, since we shall have to return to it in essay V of *The Uses of Argument*.) Now, if the ability to follow valid syllogisms and quasi-syllogisms can best be described as a basic rational competence, and is not really explained in terms of linguistic ability or incompetence, perhaps there will be nothing more to be said in other cases either. The ability to follow simple predictive arguments, whose warrants are backed by sufficiently wide and relevant experience, may just have to be recognised as another simple rational skill, which most men possess but which is lacking in some mental defectives; and for other fields, other basic skills. Could this be said for arguments in all fields whatever? Is the ability to follow, and see the force of simple moral arguments (say), also such a skill? Or simple aesthetic arguments? Or simple theological arguments? . . . At this point we come directly up against the fundamental philosophical issue: whether all fields of argument alike are open to rational discussion, and whether the Court of Reason is competent to adjudicate equally, whatever the type of problem under discussion.

Some Crucial Distinctions

One major task remains for us to perform in this essay: we have to distinguish the division of arguments into analytic and substantial from three or four other possible modes of division. The dangers resulting from confusing these distinctions, and still more from running them together, are serious and can be avoided only with care.

To begin with, the division into analytic and substantial arguments does not correspond at all exactly to the division into *formally valid* arguments and others. An argument in any field whatever *may* be expressed in a formally valid manner, provided that the warrant is formulated explicitly as a warrant and authorises precisely the sort of inference in question: this explains how mathematical computations can be formally valid, even when the data argued from are entirely past and present observations and the conclusion argued to is a prediction about the future. On the other hand, an argument may be analytic, and yet not be expressed in a formally valid way: this is the case, for instance, when an analytic argument is written out with the backing of the warrant cited in place of the warrant itself.

Nor does the distinction between analytic and substantial arguments correspond, either, to that between *warrant-using* and *warrant-establishing* arguments. In a very few cases, warrant-establishing arguments can be stated in a form which is formally valid: thus the argument, 'Jack has three sisters; the first has red hair, the second has red hair, the third has red hair; so all Jack's sisters have red hair', might be said to be at once warrant-establishing, formally valid and analytic. But, by and large, these characteristics vary independently. There can be warrant-using and warrant-establishing arguments both in the analytic field, and in other, substantial fields of argument, and one cannot seriously hope to make the two distinctions cut along one and the same line.

Again, it has sometimes been thought that one could mark off a specially 'logical' class of arguments by reference to the *sorts of words* appearing in them. In some arguments, for instance, the words 'all' and 'some' play a crucial part, and such arguments as these deserve separate consideration. But if we do mark them off from others, we must immediately observe that the division which results corresponds no more closely than the previous two to the division between analytic arguments and substantial ones. Not all arguments are analytic in which the word 'all' appears in the major premiss or warrant: this will be so only in cases where the process of establishing the warrant would involve *ipso facto* checking the truth of the conclusion now to be inferred with its aid, and we do not restrict our use of 'all' to such cases. The task of identifying analytic arguments cannot therefore be performed by looking for key words like 'all' and 'some': it can be done only by looking at

the nature of the problem under investigation, and the manner in which we establish the warrants relevant to its solution.

These three distinctions can be recognised easily enough. The fourth and last distinction is at once the most contentious and the most important. Dividing arguments into analytic and substantial is not the same, I shall argue, as dividing them into arguments whose conclusions can be inferred *necessarily* or *certainly* and those whose conclusions can be inferred only *possibly* or with *probability*. As we saw when discussing modal qualifiers, there are some arguments in which the warrant authorises the step from D to C unambiguously, and others in which the step is authorised only tentatively, conditionally or with qualifications. This division is marked in practice by the words 'necessary' or 'conclusive' on the one hand, and 'tentative', 'probable', 'provisional', or 'conditional' on the other, and it is quite independent of the division into analytic arguments and substantial ones. Yet often enough logical theorists have attempted to run these two distinctions together, identifying analytic arguments with necessary or conclusive ones, and substantial arguments with tentative, probable, or inconclusive ones. The crucial question is whether this conflation can be justified, or whether, rather, we do not have occasion in practice to classify some arguments as at once substantial *and* conclusive, or as both analytic *and* tentative.

If we pay attention to the manner in which these categories are employed in the practical business of arguing, we shall discover plenty of occasions for making use of these seeming cross-classifications. For instance, a great many of the warrants in accordance with which we argue in the explanatory sciences authorise us to draw a conclusion unambiguously and unequivocally. The arguments they figure in are, accordingly, both substantial and conclusive, and scientists who make use of such arguments do not hesitate to round them off with the words '... so necessarily C'. Arguments of this kind are commonly met with in applied mathematics, as when, using the methods of geometrical optics, one calculates from the height of a wall and the angle of elevation of the sun how deep a shadow the wall will cast on level ground when the sun is shining directly on to it – if told that the wall is 6 ft. high and the sun at an angle of 30 degrees, a physicist will happily say that the shadow *must* have a depth of ten and a half feet.

In his *Philosophical Essay on Probabilities*, Laplace draws explicit attention to this

class of substantial-yet-conclusive arguments: 'In the applications of mathematical analysis to physics,' he says, 'the results have all the certainty of facts,'¹ and he contrasts them with those arguments in which statistics are relied on, and whose conclusions are no more than probable. It is significant that he draws his distinction in just the manner he does. By applying the Newtonian system of mechanics to a problem in stellar dynamics, he reminds us we are normally led, not to a whole battery of possible predictions each with a greater or lesser expectation of eventual confirmation, but to one single, unambiguous and unequivocal solution. If we are prepared to acknowledge that Newtonian mechanics is sufficiently well established for the purpose of the problem in hand, then we must accept this particular conclusion as following necessarily from our original data.

The point can be put more strongly: given the present standing of the theory, we are entitled to dispute the necessity of the conclusion only if we are prepared to challenge the adequacy or relevance of Newtonian dynamics. This means, not just pointing out that arguments in planetary dynamics are substantial ones (so that their soundness can be questioned *without contradiction*), but showing that they are *in fact* unreliable; i.e. attacking Newtonian dynamics on its own ground. Unless we are prepared to carry through this challenge, with all that it involves, the astronomer is entitled to ignore our objections and to claim that, for his purposes, the theory provides a unique and uniquely reliable answer to his questions. An answer obtained by these methods certainly *must* be the answer, he will say, for it is the answer to which a correctly performed calculation in accordance with well-established procedures necessarily leads us.

Nor do we find these substantial-yet-conclusive arguments in the more elaborate and technical sciences alone. When Sherlock Holmes says to Watson, 'So you see, my dear Watson, it *could only* have been Joseph Harrison who stole the Naval Treaty', or 'I concluded that the thief *must* be somebody living in the house', he does not mean that he can produce an analytic argument to establish his conclusion: he means rather that, by other-than-analytic standards and by appeal to other-than-analytic warrants, the evidence admits of this conclusion alone.

How widely this point of view deviates from that of many formal logicians, we shall see in essay IV of *The Uses of Argument*. For them it is a commonplace that no argument can be both substantial and conclusive: only the conclusions

of analytic arguments, they claim, can properly be classified as necessary, and the conclusions of substantial arguments – however well established and securely based the warrants relied on in reaching them – can never be more than highly probable. Why do they embrace this conclusion? Well, they explain, one can always imagine circumstances in which we might be forced to reconsider any substantial warrant: however well established any theory may appear at the moment, it makes sense to talk of future experiences forcing us to revise it, and so long as that remains the case – as in the nature of things it always must do – it will be presumptuous of us to call any conclusion reached in this way a necessary one. We could escape from this quandary only if the idea of our having to reconsider our inference-warrant gave rise to a positive contradiction, and this could never happen except with an analytic argument, whose warrant was backed not by experience but by an entailment.

If we have occasion to recognise in practice a class of arguments which are at once substantial and conclusive, so also do we recognise a class of analytic arguments with tentative or qualified conclusions. Quasi-syllogisms once more provide a good example. As is clear from their very wording, these arguments are not absolutely conclusive: all they entitle us to infer is (say) that Petersen is *almost certainly*, or *probably*, not a Roman Catholic. At the same time, we must accept these arguments as analytic for two reasons: they satisfy our primary criterion of analyticity – the backing for the warrant employed including an implicit reference to the fact we are interested in inferring, even though we ourselves do not possess all the detailed backing; and further, the validity of such arguments must be evident as they stand, or not at all – if a man asks about a quasi-syllogism, 'Does it really follow? Is this really a legitimate inference?', we shall be as much at a loss to understand him as we should had he queried a genuine syllogism. One thing alone seems at first to count against calling quasi-syllogistic arguments analytic: the fact that data and backing taken together are, by linguistic standards, consistent with the negation of the conclusion – there is, as we saw, no positive contradiction in the supposition of Petersen's being a Swede, scarcely any Swedes being Roman Catholic, and yet Petersen's being a Roman Catholic. But then, how could one expect any *positive* contradiction here? The whole point of the qualifier 'probably' is to avoid any positive commitments, and this is its understood effect, whether it appears

in an isolated statement or in the conclusion of an argument, and whether that argument is substantial or analytic. So here we have a *prima facie* case of an argument which is analytic without being conclusive.

At this point one objection may be pressed, as follows: 'Granted that quasi-syllogistic arguments are analytic, they nevertheless do not provide the example you require. You claim that they are tentative, but you succeed in giving this impression only by suppressing some of the essential data. If you were to state explicitly all the information needed for such arguments as these to be valid, it would become clear that they are not really tentative at all, but are as conclusive as one could ask.' What sort of information might one say was being suppressed? And would it, if brought to light, remove all inconclusiveness from these arguments? Two suggestions must be considered. Quasi-syllogistic arguments, it might be said, are valid only if we can add the datum, (a), '... and we know nothing else relevant about Petersen' – given this extra datum, the argument turns into an analytic one, leading necessarily to the conclusion that the likelihood of Petersen's being a Roman Catholic is small. Or alternatively, it may be argued, we must insert the additional datum, (b), '... and Petersen is a random Swede' – making this additional datum explicit, we shall see that a quasi-syllogistic argument is really a conclusive argument in disguise.

We cannot meet this objection by a straight denial, but only by restating it in a way which removes its force. It must of course be conceded that quasi-syllogisms can properly be advanced only if the initial data from which we argue state all that we know of relevance to the question at issue: if they represent no more than a part of our relevant knowledge, we shall be required to argue not categorically but hypothetically – 'Given only the information that Petersen is a Swede, we might conclude that the chances of his being a Roman Catholic were slight...'. But does this mean that the statement, (a), was an essential item in our data, which we should never have omitted? Surely this statement is not so much a statement of a datum as a statement *about the nature of* our data: it would naturally appear, not as part of our answer to the question, 'What have you got to go on?', but rather as a comment which we might add subsequently, after having stated (say) the solitary fact about Petersen's nationality.

The objection that we have omitted the information, (b), that Petersen is a random Swede (or

a Swede taken at random) can be turned in a similar way. The information that he was a red-haired Swede, or a dark-complexioned Swede, or a Finnish-speaking Swede, could be called an 'extra fact' about him, and might possibly affect, in one way or another, our expectations about his religious beliefs. But the information that he was a *random* Swede is not like this at all. It is not a further fact about him which might be relevant to our expectations; it is at most a second-order comment on our previous information, indicating that, for all we know, we are entitled to presume about Petersen anything which established generalities about Swedes would suggest. So, once again, the so-called additional datum, (b), turns out to be not so much a datum as a passing comment about the applicability to this particular man of a warrant based only on statistical generalities.

The division of arguments into analytic and substantial is, therefore, entirely distinct from that into conclusive (necessary) and tentative (probable) arguments. Analytic arguments can be conclusive or tentative, and conclusive ones analytic or substantial. At once, one terminological precaution becomes urgent: we must renounce the common habit of using the adverb 'necessarily' interchangeably with the adverb 'deductively' – where this is used to mean 'analytically'. For where a substantial argument leads to an unequivocal conclusion, we are entitled to use the form 'D, so necessarily. C', despite the fact that the relation between data, backing and conclusion is not analytic; and where an analytic argument leads to a tentative conclusion, we cannot strictly say any longer that the conclusion follows 'necessarily' – only, that it follows analytically. Once we fall into the way of identifying 'analytically' and 'necessarily', we shall end up by having to conclude an argument with the paradoxical words, '... so Petersen is necessarily probably not a Roman Catholic', or even, '... so Petersen is necessarily necessarily not a Roman Catholic'. Perhaps, indeed, it would be better to scrap the words 'deductively' and 'necessarily' entirely, and to replace them either by 'analytically' or by 'unequivocally' according to the needs of the example.

The Perils of Simplicity

This essay has been deliberately restricted to prosaic studies of the different sorts of criticism to which our micro-arguments are subject, and to building up a pattern of analysis sufficiently complex to do justice to the most obvious dif-

ferences between these forms of criticism. Much of this distinction-making would be tedious if we were not looking ahead to a point where the distinctions would prove of philosophical importance. So, in this concluding section, we can afford not only to look back over the ground which we have covered, but also to glance ahead to see the sort of value which these distinctions will have, and which will give a point to these laborious preliminaries.

We began from a question about 'logical form'. This had two aspects: there was the question, what relevance the geometrical tidiness sought in traditional analyses of the syllogism could have for a man trying to tell sound arguments from unsound ones; and there was the further question whether, in any event, the traditional pattern for analysing micro-arguments – 'Minor Premiss, Major Premiss, so Conclusion' – was complex enough to reflect all the distinctions forced upon us in the actual practice of argument-assessment. We tackled the latter question first, with an eye to the example of jurisprudence. Philosophers studying the logic of legal arguments have long since been forced to classify their propositions into many more than three types, and, keeping our eyes on the actual practice of argument, we found ourselves obliged to follow them along the same road. There are in practical argument a good half-dozen functions to be performed by different sorts of proposition: once this is recognised, it becomes necessary to distinguish, not just between premisses and conclusions, but between claims, data, warrants, modal qualifiers, conditions of rebuttal, statements about the applicability or inapplicability of warrants, and others.

These distinctions will not be particularly novel to those who have studied explicitly the logic of special types of practical argument: the topic of exceptions or conditions of rebuttal, for instance – which were labelled (R) in our pattern of analysis – has been discussed by Professor H. L. A. Hart under the title of 'defeasibility', and he has shown its relevance not only to the jurisprudential study of contract but also to philosophical theories about free-will and responsibility. (It is probably no accident that he reached these results while working in the borderland between jurisprudence and philosophy.) Traces of the distinction can be discerned even in the writings of some who remain wedded to the traditions of formal logic. Sir David Ross, for example, has discussed the same topic of rebuttals, especially in the field of ethics. He

recognises that in practice we are compelled to allow exceptions to all moral rules, if only because any man recognising more than one rule is liable on occasion to find two of his rules pointing in different directions; but, being committed to the traditional pattern of argument-analysis, he has no category of presumptive arguments, or of rebuttals (R), in terms of which to account for this necessity. He gets around this by continuing to construe moral rules of action as major premisses, but criticising the manner in which they are normally phrased. If we are to be logical, he claims, all our moral rules should have the words *prima facie* added to them: in the absence of these words, he can see no strict possibility of admitting any exceptions.

We accordingly found it more natural to look for parallels between logic and jurisprudence than for parallels between logic and geometry: a clearly analysed argument is as much one in which the formalities of rational assessment are clearly set out and which is couched 'in proper form', as one which has been presented in a tidy geometrical shape. Granted, there is a large class of valid arguments which can be expressed in the neat form, 'Data; Warrant; so Conclusion', the warrant serving precisely as the bridge required to make the transition from data to conclusion; but to call such an argument formally valid is to say only something about the manner in which it has been phrased, and tells us nothing about the *reasons for its validity*. These reasons are to be understood only when we turn to consider the *backing* of the warrant invoked.

The traditional pattern of analysis, I suggested, has two serious defects. It is always liable to lead us, as it leads Sir David Ross, to pay too little attention to the differences between the different modes of criticism to which arguments are subject – to the differences, for instance, between warrants (W) and rebuttals (R). Particular premisses commonly express our data; whereas universal premisses may express either warrants or the backing for warrants, and when they are stated in the form 'All A's are B's' it will often be entirely obscure just which function they are to be understood as performing. The consequences of this obscurity can be grave, as we shall see later, particularly when we allow for the other defect of the traditional pattern – the effect it has of obscuring the differences between different fields of argument, and the sorts of warrant and backing appropriate to these different fields.

One central distinction we studied at some length: that between the field of analytic argu-

ments, which in practice are somewhat rare, and those other fields of argument, which can be grouped together under the title of substantial arguments, as logicians discovered early on, the field of analytic arguments is particularly simple; certain complexities which inevitably afflict substantial arguments need never trouble one in the case of analytic ones; and when the warrant of an analytic argument is expressed in the form 'All A's are B's', the whole argument can be laid out in the traditional pattern without harm resulting – for once in a while, the distinction between our data and the backing of our warrant ceases to be of serious importance. This simplicity is very attractive, and the theory of analytic arguments with universal major premisses was therefore seized on and developed with enthusiasm by logicians of many generations.

Simplicity, however, has its perils. It is one thing to choose as one's first object of theoretical study the type of argument open to analysis in the simplest terms. But it would be quite another to treat this type of argument as a paradigm and to demand that arguments in other fields should conform to its standards regardless, or, to build up from a study of the simplest forms of argument alone a set of categories intended for application to arguments of all sorts: one must at any rate begin by inquiring carefully how far the artificial simplicity of one's chosen model results in these logical categories also being artificially simple. The sorts of risks one runs otherwise are obvious enough. Distinctions which all happen to cut along the same line for the simplest arguments may need to be handled quite separately in the general case; if we forget this, and our new-found logical categories yield paradoxical results when applied to more complex arguments, we may be tempted to put these results down to defects in the arguments instead of in our categories; and we may end up by thinking that, for some regrettable reason hidden deep in the nature of things, only our original, peculiarly simple arguments are capable of attaining to the ideal of validity.

At this point, these perils can be hinted at only in entirely general terms. In the last two essays in this book, I shall make it my business to show more precisely how they have affected the actual results obtained, first by formal logicians, and then by philosophers working in the field of epistemology. The development of logical theory, I shall argue, began historically with the study of a rather special class of arguments – namely, the class of unequivocal, analytic, formally valid arguments with a universal

statement as 'major premiss'. Arguments in this class are exceptional in four different ways, which together make them a bad example for general study. To begin with, the use of the form 'All A's are B's' in the major premiss conceals the distinction between an inference-warrant and the statement of its backing. Secondly, with this class of arguments alone the distinction between our data and our warrant-backing ceases to be of serious importance. (These first two factors between them can lead one to overlook the functional differences between data, warrants, and the backing of warrants; and so to put them on a level and label them all alike as 'premisses'.) In the third place, arguments of this chosen type being analytic, the procedure for verifying the backing in each case involves *ipso facto* verifying the conclusion; while since they are, in the fourth place, unequivocal also, it becomes impossible to accept the data and backing and yet deny the conclusion, without positively contradicting oneself. These special characteristics of their first chosen class of arguments have been interpreted by logicians as signs of special merit; other classes of argument, they have felt, are deficient in so far as they fail to display all the characteristic merits of the paradigm class; and the distinctions which in this first case alone all cut along one and the same line

are identified and treated as a single distinction. The divisions of arguments into analytic and substantial, into warrant-using and warrant-establishing, into conclusive and tentative, and into formally valid and not formally valid: these are regimented for purposes of theory into a single distinction, and the pair of terms 'deductive' and 'inductive', which in practice – as we saw – is used to mark only the second of the four distinctions, is attached equally to all four.

This vast initial oversimplification marks the traditional beginning of much in logical theory. Many of the current problems in the logical tradition spring from adopting the analytic paradigm-argument as a standard by comparison with which all other arguments can be criticised. But analyticity is one thing, formal validity is another; and neither of these is a universal criterion of necessity, still less of the soundness of our arguments. Analytic arguments are a special case, and we are laying up trouble for ourselves, both in logic and in epistemology, if we treat them as anything else. That, at any rate, is the claim I hope to make good in the two essays which follow.

Chapter 33: The Skills of Argument

DEANNA KUHN

Introduction

Scope of the Investigation

The investigation to be described focuses on an individual's thinking processes, and as such it relates most directly to the sizable psychological literature on thinking and reasoning. Yet the work also addresses issues that are prominent in a number of other disciplines.

From a philosophical perspective, the present work relates to an increasing interest shown by philosophers in the nature and logic of natural language argumentation (Walton, 1989). As already mentioned, philosophers of education such as Scheffler (1965) have noted the importance of reflective thinking about thought, but their ideas have not been connected explicitly to the analysis of argumentation. Here we offer those with philosophical interests an analysis of elementary argumentative reasoning that is grounded in empirical data about the competencies and incompetencies that people exhibit in their argumentative reasoning about everyday topics.

From a language perspective, the present work relates to a growing area of research within discourse analysis pertaining to discourse that is argumentative (Grimshaw, 1990). What are the unique features that characterize argumentative in contrast to other kinds of discourse? Although it does not investigate social discourse directly, the research presented here, focused on the cognitive prerequisites of competent argument, offers some insight regarding the language of argument.

From sociological and political perspectives, the present work is relevant to a growing under-

standing of the complex interrelations that exist between individual and sociological processes (Dowd, 1990). Political scientists have for some time been interested in the political development of individuals, but they no longer treat this development simply as a process of socialization and are showing increasing attention to the cognitive underpinnings of political participation (Allen, 1989). In chapter 10 of *The Skills of Argument*, we consider the implications of our findings with respect to people's capacity for participation in the political processes involved in a democratic society.

From a psychological perspective, the present work relates directly to a number of issues that are salient in the current research literature. Most prominent among them are (a) the nature of informal reasoning and its relation to formal reasoning (Galotti, 1989), (b) the domain generality versus domain specificity of cognitive skills, (c) the development of reasoning skills, and (d) sex differences in cognitive abilities. Our findings will be considered in relation to each of these issues.

Finally, as has already been noted, a major interest has developed among educators in the teaching of thinking. The present work bears direct relevance to these efforts, and its educational implications will be considered in some detail in the concluding chapter.

Design of the Research Interview

Participants in the investigation were interviewed individually in two sessions taking place from one to several days apart. Sessions varied in length from 45 to 90 minutes and were

recorded and transcribed for subsequent analysis. The interviews took place at various locations, but always in an environment familiar to the participant – his or her school, workplace, or home. Financial compensation of \$20 was provided for each participant. In some cases, this compensation was given to the school or group to which the participant belonged and in others it was given to the individual.

At the beginning of the interview, we explained to the subject that the purpose of the project was to help us understand people's views about urban social problems. The major part of the interview consisted of eliciting and probing the subject's reasoning regarding three topics. The initial question for each topic elicited the subject's theories regarding the cause of the phenomenon:

What causes prisoners to return to crime after they're released?

What causes children to fail in school?

What causes unemployment?

These three topics were chosen from a larger group that had been pretested with a previous sample. They were chosen as ones people are likely to have occasion to think and talk about and ones about which people are able and willing to make causal inferences without a large base of technical knowledge. They nevertheless involve phenomena the true causal structure of which is complex and uncertain. These topics were also chosen as ones that represent a range with respect to the degree of personal knowledge a subject is likely to have. All subjects had been to school and, in the case of most of the older subjects, had been parents of children in school, making the school topic the one for which personal knowledge was likely to be greatest. Few, in contrast, were likely to have personal knowledge regarding the reasons for engaging in criminal activity, and unemployment was most likely to be intermediate in this respect. As reported in chapter 7 of *The Skills of Argument*, subjects' self-reports of the extent of their knowledge about the three topics (in response to the question "How much would you say that you know about this topic, compared to the average person?") corroborate this ordering. Differences in performance across topics can thus be examined in light of these at least self-reported knowledge differences. (We did not undertake to measure knowledge directly.)

After a subject offered his or her theory regarding the cause of the phenomenon, the

interviewer inquired how the subject came to hold this view. The interviewer then proceeded to the most important part of the interview, in which the subject was asked to justify the theory by providing supporting evidence. The key question was "How do you know that this is the cause?" The initial question was followed by several probes, for example, "If you were trying to convince someone else that your view is right, what *evidence* would you give to try to show this?" (The complete interview protocol is presented in appendix 1 of *The Skills of Argument*.)

In the next segment of the interview, the subject was asked to generate an opposing position: "Suppose now that someone disagreed with your view that this is the cause. What might *they* say to show that you were wrong?" This question sometimes elicited a counterargument with respect to the subject's theory and sometimes an alternative theory. In either case, the subject was asked for a rebuttal: "What could you say to show that this other person was wrong?" If subjects' initial responses did not entail an alternative theory, they were subsequently asked for one, so as to assess all subjects' ability to generate an alternative theory. If the subject was unable to generate an alternative theory, the interviewer proposed one and asked the subject to rebut it.

In the remaining part of the interview for each topic, the subject was asked for a remedy – "Is there any one important thing which, if it could be done, would lessen prisoners' returning to crime (school failure; unemployment)?" – as a way of assessing the consistency of the subject's causal theory, that is, whether the recommended remedy was consistent with the proposed cause. The interviewer ended with a series of questions that addressed subjects' epistemological reflections on their own thinking, for example, "How sure are you about what causes___?" and "Do experts know for sure what causes___?". Three final questions elicited ratings of how much subjects felt they knew about the topic compared with the average person, how important the topic was to society as a whole, and how much the topic mattered to the subject personally (the latter two relative to a list of other topics provided for comparison).

The main part of the second session involved the evaluation of evidence presented by the interviewer for two of the topics, crime and school failure. For this reason, the main interview for these two topics occurred during the first session, so as to separate it from the evidence evaluation phase. (Counterbalancing the presentation order of these two topics within the

first session established that the order itself did not affect responses.) The second session began with the main interview for the unemployment topic, followed by the evidence evaluation for the crime and school topics. Two kinds of evidence were presented for each of the two topics. What we label *underdetermined* evidence is in effect nonevidence. A scenario was presented describing a main character who exhibited the phenomenon (school failure or return to crime), but no real evidence was given regarding the cause. Subjects were thus left to draw on their own causal theories to account for the character's behavior. In the case of *overdetermined* evidence, in contrast, evidence was presented to suggest each of three different broad causes of the phenomenon, each advocated by an authority figure. Hence, if the evidence was valid and all causes were operating, the outcome could be regarded as overdetermined. Because all three co-occurred with outcome, however, whether one, two, or all three were in fact causal was indeterminate. Following their evaluation of the evidence, subjects were also asked several epistemological questions regarding certainty and influence of the evidence on their own thinking.

Participants

MAIN SAMPLE

Our aim was to interview a cross section of average people across the life span. We chose four age intervals to sample – teens, 20s (19–29), 40s (40–49), and 60s (60–69). All of the teenaged participants were ninth-graders and therefore in the age range of 14 to 15. This was the youngest age at which an extended verbal interview seemed feasible. We might have extended the range upward even beyond the 60s but decided to postpone any work with the very old, given the special methodological issues it raises.

In addition to age, two other subject variables warrant close attention – sex and education level, both variables that in previous research have been suggested to have some bearing on reasoning ability. Within each of the four age groups, participants were therefore selected from two education levels – referred to in subsequent chapters as *college* and *noncollege* – and within each education level the two sexes were equally represented. Ten people of each sex within each age group and education level participated. The number of participants in each of the four age groups was thus 40, with a total of 160 participants in the main sample.

The teenaged participants came from four New York City high schools. Those in the higher education group came from two private schools that served primarily a middle- to upper-middle-class population, with more than 90% of students going on to four-year colleges. Those in the lower education group came from two parochial schools (one girls' and one boys') serving a lower- to lower-middle-class population. Though most finished high school, 60% of students from these schools did not go on to further education; the other 40% typically enrolled in junior colleges or vocational schools. The racial composition of all of the schools was mixed black, Hispanic, Asian, and white, though the proportion of blacks and Hispanics was slightly higher in the parochial schools.

Participants in their 20s came from two schools. Those in the higher education group were university students in their junior or senior years. Those in the lower education group were students at a combined business training institute and beauty school in New York City. Students in this school were required to possess a high school diploma or to earn a certificate of equivalency concurrently with their vocational training. The racial composition was mixed black, Hispanic, Asian, and white in both schools, though the proportion of blacks and Hispanics was higher at the business institute.

The female participants in their 40s of both education levels were either attendees at a YWCA job reentry program or employees at 2 suburban junior high school (where they worked primarily in administrative positions). Male participants in their 40s of both education levels came from the suburban neighborhood in which one of the interviewers lived and were solicited through personal contacts. They were of varied occupations. In the case of both sexes, assignment to education group was based on each participant's own report. Participants categorized in the higher education group had completed at least 2 years of college (and most had completed college). Those in the lower education group had completed at least the 10th grade (though almost all had completed high school); none had attended college. Racial composition was mixed black, Hispanic, and white in roughly equal proportion in both education groups.

Participants in their 60s were members of a YMCA social group in a middle-class neighborhood in New York City. All were retired and had previously worked in a range of occupations. All were white. Assignment to education group was again based on each participant's own report.

Participants categorized in the higher education group had completed at least 2 years of college. Those in the lower education group had completed at least the 10th grade; none had attended college.

Evidence to Support Theories

To justify adequately an assertion that one has made is in some sense the heart of argumentive reasoning. An inability to answer the “How do you know?” question suggests that the assertion should not have been made. In subsequent chapters of *The Skills of Argument*, a case will be made that there are other aspects of argumentive reasoning that warrant close attention as well, but first it is essential to take a very close look at the arguments people offer to support the theories they espouse.

After subjects present their causal theories, the second segment of the interview for each of the three topics begins with the question, “How do you know that this is the cause—?” A number of probes follow, encouraging the subject to expand and become more specific, for example, “If you were trying to convince someone else that your view [that this is the cause] is right, what *evidence* [verbal emphasis] would you give to try to show this?” (See appendix 1 in *The Skills of Argument* for full sequence of probes.) Probing ends with the question, “Is there anything someone could say or do to *prove* [verbal emphasis] that this is what causes—?” (If the answer is yes, the subject is asked to describe what it would be; if the answer is no, the subject is asked to explain why not.)

Subjects’ responses to the request for evidence cover a very wide range. Not all or even a majority of responses, it turns out, fall into the category that we shall define as genuine evidence. The most prevalent response is of a type we term *pseudoevidence*; a third, smaller category of responses we term nonevidence. In this chapter, we first describe and give examples of these three forms of evidence. Next, we examine frequencies of occurrence of each of the types of evidence, overall and in relation to the major subject variables of age, education level, and sex. [...] We begin with genuine evidence, so as to provide a standard against which less successful responses can be compared.

Genuine Evidence

School failure, repeated crime, and unemployment are problems of such complexity that even

experts are unable to offer definitive evidence regarding their causes. What kinds of evidence could we expect lay people with no special knowledge or interest in the topics to generate? The evidence we categorize here as genuine is by no means conclusive, nor compelling, nor even necessarily high-quality evidence. The criteria adopted for genuine evidence, rather, are simply that it (a) be distinguishable from description of the causal sequence itself and (b) bear on its correctness. The importance of the first criterion will become more apparent when we examine responses in the pseudoevidence category, in which this differentiation is absent.

The genuine evidence that subjects generate takes a wide range of forms. We begin with what is by far the most frequent form, covariation evidence, and then proceed to a description of less common forms. Genuine evidence is typically produced only in response to one or two of the interviewer’s probes, usually those toward the end of the probe sequence, as the requests for evidence become more specific. In most of the following examples, for the sake of brevity, only that segment of a subject’s response in which genuine evidence is generated is excerpted. [...] Examples are limited to the school and crime topics, and subjects are identified in parentheses by their age group (T, 20, 40, 60), education group (C, N), sex (m, f), and topic (s, c).

COVARIATION EVIDENCE

The most common forms of genuine evidence show some reliance on the presence of covariation between alleged causal antecedent and outcome as support for the theory that the antecedent causes the outcome. Such evidence, in addition to being distinguishable from description of the causal sequence itself, as previously noted, is also characterized by some differentiation between antecedent and outcome, in contrast to the embedding of antecedent and outcome in a narrative scenario that we shall see is characteristic of pseudoevidence. Differentiation of antecedent and outcome makes it possible for variation in the antecedent to be related to variation in the outcome.

Correspondence. We begin with the weakest form of covariation evidence – evidence that does no more than note a correspondence, or co-occurrence, of antecedent and outcome. The subject who provides the first example offers such evidence only in response to the final probe. He initially identifies emotional distress

from problems at home as the cause of school failure:

(20Cms) (*Is there anything someone could say or do to prove that this is the cause?*) Just looking at their performance and just looking at their problems. (*How do you mean exactly?*) I mean by . . . well, if someone makes a study of cases of students where failures, dropouts . . . students who drop out of school . . . and sees where they have family problems, perhaps that would be solid evidence to prove what I believe.

The next example is similar. The cause the subject identifies initially is lack of parental support:

(40Cms) (*Is there anything someone could say or do to prove that this is the cause?*) Well, I think they can look at kids that are failing in school and see if the parent or parents are doing their job. (*What do you think they would find out?*) Well, I think they would find that the parents weren't there. They weren't behind the kids.

The evidence offered in the two preceding examples is clearly minimal. In both cases, however, the antecedent is distinct from the outcome, and there is an attempt to establish that there is a correspondence between the two, even though the idea of this correspondence is not developed in explicit, quantitative terms. [. . .]

Covariation. In this category, the idea of covariation becomes explicit. The two features that differentiate responses in this category from those in the correspondence category are some sense of (a) comparison and (b) quantification. Instances that represent one level of the antecedent are compared with those that represent another; the comparison is with respect to incidence of the outcome. In the first example, the subject begins with a response like those of the correspondence type but then, when asked about proof, adds the features of comparison and quantification. The cause the subject identifies is unemployment:

(40Nmc) (*Is there anything further you could say to help show that this is the cause?*) I think just the fact that people that have criminal records as a whole – there are exceptions to the rule – but as a whole don't seem to land any type of a decent job, any type of job whatsoever that has any kind of security. (*Is there*

anything someone could say or do to prove that this is the cause?) I think if they just check past records, they could prove that, as a whole, anyone that has a criminal record . . . should be able to prove that, as a whole, they don't make out as well as people without any kind of a record.

The quantification in the preceding example remains implicit, deriving from the comparison of the two groups. In the following example, in contrast, the quantification is explicit. The cause is again unemployment:

(TCmc) (*If you were trying to convince someone else that your view is right, what evidence would you give to try to show this?*) You could probably take a survey and find out the percentage of people who get jobs who have been convicts. I'm sure it's very low [. . .]

Correlated Change. Though it is usually present in the case of a causal relationship, covariation of course does not establish causality, because there may exist additional factors that also covary with antecedent and outcome and therefore have the status of potential causes. For this reason, a stronger form of evidence for a causal relationship is one in which *change* in the antecedent co-occurs with change in the outcome. Co-occurrence of change increases the likelihood that change in one factor is responsible for the change in the other. For example, the following subject identifies lack of motivation as a cause and cites as evidence the following single-case instance:

(60Cms) (*If you were trying to convince someone else that your view is right, what evidence would you give to try to show this?*) Well, I had a son who was very science involved, you know, involved scientifically. He loved science, you know, and he didn't think . . . he didn't think like things like . . . what was that, social studies, or whatever it was, that he did poorly in. He just didn't like it, and I had to have a long talk with him. After, I don't know if he failed or got a bad mark or got a low mark or whatever it was, I had a very long talk with him and that, and by constantly getting after him. I had him do his homework in that subject in front of me. I had to do it with him. I had to show . . . I was trying to show him what's good about it, cause I knew it was motivation. He just didn't care for it. And by trying to make it more interesting to him

I think he must have picked that up, because he started doing better. So to me that's proof enough in that particular thing. Now if there are other cases, I simply don't remember, but I don't . . . it seems to me it's very obvious.

Both the preceding and following examples illustrate that, like covariation evidence, the correlated change form of evidence often originates in personal experience. In the preceding case, in fact, the evidence does not extend beyond the single instance involving the subject and his son that is described. The evidence offered by the following subject is based on a larger number of instances. The cause is problems at home:

(60Nfs) (*How do you know that this is the cause?*) My husband was a teacher, and he had a class of emotionally disturbed children. It was something new they were trying at the time, and all the problem children from all the different grades came into his class, and he had to cope with each one at each level. Nine out of ten children have problems at home. There were children who were shifted from one foster home to another. There were parents where there was illness and the mother was paying too much attention to the father and not enough to the child. Drinking problems. There were problems. These were the problems. These were the problem children. (*Is there anything further you could say to help show that what you've said is correct?*) When their problems were resolved, many of the children left that class environment and went back to their original classes and did very well. So, that in itself shows that it was the problems that were at home.

Though this subject needs prompting from the interviewer to complete her argument, the form the argument takes is clear [. . .]

EVIDENCE EXTERNAL TO THE CAUSAL SEQUENCE

In all three subtypes in the covariation category of genuine evidence – correspondence, covariation, and correlated change – the function of the evidence is to establish existence of a link between an antecedent and outcome. In the external evidence category of genuine evidence, the subject goes beyond the antecedent and outcome themselves to invoke some additional, external factor. The presence of this additional actor serves as evidence supporting the claim that the antecedent actor is both present and operating to produce the outcome. The follow-

ing is an example. The cause identified initially by the subject is return to the same environment:

(20Cfc) (*Is there anything further you could say to help show that this is the cause?*) Perhaps if older brothers and sisters, or peers, or people close to prisoners, have been in prison before, that might show that this is the sort of environment that one was brought up in and knows and can easily return to.

The criminal record of siblings or peers is a factor external to the causal sequence, but if it is present, it supports the claim that poor environment is a factor that is present in the case of a prisoner returning to crime. Thus, implicit in responses of the external evidence form is the claim of covariation. But the subject goes beyond merely asserting the covariation and offers some additional evidence to support its existence [. . .]

Negative External Evidence (Counterfactual Arguments). Two final examples in the external evidence category illustrate the special case in which the subject claims that some factor external to the causal sequence is absent, rather than present, as was the case in the preceding examples. These cases are worthy of mention because they involve counterfactual reasoning, and there is evidence in the research literature on formal reasoning indicating that reasoning involving counterfactuals is considerably more difficult than reasoning based on positive cases. In the first example, failure of prison to rehabilitate is the cause the subject identifies initially:

(40Nmc) (*How do you know that this is the cause?*) Their habit patterns. All outward appearances in every case that I have known or even heard of has not changed. If they had had their head properly shrunk, everything about them would have changed . . . from their haircut right on through.

The structure of the argument in this case appears to be that if prisoners had been rehabilitated (i.e., the causal antecedent were absent), not only would the outcome (return to crime) be absent, but an additional external factor that would be present is change in other physical or psychological aspects of the prisoner's makeup. The reasoning, however, is counterfactual: Presence of the external factor would negate the presence and hence operation of the causal antecedent; the external factor, however, is *not* present, and it therefore follows that the causal

antecedent is present (the prisoner has not been rehabilitated), and this causal antecedent can be expected to lead to the outcome (return to crime).

In the second example, the cause identified is the same, failure of prison to rehabilitate:

(40Cfc) (*Is there anything someone could say or do to prove that this is the cause?*) If the statistics showed even half were successful . . . in other words, that they finished their term in prison and could go out and . . . being successful meaning that they would attain a way of life, a way of living . . . that there would be something for them outside of crime . . . I think is the only proof that I could see.

Again, the argument is counterfactual: If some prisoners were to make a successful adjustment (“attain a way of life”), it would negate the presence and hence operation of the causal antecedent (failure of prison to rehabilitate). But the subject implies that this is not the case, hence supporting the causal sequence she has identified.

INDIRECT EVIDENCE

In this final category of genuine evidence are included four forms of evidence that bear only in an indirect way on the correctness of the causal sequence identified by the subject. Direct evidence is actual or potential factual information that, if correct, supports (though does not prove) the existence of a causal link between the specified antecedent and the outcome. In the category of indirect evidence, we include those forms of evidence that might make the causal sequence more likely to be true, though not providing data directly related to it.

Analogy (Particular to Particular). Analogy is probably the most familiar form of argument in this category, one that cognitive psychologists believe plays an important role in many kinds of thinking and problem solving. In the present context, argument by analogy consists of a mapping of the alleged causal sequence from the domain in which it actually occurs onto a new domain. Because it is shown to operate similarly in the new domain, its operation in the domain under discussion is rendered more likely.

In the first example, the subject himself identifies his reasoning as analogical. The cause he identifies initially is familiarity with criminal life:

(20Cmc) (*How do you know that this is the cause?*) Well, take an example by analogy. A

college student goes to college. He'll be in an atmosphere of learning, and from there he'll either go on to a job or further his education. During these four years he's preparing for another part of his life, another few years. A prisoner, on the other hand, will be in an environment of criminals. That's all they probably talk about. That's all they have in common to talk about. I'm sure they're not talking about Plato when they're in prison. So, it's on their mind.

The analogy this subject draws between the college student and criminal is extended across multiple elements. As college prepares students for what they will do when they leave college, so prison prepares criminals for what they will do when they leave this institution. While in their respective institutions, both college students and prisoners exist in an “atmosphere,” of learning in one case, crime in the other.

The content of the next example is similar, but the analogy is not as fully elaborated. The cause again is familiarity with criminal life:

(20Cmc) (*How do you know that this is the cause?*) I think if you look at it in terms of, well, an occupation, whether crime could be an occupation or not . . . most people generally stay in an occupation their whole life, and it's very hard for them to change [. . .]

Assumption (General to Particular). Indirect evidence of this type is like analogy in the respect that there occurs a mapping from one domain to another. In the case of analogy, this mapping is from one particular domain to another particular domain. In the present case, in contrast, the mapping is from general to particular. The reasoning is based on a broad assertion, or assumption, typically about “human nature.” The causal theory with respect to the topic under discussion then becomes a particular case subsumed under the more general proposition, with the alleged truth of the general proposition serving as support for correctness in the more particular case. If the assumption is correct, the causal theory pertaining to the particular case is more likely to be correct. Following are examples for the crime topic. In the first example, the cause the subject identifies is return to the same environment:

(20Cmc) (*What causes prisoners to return to crime after they're released?*) Human beings are very much creatures of habit, and I don't think that there's such a habit as committing a crime, but everything that leads up to

committing a crime is probably habit. (*How do you know that this is the cause?*) I'm not certain, but it just seems pretty obvious from all the other spheres of life, people are so set in their ways.

In the second example, the cause is desire for material rewards:

(20Cmc) (*Is there anything someone could say or do to prove that this is the cause?*) Yes. They could say that people that don't have things... I mean, everybody wants things, especially in this country. This is a consumer society. People want to accumulate things, and that's not true of everywhere. People just want basic things, and if you don't have them, and you don't know how to get them, then, you can take them.

In the third example, the cause is emotional problems originating in childhood:

(TCfc) (*How do you know that this is the cause?*) Well, I know that children need love from their parents, and if they're neglected, they can feel hostile towards people. So, they'll... I guess they'll feel hatred towards people in general, because they were never cared for. So, I think that a broken home accounts for a lot of the hatred and the, you know, harsh feelings which cause murder and these other crimes.

In each of these cases, a general proposition is advanced that is meant to apply to a far broader range of instances than prisoners returning to crime – in these cases, to humans in general, or at least at entire culture. If the proposition is assumed, then the phenomenon under discussion is merely a particular case to which it applies, and the alleged causal antecedent by implication is present (and hence serves as at least a potential cause): If everyone behaves according to habit, so do criminals; if everyone wants to accumulate material things, so do criminals. The particular outcomes in the specific case of criminals remain, perhaps, to be spelled out, but the argument derives its force from the underlying general assumption.

Discounting (Elimination of Alternatives). A third form of indirect evidence is evidence against an alternative causal theory that the subject introduces. While the discounting of an alternative theory does not of course by itself establish that the theory advocated by the sub-

ject is correct, discounting is an important form of reasoning, for it indicates that the subject is contemplating the likely truth of the causal theory *relative to others*, an important capacity that we explore in chapter 4 of *The Skills of Argument*. Discounting sometimes stands by itself as the only form of evidence the subject offers and sometimes is offered in addition to another form of evidence that more directly supports the causal theory the subject advocates.

The first example is from a subject who begins with evidence to support the causal theory he has identified, problems at home, and then offers evidence discounting an alternative theory, intelligence:

(TCms) (*How do you know that this is the cause?*) For the most part the kids who get much lower grades, I know, have problems at home, and the kids... well, I find that kids who have normal families get the average grades for the most part, and the kids who have abnormal families get extremely high or extremely low. Well, that's obviously because of changes... either someone gets stronger or they get weaker from problems at home. (*If you were trying to convince someone else that your view is right, what evidence would you give to try to show this?*) Well, as compared with intelligence, you know, saying it's more important than that. It's just simply that a lot of intelligent kids do fail in certain classes in certain times, and certainly not consistently. You know, someone fails one class this year and gets an A in the same class the next year. (*What does this show?*) Well, that probably means something is... well, there's obviously going to be a difference, and since you can pretty much assume that the kid didn't get a lot smarter suddenly, and even without, you know, often without it [intelligence] they fail classes, and sometimes they get a tutor, sometimes they don't. Even if they don't sometimes, they still get a better grade, a lot better. So, it's not necessarily intelligence that's important [...]

Partial Discounting. A final form of indirect evidence we term *partial discounting* because it does not completely discredit the alternative causal theory. Instead, the factor is discounted at one level or end of its range, while its operation at the other end is left unspecified. Like the full discounting previously described, it is significant in that it reflects the subject's consideration of alternative theories. In the following example,

the causal theory the subject identifies is lack of motivation:

(TCms) (*Is there anything someone could say or do to prove that this is the cause?*) Some people just have lower IQs, you could say that some people tend to have lower IQs than other people. It's just the way it's going to be. Like some people are smarter than others. (*What does that show?*) Well, that some people can be really genius, one hundred seventy IQ, and just not care. So even if you're smart, it doesn't mean like you're going to not fail, because that's the way it works.

This subject notes that intelligence will not covary with outcome, specifically high intelligence can co-occur with failure, in cases in which the subject's preferred cause, lack of motivation (not caring) is operating. In this case, the preferred cause overrides the alternative one. The subject's assertion does not, however, completely discount the alternative cause, for it leaves unspecified what would happen in the reverse case in which motivation is high but intelligence low. If in this case the intelligence factor overrides the motivation factor (yielding failure), then both high intelligence and high motivation are required for success, and the intelligence factor has been only partially discounted (as it has no effect in the case of a low level of the motivation factory) [. . .]

Pseudoevidence

Though, we do not attempt a precise ordering of them, the forms of genuine evidence that have been described cover a very wide range, and it would seem likely that every subject would produce at least one of them as a means of supporting a causal theory. In fact, as we shall report in detail, for each of the three topics less than half of our subjects produce any genuine evidence at all. We thus go on now to examine other forms of responses subjects make to the request for evidence to support their theories.

By far the most prevalent is what we term *pseudoevidence*. Characterized most simply, pseudoevidence takes the form of a scenario, or script, depicting how the phenomenon might occur. The scripts observed in the present work are often expressed in general terms. Sometimes, however, they consist of one or two specific instances in terms of which the script is described. In this respect, our use of the term *script* is broader than its characteristic use by cognitive psychologists to refer to a generalized

description of a sequence of events (covering a range of specific instances). In the present case, description, either in the form of one or two specific instances or in more general, summary form, serves to show how the events depicted might plausibly lead to the outcome. Pseudoevidence can thus be thought of as evidence by illustration.

The defining characteristic that distinguishes pseudoevidence from genuine evidence is that, in contrast to the latter, pseudoevidence cannot be sharply distinguished from description of the causal sequence itself. In offering pseudoevidence, subjects may elaborate their initial depictions of the sequence generated in response to the interviewer's elicitation of the causal theory. But responses to the question "What causes ___?" do not differ sharply from responses to the questions "How do you know that this is so?" or "What evidence would you give to try to show this?"

GENERALIZED SCRIPTS

We begin with scripts that take a more generalized form. The following subject, who in the initial segment of the interview identifies problems at home, specifically divorce, as cause, provides an example of a simple, minimally elaborated script, not clearly distinguishable from specification of the cause itself. In this and several of the examples to follow, subjects' responses are quoted in their entirety, in order to provide a fuller sense of the subjects' approaches to evidence:

(TNms) (*How do you know that this is the cause?*) Well, it's like mostly when the mother and father are divorced they can, have psychological problems, you know, and they can't actually function in school. (*Just to be sure I understand, can you explain exactly how this shows that problems at home are the cause?*) Well, the kid, like, concentrates on how he's going to keep his mother and father together. He can't really concentrate on schoolwork. (*If you were trying to convince someone else that your view that this is the cause is right, what evidence would you give to try to show this?*) Well, let's see, I would take some kids maybe if their mother and father get divorced and show how it affects them mentally, you know. It makes them less alert in class. (*Can you be very specific, and tell me some particular facts you could mention to try to convince the person?*) Sometimes they have editorials in newspapers or on TV, you know, and maybe it could be a friend

of yours that it happens to. (*Is there anything further you could say to help show that what you've said is correct?*) Not at the moment. (*Is there anything someone could say or do to prove that this is what causes children to fail in school?*) Yes. It could be, you know, partly, they could be the persons that have problems at home, and can't really handle it [. . .]

Narrative Scripts. Sometimes scripts have an even stronger narrative character. The following subject, for example, initially specifies as the cause that the family does not provide support that would enable the prisoner to readjust to life outside prison:

(TNfc) (*How do you know that this is the cause?*) Cause sometimes when the wife is . . . wants to marry him or something, she don't expect him to do things – raping, robbing – because, you know, like if a family has money problems, you have to try to find a job, or do a part-time job to get money. (*Just to be sure I understand, can you explain exactly how this shows that this is the cause?*) Well, when he gets out, he goes . . . he knows where he still lives and he knows that she's still living there, and he knocks on the door, and she says, "Who are you?" He'll say, "Well, I'm your husband." She will say, "Well, my husband wasn't in prison." And she's gone and left him, and she's going to say, "You're not my husband; my husband wouldn't do such a thing." And she won't want him.

(*If you were trying to convince someone else that your view that this is the cause is right, what evidence would you give to try to show this?*) Well, I would get somebody that was in prison and tell them how prison is like. And he would see the difference of prisoners and him[self]. Prison is something on the dark side of life, instead of being outside in the world where he could see everything. (*Can you be very specific, and tell me some particular facts you could mention to try to convince the person?*) Well, when the prison . . . like when he gets out, let's say, and the wife is having a . . . has another husband, like, and she probably gets divorced while he's in prison, cause sometimes they do that, and he comes back and he don't know nothing about it. She's going to say, "Well, since you was in prison for two or three years, I couldn't wait for you." So, he would be neglected, and he would feel bad because he don't have nobody else to go to. And that's it . . . they go back to

crime. (*Is there anything further you could say to help show that what you've said is correct?*) Well, my uncle, since he knows. Eight years he was dealing in drugs and everything. He went into prison. When he came out, his wife had two kids. And she didn't want him anymore, because he was in prison. And she said, "If I marry somebody to love me and everything, he was not supposed to go out there and steal or deal with drugs. He was supposed to stay in one place, get himself a job, you know, take care of the family." But he didn't do that, so now he's in prison.

(*Is there anything someone could say or do to prove that this is what causes prisoners to return to crime?*) Yes, it is sometimes, cause the man feels hurt because if he loves somebody, and he was in prison, the other person should have the same love for him.

Though the preceding script derives from a specific instance known to the subject and is clearly driven by its narrative elements, the causal scenario remains at least a coherent, plausible account of a course of events that might lead a prisoner to return to crime. In this respect, the pseudoevidence successfully serves its function. In other cases, however, it is not entirely successful in even this respect. The script may take on such a life of its own that it becomes to some degree detached from the causal theory in connection with which it is intended to function as evidence [. . .]

Shifts from Cause to Consequence. The following example illustrates another way in which scripts sometimes go astray. Rather than retaining focus on the causal question, the subject drifts from the cause of the phenomenon to its consequences and, in this case, fails to differentiate cause and remedy. The subject initially identifies not wanting to study as cause.

(TNms) (*How do you know that this is the cause?*) Alright, if you, like, when they get homework they go home and just drop their books and go outside. (*If you were trying to convince someone else that your view that this is the cause is correct, what evidence would you give to try to show this?*) I'd just try to, try my best, you know, to make them want to study. (*Question repeated.*) Tell them that, just put a little lie into it, you know, tell him if he don't study, how will it be? They won't get a job or education. (*Can you be very specific, and tell me some particular facts you could mention*

to try to convince someone that not wanting to study is the cause of failing in school?) Okay, thinking about it, how will it look if they, when they get old enough, have to go for like an interview. (*Is there anything further you could say to help show that what you've said is correct?*) Or they have to like go to the store; they have to count money. If you go into any kind of business, when it's time to go to college. . . . When you play any sports you're supposed to know how to read, to understand the rules.

The subject's response in this case is consistent with his causal theory, but the focus is only minimally on depicting the causal sequence leading to the outcome. Instead, the subject's focus turns to the (negative) consequences of the outcome, which, if pointed out, the subject claims, might lead to remedy. Once the subject's focus shifts, the interviewer's attempts to bring him back to the question of cause are not successful.

SCRIPTS IN THE FORM OF SPECIFIC INSTANCES

Most subjects' pseudoevidence scripts are not as severely undermined by lack of focus on the causal sequence itself as are those of the preceding few subjects. The more common way in which the force of a script may be diminished is by restriction to one or two specific instances. A generalized script depicts a causal sequence as the general case, with the implication that what is being described is what usually happens. If, instead, only one or two specific instances are described, the power of the script in depicting how the phenomenon normally occurs is reduced. Implicit in the subject's response is the claim that these specific instances illustrate how the phenomenon occurs generally, but this claim neither is made explicit nor is any justification offered for it.

We turn now to some examples of scripts that are conveyed in terms of specific instances, rather than in generalized form. The two types cannot be sharply divided, however, and there are numerous cases that are intermediate between the two, as the following subject's response reflects. The cause is a combination of laziness (7) and peer pressure (15). The subject begins with specific instances:

(TNms) (*How do you know that this is the cause?*) Cause I see it around me, you know. I have friends who fail. They figure it's the right thing to do, and, you know, they just get lazy or want to hang out with their friends.

In response to the next probe, however, this subject proceeds to a generalized script that embodies the specific instances he has described:

(*If you were trying to convince someone else that your view is correct, what evidence would you give to try to show this?*) Like I said, you know, just take a person, for example, and like say he has a number of friends, and like the majority of his friends are failing, so he decides to do what they do, and maybe he could be lazy, or that could right there be peer pressure, cause they have to follow their friends in order to be in with the crowd.

In contrast to the preceding example, scripts frequently remain in the form of specific instances known to the subject [. . .]

SCRIPTS AS (UNFALSIFIABLE) ILLUSTRATION

In sum, at their most minimal, scripts simply illustrate a causal sequence. At their best, they elaborate the sequence in a way that enhances its plausibility. While the generalized form is arguably superior, the difference between scripts presented in generalized form and those embodied in specific examples from the subject's experience appears to be a surface rather than a deep one. In both cases, the scenarios subjects describe are likely to derive from experiences that they have had personally or that are known to them, and the scenario is seen as sufficient to account for the phenomenon. Subjects who generate pseudoevidence may differ, then, only in whether they choose to portray the script in specific or general form and, as one of the excerpts we examined showed, a subject may shift from one form to the other in the course of presenting a script.

Thus, whether in a generalized or specific form, pseudoevidence scripts serve the function of depicting how the phenomenon might occur, and we earlier characterized them as evidence by illustration, or example. Comments made by a number of subjects in fact explicitly equate evidence with examples:

(20Cfc) (*Is there anything someone could say or do to prove that what you've said is what causes prisoners to return to crime?*) You mean can I give you an example? (*Question repeated.*) Okay, I can give you an example. . . . [subject proceeds with an example].

Or:

(40Nfs) (*Is there anything someone could say or do to prove that this is the cause?*) I'm running

into difficulty here. (*Why is that?*) To think of another reason why . . . how you could prove it besides giving examples, or . . . ask them about their own experiences. You could ask children if you have them available, or you could ask the person. (*The person who had this view?*) Yes. (*What would that show?*) Maybe you could somehow get them to give an example.

In fact, subjects often see examples not just as evidence but as proof for their theories, as the following response shows:

TCfs) (*If you were trying to convince someone else that your view is right, what evidence would you give to try to show this?*) Well, I could give examples of people I heard about that it happened to, and I could ask them questions about what they've seen in their own classes. (*Just to be sure I understand, can you explain exactly how this would show that this is the cause?*) Because if I could give examples, they couldn't disprove my examples since they really happened. (*Is there anything further you could say to help show that what you've said is correct?*) I could ask them if it ever happened to themselves. (*What would that show?*) Well, then, if it did, it would prove it very well.

In other words, because the examples are proved, the theory is proved, suggesting again that examples *are* the evidence [. . .]

Nonevidence

We turn finally to examples from a much smaller group of subjects who offer neither genuine evidence nor pseudoevidence to support their theories. The category we term *nonevidence* covers a range of responses in which subjects (a) imply that evidence is unnecessary or irrelevant, (b) make assertions not connected to a causal theory, or (c) cite the phenomenon itself as evidence regarding its cause. While some subjects claim evidence to be unnecessary or irrelevant, it is notable that no subjects claim that they are *unable* to provide evidence – that they believe what they do but are unable to say why. All subjects offer some form of answer to questions about evidence.

EVIDENCE AS UNNECESSARY

We begin with subjects who treat evidence as unnecessary. The following subject explicitly claims that evidence is irrelevant:

(40Nfs) (*If you were trying to convince someone else that your view is right, what evidence would you give to try to show this?*) I would not try to give any evidence. I only . . . when it comes to kids, I work by my good instinct, and I would say there are sometimes parents who are totally tuned into their children will know more than the professional. If you live with your child, day in and day out, and if you can stand outside that circle and be objective, As well as subjective when you must be, you know what's happening. Sometimes being here you can analyze and know exactly what's going on more than someone who knows book theory, cause sometimes book theory is garbage. (*Is there anything someone could say or do to prove that what you've said is what causes school failure.*) I would go by my life experience. Everybody has life experience. I'm not trying to push my views on anyone else. I think my views are very liberal. That's what gets me through. But, no, I'm not going to go toe-to-toe with anyone. It's not important to me.

In contrast to the preceding subject, who emphasizes instinct or intuition as an alternative to evidence, subjects who claim that evidence is unnecessary more commonly subscribe to a simple *argument by telling*, as the following response illustrates:

(20Nfc) (*If you were trying to convince someone else that your view is right, what evidence would you give to try to show this?*) I wouldn't really give them evidence. I would just try to convince them that that was the reason why. (*How would you do that?*) I'd keep at it, you know, keep telling them that, yes, this is the reason, this is the reason. If it ends up that he doesn't believe me, or whatever, it ends right there [. . .]

EVIDENCE UNCONNECTED TO A THEORY

Subjects whose responses fall into a second category of nonevidence make reference to specific content relevant to the topic, but the content is not linked to a causal theory. The similarity between the stance taken by many of these subjects and the argument-by-telling stance of subjects in the preceding category is clear:

(TCmc) (*If you were trying to convince someone else that your view is right, what evidence would you give to try to show this?*) Well, I'd look up in books to see what percentage of people did crimes, just to get the percentage, and then

I'd check out the seriousness of the crime. I might see what type of crime it was. And, I don't know, I might if possible, try to get in to meet the people. I mean just through information, I mean give him more facts and more facts. To back up the facts I'd give him more facts. I think I could convince someone.

Again, further probing suggests that this subject has no more specific idea that would take him beyond this *argument-by-facts* stance – an idea of exactly how these “facts” could be connected to the causal theory in question:

(Is there anything further you could say to help show that what you've said is correct?) Well, I could try logic, uh . . . reason it through.

Is it possible that responses in the nonevidence category like the ones quoted thus far simply reflect the fact that the subjects do not possess the content knowledge that would enable them to put any flesh on the general “facts,” “talk,” and “telling” that they invoke. Although it cannot be ruled out as a contributing factor, this explanation rendered less likely by the fact that many responses classified as nonevidence are in fact rich in specific content. Rather than lack of content knowledge, the problem seems to be one of connecting content (whether rich or minimal) to a causal theory, so that the content bears on the theory [. . .]

EFFECT AS EVIDENCE OF ITS CAUSE

The most prevalent and in many ways most striking type of nonevidence is that in which the subject simply restates the phenomenon. In doing so, the subject makes it clear that the existence of the phenomenon itself is sufficient evidence that it is produced by the cause the subject invokes. We cite several examples. In the first, the cause the subject has identified is poor nutrition:

(20Nms) *(If you were trying to convince someone else that your view is right, what evidence would you give to try to show this?)* The points that they get in school. The grades that they get in school to show . . . *(What would that show?)* That they are lacking something in their body. That the kids who were failing lack something in their body.

The following is a parallel example for the crime topic. The cause is desire to return to prison:

(40Nfc) *(If you were trying to convince someone else that your view is right, what evidence*

would you give to try to show this?) Just things you read about in the paper and hear in the news. *(Can you be very specific, and tell me particular facts you could mention to try to convince the person?)* Well, like when people do repeated . . . keep repeating the same crime, keep being put back, and coming out. They've never learned their lesson. It doesn't bother them. So that would show that maybe they'd rather . . . they'd be happier there [. . .]

Quantitative Results

CLASSIFICATION INTO EVIDENCE CATEGORIES

In analyzing subjects' responses to the evidence segment of the interview, each unit of evidence presented by the subject is classified into one of the categories that have been described. A unit is taken to be a complete idea. On average, these are two to three sentences long. Most often, one unit occurs in response to each of the interviewer's probes, though sometimes more than one occurs. Each unit is assigned to one of the evidence categories described in this chapter. Subsequent analysis is based on which of the categories are represented in the subject's total response. Details regarding interrater reliability are given in appendix 2 of *The Skills of Argument*.

As reflected in a number of the examples that have been presented, a subject's response often spans more than one of the three major categories. In the most common combination, the subject initially offers pseudoevidence and then, in response to the interviewer's probes, proceeds to give one or more forms of genuine evidence. Other subjects, in contrast, do not proceed beyond pseudoevidence. Nonevidence most often proceeds to or alternates with pseudoevidence. For the crime topic, only 5 of the 160 subjects never go beyond nonevidence. Corresponding numbers for the unemployment and school topics are 2 and 3 subjects, respectively (with subjects distributed across age, education, and sex groupings.)

Hence, the most important contrast is between subjects who offer some genuine evidence and those who never proceed beyond pseudoevidence or nonevidence. As shown in table 1, less than half of subjects overall give genuine evidence for each of the topics. Topic differences are slight but consistent with prediction: Subjects reason best on the topic for which they are most likely to have personal knowledge (school failure) and least well on the topic for which they are least likely to have personal knowledge (return to crime). While percentages

Table 1: Percentages of Subjects Generating Genuine Evidence

	<i>Crime</i>	<i>Unemployment</i>	<i>School</i>
<i>Age group</i>			
Teens	33	38	38
20s	43	43	58
40s	48	53	55
60s	33	28	40
<i>Education group</i>			
Noncollege	16	28	29
College	61	53	66
Total group	39	40	48

are slightly higher for the two middle age groups, age group differences are not significant, nor are percentages by sex (not shown). Percentages of subjects offering genuine evidence by education level, in contrast, differ significantly. A summary of statistical tests is contained in appendix 3.¹

Among those subjects who produce some genuine evidence, the majority produce only one of the nine individual subtypes described earlier (three subtypes of covariation evidence, two of external evidence, and four of indirect evidence). A sizable minority, however, produce two subtypes, and a few subjects three or more. Mean numbers of different subtypes produced by a subject are 1.40 for the crime topic, 1.36 for the unemployment topic, and 1.45 for the school topic. These means are only slightly (nonsignificantly) lower for noncollege subjects (1.31–1.38 across topics) than college subjects (1.41–1.51 across topics) and likewise do not differ by age group or sex. Thus, subjects who produce genuine evidence do not differ in the number of different kinds of evidence they produce.

With what frequencies do the various types of genuine evidence appear? Percentages in table 2 are based on the different types of genuine evidence appearing in a subject's response. As seen there, genuine evidence most often falls into the covariation category and next most often into the indirect evidence category. These percentages do not differ significantly by education

Table 2: Percentages of Genuine Evidence in Different Categories

	<i>Crime</i>	<i>Unemployment</i>	<i>School</i>
Covariation	36	51	67
External	26	24	08
Indirect	38	25	25

level, sex, or age group. A difference across topics is reflected in table 2, however, with covariation evidence becoming more likely for topics for which subjects are more likely to have personal knowledge. Covariation evidence is more direct and straightforward than external or indirect evidence, and subjects apparently prefer it when they are able to provide it.

Frequencies of the three types of covariation evidence (correspondence, covariation, and correlated change) vary across the three topics but occur in roughly equal proportion overall. Certain content is apparently more conducive to certain forms of argument, with correspondence evidence more frequent for the unemployment topic, covariation evidence for the school topic, and correlated change evidence for the crime topic. Within the external evidence category, the simple positive form is much more common, with only four instances of the negative (counterfactual) form appearing overall. Within the indirect evidence category, there is likewise variation across topics, but overall 17% of instances are of the analogy form, 33% of the assumption form, 32% of the full discounting, and 18% of the partial discounting form.

PERCEIVED STRENGTH OF EVIDENCE

In chapter 7 of *The Skills of Argument*, we look extensively at subjects' reflections on their reasoning. One of these findings, however, warrants mention here, and that is the strength subjects attribute to the evidence they generate. The interviewer's final probe in the evidence segment of the interview, "Is there anything someone could say or do to *prove* (verbal emphasis) that this is what causes____?", yields an index of whether the subject sees the evidence offered as proving the correctness of the causal theory. Subjects who offer evidence in response to this probe, or who reiterate evidence given previously, are categorized as regarding their evidence as proof, while subjects who reply no (regardless of the nature of the accompanying justification) are categorized as not regarding the evidence they have offered as proof.

The figures in this respect are striking not only in their absolute level, but because they are independent of the actual quality of evidence. Of subjects generating genuine evidence, only 14–18% (across topics) *do not* regard the evidence they offer as sufficient to prove the theory's correctness. Despite the inferior character of their evidence, of subjects generating only nonevidence or pseudo-evidence, these figures are comparable: Only 19–22% *do not* regard

the evidence they offer as sufficient to prove the theory's correctness. The remaining roughly 80% of subjects regard their evidence as proof of the correctness of their causal theories, irrespective of the actual quality of this evidence.

Conclusions: The Limits of Pseudoevidence

The findings presented in this chapter reflect both the competence and lack of competence that people display in justifying the causal theories they hold. The majority of people do not appear able to make realistic appraisals of the strength of the evidence they generate. Yet the various forms of genuine evidence that have been described are all reasonable, valid forms of evidence that can be invoked to support a causal theory, whether or not in individual cases they constitute strong enough evidence to be persuasive. The present results show that many average people without any particular expertise either in scientific reasoning or in the topic domains being considered are able to invoke these forms of evidence as a means of argument for their beliefs. This finding, and the particular forms of evidence that are identified, are important in their own right, as we discuss further in chapter 10 of *The Skills of Argument*.

Yet the major finding of this chapter is the prevalence of pseudoevidence. Pseudoevidence is perceived by subjects who rely on it to be as powerful as is genuine evidence as a means of establishing the correctness of causal theories. What basis do we have for claiming the inferiority of pseudoevidence to genuine evidence? At their best, we observed, pseudoevidence scripts serve to establish or enhance the intuitive *plausibility* of a causal theory by portraying how the causal sequence occurs. Genuine evidence, in contrast, bears on the *correctness* of a causal theory – on establishing that it in fact operates and produces the observed instances of the outcome (although a few of the forms of genuine evidence that we have observed, notably analogy, may also contribute to enhancing the plausibility of a causal theory).

The plausibility involved in pseudoevidence has to do with *mechanism*, the means by which a cause produces an effect, as aspect of causal thinking that has received a good deal of attention by researchers studying causal reasoning, as we note further in Chapter 10 of *The Skills of Argument*. Might not we, then, simply regard pseudoevidence and genuine evidence as reflecting alternative explanatory preferences or styles?

The difference is a more fundamental one than that of style. Genuine evidence can be regarded as superior to pseudoevidence on the grounds that it is more definitive. First, plausibility is neither a necessary nor a sufficient condition for the correctness of a causal theory. Often, in the history of science, causal theories that initially appear very implausible have been proved correct, and, likewise, highly plausible theories have been disconfirmed. Second, a causal relationship between two factors can be demonstrated in the absence of any plausible theory whatsoever to connect them. Again, in the history of science, there are many cases of a causal relationship being demonstrated in the absence of an understanding of the mechanism connecting cause and effect (e.g., when a substance is found beneficial in treating a disease in the absence of an understanding of how it achieves its effect).

"Good" pseudoevidence, then, might heighten our interest in testing a causal theory, but it cannot tell us whether the theory is correct. Since physical and mental limitations permit us to explore only some theories and not others, the former function is not trivial. Yet it represents only the beginning, not the totality, of a rigorous investigation of cause.

Even more fundamentally, pseudoevidence must be regarded not as evidence at all, but as part of the theory. In proposing their theories, it is reasonable to assume that all of our subjects envisioned some mechanism whereby the alleged cause produces the effect. When, in offering pseudoevidence, they elaborate the description of this mechanism, they are elaborating the theory, not providing any evidence of its correctness. Again, even the most plausible theories may be wrong. Consonant with this claim, we noted that there is typically little differentiation between the pseudoevidence a subject offers and the subject's statement of the theory itself. Both portray a scenario of "how it happens." Genuine evidence, in contrast, is differentiated from the theory and bears on its correctness [. . .]

Raising the possibility that the theory is not correct introduces the adversarial or argumentative framework that dominates the interview. In this framework, the limitations of pseudoevidence are brought into even sharper focus. The elicitation of evidence begins with the straightforward "How do you know?" question. Plausibility, or mechanism, is conceivably relevant to the matter of how one knows that an antecedent is the cause of an outcome, and, as we saw,

subjects often begin their discussion of evidence in this vein. The interviewer goes on, however, to invoke a hypothetical other, one who later will be explicitly characterized as “disagree[ing] with your view.” The task confronting subjects, then, becomes one not just of explaining how they know, but of indicating what they would say to convince the hypothetical other (“To convince someone else that your view is right . . .”). It is implicit in the set of questions that, unlike the subject, the hypothetical other does *not* know that this is the cause and may in fact hold a different view. An explicit mode of argument is thus called for, one that may include plausibility but must go beyond it.

As we have seen, some subjects do go on to exhibit this argumentative skill, offering evidence to support the claim that the alleged cause does operate to produce the outcome. Others, in contrast, never go beyond pseudoevidence accounts of how the cause might produce the outcome [. . .]

Note

- 1 Because, as noted in above, the pattern of significant education differences and absence of differences by age group or sex is very consistent across all of our findings, we do not under-

take more complex statistical analyses of subject variables in interaction with one another, in particular of the comparability of education differences within sex and age groups, which, in any case, samples sizes are not large enough to judge with any certainty. Except where otherwise noted, however, inspection shows education differences to be comparable within sex and age groups.

Chapter 34: Reasoning and Conversation

LANCE J. RIPS

This article focuses on the nature of informal arguments, provides a model of these interactions, and reports experiments that test the model. In many arguments, people try to convince others of the truth of a claim (or the worthiness of an action), or they try to evaluate the believability of others' claims. In the following dialogue, for example, Ann tries to convince Bill of the claim in Line la:

- (1) a. Ann: There's no place on campus to get a good cup of coffee.
b. Bill: What makes you say that?
c. Ann: I've tried all the coffee shops on campus and none has good coffee.
d. Bill: You haven't tried the new coffee shop in Garrett, I bet.
e. Ann: I have too: I was there just yesterday.
f. Bill: Also, coffee shops aren't the only source of coffee on campus – maybe you can get good coffee in one of the cafeterias.
g. Ann: All of the campus coffee comes from the same supplier.
a. Bill: Okay, I guess you're right about that.

This is the type of informal argument that we explore here, and these arguments occur in many everyday contexts, including debates on medical treatments (ten Have, 1995), courtroom interactions (Riley, Hollihan, & Freadhoff, 1987), political controversies (Elster, 1995; Homer-Dixon & Karapin, 1989), class discussions (Cavall-Sforza, Lesgold, & Weiner, 1992; Chinn, 1995), scientific exchanges (Vicedo, 1991), negotiations within organizations or work groups (Coulson & Flor, 1994; Firth, 1995), marital dis-

agreements (Gottman, 1979), conflicts between children (Eisenberg & Garvey, 1981; Miller, Danaher, & Forbes, 1986), and many other social contexts (e.g., Hewitt, Duchan, & Segal, 1993; Schiffrin, 1984). They occur in traditional cultures, as well as in our own (Hutchins, 1980; Starr, 1978). And they appear in literary forms, prominently in plays, from Sophocles to Shaw.

Not every verbal dispute is an informal argument. Name-calling, exchanging demands, and exchanging threats, for example, do not have evaluating claims as a goal, and I'll use *argumentation* when necessary to distinguish informal arguments in the intended sense from other verbal encounters.¹ Argumentation is a way to manage conflicts between points of view – one that appeals to the merits of the case, the reasonableness of certain conclusions. One can evaluate argumentation in terms of the practical goals of the participants, for example, in convincing others of their claims or refuting others' claims (Hamblin, 1970). However, one can also evaluate argumentation in terms of its potential for promoting true beliefs (Goldman, 1994) or advancing understanding of an issue (Wright, 1995).

In the first part of this article, I briefly review prior approaches to argumentation in order to situate the theory to be proposed here. The central idea of the current theory is that an argument consists of a claim by one participant and a critical response by another, where the response can itself embed further claims and responses. The second part of the article defines this argument structure. In the third part, I set out a theory of how participants negotiate commitment to the claims that arise in the argument. I propose that commitment depends on the types of responses

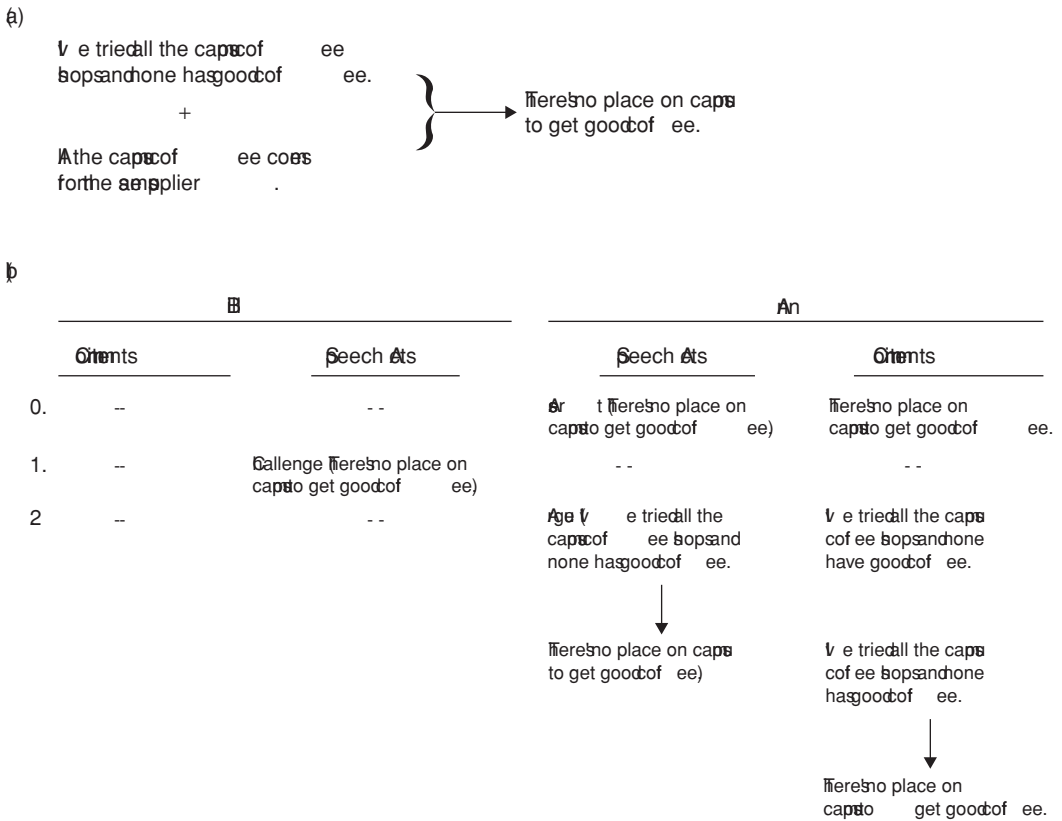

Figure 1. Partial representations of Argument 1, according to (a) a system of Fisher's (1988) and (b) a dialogue-game model by Walton and Krabbe (1995).

that participants offer (e.g., challenges, rebuttals, and acceptances), and I give a formal account of how commitment changes. Section 4 discusses tests of the model in experiments in which people read arguments and decide which characters in the argument are committed to each claim and which character has greater burden of proof. Finally, in the last section, I consider an alternative connectionist theory and draw further conclusions about the current theory.

Argumentation as Reason Giving versus Argumentation as Dialogue

The present theory unites two strands of earlier work on argumentation. One traditional perspective emphasizes the support that one statement lends another. The support might be the strong deductive connection that occurs when the supported statement must be true whenever the supporting statement is true. However, statements also gain support in non-deductive ways when the supporting statement makes the supported one more likely. Support

can accrue through plausible reasoning (Collins & Michalski, 1989), probabilistic reasoning (Jeffrey, 1965), heuristics (Kahneman & Tversky, 1984), and other strategies.

We can picture the support among an argument's statements as a network with links running from basic statements that are taken as given to the argument's main conclusion (e.g., Fisher, 1988; Thomas, 1973; Toulmin, Rieke, & Janik, 1979). Each link indicates a reason for its supported statement; so the structure consists of statements partially ordered by the support or reason relation. A link might be marked in the text of the argument by an adverbial connective, such as *because*, *thus*, or *hence* (Grosz, Pollack, & Sidner, 1989; Reichman-Adar, 1984; Schiffrin, 1987).

As an example of how this type of theory works, Figure 1a gives a reconstruction of Ann's argument 1, according to Fisher's (1988) system. The diagram shows that Ann's claims in Lines 1c and 1g provide support for her main conclusion in Line 1a. That is, the fact that none of the campus coffee shops has good coffee, together

with the fact that all of the campus coffee comes from the same supplier, supports her case that there is no place on campus to get good coffee. The bracket and plus sign in the diagram indicate that the two bracketed sentences *jointly* imply the conclusion. The notation derives from logic systems with similar display formats (e.g., Gentzen, 1935/1969), but in Fisher's system the arrows do not necessarily denote a valid relationship. Instead, the arrows show the support that the arguer intended, as determined by an analysis of the discourse. Whether the sentences at the base of the arrow actually provide (deductive or inductive) support for the conclusion is also a matter for analysis and depends on "appropriate standards of evidence or appropriate standards of what is possible" (Fisher, 1988, p. 27).

The diagram in Figure 1a gives a reasonable picture of Ann's central argument, but it leaves out much of what transpires in Argument 1. Bill explicitly challenges some of Ann's assertions, leading her to elaborate her reasons; however, these challenges do not appear in the figure. It is possible to adapt schemes like Fisher's to include challenges and criticisms, but the diagramming conventions become complicated and ad hoc. Moreover, the dialogue itself has a sequential, orderly character that is lost in Figure 1a, which focuses solely on the support relation. Ann's assertions are reactions to Bill's probes, and it is difficult to capture this interactional aspect of the reasoning in simple premise-to-conclusion links.

To get around some of these limitations, a second tradition views argumentation as a conversational or "dialectical" exchange. Informal arguments, like other conversations, take place under tacit agreements to cooperate in order to advance the discussion (Grice, 1989; Lewis, 1979; Sperber Wilson, 1986). Participants obviously disagree about specific points, but no argument is possible unless they cooperate on how the interaction should proceed (Schiffrin, 1985; van Eemeren, Grootendorst, Jackson, & Jacobs, 1993). In conducting the argument, the participants assume that there are certain relevant beliefs that they mutually accept as part of the participants' *common ground* (Clark & Schaefer, 1989). There are also relevant beliefs that one participant accepts, but that others either reject or are uncertain about, for otherwise there would be little point in the argument. Thus, a participant's goal might be to establish a belief as part of common ground by showing that it follows from other mutual beliefs. Opponents, in turn, may attempt to

make the belief a mutually rejected one. In carrying out these goals, the participants engage in a variety of dialogue moves, loosely analogous to moves in a game. Formal theories along these lines appear in the work of Hamblin (1970), Mackenzie (1979, 1984), Pilkington, Hartley, Hintze, and Moore (1992), Rescher (1977), and Walton and Krabbe (1995). Jackson and Jacobs (1980), Muntigl and Turnbull (1998), Resnick, Salmon, Zeitz, Wathen, and Holowchak (1993), and van Eemeren, Grootendorst, and their colleagues (e.g., van Eemeren, et al., 1993; van Eemeren, Grootendorst, & Snoeck Henkemans, 1996, Chap. 11) have developed more informal, discourse-based approaches to argumentative dialogues along similar lines.

In Walton and Krabbe's (1995) system for *permissive persuasion dialogues*, for example, the dialogue game consists of two players who take turns making concessions, retractions, arguments, and challenges. The goal of the game is for "each party to get each of its initial assertions conceded by its adversary and . . . to get the other party to retract its initial assertions, or at least some of them" (p. 135). A set of rules govern the commitments of the participants and limit the range of conversational moves they can make at each turn in the dialogue. Figure 1b shows the first part of Argument 1, as Walton and Krabbe's (1995) model might represent it (cf. their Figure 4.6, p. 144). The first two columns of the figure record the statements to which Bill is committed (none in this segment of the dialogue) and the speech acts he performs in each of his turns in the game; the last two columns record Ann's speech acts and commitments. The numbered rows indicate the sequence of turns. Officially, the game begins with preparatory moves in which each participant makes initial assertions and concessions. In Argument 1 the only such assertion is Ann's claim that there's no place on campus to get good coffee, and this automatically becomes a commitment of hers. According to the rules of the game, Bill's first move must either concede or challenge this assertion, and he challenges it in row 1 of the figure. The rules also specify that Ann must offer an argument for the challenged assertion in her very next move. Although Ann's actual response in Argument 1 is simply her statement about having tried all the coffee shops, we can view this as a truncated argument that could be expanded as: *I've tried all the coffee shops on campus, and none has good coffee; therefore, there's no place on campus to get good coffee.* This argument appears in Ann's speech act column. The rules dictate that

the premise of the argument and the implication itself become Ann's commitments, as shown in the fourth column.

It is difficult to continue the description of Argument 1 in this fashion because of limitations of the Walton-Krabbe system. Bill's comment in Line 1d that Ann hasn't tried the Garrett coffee shop is a challenge to Ann to defend her previous claim, but it is also an assertion in its own right. It can be attacked in turn, as Ann proceeds to do in 1e. It is possible to regard Bill's comment as the beginning of a new dialogue game that has Line 1d as its basic assertion, but within the Walton-Krabbe system there would then be no way to record the fact that this statement also criticizes what went before. In general, the dialogue-game framework makes it difficult to represent the embedded or recursive structure of support that is often typical of argumentation. Nearly any statement that is introduced into an argument can itself become the argument's focus and generate additional justification and criticism.

In the present article, I describe a theory that adheres to the conversational approach in describing argumentation as a series of moves or speech acts by two or more people as they attempt to determine what to believe. But, in addition, it introduces a set of recursive rules that make it clear, for example, how attacks can become the subject of counterattacks, as in Argument 1. Unlike many conversational approaches, these rules generate an explicit, global structure for an argument that displays the reasons and critiques for each claim. The participants' commitment to the claims is defined over this structure. That is, the theory views an argument as being more than a sequence of moves in a game, and it represents the relation among the moves in terms of support, as in the structural tradition. The theory attempts in this way to unite previous work in cognitive psychology, philosophy, and linguistics in order to understand the nature of argumentation.

Although the theory depicts argumentation as occurring between two participants, the results are also relevant to individual deliberation and reasoning. As many investigators have remarked, people's skill and fairness in reasoning depends on their considering multiple sides of an issue and avoiding bias in evaluating claims (e.g., Baron, 1991, 1995; Perkins, Farady, & Bushey, 1991; Voss, Blais, Means, Greene, & Ahwesh, 1986; Voss & Means, 1991). Reasoning, in this sense, is often a process of internal argumentation in which a person considers the potential

challenges, refutations, and justifications of an initial position (e.g., Billig, 1987; Ford, 1994; Kuhn, 1991); Hintikka (1984) traces this idea to Plato and Peirce. Sophisticated arguments in the humanities and social sciences, for example, usually take the form of an alternating sequence of claims, justifications, and potential counterclaims. Similarly, recent theories of individual decision making depict choice as a matter of internally weighing arguments for and against the options (Curley, Browne, Smith, & Benson, 1995; Hogarth & Kunreuther, 1995; Shafir, Simonson, & Tversky, 1993). Thus, describing multiperson argumentation may aid in analyzing single-person reasoning and in improving thinking and decision making.

Clearly, argumentation is not the only way to settle disagreements or to gain new knowledge. Other methods may be more appropriate for certain purposes or for certain individuals (see, e.g., Clinchy, 1989). Nevertheless, argumentation is an important tool for understanding, and it deserves closer attention from cognitive psychology than it has received. The goal of the present article is to provide a starting point for a rigorous theory of argumentation that goes beyond the somewhat unsystematic treatment common in textbooks in informal logic and critical thinking.

Argumentation Structure

According to the present theory, arguments are sequences of critical reactions to a claim. Suppose, for example, that Ann utters Line 1a, there's no place on campus to get a good cup of coffee. Making this claim is not only a way to express a personal conviction, but also a way to get Bill to adopt the same belief. Unless Ann and Bill are simply engaged in small talk, Ann initially thinks Bill may not believe Line 1a; otherwise, she has little reason for stating it. By asserting 1a, Ann expects to get Bill to state his relevant beliefs, probably in the hope that Bill will affirm it. If all goes smoothly, Bill will accept Line 1a, either on the basis of his prior conviction or on Ann's authority, and 1a will then be part of these participants' common ground. Phrases such as "You're right about that," "That's true," and "I agree" accept the previous assertion and end the issue. We can refer to these phrases as *accepters* (similar to Resnick et al.'s, 1993, concessions), and the final line in Argument 1 is of this type. Arguments arise, however, when the listener doesn't immediately accept the initial claim. In the sample dialogue, instead

of accepting Line 1a at the outset, Bill delays until he explores its support.

Rules for Argument Structure

This section surveys some possible reactions to claims and attempts to show how they fit together and lend structure to an argument. What sorts of conversational moves do arguments contain? Faced with claim 1a, Bill has a number of options in addition to agreeing with it. First, if he is uncertain whether he should believe the claim, he can ask for reasons. For example, Bill can ask, "What makes you say that?" as he does in Line 1b, or ask some similar question (e.g., "Why?" or "How come?"). This challenges Ann to justify her original claim by asserting reasons in its favor. Her response in Line 1c (i.e., *I've tried all the coffee shops on campus and none has good coffee*) justifies the claim by citing evidence. However, clarifying or explaining the original claim can also justify it in some contexts (Brem & Rips, 1995; Ranney, Schank, Hoadley, & Neff, 1994). Note that Ann's 1c is itself a claim and is open to requests for justification, just as was 1a. Thus, arguments allow embedding and repeating of the participants' moves, as we saw earlier.

Bill's question in Line 1b probes the reasons for 1a, but he could also ask for the point of the statement (i.e., the conclusion that the statement supports). If Bill suspects that Line 1a was uttered with a motive, as a step leading to a further claim, he could ask Ann where she was going:

- (2) Bill: {So (what)? | What's the point? | What do you say that for?}

Bill's 1b seeks justification for the previous statement, whereas the questions in 2 seek the conclusion toward which it is headed. (Some questions, such as "Why do you say that?" seem appropriate for both purposes; see Graesser & Person, 1994; Zwicky & Zwicky, 1973, for related distinctions.) Although the justification in Line 1c appropriately answers 1b, it cannot easily answer 2, except perhaps to clarify or to paraphrase the original claim. Instead, 3 more naturally follows 2:

- (3) Ann: I've decided to open my own coffee shop in Swift Hall.

To distinguish sequences such as 1b–1c from those such as 2–3, we can call the former pair a *justification query* and a *justification* and the latter pair a *conclusion query* and a *conclusion*.

Instead of asking for a justification or a conclusion, Bill could attempt to refute Ann's claim. In responding to 1c, for example, Bill attacks the claim directly by offering the counterclaim in 1d that Ann has not tried the new coffee shop in Garrett. Like 1a and 1c, 1d is a claim in its own right and is subject to the same types of replies. Ann could challenge 1d by asking for a justification, or she could attempt to refute 1d by making her own counterclaim, as she does in 1e. Pollock (1989) called statements like 1d–1f *defeaters*, because their aim is to defeat an earlier piece of the argument. Pollock distinguished between *rebutting defeaters*, such as 1d and 1e, that directly conflict with an earlier claim, and *undercutting defeaters*, such as 1f, that attack the relation between a claim and its support (see, also, Flowers et al., 1982). For example, in Line 1f, Bill attempts to undercut the relation between 1c and 1a by noting that coffee shops are not the only place on campus for coffee. According to Bill, Ann's statement that all the coffee shops have bad coffee does not sufficiently support her claim that there's no good coffee on campus.

Claims, challenges, defeaters, and accepters give arguments their structure. It is possible to depict this structure in a number of ways, using rules, schemas (Rumelhart & Norman, 1988), superstructures (van Dijk and Kintsch, 1983), context spaces (Reichman-Adar, 1984), discourse spaces (Allen, 1995), or similar representations. These formats have different advantages, but for present purposes the differences between them are not crucial. For simplicity in representing arguments, I adopt simple rewrite rules for dialogues, leaving open the possibility that extending the theory may require more complex representations. In the examples given here, the claims, challenges, and other moves correspond directly to text in the dialogue, with possibly more than one move per speaking turn. In naturally occurring arguments, however, participants may leave some of these items implicit.

The rules in Table 1, then, summarize the possibilities discussed so far. Each of these rules means that the discourse component on the left decomposes into those on the right, as in other rewrite rules. However, the plus signs in Rules A, C, and others indicate not only the order of the components, but also a change of turn from one speaker to another. Thus, Rule A means that an argument consists of a claim by the first participant (indicated by the subscript 1) followed by a response by the second participant (subscript 2). An asterisk following a component indicates that

Table 1: Structural Rules for Two-Person Argumentation

A. Argument \rightarrow {Claim ₁ + Response ₂ * Claim ₁ + \emptyset ₂ } ^a
B. Response ₂ \rightarrow {Challenge ₂ Rebutting Defeater ₂ Acceptor ₂ } ^a
C. Subargument _i \rightarrow {Claim _i + Subresponse _{3-i} * Claim _i + \emptyset _{3-i} } ^a
D. Subresponse _i \rightarrow {Challenge _i Rebutting Defeater _i Undercutting Defeater _i Acceptor _i } ^a
E. Challenge _i \rightarrow {Justification Query _i + Justification _{3-i} * Justification Query _i + \emptyset _{3-i} Conclusion Query _i + Conclusion _{3-i} * Conclusion Query _i + \emptyset _{3-i} } ^a
F. Justification Query _i \rightarrow {Why? Why do you think so? How come? ... }
G. Conclusion Query _i \rightarrow {So? What's the point? What do you say that for? ... }
H. Justification _i \rightarrow Subargument _i
I. Conclusion _i \rightarrow Subargument _i
J. Rebutting Defeater _i \rightarrow Subargument _i
K. Undercutting Defeater _i \rightarrow Subargument _i
L. Acceptor _i \rightarrow {That's right You're right about that I agree ... }

Note. Subscripts on constituents indicate the first speaker ($i = 1$) or the second speaker ($i = 2$). The expression $3 - i$ indicates a change of speaker (if $i = 1$, then $3 - i = 2$; if $i = 2$, then $3 - i = 1$). Asterisks denote possible repetition of the same constituent.

^a Acceptors and null responses (\emptyset) can appear only on the right-most branch of the lowest argument or subargument that dominates them.

the constituent can be repeated. Thus, after the first participant's claim, the second participant can produce more than one response (e.g., several attempts to defeat the original claim). Bracketed items separated by vertical bars, as in A–G, are alternative constituents, only one of which can be selected on a given turn. For example, Rule B stipulates that a response can consist of a challenge, a rebutting defeater, or an acceptor. The rules in Table 1 are not exhaustive because it is possible to analyze some of the categories in more detail.² The present rules, however, provide a working hypothesis that will allow us to test their accuracy.

As an example of how these rules operate, Figure 2 shows the structure they generate for Argument 1. (I have omitted subscripts for the participants because the participants' names appear at the terminal nodes.) Ann's statement 1a is the argument's initial claim, and the rest of the argument is a response to that claim. Within this response, Ann's justification in 1c is an embedded claim that elicits an embedded response from Bill (in this case, a rebutting defeater). The argument could be continued through repeated application of the same rules.³

Some Advantages of the Structural Rules

Argumentation does not normally occur in isolation, but as part of larger interactions. It is unlikely for this reason that the rules in Table 1 are mentally isolated from the more general procedures people use in coping with conversation. People's ability to understand argumen-

tation shades into their ability to understand instructions, excuses, and other discourse types. Nonetheless, the rules in Table 1 possess an internal structure that may give rise to consistent impressions and modes of response. The concept of argumentation is thus like many other concepts (e.g., *tree*, *shrub*) that exhibit coherence despite close connections to other categories. The systematic patterns that occur in arguments make them a reasonable topic of theorizing.

One advantage of these rules is that they illuminate the two-sidedness of arguments by means of the claim-response pairings in Rules A and C. In this respect, the current theory is similar to that of Jackson and Jacobs (1980). In their approach, argumentation is based on a speech-act pair (e.g., a proposal and a refusal) in which the second act of the pair indicates some type of disagreement. The rest of the argument is an attempt to manage this conflict. The rules in Table 1 generalize and formalize this idea. Every claim implies the possibility of a response, so every claim is subject to challenge and criticism. Justifications and defeaters are themselves claims and have responses like any other.

Within this framework, participants can fail to respond to a specific claim, either because their response is preempted by another participant or because they choose to return to an earlier point in the dialogue. Within the context of an argument, however, these skipped responses are meaningful; they are "official silences" that arguers and onlookers can interpret (Schegloff, 1972). Rules A, C, and E provide for these skipped responses, representing them by means

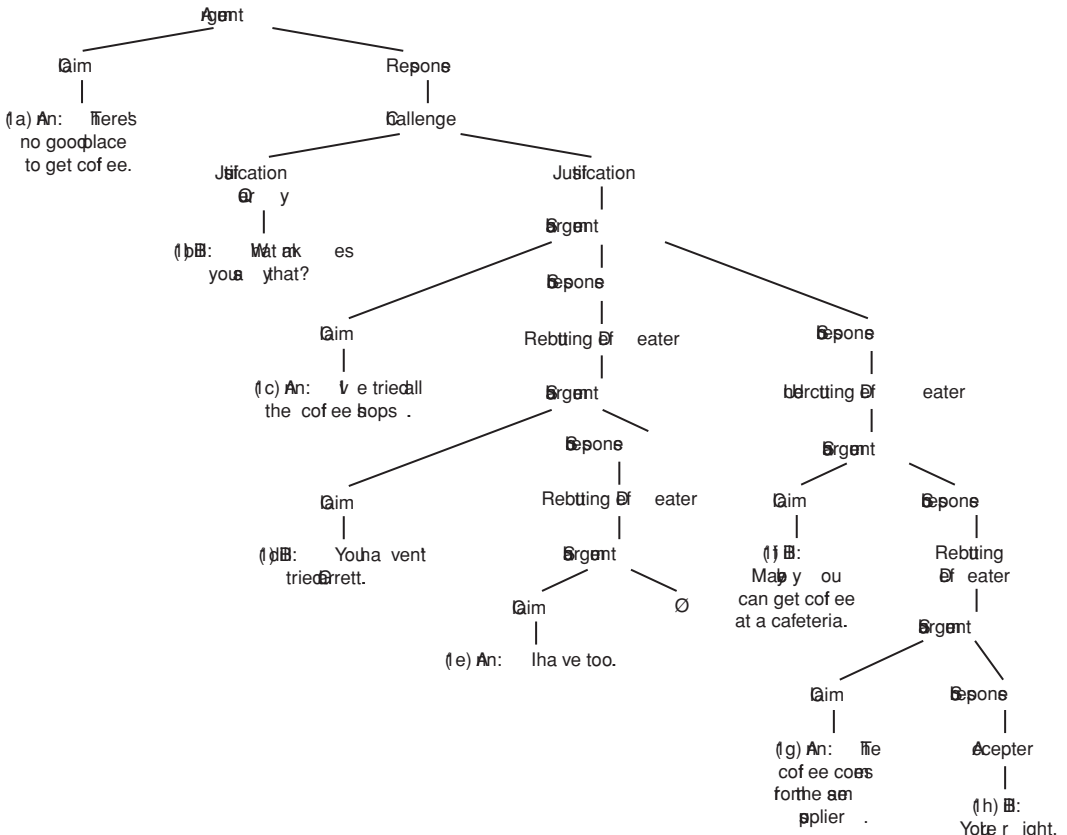

Figure 2. A structure diagram for Argument 1, according to the rules of Table 1.

of the null symbol (\emptyset). An example of a skipped response occurs at 1f in the sample dialogue: Instead of responding directly to Ann's claim that she was in the Garrett coffee shop, Bill backs up to re-attack her justification in 1c. Participants often preface these jumping-back points by phrases such as *anyway*, *besides*, *in any case*, *at any rate*, *in any event*, and similar markers (Grosz et al., 1989; Reichman-Adar, 1984). Skipped responses also mean that a single conversational turn can contain more than one terminal constituent in the argument structure. In place of 1g, for example, Ann could have said, *All the campus coffee comes from the same supplier; and besides, I've tried the coffee at the cafeterias, too*. Ann would thus be preempting Bill's response to her claim about the supplier. She hurries on to give a second defeater to 1f without giving Bill a chance to respond to her first defeater.

The representation also distinguishes the different lines of argument as separate branches in the structure. For example, Bill makes two different attacks on 1c (i.e., that Ann hasn't tried all the coffee shops and that coffee shops aren't the only places for coffee), and these two lines

appear as two branches in Figure 2. The rules are compatible, too, with different styles of argumentation. More combative styles are likely to exhibit many rebutting defeaters and challenges; more conciliatory styles would exhibit more accepters.

Some Limitations of the Structural Theory

The rules in Table 1 describe some ways arguments develop. The present claim is that people hearing or reading an argument extract some structure analogous to the one these rules generate, but, of course, they get more out of an argument than the bare structure. In the following parts of this article, I take up two additional aspects of argumentation: information about which participants are committed to which claims and which participant has greater burden of proof. However, there are other aspects that the theory does not address. First, the justification and defeater categories in Table 1 capture the way participants publicly position their utterances within the argument, but they do not convey how successful these attempts are.

Some justifications and defeaters are obviously stronger and more convincing than others, but the participants and the audience would have to evaluate this by independent means. The structural rules may be preliminary to such an evaluation because understanding the role of an utterance in the argument is fundamental to assessing it. But the rules don't by themselves decide the assessment. (The limitation here is similar to that of the support links in Fisher's theory, discussed earlier.)

Second, challenges and defeaters in arguments are potentially embarrassing to participants and so add an emotionally threatening element. It is often in the interest of both participants to maintain each other's dignity or "face," and for this reason they may couch their responses in ways that preserve the other's self-esteem (Brown & Levinson, 1987). For example, instead of Bill's forthright *Id*, he could hedge by saying "I wonder whether you've tried the new coffee shop in Garrett" or "Have you heard about the new coffee shop in Garrett?" These aspects of politeness and tact are important elements in argumentation (Muntigl & Turnbull, 1998), but the present theory does not treat them because they belong to a much wider class of conversational settings, including invitations, requests, advice giving, and many others.

Third, the rules in Table 1 are limited to two-sided argumentation. Some issues have more than two sides, of course. A group may have to decide which of many possible actions to take to achieve a goal, with each action having its own advocates. In the present article, I develop the two-sided case as a starting point, leaving to further work the task of generalizing to more than two speakers.

It should also be clear that the rules do not describe the strategies participants use to generate their contributions to a debate. Although the rules in Table 1 are part of the knowledge they employ in planning their conversational moves, participants choose these moves on the basis of many background factors, including their knowledge of the argument's subject matter, their memory of previous conversations, and their judgment of whether a retort is likely to offend their opponent. I mention a few of the issues concerning argument production at the end of this chapter, but the theory aims to account for argument comprehension. A related point is that people may sometimes organize their arguments around some global attitude (e.g., support or opposition to a general point of view) that does not appear in the dialogue as

a specific claim. These attitudes then impose a more abstract structure on the argument than the one I describe here. Although the Table 1 rules don't represent these global attitudes, there is no reason to think the rules conflict with them.

Finally, because a number of investigators have criticized the use of rewrite rules in describing the structure of stories, one should consider whether the same criticisms apply here (see Black & Wilensky, 1979, and Garnham, 1983, for critiques of story grammars, and Rumelhart, 1980, for a response). Many of the criticisms have focused on the difficulty of using these grammars to parse a story in initial comprehension. Because the story grammars' categories (e.g., *setting* or *resolution*) can contain an unlimited number of possible texts, comprehenders have to understand the content of the text before they can assign it to the appropriate category. This reverses the order of operations in traditional theories of comprehension, where people first extract grammatical structure and then use the structure to interpret the text. Whatever problems this poses for story grammars, however, the present theory is not intended as a parser for arguments. The rules of Table 1 describe the structure that people uncover in thinking about an argument, and they presuppose many lower-level abilities in understanding its sentences initially. Although the rules may help guide interpretation by allowing people to anticipate upcoming segments of the argument, they are obviously only one part of the text comprehension process. (See Cohen, 1990, for suggestions on parsing onesided arguments.) Similarly, the point of the present rules is not to distinguish between "grammatical" and "ungrammatical" arguments, but to describe one dimension along which arguments can vary. It seems uncontroversial that people recognize justifications, accepters, and defeaters as components of arguments, and the rewrite rules state generalizations about how arguments configure these components.

An Application to Trial Proceedings

The rules in Table 1 specify the types of conversational moves that make up the core of argumentation, and it is easy to use the rules to construct dialogues, such as Argument 1, that appear to be well-formed arguments. It is another question, however, whether the rules also pick out instances of argumentation that occur in natural contexts. Can the rules distinguish arguments from other types

Table 2: Two Excerpts from the Simpson Civil Trial That Served as Stimulus Passages

Passage 1

Mr. Petrocelli: Well, Your Honor, for the record, I want to say I think the comments of Mr. Baker were not warranted.

The Court: I'm not concerned with Mr. Baker's comment.

Mr. Petrocelli: This a public proceeding. I don't think he has any right making those comments and talking about referring matters to the State Bar. Maybe we ought to talk about Mr. Taft, his colleague.

The Court: Mr. Petrocelli, Mr. Baker, as you know, I'm not influenced by any of this personality interchange. I've always wanted counsel to desist from that. I will continue to ask counsel to desist from that. I made no complaints about whatever things you want to say about me. I could only make a record. And I'm going to deny the motion because I think it's untimely. I think you had ample opportunity to make the effort to make the correction, and it's too late.

Passage 2

Mr. Blasier: Tell you what Dr. Gerdes is going to say, if you like. [Pause in proceedings for the Court to review document.]

The Court: Okay, go ahead.

Mr. Blasier: He is also going to testify that those results in 30 and 31 are not valid because of the – the extraneous alleles, which showed up in the positive controls; that because of those alleles showing up where they're not supposed to be, that those whole – that whole series of tests is invalidated.

The Court: By whom? Tests by whom?

Mr. Blasier: All of them by DOJ. I'm sorry. I think it's DOJ on 30 and 31; that they had extraneous alleles on the positive controls. He's also going to testify that Bundy drop 52 shows evidence of contamination, as well, with an extra 1.3 allele as a result of possible cross-contamination at the crime scene.

of conversations (e.g., advice giving or permission seeking) in the form they take in ordinary speech? One source of evidence comes from a recent analysis by Muntigl and Turnbull (1998) of naturally occurring arguments among family members and among university students. The types of exchanges that Muntigl and Turnbull identified bear a close correspondence to the categories in Table 1. Their irrelevancy claims (e.g., "You're straying off the topic") are similar to undercutting defeaters, challenges to justification queries, and contradictions (e.g., "I don't hate him") to rebutting defeaters. (Muntigl & Turnbull also recognize a category of counterclaims [e.g., "Yeah but it's still not what I like"], which might be analyzed as an acceptor followed by a defeater for an earlier claim.) This convergence between categories provides independent support for the Table 1 rules.

Further support for the rules comes from two-person interactions that occur in trial transcripts. Obviously, legal proceedings contain many argumentative exchanges, but they also contain other kinds of interaction, such as petitions to the judge. Thus, it is possible to ask whether the rules in Table 1 describe (independently identified) arguments rather than nonar-

guments in the proceedings. As a way of exploring this issue, 20 excerpts were selected from the O. J. Simpson civil trial because the complete transcript is readily available in digital form.⁴ The excerpts were dialogues from sidebar discussions (either between the judge and a lawyer or between two lawyers) that took place near the middle of the trial (between December 3 and December 11, 1996). Each excerpt conformed to the following constraints: (a) It consisted of at least four consecutive speaking turns, two each from the two participants; (b) the participants' statements were addressed to each other (rather than to a third party); and (c) no single turn contained more than nine sentences. The last constraint was intended to eliminate long speeches that a participant had prepared prior to the time of the dialogue. The 20 excerpts were random selections from the dialogues that met these restrictions. The length of the passages varied from 4 to 20 turns (31 to 425 words). Table 2 shows two examples that illustrate the range of the dialogues.

These trial excerpts contain many sorts of conversational moves, including queries of fact (e.g., "Tests by whom?"), requests for permission ("Then let us lead as well, Your Honor"),

offers ("Tell you what Dr. Gerdes is going to say, if you like"), refusals ("I'm inclined not to permit him to testify unless he's subject to a deposition"), grantings of requests ("Okay, go ahead"), and many others. Some of these speech acts can occasion an argument (e.g., a refusal can lead to an argument about its fairness) or can be embedded in an argument (e.g., questions of fact can occur when one participant is trying to understand another's position), but are not part of the arguments, according to the current theory. In order to predict whether an excerpt is an argument, it is necessary to find a way to separate these extraneous speech acts from those of the rules in Table 1 because the theory holds the latter to be constitutive of argumentation. For the sake of objectivity and simplicity, two assistants independently classified each turn according to whether it contained an explicit phrase indicating that it was a defeater (e.g., the phrases "... is irrelevant," "... is meaningless," "No, it's... [rather than -]," "No, it's not... [it's -]," etc.), a justification query (e.g., "Why assume...?", "Why is... relevant?," "Why is... reasonable/unreasonable?"), or a conclusion query (e.g., "Where is... leading?," etc.). These categories are the ones from Table 1 that are most easily identified and most representative of arguments; thus, they should provide a rough index of the character of the excerpt.⁵ The Spearman correlation between the number of such categories that the two assistants identified was .75 across passages ($df = 18, p < .001$). For example, both assistants marked each exchange as a defeater in the first passage in Table 2. Both also marked the fourth exchange of the second passage as a query. (One assistant also marked the second exchange as a query, presumably on the grounds that it elicits an explanation from the attorney.)

The theory predicts that the larger the number of these Table 1 categories, the more likely it is that the passage will appear to be an argument. As a test of this prediction, 27 Northwestern University undergraduates read the same 20 excerpts and rated how typical each was of conversational argumentation. They made their ratings on an 11-point scale, with 0 defined as *very atypical* and 10 defined as *very typical*. As examples of their decisions, they gave the first passage in Table 2 a mean rating of 7.0, and the second a rating of 4.1. In line with the hypothesis, the Spearman correlation between their mean typicality rating and the mean number of argument categories in a passage was .70 ($df = 18, p < .001$). Of course, coding of the excerpts takes

into account only one aspect of the Table 1 rules; so, at best, it provides only a partial test of the present framework. More stringent tests appear later. Nevertheless, it provides a hint that the framework is pertinent to arguments as they occur in everyday contexts.

Principles of Commitment

One reason that argument structure is important is that it defines which claims become part of common ground and, hence, which issues get settled during an argument. In order to understand this process, I focus on how participants publicly commit themselves to a claim because if both participants are publicly committed to the same claim, that claim becomes part of common ground. (See Bly, 1993, for the notion of a negotiated common ground.) Once a participant's claim is admitted to common ground, then that participant can use it to support other points. By the same token, the greater the number of the participant's claims that are still under contention, the greater his or her burden of proof in the argument, other things being equal.

In this section of the article, I develop a theory of how participants commit themselves to claims and how they retract commitment. This theory then generates predictions for experiments in which subjects judge the commitments of speakers.⁶ The central notion is that when people read or hear an argument they keep a running mental record of the participants' commitments. For this purpose, they maintain mental *commitment stores* or *commitment tags*, a notion that originates in formal theories of argumentation (Hamblin, 1970). In the present model, the commitment tags are mental representations that record for each claim C and participant S, whether S accepts C, rejects C, or is neutral with respect to C at the current stage of the debate. The commitment tags will typically change during the debate, as participants accept and reject each others' assertions. In this theory, conventions or principles governing argumentation determine how people tag claims on the basis of the structure of Table 1.

The first subsection presents some principles governing commitment and shows how they apply to Argument 1. The strategy is to describe a set of principles that has certain ideal properties, properties that push participants toward agreeing with each other on which claims they should accept or reject. I discuss these ideal properties in the second subsection, and Appendix A [of Rips, 1998] contains

proofs that they hold. It is obvious, however, that real arguments do not always end in consensus. Sometimes we recognize that one participant accepts and the other rejects a claim; sometimes we see that one participant is neutral about a claim (and the other nonneutral) when the debate ends. We can model these residual disagreements by identifying within the ideal set certain principles that people do not always employ. Failure to apply these principles thus provides obstacles to agreement. This theory, called the *commitment change* model, is taken up in the third subsection, and the rest of the article tests some of its implications.

Clearly, participants may have many private beliefs about an issue that may or may not surface during a debate. In this article, I concentrate on public commitments, not because private ones are unimportant, but because the focus is on how an audience comes to understand arguments that others put forth. From the point of view of someone listening to an argument, the publicly established commitments are usually the main sources of evidence about the participants' positions.

Some Principles of Commitment

Table 3 lists some hypothetical principles that might determine commitment. These principles are rules that people may follow as they listen to or read an argument, and they distill possible inferences that people might use in deciding who is committed to which claims. The rules constitute an idea about what one is entitled to conclude about the commitments, based on participants' explicit statements of agreement (or disagreement) and tacit knowledge of argumentation strategies. Taken together, these rules have properties of completeness or closure (as later sections show). The rules lead to agreement among participants, and for this reason, they can be considered ideal or "normative." There are other normative considerations, however, that these rules do not necessarily fulfill. For example, they may or may not reliably promote true beliefs or provide deeper understanding of an issue.

The most obvious rules (and probably the ones most likely to be obeyed in comprehension) are the *assertion principle* and the *acceptance principle*, listed at the top of Table 3. According to the assertion principle, participants commit themselves to their own claims when they assert them. For example, Ann commits herself to Line 1a by virtue of asserting it at the beginning of

the dialogue, and 1a would therefore be tagged as one of Ann's commitments. The same goes for the claims in 1c to 1g. The assertion principle follows simply from what it means to make an assertion. Although there are special devices that allow participants to withhold commitment from some of their own statements (e.g., by saying that they are assuming something "for the sake of the argument" or that they are playing "devil's advocate"), these cases have to be marked as hypothetical. A second, equally obvious, principle is that when a participant explicitly accepts a claim (via Rule L of Table 1), then the participant is committed to the opponent's last claim. Thus, Bill commits himself to Ann's claim 1g at the end of the sample argument because of his acceptor in 1h, and 1g therefore becomes part of common ground. This is the acceptance principle in the table.

More interestingly, some of the rules imply that accepting a lower claim in the argument structure can also affect whether higher claims become part of common ground. (The experiments later in this article test this assumption.) Suppose, for example, that in 1d Bill were to accept Ann's justification, instead of trying to defeat it. That is, instead of saying "You haven't tried the new coffee shop..." he simply says "Okay, you're right." Accepting the justification means that Ann's second claim ("I've tried all the coffee shops on campus...") becomes common ground by the acceptance and assertion principles, but what of Ann's original claim 1a ("There's no place on campus to get a good cup of coffee")? If the argument ends at this point, then it seems that Bill has implicitly accepted the original claim by virtue of accepting its justification. So both of Ann's previous claims would then be part of common ground. If the argument continues, however, then it is possible for Bill to ward off committing himself to the original claim by attempting to defeat it on other grounds. This suggests that, in informal reasoning, commitment to a justification implies default commitment to the justified claim, and justification principle (a) in Table 3 states this policy. A participant can later reverse this commitment, however, by defeating the claim directly or undercutting the relation between it and the justification, as other principles in the table make clear. Table 3 also contains a parallel conclusion principle for arguments resulting from Rule I of Table 1.

Accepting a defeater can also have implications for commitment to higher claims. An example occurs at the end of Argument 1. Ann's

Table 3: Some Principles of Commitment in Two-Person Arguments**Assertion Principle**

A participant who asserts a claim accepts that claim.^{a,b,c}

Acceptance Principle

A participant who utters an acceptor (e.g., "I agree") accepts the previous claim.^{a,b,c}

Rebutting Principles

- (a) A participant who accepts a rebutting defeater to a claim rejects that claim, unless the defeater is undercut for the participant (see undercutting principle [a]).^{a,b,c,d}
- (b) A participant who rejects a rebutting defeater to a claim accepts that claim.^{c,e}

Justification Principles

- (a) A participant who accepts a justification for a claim accepts that claim, unless the justification is undercut for the participant (see undercutting principle [a]).^{a,b,c,d}
- (b) A participant who rejects a justification for a claim rejects that claim.^{a,b,c,d}
- (c) A participant who passes up the chance to respond to a justification query for a claim rejects that claim. In these circumstances, the participant uttering the justification query also rejects the claim.^{b,c,d}

Conclusion Principles

- (a) A participant who accepts a claim that directly supports a conclusion accepts that conclusion, unless the conclusion is undercut for the participant (see undercutting principle [a]).^d
- (b) A participant who rejects a claim that directly supports a conclusion rejects that conclusion.^e

Undercutting Principles

- (a) A justification, conclusion, rebutting, or undercutting defeater is undercut for a participant if the claim is followed by an odd-numbered string of undercutting defeaters that the participant accepts.^{a,b,c,d}
- (b) A participant who accepts an undercutting defeater accepts the supporting claim (justification, rebutting defeater, undercutting defeater, or claim supporting a conclusion) of the undercut pair.^{a,b,c,d}
- (c) A participant who accepts an undercutting defeater for a justification (conclusion) rejects the justified claim (conclusion), unless the defeater is undercut for the participant (see undercutting principle [a]).^{a,b,c,d}
- (d) A participant who accepts an undercutting defeater for a rebutting defeater accepts the claim against which the rebutting defeater was aimed, unless the undercutting defeater is itself undercut for the participant (see undercutting principle [a]).^{c,e}
- (e) A participant who rejects an undercutting defeater for a justification (conclusion) accepts the justified claim (conclusion).^c
- (f) A participant who rejects an undercutting defeater for a rebutting defeater rejects the claim against which the rebutting defeater was aimed.^e

Skipped-Response Principle

A participant who passes up the opportunity to respond to a claim accepts that claim.^{b,c,e}

^a Received empirical support in either Experiment 1 or Experiment 2.

^b These principles are required for the determination theorem (Appendix A in Rips, 1998).

^c These principles are required for the mutual determination theorem (Appendix A in Rips, 1998).

^d These principles are the moderate items for model fitting.

^e These principles are the liberal items for model fitting.

final claim ("All of the campus coffee comes from the same supplier") is a rebutting defeater for Bill's prior assertion in 1f, "... maybe you can get good coffee in one of the cafeterias," and this implies that Ann rejects 1f. Rebutting principle (a) in the table makes this explicit by requiring participants who accept a rebutting defeater to reject the defeated claim. Notice that this same principle also applies to Bill when he agrees in the final line to Ann's last claim. At this point,

Bill is agreeing to a defeater for his own prior assertion, and this puts him in a position where he must also back off that assertion. The upshot is that, at the end of the dialogue, Ann and Bill mutually reject 1f by rebutting principle (a) and mutually accept 1g, by the assertion and acceptance principles.

Conservative versus liberal commitment. The commitment principles seem straightforward so far, but there is a grey area where intuitions

may differ. At one extreme, people could view almost any conversational move as changing the speaker's commitment to earlier claims, and one can write commitment principles that implement that policy. The effect would be that commitment to an individual claim would fluctuate rapidly during a debate. We call this approach a *liberal* policy toward commitment. At the opposite extreme, a *conservative* commitment policy would make a speaker's commitment to a claim less likely to change on the basis of later conversational moves. Speakers would tend to retain their initial positions toward a claim through subsequent exchanges.

The following sections develop and test models of argumentation based on both conservative and liberal policies. For the moment, however, the commitment principles will be formulated in a way that reflects the liberal view. The conservative view omits some of the principles in question, thus preserving the status of the participants' commitment prior to the conversational move.⁷ Liberal policies often reflect inferences based on participants' choice of strategies, inferences that conservatives don't gamble on.

The difference between liberal and conservative commitment policies comes into focus when a participant ignores an opportunity to respond. Sometimes a participant preempts another's response by rushing to make a further point, and in such situations the second participant's silence clearly does not imply either acceptance or rejection. Sometimes, however, a participant deliberately passes up the chance to respond. For example, as we noticed earlier, Bill chooses not to respond directly to Ann's claim *le* (i.e., her assertion that she was just in the Garrett coffee shop), and instead he returns at *1f* to attack an earlier point. This leaves the empty response (\emptyset) that appears in Figure 2. Formal models of dialectical argument (Hamblin, 1970; Mackenzie, 1979; Rescher, 1977;

Walton & Krabbe, 1995) all adopt the liberal stance that any such failure to respond immediately to a claim is a concession: Because Bill does not respond to *le*, he is automatically committed to it. For example, Walton and Krabbe's (1995) model of permissive persuasion dialogues (PPD) requires that

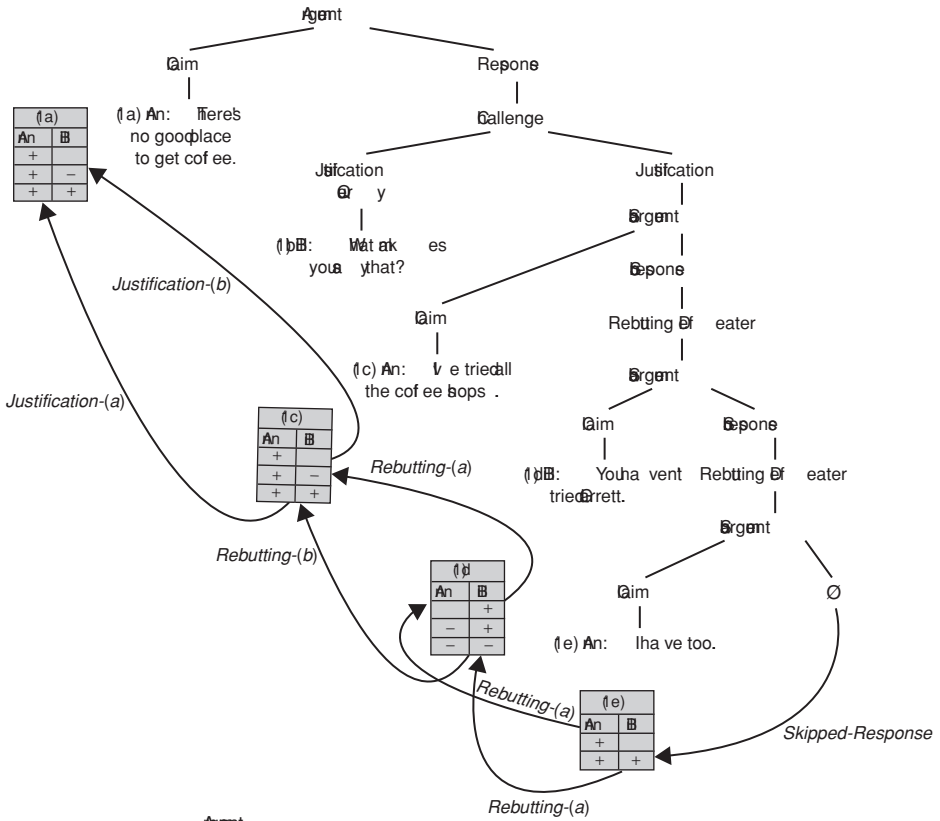

If a party makes an assertion, the other party, in the very next move, is to make clear its position with respect to that assertion (unless this assertion is already among the latter party's concessions or has already been challenged); that is, it should either challenge or concede the new assertion. . . . [This principle] stipulates that in PPD unchallenged assertions count as conceded. We do not see any reason to admit a middle position. If you do not want to concede something, just challenge it. (p. 137)

A similar skipped-response principle appears in Table 3, but it is not obvious that this principle applies in a blanket way to everyday arguments. (The experiments in the following part of the chapter provide evidence that conservative participants do not follow it.)

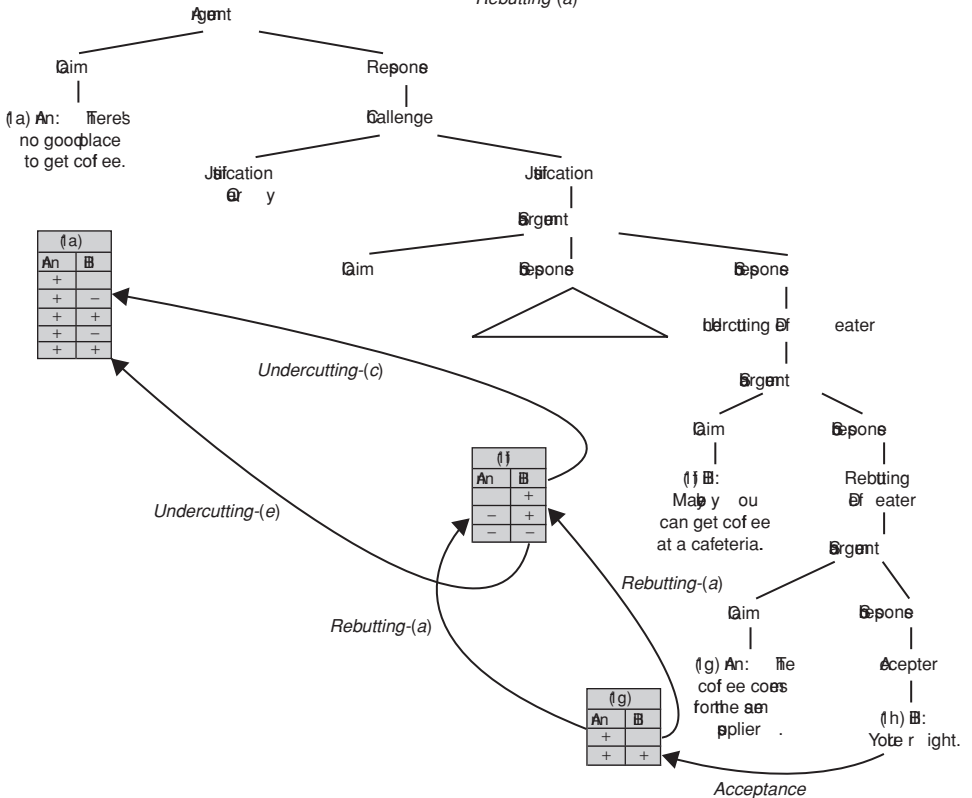

An example of commitment change in arguments. We can summarize the commitment principles of Table 3 in terms of our running example. Figure 3 illustrates the way in which Ann's and Bill's commitments change as Argument 1 unfolds. In this figure, commitment tags for each claim (the shaded boxes) appear next to the argument structure, and labels at the top of the tag identify the claim it represents. Each tag is in tabular form (as a kind of score card) with the first column containing Ann's commitments for the claim and the second column containing Bill's. The individual entries indicate whether each participant accepts the claim (+), rejects the claim (-), or remains neutral (blank). The rows show how commitments for the claim

Figure 3. An illustration of changes of commitment in Argument 1, according to the rules of Table 3. Panel (a) represents commitment changes that occur during the first five lines of the argument; Panel (b) represents changes that occur in the last three lines. Each of the shaded boxes (commitment tags) within the figure indicates whether Ann and Bill accept (+), reject (-), or are neutral (blank) about the adjacent claim. The first column of a box represents Ann's commitments; the second column represents Bill's. The rows of each box show how commitments for the claim change as the argument progresses. The first row gives Ann's and Bill's commitments when the claim is first uttered, the second row shows their commitments to the claim when a later part of the dialogue next alters one of the commitments, and so on. The last row in the box shows Ann and Bill's commitments at the end of the argument. The arrows between the boxes indicate how commitment to later claims affects commitment to earlier ones. The name of the rule that produces this change labels the arrow. (See Table 3 for a description of these rules.)

(a)

(b)

change at successive stages of the argument: The first row of each box shows Ann's and Bill's commitments at the point at which the claim is first uttered; the second row shows their commitments to the same claim when a later exchange in the dialogue alters one of the commitments. The final row in the box shows Ann's and Bill's commitment to the claim at the end of the argument. The arrows between the boxes show how commitment to later claims affects commitment to earlier ones. For example, an arrow from a plus entry for Ann in a lower box to a minus entry for her in an upper box means that her acceptance of the lower claim implies her rejection of the upper claim, according to one of the Table 3 rules. The name of the rule in question labels the arrow.

To see how this notation works, consider the box at the upper left corner of Figure 3a, which represents commitments for claim 1a (i.e., that there's no place on campus to get good coffee). When Ann first makes this claim, she accepts it (by the assertion principle), and Bill is neutral about it. The first row of the box represents this with a plus sign in Ann's column and a blank in Bill's. As the dialogue progresses, Ann justifies this claim ("I've tried all the coffee shops..."), and Bill attacks Ann's justification ("You haven't tried the coffee shop in Garrett..."). By justification principle (b) in Table 3, Bill's rejection of the justification entails his rejection of the justified claim 1a itself. This latter rejection appears in the second row of the upper-left box as a minus sign in Bill's column. The arrow pointing to this entry means that his rejection of 1c (the minus sign at the base of the arrow) is what causes his rejection of 1a (the minus sign at the head of the arrow). The label *Justification-(b)* indicates the relevant principle for this change. Because Ann is still committed to 1a, Ann's column in the second row retains the plus sign.

A little later in the argument, Bill skips a response to Ann's claim 1e that she has tried the Garrett coffee shop. This sets off a complicated chain reaction: First, skipping the response tacitly concedes 1e by the skipped response rule (see the plus sign under Bill's column in the box for 1e). Second, conceding 1e forces Bill to retract his own assertion that Ann hasn't tried Garrett, as shown by the minus sign in Bill's column in the 1d box. Third, retracting 1d means Bill must accept 1c, which 1d was originally supposed to defeat. And, finally, accepting 1c causes Bill to accept 1a because 1c justifies it. The third row of the 1a box represents this realignment, where both participants accept 1a. The remain-

ing boxes in Figure 3a show in a similar way the changes in commitments to claims 1c, 1d, and 1e.

Panel a in Figure 3 shows the commitment changes in the first part of the argument (through Line 1e), using the full set of rules in Table 3. The remaining changes for Lines 1f through 1h appear in Figure 3b.⁸ At the end of Argument 1, Ann and Bill mutually accept 1a, 1c, 1e, and 1g, and mutually reject 1d and 1f. Ann has a clear advantage here because all her claims have become mutually accepted, whereas all Bill's claims are mutually rejected at the conclusion of the dialogue. These commitment tags are, no doubt, subject to memory limitations: If there are many claims and many participants, people may lose track of which participants are committed to which claims. This can interfere with people's ability to follow an argument. The experiments reported here, however, attempt to minimize memory difficulties by allowing subjects to review the argument text.

As this example hints, tracing the kinematics of commitment can pose some intricate cognitive problems. Initially disputed claims can become accepted or retracted on the basis of later moves in the dialogue, when supporting and defeating claims are themselves accepted or retracted.

A Theory of Commitment in Arguments

The commitment principles of Table 3 provide a type of evaluation for informal arguments that bears similarities to the semantic evaluation of arguments in formal logic (Tarski, 1936/1956) and formal linguistics (Chierchia & McConnell-Ginet, 1990). Formal semantics specifies conditions, under which individual sentences are true or false in particular situations. It then defines a formal argument as valid just in case the conclusion of the argument is true in all situations in which the premises are true. In the present endeavor, we are not concerned with determining the truth of claims or the overall validity of an argument, but we can look at conditions under which the argument's participants end up committed (positively or negatively) to its claims and conditions under which they agree in their commitment. This provides a type of consensus analog to truth. In this subsection we develop some of the formal properties of the Table 3 commitment principles. As we noted earlier, however, some of these principles must be relaxed when we attempt to model real argumentation, a task that we discuss in the subsection that follows.

The purpose of developing the formal properties of the full set of rules is to see in what ways people can fall short of achieving full consensus in an argument.

Determination of arguments. Consider an argument between two participants. A claim in such an argument is *determined* if each participant either accepts or rejects the claim. Thus, a claim will be *undetermined* only if one or both participants are neutral about it (i.e., neither accept nor reject it). A claim is *mutually determined* if the participants both accept or both reject the claim. By extension, an entire argument structure is determined if each claim in it is determined; similarly, an argument structure is mutually determined if each claim in it is mutually determined. In a mutually determined argument, some claims can be mutually accepted while others are mutually rejected; however, no claim can be accepted by one participant and rejected by the other. All mutually determined claims are determined claims, and all mutually determined arguments are determined arguments, by these definitions. At the end of Argument 1, for example, the argument is mutually determined (and, hence, determined), because as Figure 3 shows, the participants ultimately concur in accepting or rejecting each claim. One question, then, is under what general conditions is an argument necessarily determined or mutually determined.

The liberal principles in Table 3 tend to make informal arguments determined ones, but they do not quite suffice to do so. First, as noted earlier, if a participant preempts the response of his or her opponent, then there is no way to tell whether the opponent accepts or rejects the first claim. (For example, if Ann asserts that there is no good coffee and then, without allowing Bill a chance to reply, goes on to make another claim, we don't interpret the absence of Bill's response as acquiescence to the statement about coffee.) Second, arguments that contain conclusion queries can sometimes be undetermined, even under the full set of principles in Table 3. For example, consider Argument 4, which begins with a claim and a conclusion query:

- (4) Ann: There's no place on campus to get a good cup of coffee.
 Bill: What do you say that for?
 Ann: ...

If Ann simply ends the argument at this point by ignoring Bill's question, should Bill reject her claim? Ann's failure to supply a conclusion that follows from her claim does not seem to be a

reason for rejecting the claim and provides no reason at all for accepting it. Similar problems surround accepted conclusions. Third, whether a participant accepts or rejects a claim depends on how we combine the different responses to that claim. Because a participant can give more than one response to a claim according to the Table 1 rules, it is possible that the participant will accept the claim in a first response and will reject it in a second. A participant is typically credited with the commitment that he or she adopts last; later responses take precedence over earlier ones. The discussion in the previous subsection used this policy implicitly, and it seems the most natural one for everyday arguments. An alternative policy is to average earlier responses with later ones; but if responses can cancel in determining commitment, then participants can end an argument neither accepting nor rejecting a claim.

With these three exceptions, however, the Table 3 principles yield determined arguments. Appendix A [in Rips, 1998] proves that if an argument (a) contains no conclusion queries, (b) contains no preempted responses, and (c) assigns commitment on the basis of the last principle that applies to a claim, then the argument is determined. The commitment principles necessary for determination are noted in Table 3.

Mutual determination of arguments. Under this regime, arguments still need not be *mutually determined*. Exceptions occur when a claim that the participants have come to reject is then accepted by one of them. At the end of the bizarre dialogue in Argument 5, for example, Ann would reject and Bill would accept Ann's first claim:

- (5) Ann: There's no place on campus to get a good cup of coffee.
 Bill: No, you can get good coffee at Garrett.
 Ann: Okay, you're right about that.
 Bill: And you're right, too, that there's no place on campus to get a good cup of coffee.

What seems strange about this case is not that Bill changes his mind about Ann's first claim: Arguments must allow participants to change their position, for otherwise there would be little reason for them to attempt to convince each other. Also, Argument 5 is structurally sound because the Table 1 rules will generate it. Rather, what is odd is that Bill spontaneously accepts a claim that he has just attacked without Ann giving any further support for it. If these situations are eliminated, then the rules in Table 3

imply that arguments are mutually determined. I will label these exceptions by saying that a participant *resurrects* a claim if he or she accepts a claim that the opponent asserted and now rejects. Appendix A [of Rips, 1998] proves that if an argument contains no resurrected claims and also obeys the conditions mentioned in the preceding paragraph, the argument is mutually determined. (A few additional principles from Table 3 are necessary for this result beyond those needed for proof of determination, and these are noted in Table 3.)

The import of the proof can be summarized in the following way: No matter how many times participants disagree within a line of argument, eventually that line must come to an end. The end could come through an acceptor or it could come through silence (a skipped response), but because the skipped response principle equates these options, the line always ends in agreement. The remaining rules propagate the agreement to higher levels of the argument. Thus, within the confines of the rules of Table 1, participants lack a way to perpetuate a disagreement. The ability to “agree to disagree” calls for a metacognitive skill that goes beyond what these rules supply.⁹

A Probabilistic Model of Commitment

The commitment principles in Table 3 make for consensus. But, on intuitive grounds, arguments are not always mutually determined, even when they follow the structure of Table 1. Sometimes participants are left at the end of an argument disagreeing about whether a claim should be accepted or rejected. Sometimes a participant is left in a neutral state about a claim, neither accepting nor rejecting it; so the argument as a whole is not determined, much less mutually determined. Because the goal of this article is to account for people’s comprehension of arguments in a realistic fashion, I will explore the way actual comprehension differs from the Table 3 ideal. This subsection formulates a probabilistic model that adapts Table 3 to allow disagreement and to account for empirical data.

Modeling conservatives, moderates, and liberals. The Table 3 principles as a group make for an extremely liberal policy toward commitment in which participants switch their attitude toward claims whenever any hint about this appears in the debate. Relaxing some of these principles would allow people to adopt a more inertial, conservative policy and would allow initial differences in their positions to remain in force at the end of an argument.

Suppose, in particular, that people adopt one of three possible views about commitment – a conservative, a moderate, or a liberal view – that differ in how many of the commitment principles they accept. Conservatives recognize only the strongest, most obvious forms of evidence for change of commitment; moderates recognize somewhat wider forms of evidence; and liberals the widest, most inferential forms. Thus, conservatives adopt only a minimal number of principles from Table 3, moderates a slightly larger subset, and liberals the full set of principles. Empirical judgments about whether a participant in an argument is committed to some claim will then reflect the proportion of conservatives, moderates, and liberals among the population.

Of the items in Table 3, the assertion and acceptance principles seem unavoidable in any rational exchange, and they must be part of even the most conservative policy. Similarly, conservatives must also recognize that if one participant directly attacks another’s claim, then in some cases the first participant rejects that claim (see rebutting principle [a]). It is not so obvious, however, that people *always* interpret rebutting defeaters as entailing rejection of the defeated claim. It is possible to hold that if a participant accepts a claim and later comes to accept a defeater for it, then the participant could still cling to his or her original commitment. (Evidence for this appears in connection with the second study reported later.) A *restricted* version of rebutting principle (a) allows for this possibility: It specifies that if a participant accepts a rebutting defeater for a claim, then he or she rejects that claim, provided that this participant has not yet taken a stand on the claim. Thus, the conservative position adopts only the assertion and the acceptance principles, along with restricted rebutting (a), and we can refer to these items as *conservative* principles. They have the effect that participants always remain committed to their own claims and never accept others’ claims except by explicitly uttering an acceptor. In the case of Argument 1, this conservative policy means that Ann accepts her own claims 1a, 1c, 1e, and 1g at the end of the argument and rejects Bill’s 1d and 1f, which she attacks directly. Bill would accept his own 1d and 1f, would remain neutral about Ann’s 1a and 1e, would reject her 1c, and would accept Ann’s claim 1g because of the acceptor in the final line.

A moderate policy would allow participants to convince each other by successfully supporting or defeating claims. Accepting a rebutting defeater for a claim, accepting support for a

claim, or undercutting a justification or defeater can all change a participant's commitments, according to this moderate position. The principles that implement such changes are rebutting principle (a) in its unrestricted form, justification principle (a), conclusion principle (a), and undercutting principle (a), and we refer to these as *moderate* principles in what follows. Moderate participants adopt these principles (along with assertion and acceptance). As a result, these participants would judge that Bill rejects 1f in Argument 1, because this follows from unrestricted rebutting (a). For the remaining claims, however the participants' commitments will be the same as the conservative view, described earlier.

The liberal view adds the remaining principles: rebutting (b), justification (b)–(c), conclusion (b), undercutting (b)–(f), and skipped response. We've seen the effect of these principles in Figure 3: Ann and Bill should both accept 1a, 1c, 1e, and 1g and reject 1d and 1f. These *liberal* principles have the status of closure rules that force commitment whenever this is possible, as Appendix A [in Rips, 1998] demonstrates. They lead participants to take the same stand (acceptance or rejection) toward each claim.

Predictions about commitment. The following part of this article reports experiments in which subjects read arguments and decided which of the arguments' participants were committed to each claim. The data from the experiments include the proportion of subjects who said that Participant S accepts Claim C, the proportion who said that S rejects C, and the proportion who said that S is neutral about C. To predict these proportions, the present commitment change model assumes that they reflect a mixture of responses from different groups of subjects. Liberal, moderate, and conservative groups respond according to the principles defined earlier. As in nearly all experiments, however, some subjects probably failed to follow instructions and responded to the questions on a random basis through lack of motivation, lack of attention, or other factors. These inattentive subjects constitute a fourth group. Let p_c represent the proportion of conservatives, p_m the proportion of moderates, and p_l the proportion of liberals in the subject sample. The remaining proportion $(1 - p_c - p_m - p_l)$ are the random responders.

To predict responses to questions about whether an individual speaker is committed to a specific claim, we must determine separately whether liberal, moderate, and conservative subjects will view the speaker as accepting, rejecting, or remaining neutral toward it. As an exam-

ple of how these assumptions operate, consider Ann's claim 1a in Argument 1. As we saw earlier, Ann commits herself to this claim (by the assertion principle) when she utters it, and none of the Table 3 principles change that commitment. Because conservatives, moderates, and liberals all subscribe to the assertion principle, all three groups should view Ann as committed to 1a at the conclusion of the argument. The only subjects who could view Ann as neutral about or as rejecting 1a are the inattentive ones. Because these subjects respond randomly, a third of them should say that Ann accepts 1a, a third that she rejects it, and a third that she is neutral about it. If we write $P(S, C, +)$ for the overall proportion of subjects who say that speaker S accepts claim C, $P(S, C, -)$ for the proportion who say that S rejects C, and $P(S, C, 0)$ for the proportion who say that S is neutral about C, then Equations 1, 2, and 3 give the predictions about Ann's commitment to 1a at the end of the argument:

$$P(\text{Ann}, 1a, +) = p_c + p_m + p_l + .33(1 - p_c - p_m - p_l). \quad (1)$$

$$P(\text{Ann}, 1a, 0) = .33(1 - p_c - p_m - p_l). \quad (2)$$

$$P(\text{Ann}, 1a, -) = .33(1 - p_c - p_m - p_l). \quad (3)$$

The final term in each of these equations (i.e., $.33[1 - p_c - p_m - p_l]$) represents chance responses from the inattentive subjects.

Predictions about Bill's commitments to 1a are more complicated, both because there are more points at which he can change his mind and because they have more long-range effects. Figure 3 shows that Bill is initially neutral about 1a, rejects it as the result of his defeaters, and finally accepts it when he agrees with Ann at the end of the dialogue. Liberal subjects apply all the commitment principles responsible for these changes, so they should see Bill as accepting 1a at the end of the argument. Conservative and moderate subjects, however, fail to apply some of the principles in the chain, leading them to see Bill as neutral toward 1a. None of the principles they adopt cause them to see Bill as changing his initial neutral stance. Using the earlier notation, Equations 4, 5, and 6 give the predictions about Bill's commitment to 1a:

$$P(\text{Bill}, 1a, +) = p_l + .33(1 - p_c - p_m - p_l). \quad (4)$$

$$P(\text{Bill}, 1a, 0) = p_m + p_c + .33(1 - p_c - p_m - p_l). \quad (5)$$

$$P(\text{Bill}, 1a, -) = .33(1 - p_c - p_m - p_l). \quad (6)$$

Table 4: Sample Arguments from Experiment 1

<i>One-Branch Argument</i>	<i>Two-Branch Argument</i>	<i>Three-Branch Argument</i>
1. Bob: The El is the best form of transportation around here.	1. Bob: The El is the best form of transportation around here.	1. Bob: The El is the best form of transportation around here.
2. Fran: Why do you say that?	2. Fran: Why do you say that?	2. Fran: Why do you say that?
3. Bob: It's fast and goes wherever you might have to go.	3. Bob: It's fast and goes wherever you might have to go.	3. Bob: It's fast and goes wherever you might have to go.
4. Fran: The El isn't that fast. It takes a long time to get downtown from Evanston.	4. Fran: It doesn't go to Hyde Park.	4. Fran: [That's true, but] the El stops are in dangerous areas.
5. Bob: It's not that long – an hour at the most.	5. Bob: It goes to Hyde Park; I was just there the other day.	5. Bob: The El stops are relatively safe, if you ask me.
6. Fran: The length of time is a lot longer, since you wait at Howard while switching trains.	6. Fran: [Okay, that's true, but] the El also doesn't go to within walking distance of some places downtown.	6. Fran: [Well, I guess that's true, too, but] it is really inconvenient to change trains at Howard.
7. Bob: Look, I go downtown 4 days a week to work, and I have never had to wait more than five minutes.	7. Bob: Look, I go downtown 4 days a week, and I have never had to walk more than 4 blocks to my destination.	7. Bob: How can you say that – there is usually a train waiting there to board.
8. Fran: I have heard that it can take as long as a half hour at Howard until the next train comes.	8. Fran: [I guess that's true, too, but] the El also does not go to Oak River.	8. Fran: [All right, you've convinced me, but] the Metra is a much better alternative in all areas of concern.
9. Bob: Okay, you're right about that.	9. Bob: Okay, you're right about that.	9. Bob: Okay, you're right about that.

Note. Material in square brackets appeared only in explicit versions of arguments. The remaining material appeared in both explicit and implicit versions.

Predictions for Ann's and Bill's commitment to other lines and at other points in the argument can be derived in a similar way.

Empirical Implications

The commitment change model makes a number of predictions about the way people comprehend arguments. This section reports three studies that test these predictions. The first examines how people decide whether a given participant is committed to a claim, and it allows a direct test of the model against subjects' judgments. The second experiment examines the difference between rebutting and undercutting defeaters, and the third investigates the effect the commitment principles have on subjects' judgments of burden of proof.

Experiment 1: Argument Structure and Commitment

To follow an argument, people need to identify those claims to which each participant is committed. The commitment change model pro-

vides a way to predict the likelihood that they will recognize each claim as one that a participant in an argument accepts, rejects, or is neutral about. These predictions can be assessed by fitting them explicitly to subjects' judgments about a set of stimulus arguments.

In addition to global quantitative predictions, we can use the same arguments to test two of the specific rules in Table 3: rebutting principle (a) and the skipped response rule. To see how this can be done, consider the three sample arguments in Table 4. All three arguments begin with a claim, a justification query, and a justification, and then proceed with a series of rebutting defeaters. The arguments always end with the first speaker uttering an accepter. In the first one-branch argument, each participant tries in turn to rebut the opponent's preceding claim. In the two- and three-branch arguments, however, the second speaker gives up on the initial line of argument and returns to attack one of the earlier points in a new way. This happens twice in the two-branch arguments at Lines 6 and 8, and three times in the three-branch arguments at Lines 4, 6, and 8. In the two-branch dialogue,

for example, Fran decides at Line 6 not to pursue the issue of whether the El goes to Hyde Park and instead attacks Bob's claim about the El going everywhere ("The El also doesn't go to within walking distance of some places downtown"). (For the moment, ignore the material in square brackets; I will return to it later.)

This difference in the structure of the arguments allows a test of the rebutting principle. Notice that Bob's final acceptor in Line 9 has different implications for commitment in the three arguments. In all arguments, what Bob accepts is Fran's rebutting defeater in Line 8, but Line 8 is directed toward different claims in these arguments. Fran's defeater attacks Line 7 in the one-branch arguments, Line 3 in the two-branch arguments, and Line 1 in the three-branch arguments. Thus, if subjects adhere to rebutting principle (a) in its unrestricted version, they should recognize that Bob has to retract these lines, producing a different pattern of judgment about Bob's commitments across the three arguments.

A second aspect of these arguments gives us a direct test of the skipped response principle. When Fran returns to an earlier point in the two- and three-branch arguments, she is passing up the opportunity of responding to Bob's preceding claim. For example, Fran skips a response to Bob's claim (in Line 5 of the two-branch argument) that the El goes to Hyde Park. If subjects follow the skipped response rule, they should therefore see Fran as implicitly conceding Line 5. To check this, we can compare subjects' responses here to those from a similar argument in which Fran explicitly concedes Line 5 before going on. In the *explicit* version of the argument, Fran says "Okay, that's true, but..." before returning to the earlier point. If subjects subscribe to the skipped response principle, they should decide that Fran accepts Bob's previous claim in both the explicit and the *implicit* versions. If they don't subscribe to it, they should decide that Fran is neutral about Bob's claim in the implicit version, but that she accepts the claim in the explicit one. The text in square brackets in Table 4 is the material added to the implicit version to produce the explicit version of the same argument.

Method

In a test of these predictions, subjects read a series of arguments (in the form of dialogues between two characters) and selected those

claims to which each character was committed. The arguments were about everyday issues, such as whether animal rights activists are too outspoken or whether the El is the best form of transportation in Chicago. There were 12 such topics, and the topics were rotated through six different argument types. These varied in both the number of branches in the argument structure (one, two, or three branches) and the presence or absence of skipped responses (points at which a participant fails to respond directly to the preceding claim). Figure 4 shows the three different structures in abbreviated form. (I have omitted intermediate nodes in the diagrams where they are predictable from other information in the trees.) The implicit versions of the two- and three-branch arguments contained skipped responses at the points marked by a \emptyset in the figure. The explicit arguments contained acceptors (e.g., "Okay, you're right but...") in place of the \emptyset s. All arguments, however, contained the same number of claims and the same number of speaking turns.

In this experiment, 48 subjects read explicit versions of the arguments, and 48 read implicit versions. (The explicit/implicit difference affects only the two- and three-branch arguments; there are no skipped responses in the one-branch items. Thus, all subjects saw the same one-branch arguments.) Each subject saw one-, two-, and three-branch arguments on different trials. The topics of these arguments varied for a given subject, but across subjects the topics appeared equally often in the three argument types. Subjects read the arguments in a booklet, containing one argument per page. The argument lines were numbered as in Table 4. At the bottom of each page was a response form that asked subjects to decide for each claim whether, at the end of the argument, the first speaker was "committed to the statement" or was "never committed or is no longer committed" to the statement. Subjects made a similar choice for the second speaker. The instructions stressed that subjects were to base their decisions on what the characters publicly declare in the dialogue and not on any private beliefs that the characters might harbor. The critical arguments appeared in the booklets intermixed with nine filler arguments of a variety of forms. The arguments' order varied so that each argument appeared equally often in each serial position in the booklet across subjects. All subjects were introductory psychology students at Northwestern University.

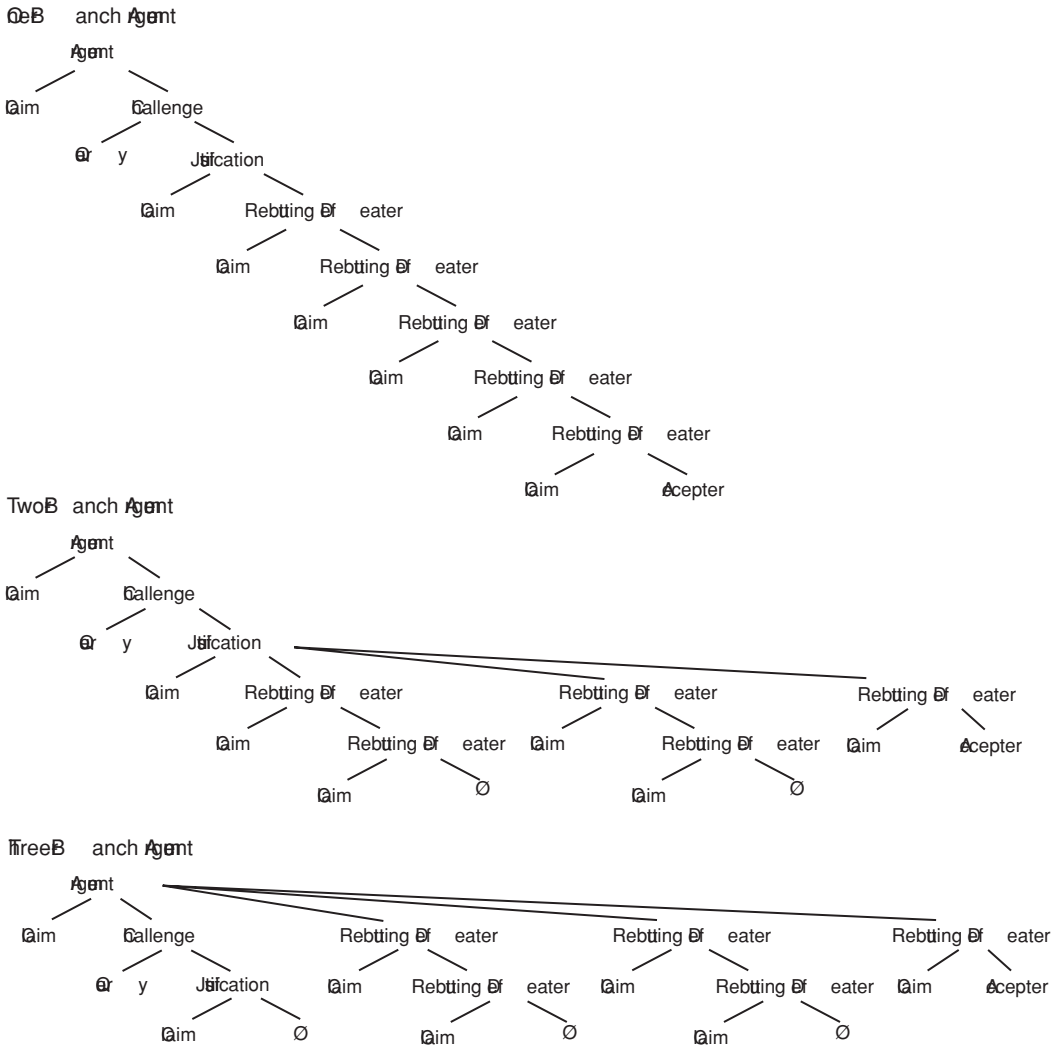

Figure 4. Structure diagrams for the three argument types that served as stimuli in the first and third studies.

Results on the Rebutting and Skipped Response Principles

The data from Experiment 1 consist of the proportion of subjects who judged that each participant was committed to the individual claims. In evaluating these results, let's look first at the qualitative predictions, then at the quantitative ones. As mentioned earlier, rebutting principle (a) in its unrestricted form predicts different patterns of commitment in the three argument structures. The first speaker's acceptor in Line 9 implies that he or she should retract Line 7 in the one-branch arguments, Line 3 in the two-branch arguments, and Line 1 in the three-branch arguments (see Figure 4). Table 5 gives

the data relevant to this prediction. The cells represent the proportion of trials on which subjects judged that the first speaker was committed to Lines 1, 3, and 7 in each of the three argument structures. In terms of the sample arguments in Table 4, for example, the first row of Table 5 corresponds to the proportions of subjects who said that Bob was committed to Line 1 ("The El is the best form of transportation . . ."), Line 3 ("It's fast and goes wherever you might have to go"), and Line 7 ("I have never had to wait more than five minutes . . .") in the one-branch arguments. Similarly, the second row corresponds to the first speaker's commitment to Lines 1, 3, and 7 in the two-branch arguments, and the third row to the first speaker's commitment to Lines 1, 3, and 7

Table 5: Proportion of Subjects Who Judged That Speaker 1 Was “Committed” to Lines 1, 3, and 7 in the Arguments

Argument Structure	Line Number		
	1	3	7
One-branch	.938	.906	.667
Two-branch	.947	.800	.884
Three-branch	.823	.926	.927

Note. $n = 96$. Rows of the table refer to the one-, two-, and three-branch arguments shown in Figure 4.

in the three-branch arguments. (The tabled proportions, of course, include all argument topics, not just the sample.)

The diagonal cells in Table 5 running from the lower left to the upper right represent those lines that the first speaker should retract, according to (unrestricted) rebutting principle (a). Thus, the first speaker should be less committed to these items than to the remaining entries in the table, and the data confirm this prediction. The overall proportion of committed responses for these to-be-retracted lines is .763; for the remaining lines .921. The interaction between argument structure and line is significant by a repeated-measures analysis for categorical data, $\chi^2(4, N = 94) = 33.04, p < .001$ (Agresti, 1990, chap. 11; Koch, Landis, Freeman, Freeman, & Lehnen, 1977). The effect appears larger for the one-branch arguments than for the two- or three-branch arguments, probably because the to-be-retracted line, its rebutting defeater, and the acceptor appear together in the one-branch items (in Lines 7, 8, and 9). In the other structures, the retracted line is separated from the defeater and its acceptor. Notice that the proportion of committed responses, for the retracted lines is still fairly high. According to the model, this is due to the presence of conservative subjects (see the later discussion of model fitting).

Although the results in Table 5 lend support to rebutting principle (a), other data from this experiment tend to disconfirm the skipped response principle. The difference between the implicit and the explicit arguments indicates that subjects do not process skipped responses in the same way as accepters, contrary to the formal models by Hamblin (1970), Rescher (1977), Walton and Krabbe (1995), and others mentioned earlier. Consider first the implicit argu-

ments – the ones containing skipped responses. The first speaker’s Lines 5 and 7 in the implicit two-branch arguments and Lines 3, 5, and 7 in the implicit three-branch arguments all appear just before a skipped response by the second speaker (see Table 4). If a skipped response is equivalent to an accepter, then subjects should judge that the second speaker is committed to these five lines. However, the overall proportion of committed responses for Speaker 2 is only .200 for these items. The explicit arguments (accepters replace skipped responses) produced a very different outcome. In these arguments, the same lines appear just before the accepter (“That’s true, but...”), and the proportion of committed responses for these items jumps to .680.¹⁰ Thus, subjects clearly do not see these arguments, as equivalent.

Model fitting. Equations similar to those in Equations 1 through 6 can provide quantitative predictions for these data. For this purpose, assume that subjects respond “committed” if they think that the participant in the argument accepted the claim and respond “uncommitted or never committed” if they think the participant was neutral about or rejected the claim. Figures 5 and 6 plot the proportion of these committed responses separately for each structure and participant. Figure 5 contains the data for the one-branch arguments and for implicit versions of the two- and three-branch arguments. (The results for one-branch arguments combine the responses from the two groups of subjects.) Figure 6 plots the data for the explicit versions of the two- and three-branch arguments.

A nonlinear least-squares procedure fit the model to all 70 points in Figures 5 and 6, optimizing the values of the three parameters p_c , p_m , and p_l . The resulting estimates showed a large proportion of conservative responses ($p_c = .49$), a smaller proportion of moderate responses ($p_m = .15$), and a tiny proportion of liberal responses ($p_l = .03$). The latter value suggests that the model could achieve nearly equivalent accuracy on the assumption that there were *no* liberal responders. To test this assumption, one can compare the fits of the three-parameter model to a simpler two-parameter version in which p_l is set to 0. A likelihood ratio test (Bates & Watts, 1988) found no significant difference in the fit of the two models, $F(1, 67) < 1$. Further reduction in the number of parameters, however, did result in lack of fit. If p_m is also set to 0, the likelihood ratio test is $F(1, 68) = 19.29, p < .001$. We can therefore adopt the two-parameter

Figure 5. Observed responses (points) and predicted responses (lines) from implicit arguments in Experiment 1. The y axis shows proportion of trials in which subjects identified the speakers as committed to each claim. The top two panels provide data from the one-branch arguments, the middle two panels from the two-branch arguments, and the bottom two panels from the three-branch arguments. Panels 1, 3, and 5 show commitments of first speaker (circles); Panels 2, 4, and 6 show commitments of second speaker (squares).

model in which $p_c = .49$ and $p_m = .17$. These estimates accord with the qualitative findings in that there is little evidence for the skipped response principle (a liberal rule) but significant effects for unrestricted rebutting (a moderate rule). R^2 for this model is .89 and root mean square deviation (RMSD) is .106.

The predictions from this two-parameter model appear as solid lines in Figures 5 and 6. Two main types of deviation appear in the figures. First, subjects' responses tend to be more

extreme (closer to 0 or 1) than predicted for the first two claims. The prominence of these two claims at the beginning of the argument may help subjects keep their status straight; commitments to later claims may be cloudier for subjects because of the rapid changes that take place in the debate. Second, Figure 6 reveals that although the model generally predicts the correct shape of the distributions for the explicit arguments, it overpredicts the committed responses for the second speaker and

Figure 6. Observed responses (points) and predicted responses (lines) from explicit arguments in Experiment 1. The y axis shows proportion of trials subjects identified the speakers as committed to each claim. The top two panels provide data from the two-branch arguments, and the bottom two panels from the three-branch arguments. Panels 1 and 3 show commitments of first speaker (circles); Panels 2 and 4 show commitments of second speaker (squares).

underpredicts those of the first speaker. One possible reason for this is that the second speaker tends to concede points explicitly as soon as they are attacked in these arguments, whereas the first speaker makes a concession only in the final line. This may create a global impression – not captured by the model – that the second speaker is uncertain about, and therefore less committed to, the topic of the argument, relative to the first speaker. In line with this hypothesis, lack of fit is somewhat greater for the three-branch arguments (where the second speaker makes three concessions) than in the two-branch arguments (where the second speaker makes two concessions).

Individual differences. The model assumes that (apart from the inattentive subjects) individuals adopt a conservative or a moderate stance and respond to each argument on this basis. Thus, it should be possible to classify subjects as conservatives or moderates from the data. For these

arguments, conservatives and moderates differ in their responses when a character in the dialogue accepts a defeater for one of his or her own earlier claims and is therefore faced with retracting that claim. Moderates believe that the character retracts the claim because they subscribe to the unrestricted rebutting principle (a), whereas conservatives believe that the character remains committed to the claim because they subscribe to the restricted rebutting principle. In the explicit arguments, this situation occurs in seven places (e.g., for Speaker 1 with respect to Line 7 in the one-branch arguments, for Speaker 2 with respect to Line 4 in the two-branch arguments, etc.); thus, these are the places to look for individual differences.

It is possible to check on these individual differences by applying cluster analysis to the subjects' responses to these seven critical lines. The clusters may be blurred, both because of the presence of inattentive subjects and because

errors can occasionally affect the responses of even a card-carrying conservative or moderate; nevertheless, the analysis should recover clusters corresponding roughly to the conservative and the moderate groups if the commitment change model is correct. For these purposes, the analysis used the 48 subjects in the explicit condition and computed a measure of similarity between each pair of subjects. (The implicit condition contains a smaller number of items that distinguish conservatives and moderates, and for this reason the analysis omitted the subjects in that condition.) The similarity measure gave each pair of subjects a score of 1 if they agreed in their responses to all seven critical items, a score of 6/7 if they agreed on six, a score of 5/7 if they agreed on five, . . . , and a score of 0 if they agreed on none. This set of scores then provided input to a clustering routine, Johnson's (1967) hierarchical clustering scheme (HCS). HCS has the advantage of producing hierarchical clusters based on non-metric assumptions. The present analysis used HCS's maximum or complete linkage option, which generally yields more compact and interpretable clusters than the program's other methods. The output revealed two main clusters of subjects, differing as expected in their tendency to see the arguments' characters as committed or not committed to their own earlier claims. The larger cluster contained 34 subjects who usually judged the characters as committed to the seven critical lines. The mean number of committed responses for this group was 5.0 of 7. The smaller cluster contained the remaining 14 subjects, with an average of only 2.4 committed responses per subject ($W^* = 4.34$, $p < .0001$, by a Wilcoxon two-sample test). This division into more conservative and more moderate groups is not a necessary result of the scoring or clustering procedures because they could equally well pick out clusters based on subjects' responses to the first or second character, to the one-branch versus two- or three-branch arguments, or to many other factors. Thus, the analysis lends further support to the present framework.

Experiment 2: Rebutting versus Undercutting Defeaters

The arguments in Table 4 all contained rebutting defeaters, but the theory also allows a participant to use undercutting defeaters to weaken an opponent's case. As the commitment principles make clear, the difference between these two kinds of defeaters has implications for which

claims the participant accepts and rejects. For example, consider the two dialogues in Argument 6 and 7:

- (6) a. Bob: Giordano's has the best pizza in Chicago.
 b. Fran: Why do you say that?
 c. Bob: It has incredible stuffed pizza.
 d. Fran: The stuffed pizza at Giordano's isn't all that great – the stuffed pizza is too greasy and that makes the crust soggy.
 e. Bob: Okay, you're right about that.
- (7) a. Bob: Giordano's has the best pizza in Chicago.
 b. Fran: Why do you say that?
 c. Bob: It has incredible stuffed pizza.
 d. Fran: The quality of their stuffed pizza doesn't mean that they have the all around best pizza – their thin crust isn't good at all.
 e. Bob: Okay, you're right about that.

These arguments are identical, except for their fourth line. On one hand, Fran's rebutting defeater in 6d implies that she rejects Bob's justification in the preceding line. On the other hand, her undercutting defeater in 7d does not imply that she rejects 7c: The undercutting defeater attacks the relation between 7c and 7a, not the acceptability of 7c itself. We would therefore predict that subjects would be more likely to say that Fran rejects 6c than that she rejects 7c. More interesting, the same is true of Bob's commitments. Because he accepts the rebutting defeater for 6c, he should reject that claim, according to unrestricted rebutting principle (a). However, accepting an undercutting defeater does not oblige him to retract 7c.

This distinction between defeaters isn't always available in earlier models of argumentation. For example, Rescher's (1977) theory assumes that

moves of the form X/Y [i.e., X normally obtains when Y does] are always "correct" in the setting of a disputation; that the disputants cannot make . . . erroneous claims regarding purely evidential relationships. We thus exclude the prospect of incorrect contentions about the merely probative issue of what constitutes evidence for what. Accordingly, the disputing parties can avoid addressing themselves to the proprieties of the reasoning and need only attend to issues of substance in the development of the argumentation. (p. 8)

Table 6: Observed and Predicted Proportion of Trials on Which Subjects Judged That Speaker 1 and Speaker 2 Accepted, Rejected, or Were Neutral about the Argument's Claims

Speaker	Argument Line								
	Line 1			Line 3			Line 4

Pred.	.064	.587	.349	.349	.587	.064	.870	.066	.064

Note. Acc. = accept; Neut. = neutral; Obs. = observed; Pred. = predicted. See Arguments 6 and 7 in the text for arguments with rebutting defeaters and undercutting defeaters.

It is therefore worth investigating whether people recognize the distinction between an attack on earlier claims and an attack on reasoning.

Method

As a test of whether people are sensitive to this difference, subjects read a set of arguments and decided for each claim, whether the participants in the argument: (a) accepted the claim, (b) rejected the claim, or (c) neither accepted nor rejected it. Subjects made separate judgments for each character, as in the preceding experiment. We used a three choice response, rather than the committed/not committed format from the earlier study, because the predicted difference between rebutting and undercutting defeaters depends partly on whether participants reject a claim, as opposed to being merely neutral about it. With the exception of these response options, however, the procedure was like that of the first study. The stimulus items were similar to Arguments 6 and 7 in having a justification followed by either a rebutting or an undercutting defeater, followed by an acceptor. We created pairs of arguments, such as Arguments 6 and 7, for each of the 12 topics we used in the earlier study. Each subject received only one argument from each pair, but an equal number of the two basic argument types (arguments with rebutting defeaters and arguments

with undercutting defeaters). Thirty-two introductory psychology students participated in the study.

Results on Types of Defeaters

Table 6 shows the response distributions from these subjects for arguments with rebutting defeaters (at the top) and arguments with undercutting defeaters (bottom). The distributions for the first and fourth lines of the arguments – corresponding to Lines 6a and 7a and 6d and 7d – are fairly similar across the two argument types. The distribution for the third line, however, changes radically. Subjects are less apt to say that the characters accept Line 3 when it is followed by a rebutting defeater than by an undercutting defeater. (Compare the accept responses for Line 3 in the arguments with rebutting defeaters to those for undercutting defeaters.) This result is what one would expect from the difference between the commitment rules for the two defeater types. This difference produced a significant interaction between line of the argument (first, third, or fourth) and argument type (rebutting vs. undercutting), $\chi^2(4, N = 32) = 65.71, p < .001$ (Agresti, 1990, chap, 11; Koch et al., 1977).

Many more subjects said that the second speaker rejected Line 3 than that the first speaker rejected Line 3 in the rebutting arguments (see

Table 6). For example, about half the subjects said that Bob rejects his own claim 6c by the end of the argument, whereas nearly all agreed that Fran rejects 6c. This is consistent with our treatment of rebutting principle (a). Conservatives adhere to the restricted version of this principle, and they thus apply rebutting (a) to a claim only if a speaker hasn't previously taken a positive or negative stand on it. Once the speaker is committed (i.e., nonneutral), however, that position locks in for conservatives. In Argument 6, for example, Bob commits himself to the position that Giordano's has incredible stuffed pizza by asserting it in 6c, and conservatives believe this is the position he maintains. However, Fran's initial response to it in 6d is an attack, which conservatives view as rejecting 6c. The presence of conservative responses therefore accounts for the asymmetry in the data.

Model fitting. The commitment change model produces a good fit to the proportions of accepted and of rejected responses (a total of 24 data points). (The neutral responses add no further information because the proportion of neutral + accepted + rejected responses equals 1 for each line and speaker.) R^2 for these items is .958 and *RMSD* = .069. The predicted values from the model appear under the observed values in Table 6 (predictions for neutral responses were calculated by subtraction). Parameter values for the proportion of conservative and moderate subjects are roughly similar to those of the earlier study. Here, $p_c = .34$ and $p_m = .18$, compared with .49 and .17 in the preceding experiment. However, this study produced a larger proportion of liberal subjects, $p_l = .28$, compared with a near-zero value earlier. The model needs a larger proportion of liberals because many subjects view the speakers as rejecting the initial claim in the arguments with undercutting defeaters. Undercutting principle (c) is responsible for this rejection, a principle that is currently assumed to be a liberal one. Two other liberal principles help account for aspects of the data: Undercutting principle (b) for the proportion of accepted responses by Speaker 2 in undercutting arguments, and justification principle (b) for rejected responses by both speakers in rebutting arguments. It is possible, of course, that these principles should be reclassified as moderate, but it is also possible that other features of the experiment encouraged liberal responding. For example, the relatively short arguments may have played a role: Liberals have to compute many more changes in commitment than conservatives. Longer arguments, such as those in the pre-

ceding study, may therefore discourage liberal responding.

In sum, the results of this study suggest that people discern the difference between an attack on an earlier assertion and an attack on its support. The ability to capture this difference allows the present system to describe a wider range of arguments than can models like Rescher's (1977). However, the fact that people can recognize the distinction doesn't imply that people are equally able to produce such attacks in their own arguments. Claims are more salient than interclaim relations, and it may therefore be easier to formulate objections to claims (i.e., rebutting defeaters) than objections to the claims' support (undercutting defeaters). Evidence along these lines comes from a recent study by Shaw (1996), who asked subjects to provide objections to arguments from newspapers, magazines, and textbooks. The subjects' objections contained a larger proportion of rebutting defeaters than undercutting defeaters across all arguments.

Experiment 3: Burden of Proof

In legal terminology, *burden of proof* has technical meanings having to do with which party is obliged to produce evidence relevant to some decision (Wigmore, 1935). But there is also a more informal sense, discussed by Whately (1855), in which the person with the burden of proof is the one who has most to do to support his or her position (see Gaskins, 1992, for a discussion). Burden of proof determines the default winner of the argument if no further support is offered. It's likely that many factors influence people's perception of burden of proof, including, of course, how sensible the individual claims are. If a participant makes an outlandish claim, then that will increase the person's burden of proof, all else being equal. In the present context, however, we are interested in how argument structure and commitment contribute to burden of proof, in a way that goes beyond the plausibility of the independent claims.

We have seen that the commitment principles of Table 3 determine which claims become mutually accepted during the course of an argument, and mutual acceptance should predict systematic shifts in perceived burden of proof. If a claim becomes mutually accepted, then the participant who offered it need no longer defend it. Because there are fewer claims that the participant must now establish, his or her burden will be lighter. By contrast, a claim that is mutually rejected or *open* (i.e., not mutually determined)

can increase a participant's burden. The participant must find new ways to support claims that are currently under contention and new ways to shore up previous points when currently supporting claims fail. The theory should therefore predict that the smaller the number of mutually accepted claims and the larger the number of mutually rejected or open claims, the greater the burden of proof.

To check this prediction, consider the arguments with rebutting defeaters from the first study (see Figure 4 and Table 4). In the explicit versions of the arguments, the second speaker accepts no claims in the one-branch arguments, accepts two claims in the two-branch arguments, and accepts three claims in the three-branch arguments. The first speaker accepts one claim in each of the three argument types. The second speaker's concessions mean that the conceded claim is mutually accepted, and this should decrease the first speaker's burden of proof. Subjects should therefore perceive the first speaker's burden decreasing from one-branch to two-branch to three-branch structures. In the implicit version of the arguments, the second speaker never accepts a claim outright; this speaker's concessions (if any) occur only through skipped responses. The second speaker again accepts one claim in each argument type in Line 9. Thus, if subjects ignore the skipped response principle (as seems likely, based on Experiment 1), burden of proof for the two speakers should be approximately constant across the three implicit argument types. If subjects adopt the skipped response principle, the results for implicit arguments should be identical to those for explicit ones. Other aspects of the argument do not alter the balance of accepted to nonaccepted claims across the different structures and, hence, do not affect these predictions.

Method

During the experiment, subjects decided which of the two characters in the dialogues had the greater burden of proof and rated their confidence in their decision. The stimulus arguments were the same as in the first experiment, as was the general procedure. The main change was that, after reading an argument, the subjects were to decide "which character has the most to do in order to prove that he or she is right." The words "had most to do" appeared as a proxy for "burden of proof" to avoid confusing subjects about the legal connotations of the latter

Table 7: Mean Signed Confidence That the First Speaker Has Burden of Proof (–10 to 10 Scale)

Version	Argument Structure		
	One-Branch	Two-Branch	Three-Branch
Explicit	4.31	1.39	0.35
Implicit	2.31	2.27	1.43

Note. $n = 48$.

term. To record their answer, subjects checked one of two boxes, each labeled with the name of one of the two speakers (e.g., *Fran* and *Bob* in the case of the Table 4 arguments). They then rated their confidence on a 0-to-10-point scale, where 0 was marked *not at all confident* and 10 was marked *completely confident*. Forty-eight subjects read implicit arguments and an equal number read explicit arguments. Half the subjects in each group saw the check boxes listed with the first speaker first; the remaining subjects saw the second speaker listed first.

Results

To analyze these results, we calculated signed confidence ratings by multiplying each rating by +1 if the subject said that Speaker 1 had greater burden of proof and by –1 if the subject said that Speaker 2 had the greater burden. Thus, numbers near +10 indicate great conviction that Speaker 1 has the burden, and numbers near –10 indicate great conviction that Speaker 2 has the burden. Table 7 displays the mean ratings, according to the number of branches in the argument and whether the argument was implicit or explicit. (On 6 of 288 trials, subjects failed to mark their choice of speaker or failed to rate their confidence. These data were replaced by the mean of the relevant condition for purposes of analysis.)

Note first the predicted decrease in Speaker 1's burden for explicit arguments, a difference of 3.96 scale points between the one- and the three-branch structures. The implicit arguments show a smaller decrease, 0.88 points. The overall difference is significant by an analysis of variance, $F(2, 188) = 3.26, p < .05$. The interaction with argument version (explicit vs. implicit) was not significant, $F(2, 188) = 1.63, p > .10$. However, when examined separately, the decrease for the explicit version is significant, $F(2, 94) = 4.28, p < .05$, whereas the decrease for the implicit version is not, $F(2, 94) < 1$.¹¹

Table 7 also shows a second important fact about burden of proof: Subjects tend to see the first speaker as saddled with the burden in all six conditions. If subjects believed that the first and second speaker had the same burden across trials, the grand mean in Table 7 would be 0. In fact, the mean of the signed ratings is 2.05, significantly greater than 0, $t(95) = 4.36$, $p < .001$. This goes along with the results of several earlier experiments (Bailenson & Rips, 1996), using arguments of a variety of types. In these studies, the person making the first claim typically had greater burden of proof. We have called this effect *antiprimacy* because the first claim places its speaker at a disadvantage. In some of Bailenson and Rips's experiments, the first speaker is not the speaker making the first claim: The argument could begin with a question or with material that is irrelevant to the upcoming debate. What matters in these arguments is not the first speaker, but the first claimant, presumably because the first claim takes a stand on an issue that sets the agenda for the rest of the discussion.¹²

Implications and Extensions

The goals of the present article have been to construct a theory of two-person arguments and to use the model to predict some of these arguments' empirical properties. The model consists of two layers: a structural layer that defines the conversational moves that take place in arguments and a commitment layer that determines which claims participants in the argument accept or reject. The structural layer specifies the arrangement of claims, challenges, justifications, and defeaters, as well as their interrelations in the debate. The main idea behind this layer is that arguments are built recursively from claim-response pairs: Each new assertion by a participant implies the possibility of a critical response by an opponent. Because the response can itself be a claim, this pattern can generate complex embedded structures, such as the ones in Figures 2 and 4.

The commitment layer is defined over the argument's structure. Rules of commitment determine whether a participant publicly accepts, rejects, or is neutral about a claim, based on the participant's conversational moves. Participants can accept a claim directly by asserting it or by explicitly agreeing to it (e.g., by saying "That's right"), and they can accept a claim indirectly by agreeing to one of its justifications. Participants can also reject a claim directly by issu-

ing a rebutting defeater or indirectly by agreeing to an opponent's defeater. The aim has been to trace participants' public commitments, and the theory focuses on how an audience perceives what transpires during an argument. However, the commitment principles also define the tools participants can use to convey commitments they hold privately, as discussed later.

The experimental studies suggest that people perceive commitment as changing rather gradually in the course of a debate. Although people believe that commitments can change, there are limits to the changes they countenance. In the context of our stimulus arguments, they did not view failing to respond to a claim as a concession. Similarly, they did not view rejecting a rebuttal to a claim as equivalent to accepting it. This attitude toward commitment change allows people to see some arguments as necessarily incomplete, in the sense that some of an argument's claims remain essentially unresolved at the end of the discussion. The experimental results also show that people discriminate between attacks on claims and attacks on the justification or support relation that holds between claims. The principles, of commitment change that receive empirical support in Experiment 1 or Experiment 2 are noted in Table 3. Of the remaining principles, Experiment 1 tested skipped response directly and rebutting (b) indirectly, but obtained no support for them. The rest of the principles have yet to be tested.

The results also suggest that the structural and commitment layers contribute to the audience's perception of burden of proof. People believe that the participant who makes the first substantive claim acquires the burden of proof, but that this burden can be reduced or eliminated if the opponent concedes other claims. In general, the findings suggest that the model proposed here can provide the beginnings of a systematic, theoretical account of argumentative reasoning. In this final section, I consider some additional questions about the nature of argumentation by exploring issues surrounding argument production and by comparing the model to a connectionist alternative.

Argument Generation

The present model is a theory of how people comprehend arguments that they read or hear, but we assume that some of its tenets also apply to active participants. Participants in an argument must also have information about its structure in order to contribute in appropriate ways.

They need to understand the sequence of conversational moves that precedes their own next move, and they need to recognize which earlier claims have been accepted or rejected by their opponents. Contributing to an argument, however, also involves knowledge that goes beyond what our theory supplies. It's useful to consider the nature of this additional knowledge, because doing so clarifies some limits on the theory and some possibilities for extending it.

The commitments discussed here are ones the participants trade publicly in the debate; however, individual participants also have access to their own private stock of beliefs and opinions (those that Walton & Krabbe, 1995, call *dark-side commitments*). It is obvious that participants don't volunteer claims at random, but instead use their prior beliefs to determine their best next response. Their purpose may be to convince an opponent of the correctness of one of these prior beliefs, and they may draw on other prior beliefs to supply it with justifications. Moreover, participants may have hypotheses about their opponent's unstated beliefs and can select their conversational moves to capitalize on these opinions. Thus, beliefs provide constraints on what participants assert during an argument and on what they are likely to accept. These underlying beliefs may vary, even within the context of persuasive dialogues. Argumentation can convey new information or help formulate a new position, not just inveigle concessions from an opponent. For that reason, a realistic theory of argument production has to allow for adoption of new beliefs and for use of these beliefs in later parts of the debate.

Producing arguments also means devising strategies for fulfilling the aims of the argument. In part, this entails following the claim-response pairings that the argument structure dictates. Challenges, for example, should be followed by justifications; defeaters by challenges or counter-defeaters. These are rules of argument "etiquette" or good conduct (Cavalli-Sforza et al., 1992; van Eemeren et al., 1996, chap. 11). There must be additional strategies, however, for furthering the participants' goals. This is the traditional domain of rhetoric, the study of methods for tailoring arguments to specific audiences to improve their effectiveness. Rhetorical strategies can produce "an organized chain of arguments about *this* subject for *this* audience that will bridge the gap between what you believed when you came and what I want you to believe when you depart" (Booth, 1967, p. 10 [italics in original]). Participants' choice of a rhetorical

strategy will depend in part on their representations of their opponents' beliefs because it is to the participants' advantage to show that the opinion they are advocating follows from the opponents' own point of view (Perelman, 1982).

Research on persuasion in social psychology is relevant to the study of strategy choice because this research has examined factors that make for more convincing messages (see McGuire, 1985, for a review). Most of these experiments, however, have concentrated on the effects of one-sided arguments that the experimenter presents, rather than two-sided arguments in which the subjects produce their own line of reasoning. This focus on preformulated messages is probably due to the methodological difficulties associated with studying interactive contexts, but the result is that we currently have little empirical knowledge about how people choose to argue when they are confronted with an opponent who can parry their remarks. The hope is that the present model can contribute to research on persuasion by defining a more interactive framework within which we can formulate specific hypotheses about argument strategies.

Comparison with Connectionist Approaches

I noted earlier that models of informal reasoning have usually focused either on the support relation that unites individual premises and conclusions or on participants' moves in formalized argument games. The first type of model is difficult to extend to contexts that include challenges and criticisms; the second type tends to ignore the embedded structure that informal arguments often have. To capture both the structural and conversational aspects, some recent theories have studied naturally occurring arguments, with a view both to the justification and criticism in which participants engage (e.g., Muntigl & Turnbull, 1998; van Eemeren et al., 1993; Resnick et al., 1993). The present theory is similar to those in this third class, though it proposes structural rules (Table 1) and commitment rules (Table 3) that are more explicit than those usually appearing in these frameworks.

The current stock of theories, however, do not exhaust the potentially valuable approaches in this area. It might be possible, for example, to capture some of the back and forth of argumentation in another manner by modeling commitment as excitation or inhibition within a connectionist framework. The purpose of exploring this framework here is not so much to set it up as

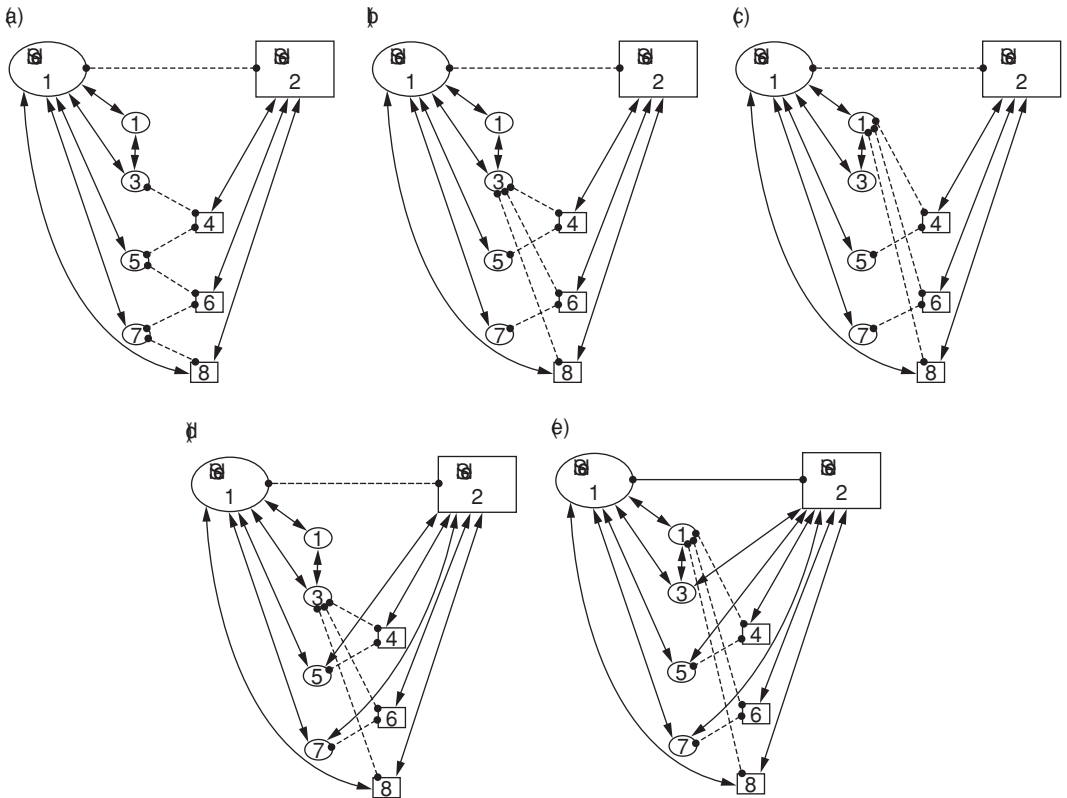

Figure 7. Connectionist networks corresponding to (a) one-branch arguments, (b) implicit two-branch arguments, (c) implicit three-branch arguments, (d) explicit two-branch arguments, and (e) explicit three-branch arguments. Small numbered units represent individual claims; large units represent the two sides or participants in the debate. Solid lines are excitatory connections; dashed lines are inhibitory connections.

a rival to the rule-based theory, but to see which aspects of argumentation are best suited to each approach.

Consider a (local) connectionist network for the arguments in Table 4 in which each claim appears as an individual node or unit. One way of hooking up networks for these arguments appears in Figure 7, where the networks on the top represent one-, two-, and three-branch arguments in their implicit versions, and the networks on the bottom represent the explicit versions of the two- and three-branch items. For clarity, the figure shows the claims of the first speaker as rounded nodes and the claims of the second speaker as square nodes, although the two types of nodes are treated identically in the model. If one claim provides support for another, an excitatory link (solid line) connects the unit representing the first claim to the unit representing the second. Likewise, if one claim provides a rebutting defeater for another, an inhibitory link

(dashed line) connects the first to the second. I assume for the time being that excitation or inhibition can spread in either direction across a link.¹³

One can also associate with each claim-unit a level of activation that varies from some maximum value (+1) when the claim has greatest support to some minimum value (−1) when its negation has greatest support. Activation of a unit can thus represent the degree of commitment that resides in each claim, with positive numbers being degrees of acceptance and negative numbers degrees of rejection. Of course, the commitment that one participant has invested in a claim will generally differ from the commitment of another participant, as shown earlier. In order to represent this difference, one can include units that correspond to each participant or “side” of the debate. These side-units (larger nodes at the top of the diagrams in Figure 7) have excitatory connections to the claims that

the participant asserts or agrees to, and the side units connect to each other through inhibitory links. Separate runs of the model can then obtain the commitments of each participant by activating that participant's side (i.e., clamping the side-unit at 1) and seeing how activation spreads over the claims. Activation of all units (claims and sides) is adjusted at each cycle as a function of the net level of excitation and inhibition flowing into them, as in Thagard's (1989) ECHO model of explanatory coherence or other models of hypothesis competition (see Rumelhart, Hinton, & McClelland, 1986).

How well does the model of Figure 7 do in predicting the commitment data of our first study? Simulation of the model obviously depends on the weights of the excitatory and inhibitory connections. For simplicity, the model assumes that all excitatory connections have the same weight, w^+ , and all inhibitory connections have the same weight, w^- . A nonlinear least-squares procedure was used to estimate these parameters, as in the earlier studies. Details of the model-fitting appear in Appendix B [in Rips, 1998]. R^2 over all 70 data points is .85 and $\text{RMSD} = .126$, slightly inferior to the comparable figures for the earlier model (.89 and .105, respectively). The obtained value for the excitation parameter w^+ is .15 and the value for the inhibition parameter w^- is $-.10$.

The predictions show that the connectionist model does quite well in fitting the middle lines of the arguments, but exhibits some deviations for the last claim (Line 8), especially for Speaker 1. For this line, the predicted commitment score is markedly less than the obtained proportions. Speaker 1 concedes this claim outright in Line 9; so this speaker's commitment should be high, as subjects affirmed in our first study (see Figures 5 and 6). However, connections from other units keep activation relatively low at Line 8 and prohibit the model from accurately accounting for the data.

There may, of course, be other network implementations whose predictions improve on the version considered here.¹⁴ For example, it is likely one could get better fits by individually weighting the links in Figure 7, by adding new links, or by increasing the number of parameters. In general, the network approach has the advantage of simplicity in treating commitment in a unified way. However, the commitment-rule approach has the advantage of greater explicitness in explaining how commitment is determined. It also has the advantage of distinguish-

ing in a straightforward way between rebutting defeaters and undercutting defeaters, which are more difficult to represent in a connectionist network. It may prove useful in future research to build a theory that merges these advantages: It seems feasible, for example, to construct a two-stage model in which commitment rules decide initially where the excitatory and inhibitory links should appear; in the second stage, activation could then determine the degree or strength of commitment. Such a model could resemble older network theories (e.g., Anderson, 1983) or more recent hybrid systems (e.g., Sun, 1995).

Conclusion

In traditional studies of reasoning in psychology, subjects usually inspect a group of premises, such as *All grizzlies are mammals* and *Fred is a grizzly*, and then generate a conclusion that is supposed to follow from them (or evaluate a conclusion that the experimenter proposes). Investigators have followed this procedure, both in studying deductively valid arguments and inductively strong ones (e.g., Osherson, Smith, Wilkie, Lopez, & Shafir, 1990; Rips, 1975). This focus on premise-conclusion arguments is an important analytic tool that isolates the way in which one set of statements transmits support to another. Human reasoning, however, takes place in more extended contexts than one-step (and one-sided) arguments, as many critics have pointed out. An individual reasoning step can sometimes be construed as a transition from premises to a conclusion, but in the larger context the premises are rarely held constant. Nearly any claim that's introduced into the discussion is subject to potential justification. Moreover, extended reasoning often occurs between multiple agents. Agents can demand further support for another's assertions or can criticize those assertions. Multiple agents are obvious in external debates and discussions, such as our stimulus examples; but we can also think of many internal deliberations as including multiple mental agents advocating rival positions.

Although investigators have recognized the pervasiveness of multiple-step, multiple-sided reasoning, there have been relatively few psychological proposals about its internal structure. The present suggestion is that a more adequate theory of reasoning should consider individual claims in relation to a larger, varied set of potential responses. Claims can link to others, not just

through inductive and deductive support, but also through adversarial challenges and critiques. These critiques in turn create the possibility of further bondings and prompt extended webs of inferences. The model proposed here exhibits some of these potential relations.

Notes

- 1 Intermediate cases include formal debates and adversary arguments (Flowers, McGuire, & Birnbaum, 1982) in which the participants don't attempt to convince their opponents of the truth of their position. Nevertheless, the participants in such encounters do appeal to reasons in supporting their own positions and in attacking those of their adversary. These debates appear to be addressed to an actual or to an ideal audience that is evaluating the rival claims. As such, they have much the same structure as the argumentation considered here.
- 2 As mentioned earlier, it is possible to make more fine-grained distinctions among types of justifications, separating explanations, evidence, and clarifications (see Brem & Rips, 1995). Similarly, one could divide rebutting defeaters into those that are direct contradictions of previous statements (e.g., "The coffee in Garrett is great." "No, it's not.") from more guarded attacks ("Do you go there much?"). One might also distinguish rebutting defeaters based on fact versus opinion. These distinctions are important ones to pursue in further work on argumentation especially because they may affect the strength of a participant's case (see Farley & Freeman, 1995). The present theory concentrates, however, on the large-scale structure.
- 3 Table 1 distinguishes two types of responses, Responses and Subresponses, for technical reasons: Because undercutting defeaters can only occur in the context of justifications, conclusions, or (superordinate) defeaters, the rules must separate these contexts from others. Subresponses represent the context where undercutting defeaters can occur. Thus, after the topmost level of the argument, the structure is fully recursive, allowing subarguments to be embedded in subresponses *ad infinitum*. The left-to-right ordering of constituents in the rules are intended to correspond to the chronological sequence of the dialogue. This means that the rules allow a speaker to return to an earlier point in the current branch of the tree in order to start a new branch, but they prohibit a speaker from returning to an earlier branch. It is unclear whether this restriction is violated in arguments, but to accommodate such backward moves, the rules could be revised to include a separate index for the order of the contribution.
- 4 One location for an online copy of the civil proceedings is <http://cnn.com/US/OJ/simpson.civil.trial/>.
- 5 Other categories from Table 1 depend more heavily on context and are more difficult to code. For example, whether a sentence such as "I've tried all the coffee shops on campus" is a justification, as in Argument 1, or a simple statement of fact depends on what precedes it in the discourse. Some of this discourse context was not available in the excerpts because of the way the samples were selected. This partly motivated the focus on explicit defeaters and justification queries.
- 6 In this article, I use *participants* or *speakers* to refer to the characters in the stimulus dialogue and *subjects* to refer to people taking part in the experiment.
- 7 The conservative approach to commitment is related to the conservative theory of epistemology that Harman (1986) has advocated. According to this approach, people are justified in continuing to maintain their current beliefs, even when they are unable to remember their reasons for originally believing them. Only positive reasons to doubt current beliefs are grounds for changing them.
- 8 For example, the upper left box in Figure 3b shows further changes of commitment to 1a that take place during Lines 1f to 1h of the argument. Bill's undercutting defeater in 1f means that he rejects 1a, due to undercutting principle (c); so the fourth row of the box contains a negative sign for Bill. At the end of the argument, though, Bill explicitly accepts Ann's rebutting defeater for 1f, and he must therefore retract it. Because 1f was supposed to undercut justification for 1a, Bill ends up reaccepting 1a by undercutting principle (c). The last row of the upper left box shows the state at the end of the argument with both Ann and Bill subscribing to 1a.
- 9 It is possible, of course, to write a set of rules in which a rebutting defeater would end a line of argument. However, such rules would not capture the intuition that rebutting defeaters ("That's not true!") always seem to imply the possibility of further rebuttal ("It is true!") rather than an end to debate. For this reason, the Table 1 rules specify that responses (possibly skipped responses) follow defeaters.
- 10 Still, although skipped responses are not as powerful as accepters, they may increase the second speaker's perceived commitment to the preceding claim, relative to a more neutral baseline. For example, Lines 5 and 7 in the two-branch arguments are followed by Speaker 2's skipped responses, whereas Line 1 is followed by a query from the same speaker. If skipped responses increase perceived commitment, we should expect higher scores for 5 and 7 than for

1. There is a small, marginally significant trend in this direction, with proportion of committed responses equal to .163 for the fifth and seventh lines and .065 for the first line, $\chi^2(2, N = 48) = 4.80, p = .09$. In general, though, the small size of this difference suggests that few of our subjects applied the more liberal commitment principles. It is also possible that people might follow the skipped response principle in special contexts. For instance, if an initial claim is obviously strong, then skipping a response to the claim might appear as a concession. This possibility needs to be tested, but note that some of the skipped claims in the stimulus arguments do seem quite strong (see Table 4) and yet did not produce a significant effect.
- 11 One anomaly in the data is the difference in the first column of Table 7. The one-branch arguments were identical for the implicit and explicit groups because no skipped responses occurred within these items. The difference between them may be due to subjects in the two groups normalizing their responses on the rating scale.
- 12 The first speaker had a female name and the second had a male name in five of the stimulus arguments, whereas these positions were reversed in the remaining seven arguments; hence it is possible to test after the fact whether subjects assigned greater burden to the female or to the male. For this purpose, the confidence ratings were rescored so that +10 indicated high confidence that the female speaker had the greater burden of proof and -10 indicated high confidence that the male speaker had the greater burden. Mean confidence was -0.46 (i.e., in the direction of greater burden on the male), but was not reliably different from 0, $t(95) = -1.08, p = .28$. Although there is no evidence here for gender bias, it is certainly possible that such effects depend on interactions with other factors, such as the content of the argument or the gender of the subjects, factors that were not controlled (see, e.g., Carli, 1990).
- 13 The postmortem in the text suggests that it might be possible to reduce the model's misprediction by rethinking the nature of the links in Figure 7. In the simulations just reported, excitation or inhibition from earlier lines in the argument can flow to later lines. This accords with ECHO in which all links are bidirectional, but it may be unrealistic for the present arguments. Arguments unfold sequentially in a way that may give precedence to later responses. Indeed, this is an assumption of my initial theory (see A Theory of Commitment in Arguments section and the right branch condition in Appendix A of Rips, 1998). If excitation and inhibition can flow only from later lines to earlier ones, this would avoid part of the inhibition that suppresses the activation of Line 8. Unfortunately, however, further simulations suggest that changing the model in this way produces other deficiencies. These simulations removed the interclaim connections in Figure 7 that pointed from earlier claims to later ones. (Connections to and connections between side-units remained bidirectional.) The degree of fit for this revised version was about the same as the original connectionist model ($R^2 = .85$ and $\text{RMSE} = .122$). Although the revision succeeded in reducing the discrepancy for Line 8, it increased the lack of fit for Speaker 2 in the explicit arguments. Predictions for Lines 4 and 6, in particular, were too large by 26 percentage points in the two-branch arguments and by 37 percentage points in the three-branch arguments. In the model, Lines 1 and 3 receive some indirect excitation from side 2 through Lines 5, 7, 8, and the side 1 unit, as Figure 7 illustrates. Activation at Line 1 or 3 can exert an inhibitory force on Lines 4 and 6 in the original connectionist model, due to the backward connections. Removing these connections in the revised model increases activation at Lines 4 and 6 and results in the overpredictions at these points.

PART III: INTERACTIONS OF REASONING IN HUMAN THOUGHT

Section 9: Reasoning and Pragmatics

Chapter 35: Specificationism

ELIJAH MILLGRAM

During the 1970s and 1980s, various French government bodies, along with their primary contractor, Matra Transport, invested on the order of half a billion francs in a futuristic guided transportation system called Aramis.

Aramis was . . . the niftiest of all, it was the programmed metro seat. The traveler merely goes to the station. He sits down, punches in the program, and opens up his newspaper. When the thing stops, he looks up, puts away his paper, and there he is, where he wanted to go. It's point-to-point, with no connections, no stops at intermediate stations.

The ideal, for passengers, . . . is what? It's not to think, not to slow down, not to transfer, and to arrive at their destination nevertheless.

That's point-to-point transportation. That's Aramis.¹

Someone who spends a sizable portion of his weekday in rush hour traffic might well respond enthusiastically to such a description: it's a great idea, and we should build it! To which the right answer would be, of course, build *what*? What we have had described isn't yet a goal that's definite enough for anyone to start taking steps, such as having suppliers bid on a part. You first have to design it, that is, to finish deciding just what it is you want built.

The sort of thought that goes into the design phase of such a project is the *specification* of an initial, very thin description of a goal, and over the past few decades it has come in for increasing

I'm grateful to Chrisoula Andreou, Sarah Buss, Henry Richardson, Sherri Roush, Bill Talbott, and the editors of the present volume for comments on earlier drafts. Some of this material was presented to a class on Engineering Ethics at the University of Utah; thanks to the students for their constructive and critical responses, and to Margaret Battin for hosting my visits to her classroom. My commentary draws on earlier work of mine, and I'm also grateful to Blackwell Publishing for permission to reprint material from pp. 218–219 of "Williams' Argument against External Reasons," *Nous* 30(2), 1996; to MIT Press for permission for material from the Introduction to *Varieties of Practical Reasoning*; to Cambridge University Press, for material from pp. 155–156 of *Ethics Done Right*; to *The Monist*, for permission to reprint material from "Pleasure in Practical Reasoning," *The Monist* 76(3), pp. 409–412 (copyright © 1993, THE MONIST: An International Quarterly Journal of General Philosophical Inquiry, Peru, Illinois, 61354, reprinted with permission); to Harvard University Press (adapted by permission of the publisher from *Practical Induction* by Elijah Millgram, pp. 135–138, Cambridge, MA: Harvard University Press, Copyright © 1997 by the President and Fellows of Harvard College); and to Oxford University Press, for material from my review of Henry Richardson, *Practical Reasoning about Final Ends*, in *Mind* 105(419), 1996, pp. 504–506; by permission of the Mind Association. Material from "Commensurability in Perspective," *Topoi* 21(1–2), 2002, pp. 219–221 (©2002 Kluwer Academic Publishers), is used with kind permission of Springer Science and Business Media. Finally, a number of excerpts are adapted by permission of the publisher from *Aramis: Or, the Love of Technology* by Bruno Latour, translated by Catherine Porter, pp. 28–29, 54, 69–70, 89–90, 105, 112, 183–184, 238–239, Cambridge, MA: Harvard University Press, Copyright ©1996 by the President and Fellows of Harvard College.

attention on the part of philosophers who work on practical reasoning.

I

“Practical reasoning” is philosopherspeak for figuring out what to do, and is contrasted with theoretical reasoning, that is, figuring out what to believe, or what the facts are. The current debate in the field is focused on the question of what can count as a reason for action, or (a closely related question) on what patterns of inference appear in deliberation about what to do. The question is not in the first place descriptive: it is not about what sorts of cognitive activity actually lead up to decisions. (Decisions can be made for bad reasons, or no reasons at all, and still be preceded by cognitive activity.) Rather, it is advisory or commendatory: it is about what considerations legitimately *count* as reasons – *good* reasons – for action, or about what sorts of cognitive activity deserve the honorific title “reasoning.” It is about what you *should* treat as a reason to do something, or, in short, it is a question about how to make up your mind, *not* about how people *do* make up their minds.

The received view in this area is instrumentalism, which has it that all practical reasoning is means-end reasoning. That is, it holds that practical reasoning consists in finding ways to attain one’s goals or ends, or equivalently, to satisfy one’s desires or preferences. Instrumentalism is an exclusionary position; since it holds that *only* means-end reasoning counts as practical reasoning, there is no such thing as reasoning about what one’s ultimate or primary or final ends (or desires or preferences) should be in the first place.² On the instrumentalist view, anything that at first glance appears to be reasoning about one’s final ends is not in fact *reasoning* at all, but something on a par with free association: the cognitive activity that leads up to the adoption of a final end cannot be correctly or incorrectly performed; it just *happens*, and when someone adopts an end, and it is not a means of attaining some further end he already has, we are never in a position to complain that his new end is mistaken.

Specificationism is an alternative to the instrumentalist default position. The specificationist view has it that at least some practical reasoning consists in filling in overly abstract ends (and other items as well) to arrive at richer and more concretely specified versions of those ends. Since many of our ends are simply too vague or indefinite to serve as starting points for means-

end reasoning, instrumentalist practical reasoning could not get going if one did not first further specify the overly indefinite ends; only when supplemented with the rational specification of ends is instrumental reasoning viable at all. In Musil’s *The Man without Qualities*, Count Leinsdorf decides to do Something Big to celebrate the jubilee of Emperor Franz Josef, something “to put Austria in the vanguard, . . . and enable it to find its own true being again”; but that idea is not enough to go on, if one is actually *planning* the event, and much of the novel tracks the not-very-successful deliberations (and antics) of the committee put together to determine what that Something Big will be. If what I want is to write a very good paper, I am not yet in a position to do anything about it; I must first settle on a much more definite conception of what sort of paper it is I wish to write. Before searching for the means to return the patient to health, the physician must first decide whether health, in the patient’s circumstances, would be a matter of prolonged life expectancy, or improved quality of life – and given the hard trade-offs, in what quality of life should be taken to consist. As Aristotle pointed out, we all want a well-lived life, but, as he famously went on to ask, what would that amount to? We may have decided that our new political party stands for the common good, but that is not yet a platform; in hashing out a platform we will be specifying a conception of what the common good is, and thus, our common end. Or, finally for now, perhaps, we want to be entertained this evening. If that is, so far, *all* we want, we aren’t yet in a position to do anything about it; first, we have to settle on what kind of entertainment we’re after. (Is it passive, in which case we can turn to the movie listings? Or the sort of active entertainment that might send us out for a night of clubbing?)³

The purpose of this chapter is first of all to present an accessible and up-to-date exposition of the current state of play in the development of this position.⁴ Specificationism has encountered ongoing resistance, and I will try to show how the main objections to it have been attempts to express a single underlying concern. I’ll discuss the ways in which the position has been – and might further be – developed in response to those objections. And, finally, I will argue that specificationism poses a challenge to the ways that philosophers in the analytic tradition have become accustomed to thinking both about instrumental reasoning and about rationality more generally.

2

Some methodological preliminaries are in order. A theory of practical reasoning ought to give us guidance when we are trying to decide what to do (and it ought to allow us to assess the quality of other parties' decisions). But specificationism as we have just introduced it is still too vague actually to be applied; told that part of your deliberative task is to arrive at more concrete versions of your goals, you still do not know *what it is* to go about that. Evidently, specificationism itself must first be further specified.

That is as it should be. Since the problem of how to deliberate is itself a practical problem, a solution to it must be arrived at by means that that solution – that theory of practical reasoning – itself endorses. When the theory is specificationist, we should not be surprised if it turns out that we have to arrive at that theory by specificationist means.⁵

What we're after might be with equal justice described as a better fix on the end of specifying one's ends, or a theory of how it is done correctly, or a method for doing it, or rules for doing it, or a standard for determining when one's ends have been specified properly. Evidently, the distinction between specifying goals, rules, methods, standards and so on is artificial, and we shouldn't be resting too much weight on it. I will start out by conducting the discussion in terms of ends or goals, but move onto to alternative objects of specification in due course.⁶

Specifying specificationism is an especially delicate exercise. Until the view has been specified enough to be applied to this very problem, how can we tell whether one candidate specification or another is acceptable? It might seem that any argument we give for one version or another of the theory will be viciously circular.

This is the first of a series of related and progressively deeper worries that we are going to encounter about the position, and by way of postponing our engagement with them, notice that the successful specification of one's ends does not normally proceed in a vacuum, but is given traction by a terrain of live possibilities. Having already decided to go for a walk, I may need to determine what kind of a walk it will be; by choosing a direction, I determine whether it will be merely a stroll through the streets, or an occasion to commune with Nature. When I do so, I do not simply make up a more specified description of going for a walk, but rather take into account the actually available options (here, what kinds of walks are to be had by going in

different directions). The illustration is a reminder that different specifications of an end will be appropriate in different circumstances; there is no such thing as the uniquely correct specification of an end, let the circumstances be what they may.

This implies that there will be no uniquely correct specification of specificationist theory, but, rather, different versions of it shaped by (and to) the option spaces presented by particular concrete problems. Consider a social procedure for specifying ends (thus, an implicit specification of the specification of ends), and one that academics ought to find familiar. Agencies that support research may want to fund work that is original, promising, agenda-setting, and so on. This kind of end is not specific enough to guide any actual course of research (and if the agency laid out guidelines concrete enough to guide an actual course of research, it would thereby fail to be original, promising, and so on). So such agencies solicit proposals on the part of researchers, and constitute a panel whose task is to select those that are original, promising, and so on. Such a proposal amounts to a concrete specification of the agency's originally indefinite goals, and the selection process amounts to adopting one such specification (hopefully, the best). The procedure turns the choice of specification into a comparison problem.⁷

This is a workable way of disbursing research funding – and notice that it is clear enough how we would go about arguing for it, which suggests that the threatened circularity may not always be an obstacle to making up one's mind when the facts about the surrounding circumstances can be brought to bear – but it would be a terrible way to write the next chapter of your novel, or to determine the shape of an adolescent's emerging self-image, or, as we will shortly see, to solve certain sorts of engineering problem. To recap, specificationism itself needs specifying, and how a specification should proceed depends on surrounding circumstances (where that dependence allays the worry, anyway for now, that just anything goes). So the question is not: What is *the* right way to specify specificationism?

Let's serve our own purposes by adding a slight additional specification of the theory ourselves. We want specificationism to be a full-fledged alternative to the notion that all practical reasoning is means-end reasoning. But if all we have said is that specification adds content to ends, then what we have is less than the alternative we are after: Some specification of ends can,

of course, be merely instrumental. To return to an earlier example, when my goal is to write a very good paper, much of the further specification that is necessary before I can actually start to write is noninstrumental (I still need a much more definite conception of what it is I want to write). When my goal is write my way through the paper I have thoroughly outlined, the point of the further specification – of the way I frame the sentences – is to serve the already fully specified goal.

The reader is warned that this distinction is almost never made in the literature, and that it is very easy to lose track of it. In particular, “constitutive” reasoning is often contrasted with instrumental reasoning; when this contrast is drawn, instrumental deliberation is typically thought of as reasoning about causal connections (to get the ball into the outfield, I have to hit it with the bat), and constitutive deliberation, as a matter of determining the parts or elements or components of something (to win the game, we must score more runs than the opposing team, and avoid being disqualified by the way we do it).⁸ Both types of reasoning may be a matter of figuring out how to get something fairly definite that one already wants (e.g., winning the game), and when they are, they come under the heading of instrumental reasoning, as I am now using the term. Constitutive reasoning, when it is not simply a matter of joint constraint satisfaction (with fully specific constraints: We will turn to the possibility of underspecified constraints in due course), or helping oneself to a listing of standard constituents, may also be noninstrumental (in my sense); that is, it may amount to figuring out what one wants in the first place, rather than what is involved in getting what one already wants. Because we are interested in specificationism as an alternative to the dominant theory of practical reasoning, let’s specify that the type of specification we are considering is *noninstrumental* specification of ends.

Talking one’s way through such a position is best done using an example that is both rich and taken from the real world. The standard illustrations (the previous section rehearsed a representative sample) tend to be either toy, or taken from ethical or moral domains. But it is probably better strategy to do one thing at a time, in this case, to investigate specificationist reasoning in a way that does not require us to cope with difficult moral questions at the same time. For this reason, industrial engineering and design, where specificationist reasoning takes you from concept to blueprints, and espe-

cially the design of novel products and technologies, seem to me to be a better testbed for this theory of practical rationality than the staple ethical and moral problems. Such cases come with a built-in advantage: Because the deliberation is institutional, rather than individual, it is often much easier to see what is going on. Institutions leave paper trails.⁹

The illustration I will use is the retro-futuristic transit system with which I began the paper. In 1987, the Aramis project was canceled, and in 1993, a postmortem by Bruno Latour, the bad boy of French philosophy of science, appeared in print.¹⁰ I’ll give enough detail for the reader to follow the thread of my argument, but if more texture – or a reality check on the claims I will be making – is needed, I recommend *Aramis, or the Love of Technology* as a fascinating afternoon’s read. I’ll put in place a bit more of the example now, both in order to give some of the flavor of what specification of ends looks like in a realistic case, and to make a couple of obvious but important points about it.

3

Suppose we have reached the stage at which the “programmable metro seat” consists of car-sized cars (that is, at which it is no longer being thought of as conceivably turning out to be a high-speed ski lift). If the system is to process enough passengers, these cars must be able to form trains, that is, to move together at the same velocity, with very small distances between them. Starting and stopping at stations dramatically cuts the average speed of a train, and because this version of Aramis is intended to provide dense coverage for an urban area, it would have many stations. The price paid in terms of transit time would be high. Here the decision is made that this “train” is to continue moving; its cars will slip into and leave the stream of traffic.

At this point in the process of specification, a further engineering decision is made not to manage the coupling and uncoupling of cars entering and leaving the “train” mechanically. Instead, what we would now call virtual coupling is to be used.

The big challenge with Aramis is that the cars are autonomous; they don’t touch each other, yet they work together as if they were part of a train. They have nonmaterial couplings – nothing but calculations. (54)

Because the cars are very tightly spaced, and because there is nothing physically holding the

cars in place, the cars must keep their own position quite precisely. If a computer is to control the car with sufficient precision, a new sort of motor is required,

an electric motor that doesn't involve a power transfer. You don't have a shaft or sprocket; there are no mechanical parts, except for the rotor, which is the axle. You have little notched wheels that allow very finely tuned displacements. (105)

This is a demand that is concretely specified enough to assign to a team of engineers; "the rotary . . . variable-reluctance motor" (104) turned out to be one of the few working devices produced by the Aramis project.

Perhaps some of these decisions could have been made differently, and something else would have been called (would have, if it had been built, *been*) Aramis. "The people carrying the ball for the project make a major decision as to what is negotiable and what isn't. Implementation, size, operation, financing, the dense network – all these are open to discussion; the mobile unit with nonmaterial couplings is not" (112). Once these decisions are made, "Aramis" is *more specified* than it had been.

Even this much is enough to allow the following remarks. First, faced with our toy introductory examples, an instrumentalist might have been inclined to respond that the problem was simply not knowing what one wants, and that is not something which calls for a novel theory of deliberation. (If you don't know *what* you want, that is *your* problem . . . not logic's problem.) But in this more elaborate case, it is clear that insisting that a deliberator ought to know what he wants up front, without doing anything that would count as thinking about it first, is unrealistic and unreasonable. Aramis would have had no chance at all of being a successful project unless a great deal of thought was put into determining what the fully specified goal was to be, and without such thought, there would be no reason for anyone to take the proposal seriously.¹¹ So we need to make room in our intellectual scheme of things for something that counts as thought of this kind.

Second, we can explain a couple of lacunae in Latour's treatment. In a postmortem of this kind, it is normal to try to answer two questions, whether the project was technically feasible, and whether it was economically viable. Latour insists on not answering either question. Whether Aramis was technically feasible would depend on what it was specified to be; obvi-

ously, some specifications would have been feasible, and others would not. (And likewise for economic viability – but I'll return to the question of Aramis's economic viability shortly.) The general point is that when we are involved in the specification of ends such questions stop having straight answers.

Third, for closely related reasons, when we are in the course of specifying ends of this sort, cost-benefit or expected-utility calculations become unavailable. These techniques have us make decisions by assessing the costs and benefits of outcomes, weighting them by the likelihood that they will occur, and choosing the outcome with highest expected value. But until we know what Aramis is, we cannot say what the costs or benefits or likelihoods involved in proceeding are. (Cost, benefits, and probabilities of *what*?) I will return below to a deeper relative of this problem.

4

Specificationist deliberation is meant to be a form of practical reasoning. Sarah Broadie allows that we move from less to more definite specifications of our ends, but she denies that this could be really be *reasoning*. Since the conclusions of such trains of thought have more content than their starting points, the starting points do not constrain the conclusions, and we have no way to distinguish correct specifications from incorrect specifications. The specification of an end, she argues,

is a move from the less to the more determinate, which latter, precisely because it is more determinate, cannot be entailed by what is less so. It might seem that with suitable extra premisses there could be a logically acceptable inference from the indeterminate to the determinate end. After all, there is no acceptable inference from the determinate end to the means except via additional [empirical] premisses. . . . But . . . what additional premisses would do the trick? (a) Factual premisses, whether particular or general, would not help; nor (b) would any purely logical propositions. The addition (c) of some formal propositions about *eupraxia* [the Aristotelian end whose specification Broadie is discussing], such as that it is "self-sufficient" or "lacking in nothing," would not logically enable one to interpret the pursuit of *eupraxia* as the pursuit of *S* (where *S* is something more specific); whereas (d) inserting

a premiss that specifies *eupraxia* substantially might of course sustain the inference to a no less substantial conclusion, but only by thrusting back to an earlier stage the problem of how such propositions are obtained in the first place.¹²

It is easy to dismiss this argument too quickly. After all, Broadie is in the odd position of someone who holds that, whatever engineers were doing when they designed the ARPAnet, or the F-16, or any other innovative technology that satisfied a vague set of requirements in ingeniously new ways – or for that matter, when they ultimately failed to design Aramis – it couldn't have been *thinking*.¹³ And her argument relies on more than one problematic premiss, the first of which is that the more determinate cannot be inferentially extracted from the less. If the determinateness of one's starting point is not merely stipulatively linked to the determinateness of one's conclusion, we may expect to find any number of counterexamples in which determinateness increases as the inference is traversed. (Turning over several indistinct and hazy recollections of the previous day, I suddenly realize *exactly* what Sandra is up to.) Moreover, while the criterion she invokes – that if a train of thought is to be reasoning, there can be nothing in the conclusion that was not already in the premises – seems obvious to contemporary philosophers, the very opposite seemed just as obvious not so long ago. John Stuart Mill, not atypically of his time and in line with much tradition, took it for granted that a train of thought could not count as reasoning unless there was *more* to the conclusion than to the premises.¹⁴ So the insistence that inference is conservative in this respect can look a lot like twentieth-century parochialism.

Second, Broadie takes it that the supplemental premisses in a completed specificationist argument must have practical force or content – they must be evaluative, or contain operators like *should* or *ought* – and she apparently assumes that no such claim could be empirical; this is why she concludes that empirical premisses cannot fill in the gaps in a specificationist train of thought.¹⁵ But it should not be obvious that premisses with practical force cannot be empirical. Suppose I am faced with a problem we have already mentioned in passing, that of deciding what would make for an entertaining evening. Mummenschanz is at the McCarter Theater, and I have not seen them, nor, I gather, anything like them, before. I have factual premisses, in the form

of a friend's description (“they mime inanimate objects”), and these premisses do not help. Logical and formal propositions do not help either. What I need is a premiss of Broadie's type (d), one that specifies my end of being entertained substantially and in the relevant respects; we can allow knowing whether Mummenschanz will *be* entertaining to stand in for such premisses here. (“Entertaining” is a so-called thick ethical concept, and has an action-guiding *should* built into it.¹⁶)

As Broadie insists, the demand for such premisses raises “the problem of how such propositions are obtained in the first place.” She intends mention of the problem to have the force of a rhetorical question, for she concludes that no such premisses are available. But consideration of a concrete situation in which the demand arises makes it obvious how such premisses are obtained: I can go to McCarter, and discover, by observation, whether Mummenschanz is entertaining or not. In short, premisses that are both empirical and evaluative (or prescriptive) are available, and the specification of ends is plausibly a form of rational deliberation that relies essentially on practical experience.¹⁷

Since there are more than enough places in Broadie's argument at which to dig in one's heels, why not shrug off the concern expresses? In my view, that would be a mistake. One way to see the underlying problem is as an issue of control: There are usually many ways one can make an abstract goal more concrete; what is there to make some of these right and the others wrong? To take up our main example once more, there were various ways that Aramis was reconceived over the course of its stop-and-go development. At one stage, it was an airport shuttle, Orly's version of the familiar monorail or light rail connecting the terminals. At another, it was vastly more ambitious: a network carrying four-seat cars from any point in an urban area to any other point; that is, it was a system combining the functionality of a fleet of taxis with that of a subway system. At another, it was a low-tech people mover, the sort of thing familiar from Disney's amusement parks, and meant to be installed at a Paris World's Fair. And at yet a fourth stage, Aramis had become a suburban commuter train, whose larger cars were joined in pairs – but a train that would split at junctions, with some cars going to one suburb, and the other cars to another. The different versions of Aramis were *so* different that one is left wondering whether just about *anything* would have counted as a specification of the initial goal. But

in that case we would not be examining a deliberative process that could have been executed incorrectly, and so, we would not be examining a process that is to be understood as inference or reasoning.

5

Henry Richardson has taken up the challenge of showing where the added content comes from (1994). There is an additional, so-far-unmentioned reason for the specification of ends. Many of our ends conflict, but often these conflicts (whether between one's own ends or the ends of different people) can be removed by *cospecification* of the ends in question. Since the point of practical reasoning is deciding what to do, and since deciding what to do requires resolving conflicts between ends, ends are to be specified jointly so as to make them jointly achievable (and more generally, to make them cohere with one another and with other background elements of one's evaluative system). To return to one of the small-scale examples on the table, if I want to go for a walk, and I want to get exercise, and these ends conflict (how will I find time for both?), I could further specify the walk as the uphill, brisk kind, and the exercise as low-key, outdoor, not-necessarily-aerobic activity. If I do, the need to trade them off against each other is sidestepped.

(A caveat: I remarked earlier that specifications do not go ahead in a vacuum, and that there is no such thing as the correct specification of an end, regardless of surrounding circumstances. That observation holds of Richardson's further specification of specificationism. Perhaps the point is not always to resolve conflict; one might, for instance, sharpen up vague ends or rules in order to introduce conflict between them – say, in the name of brand differentiation, or as a negotiating tactic, or as a way of escalating hostilities.¹⁸ Or, again, to develop the example we borrowed from Williams, if one of my insufficiently specified ends is to be entertained this evening, and the other is to keep a depressed, and so unentertaining friend company, I could specify my end of being entertained as being entertained passively, and keeping company as sitting side by side in silence in a dark movie theater. But even if this solution eliminates the conflict, it may raise, in some circumstances, anyway, the question of just what kind of a friend I am. Sometimes the right thing to do is to *acknowledge* a conflict, rather than to specify one's way around it.)

In introducing cospecification, I compressed into a parenthesis Richardson's insistence that it is not just ends in the mix. To see what that comes to, let's take a look at an especially problematic instance of it in the history of Aramis; the excerpt reproduced below is from interviews conducted with former RATP and Matra personnel.

[M. Berger:] "You have to understand intrinsic security. That's the underlying philosophy of the SNCF and the RATP. What it means is that, as soon as there is any sort of problem, the system goes into its most stable configuration. It shuts down. Broadly speaking, if you see the subway trains running, it's because they're authorized *not to stop!* That's all there is to it: they're always in a status of reprieve.

"As soon as this authorization stops coming through, the trains stop running. The emergency brake comes on, and everything shuts down. So everything has to be designed from A to Z – everything, the signals, the electric cables, the electronic circuits – with every possible type of breakdown in mind."

"That's why they call it *intrinsic*: it's built into the materials themselves. For example, the relays are specially designed so they'll never freeze up in a contact situation. If there's a problem, they drop back into the low position; their own weight pulls them down and they disconnect. The power of gravity is one thing you can always count on. That's the basic philosophy."

[M. Cohen:] "There was no hope for Aramis if you had to bring in the principles of intrinsic security. Not a chance."

[Interviewer:] "I thought that was the basic philosophy in transportation."

[M. Cohen:] "Not at all. An airplane doesn't have intrinsic security. Just imagine what would happen in an airplane if everything came to a halt whenever there was a minor incident! Well, people take planes, they accept the risk; this is *probabilistic* security. It was the same with Aramis. (69f)

Notice first that what must be cospecified with Aramis is a *standard* it must meet; security can be specified to be either intrinsic or probabilistic. Latour plausibly suggests that when an enterprise is large enough and innovative enough, it will not succeed unless not only the ends but the standards to be met are specified along the way. Call cospecification that restricts itself to modifying ends *narrow*; call cospecification that specifies standards, values, and so on, *wide*.¹⁹

Since we evidently cannot get by without wide cospecification, and since it is evidently the more problematic of the two, let's specify that the sort of specification we are interested in involves wide rather than narrow cospecification.

This is not an isolated or unique example. Recall the unanswered question of whether Aramis was economically viable. The obstacle to answering it is not just that, until we are fairly far along the process of specification, we do not know what it is that might or might not be viable. It is that the answer depends on how you specify economic viability. When we are counting up customer receipts, do we count commuters who have already paid for their monthly transit passes, and who begin using Aramis when it comes on line? Or do we just count the commuters who give up their cars and buy passes because Aramis is now available? Is a ride on Aramis valued as just another subway ride? Or does the municipality accept the idea that a more comfortable and more convenient trip is worth more? Do we count the decrease in automobile traffic? If so, how much?

Latour puts the point this way:

Every technical project has to define a type of economic calculus that makes it more profitable.

The relation between the economic calculation in camera and that in the greater Paris region is a relation to be established, to be performed, to be maintained. It is no more a given than any of the other relations. The profitability of the network and the efficiency of the rolling stock are twin notions that are negotiated and gradually realized as functions of success or failure. They follow; they do not lead. They are decided; they are not what makes it possible to decide.

And so we have a fine scientific controversy opening up within economics to determine whether "socioeconomic profitability" is acceptable or not. If politics imposes its will on the Budget Office, then the Budget Office has to take into account the calculation of passenger time and comfort, and Aramis becomes *profitable* once again. If politics hesitates, then the Budget Office imposes its own method of calculation, and Aramis goes back into the red. Aramis will survive only if it extends the scope of its network to the point where it makes humans in Paris move and modifies the usual calculation methods of the Budget Office. (183f.)

The specification of ends involves – in at least the large and important cases – cospecification of standards. And that leads us to further formulations of the objection we have been entertaining.²⁰

6

If Latour is right, when the projects are large, we had better specify cospecification as wide cospecification. But that should worry us; didn't NASA famously cospecify the design for the Space Shuttle together with safety standards for the Shuttle, with results that speak for themselves? (As Stuart Russell once put it, discussing problems in robotics: "The performance standard must ultimately be externally imposed... particularly since, for the purposes of building useful artifacts, modification of the performance standard to flatter one's behavior does not exactly fit the bill."²¹) With enough political muscle, couldn't the accounting be made to come out any which way at all, and in that case, isn't it just a matter of politics at its most raw: the specification supported by the player with the most power wins? But then why is what we are examining a form of *inference* at all?

Let's consider two higher-resolution diagnoses of the problem, one due to Aurel Kolnai, and formulated when he kicked off the current discussion of specificationism several decades back, as well as a more recent treatment developed by Candace Vogler in the course of an argument for a position closely related to instrumentalism.

Kolnai argued that the process of specification is inevitably irrational and self-deceiving. You specify ends by reference to further ends. In so doing, you must treat the further ends as fixed, and as having fixed weights. The further ends are initially indeterminate also, and must be specified themselves in light of still further ends. The still further ends include, among others, the ends you were initially trying to specify. So the specification of the initial ends depends on the outcome of that very specification; the specification of ends generally is viciously circular.

Although this form of practical "rationality" is inevitably irrational and self-deceptive, it is going to be there come what may: the blueprints for Aramis are not going to happen by themselves. Accordingly, Kolnai depressingly labeled his conclusion the "Fundamental Paradox of Practice."²²

Vogler's diagnosis is that rationality, inference, reasoning, reason, and so on are all (in the jargon of analytic metaethics) *normative* notions; or, as I put it earlier, the status of being a reason is advisory or commendatory, not merely causal. Normativity involves a contrast between doing it right and doing it wrong, and giving that contrast genuine content requires having an independent standard to which one can hold one's reasons, inferences, reasoning, and so on. Means-end reasoning provides such a standard, namely, whether your end is achieved by the means you propose to take to it. But alternatives like specification (as we have just seen) do not; the standards are mutable, and are adjusted to suit the ends on which one is working.²³

Only means-end (or, as she calls it, "calculative") reasoning is first-class practical reasoning.²⁴ How then to make sense of the fact that we evidently *do* think about how our ends should be concretized and tightened up? Her answer is that the specification of ends is itself merely a means to an end, namely, the end of deciding what to do. The end of making up one's mind provides just the sort of independent standard for success or failure that seemed to be missing from the process; but then the specification of ends is just more means-end reasoning, and not an alternative to means-end reasoning.²⁵

Aramis can serve not just as an illustration of these complaints, but as a reality check for them. "Nominal Aramis" – the project engineers' name for the initial thinly specified end – had been personalized point-to-point transportation; as we have seen, at the relatively early stages of the project it was conceived as a network of track carrying small (four-seat) vehicles from any point in the network to any other. Very quickly, however, as this excerpt from a further interview explains, cost considerations showed this plan to be simply not feasible.

[M. Gueguen:] "The very thing that made Aramis so different, its ace-in-the-hole, was scuttled at the start. . . . What costs the most in a guided-transportation system like Aramis that has an exclusive guideway? It's the infrastructure – the bridges, the tunnels, the viaducts, the tracks. . . . [But] cars that stop have to have a shunt line to separate them from the train. They also need room to slow down, plus a platform long enough to accommodate the number of cars, plus another shunt line so they can speed up and rejoin the train, which is running – or so Matra

was saying at the time – at about 50 kilometers an hour without stopping. Do you see? . . . there are actually *two* tracks almost the whole way. So even if Aramis is a narrow-gauge system, you have to carve out tunnels and make trenches for a very wide gauge! This is how an attractive advantage turns into a disadvantage. That's why the project changed shape so fast; it was impossible.

"So they said, 'Okay, PRT service is really two things: no intermediate stops, no transfers.' They kept the second, but they gave up the first. . . ." (89)

In the face of financial pressure to make Aramis look much more like a traditional light rail system – and in fact as Aramis succumbed to the pressures, the size and seating capacity of the cars grew, first to ten persons, and eventually to twenty – no one attempted to conjure up an accounting method that would make Nominal Aramis break even. No one tried to change the "weights" of further ends so as to keep Nominal Aramis in play. While there was some wiggle room in the choice of economic and financial standards that the project had to meet, there wasn't *that* much wiggle room.

Let's return to the interview we quoted when we were discussing the specification of security standards. The second interviewee continues:

"I've finally concluded that in transportation, the only philosophy that allows a decision-maker to make a decision is intrinsic security. Not for technological reasons. When you say 'intrinsic,' it means that, if there's an accident, people can say: 'Everyone involved did everything humanly possible to provide a response for all the possible breakdowns they were able to imagine.' This way the decisionmakers are covered. They can't be blamed for anything.

"In probability theory, you say simply: 'If event *x* happens, and if event *y* then occurs, there is a risk of *z* in 1,000 of a fatal accident.' And this is accepted, because the probability is slight. This approach is unacceptable for a decisionmaker in the field of public transportation." (70)

The project's clients were government agencies run by public servants, and the need to keep accidents off the front page of the newspaper turned out to be a rigid constraint on the design of the system.²⁶ That's not to say it was enough of a constraint to obviate the need to specify

standards in surprising ways. As it happened, the security standard ended up being specified in neither of the ways we have just seen. Pairs of cars were mechanically bolted together, the idea being, roughly, that if one set of brakes failed, there would always be the brakes on the second car. Here security was being specified as *redundancy*, but in a way that took into account the indefeasible political imperative. Briefly, the arguments we extracted from Kolnai and Vogler turn on the thought that, when you can cospecify the standards along with the ends for which they are standards, anything goes. But, as the evolution of Aramis teaches us, anything *doesn't* go. Now, these cases might suggest the view that mere politics (rather than the merits of the competing reasons) determines what goes and what doesn't, and I will take up that issue in a moment; first, however (not least because it is advanced in one of the more important recent discussions of practical reasoning), I want to explain why Vogler's alternative account of specification cannot be correct.

In the specification of ends, there is clearly *some* contrast between doing it right and doing it wrong. Take Aramis: if the perfume of that name, which one today finds at the cosmetics counters, turned out to be the result of the episode of specification we have been examining, we could be quite sure that something had gone wrong.²⁷ When it comes to practical reasoning, Vogler is committed to accounting for any such contrast in terms of the adequacy of means taken to a given end. This is why she treats the specification of ends as a means to the end of deciding what to do.

But the end of deciding what to do is too vague and indefinite an end to put one in a position to take steps toward it. Before that end can provide the accountability we have on hand, it must itself first be further specified. After all, specifying Aramis to be a perfume would give one a way of deciding what to do – one could at that point start calling the scent manufacturers – but that would not be a satisfactory specification of Nominal Aramis. To vary the example, if you are the public prosecutor, and your end is (so far, just) to deal with some criminal, not only is the end underspecified, but your further end, of deciding what to do, is also underspecified. If the former end turns out to be to deal *fairly and legally* with the criminal, then the deliberative process is identified with the operation of the judicial system. If it's to deal with him *expeditiously, decisively and permanently*, then deciding what to do is something that a handful of

good old boys can do in a back room. If it's to deal with him *humanely*, you may need to move him to a different jurisdiction, where the judicial process will take a different form . . . and so on. Before taking steps toward the end of deciding what to do, in such a case that end itself needs to be further specified. In short, Vogler's replacement for specificationist practical reasoning will only work if specificationist practical reasoning already works on its own.²⁸

Let's return to the thought that the specification of an end wins out when the standards in play have been cospecified to make it the winner; that our examples suggest that what the standards end up being, and how much latitude there is in specifying them, is a matter of who has how much political muscle; that what it is to be a correctly specified end turns out to be no more than a matter of Lenin's "who whom"; and consequently that the specification of ends is rationalization rather than reasoning. (In this case, that Aramis died only because it lacked a sufficiently powerful patron.) Latour shows us how, in the case we have been considering, this cynical conclusion underestimates what is up for grabs in the course of wide cospecification.

Who the actors are (or, as philosophers sometimes say it nowadays, what the units of agency are) is also part of a wide cospecification. Consider two strikingly different versions of Aramis which took shape over the course of the project: The little airport shuttle, and something that might ultimately be the replacement for the subways and commuter rail lines of Paris. If Aramis turns out to be the first, it's a very small part of Matra's business; there will be a small unit inside Matra Transport that has a real stake in Aramis's existence, but Matra as a whole won't really care. (That small unit will keep having to work at convincing Matra's management that Aramis is important, that continued support is justified, and so on.) Whereas if Aramis becomes the mass transit system of the capital of France, it ends up being practically all of Matra Transport's business, in which case, Matra will just identify its interests with Aramis. Who Aramis's patron is (and how big and politically powerful it is) depends on what Aramis turns out to be.

It's easy to think that the cospecification of units of agency is only a feature of institutional deliberation, but not of practical reasoning done by individual human beings. On the contrary, people ordinarily do many things at once, and they allocate more resources to some tasks, and less to others, depending on what the task is. It is not as though there is a part of me, with fixed

resources, already devoted to such-and-such a task, regardless of what it turns out to be: a part able to muscle other parts of myself into making the task happen *its* way. If gardening means having a little window box, it gets five minutes a week, and I don't care much about it; if gardening means an elaborate flower bed, I give it a few hours a week, and I'm proud enough of my flowers to care a good deal. That is, leaving the metaphor of subpersonal parts to one side, my commitment to the task depends (among other things) on how ambitious it is; although, as before, not everything is up for grabs, we often cannot explain how ambitiously the task is specified simply by appealing to my prior commitment.

7

We have seen what in retrospect look like a series of attempts to articulate a single and persistent worry about specificationism. Vogler's objection is perhaps the most revealing of them because it shows how the underlying concern depends on a presupposition widely shared by analytic philosophers: that a distinction between correct and incorrect – between doing it right and doing it wrong – requires the availability of an independent standard for correctness.

This is a very natural thought, but our discussion of specificationism has made it clear that if the specification of ends is a form of practical reasoning (thus, something to which the contrast between correct and incorrect execution can be applied), it is one for which independent standards are not going to be generally available. The observation that led Kolnai to call his version of the complaint the Fundamental Paradox of Practice was that we simply cannot get by without the specification (and, we have observed further, the *wide* specification) of ends. It is so fundamental, pervasive, and inevitable a feature of human deliberative practice that if we cannot make it out to be a locus of rationality, then when we make the decisions that most need to be made thoughtfully, we are really only just *pretending* to think. That is a very good reason to reconsider this part of our inherited model of rationality. Instead of throwing up our hands and rhetorically asking why, if you don't have independent standards, you couldn't just get away with *anything*, it is time to try to figure out how one could successfully use standards (for they clearly are being used in our extended example) which are *not* independent of the items to which they are to be applied.

I want to wrap up by first touching on the recently popular reflective equilibrium approach to rationality, and then returning briefly to the dispute between instrumentalists and specificationists.

The advocates of reflective equilibrium will respond to the point I have just made by telling us that it is old news. Its initial characterization in the philosophical literature – “[a] rule is amended if it yields an inference we are unwilling to accept; an inference is rejected if it violates a rule we are unwilling to amend” – treats neither rules nor the inferences they are rules for as an independent standard; each is to be modified in light of the other.²⁹ And it is even old news for specificationists: Richardson's treatment, for instance, explicitly appeals to it.³⁰

But acknowledging the need for reasoning of this kind is not the same as having a thought-out account of how to do it, and specificationism shows us how far we are from having such an account. “Reflective equilibrium” is a new name for what was formerly called “coherence.”³¹ Now coherence is a vague concept; we should expect it to require specification; indeed, there are already a number of substantively different and less woolly variations on it, with indefinitely many more waiting in the wings. Reflective equilibrium has already been specified twice under its own name: once as *narrow* reflective equilibrium, in which rules and the instances that fall under them are mutually adjusted, and again as *wide* reflective equilibrium, where the elements to be coordinated include values, relevant beliefs, and even emotions.³² That is, reflective equilibrium (or coherence) is itself underspecified, and has to undergo further specification before – or anyway, as – it is put to use: different specifications of coherence or reflective equilibrium will produce substantively different answers to first-order specification problems.³³

As before, different enterprises will require different specifications; there is no single version of reflective equilibrium that will prove correct across the board. For instance, on the one hand, narrow reflective equilibrium is adapted from a domain for which it is obviously correct: when a linguist is trying to construct a grammar for a language, he begins by asking native informants for their linguistic intuitions about a wide range of utterances. (Is *this* one grammatical or ungrammatical? How about *that* one?) Proceeding from this data, he formulates a set of rules which largely classify the utterances as the native speakers do. When the rules and native judgments disagree, sometimes he rules in favor

of the native speakers, and replaces the proposed rule with a more contoured one. And sometimes he overrules the native speakers, dismissing one utterance or another as ungrammatical. Eventually, he arrives at a set of rules that systematize his data, along, of course, with a list of the data that fail to conform to his rules.³⁴ On the other hand, moral philosophers who deploy reflective equilibrium have almost uniformly rejected its narrow version in favor of wide reflective equilibrium – and, let’s just allow, for good reason.

One cannot merely appeal to reflective equilibrium itself to settle how reflective equilibrium is going to be specified. One reason for not going second-order at this point – that is, requiring that the specification of reflective equilibrium be in reflective equilibrium with the very elements it is supposed to bring into reflective equilibrium, and taking that to solve the problem – is that many fully appropriate specifications of the concept (such as narrow reflective equilibrium, or MDL, or the coherence concepts due to Thagard and his collaborators³⁵), are not defined so as to permit reflexive application. Another is that we do not know how to exclude bizarre but self-endorsing specifications of coherence or reflective equilibrium. This is not to say that there aren’t specifications of reflective equilibrium which, when brought to play in the specification of specificationist reasoning, bring you around to the right specification. And it’s not to say that the circularity is necessarily vicious. It is, rather, that we don’t yet understand how to talk or think our way through the mutual interplay of specification and reflective equilibrium so as to show that and how it is not vicious.

The reflective equilibrium approach may be committed to the idea that reasoning proceeds without an independent standard. But attention to the problems of specificationism shows that its advocates haven’t figured out how to actually explain such reasoning. “Reflective equilibrium” is another label for the problem, rather than (so far) a solution to it. And that brings us back around to the point where our series of progressively more forcefully articulated versions of the primary objection to specificationism had led us: specificationism is philosophically important not least in that it shows us that we need to rethink our philosophical model of rationality from the ground up.

I began by introducing specificationism as an alternative to instrumentalism, and readers are likely to worry that they haven’t seen a convincing refutation of the opposing view. (If you have instrumentalist leanings, you are likely to have

been wondering whether cases such as Aramis can be fully accounted for by appealing to background goals and constraints, and inclined to insist that if they can’t, well then, they cannot *really* have been reasoning after all.) Now, supplying a decisive refutation of instrumentalism is not part of the present agenda, for two reasons. First, the task here is describe the current state of play, and specificationists for the most part treat it as obvious that solely instrumental reasoning is a nonstarter; so they do not go out of their way to provide arguments that it is. Second, while for my own part I don’t think that instrumentalism is a sustainable position, neither do I think that the best available arguments against it are specificationist.³⁶ Nonetheless, it does seem to me that specificationism has an occasion to bring its motivating insight to bear at the heart of the instrumentalist view, and that it is worth considering how that would go.

Instrumentalism is, once again, the idea that practical rationality is exclusively means-end rationality. But the means-end connection is one of the most mysterious notions in philosophy. Most philosophers tend to suffice with stating that a means is something one could bring about that would cause one’s end; that doesn’t make it any less mysterious. The academic industry engaged in analyzing causation is good evidence that causation is philosophically mysterious itself;³⁷ means are causes, and causes are philosophically mysterious; so means to ends are philosophically mysterious, too. Perhaps more pressingly, giving a satisfactory analysis of what it is to be a means to an end would involve explaining what makes something a *better* or *worse* means to one’s end. Doing that would entail being able to give a noncircular explanation of what’s wrong with Rube Goldberg machines (why they are instrumentally irrational solutions to the problems they purport to address).³⁸ And that’s something no philosopher knows how to do.

A specificationist has available a diagnosis of this obscurity: what it is to be a means to an end is not yet sufficiently specified to serve as an anchoring concept for a theory of rationality. Just to provide a sense of what the alternatives can look like: Sometimes means are the sort of discrete sequenced steps you can represent in flow charts, and they temporally precede the ends; sometimes they are top-down adjustments to system-level variables, as when the Fed lowers the interest rate; sometimes a means consists in doing something after the fact to change the significance of an earlier event; sometimes a means

is temporally posterior to the end it promotes in still other ways, as when, to move muscles in your arm that are not subject to direct voluntary control, you move your fingers; sometimes a means embeds its ends, as when one utters the phoneme “t” by uttering a syllable containing it; and the list has only just been started.³⁹ When one does specify the means-end relation – in different ways, of course, depending on what the practical problem is – then if one takes oneself to be specifying it correctly, one will not be in a position to insist that the honorific “practically rational” has to do only with the assessment of means-end reasoning, full stop (and not with the assessment of the specification of ends or standards). But the real point of the suggestion is not the quick refutation of instrumentalism. The more profitable and constructive use of the specificationist insight would be to organize our efforts to give concrete content to the instrumentalist’s core concept. That would benefit philosophers on all sides of the debate.

Notes

- 1 Latour 1996: 28f. I’ll give subsequent references to this book as stand-alone page numbers in the running text. Despite the now antiquated technology the project used, it is still surprisingly futuristic. See Weiss 2002.
- 2 The contrast here is with subsidiary ends or subgoals, adopted as means to further ends or goals; instrumentalists have no problem with these. For the sake of brevity, from here on out I won’t list the alternative formulations (preferences, desires, etc.). For complications and further glosses, see the text surrounding note 8, as well as note 23, and the final section of the paper.
- 3 For the first example, see Musil 1996: Vol. i, 89 and *passim*. The second example is due to Allen Coates, the third and fifth to Kolnai 2001, and the last is from Williams 2001. The reading of Aristotle as a specificationist is due to Wiggins 2001; Kolnai, who takes Aristotle to be an instrumentalist, presents specificationism as an alternative to Aristotle’s view.
- 4 The chapter will thus be an exception to the rule that philosophical essays are arguments for positions invented and endorsed by their authors: The idea is not my own, and while I think it is likely to be correct, I think the jury is (and ought to be) still out. (In my view, it clearly *is* interesting and important enough to deserve the sort of treatment I will try for here.)
- 5 That the form one’s practical reasoning is to take is a choice, and not a matter of fact simply to be discovered, is by no means a consensus in the field. For dissent, see Velleman 2000: esp. 229–230.
- 6 See Richardson 1990 for a treatment of the specification of norms or rules.
- 7 The technique places a great deal of reliance on the taste of the panelists, and one might worry that this is consequently not really *reasoning* after all. However, the judgments of taste occupy determinate positions in the larger structure of comparisons; they are used in the course of deliberation, but do not replace it. Moreover, those judgments may be articulated and argued about; for instance, they are importantly normally anchored to panelists’ sense of the state of play in their disciplines.
- 8 See Schmidtz 2001: 238; Vogler 2002: 127 ff. Schmidtz contrasts “final” with “constitutive” ends; Vogler’s term for constitutive but instrumental reasoning is “part-whole calculation.”
I expect that the common contrast of instrumental or means-end reasons with constitutive reasons is to be blamed on thinking that a means must be a cause, and a cause must be physically distinct from its effects. But this does not seem to me to be a useful distinction to introduce into discussions of practical deliberation.
Philosophers are not alone in failing to mark the distinction between the two versions of constitutive reasoning; see, e.g., Newell 1990: 174ff, on “impassé resolution.”
- 9 But we should not forget the following concern. It may be the case that institutional deliberation does – and ought to – proceed differently than practical reasoning performed by individuals. (The U.S. government deliberates by having representatives of its geographical parts assemble in Washington, where they dicker over the distribution of pork to the parts. But the right way for *you* to decide what to do is not to have your organs and limbs vote their interests.)
- 10 The example is in some ways a tricky one. One objection to using it is that Aramis, taken as a whole, is a *failed* case of practical reasoning: no specification was ever settled on, and the system was never built. My own reading of it is that Latour is recounting precisely that: A case of failed practical reasoning. But one might take the view that the failure was so bad that we should not really regard it as an instance of practical reasoning at all (in roughly the way we would not regard certain kinds of monkeying around in the kitchen as cooking at all). For this reason, I am going to be focusing on shorter deliberative episodes in the history of Aramis. (I’m grateful to Candace Vogler for pressing me on this point.)
One might reply that, one’s initial reactions notwithstanding, the Aramis episode is a *successful* instance of practical reasoning; after all, they ended up deciding to cancel it, and that was a decision, too. (This suggestion is due to Henry

Richardson.) But here I think we need to distinguish between the decision to sit tight that results from successful deliberation, and the kind of throwing up one's hands in confusion that results in sitting tight. Latour describes an autobiographical character engaged to do the post-mortem because, after all that argument (and all that money), no one knew *what* to think.

- 11 A related point is that Aramis also shows that it is unrealistic to try to decompose specificationist reasoning into theoretical reasoning (i.e., reasoning about matters of fact), here, about what options are available, and an instrumentalist decision among the options. For an instrumentalist – again, a solely means-end – decision to be feasible, one has to have available goals or ends that (already) discriminate among whatever the options turn out to be. And in the specification of a project as elaborate as Aramis, it is very implausible that one starts out equipped with such ends. For a sketch of an argument supporting this last claim, see note 36.

There can be other, political reasons for not being overly definite at the outset. Latour emphasizes that studied ambiguity – underspecification – is almost always necessary, in projects the size of Aramis, for getting an effective coalition of supporters to sign on. (48)

- 12 Broadie 1987: 238f.
 13 For a history of the specification of the ARPAnet – the ancestor of today's Internet – see Abbate 1999; for the F-16, see Fallows 1982: 95–106.
 14 Mill 1967–1989: Vol. 7, 158–162.
 15 Her assumption is not unusual, however; Anderson, 2005, discusses its role in the nineteenth-century psychology debate.
 16 The contrast is with “thin” concepts such as “good” and “right.” Discussion of thick ethical concepts was introduced into the current philosophical literature by Williams 1985: 140f. for a survey of the literature on thick ethical concepts, see Millgram 1995; for a recent follow-up, see Putnam 2002: 34–43.
 17 Testimony may of course take the place of experience, as when I am told not only that the performance is mime of such-and-such a kind, but that it is vastly entertaining. But here I rely on experience indirectly.

I have elsewhere called the view that empirical judgments can have practical content *practical empiricism*. (Millgram 2001: 16–17; for an argument in favor of the view, see Millgram 1997.). Perhaps because both practical empiricism and specificationism share the claim that one can deliberate about one's ends, I have occasionally seen the two views conflated; so here is a quick compare-and-contrast. Practical empiricism turns on the idea that you have to learn what matters from experience, using practical versions of observation and inductive arguments

from those observations. Specificationism, once again, turns on the thought that that your ends might have so little content that it would be premature to go looking for means to them, and so that a preliminary stage of adding content has to be understood as practical reasoning. As far as practical empiricism is concerned, your views about what matters could be already fully specific when they are acquired; this would allow you to skip the specification stage entirely. As far as specificationism is concerned, you could make your ends more concrete without appealing to experience at any point.

- 18 I owe this suggestion to Curtis Bridgeman. Richardson 1994: 20 ff., 152 f., 157, allows that coherence is not “indispensable,” but does argue that it “is typically rational to pursue.”
 19 I'm following analogous terminology which I'll introduce later.
 20 Specificationists argue among themselves about whether the position was Aristotle's (see note 3), so notice that an instance of the phenomenon we are examining – that in some cases of specificationist reasoning, the conditions for a successful specification are specified along with the solution itself – can be found in his *Nicomachean Ethics*. Aristotle takes it that everyone wants to live well, that is, to lead a happy and successful life, and his problem becomes that of specifying what such a life comes to. His *Ethics* is a sketch of the results of the deliberative exercise, or rather, of two different sets of results, since it's typical of vague or indefinite goals that you can specify them in more than one way. The contemplative life sketched in Book X and the active political life of Books I–IX are two alternative blueprints which Aristotle gets by running through the specificationist exercise twice.

Now the standards – such as “completeness” and “self-sufficiency” – that Aristotle announces a life must meet in order to count as *eudaimon* end up amounting to very different things in Books I–IX and X, respectively. For instance, in Books I–IX, being self-sufficient means having everything you need for a happy life; if the active life requires friends, as Aristotle thinks it does, part of being happy is having friends. In Book X, however, being self-sufficient means *not* needing things; the contemplative life is happy in part because someone who is thoroughly engaged in contemplation does not need any friends.

- 21 Russell 1989.
 22 Kolnai 2001: 272 ff. There are various ways one could object to this argument as well. First, as we've seen, weighting is probably too crude a way of thinking about it. Second, circularity is not always vicious (constraint satisfaction problems containing cycles can have unique best solutions). Third, weights can be frozen into place by one's choices: Latour points out that once the Paris subway system had chosen a track gauge

- incompatible with that of other train systems, and had dug tunnels for that gauge, it became very difficult indeed to reverse that decision.
- 23 This allows us to specify more tightly the distinction between instrumental and specificationist reasoning. On the instrumentalist view, one's goals or ends or desires together amount, at any stage of one's reasoning, to the sole standard for one's actions. So while further specifying those ends is indeed a step toward attaining those ends, because it amounts to changing the standard, it is not accepting the instrumentalist standard as is. (An analogous contrast might be that between views on which the legislature is the sole source of the law, and those on which judges, by setting precedents, are adding to the law; thus, one worry for instrumentalism is that it may be unable to reconstruct legal reasoning.)
- 24 Although Vogler does allow for second-class reasons that adduce the fact that an activity is pleasant, or that an action fits a pattern anchored in one's life.
- 25 Vogler 2002: 159–169. There are worries one might reasonably have about this move. When inductive reasoning is executed in order to arrive at an inductive conclusion, does that “in order to” make the inductive reasoning merely means-end reasoning? And if that is the wrong conclusion to draw, why should specificationist reasoning be treated any differently?
- 26 Although not one that had been articulated ahead of time: it was not as if the requirement that the system be safe had, at the outset, been given even this shape. Remember, we have here an administrator giving his retrospective diagnosis of what he regards as a fatal problem with the way the specification of security evolved.
- 27 One might suppose that there is an easy explanation at hand, namely, that Aramis was originally specified as a transit system, that a more fine-grained specification is acceptable only when it preserves the content of the thinner initial specification, and that a perfume is not a transit system. But Aramis also convincingly demonstrates that the principle this explanation invokes is false. Many quite reasonable specifications of Aramis were being explored that gave up one or another aspect of the initial description of Nominal Aramis.
- Richardson 1994: 245f, accounts for this sort of flexibility by distinguishing “abstraction” (an upward move, as it were, in a taxonomic structure) from specification (the corresponding downward move), and taking abstraction to alternate with specification proper. The important point for now is that, while we can be for the moment agnostic as to how they are managed, ambitious, Aramis-scale specifications will not be successful without such adjustments. Since there is no point in focusing on a method that will not work in the cases for which we most need it, let's specify that the specification of ends and the like be such as to allow adjustments of this kind, however in the end they turn out to be implemented.
- 28 A bit of experimentation confirms that, for any more specified version of the end of deciding what to do, one can come up with circumstances in which it is not sufficiently specified to proceed. We have already seen that there is no such thing as the generically correct specification of an end; rather, what the correct specifications might be depends on the concrete circumstances in which the problem arises. So it is not as though the generic end of deciding what to do might be replaced by a more specific goal that would successfully control one's specifications in any and all circumstances, and so which you could treat as the anchoring end of your instrumentally construed practical reasoning. If the detailed goals you would need to serve as a standard for the specification of your end must vary from occasion to occasion, but you cannot deliberate your way to them (because specificationist deliberation has been ruled out as a form of practical inference), then the chances of your coming up with them when and as you need them are *very* small.
- Notice, for instance, that the most obvious candidate – adding “in a way that's responsible to the initial specification” to the end of deciding what to do – won't do. As before, the new goal (of deciding to do *that*) inherits all the indefiniteness of the original and underspecified goal. If the end of being entertained this evening is not specified enough to serve as a starting point for thinking about what steps to take toward it, then the end of deciding (how) to be entertained this evening is also insufficiently definite. For instance, if entertainment is understood to importantly involve a significant degree of spontaneity, then a decision process that selects a form of entertainment for the evening should not be overmethodical. But if entertainment is the sort of thing that squeezes every drop of excitement out of one's scarce and precious free time, then the planning for it had better be extremely thorough. Before the end of entertainment has been further specified, the end of deciding on that specification is also not yet specified enough for one to start taking steps toward it.
- 29 Goodman 1983: 64, emphasis deleted; Goodman is describing how to arrive at a reflective equilibrium between rules of inference and our judgments about particular inferences.
- 30 Richardson 1994: 178–90.
- 31 Elgin 1996: 13, 107, distinguishes the two; coherence addresses only the mutual fit of the elements of the system, whereas reflective equilibrium addresses as well the initial tenability of those commitments (or our antecedent

commitments to them). Elgin's choice of terminology is of course up to her; however, it is standard in contemporary coherentism to include ways of taking initial tenability into account. See, for instance, Thagard 1989 and Thagard and Verbeurgt 1998 for two different specifications of coherence which do this.

- 32 For the distinction, see Daniels 1979. For the inclusion of emotions in wide reflective equilibria, see Elgin 1996: Ch. 5; Richardson 1994: 178f. (where this partial specification of it is called "reflective sovereignty"). As before, because there are many different ways of managing such adjustments, it is not as though there will be just one way of specifying wide reflective equilibrium.
- 33 For an argument that one cannot simply leave one's coherence concept vague, see Millgram 2000.
- 34 This account of narrow reflective equilibrium brings it fairly close to yet another coherence concept, Minimum Description Length (MDL). For an introduction, see Grünwald 2005.
- 35 See notes 31 and 34.
- 36 For one of the classic objections, see Nagel 1978: 27–32; for an objection of my own, see Millgram 1997: Ch. 2.

It is not that specificationists are unable to fill out what they take to be the obvious point. For instance, against the form of instrumentalist resistance I parenthetically sketched, a specificationist might point out that the specificity of one's background goals and constraints trades off with their portability; that background goals and constraints are only plausibly available in unfamiliar choice situations if they are highly portable; thus, that they will not be specified enough to drive solely instrumental reasoning in the cases for which one most needs them.

- 37 For an introductory overview, see Sosa 1980.
- 38 For a representative sample of his work, see Goldberg 2000.
- 39 For discussion of the second sort of case, see Thalos 1999; for the third, see Nehamas 1985; I'm grateful to Irene Appelbaum for the last two examples. Perhaps this very lack of specificity explains why instrumentalists like Vogler have been tempted to try to reconstruct specificationist deliberation of ends as an early phase of instrumental reasoning: they sense that this is one way in which they might further specify their own inchoate core concept.

Chapter 36: Presupposition, Attention, and Why-Questions¹

JONATHAN E. ADLER

Philosophers and psychologists share an interest in understanding the everyday activity of explaining, which I take up as it intersects pragmatics and reasoning. How does the distinction between the *focus* and the *presuppositions* of *why-questions* orient or bias answers to those questions and what are the implications for conclusions drawn of systematic errors and fallacies, particularly in how subjects respond to why-questions about chance phenomena?²

The pragmatics perspective is usually construed as an attempt to show that the experimenter's presentation misleads subjects with the implication that the experimenter's ascription of errors and fallacies is not warranted. Schwarz (1996), in a book extending research on pragmatic influences on experimental judgments, writes in an introductory chapter:

Research participants... have no reason to suspect that the researcher is not a cooperative communicator and are hence likely to find meaning in the researcher's contributions.

The findings reviewed in the following chapters suggest that this basic misunderstanding about the cooperative nature of the communication in research settings has contributed to some of the more puzzling findings in social and psychological research and is, in part, responsible for the less than flattering picture of human judgmental abilities that has emerged from psychological research. (1996: 5)³

The role of pragmatics that I explore is related, but it leads to a different, although strictly compatible, conclusion. Pragmatics contributes to explaining subjects' responses. But

the contribution I follow out supports ascriptions of erroneous reasoning. I take for granted that explaining is not justifying. Unless my account of the influence of pragmatics on subjects' responses is viewed only as a contribution to explaining, not justifying, those responses, my argument will appear incoherent.

1. Why-Questions: Presupposition and Focus

Why-questions generally structure the set of answers contrastively (Dretske 1972). I might not be able to explain why I rode on the third car of the train, but I may still be able to explain why I rode on the third car *rather than* the last one (because to exit from the last one at my station you have to walk to forward cars). For a more developed example: Asking, "Why did Jim *kiss* Mary?" (with emphasis on "kiss") presupposes that Jim and Mary did something together and focuses us on Jim having kissed – rather than, say, calling, blessing, cursing, hugging – Mary. Asking instead, "Why did *Jim* kiss Mary?" presupposes that someone kissed Mary and shifts focus on Jim's having done it, rather than, say, Tom, Jane, or Tony. The response "Because that is how Jim greets his close friends" is a candidate answer to the first, but not to the second, and conversely for "Unlike the others, only Jim had the opportunity to greet Mary." If you gave the latter answer to the former question, the questioner might naturally respond, "I know that only Jim had the opportunity to greet Mary. I wanted to know why he greeted her with a kiss."

A difference in emphasis or stress is generally implicit in the formulation of the question, due to natural stress patterns (usually favoring the subject term) or to emphasis or to the

operation of certain particles (e.g., “only”) or to conventions such as that old information comes first. The question “Why did Jim kiss Mary?” reports the old information or norm that Jim kissed someone and then it offers the new, deviant, or surprising information that it is Mary. Semantically equivalent forms can have different foci: Why was Mary kissed by Jim – the focus is now on Jim, whereas previously it was on Mary. A difference in focus is also affected by mutual beliefs as to what is known and what is in question, which can resolve potential conflicts among the different criteria of focus. If it is mutual between speaker and hearer that someone kissed Mary, the focus will turn to Jim. So, a standard – unmarked – informative answer to a why-question will respond to its focus – why, in the original case, did Jim kiss Mary, rather than someone else; and not why Mary was kissed by Jim, rather than someone else.

The contrastive and related structuring of why-questions renders the explanatory task feasible and economical. There are an unlimited number of necessary conditions in any causal chain to an event. By presupposing most of these, focus is fixed on the few causes that make the difference between the event’s occurring or not in the circumstances. Explaining the hole in the couch can be accomplished by reporting only that a lit cigarette was dropped on it, even though the burn depends on various standing conditions like the presence of oxygen. Focus-presupposition structuring is in the spirit of Grice’s (1989) maxim of orderliness and the related economizing that Sperber and Wilson (1986) treat as one of the two factors which determines the relevance of a conversational contribution.

2. The Deflationary Claim and the Reformulation Strategy

Hilton (1990) and Kahneman and Miller (2002) converge on applying the pragmatics of why-questions to counterfactual reasoning, the integration of base-rates, and actor-observer asymmetries in attribution theory. The latter two are tightly connected. In accord with related research, attribution studies find that subjects tend to answer seemingly neutral questions like “Why did Jones help Smith with his move?” by citing the actor’s traits (e.g., Jones is helpful), rather than because of the nature of the situation.⁴ The response occurs where the background information is limited and neutral, and even in the absence of any further information at

all. Subjects’ explanation by appeal to the traits of the actor – a *correspondent inference* – is held to exhibit a bias referred to as “the fundamental attribution error.”

The rational model for attribution is, in simplest form, Mill’s method of difference: If two otherwise similar events differ only in the presence in one of a certain factor, and if the event with that factor led to an effect (if, among viable candidate causes, omitting that factor alone fails to yield that effect), then that factor is its cause. (In its more complex and realistic form, Mill’s method of difference transforms into the analysis of variance.) If many people help Smith, if the “consensus” for helping Smith is high anyway, there is nothing special about Jones’s helping him. So, if the formal attribution model holds, subjects’ learning that many help Smith should diminish the inference to Jones as the locus of responsibility. But the finding is that it does not significantly do so, supporting the claim of a fundamental attribution *error*.

To demonstrate the role of pragmatics in such findings, experimenters vary the formulation of a why-question or of background knowledge. If the answers subjects now provide varies with these alterations in presupposition and focus, the results are taken to weaken conclusions that subjects’ responses to the original question are biased or flawed or errors. I’ll call this the *deflationary claim*:

In respect of studies . . . , the negative conclusions (of errors and worse) that have been drawn are unwarranted.

The deflationary claim is taken to follow from showing that the findings critical of subjects’ judgments are strongly question-formulation dependent. Consequently, either subjects’ responses are not genuine errors, given the real question communicated, or even if they are errors, they are transient or superficial, since the correct answer will be elicited by a mere reformulation of the question. (As is evident from these and other writings, Hilton holds this claim far more widely and deeply than do Kahneman and Miller.) Hilton (1990) writes:

many biases in causal explanations may not reflect variations in underlying beliefs about causal processes, but may instead be due to the dynamics of interpersonal question-answer processes. (73)

Kahneman and Miller’s (2002) norm theory is offered to explain our tendencies to belief perseverance, as well as to the fundamental

attribution error. Once a norm is activated, which is “rapid and automatic,” it is not subject to voluntary control:

Any observation of behavior – even if it is discounted or discredited – increases the normality of subsequent recurrences of compatible behavior. (361)

Kahneman and Miller (2002) observe that presupposition affects *mutability* (the alterability of a situation, particularly under counterfactual suppositions): “the mutability of any aspect of a situation increases when attention is directed to it and that unattended aspects then become part of the presupposed background.” (353) To illustrate that a “Why question implies that a norm has been violated” and that “A why question, then, presupposes that some state X is the case, and also implies an assertion that not-X was normal,” they offer the following illustrative exchange:

Q: “Why did Joan pass this math exam?”

A: “She used the Brown textbook.”

In accord with Dretske’s analysis, they take the why-question to indicate that

a particular event is surprising [Joan’s passing] and requests the explanation of an *effect*, defined as a contrast between an observation and a more normal alternative [Joan’s failing]. (362)

Kahneman and Miller observe that differences in the explanations provided follow upon differences in stress or emphasis. They conclude that the alteration in response justifies the deflationary claim: The difference in responses “*reflect different interpretations of an ambiguous question rather than different causal beliefs*” (364, my emphasis).

Another example that Kahneman and Miller offer is of a woman picking out causes of her husband’s illness different from her doctor’s, which they compare to the actor-observer asymmetries posited in attribution theory. However, the differences cannot be explained simply in those terms:

The contrast could not be explained by differences of knowledge... or of perceptual salience... It is not explained by the distinction between a state of self-consciousness and other states of consciousness... Nor is it compatible with the hypothesis that the focus of attention is assigned a dominant causal role... inasmuch as the husband surely plays

a more focal emotional role for the wife than for the physician. (365)

Rather,

The hypothesis of the present treatment is that the same events evoke different norms in the wife and the physician of the example, and in actors and observers in other situations.

Accordingly, the conclusion they draw parallels Hilton’s (1990):

Different descriptions of the same event can appear to provide conflicting answers to the same question, when in fact they are concerned with different questions. This proposal can be subjected to a simple test: Do the observers actually disagree? A negative answer is suggested by several studies. (365)

The conclusion that the alternatively focused questions are (contrastively) different questions is crucial for the deflationary conclusion. In studies of “framing” (e.g., Tversky and Kahneman 1981) different answers to formally equivalent, though variably formulated questions (by, e.g., changing reference points or altering expressions to be stated in gains, rather than losses) are taken as evidence of suggestive, but strictly irrelevant, influences on subjects’ judgments and so unresponsive of a deflationary claim.

Hilton notes that the actor-observer asymmetry of attribution theory is that

Actors tend to explain events by reference to characteristics of the situation, whereas observers tend to explain events by reference to personal characteristics. (74)

The link between attribution theory and presupposition/focus, already touched on, is that

an actor presupposes his or her presence as a constant background factor and asks him- or herself what is special about the situation that caused his or her behavior. In contrast, observers treat the situation as background and focus on what is special about the actor that differentiates him or her from other people in the same situation. (74)

The conjecture is that

if the causal question is disambiguated by specifying the relevant reference class for the target event, then the actor-observer difference should disappear. This is what McGill (1989) found.

From the original question “Why did you [your best friend] choose this major?,” two “disambiguations” were offered, which *overtly* direct focus:

Why did you [your best friend] in particular choose this major? (Person focus, stimulus background)

and

Why did you [your best friend] choose this major in particular? (Person background, stimulus focus)

The reformulations elicit from subjects the sought for answer. The central finding is similar to that reached by Kahneman and Miller:

Consistent with the conversational model, subjects gave explanations that were relevant to the explicit focus of the question. . . . No effect of actor-observer differences were found in the presence of this explicit focus manipulation. As McGill observed, these results are consistent with the view that actor-observer differences in causal explanation are due to the implicit focus and may *not reflect differences in underlying beliefs about the true causes of behavior*. (74, my emphasis)

McGill (1989) did similar studies to explain-away asymmetries in attributions of one’s success (as due to internal factors) and failure (as due to external factors).

Granted that the *reformulation strategy*, as I’ll refer to it, works in Hilton (1990) and Kahneman and Miller’s (2002) applications, does a presupposition-focus role always justify such a deflationary conclusion? I’ll argue for a negative answer, as just hinted at: there are important cases in which a pragmatic analysis helps to explain observed biases or flaws in reasoning, rather than to explain them away.

3. Why-Questions and Chance Explanations: A Presuppositional Incompatibility

In light of this convergence to the deflationary claim, I want to look at neighboring studies, whose findings also seem affected by a presuppositional structuring of why-questions, yet which do not support a deflationary claim. I’ll begin by applying the reformulation strategy found in Hilton (1990) and Kahneman and Miller (2002). The results will not be a similar alteration in subjects’ judgments, I conjecture, or they would introduce confounds of their own.

In a study (Jepson, Krantz, and Nisbett 1983) of the understanding of the law of large numbers and regression by those untrained in statistics, subjects are asked to answer a set of questions for which open-ended, discursive, answers are sought on a variety of topics. I first abbreviate two on baseball batting averages:

1. After the first two weeks of the baseball season the leader has a batting average that is over .450. Yet, no batter ever finishes a season with a better than .450 average. What do you think is the most likely explanation for the fact that batting averages are higher early in the season? (500)

A typical answer of subjects is:

As the season commences a player will, I think, become less motivated to impress people with a powerful bat – he is taking a sort of ho-hum attitude about it.

The favored response is anything like:

The amount of times at bat versus the result is far greater earlier in the year than at the end of the year. . . . The more frequency he [a player] bats the clearer the truth information as to how well a batter hits. (500)

The second is suggested by Nisbett and Ross’s (1980) discussion of the “sophomore slump” (164–165):

2. Why did [baseball] rookie Smith, who did so well his freshman year (‘rookie of the year’), do so much worse his second year?

The fairly typical answers are that he was spoiled by success, that the pitchers caught on to how to throw to him, that he was exhausted after his first year and stopped training as hard, and so on. These answers are comparable to those, reported in the early work of Kahneman and Tversky (1982a). Flight instructors claimed that because criticism of their students for very bad performance was followed by better performance, and conversely for praise for very good performance, they would alter their teaching accordingly (to offer only criticism).

Contrast these candidate answers with the favored one:

by chance alone [i.e., regression to the mean], some mediocre athletes will perform exceptionally well in their first year but perform less well in subsequent years. . . . In other words, the best explanation for a sophomore slump

is that the first year was atypical for the performer in question while the second year showed regression toward his “true” ability level or performance base line. (165)

In general, the experimenters found that

Most of these answers presumed, either tacitly or explicitly, that the sample was adequate and showed no recognition of the uncertain or probabilistic nature of events of the kind presented in the problems. (496)

However, the actual results displayed a good deal of variation. Specifically, when the problems are ones that are more readily regarded as objective and measurable, subjects are more inclined to offer statistical answers. For [1], 34 percent provided a statistical answer, and 66 percent either an “intermediate” or “deterministic” one. For the sake of brevity, I shall ignore these individual differences, despite their significance. Systematic statistical answers are correlated with higher SAT scores (Stanovich 1999). Still, when I refer to subjects answers, it will be just to the nonstatistical ones, since that represents, in brief form, the dominant finding.

The findings are explained in familiar ways as due to the use of faulty, but easy to apply, assumptions or heuristics, especially representativeness (a judgment of similarity). These assumptions or heuristics obscure the role of chance or randomness (Kahneman, Slovic, and Tversky 1982). The explanations that subjects offer, for example, that the batter became too cocky, are similar to ones that make good common sense. Performers who become conceited due to their success in a skilled demanding activity relax their efforts and then do worse.

Con conversationally, the focus of the why-question for [2] is Smith’s doing worse his sophomore year, rather than the same or better. The focus of the why-question for [1] is similar – why those who bat over .450 at the beginning of the season finish lower at the end, rather than around the same or better. Both why-questions seek *puzzle-reducing* explanations, rather than neutral, *information-seeking* explanations, since each implies that there is something unexpected or deviant or out of the normal about the phenomena observed.

Why-questions presuppose that an observation or phenomena *calls for explanation*. Someone’s winning a fair, large lottery, however improbable, does not call for explanation, since someone had to win and each ticket had an

equal chance. But if the answers of only two students to a many-question multiple choice test is the same, including the same errors, then, as so described, it calls for explanation, even if more probable as a chance occurrence than winning a lottery.⁵

The why-question automatically introduces as background a bias that what is to be explained is deviant. As Nozick (1981) observed, we ask “Why is there something rather than nothing?” treating the natural state as one of nothing existing, and something as the deviation from it. To reduce the puzzle is to explain how we moved from the latter to the former. (There is a partial parallel to our hearing asymmetrically, for example “Why is South Korea like Japan?” [Tversky 1977]. The parallel is only partial because asking “Why is there nothing rather than something?” alone presupposes a blatant falsity.)

Events or occurrences that are surprising or disturb expectations call for explanation. Is surprise or the disturbance of expectations sufficient? If I expect that the person I will meet at a conference is male because “his” name is “Tony,” and it turns out that Tony is a female, I am surprised (and it disturbs my expectations). But it does not call for explanation. A call for explanation requires also that the event or occurrence is puzzling, a prominent way to surprise or to disturb expectations. A good explanation shows that the phenomena, contrary to our initial reaction, was bound to occur.

The pragmatic problem this presupposition of the why-question raises in the baseball studies is that the call for explanation is *incompatible* with the experimenters favored account. The regression or chance account explains the alteration observed only by denying the presupposition of the question that there is either significant discrepancy in early/late baseball batting averages or in a “sophomore slump” – a strikingly unexpected decline in the sophomore year of baseball players who do outstandingly well their freshman year. It is plausible that the formal incompatibility generates a psychological barrier to, or bias against, the chance or regression account, which plays a role in explaining the results. But the arguments and certainly the evidence for this conclusion are inconclusive.

The chance or regression answer is presuppositionally incompatible with any of the subjects’ answers, so that a reformulation strategy like those adopted by Hilton (1990) and Kahneman and Miller (2002) is unlikely to move subjects

to the sought for – chance – response. Reformulations that closely adhere to the above models by altering the location of stress include:

- 1a. After the first two weeks of the baseball season, the leader has a batting average that is over .450. Yet, no batter ever finishes a season with a better than .450 average. What do you think is the most likely explanation for the fact that *batting averages* are higher early in the season?
- 2a. Why did [baseball] *rookie Smith*, who did so well his freshman year (“rookie of the year”), do so much worse his second year?

Other reformulations are clearly possible to move the stress or emphasis, and so focus, elsewhere. Still, in the absence of any further context, these reformulations either do not make much sense or they are misleading. To place stress on Smith [in 2a] falsely implicates that the poorer showing is special to him, an issue to which I return below. In any case, neither of these reformulations, nor others that simply alter focus, are likely to yield a dominant shift to a regression or law of large numbers explanation.

Compare them to the following heavy-handed reformulations:

- 1b. After the first two weeks of the baseball season the leader has a batting average that is over .450. Yet, no batter ever finishes a season with a better than .450 average. Is this surprising? However you answer the previous question, what do you think is the most likely explanation for the fact that the average of the leading batter is so much higher early in the season than at the end?
 - 2b. Rookie Smith, who did so well his freshman year (“rookie of the year”), did much worse his second year.
- Q: “Whether this is surprising [unexpected] or not, how do you explain it?”

These alternative questions are more promising than the previous ones [1a/2a] to impose hurdles to the subjects’ standard responses, rather than an admission that one does not know. They are also likely, though much less so, to elicit the chance or regression response. However, these reformulations [1b/2b] are more intrusive and extreme than the previous ones, which merely shift focus. They attempt to neutralize key presuppositions, undermining the appropriateness

of asking the respective questions. Because of this confound and for a number of related reasons, which I pursue, even if the promise of these reformulations are empirically confirmed, they provide little support for a deflationary claim.

4. Reformulation: Light and Heavy-Handed

These last reformulations [1b/2b] do not merely generate a different focus than the original ones, they emphasize that focus, as with the studies that Hilton (1990) discusses, which depend on the overt “in particular.” These heavy-handed reformulations raise doubts about the pragmatic equivalence to either the original or, more crucially, to the natural way of asking the intended question, even if unavoidable with written instructions. To make sense of the “in particular” subjects are compelled toward the desired focus. The directing of focus does not correspond to the easy and implicit way that it is normally realized, even if requiring some contrivance or awkwardness (e.g., switching to the passive voice). In the opening examples, for comparison, shifts in focus arose from minor differences in formulation or stress.

A different study helps to sharpen the concern. In a recent article, Johnson-Laird reports (2005: 201) on the following problem:

If a pilot falls from a plane without a parachute, the pilot dies. This pilot did not die, however. Why not?

Most people respond, for example, that

The plane was on the ground.

The pilot fell into a deep snow drift.

Only a minority draws the logically valid conclusion:

The pilot did not fall from the plane without a parachute.

After presenting the example, Johnson-Laird comments:

Hence, people prefer a causal explanation repudiating the first premise to a valid deduction, albeit they may presuppose that the antecedent of the conditional is true. Granted that knowledge usually takes precedence over contradictory assertions; the explanatory mechanism should dominate the ability to make deductions. (Johnson-Laird 2005: 201)

Johnson-Laird's why-not question presupposes both that the pilot did not die and crucially that his not dying calls for explanation.⁶ The subjects' answers accept the latter presupposition, while a "valid conclusion" answer would reject it. Clearly, if the pilot did fall with a parachute, there is no call to explain his not dying.

One simple reformulation would alter focus by a shift in stress:

3. If a pilot falls from a plane without a parachute, the pilot dies. This pilot did not die, however. Why not?

With sufficient stress, I expect that subjects will be moved to shift their answers to the explaining-away (presupposition-rejecting) response: "The pilot did not fall from the plane without a parachute." But even if so, we are not inclined to draw a deflationary conclusion. The alteration in stress cues subjects to a conditional reading of the "if" clause, whereas subjects seem to be treating it more as a task-demanded supposition (a conditional assertion), responsive to the why-question.

The reformulation strategy is most effective for supporting a deflationary claim as the reformulation is the more minimal. The danger of heavy-handed reformulations for a deflationary end is reminiscent of the obvious difficulty that Socrates' leading questions to the slave-boy in the *Meno* (Plato 1981) pose. Socrates intends to show that the slave-boy innately knows how much one must increase the sides of a square to double its area. Socrates draws the crucial geometrical model and his questions guide the slave-boy to just the relevant observations of the model. But Socrates must claim not to be instructing the slave-boy, which is undermined by his very method.

In our main example, the presupposition of the why-question removes from candidacy a statistical answer. However, the failure of a simple reformulation strategy shows that the statistical answer is not just waiting in the wings for the right elicitation, which raises a question: If a shift in focal attention (to what?) will not elicit a statistical answer, exactly what role does presupposition play? (How do we know presupposition is actually at work in the answers subjects' offer, rather than a general distaste for statistical or chance explanations?) I address the question subsequent to setting out more of the relevant workings of presupposition.

5. Presuppositional Workings: Norms

The presupposition of the why-question of a call for explanation places a chance, statistical, or regression account in a presuppositionally rejected position. The force of presuppositional placement reflects its workings, which are now divided in two: Those due to pragmatic norms, treated in this section, and those due to psychological workings, treated in the next. In both ways, and in an extension of my previous discussion, what is presupposed – such as that the sophomore slump calls for explanation (or that it even exists) – is less available to subjects, and that lesser availability helps to explain subjects' dominant answers.

Presuppositions influence our judgments or inferences as reasons, not mere primes. In studies of dichotic listening, the hearing of one word primes or causally triggers an association that leads to the selection of a matching word from a list without an implied claim that one is the reason for the other (e.g., "basketball," "tall"). Well-known studies by Loftus (1975) and her associates help to clarify the distinction. In one study, subjects view a film. Those who are asked "Did you see the children getting on the school bus?" report having seen a school bus (unlike control groups), although none were present. Did the presupposition of the question that the children get on the school bus influence the subjects' judgment as a presupposition? The result should then be different if the experimenter had first asked "Was there a school bus present?," placing the previous presupposition now in focal position. If the presupposition of the question did play a role as a presupposition, not just as a prime, acceptance of it would be the subjects' reason for judging that they saw the children on the school bus. If, however, it functioned only as a mere prime or causal trigger, as with the dichotic listening studies, the influence should hold even if the experimenter had casually observed "I was late because a school bus got stuck in front of me." The former influence – as a reason and presupposition – should be stronger. Analogously, in the sophomore slump study, the experimenter's question "Why did Rookie Smith...?" provides the hearer (subject), who accommodates to it, with a reason to treat Smith's sophomore slump as calling for an explanation.

Introducing a presupposition by a question rather than an assertion is a more subtle way to influence subjects' judgments, since a question

questions, it does not state. But in answering a question or accepting an assertion or even in offering a standard challenge “How do you know that *p*?” the hearer represents himself as endorsing the presupposition. Yet, the speaker claims the truth of what he asserts, not what he presupposes.⁷

However, the norms of presupposition, like other conversational norms, can be violated, as well as denied or challenged. S: “Even Mikey likes Life” (a breakfast cereal). H: “Why do you say ‘Even Mikey’? He actually likes a lot of foods.” The regular option to challenge a presupposition weakens the usual charge associated with a pragmatic approach to reasoning studies that subjects are misled.

We are familiar with challenges to why-questions by appeal to chance: “Why did the phone company give me a number that is so hard to recall, but they gave my friend Bill one that is so easy?” “There’s no why to it. It’s just chance.” Or, if the roulette wheel comes up red six times in a row, one gambler says to the other, “The roulette wheel must be fixed to favor red. How else do you explain these outcomes?” His buddy responds, “Look, there is no ‘why’ about it. It’s just chance. There are bound to be some runs that involve getting many reds in a row.” (A similar presupposition-rejecting response would be appropriate if the friend commits a “gambler’s fallacy”: “It’s now much more likely to come up black next.”). Regression provides the basis for a closely related, though less frequent, way to challenge a why-question: “Jim’s sisters are both such huge successes, how come he has not done nearly as well?” “But you cannot expect most anyone to match that stand out achievement, even a sibling.”

As an implicit denial of the call for an explanation, the presupposition-rejecting response “Look, there is no ‘why’ to it, it’s just chance” expresses our folk understanding. Although our folk understanding leaves room for chance or randomness to be involved in whole or partial explanations, they differ, as indicated, from standard presupposition-accepting ones, which remove puzzlement or perplexity or surprise, usually positing the workings of an underlying mechanism, not, effectively, the denial of one. Correspondingly, there is a conversational difference between reporting on an observation with the implication that it calls for explanation and not so implying.

In particular, only the former achieves, on its surface, relevance for the hearer. If the observa-

tion to which the why-question is directed is not surprising, the speaker lacks a mutually apparent reason to introduce his question. Speakers are expected to report only those observations or beliefs that purport to have some informational value to the hearer. Placing the presupposed fact – that the observation calls for explanation – into a focal position [1b/2b] is in tension with the expectation that reporting the observation will be informative to the hearer (subjects).⁸ The why-question innocently misleads subjects to expect that a distinctive mechanism is involved in accounting for the change in performance, rather than a process that implies that the change is insignificant, since only the workings of chance.

Subjects’ tacit acceptance of the presupposition (that the baseball phenomena call for a nonchance explanation) is a correlative of the unavailability of the chance account, though, as just noted, we have all had occasion to challenge that kind of presupposition. What kind of unavailability is generated by presupposition in cases like those before us? Why is it generally difficult to challenge presuppositions, though we do so when the contrary beliefs are salient? What are the (further) difficulties specific to explanatory presuppositions?

As noted above, asking someone a question presupposes that he is competent to answer it. The question itself is simply a request for information from another, so that it does not place any restraints on how the informant answers. More basically, presuppositions, especially presuppositions of a question, are difficult to challenge because they appear not to be subject to challenge. They are not asserted and so, recall, do not enter claims, which are a call on attention.

Hearers represent themselves as accepting presuppositions in accepting (or denying) the assertion. Once the hearer has accepted a presupposition, however inadvertently, which he subsequently questions (i.e., he challenges the speaker), he takes back a concession already granted. The hearer thereby admits that he wasted the speaker’s time in a kind of pretense, even though misleading himself as well. The dilemma, somewhat like that for complex questions, is that hearers are generally only positioned to challenge a presupposition by accepting the assertion, and thereby the presupposition.

Another barrier to challenging a presupposition is specific to why-questions and its kin, and it is at the historical root of the discussion of presupposition: The natural reading of the

why-p question is contrastive (an internal negation): "Why did Smith do so much worse his second year, *rather than the same or better?*" The implied contrastive contraries nevertheless share the presupposition that it is a fact that Smith's performance changed unexpectedly. The question then appears to exhaust the field, as if the alternative is the contradictory (an external negation), leaving no room for an option that rejects the presupposition.

A different barrier is the norm of politeness, which is a way to avoid the speaker's "losing face," and thus a way to promote cooperation (Brown and Levinson 1978). The politeness involved is the routine kind, as in stating requests as questions, which operate best as habitual or automatic. To challenge a presupposition is to challenge the speaker's entitlement to enter the assertion. In the "Emperor's New Clothes," challenging the Emperor's statements and questions ("What do you think of my robe?") threatens impoliteness in two ways, leaving aside that he is Emperor: To challenge his presupposition that he is wearing clothes is more of a rebuke than challenging the focal matter of their quality, and the more evident the falsity of what a speaker says, the harsher the challenge that calls attention to it.

Finally, presuppositions are sometimes taken for granted not because of their presumed evident truth, but because of their insignificance relative to what the speaker intends to communicate. In these cases, to deny a presupposition is either to be obtuse to the speaker's intended communicative purpose or to be a stickler. To adapt a well-known example: At a party, you and the hearer are looking in the same direction. You say of the person that you are gesturing toward, "The man drinking the martini is a spy." The actual content of this "referential use" of the presupposition that the man is drinking a martini is unimportant, so long as it succeeds at yielding attention to the intended man. If the hearer believes that the man is drinking water and he offers that belief as the basis to challenge the speaker's presupposition, he would either miss the speaker's obvious main point (that the man is a spy), or else, he is playing the stickler, whose challenge just interferes with communicative purposes.

6. Presuppositional Workings: Attention

The pragmatic and normative obstacles are presumably best enforced or learned by coming to operate as habits. Focus undermines avail-

ability by placing presuppositions in the background, diminishing the burdens on the "scarce resource" of attention (Kahneman 1973), providing an effortless mechanism to maintain the pragmatic norms. You avoid the temptation to violate a norm, if you do not notice opportunities for violation. The presupposition of a call for explanation removes a chance or regression answer from even candidacy to answer the why-questions, merely as a by-product of focus elsewhere.

The key pragmatic difference between what a speaker presupposes and what he asserts is also the key psychological difference – a speaker *claims* the truth only of what he asserts, not what he presupposes. Presuppositions are more difficult than the corresponding focal assertions to *recognize* as open to denial or to challenge than the focal assertion. Lewis (1983) extends something like Grice's cooperative principle to presuppositions:

it's not as easy as you might think to say something that will be unacceptable for lack of required presuppositions. Say something that requires a missing presupposition, and straightaway that presupposition springs into existence... (234; for related discussion see essays 1 and 2 in Stalnaker 1999, including presupposition as mainly pragmatic and psychological, not semantic, phenomena).

In the previous example, if I assert "Even Mikey likes *Life*", and you have no reason to doubt it, as when you do not know Mikey well, then "straightaway" you accept that Mikey is antecedently unlikely to like *Life*, rather than place the burden on the speaker to provide evidence. The accommodation by hearers to speakers' presuppositions is standardly automatic and nonconscious. Nevertheless, it counts as an endorsement or commitment or some similar positive normative judgment, since the presupposition is comprehended and it goes unchallenged. Not to say "no," given the governing default norms, is to acquiesce to "yes."

The psychological operation fits with Gestalt principles for organizing a perceptual field into a foreground against an unnoticed background, which, nevertheless, serves to highlight and orient the perceiver to what is foreground. Speakers' presuppositions are to be treated as background, yet they may amount to new information for the hearer. If I say, "My guru is coming for dinner," I presuppose that I have a guru, and by so doing, I may intend to convey new

information to the audience (Stalnaker 1999: 49–52).⁹

One Gestalt-like reason to expect self-other asymmetries in attribution is a difference in perceptual salience: To understand others' actions, we view the individuals as prominent against a background of circumstances, whereas the reverse is true for our own actions (the circumstances eliciting the actions is more prominent). Research on the role of attention in visual perception, as well as in verbal comprehension, shows the narrowness of attention compared to what is processed. Even Pylyshyn (2003: Ch. 4), an enemy of top-down penetration of visual perception, allows that cognition can affect early vision by selectively directing visual process. "Dichotic presentations" in tests of verbal comprehension show that information in "rejected" channels affects interpretation in the accepted channel (Lackner and Garrett 1972).

A first step in trying to locate presuppositional inattention among research on selective perception or "inattention blindness" (Mack and Rock 1998) is with "change blindness," in which substantial and meaningful, but non-prominent, objects are missed. They are either unseen or, more plausibly, seen but inaccessible to working memory or to reporting. Unsurprisingly, but still significantly here, more severe change blindness is found with alterations in the scene's background than in the foreground, even when the changes in the background are more extensive. Also, semantic priming can reduce change blindness (Turatto, Angrill, Mazza, Umiltà, and Driver 2002). However, unlike for change blindness (or "blind-sight"), presuppositional inattention escapes notice within the domain of what is comprehended and accessible.

A better model is provided by the following unremarkable vignette: About a half-hour after leaving a restaurant, I suddenly and vividly realized that I left the restaurant with the bill unsigned and my credit card on the table. I comprehended these items on the table when I was in the restaurant, otherwise I could not have so vividly recovered them from memory. The model, though better, is still very imperfect. In the studies, attention is directed toward the task and its content, whereas in the restaurant scenario there is no external or explicit directing of attention at all. The memory just pops back due, presumably, to some haphazard cue or stimulus. In this respect, the restaurant scenario is the more realistic (and the more appropriate model for evaluation of pragmatic influences). No one

is selecting information for you to comprehend, setting you a task based on that information, and eliciting an answer.

This disparity between focal attention and cognitive illusions can be obscured by comparisons between the coexistence of knowledge and perception in perceptual illusions like the Mueller-Lyer illusion (Sloman 2002). Ordinarily, although you know about the Mueller-Lyer illusion, no one tells you that right now you are looking at a Mueller-Lyer pair embedded in a natural context. When you are not given advance preparation and you are asked: What are their relative sizes? You answer that one is much larger than the other. You do not experience any conflict.

The workings of attention induced by presupposition apply to other studies, like those on base rates. But such applications suggest a conflict. In a recent article, Kahneman and Frederick (2005) observe that in the Kahneman and Tversky studies (on base rates 1982b and conjunction Tversky and Kahneman 2002), the information favoring an alternative analysis was not always presented in a "subtle" way, but in a pointed way. Yet, subjects still ignore it:

The engineer-lawyer problem (Kahneman and Tversky, 1973) included special instructions to ensure that respondents would notice the base rates of the outcomes. The brief personality descriptions shown to respondents were reported to have been drawn from a set containing descriptions of 30 lawyers and 70 engineers (or vice versa), and respondents were asked 'What is the probability that this description belongs to one of the 30 lawyers in the sample of 100?' To the authors' surprise, base rates were largely neglected in the responses, despite their salience in the instructions. Similarly, the authors were later shocked to discover that more than 80% of undergraduates committed a conjunction error even when asked point blank whether Linda was more likely to be 'a bank teller' or 'a bank teller who is active in the feminist movement' (Tversky and Kahneman 1983). The novelty of these additional direct or 'transparent' tests was the finding that respondents continued to show the biases associated with representativeness even in the presence of strong cues pointing to the normative response. (276)

(In the section called "transparent tests" for the "Linda" conjunction study, a majority of subjects do not convert to the "bank teller" answer,

though a substantial number change, when Tversky and Kahneman offer an explicit argument that every feminist bank teller is a bank teller, but not conversely [1983/2002].)

One way of expressing the compatibility of Kahneman and Frederick's (2005) claim with my proposals is that they are concerned with the explicitness of the information presented to subjects, in order to study how strong are the heuristics influencing subjects. My concern is with the organization of the information, which determines what is background (unnoticed) and focal, as well as the sources that promote this organization. (The organization would be pointless if we were Cartesian minds, where all thoughts and their components are equally in awareness.) Presuppositional inattention presumes comprehension, so that it is obviously compatible with a "transparent" presentation.

Presuppositional structuring is necessary to keep linguistic communication from demanding too much. For, at its most basic, linguistic communication is a directive to hearers to focus attention on the speaker's contribution to recover his communicative intention. To lessen the demands on attention, a good amount of what is linguistically communicated, as through implicature, is implicit. It draws on what is presupposed or placed in the background. Since its working in informing comprehension must be largely automatic and non-conscious, implicitness is easily exploited, as with the child's joke, "How many animals of each kind did Moses take on the ark?" (Erikson and Mattson 1981; Reder and Cleeremans 1990 observe that people notice the false information when "Moses" is placed in focal position, although their reformulation involves other alterations: "Was it Moses who took two animals of each kind on the ark?").

We exploit the great breadth of consciousness or attention in very different mental activities. We manipulate our focus and attention in such ordinary activities as reading literature or watching TV or movies. We make-believe, mentally bracketing our knowledge that the story is fictional to absorb ourselves psychologically and emotionally in the story. We know that whenever we need to, we can end the bracketing, although sometimes we bracket so well as to convince (deceive) ourselves. The townsfolk in 'The Emperor's New Clothes' seek to avoid the affront to the Emperor by positioning themselves not to notice that he is naked, which, of course, requires that they do already notice that he is naked. They must deceive themselves

otherwise including that they are attempting to deceive themselves.

In both the treatment of norms of presupposition and in their workings, I have noted various ways in which presuppositions strength is variable and subject to our intervention. Hilton (1990) and Kahneman and Miller (2002) do not address the strength of presuppositions or focus. I suspect it is because the workings are largely automatic and nonconscious. They then consign the operation to the broad category of "outside our control." However, while presuppositions do work that way, the possibility of challenge or denial remains as part of those workings. The treatment of presuppositions as outside our control is also misleading. The treatment obscures normative and psychological sources of resistance to challenges: Despite its normal non-conscious workings, what is presupposed by a hearer in accepting a question, garners thereby, although tacitly, his positive evaluation, as is true of the original perplexity – to deny a statement containing a presupposition is to represent oneself as endorsing it.

7. Reinforcement and Understanding: Pragmatics over Time

A central aim in the previous sections is to show that pragmatics can have a role in explaining the results on studies of reasoning – specifically, studies of explanatory reasoning about sets of events governed by the law of large numbers and regression – without that role supporting a deflationary claim, particularly one justified by a reformulation strategy. A thoroughgoing attempt to invoke pragmatics to explain away the critical import of the reasoning studies is implausible, since the results of very different experiments converge. In a range of studies, an unobtrusive reformulation strategy is not readily available or it meets with only limited success (e.g., the base rate and conjunction studies). Also, over many of these studies, Stanovich (1999) has developed insights as to systematic individual differences correlated with greater intelligence for those who provide the favored answer.

The pragmatics of why-questions imposes a barrier to recognizing an alternative (statistical) answer and to placing in focal position the assumptions informing subjects' answers. The workings, as largely appearing successful and so confirming those assumptions, reinforce a weak or poor understanding of statistical influences.

In defending these claims, I complete an answer to a dilemma for my account: If subjects do shift answers with the (b) variations, then either the pattern follows the previous examples (from Hilton [1990] and Kahneman and Miller [2002]), which supports a deflationary claim or else, it is due to the posing of “leading questions.” Because the latter strongly cues subjects, it diminishes the value of the study for investigating subjects’ understanding of the law of large numbers or regression. If, instead, subjects do not shift answers markedly toward a statistical one, the failing undermines the role accorded to presupposition/focus in accounting for subjects’ erroneous responses.

I reject both horns. Subjects are moved away from their non-chance explanations, but not due to simple shifts of attention. The role for attention is intertwined with difficulties in understanding, rather than an alternative to it. The intertwining is a result of a regular presupposition-rejecting position for chance, statistical, or regression accounts of a phenomena.

The claim of poor understanding holds only if the scope of one’s application of a rule or a principle is a facet of one’s competence with that rule or principle, when there is no external interference. A decent, if informal, understanding of regression or the law of large numbers should itself cue subjects to override various intuitive or familiar solutions. There is nothing deviant when an unusually good performance is followed by a much worse one, and, in fact, the contrary is expected, as holds for extreme values in small samples. I grant that the workings of focal attention direct subjects away from a chance account, and to that extent, excuse their erroneous answers. But so what? The poor understanding remains. There is no implication, unlike for those cases where the reformulation strategy clearly succeeds and supports a deflationary claim, that merely bringing the presupposition to focal attention will elicit the statistical explanation.

Given the previous discussion of the presupposition of why-questions, I will lay out these further claims in steps that guide this closing section:

(1) The presuppositions and related assumptions that inform and mislead subjects’ judgments, even if conversationally appropriate given the why-question, are unlikely to yield predictions (expectations) that noticeably falsify or bring criti-

cal attention to these assumptions for one important reason.

- (2) A cooperative world facilitates their inferential and predictive success. Even when these assumptions misguide, they are not in a position to be targeted for the failings.
- (3) The positioning of these assumptions away from falsification or critical attention is a regular product of pragmatics, not due to a particular, labile, formulation, so it is likely to affect thought or understanding generally, not restricted to conversation.
- (4) Since the directing away from a chance explanation follows from what are presumed to be rational rules of conversation that are not conducive to clean falsification and which are not themselves recognized as playing this role [1], and the positioning is pervasive in our activities [2], there is reinforcement of the reasoning, assumptions, and pragmatics guiding subjects’ answers.
- (5) Reinforcing the underlying assumptions and practice informing those answers fosters or reinforces a poor understanding of chance or probability, including an illusory sense of understanding.

Since the explanations subjects’ provide as answers fail, why doesn’t experience or feedback teach us otherwise, when accordingly our reasoning does fail?¹⁰ Why doesn’t faulty explanations produce errors, so that we would learn either that chance does explain (or explain-away) or that the assumption that a phenomena calls for explanation can be challenged, or that questions, particularly why-questions, bias or restrict candidate answers? Why can’t the potential offense or harm to conversational practice of entering a statistical challenge be neutralized by qualification in the privacy of the mind for what it is problematic (to recognize or impolite) to assert? (For discussions of these questions, though not centering on explanation, pragmatics, and chance, see Nisbett and Ross 1980: Ch. 11; Bishop and Trout 2005: Ch. 2).

Even when assumptions lead to errors, failure is not enough to improve one’s understanding. The errors must be noticeable (as errors) with the subject recognizing the source of the error. The difficulty of achieving these realizations is already indicated by the problems of attention that are consequent on the pragmatics

involved, as well as the workings of belief. Falsification motivates learning only if vivid. But for the ascription of traits or responsibility, the most available source of potential falsification is the judgment of others in one's social group, not a rigorous testing ground. For the why-questions directed to the baseball disparities (early/late averages; freshman/sophomore performance), none of the candidate answers is at all likely to lead to an everyday inquiry or comparisons that would expose the failing, as in controlled studies. If a particular baseball player did do as well the next year that will hardly count as falsification of the obviously rough explanations that subjects provide. When a failure to appreciate the role of chance does impact on your actions – why did my son do so exceptionally well in school his freshman year and much less well his second – the connection with how one judges in a very different domain, like those about batting averages in baseball, is not yet illuminated or invited, unless one is antecedently motivated to generalize about the failure (to express it as a principle or to discover its causes).

A related conceptual barrier to an invitation for a statistical explanation is that subjects' (nonstatistical) answers claim completeness. Subjects present their answers, like that success made the player too cocky, so as to implicitly claim that they have fully explained the sophomore slump. Even when their correlative predictions noticeably fail, it will not implicate a chance explanation, rather than one of the competing, presupposition-accepting, explanations. The presupposition that rejects the chance account holds of each of the contrary candidate answers. In the studies presented in Hilton (1990) and Kahneman and Miller (2002), their reformulations are compatible with the basic presupposition of a why-question (of something calling for explanation because it is puzzling, deviant, unexpected, etc.). Correspondingly, subjects' answers, as responding to differently focused questions, are complementary. To refer back to the opening illustration, if you know that Jim and Mary greet each other by kissing, you learn more when you learn that among Jim, Tony, and Jane only Jim and Mary are socially close enough to greet by kissing. You now have more facets of an understanding of why Jim kissed Mary rather than not.

The prospects for noticeable falsification are weakened further according to the third claim above:

The positioning of these assumptions away from falsification or critical attention is a regular product of pragmatics . . . and a common occurrence given that conversation and explanatory interests are pervasive activities . . .

Why-questions or their cognates are common, reflecting our immense curiosity and interest in understanding (Keil and Wilson 2000).¹¹ Nisbett and Ross (1980) report on a study of a wide variety of conversations in which "Statements expressing or requesting causal analysis [explanations] were remarkably frequent, accounting for 15 percent, on the average, of all utterances" (184). This commonness is especially unsurprising given the interrelations of explanation and reasons: If A (e.g., to buy a ice cream cone) is X's reason to do C (e.g., to go to the ice cream store), then A explains why X went to the ice cream store. (The connection does not require the reasons to be that of an agent: The reason that the glass broke is that it fell off the counter. Then the explanation of why the glass broke is that it fell off the counter.) Under realistic conditions of a not markedly uncooperative world, there seems to be an advantage in having a workable explanation to provide guidance and confidence to act and to speak, even though (recognized) ignorance is usually much better than false belief.

In the recent survey article referred to earlier, Johnson-Laird (2005) refers to a study (with Anderson) that shows our great "propensity to explain":

The participants received pairs of sentences selected *at random* from separate stories:

John made his way to a shop that sold TV sets.

Celia had recently had her ears pierced.

In another condition, the sentences were modified to make them coreferential:

Celia made her way to a shop that sold TV sets.

She had recently had her ears pierced.

The participants' task was to explain what was going on. They readily went beyond the given information to account for what was happening. They proposed, for example, that Celia was getting reception in her earrings and wanted the TV shop to investigate, that she wanted to see some new earring on closed circuit TV, that she had won a bet by having her ears pierced and was spending the money on a TV set, and so on. Only rarely were

the participants stumped for an explanation. They were almost as equally ingenious with the sentences that were not co-referential. (Johnson-Laird 2005: 201)

Why-questions motivate inquiry, a source for acquiring new beliefs. Their call for explanation satisfies on its surface the conversational expectation of relevance. However, the problematic lesson then taught is that, except where special justification is introduced, small samples, vivid cases, and uncharacteristic performances are more common as conversational contributions than the contrary (what is normal or expected or familiar). You will more readily notice and you will more readily comment to others on bad service at a favorite restaurant rather than another instance of their consistently good service.

What is communicated implicitly with these contributions is that the occurrences reported are important or significant – they are worth attending to. Yet, if a reported phenomena is really just the expected consequences of the law of large numbers or regression, it is a product of random factors of little further informative value. The bad service at this meal pales in significance compared to the underlying quality control mechanisms that provide for the otherwise unremarkable expectation of a high level of service.

The pragmatic norms render it difficult to block these implications, as we found for the various reformulation strategies ((a), (b) above). In particular, in the case of the heavy-handed (b) reformulations, the why-question secures relevance and informativeness only if the presupposed call for explanation stands. If the observation to which the why-question is directed does not call for explanation, there is loss of point for asking the hearer to explain it, as with “Why did a 3-side turn up when I rolled the die?”

For presuppositions, specifically, we should expect to run into problems of relevance since, as Grice (1989) observed, they are neither detachable (via reformulation) nor cancelable, unlike standard conversational implicatures.¹² To place stress on Smith [in 1a] falsely implicates that the poorer showing is special to him (and analogously, for stress on his sophomore year). In the [b] cases (“Is this surprising? . . .”), the attempt is to eliminate any presuppositional bias. But the cost is wordiness and a burden on comprehension, which will be construed as attempting to do more than merely shift focus, normally accomplished with little burden (Grice 1989: 27; Sper-

ber and Wilson 1986). The reformulations (b) just introduced are odd, anyway, since if the experimenter knows that the phenomena is surprising, he should state it in the standard, briefer presuppositional form as earlier ([1] and [2]). If, however, he does not know even that it is surprising, how is it that I – the subject – am to know?

A related, but more pertinent, problem is noted above: to introduce the “Is this surprising?” question or the “whether or not it is surprising” disclaimer interferes with the aim of discovering the subjects’ assumptions. It also lacks the overt relevance of the original question for raising a puzzle that a speaker is asked to resolve. (Of course, we are all familiar with institutional settings, where this presupposition fails. In schools, teachers ask students questions, where it is expected that the teacher does already know the answer. But, on this reading, the task would be a kind of pretense.)

The reinforcement role of pragmatics in supporting both a valuable conversational practice and yet, a poor understanding, answers a worry that the connection posited between presuppositional inattention and why-questions risks tautology: If you don’t understand an activity (e.g., American football), you are not going to attend to – notice – an action defined by that activity, at least as so described, even if looking right at it (e.g., a strong left side tackle sweep). If your judgment (implicitly) excludes a kind of answer to a problem, isn’t it self-evident that you will not attend to such a candidate answer (so described), even if right before you? (In change blindness, the converse is unsurprisingly found: the more you know of a subject, the less susceptible you are to change blindness in alterations within the domain of that subject; see Werner and Ties 2000).

There is a further, deeper concern that cannot be answered without empirical investigation.¹³ Statistical explanations might be disfavored compared to more familiar mechanical ones generally, antecedent to any conversational role. Ahn et al. (1995) found that if subjects are asked to raise questions themselves to elicit information as to why an event took place (e.g., Margie did not dance the tango at the party), their questions refer much more to mechanisms (e.g., did Margie have a sore foot?), rather than to statistical ones, in particular, attributional ones about consensus (e.g., did others not dance the tango?). I already conceded that the presuppositional role posited here is not the usual kind where a different focus (via a reformulation strategy) will

immediately bring a statistical explanation forward.

The additional response now available, admittedly partial and waiting on empirical testing, is that the influence of pragmatics proposed is not primarily to single cases. The influence is long term, affecting the understanding of the law of large numbers, regression, and related matters of chance in everyday circumstances, where understanding includes sensitivity to scope of application.

Although a major theme is the long-term reinforcement of poor understanding and misleading assumptions, rooted in necessities of practice, common habits, and a "cooperative" world, there is no pessimism that follows about possibilities for improvement (Jepson et al. 1983, along with the companion studies and Fong et al. 1986, are motivated by [promising] efforts to improve statistical thinking. Those with statistical knowledge were intended to be excluded from the Jepson et al. 1983 study.) Since the poor understanding is supported by a natural division between what is background and what is foreground, there is an opening for learning, whereby what has been backgrounded through presupposition is brought to attentional focus, even if not merely through reformulations.

Notes

- 1 Thanks to Catherine Z. Elgin, Georges Rey, and Lance J. Rips for very valuable comments.
- 2 On the model of Geurts and van der Sandt (2004), focus generates a background, which becomes the presupposition. The presupposition-focus difference applies well beyond why-questions, e.g., "When did John come home?" focuses the hearer on the time that the presupposed fact occurred. Also, of course, not all explanatory requests take the form of why-questions and not all why-question expressions are communicated as seeking explanations, e.g., "Why do I have to tell you again to clean your room?"
- 3 See also Stenning and van Lambalgen 2004; Stenning et al. 2006: Ch. 3 on how pragmatics and interpretation introduce complexities in drawing conclusions from empirical studies of weaknesses in subjects' reasoning particularly in logical tasks.
- 4 On cross-cultural variation in attribution, see Nisbett et al. 2001.
- 5 Not all why-questions have this pragmatic feature. Consider a model question for introducing Plato's theory of forms as an answer: "Why is the painting, the supermodel, and the sunset all rightly called 'beautiful'?" But it is plausibly objected that this question attempts to generate a perplexity, where none exists. One traditional – nominalist – answer is simply that each one of those objects or phenomena is beautiful.
- 6 However, there is a difficulty: The "why not" question seems to induce a "suppose" rather than a pure "if" reading of the opening conditional.
- 7 The latter is tightly related to the former, on some views coindexed to it. See Geurts and van der Sandt (2004).
- 8 On the significance of a phenomena calling for explanation for the "stability" of an explanation, see Garfinkel 1981; White 2005.
- 9 For a similar observation, concluding that the requirement is that the "supposition" is noncontroversial, rather than common knowledge, see Grice 1989: 274. Even in relation to explicit questions, one's asking of a question may effectively be to enter an assertion, rather than presupposing it, e.g., "Did you hear that Johnson was fired?"
- 10 Bishop and Trout (2005) formulate the following ("Aristotelian") sensible principle:
in the long run, poor reasoning tends to lead to worse outcomes than good reasoning. (20)
- 11 Levinson (1995) writes:
We see design in randomness, think we can detect signals from outer space in stellar X-rays, suspect some doodles on archaeological artifacts to constitute an undiscovered code, detect hidden structure in Amazonian myths. If we are attuned to think that way, then that is perhaps further evidence for the biases of interactional intelligence: in the interactional arena, we must take all behaviour to be specifically designed to reveal its intentional source. (245)
- 12 The pragmatic issues of presupposition that apply here do not fall snugly under Grice's cases of a clash of maxims. Gricean clashes are always resolvable so as to facilitate realization of communicative intent, which is not so in the cases that concern us.

Chapter 37: Further Notes on Logic and Conversation

H. PAUL GRICE

I would like to begin by reformulating, in outline, the position which I took in an earlier article (“Logic and Conversation”).¹ I was operating, provisionally, with the idea that, for a large class of utterances, the total significations of an utterance may be regarded as divisible in two different ways. First, one may distinguish, within the total signification, between what is said (in a favored sense) and what is implicated; and second, one may distinguish between what is part of the conventional force (or meaning) of the utterance and what is not. This yields three possible elements – what is said, what is conventionally implicated, and what is nonconventionally implicated – though in a given case one or more of these elements may be lacking: For example, nothing may be said, though there is something which a speaker makes as if to say. Furthermore, what is nonconventionally implicated may be (or again may not be) conversationally implicated. I have suggested a Cooperative Principle and some subordinate maxims, with regard to which I have suggested: (i) that they are standardly (though not invariably) observed by participants in a talk exchange; and (ii) that the assumptions required in order to maintain the supposition that they are being observed (or so far as is possible observed) either at the level of what is said – or failing that, at the level of what is implicated – are in systematic correspondence with nonconventional implicata of the conversational type.

Before proceeding further, I should like to make one supplementary remark. When I speak of the assumptions required in order to maintain the supposition that the cooperative principle and maxims are being observed on a given occasion, I am thinking of assumptions that are

nontrivially required; I do not intend to include, for example, an assumption to the effect that some particular maxim is being observed, or is thought of by the speaker as being observed. This seemingly natural restriction has an interesting consequence with regard to Moore’s “paradox.” On my account, it will not be true that when I say that *p*, I conversationally implicate that I believe that *p*; for to suppose that I believe that *p* (or ‘rather’ think of myself as believing that *p*.) is just to suppose that I am observing the first maxim of Quality on this occasion. I think that this consequence is intuitively acceptable; it is not a natural use of language to describe one who has said that *p* as having, for example, “implied,” “indicated,” or “suggested” that he believes that *p*; the natural thing to say is that he has expressed (or at least purported to express) the belief that *p*. He has of course committed himself, in a certain way, to its being the case that he believes that *p*, and while this commitment is not a case of saying that he believes that *p*, it is bound up, in a special way, with saying that *p*. The nature of the connection will, I hope, become apparent when I say something about the function of the indicative mood.

In response to “Logic and Conversation,” I was given in informal discussion an example which seemed to me, as far as it went, to provide a welcome kind of support for the picture I have been presenting, in that it appeared to exhibit a kind of interaction between the members of my list of maxims which I had not foreseen. Suppose that it is generally known that New York and Boston were blacked out last night, and A asks B whether C saw a particular TV program last night. It will be conversationally unobjectionable for B, who knows that C was in New

Reproduced with permission from Grice, H. P. (1978) Further notes on logic and conversation. *Syntax and Semantics*, Vol. 9. pp. 113–127. New York: Academic Press.

York, to reply, *No, he was in a blacked-out city*. B could have said that C was in New York, thereby providing a further piece of just possibly useful or interesting information, but in preferring the phrase *a blacked-out city* he was implicating (by the maxim prescribing relevance) a more appropriate piece of information, namely, why C was prevented from seeing the program. He could have provided both pieces of information by saying, e.g. *He was in New York, which was blacked out*, but the gain would have been insufficient to justify the additional conversational effort.

Rather hurriedly, at the end of "Logic and Conversation," I mentioned five features which I suggested that conversational implicatures must possess, or might be expected to possess. I was not going so far as to suggest that it was possible, in terms of some or all of these features, to devise a decisive test to settle the question whether a conversational implicature is present or not – a test, that is to say, to decide whether a given proposition *p*, which is normally part of the total signification of the utterance of a certain sentence, is on such occasions a conversational (or more generally a nonconventional) implicatum of that utterance, or is, rather, an element in the conventional meaning of the sentence in question. (I express myself loosely, but, I hope, intelligibly.) Indeed I very much doubt whether the features mentioned can be made to provide any such knock-down test, though I am sure that at least some of them are useful as providing a more or less strong *prima facie* case in favor of the presence of a conversational implicature. But I would say that any such case would at least have to be supported by a demonstration of the way in which what is putatively implicated could have come to be implicated (by a derivation of it from conversational principles and other data); and even this may not be sufficient to provide a decisive distinction between conversational implicature and a case in which what was originally a conversational implicature has become conventionalized.

Let us look at the features in turn. First, nondetachability. It may be remembered that I said that a conversational implicature might be expected to exhibit a fairly high degree of nondetachability insofar as the implicature was carried because of what is said, and not by virtue of the manner of expression. The implicature is nondetachable in so far as it is not possible to find another way of saying the same thing (or approximately the same thing) which simply lacks the implicature. The implicature which attaches to the word *try* exhibits this feature.

One would normally implicate that there was a failure, or some chance of failure, or that someone thinks/thought there to be some chance of failure, if one said *A tried to do x*; this implicature would also be carried if one said *A attempted to do x*, *A endeavored to do x*, or *A set himself to do x*.

This feature is not a necessary condition of the presence of a conversational implicature, partly because, as stated, it does not appear if the implicature depends on the manner in which what is said has been said, and it is also subject to the limitation that there may be no alternative way of saying what is said, or no way other than one which will introduce peculiarities of manner, e.g. by being artificial or long-winded.

Neither is it a sufficient condition, since the implicatures of utterances which carry presuppositions (if there are such things) (*He has left off beating his wife*) will not be detachable; and should a question arise whether a proposition implied by an utterance is entailed or conversationally implicated, in either case the implication will be nondetachable. Reliance on this feature is effective primarily for distinguishing between certain conventional implicatures and nonconventional implicatures.

Finally, cancellability. You will remember that a putative conversational implicature that *p* is explicitly cancellable if, to the form of words the utterance of which putatively implicates that *p*, it is admissible to add *but not p*, or *I do not mean to imply that p*, and it is contextually cancellable if one can find situations in which the utterance of the form of words would simply not carry the implicature. Now I think that all conversational implicatures, are cancellable, but unfortunately one cannot regard the fulfillment of a cancellability test as decisively establishing the presence of a conversational implicature. One way in which the test may fail is connected with the possibility of using a word or form of words in a loose or relaxed way. Suppose that two people are considering the purchase of a tie which both of them know to be medium green; they look at it in different lights, and say such things as *It is a light green now*, or *It has a touch of blue in it in this light*. STRICTLY (perhaps) it would be correct for them to say *It looks light green now* or *It seems to have a touch of blue in it in this light*, but it would be unnecessary to put in such qualificatory words, since both know (and know that the other knows) that there is no question of a real change of color. A similar linguistic phenomenon attends such words as *see*: If we all know that Macbeth hallucinated, we can quite safely say

that Macbeth saw Banquo, even though Banquo was not there to be seen, and we should note conclude from this that an implication of the existence of the object said to be seen is not part of the conventional meaning of the word *see*, nor even (as some have done) that there is one sense of the word *see* which lacks this implication.

Let us consider this point in relation to the word *or*. Suppose that someone were to suggest that the word *or* has a single 'strong' sense, which is such that it is part of the meaning of *A or B* to say (or imply) not only (i) that $A \vee B$, but also (ii) that there is some non-truth-functional reason for accepting that $A \vee B$, i.e. that there is some reasonable (though not necessarily conclusive) argument with $A \vee B$ as conclusion which does not contain one of the disjuncts as a step (does not proceed via *A* or via *B*). Now it would be easy to show that the second of the two suggested conditions is cancellable: I can say to my children at some stage in a treasure hunt, *The prize is either in the garden or in the attic. I know that because I know where I put it, but I'm not going to tell you.* Or I could just say (in the same situation) *The prize is either in the garden or in the attic*, and the situation would be sufficient to apprise the children of the fact that my reason for accepting the disjunction is that I know a particular disjunct to be true. And in neither case would I be implying that there is a non-truth-functional ground, though I am not relying on it; very likely there would not be such a ground. To this objection, the "strong" theorist (about *or*) might try the move "Ah, but when you say $A \vee B$, without meaning to imply the existence of a non-truth-functional ground you are using $A \vee B$ loosely, in a relaxed way which the nature of the context of utterance makes permissible." At this point, we might (i) produce further cancellation cases, which were less amenable to representation as 'loose' uses, e.g. to the appearance of disjunctions as the antecedents of conditionals (*If the prize is either in the garden or in the attic, Johnny will find it first*), (ii) point out that to characterize a use as 'loose' carries certain consequence which are unwelcome in this case – if to say *Macbeth saw Banquo* is to speak loosely, then I speak 'under license' from other participants; if someone objects, there is at least some onus on me to speak more strictly. But not even a stickler for correct speech could complain about the utterance (in the described circumstances) of *The prize is either in the garden or in the attic.*

But the strong theorist has another obvious resource: He may say that there are two senses of the word *or*, a strong one and a weak (truth-

functional) one, and that all that is shown by the success of the cancellability test is that here the sense employed was the weak one. To counter this suggestion, we might proceed in one or more of the following ways.

1. We might argue that if *or* is to be supposed to possess a strong sense, then it should be possible to suppose it (*or*) to bear this sense in a reasonably wide range of linguistic settings; it ought to be possible, for example, to say *It is not the case that A or B* or *Suppose that A or B*, where what we are denying, or inviting someone to suppose, is that A or B (in the strong sense of *or*). But this, in the examples mentioned, does not seem to be possible; in anything but perhaps a very special case to say *It is not the case that A or B* seems to amount to saying that neither A nor B (that is, cannot be interpreted as based on a denial of the second condition), and to say *Suppose that A or B* seems to amount to inviting someone to suppose merely that one of the two disjuncts is true. A putative second sense of *or* should not be so restricted in regard to linguistic setting as that, and in particular should not be restricted to "unenclosed" occurrences of A or B – for these an alternative account (in terms of implicature) is readily available. The strong theorist might meet a part of this attack by holding that the second condition is not to be thought of as part of what is said (or entailed) by saying A or B , and so not as something the denial of which would justify the denial of A or B ; it should rather be thought of as something which is conventionally implicated. And to deny A or B might be to implicate that there was some ground for accepting A or B . But he is then open to the reply that, if a model case for a word which carries a conventional implicature is *but*, then the negative form *It is not the case that A or B*, if to be thought of as involving *or* in the strong sense, should be an uncomfortable thing to say, since *It is not the case that A but B* is uncomfortable. In any case the nature of conventional implicature needs to be examined before any free use of it, for explanatory purposes, can be indulged in.

2. We might try to convince the strong theorist that if *or* is to be regarded as possessing a strong sense as well as a weak one, the strong sense should be regarded as derivative from the weak one. The support for this contention would have to be a combination of two points: (i) that the most natural expression of the second condition involves a use of *or* in the 'weak' sense; and even if the weak use of *or* is avoided the idea seems to be explicitly involved; it is difficult to suppose that people could use a word

so as to include in its meaning that there is evidence of a certain sort for a proposition without having a distinct notion of that for which the evidence is evidence. (ii) One who says that A or B, using *or* truth-functionally, could be shown in normal circumstances to implicate (con conversationally) that there are non-truth-functional grounds for supposing that A v B. For to say that A or B (interpreted weakly) would be to make a weaker and so less informative statement than to say that A or to say that B, and (on the assumption, which I shall not here try to justify, that it would be of interest to an audience to know that one of the disjuncts is true) would therefore be to make a less informative statement that would be appropriate in the circumstances. So there is an implicature (provided the speaker is not opting out) that he is not in a position to make a stronger statement, and if, in conformity with the second maxim of Quality, the speaker is to be presumed to have evidence for what he says, then the speaker thinks that there are non-truth-functional grounds for accepting A or B. We might next argue that if the strong sense of *or* is derivative from the weaker sense, then it ought to conform to whatever general principles there may be which govern the generation of derivative senses. This point is particularly strong in connection with a suggestion that *or* possesses a derivative sense; for we are not particularly at home with the application of notions such as 'meaning' and 'sense' to words so nondescriptive as *or*; the difficulties we encounter here are perhaps similar to, though not so severe as, the difficulties we should encounter if asked to specify the meaning or meanings of a preposition like *to* or *in*. So I suspect that we should need to rely fairly heavily on an application to the case of *or* of whatever general principles there may be which apply to more straightforward cases and which help to determine when a derivative sense should be supposed to exist, and when it should not.

[It might be objected that whether one sense of a word is to be regarded derivative from another sense of that word should be treated as a question about the history of the language to which the word belongs. This may be so in general (though in many cases it is obvious, without historical research that one sense must be secondary to another), but if I am right in thinking that conversational principles would not allow the word *or* to be used in normal circumstances without at least an implicature of the existence of non-truth-functional grounds,

then it is difficult to see that research could contribute any information about temporal priority in this case.]

I offer one or two further reflections about the proliferation of senses.

1. I would like to propose for acceptance a principle which I might call Modified Occam's Razor (M.O.R.) *Senses are not to be multiplied beyond necessity*. Like many regulative principles, it would be a near platitude, and all would depend on what was counted as "necessity." Still, like other regulative principles, it may guide. I can think of other possible precepts which would amount to much the same. One might think, for example, of not allowing the supposition that a word has a further (and derivative) sense unless the supposition that there is such a sense does some work, explains why our understanding of a particular range of applications of the word is so easy or so sure, or accounts for the fact that some application of the word outside that range, which would have some prima facie claim to legitimacy, is in fact uncomfortable. Again one might formulate essentially the same idea by recommending that one should not suppose what a speaker would mean when he used a word in a certain range of cases to count as a special sense of the word, if it should be predictable, independently of any supposition that there is such a sense, that he would use the word (or the sentence containing it) with just that meaning. If one makes the further assumption that it is more generally feasible to strengthen one's meaning by achieving a superimposed implicature, than to make a relaxed use of an expression (and I don't know how this assumption would be justified), then Modified Occam's Razor would bring in its train the principle that one should suppose a word to have a less restrictive rather than a more restrictive meaning, where choice is possible.

What support would there be for M.O.R.? Perhaps we might look at two types of example of real or putative derivative senses. One type (unlike the case of *or*) would involve "transferred" senses; the other would involve derivative senses which are specificatory of the original senses (the proposed derivative sense of 'or' would be a special case of this kind).

a. Consider such adjectives as *loose*, *unfettered*, and *unbridled* in relation to a possible application to the noun *life*. (I assume that such an application of each word would not be nonderivative, or literal; that the ambiguous expression *a loose liver* would involve a nonderivative sense of *loose*

if uttered e.g. by a nurse in a hospital who complained about the number of patients with loose livers, but not if uttered censoriously to describe a particular man.) It seems to me that (in the absence of any further sense for either word) one might expect to be able to mean more or less the same by *a loose life*, and *an unfettered life*; the fact that, as things are, *loose life* is tied to dissipation, whereas *unfettered life* seems quite general in meaning, suggests that perhaps *loose* does, and *unfettered* does not, have a derivative sense in this area. As for *unbridled life* (which one might perhaps have expected, *prima facie*, to mean much the same as *unfettered life*), the phrase is slightly uncomfortable (because *unbridled* seems to be tied to such words as *passion*, *temper*, *lust*, and so on).

b. As for words with specificatory derivative senses, there seems to be some tendency for one of two things to happen: Either the original general sense becomes obsolete (like *car*, meaning 'wheeled vehicle'), or the specificatory condition takes over; we should perhaps continue to call gramophone records *discs* even if (say) they came to be made square (provided they remained not too unlike discs, in the original sense of the word) and perhaps the word *cylinder* exemplifies the same feature. But there are words of which neither is true: an obvious example is the word *animal* (meaning [*i*] 'member of animal kingdom', [*ii*] 'beast'). There is here some sort of a parallel, in relation to M.O.R. and its variants, between *animal* and the candidate word *or*. *Animal* perhaps infringes a weak principle to the effect that a further sense should not be recognized if, *on the assumption that* the word were to have a specificatory further sense, the identity of that sense would be predictable; for it could no doubt be predicted that *if* the word *animal* were to have such a sense, it would be one in which the word did not apply to human beings. But it would seem not to be predictable (history of language apart) that anyone would *in fact* use the word *animal* to mean 'beast', whereas given a truth-functional *or* it is predictable (assuming conversational principles) that people would use *A or B* to imply the existence of non-truth-functional grounds. So, at least, so far as I can see (not far, I think), there is as yet no reason not to accept M.O.R.

2. We must of course give due (but not undue) weight to intuitions about the existence or nonexistence of putative senses of a word (how could we do without them?). Indeed if the scheme which I have been putting before

you is even proceeding in the right direction, at least some reliance must be placed on such intuitions. For in order that a nonconventional implicature should be present in a given case, my account requires that a speaker shall be able to utilize the conventional meaning of a sentence. If nonconventional implicature is built on what is said, if what is said is closely related to the conventional force of the words used, and if the presence of the implicature depends on the intentions of the speaker, or at least on his assumptions, with regard to the possibility of the nature of the implicature being worked out. then it would appear that the speaker must (in some sense or other of the word *know*) know what is the conventional force of the words which he is using. This indeed seems to lead to a sort of paradox: If we, as speakers have the requisite knowledge of the conventional meaning of sentences we employ to implicate, when uttering them, something the implication of which depends on the conventional meaning in question, how can we, as theorists have difficulty with respect to just those cases in deciding where conventional meaning ends and implicature begins? If it is true, for example, that one who says *that A or B* implicates the existence of non-truth-functional grounds for A or B, how can there be any doubt whether the word 'or' has strong or weak sense? I hope that I can provide the answer to this question but I am not certain that I can.

3. I have briefly mentioned a further consideration bearing on the question of the admissibility of a putative sense of a word, namely, whether on the supposition that the word has that sense, there would be an adequate range of linguistic environments in which the word could be supposed to bear that sense. Failure in this respect would indicate an implicature or an idiom.

There are, I am certain, other possible principles which ought to be considered; in particular I have said nothing, or nothing explicitly, about the adequacy of substitutability tests. But I propose to leave this particular topic at this point.

I have so far been considering questions on the following lines: (*i*) On the assumption that a word has only one conventional meaning (or only one relevant conventional meaning), how much are we to suppose to be included in that meaning? (*ii*) On the assumption that a word has at least one conventional meaning (or relevant conventional meaning), are we to say that it has one, or more than one, such meaning? In particular, are we to ascribe to it in a second

sense/meaning, derivative from or dependent on a given first meaning/sense? We should consider also examples of elements in or aspects of utterances which, not being words, are candidates for conventional meaning (or significance).

Stress

Some cases of stress are clearly relevant to possession of conventional meaning, e.g. (fixed) stress on particular syllables or a word: contrast *cóntent* and *contént*. (Though we would not assign meaning to the stress itself.) I am not concerned with cases of that sort, but with the cases in which we think of a word as being stressed, and variably so: stressed on some occasions but not on others.

We might start by trying to think of stress as a purely natural way of highlighting, or making prominent, a particular word: compare putting some object (e.g. a new hat) in an obvious place in a room so that someone coming into the room will notice or pay attention to it. But there are various suggestible ways of doing this with a word: e.g. intoning it, saying it in a squeaky voice. Such methods would not just be thought unusual, they would be frowned on. They would also very likely fail to achieve the effect of highlighting just because there is an approved way of doing this. So there is a good case for regarding stress as a conventional device for highlighting. But to say this much is not to assign to stress a conventional significance or meaning; it is only to treat it as a conventional way of fulfilling a certain purpose, which is not yet established as a purpose connected with communication. But stress clearly does in fact on many occasions make a difference to the speaker's meaning; indeed it is one of the elements which help to generate implicatures. Does this fact require us to attribute any conventional meaning to stress?

In accordance with the spirit of Modified Occam's Razor, we might attribute conventional meaning to stress only if it is unavoidable. Thus we might first introduce a slight extension to the maxim enjoining relevance, making it apply not only to what is said, but to features of the means used for saying what is said. This extension will perhaps entitle us to expect that an aspect of an utterance which it is within the power of the speaker to eliminate or vary, even if it is introduced unreflectively, will have a purpose connected with what is currently being communicated; unless, of course its presence can be explained in some other way.

We might notice at least three types of context in which stress occurs which seem to invite ordering:

1. Includes replies to "W" questions:
(A: *Who paid the bill?* B: *Jónes did.*
A: *What did Jones do to the cat?* B: *He kicked it.*)

and exchanges of such forms as:

- A: $S(\alpha)$
B: $\bar{S}(\acute{\alpha}): S(\acute{\beta})$

(for example:

- A: *Jones paid the bill.*
B: *Jónes didn't pay the bill; Smith paid it.*)

In such examples (i) stress is automatic or a matter of habit (maybe difficult to avoid) and (ii) we are not inclined to say that anything is meant or implicated. However, the effect is to make perspicuous elements which complete open sentences for which questions (in effect) demand completion or elements in respect of which what B is prepared to assert (or otherwise say), and what B has asserted, differ.

2. Such cases as incomplete versions of the conversational schema exemplified in the second of the above examples:

a. Without a preceding statement to the effect that Jones paid the bill says *Jónes didn't pay the bill, Smith did*. Here, given that this sentence is to be uttered, the stress may be automatic, but the remark is not prompted by previous remark (but is volunteered), and we are inclined to say that the implicature is that someone thinks or might think that Jones did pay the bill. The maxim of relation requires that B's remark should be relevant to some thing or other, and B, by speaking as he would speak in reply to a statement that Jones paid the bill, shows that he has such a statement in mind.

b. B just says *Jónes didn't pay the bill*. B speaks as if he were about to continue as in (a); B implicates that someone (other than Jones) paid the bill.

In general, $S(\acute{\alpha})$ is contrasted with the result of substituting some expression β for α , and commonly the speaker suggests that he would deny the substitute version, but there are other possibilities: e.g. *I knéw that* may be contrasted with *I believed*, and the speaker may implicate not that he would deny *I believed that p*, but that he would not confine himself to such a weaker statement (with the implicit completion *I didn't merely believe it*).

This last point has relevance to the theory of 'knowledge'. According to a certain 'strong' account of knowledge,

- A knows that p* = (1) *p*
 (2) *A thinks that p*
 (3) *A has conclusive evidence that p*

This presents possible difficulties of a regressive nature:

1. Does A have to know that the evidence for *p* is true?
2. Does A have to know that the evidence is conclusive?

But in general the theory seems *too* strong. An examination candidate at an oral knows the date of the battle of Waterloo. He may know this without conclusive evidence; he may even have answered after hesitation (showed in the end that he knew the answer). I suggest something more like the following:

- A knows that p* = (1) *p*
 (2) *A thinks that p*
 (3) *Some conditions placing restriction on how he came to think p* (cf. causal theory).

If I say *I know that p* then perhaps sometimes there is a nonconventional implicature of strong or conclusive evidence (not mere thinking that *p*, with *p* true)—cf. *He loves her*. And this is not the only interpretation of stress: it can mean, 'You don't need to tell me'.

Irony

The second example of an element in, or aspect of, some utterances, with regard to which there might be some doubt whether or not it has a conventional meaning, emerges from my (too) brief characterization of irony in "Logic and Conversation". (I have profited at this point from discussion with Professor Rogers Albritton.) There was certainly something missing in the account which I gave; it seems very dubious whether A's knowledge that B has been cheated by C, that B knows that A knows that this is so, that B's remark *He is a fine friend* is to be presumed to relate to this episode, and that the remark is seemingly false (even obviously false), is enough to ensure, with reasonable certainty, that A will

suppose B to mean the negation of what he has made as if to say. A might just be baffled, or might suppose that, despite the apparent falsity of the remark, B was meaning something like *He is, usually, a fine friend: how could he have treated me like that?* It was suggested to me that what should have been mentioned in my account was first, a familiarity with the practice of using a sentence, which would standardly mean that *p*, in order to convey that not-*p* (a familiarity which might be connected with a natural tendency in us to use sentences in this way), and, second, an ironical tone in which such utterances are made, and which (perhaps) conventionally signifies that they are to be taken in reverse.

This suggestion does not seem to me to remedy the difficulty. Consider the following example. A and B are walking down the street, and they both see a car with a shattered window. B says, *Look, that car has all its windows intact*. A is baffled. B says, *You didn't catch on; I was in an ironical way drawing your attention to the broken window*. The absurdity of this exchange is I think to be explained by the fact that irony is intimately connected with the expression of a feeling, attitude, or evaluation. I cannot say something ironically unless what I say is intended to reflect a hostile or derogatory judgment or a feeling such as indignation or contempt. I can for example say *What a scoundrel you are!* when I am well disposed toward you, but to say that will be playful, not ironical, and will be inappropriate unless there is some shadow of justification for a straightforward application – for example you have done something which some people (though not I) might frown upon. If when you have just performed some conspicuously disinterested action I say, *What an egotist you are! Always giving yourself the satisfaction of doing things for other people!*, I am expressing something like what might be the reaction of an extreme cynic. Whereas to say *He's a fine friend* is unlikely to involve any hint of anyone's approval.

I am also doubtful whether the suggested vehicle of signification, the ironical tone, exists as a specific tone; I suspect that an ironical tone is always a contemptuous tone, or an amused tone, or some other tone connected with one or more particular feelings or attitudes; what qualifies such a tone as ironical is that it appears, on this and other occasions, when an ironical remark is made. This question could no doubt be settled by experiment. Even if, however, there is no specifically ironical tone, it still might be suggested that a contemptuous or amused tone, when conjoined with a remark which is blatantly

false, conventionally indicates that the remark is to be taken in reverse. But the suggestion does not seem to me to have much plausibility. While I may without any inappropriateness prefix the employment of a metaphor with *to speak metaphorically*, there would be something very strange about saying, *to speak ironically, he is a splendid fellow*. (i) To be ironical is, among other things, to pretend (as the etymology suggests), and while one wants the pretense to be recognized as such, to announce it as a pretense would spoil the effect. (ii) What is possibly more important, it might well be essential to an element's having conventional significance that it could have been the case that some quite different element should have fulfilled the same semantic purpose; that if a contemptuous tone does in fact conventionally signify in context that a remark is to be taken in reverse then it might have been the case that, e.g. a querulous tone should have been used (instead) for the same purpose. But the connection of irony with the expression of feeling seems to preclude this; if speaking ironically has to be, or at least to appear to be, the expression of a certain sort of feeling or attitude, then a tone suitable to such a feeling or attitude seems to be mandatory, at any rate for the least sophisticated examples.

Truth

It may be remembered that among the "A-philosophical" theses which I listed at the beginning of the first lecture of the series of which this article was the third was the original version of a "speech act" account of truth which Strawson put forward many years ago.² As I said at the time, his view, or at least the expression of it, has undergone considerable modification since then, and I am not here concerned with any but the original version of his thesis. He was influenced, I think, by three main considerations: (i) that the word *true* is properly, or at least primarily, to be applied to statements (what is stated), in view of the difficulties which he thought he saw in the thesis that it should be understood as applying to utterances; (ii) that given that the previous supposition is correct, no theory which treats truth as consisting in a relation (or correlation) between statements and facts will be satisfactory, since statements and facts cannot be allowed to be distinct items in the real world; (iii) Ramsey's account of truth³ namely, that to assert that a proposition is true is to assert that proposition, is correct, so far as it goes; and (iv) it does not go far enough, since it omits to take

seriously the fact that we should not always be willing to tolerate the substitution of, e.g. *It is true that it is raining* for *It is raining*. So he propounded the thesis that to say of a statement that it is true is (i) in so far as it is to assert anything, to assert that statement and (ii) not merely to assert it, but to endorse, confirm, concede or reassert it (the list is not, of course, intended to be complete).

Such a theory seems to me to have at least two unattractive features, on the assumption that it was intended to give an account of the meaning (conventional significance) of the word *true*. (i) (A familiar type of objection) it gives no account, or no satisfactory account, of the meaning of the word *true* when it occurs in unasserted subsentences (e.g. *He thinks that it is true that . . .* or *If it is true that . . .*). (ii) It is open to an objection which I am inclined to think holds against Ramsey's view (of which the speech act theory is an offshoot). A theory of truth has (as Tarski noted) to provide not only for occurrences of *true* in sentences in which what is being spoken of as true is specified, but also for occurrences in sentences in which no specification is given (e.g. *The policeman's statement was true*). According to both the speech act theory, I presume, and to Ramsey's theory, at least part of what the utterer of such a sentence is doing is to assert whatever it was that the policeman stated. But the utterer may not know what that statement was; he may think that the policeman's statement was true because policemen always speak the truth, or that that policeman always speaks the truth, or that policeman in those circumstances could not but have spoken the truth. Now assertion presumably involves committing oneself, and while it is possible to commit oneself to a statement which one has not identified (I could commit myself to the contents of the Thirty-Nine articles of the Church of England, without knowing what they say), I do not think I should be properly regarded as having committed myself to the content of the policeman's statement, merely in virtue of having said that it was true. When to my surprise I learn that the policeman actually said, *Monkeys can talk*, I say (perhaps), *Well, I was wrong*, not *I withdraw that*, or *I withdraw my commitment to that*. I never was committed to it.

My sympathies lie with theories of the correspondence family, which Strawson did (and I think still does) reject, but it is not to my present purpose (nor within my capacities) to develop adequately any such theory. What I wish to do is to show that, on the assumption

that a certain sort of theory of this kind is correct, then, with the aid of the apparatus discussed in "Logic and Conversation" it is possible to accommodate the linguistic phenomena which led Strawson to formulate the original version of the speech act theory. Let me assume (and hope) that it is possible to construct a theory which treats truth as (primarily) a property of utterances; to avoid confusion I shall use, to name such a property, not 'true' but 'factually satisfactory'. Let me also assume that it will be a consequence of such a theory that there will be a class *K* of utterances (utterances of affirmative S-P sentences) such that every member of *K* (i) *designates*⁴ some item and *indicates*⁴ some class (these verbs to be explained within the theory) and (ii) is factually satisfactory if the item belongs to the class. Let me finally assume that there could be a method of introducing a form of expression *It is true that . . .* and linking it with the notion 'factually satisfactory', a consequence of which would be that to say *It is true that Smith is happy* would be equivalent to saying that any utterance of class *K* which designates Smith and indicates the class of happy people is factually satisfactory (that is, any utterance which assigns Smith to the class of happy people is factually satisfactory).

If some such account of *It is true that . . .* is correct (or indeed any account which represents saying *It is true that p* as equivalent to saying something about utterances), then it is possible to deal with the linguistic facts noted by Strawson. To say *Smith is happy* is not to make a (concealed) reference to utterances of a certain sort, whereas to say *It is true that Smith is happy* is to do just that, though of course if Smith is happy it is true that Smith is happy. If I choose the

form which does make a concealed reference to utterances, and which is also the more complex form, in preference to the simpler form, it will be natural to suppose that I do so because an utterance to the effect that Smith is happy has been made by myself or someone else, or might be so made. Such speech acts as endorsing, agreeing, confirming, and conceding, which Strawson (presumably) supposed to be conventionally signalled by the use of the word *true* will be just those which, in saying in response to some remark "that's true," one would be performing (without any special signal). And supposing no one actually to have said that Smith is happy, if I say "It is true that Smith is happy" (e.g. concessively) I shall implicate that someone might say so; and I shall not select this form of words as, for example, a response to an inquiry whether Smith is happy, when I should not wish this implicature to be present.

Chapter 38: The Social Context of Reasoning: Conversational Inference and Rational Judgment

DENIS J. HILTON

Most psychologists conceive of judgment and reasoning as cognitive processes, which go on “in the head” and involve intrapsychic information processing (e.g., Kahneman, Slovic, and Tversky, 1982; Nisbett and Ross, 1980). Although it is incontestable that processes of attention, memory, and inference underpin judgment and reasoning, psychologists have perhaps overlooked the extent to which these mental processes are governed by higher-level assumptions about the social context of the information to be processed. On the other hand, philosophers have in recent years drawn attention to the extent to which reasoning from ordinary language is shaped by the nature of social interaction and conversation (Austin, 1962; Grice, 1975; Hart and Honoré, 1959/1985; Mackie, 1974; Searle, 1969; Strawson, 1952). These higher-level assumptions can determine what we attend to, which memories we search, and what kinds of inference we draw.

Consider the way the word *family* can be differentially interpreted according to context and thus lead to seemingly inconsistent judgments expressed in a conversational exchange (cf. Strack, Martin, and Schwarz, 1988):

Q. How is your family?
A. Fairly well, thank you.

A married man might reply this way if he considers that his wife has recently been saddened by the loss of a close friend but that his two children are in good form. The respondent interprets *family* to mean *the wife and kids*.

Suppose, however, that a woman had asked this man about his wife and then his family. The exchange might have run as follows:

Q. How is your wife?
A. Not too good, I'm afraid.
Q. And how is your family?
A. Extremely well, thank you!

In this case, the respondent would normally feel bound to interpret *family* as *the kids* because he already gave information about his wife and did not wish to burden the questioner with redundant information that she already has. So he gives an answer about his family that is apparently inconsistent with his earlier answer to the same question, “How is your family?”

From one point of view, giving two different answers to the same question asked on different occasions may seem irrational. After all, inconsistency is usually taken as a sign of illogicality and irrationality in ordinary life (Strawson, 1952). We might therefore be tempted to conclude that our imaginary interlocutor is mentally unable to deliver a stable and consistent evaluation of his family's well-being and is therefore irrational. We might suppose, for example, that he is unable to activate the same representation of the concept *my family* on the two occasions that the question is asked because of defective or biased memory retrieval processes. This kind of argument is familiar from much research on rational judgment. Thus, irrationality is often demonstrated experimentally through producing different responses to the

same question asked in different contexts, such as in the study of framing effects on risky choice (Tversky and Kahneman, 1981) and preference reversals (Payne, Bettman, and Johnson, 1992) or through question-order effects on responses in survey research (Schuman and Presser, 1981).

However, attributing irrationality to the respondent in the above case may be premature. Norms of rational communication (e.g., Grice, 1975) require a speaker to be cooperative with a hearer by not burdening him or her with redundant information. Specifically, in the case where the hearer has just been told about the health of the speaker's wife, one can argue that interlocutors are entitled to assume that the reference to *family* meant *just the kids*, rather than *the wife and kids*. This interpretation of the word *family* is conversationally rational in the context of the previous exchange about the health of the speaker's wife. The context-dependent interpretation of the word *family* would thus absolve the speaker of the charge of cognitive inconsistency. Rather, he has cooperatively and rationally altered his answers to the question as a function of the interactional context.

Recognition of conversational constraints on utterance interpretation and inference may thus have important implications for experimental psychologists. No psychological experiment or investigation takes place in a social vacuum. All experiments and surveys are forms of social interaction between the experimenter and participant, which invariably involves communication through ordinary language. Thus, survey researchers who attribute inconsistent patterns of response to questions to cognitive shortcomings, or experimental psychologists who explain patterns of judgment in terms of purely intrapersonal variables – such as memory capacity, attention factors, memory activation levels, search strategies, and judgmental heuristics – may be in danger of committing an attribution error (cf. Cheng and Novick, 1990). They may be in danger of misattributing patterns of inferential behavior to features of the person and overlooking how it is constrained by its interpersonal context.

Theories of judgment should therefore include a front-end component that determines how the incoming message is interpreted in its context. This may remove many anomalies in the interpretation of respondents' behavior. It has been a perennial problem for students of judgment and reasoning to determine whether a mistake is due to incorrect reasoning about the

information given or to the application of correct reasoning procedures to incorrect or irrelevant information that a respondent has incorporated in his or her representation of the reasoning problem (Henle, 1962; Johnson-Laird, 1983). Conversational assumptions often require one to go beyond the information explicitly given in an utterance. Thus, the final judgment may often be highly rational given the participant's use of these assumptions in forming a representation of the reasoning task.

Although many researchers have noted that widely shared assumptions about cooperative communication (Grice, 1975; Levinson, 1983) may license interpretations of the experimental task that the experimenter may not have intended, work on this topic remains fragmentary and underdeveloped in nature. On the one hand, experimental psychologists typically define a particular judgment phenomenon first and then consider how it might be analyzed from the point of view of conversational pragmatics. This practice has led to the accumulation of piecemeal knowledge about the relation between conversational pragmatics and rational inference. Thus, the conversational aspects of such diverse phenomena as the base-rate fallacy (Krosnick, Li, and Lehman, 1990; Schwarz, Strack, Hilton, and Naderer, 1991), the conjunction fallacy (Dulany and Hilton, 1991; Markus and Zajonc, 1985; Morier and Borgida, 1984; Politzer and Noveck, 1991; Tversky and Kahneman, 1983), actor-observer differences in causal explanation (Hilton, 1990a), conservation judgments (Donaldson, 1978, 1982; McGarrigle and Donaldson, 1975), and interpretation of survey questions (Schwarz and Strack, 1991; Tourangeau and Rasinski, 1988) have been for the most part considered independently of each other. In addition, articles that review several phenomena from the point of view of conversational pragmatics do not offer an integrated view of the philosophical and linguistic bases of conversational inference that would enable its relation to rational judgment to be explicated systematically (e.g., Adler, 1984; Bless, Strack, and Schwarz, 1993; Cohen, 1981; Hilton, 1990a; Macdonald, 1986; Schwarz, 1994; Shanon, 1988).

I therefore begin by reviewing some of the logical and linguistic properties of conversational inference with particular reference to the question of rationality in research on judgment and reasoning. I show how these logico-linguistic properties may be moderated by inferences

about the social context of communication and particularly the hearer or respondent's attributions about the speaker or experimenter (e.g., the speaker's knowledge, intentions, and group membership). This attributional model generates predictions about the ways conversational inference may affect the representation of judgment and reasoning tasks. I apply the model to the analysis of experiments on reasoning drawn from developmental psychology, social psychology, cognitive psychology, and decision research. I show that the attributional model of conversational inference organizes phenomena found in these diversified literatures within a common framework and enables the reinterpretation of many judgment biases in terms of conversational inference processes. More important, the framework can help elucidate which biases are not susceptible of explanation in conversational terms. I conclude by discussing methodological implications for future research.

Properties of Conversational Inference

Inductive Nature of Conversational Inference

Conversational inference is itself a form of judgment under uncertainty. Hearers have to make hypotheses about the speaker's intended meaning on the basis of what is explicitly said. For example, most hearers routinely go beyond the information given in the utterance "I went to the cinema last night" to infer that the speaker meant to convey that he or she saw a film last night. The additional information conveyed in this way by the speaker is termed a *conversational implicature* (Grice, 1975). Grice argued that to understand a speaker's full meaning, the listener must understand both the meaning of the sentence itself (what is said) and what it conveys in a given context (what is implicated).

Conversational inference shares some important properties with inductive inference (Levinson, 1983). First it is ampliative, that is, the conclusion contains more information than the premises. For example, by observing that the first 1,000 carrots that I dig up are orange, I make the stronger conclusion that "All carrots are orange." The inference that the speaker went to the cinema and saw a film contains more information than the assertion that he or she just went to the cinema. Consequently, the conclusions of both conversational and inductive inference are defeasible, that is, they can be canceled by the addition of new information. Thus, just as the

conclusion that "All carrots are orange" may be canceled by digging up a 1,001st carrot that is brown, so the speaker may cancel the implicature that he or she saw a film at the cinema last night by saying, "I went to the cinema last night but couldn't get in."

Conversational inference is unlike deductive inference, where conclusions contain no new information but simply demonstrate what can be inferred from the premises, and cannot be canceled by the addition of new information. Thus, the fact that Socrates is mortal necessarily follows from the fact that Socrates is a man and all men are mortal. Nothing can be done to change this conclusion except to change the original premises.¹

Consequently, in conversational inference – as in inductive inference – one encounters Hume's problem, namely that one can never draw correct conclusions with certainty. Just as theory is underdetermined by data, so hypotheses about the speaker's intended meaning are underdetermined by what is said. There may be an innumerable number of theories or hypotheses about intended meaning that are consistent with the data given and thus have the chance of being true. How does one decide which theory or hypothesis is best?

There are some criteria for determining the rational choice of a hypothesis in both cases. In fact, proposals made by philosophers of science and philosophers of language are broadly similar. Roughly speaking, rational inferences are those which, as well as being likely to be true, convey the most new implications for the least effort. This position is implicit in Popper's (1972) injunction that scientific hypotheses be "powerful and improbable," in Wilson and Sperber's (1985) suggestion that the relevance of an inference should be calculated in terms of the number of implications it carries for the amount of processing effort needed, and in Grice's (1975) logic of conversation.

Grice's (1975) statement of the cooperative principle underlying conversation and the conversational maxims that derive from it are detailed in the Appendix. Grice's logic of conversation describes a form of rational communication in which the maximum amount of valuable information is transmitted with the least amount of encoding and decoding effort. Although some theorists have sought to revise this approach, for example, by reducing all the maxims to a superordinate one of relevance (Sperber and Wilson, 1986), Grice's approach is adopted here because of its ability, when suitably interpreted,

Table 1: Assumed Characteristics of Message and Speaker Implied by Grice's Logic of Conversation

<i>Assumption/Maxim of Conversation</i>	<i>Message Characteristics</i>	<i>Characteristics Attributed to Speaker</i>
Cooperativeness	Observes four maxims (see below)	Intentional Helpful
Quality	Truth value probability	Sincerity Honesty Reliability Competence
Quantity	Informativeness	Mutual knowledge Group membership
Relation	Goal relevance	Interactional goals
Manner	Clarity	Knowledge of language

to explain a wide range of phenomena in conversational pragmatics (for more detailed discussion, see P. Brown and Levinson, 1987; Grice, 1989; Levinson, 1983, 1987; Neale, 1992). As is shown below, the cooperative principle and the subordinate maxims seem to correspond to important psychological dimensions and the tensions between them to produce important logical and linguistic consequences.

Attributional Bases of Conversational Inference

Grice's (1975) assumption of cooperativeness and the corresponding maxims of conversation depend on the hearer making certain default attributions about the speaker. In particular, the assumption of cooperativeness presupposes that utterances are produced by an intentional agent who wishes to cooperate with us and has the ability to realize this intention. I argue that each set of conversational maxims implies certain kinds of attributions about the speaker (see Table 1).

The maxims of *quality* concern the likely truth value of an utterance. Thus, if the hearer attributes properties such as sincerity, reliability, and knowledgeability to the speaker, then the hearer may well consider the probable truth value of an utterance to be high. If, on the other hand, the hearer considers the speaker to be insincere, unreliable, or unknowledgeable, then the hearer may well consider the probable truth of the utterance to be low.

The maxims of *quantity* concern the perceived informativeness of an utterance. Speakers should not burden hearers with information

they are already likely to know. What speakers and hearers take for granted may depend in part on perceptions of class membership. Competent members of western society do not need to be told why a customer who ate a good meal in a restaurant with good service left a big tip. From their own world knowledge, they are able to make the necessary bridging inferences (Clark and Haviland, 1977; Schank and Abelson, 1977). Thus, hearers often go beyond the information given in making inferences because they assume that the relevant information they are likely to know has already been omitted.

The maxim of *relation* enjoins speakers to mention information that is relevant to the goals of the interaction. Hearers are entitled to assume that any relevant information they are not likely to know has been included. They are also entitled to assume that information that has been included is relevant, otherwise why mention it? One problem for experimental research is that psychologists routinely violate this assumption by introducing information precisely because it is irrelevant to the judgment task (e.g., Nisbett, Zukier, and Lemley, 1981). If bearers (participants) continue to attribute essentially cooperative intentions to speakers (experimenters), then they are liable to be misled by the information given.

The maxims of *manner* enjoin speakers to be brief, orderly, clear, and unambiguous. The extent to which speakers can adhere to these prescriptions often depends on their command of the language. Hearers may take this into account when interpreting utterances. For example, a German tourist in England might conceivably ask a native for directions to "the

Townhouse" when he or she meant "the Town Hall." Rather than direct the tourist to the nearest renovated Georgian residence in the center of town, a cooperative hearer might attribute the speaker's unclarity to inexperience with British English and direct her or him to the Town Hall. Usually such misunderstandings in conversation can be corrected through discussion. However, such opportunities for repair do not exist in experimental and survey research. Consequently, experimenters may notice ambiguities in their response formats that are systematically reinterpreted by participants, thus leading to systematic biases in the results obtained. This seems to have been the case in much basic attribution research (Hilton, 1990b).

Although Grice (1975) formulated his maxims as injunctions to the speaker ("Be brief," "Be clear," etc.), they can also be understood as general expectations about discourse built into the comprehension processes of hearers (cf. Dulany and Hilton, 1991). I assume that these assumptions are used flexibly in utterance interpretation. For example, as Grice (1975) intended, I assume that the maxims of conversation guide utterance interpretation both when they are respected and when they are flouted. There is considerable evidence that such assumptions are used in language understanding (see Clark, 1985, 1992; Clark and Schober, 1992; Kraut and Higgins, 1984, for reviews). I do not, however, commit myself to a psycholinguistic process model that specifies how these constraints are used in comprehension (cf. Dascal, 1989; Gibbs, 1984, 1989). I simply assume that these higher-order assumptions are guided by attributions about the speaker and that they are used to choose interpretations of utterances that are rational in the conversational context.

Attribution Processes in the Interpretation of Utterances

Grice's (1975) maxims of conversation are often considered as descriptive of the rules of idealized conversations between cooperative rational hearers. However, Grice clearly considered that speakers are flexible with the maxims of conversation and indeed often flout them deliberately to create special effects such as metaphor and irony. However, when speakers flout the maxims of conversation, hearers have to *calculate* the intended implicatures by working out the speaker's intentions. This is clear from Grice's example of an unusually short letter of recommendation that violates the maxims of quantity

by not giving enough information to evaluate a job candidate properly:

A is writing a testimonial about a pupil who is a candidate for a philosophy job, and his letter reads as follows: "Dear Sir, Mr. X's command of English is excellent, and his attendance at tutorials has been regular. Yours, etc." (Gloss [explanation]: A cannot be opting out since if he wished to be uncooperative, why write at all? He cannot be unable, through ignorance, since the man is his pupil. He must, therefore, be wishing to impart information that he is reluctant to write down. This supposition is tenable only if he thinks Mr. X is no good at philosophy. This, then, is what he is implicating.) Grice, 1975, p. 52

The calculation of implicatures clearly involves inferences about the speaker's knowledge of the topic under discussion (the pupil) and his intentions (not to be openly critical). In this example, Grice (1975) appealed to a higher-order assumption about the writer that he or she is cooperative. However, it is easy to imagine how other beliefs about the speaker would incline one to either accept or reject the proposed interpretation of the letter. For example, if one knew that the writer is normally very knowledgeable about and supportive of his pupils about whom he writes at great and glowing length, then one would certainly be inclined to accept Grice's proposed interpretation. On the other hand, if one knew that the pupil was a blunt-speaking person with ideas of his or her own and that the teacher was a rather dogmatic type, one might be inclined to consider the hypothesis that the writer has been offended by this pupil and wishes to stop him or her embarking on an academic career precisely to prevent the development of a brilliant philosophical opponent.

Such beliefs about the stable personality characteristics of actors are termed by social psychologists *dispositional attributions*. An important statement of the process of dispositional attribution by Jones and Davis (1965) bears some important resemblances to the process of utterance interpretation proposed here. Both processes begin with an action (behavioral act or utterance) that is to be explained in terms of intentions (e.g., to help or to harm) in both models. In both cases, dispositional attributions may be particularly likely to be triggered by unusual actions (e.g., socially undesirable behaviors or flouting the maxims of conversation) that may lead to inferences about the nature of the

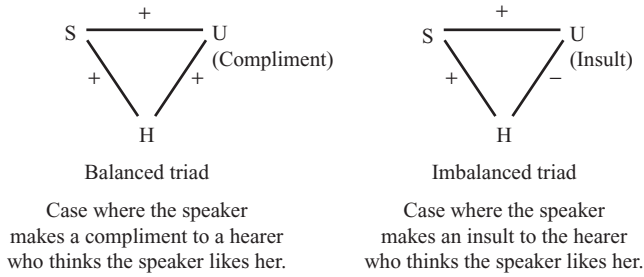

Figure 1. Examples of balanced and imbalanced speaker-hearer-utterance relationships. S = speaker; H = hearer; U = utterance; + = positive relationship between elements; - = negative relationship between elements.

person or speaker (that they are a kind or unkind person in general). Thus, it should be of little surprise that Grice's (1975) model of utterance comprehension should be compatible with models of action attribution (Jones, 1979; Jones and Davis, 1965; Jones and McGillis, 1976), given his insistence that communication should be viewed as a form of action governed by the same general concerns of rationality as action in general.

The attributional model of utterance comprehension assumes that, all things being equal, the average hearer will assume that the average speaker is cooperative. However, if relevant evidence or beliefs are at hand, then the hearer may revise this assumption in a process of dispositional attribution. Attributional processes are particularly likely to be triggered by unexpected or undesirable events (Bohner, Bless, Schwarz, and Strack, 1988; Brown and van Kleeck, 1989; Hastie, 1984; Hilton and Slugoski, 1986; Weiner, 1985). Consequently, one may expect more attributions to be made about a speaker when he or she flouts the maxims of conversation by being untruthful, uninformative, irrelevant, and unclear than if he or she respects them by being truthful, informative, relevant, and clear. Consistent with this position, Turnbull and Smith (1985) found that neutral observers perceived a person who conveyed a defective answer as being inconsiderate and hostile and as having a negative and distant relationship with the questioner.²

The emphasis in classic models of dispositional attribution is a bottom-up one: The direction of inference most studied is from acts (utterances) through intentions to dispositions (Jones, 1979; Jones and Davis, 1965). In this view, information in the form of acts or utterances may lead to revision of prior beliefs about the actor or speaker. However, a reverse top-down direc-

tion of inference is also quite possible, where the observer holds strong prior beliefs about the actor, such as knowledge of his or her social category membership (Jones and McGillis, 1976). In the realm of utterance comprehension, Slugoski and Turnbull (1988) produced evidence for such top-down inference processes by showing that neutral observers revised their interpretation of literal insults and compliments in line with their knowledge of the interactants' relationship. Thus, if the interactants in question were known to hate each other, observers would reinterpret a literal compliment ("Wow, that's a great hairstyle you just got!") as a sarcastic insult ("What an awful hairstyle!"). Conversely, literal insults from friends were reinterpreted as playful banter.

The relationship among a speaker, a hearer, and an utterance can be represented as a cognitive triad (see Figure 1). According to Heider (1958), perceivers will try to ensure cognitive balance by ensuring that the signs connecting the elements of the triad multiply out positively. In Slugoski and Turnbull's (1988) experiment, the speaker or subject (S) always has a positive relationship of possession to the utterance he or she makes because he or she "owns" it. If the hearer or observer (H) believes that the speaker or subject (S) likes him or her (H), then S and H have a positive affective relationship. A compliment to the hearer or observer (H) indicates a positive relationship between H and U, resulting in three positive signs and a balanced relationship. However, if an imbalanced triad is produced when the speaker makes a literal insult to a hearer who believes the speaker likes him or her, cognitive imbalance is created due to the negative relationship between H and U. This can be reduced by changing the signs of one of the relationships. This can be achieved by (a) reinterpreting the insult as a compliment;

(b) reinterpreting the speaker's attitude to the hearer as negative rather than positive; or (c) disowning the speaker's possession of the remark ("Something got into him," "He was in a bad mood," "He didn't really mean it").

Interpreting an utterance thus requires a kind of cognitive balancing act (cf. Brown and van Kleeck, 1989). Although the previous example and Figure 1 are only schematic, they do illustrate how the hearer's perceptions of the speaker and the utterance can be reconciled according to the principles of cognitive consistency. Both top-down (revision of utterance interpretation) and bottom-up (revision of beliefs about the speaker) processes of inconsistency resolution can occur. Following research on inconsistency resolution, I speculate that weakly held beliefs will be modified more than strongly held ones (Tannenbaum, 1968). Thus, if a hearer is confident that the speaker likes the hearer, the hearer will probably change the interpretation of a literal insult to a conveyed compliment. However, if the hearer has no prior preconceptions about the speaker's attitude to the hearer, then the hearer may infer that the speaker is hostile to the hearer. This process of reinterpretation to preserve cognitive balance is consistent with Asch's (1940) demonstration of "change of meaning" effects.

The attributional model of conversational inference claims that the application of higher-order assumptions about conversation is relativized to particular characteristics known or assumed about the speaker, such as the degree of cooperativeness, friendliness, group membership, knowledge about the topic, beliefs about the hearer, and skill in the language. Consistency and coherence criteria are used to choose the speaker's most likely intended meaning and thus the most rational interpretation of an utterance.

Although the attributional model of conversational inference has been developed from Grice's (1975) characterization of the logic of conversation, its main assumptions are quite consistent with other approaches to conversational pragmatics (e.g., Allwood, 1987; Recanati, 1993; Sperber and Wilson, 1986). All share the view that conversational utterances are interpreted in the light of higher-order assumptions about the speaker's intentionality. They could therefore allow that the most rational interpretation of an utterance is the one most consistent with relevant beliefs held about the speaker. Below, I consider how beliefs about the speaker may determine the interpretation of an utterance in a routine way.

Attributions about the Speaker and the Choice of Rational Interpretations

As noted above, a major criterion for attributing rationality is consistency (Strawson, 1952). Below, I show how rational interpretations of utterances are selected because they are consistent with the conversational context and specifically with beliefs about the speaker. I begin with an example of how attributions about the speaker might guide interpretations of the quantifier *some*.

The trade-off between the maxims of quality and quantity implies that speakers should try to be as informative as possible without running the (undue) risk of being false. Consequently, the interpretations hearers choose may in large part depend on attributions they have made about the speaker's knowledge of and interests in the topic under discussion. Here's an example:

1. Some of the police officers beat up the protester.

This statement could convey one of two different implicatures. It could mean one of the following:

2. Some of the police officers beat up the protester (but the speaker knows that not all of them did).
3. Some of the police officers beat up the protester (but the speaker does not know whether all of them did).

Levinson (1983) characterized the first implicature as a *K*-implicature (because the speaker knows that the stronger assertion is not the case) and the second as a *P*-implicature (because the stronger assertion is possible, because of the speaker's lack of relevant knowledge). One may reasonably surmise that the hearer is more likely to draw the *K*-implicature if he or she considers the speaker to be very knowledgeable about the topic (e.g., an eyewitness who was there) than not knowledgeable (e.g., a person reporting the incident second-hand).

However, in some circumstances the hearer may not draw the *K*-implicature even if he or she assumes that the speaker is indeed knowledgeable about the event under discussion. Such would be the case if the speaker were a policy spokesperson at a press conference who wished to limit perceptions of police brutality in a critical public. The spokesperson may not want to tell lies, thus observing the maxim of quality, but may only commit to the weakest possible statement about police aggression that is consistent

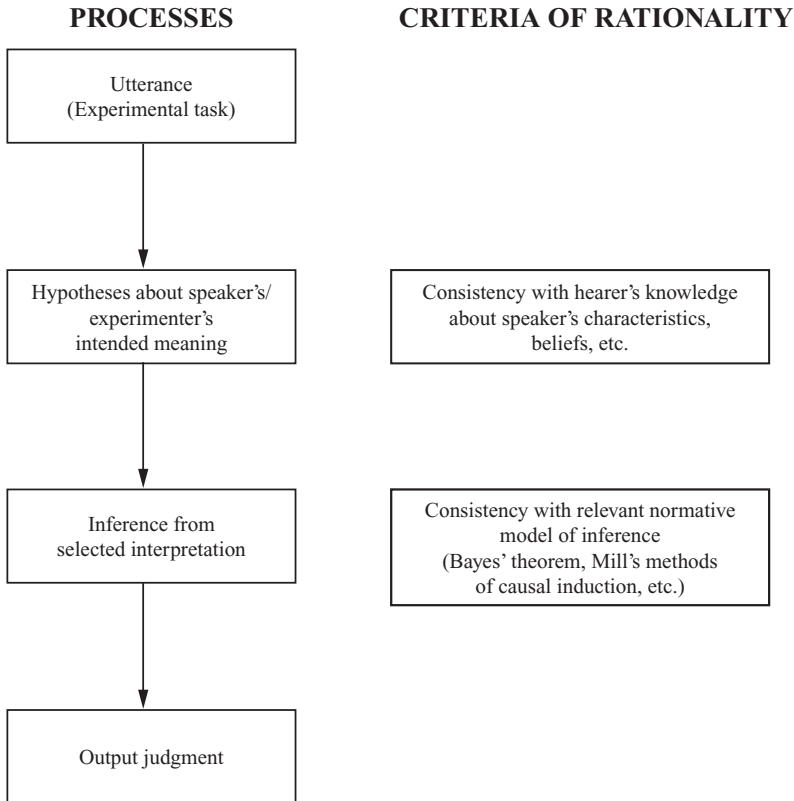

Figure 2. Two-stage resolution of uncertainty: utterance interpretation and judgment.

with evidence known to the public. If the hearer attributes noncooperativeness of this kind to the speaker, then the hearer may assume that the spokesperson may be seeking to avoid commitment to stronger statements that would be relevant but damaging to presentational goals that the police force might have.

It is not difficult to think of other factors that might affect the interpretation of such statements. For example, if the hearer knows that the speaker is a foreigner with a limited command of English and does not know such words as *a few* or *many* which the speaker might have used to specify the proportion of police involved, then the hearer might treat *some* as being vague and consistent with either a low or high proportion of police (for a further discussion of pragmatic interpretation of quantifiers, see Politzer, 1993).

Consistency in Interpretation and Reasoning

In experimental tasks, there are two major stages for arriving at a judgment from the information

given, both of which require the participant to make rational choices. The first comprises the interpretation of the task by the participant. Here the participant chooses the most rational interpretation using the criterion of consistency with higher order assumptions about conversation and knowledge about the discourse context, specifically, attributions about the speaker. The second stage involves applying a normative model of reasoning to the representation formed, for example, by applying Bayes' theorem to a belief updating problem (Kahneman and Tversky, 1973), Mill's method of difference to a causal problem (Hilton and Jaspars, 1987), or laws of physics to conservation problem (Piaget and Inhelder, 1969). A schematic diagram of this two-stage process is given in Figure 2.

Most research on judgment and reasoning has focused on the second stage of rational inference. As is seen below, anomalies found in experiments on judgment and reasoning have typically been attributed to inadequate understanding of normative models of inference, such as Bayes' rule (Kahneman and Tversky, 1973),

Mill's method of difference (Hilton and Jaspars, 1987), or the laws of conservation (Piaget and Inhelder, 1969). However, less attention has been paid to the first stage of rational inference. Clearly, apparently "irrational" judgments may be due to interpretations made at the conversational inference stage.

I argue that participants enter the experimental and survey situation with prior expectations about the experimenter. Manipulating participants' perceptions of the experimenter or survey researcher's cooperativeness, intentionality, authority, and knowledge should affect the interpretations made and thus the final judgments produced. In addition, the general assumption of cooperativeness may cause information normally thought of as incidental to the experimental task – such as response scales – to be treated as relevant. These interpretations are orderly in the sense that certain patterns of conversational inference (e.g., that triggered by part-whole contrasts) can be found across a variety of experimental tasks (probability judgment, conservation, and surveys). They are rational because these interpretations seem to make the most sense given reasonable attributions about the speaker.

Next, I review evidence that supports these claims. First, this provides support for the attributional model of conversational inference by showing how information about source characteristics such as the intentionality, cooperativeness, and authority of the speaker changes output judgments. Even where task interpretations have not been directly assessed, this at least offers prima facie evidence that participants may be applying Grice's (1975) maxims of conversation to the interpretation of experimental messages. And second, in so doing, this also calls into question the classification of some of the participants' responses as errors.

Attributions about the Experimenter and Rational Inference

There is general evidence that experiments may be regarded as social interactions in which the participant's attributions about the experimenter affect his or her behavior. Social psychological research clearly suggests that participants attribute serious purposes even to patently absurd experiments (Orne, 1962). They behave in a highly cooperative manner in response to some very questionable experimental demands when they perceive the experimenter as authoritative, but they reduce this compliance when the

experimenter is perceived as lacking in authority (Milgram, 1974). In addition, it is well known that source attributes such as expertise, credibility, and prior attitude affect participants' responses to experimental attempts at belief changes (e.g., McGuire, 1969).

In addition, Singer, Hippler, and Schwarz (1992) showed that respondents to survey questionnaires may possess a certain amount of skepticism as to the researcher's trustworthiness. These researchers found, for example, that overly emphatic confidentiality assurances may lead respondents to have less faith that the confidentiality of their responses would be respected. In sum, I surmise that adult experimental participant and survey respondents are generally compliant and treat the experimenter as authoritative and cooperative, albeit with some skepticism.

Assumption of Intentionality in Conversational Inference

The most fundamental assumption we make in hearing conversation is that utterances are intentionally produced by the speaker. If they were not, there would be no basis for making judgments about the credibility, informativeness, purpose, or style of what is said on the basis of perceptions of the speaker. Unless told otherwise, respondents seem to be very resistant to attributing experimental manipulations to the operation of random or accidental processes. Respondents are very liable to perceive palpably random behavior in experiments as if they were guided by intentions. Examples are the description of the random movement of dots in a film in terms of intentional actions such as "chase" and "follow" by 49 out of 50 of Heider and Simmel's (1944) participants. Oatley and Yuill (1985) found that cues such as "jealous husband" led participants to exert considerable ingenuity in explaining why the dots in Heider and Simmel's film moved as they did. Perhaps most germane to the present issue is the behavior of naive users of Weizenbaum's (1976) ELIZA system. Although ELIZA produces some rather stereotyped examples of therapeutic discourse through the operation of an English language generator coupled with some random response selectors and a few procedures for recognizing key words, users are very prone to adopt an "intentional stance" (Dennett, 1984) to explain ELIZA's behavior and assume that ELIZA's utterances are produced by a human being (Boden, 1977).

People appear to distinguish between behavior that they are told is produced by a person or by some impersonal agent. For example, Faucheux and Moscovici (1968) showed that participants' strategies in an experimental game were affected by information indicating that their partner was a person or nature. Gibbs, Kushner, and Mills (1991) also showed that information about authorial intentions affected metaphor comprehension. Participants who were told that the metaphors they were given were produced by 20th-century poets rather than by a computer were more likely to judge them meaningful, produced more interpretations of them, and made meaningfulness judgments faster. Consequently, variables that undermine the perception that the actions performed by the experimenter are intentional, in line with the attributional model, may have critical effects on how experimental manipulations are interpreted and responded to. As is shown below, this often seems to be the case.

Accidental and Intentional Transformations in Conservation Experiments

The procedures devised by Piaget to test children's ability to conserve quantities such as number and mass (Piaget and Inhelder, 1969) have been very widely used in developmental psychology. For purposes of exposition, one of the procedures used to test conservation of number is considered in detail. For example, a child may be shown two rows of four counters that are equal in length. The child is asked whether there is more in one row than in the other or whether they are the same. Typically, the child agrees that they are the same. The experimenter then modifies one of the rows so that the same four counters are now arranged in a longer row and repeats the question. Commonly, children younger than 7 years old will reply that there is more in the longer row. This is taken to imply that the child has failed to conserve the number of counters and perhaps has confused length with number.

However, note that the traditional Piagetian procedure involves an obviously calculated and deliberate transformation of the experimental array by the experimenter. Children may therefore have made the inference that the transformation was meant to be significant in some way. For example, the children may have recognized that the two rows still had the same number of counters, but they may have decided that the experimenter is interested in determining

whether the child has recognized that the length dimension has been changed. Children may therefore have reinterpreted the question focus from number to length to give the experimental manipulation relevance (cf. Donaldson, 1982).

McGarrigle and Donaldson (1975) tested this hypothesis by effecting the transformation "accidentally." Specifically, after the child had been shown the two rows of counters and asked which one had more, a "naughty teddy" was introduced who "accidentally" disturbed the length of one of the rows in the process of "spoiling the game" (p. 343). Of course, the teddy's behavior was carefully contrived to transform the length of counters exactly as much as the experimenter did in the normal procedure. Although the transformation was objectively the same, the children's performance in the accidental condition was vastly superior to that obtained in the intentional condition. Using one criterion of conservation, 50 of the 80 children between 4 years old and 6 years old showed conservation in the accidental condition, whereas only 13 children showed conservation in the intentional condition.

This result has been replicated and extended to other Piagetian conservation procedures (for a review, see Donaldson, 1982). Moreover, it is consistent with other studies that suggest children only judge the shorter line as having more when they have been asked to make an initial judgment of whether the two lines were equal (Rose and Blank, 1974). Clearly, when the array has been transformed and the question has been asked again, children seem to experience a demand to change their response and may reinterpret the question. When children were not asked to make an initial commitment before the transformation, they were more likely to give correct answers to the question asked after the transformation.

Siegal, Waters, and Dinwiddy (1988) extended these results by investigating whether 4-, 5-, and 6-year-old children are aware of how demand effects may influence responses. They showed children a puppet doing a conservation task. In one condition, the puppet underwent the one-question procedure of Rose and Blank (1974) and in the other, the two-question procedure. They found that children attributed the incorrect responses in the two-question task to external factors (e.g., to please someone else) but attributed the same responses in the one-question task to internal factors (e.g., because they really thought it was true). Children thus seem to be aware of the role of

social pressures in determining responses in such experiments.

Although Donaldson (1982) was careful to note that many nonconserving responses are still made in the accidental condition, she also noted that conventional conservation procedures seriously underestimate children's ability to conserve. In particular, many failures to conserve that have been attributed to cognitive deficits such as "perceptual domination" (Piaget and Inhelder, 1969) or "attentional deficits" (Gelman, 1969) may simply reflect the operation of generally adaptive principles of conversational inference.

Intentional and Random Presentations of Information in Base-Rate Experiments

One of the most widely known studies on decision making has been the engineers-and-lawyers problem introduced by Kahneman and Tversky (1973) and described in a *Science* article (Tversky and Kahneman, 1974). Berkeley and Humphreys (1982) found that the *Science* article was cited 227 times between 1975 and 1980, with approximately one fifth of the citations coming from sources outside of psychology, all of which used the citation to support the claim that people are poor decision makers.

Kahneman and Tversky's (1973) basic finding was that participants were more likely to rely on individuating information about the target than on base-rate information. For example, participants in some conditions were told that the target person "shows no interest in political and social issues and spends most of his free time on his many hobbies which include home carpentry, sailing, and mathematical puzzles" (p. 24). They were then presented with base-rate information indicating that the target person came from a sample of 100 people that included either 30 or 70 engineers, depending on the experimental condition. The participants predicted that the target person is probably an engineer, regardless of which base-rates they had been given. Kahneman and Tversky attributed this underuse of base-rate information to the operation of the representativeness heuristic, that is, participants based their decision about the probability that the target was an engineer on the similarity of the target to a stereotype of engineers.

However, evidence has since suggested that this phenomenon of "underuse of base-rate information" is restricted to "word problems" in which the base-rate information is presented verbally to participants in the form "30% of

the group are engineers," etc. Thus, studies that present base-rate information to participants in the form of learning trials show that participants can use base-rate information appropriately when making judgments (Christensen-Szalanski and Beach, 1982; Medin and Edelson, 1988). Other studies that have required participants to make judgments in which they have prior real-world experience or expertise also have found no tendency to underutilize base-rate information. For example, participants use their own implicit knowledge about the base-rate of diseases when judging the probability of a doctor's prediction that they will suffer from a particular illness (Wallsten, Fillenbaum, and Cox, 1986; Weber and Hilton, 1990). Doctors make appropriate adjustments for the base-rate probability of illnesses in a diagnosis task where they deploy implicit knowledge about symptom-group associations (e.g., weight loss in young girls suggests anorexia, but weight loss in old men suggests cancer) in medium-fidelity diagnosis tasks (Fox, 1980; Weber, Böckenholt, Hilton, and Wallace, 1993), whereas they fail to use explicitly presented base-rate information in a medical prognosis task presented in the form of a verbal vignette (Eddy, 1982). Consequently, participants' use of the representativeness heuristic may be governed by contextual factors, such as the assumptions that participants make about verbally presented base-rate information.

In fact, participants' use of base-rate information has been shown to be affected by various pragmatic factors. Krosnick et al. (1990) noted that participants always read individuating information first and base-rate information second in Kahneman and Tversky's (1973) procedure and other similar ones. Krosnick et al. hypothesized that the order of presentation of information may have served as a cue to participants to weight the initial information more and the later information less. Consistent with this reasoning, they found that participants used the base-rate information more when it was presented first. Krosnick et al. also took memory measures and were able to rule out the hypothesis that the greater weighting of earlier information was due to enhanced recall at the time of judgment.

If participants were indeed using order of presentation as a cue to determine the intended relevance of the information, then the significance of the cue should be invalidated if the participant believes that the cue has not been produced intentionally by the experimenter. This indeed

appears to be the case. Krosnick et al. (1990) found that the order effect disappeared when participants were told that the order of presentation had been randomly determined.

Ginossar and Trope (1987, Experiment 6) presented the engineers-and-lawyers problem to participants as if the information had been generated as part of a card game. Framing the description as having been produced by a game of chance would undermine the assumption that the information was produced as part of an intentional communication. Consistent with the attributional model, they found that participants were more likely to use base-rate information in this condition.

Schwarz, Strack, et al. (1991) used a related manipulation that undermines the assumption of intentionality. They told participants that the individuating information had either been produced by a panel of psychologists or statisticians who had conducted the original set of interviews with the sample of engineers and lawyers or had been drawn randomly from the psychologists' or statisticians' files by a computer. In all cases, participants were given the personality description that is representative of an engineer and were told that there were 30 engineers in the sample of 100. When told in the psychology condition that the individuating information had been given to them by a human researcher, participants on average estimated the probability that the target was an engineer at .76, replicating Kahneman and Tversky's (1973) original findings. However, when told that the statements had been drawn at random from the psychologists' file by a computer, the participants' average estimate was .40, in line with the normative use of base-rate information.

On the other hand, in the statistics condition, participants were more likely to weight individuating information when it was drawn at random by a computer from a larger sample of descriptive information ($M = .74$) than when it was written by a nonspecified researcher ($M = .55$). One possible explanation is that random sampling is a valued procedure in a statistics framework, and therefore participants attached greater significance to the representative (i.e., randomly selected) information. Although this explanation is post hoc, it does underscore the importance of attention to participants' inferences about the particular expertise and credibility possessed by the source of information. As is shown below, explicit information about the source does indeed affect participants' judgments in this task.

Source Characteristics and the Use of Base-Rate Information

Grice's (1975) maxim of quality enjoins speakers not to say what they know to be false, or at least not to say what they lack adequate evidence for. Consequently, varying the credibility of the speaker should affect the weight attached to the speaker's messages. Ginossar and Trope (1987, Experiment 5) varied the credibility of the source of information in the engineers-and-lawyers problem. They found that participants rated the personality description as having the highest probability of being true when the source was a trained psychologist ($M = .78$), lowest when the source was a palm reader ($M = .31$), and intermediate when the source was a beginning interviewer ($M = .59$).

Although Ginossar and Trope (1987) discuss these results in the terminology of "rule activation," "accessibility," and "mismatching" (pp. 465–471), unlike Krosnick et al. (1990) they took no measures – such as salience or availability – in any of their experiments that explicitly addressed such cognitive hypotheses. Interestingly, their salience manipulations that led to greater use of base-rate information involved violations of conversational norms, either by presenting prior tasks with uninformative nondiagnostic information before the target task (Experiment 1) or by rewriting the target task in a list style uncharacteristic of normal conversational communication (Experiment 2). Consequently, their results may also be treated as just as consistent with the attributional model that suggests the weighting of individuating information is based on inferences about the Gricean quality of that information, based on perceptions of the source.

In a related vein, Zukier and Pepitone (1984, Experiment 1) enjoined their participants to either behave like clinicians or scientists in making judgments. Thus, when the task was framed as being one of "clinical judgment," participants were asked to call on their "general knowledge, sensitivity, and empathy" in understanding "the individual's personality, profession, and interests" (p. 353). Although not discussed in Gricean terms, these instructions clearly invite participants to stretch the maxim of quality and say what, in other circumstances, they might feel they lack evidence for. On the other hand, the instruction in the scientist condition to behave like "a scientist analyzing data" (p. 353) seems to enjoin participants to be strict with the maxim of quality and not to say what they lack adequate

evidence for. As might be expected, the results showed that participants are more likely to weight individuating information in the clinical condition than in the scientist condition. Interestingly, participants in the scientist condition gave lower probability estimates overall for both the stereotypic and neutral personality descriptions. This would be consistent with a general orientation toward caution and consistent with a strict application of the maxim of quality.

In sum, the above studies on the engineers-and-lawyers problem suggest that participants' use of base-rate information is governed by their assumptions about its conversational quality and relevance. When participants' assumptions about the intentionality, relevance, and quality of the information are undermined, participants tend to use base-rate information more (Ginossar and Trope 1987; Krosnick et al., 1990; Schwarz, Strack, et al., 1991; Trope and Ginossar, 1988). When, in line with the precepts of conversational inference, the participants are enjoined to go beyond the information given they weight individuating information; whereas when they are enjoined to be scientific, they stick to hard facts and figures (Zukier and Pepitone, 1984). This pattern of results suggests that participants typically enter the psychology experiment with the default assumption of conversational rationality that enjoins them to go beyond the information given in making inferences about what is required of them. More important, however, they can make inferences that correspond to scientific norms when their conversational assumptions are canceled by the context. Consequently, the production of bias in such tasks may be less attributable to cognitive factors such as representativeness (Kahneman and Tversky, 1973) or availability (Ginossar and Trope, 1987) than was first thought and may be more attributable to inferences about the social context of the experimental message that are guided by conversational assumptions. Below, I consider another example of how the operation of the representativeness heuristic may be constrained by conversational norms.

Assumed Relevance of Nondiagnostic Information: Accountability and the Activation of Conversational Norms

Although Grice's (1975) maxim of relation prescribes that speakers should include only relevant information, experimenters routinely violate this assumption by deliberately including information that is meant to be irrelevant to the

task. A clear example of this is the "dilution" effect studied by Nisbett et al. (1981). They found that participants rationally used information about a target person such as IQ or an effort that is diagnostic of that person's grade point average. However, when the description of the target person included information that was not relevant to the judgment task (such as age, hair color, etc.), participants made less use of the diagnostic information. From the point of view of probability theory, there is no rational reason for this, as the diagnostic information is still as predictive when presented with nondiagnostic information as when presented alone. Nisbett et al. posited an intrapsychic explanation in terms of the representativeness heuristic due to the dilution of the diagnostic information with irrelevant nondiagnostic information, which reduced the perceived similarity of the target person to the target category (cf. Tversky and Kahneman, 1974).

However, as Tetlock and Boettger (1991) pointed out, the effect is also consistent with an explanation in terms of rational processes of conversational inference. Participants may assume that all the information that they are given, whether diagnostic or nondiagnostic, is mentioned because it is relevant. They may therefore weight all the information as diagnostic. On the assumption that nondiagnostic information is weighted negatively, the dilution effect would be observed. Such an effect would be removed if participants believed that the information had been presented without conscious design.

Tetlock and Boettger (1991) therefore presented the information to participants as having been screened for its relevance (thus activating conversational norms) or randomly sampled from a computer database (deactivation of conversational norms), with no information about the conversational relevance of the information. Half the participants were subjected to an accountability manipulation, being told that they would have to explain their decision to others when the experiment was over. This manipulation has been extremely successful in attenuating biases in judgment usually attributed to heuristics because of its presumed effect in inducing more cognitive effort (for a review, see Tetlock, 1992).

Tetlock and Boettger (1991) found that the accountability manipulation led to more use of the nondiagnostic information in the conditions where conversational norms had been activated or no information either way had been given. This is consistent with participants' belief that

the nondiagnostic information must be relevant (otherwise, it would not have been mentioned), and the accountable participants' wish to perform well in the judgment task by making maximum use of information that they presume has been guaranteed by the maxim of relevance. These results replicate the findings of Tetlock and Boettger (1989) and suggest that the participants' default assumption is that conversational rules are operative in the experiment. Significantly, when conversational norms have been deactivated, participants were less likely to use the nondiagnostic information, and thus exhibit the dilution effect. Compared with nonaccountable participants in this condition, accountable participants were actually less likely to fall prey to this error, further reinforcing the view that the dilution effect is attributable to the unreciprocated respect participants have for conversational norms in this particular experimental paradigm.

Attributions of Cooperativeness and the Effect of Leading Questions

The default assumption made by Grice's (1975) model of conversational inference is that utterances are cooperatively produced. The attribution of cooperativeness to the speaker is, of course, a special case of the attribution of intention. Other intentions, including adversative ones, may also be attributed to the speaker. Children, of course, are often subjected to trick questions in testing situations by adults. Winer, Hemphill, and Craig (1988) showed that both children and adults give more nonconserving responses when the question seems to imply that conservation is not possible. Thus, the question, "When do you weigh the most, when you are standing or crouching?" seems to imply that body weight changes from one state to another. This question leads to more responses that indicate the weight changes from one state to another than when the question is asked with the tag "or do you weigh the same?" (p. 198).

Kwoc and Winer (1986) explored social context variables that would lead children to reject misleading questions. Children were given classifications tasks in which they were shown a picture and asked whether it was X or Y, when in fact it was both. Thus, when shown a picture of a dog, children were asked, "Is this a dog or an animal?" When shown a picture of a black square, they were asked, "Is this black or a square?" Some children had previously been exposed to a training set in which questions fla-

grantly violated conversational norms. For example, they were shown a picture of a couch and asked, "Why is this a car?" These children were more likely to reject the misleading implication of the classification question that the object could not be both than children who had not been exposed to the questions that violated the rules of conversation. In a second experiment, Kwoc and Winer found that third graders were more likely to reject the misleading implication of the question when they were asked by another third grader than by an adult.

Both children and adults are vulnerable to misleading questions. Children are less vulnerable when the questions are asked by low-credibility sources, such as other children. In addition, children's susceptibility to misleading questions decreases when they have experienced flagrantly bizarre questions asked by the adult, presumably because the credibility of the adult experimenter is then undermined (for an extensive review, see Siegal, 1991).

Conversational Inference and the Effect of Leading Questions on Memory

One of the best-known *framing* effects concerns the effect of leading questions on memory. In a classic experiment, Loftus and Palmer (1974) showed that the presuppositions loaded into questions about an automobile accident affected participants' memory about that accident. Thus, if participants were asked how fast a car was going when it *smashed* into a truck, they were more likely to give a higher estimate of the speed of the car in a subsequent memory test than if they had been asked how fast the car had been going when it *hit* the truck. These findings were consistent with other results that showed participants were inclined to accept presuppositions associated with descriptions of scenes, even when those presuppositions were not actually true of the scenes described (Hornby, 1972, 1974).

However, the effect of leading questions on memory may occur only in social settings where the cooperativeness principle is assumed to hold valid, such as psychology experiments. Participants may have assumed that the experimenter in Loftus and Palmer's (1974) study was cooperative and thus have uncritically accepted the presuppositions loaded into the question. To test this interpretation, Dodd and Bradshaw (1980) found no effect of leading questions on memory as compared with a control condition when the source was specified as a lawyer representing the

defendant, although they were able to replicate the original result when the source of the leading question was the experimenter, as in Loftus and Palmer's original procedure.

Dodd and Bradshaw's (1980) results are consistent with the suggestion that when the leading question was attributed to an adversative source, such as a defending lawyer in an American court, participants suspended the assumption of cooperativeness and thus were not vulnerable to the biasing effects of leading questions. Interestingly, participants were still vulnerable to biasing effects from the recall probes about the speed of the car, which varied the descriptive cues used ("How fast was the car going when it hit/collided with/smashed" . . . , etc.). However, the recall probes all emanated from the same source (the experimenter) regardless of experimental condition and thus may still have been treated as guaranteed by the assumption of cooperativeness and used to infer the speed of the vehicle. Consequently, although the Loftus and Palmer (1974) results are typically discussed as demonstrating the effect of cognitive biases on memory, they may be plausibly attributed to the operation of conversational assumptions, which guide reconstructive inferences about the speed of the car. This interpretation is consistent with the findings of Strack, Schwarz, Bless, Kübler, and Wänke (1993) who showed that when participants are made aware of the priming episode, they appear to discount its influence, much in the manner suggested above. However, as Martin, Seta, and Crelia (1990) suggested, such discounting may require extra cognitive effort and therefore occur only when people are motivated by the task and have sufficient cognitive resources to allocate to it.

Given–New Contract and Mutual Knowledge

Grice's (1975) logic of conversation requires that speakers should be brief (satisfying the maxim of manner) and informative (satisfying the maxim of quantity). For this reason, speakers often do not explicitly refer to old information, treating it as given. Correspondingly, hearers are expected to focus on the new information contained in an utterance. This expectation is sometimes referred to as the *given–new contract*. Considerable evidence exists that speakers are sensitive to the mutual knowledge they share with listeners in the formulation of their utterances and that hearers are better at decoding messages from speakers with whom they share

common ground (Clark, 1985, 1992; Fussell and Krauss, 1989, 1992; Krauss and Fussell, 1991).

The given–new contract can force reinterpretations of *wholes* in the context of *parts* that they logically include. As Adler (1984) noted, children may interpret the class-inclusion questions in Piagetian conservation experiments this way: If asked the question, "Are there more primulas or are there more flowers?" children may treat *primulas* as given information and re-interpret *flowers* to mean flowers other than primulas and correspondingly answer that there are more primulas than flowers. Politzer (1993) presented experimental evidence that supports this analysis. As is shown below, this subtraction rule can explain many patterns of response that might otherwise be attributed to cognitive deficiencies, as done in Piagetian experiments.

Part–Whole Contrasts and Children's Learning of Names

The given–new contract, and the assumptions behind it, often forces contextually based interpretations of what is said. For example, Markman and Wachtel (1988) showed 3- and 4-year-old children a familiar object, such as a banana, and an unfamiliar one, such as a lemon wedge-press. Children were then asked, "Show me the *x*," where *x* was a nonsense syllable. Children almost invariably selected the unfamiliar object. Clearly, children's reasoning may be based on conversational assumptions that a cooperative experimenter would have said, "Show me the banana" if they had wanted the banana, so the unfamiliar word must refer to the unfamiliar object. Only if the adult were violating Grice's (1975) maxim of manner, and using an obscure, unknown word to refer to the banana when a well-known one (*banana*) exists, could the adult have reasonably intended the nonsense syllable to refer to the familiar object.

Markman and Wachtel (1988) extended this procedure to the study of part–whole relations. They showed children pictures of an object with a salient part. The object (e.g., a lung) was either familiar or unfamiliar to the children, whereas the part (e.g., a trachea) was always unfamiliar. When the object was unfamiliar, children tended to treat the new word (i.e., *trachea*) as referring to the whole object (i.e., *lung*). However, when children already knew the word *lung*, they were more likely to interpret the unfamiliar word *trachea* as referring to the specific part of the lung (i.e., the trachea). Clearly, the children may have been reasoning that the adults wished

to be informative by Grice's (1975) maxim of quantity and asked the children to name the object that they did not know. Otherwise, this particular conversation would seem to have no point.

Subsequent research has shown conditions in which children do not follow the principle of mutual exclusivity and accept that two expressions can refer to the same object. For example, when context suggests that one word indicates a subset of another larger set (e.g., dingo dogs and dogs), children between 3 and 5 years old consider that both expressions refer to members of the lower-level category (Au and Glusman, 1990; Gelman, Wilcox, and Clark, 1989). This effect seems acceptable conversational practice: Using a more specific term to refer to a previously categorized object adds precision even though the object may have been categorized at a more general level.

Another condition in which children do not follow the assumption of mutual exclusivity is when they know that the speaker is bilingual and may use words from both languages to describe the same object. In such cases, bilingual children between 3 and 7 years old who have heard the experimenter use both languages readily accept that two words can refer to the same object, as do monolingual children between 3 and 5 years old who have been led to believe that they are going to learn words from the foreign language. Clearly, children's expectations about their interlocutor's capacities and intentions can determine whether they assume mutual exclusivity of names. For example, in a teaching or testing situation, it is still informative and relevant for the adult to teach or test for Spanish vocabulary even if the adult knows the child has the requisite English vocabulary and thus attributes two different names to the same object.

Although the nonapplication of mutual exclusivity seems very consistent with Gricean rules of inference, none of the articles cited explicitly use this approach. However, children's decisions about the rational interpretation of the referents of names can be explained in terms of the assumption that the speaker was trying to be informative. If children's successful performance in naming objects in these tasks depends on conversational assumptions, this hypothesis could be tested by performing experiments that use nonadult interlocutors for the children (e.g., naughty teddies and other children) or that explicitly signal to the children that their normal conversational assumptions should be

suspended (see Kwock and Winer, 1986; for a thorough discussion of such techniques, also see Siegal, 1991).

Part-Whole Contrasts and the Interpretation of Survey Questions

Strack et al. (1988) reasoned that if a specific question precedes a general one that logically includes it, hearers interpret the general question to exclude the information already mentioned in the first question. Suppose a female survey respondent is asked about satisfaction with her life in general, she is likely to report her global satisfaction with her personal and professional life. If, however, she is asked first about her professional life and then about her life in general, she will treat life in general as referring to nonprofessional parts of her life if she wishes to respect the maxim of quantity and give her questioner new information.

Strack et al. (1988) applied this reasoning to the analysis of seemingly inconsistent responses to survey questions. In one condition, which they termed the *conversational context*, Strack et al. introduced the two questions by saying, "Now, we would like to learn about two areas of life that may be important for people's overall well-being: (a) happiness with dating, (b) happiness with life in general" (p. 434). In this condition, they hypothesized that the focus of the general question be interpreted as excluding the focus of the specific question that has been asked first. Because answers to the two questions would be based on different information, there should not be much correlation. When students were asked to rate their satisfaction with life in general after rating their satisfaction with their dating life, the correlation was very low (.26).

However, when the specific question was asked at the end of one page and the general question was asked at the beginning of the next page, Strack et al. (1988) reasoned that the two questions would not be perceived as being related and that these should be no such subtraction effect. Consistent with this reasoning, a much higher correlation (.55) was obtained for respondents' ratings of their responses to these two questions in this condition. Similar results were obtained by Schwarz, Strack, and Mai (1991).

Consequently, seemingly inconsistent responses can be explained in terms of conversational pragmatics. Also important to note is that the exclusion of the information from the preceding question (e.g., about the respondent's

satisfaction with his or her marriage) from the response to the subsequent question (e.g., about satisfaction with life in general) cannot be explained in terms of priming theories. Because the information about marriage has been so recently mentioned, it should be highly available in memory and thus, according to a straightforward priming theory, have more impact on the subsequent judgment. Although cognitive accessibility may often affect salience, principles of conversational inference can override the application of the availability heuristic (cf. Strack, 1992).

Part-Whole Contrasts and the Conjunction Fallacy

Dulany and Hilton (1991) applied this logic to the analysis of Tversky and Kahneman's (1983) conjunction fallacy task. In the best-known version of this task, participants read a detailed description of a target person:

Linda is 31 years old, single, outspoken, and very bright. She majored in philosophy. As a student she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations. (p. 297)

Participants are then asked to check which one of the following two alternatives is most probable:

Linda is a bank teller. (*T*)
Linda is a bank teller and is active in the feminist movement. (*T and F*) (p. 297)

Tversky and Kahneman (1983) reported that 85% of the participants rated the conjunction of constituents (*T and F*) as more probable than the single constituent (*T*). This *conjunction effect* is considered a fallacy because a conjunction of two constituents cannot be more probable than one of the constituents alone. The logic of extensional sets requires that the class of people who are bank tellers and feminists be a subset of the class of people who are bank tellers. Tversky and Kahneman argued that people make this error in probability judgment because they are guided by the representativeness heuristic, which finds the conjunction (*T and F*) to be more similar to the *model* (i.e., the target description of Linda) than the constituent (*T*) alone and therefore is judged as more probable. As support of this, they noted that very few participants commit the conjunction fallacy in the *no-model* condition where minimal information about the target ("Linda is 31

years old") is presented because this fails to activate the representativeness heuristic.

Several researchers have argued from conversational principles that participants interpret "Linda is a bank teller" (*T*) to mean Linda is a bank teller who is not active in the feminist movement (*T and not F*) in this context (Morier and Borgida, 1984; Politzer and Noveck, 1991). If so, the judgment that *T* is more probable than *T and F* is no longer a fallacy because *T* is implicitly read as indicating another kind of conjunction, namely, *T and not F*. On the basis of an analysis of attribution processes in conversational inference, Dulany and Hilton (1991) sought to predict the conditions under which participants would draw the absolving interpretation of "Linda is a bank teller." They argued that the rich information given to the participant in the model condition may justify the inference that the experimenter knows a lot about the target. The participant may reason that if the experimenter knows a lot about the target, Linda, then the reason the experimenter omitted to say that Linda is active in the feminist movement is because he or she knows this not to be the case, thus conveying a *K-implicature* (Levinson, 1983) that Linda is not active in the feminist movement. By contrast, in the no-model condition, the participant may reason that the experimenter did not say that Linda is a bank teller because he or she does not know whether this is the case or not, thus implying the *P-implicature* (Levinson, 1983) that it is logically possible that Linda either may or may not be a bank teller. The *P-implicature* corresponds to the extensional interpretation of the constituent that would imply that the conjunction effect is indeed a logical fallacy. Dulany and Hilton found that participants did in fact draw more *K-implicatures* in the model condition as predicted. Thus, they were most likely to make interpretations that would absolve them of charges of fallacious reasoning in just those conditions where they were most likely to judge the conjunction as more probable than the constituent. When interpretations were controlled, Dulany and Hilton found a greatly reduced fallacy rate of 25% to 30%.³

Tversky and Kahneman (1983) acknowledged that participants may be interpreting *T* to mean *T and not F* and sought to deal with this problem by developing a *direct* version of the task in which the extensional nature of the conjunct was explicitly stated. Thus they asked participants to judge the probability of "Linda is a bank teller whether or not she is active in the

feminist movement.” However, this phrasing is also unsatisfactory as it could be reinterpreted as “Linda is a bank teller even if she is active in the feminist movement,” in much the same way as “We will go to the zoo tomorrow whether or not it rains” can be interpreted as “We will go to the zoo tomorrow even if it rains. Following Grice’s (1975) maxim of manner, Dulany and Hilton (1991) developed a less ambiguous version of the direct test and found less than half the conjunction fallacies obtained by Tversky and Kahneman. Thus, it seems that ambiguities in the wording used may have led Tversky and Kahneman to overestimate the number of conjunction fallacies committed.

In a closely related analysis, Politzer and Noveck (1991) showed how changes to the linguistic structure of the conjunction task that preserve its logical form also reduce error rates. In one of their problems, participants were told that Daniel was a bright high school student and were then asked to judge the probability of the following three predictions about his performance in further studies:

- Daniel entered medical school. (*M*)
- Daniel dropped out of medical school for lack of interest. (*presupposed M and D*)
- Daniel graduated from medical school. (*presupposed M and G*) (p. 93)

In this case, the constituent “Daniel entered medical school” is presupposed by his later dropping out or graduating. Following the conjunction rule, the implicit conjunctions should be judged as less probable than the constituent. Thirty percent of the participants did in fact judge one of the conjunctions (*presupposed M and D or presupposed M and G*) to be more probable than the constituent (*M*), thus committing the fallacy.

The Daniel problem resembles Tversky and Kahneman’s (1983) Linda problem in terms of the class inclusion relations between the alternatives but differs in that these class inclusion relations are not suggested explicitly. However, it is possible to change the Daniel problem such that these relations are expressed explicitly through the connective *and*, as follows:

- Daniel entered medical school. (*M*)
- Daniel entered medical school and dropped out for lack of interest (*M and D*)
- Daniel entered medical school and graduated. (*M and G*) (p. 93)

Politzer and Noveck (1991) argued that as in the Linda problem, the use of *and* will force

the implicature that the constituent implies a conjunction (either *M and not D* or *M and not G*). In this explicit condition, 53% of the participants rated one the conjunctions (*M and D* or *M and G*) as more probable than the constituent (*M*). Politzer and Noveck thus claimed that making the inclusion relation explicit through the use of the connective *and* actually worsens performance, thus casting doubt on Tversky and Kahneman’s (1983) claim that “people are not accustomed to the detection of nesting among events, even when the relations are clearly displayed” (p. 304). Equally, they observed that the increase in the error rate produced by the introduction of *and* seems to contradict Tversky and Kahneman’s (1983) view that “the conjunction fallacy is not restricted to esoteric interpretations of the connective *and*” (p. 303).

Unlike Dulany and Hilton (1991), Politzer and Noveck (1991) did not assess how their manipulation of the explicitness of the class inclusion relation might have affected the implicature drawn from the constituent. Nevertheless, although much remains to be done to elucidate how the response alternatives used in conjunction tasks are interpreted (see Adler, 1991; Fiedler, 1988; Wolford, Taylor, and Beck, 1990, for alternative approaches), enough already seems to have been done to illustrate the value of using conversational pragmatics to analyze these issues.

Relevance of Incidental Information

Grice’s (1975) maxim of relation enjoins speakers to be relevant. Speakers should not mention irrelevant information. Thus, hearers are entitled to assume that all the information given to them is relevant to the task at hand and, according to the maxim of quality, not misleading in any way. However, experimenters often include irrelevant information that may in fact be used by participants to interpret their experimental task. As is shown below, such irrelevant information may be conveyed through the kinds of dependent measures used or through interpretations of the independent variables that were not intended by the experimenter.

Relevance of Information Contained in Response Scales

Although experimenters generally use response scales to assess participants’ judgments and not to influence them, there is considerable evidence that participants often use response scales as cues

about the character and extent of the behavior probed (Schwarz, 1990; Wyer, 1981).

For example, the range indicated by the response scale may cue participants' interpretation of the behavior. Schwarz, Strack, Mueller, and Deutsch (1988) asked participants how often they had felt really irritated recently. One group of participants was given a scale ranging from *several times daily* to *less than once a week*, whereas other participants were given a scale ranging from *several times a year* to *less than once every three months* (p. 112). They argued that participants would use their world knowledge to decide what kind of irritations were implied by the experimenter's question. Consistent with their reasoning, participants given the former scale reported less extreme examples of irritation (e.g., having to wait for service in a restaurant). Participants given the latter scale reported more extreme examples of irritation (e.g., having a fight with one's spouse).

The numeric values assigned to points on a rating scale may also affect how a survey question is interpreted. Suppose respondents have to evaluate how successful they have been in life on an 11-point rating scale, ranging from *not at all successful* to *extremely successful*. However, the numerical labeling of the scale may influence how the question is perceived. Thus, if the 11 points on the scale are labeled from 0 to 10, respondents may interpret *not at all successful* to indicate lack of outstanding success. On the other hand, a scale ranging from -5 through 0 to 5 may lead them to interpret *not at all successful* as *extremely unsuccessful*. Accordingly, respondents may mark the absence of outstanding successes as 0 on the 0 to 10 scale, but also as 0 on the -5 to 5 scale, because they interpret -5 to mean a resounding failure rather than the absence of success. This would lead to greater use of the bottom end of the 0 to 10 scale than the -5 to 5 scale, where the bottom end would be reserved for resounding failures. Schwarz, Knäuper, et al. (1991) did indeed observe that 34% of the respondents checked the lower half of the 0 to 10 scale, whereas only 13% checked the lower half of the -5 to 5 scale. Subsequent studies also indicated that respondents were more likely to treat 2 on a 0 to 10 scale as indicating the absence of success but -4 on a -5 to 5 scale as the presence of failure, although the two scales are formally identical.

Respondents may also use response scales to decide the likely frequency of a target behavior. For example, Schwarz, Hippler, Deutsch, and Strack (1985) asked German adults to rate

how frequently they watched television. Half the respondents received a scale ranging in $\frac{1}{2}$ -hr steps from *up to $\frac{1}{2}$ hour* to *more than $2\frac{1}{2}$ hours*, and the other half received a scale ranging from *up to $2\frac{1}{2}$ hours* to *more than $4\frac{1}{2}$ hours* (p. 390). Only 16% of the respondents who received the low-frequency scale reported watching television for more than $2\frac{1}{2}$ hours, whereas 38% of the respondents who received the high-frequency scale did so. Similar effects of range of response alternatives for estimations of sexual intercourse and masturbation in dating couples exist (Schwarz and Scheuring, 1988).

Moderating Effect of Expertise on Range Effects

It might be conjectured that the effect of scale ranges on frequency estimation may reflect anchoring effects (Tversky and Kahneman, 1974). However, respondents' susceptibility to the effect of scale ranges is mediated by their knowledgeability of the topic in question. Thus, U.S. college students were least likely to be biased by scale ranges when estimating their own or a friend's frequency of watching television than when estimating the television consumption of a typical undergraduate. Moreover, college students who are high on private self-consciousness (Fenigstein, Scheier, and Buss, 1975) are less likely to be influenced by scale ranges than students low on private self-consciousness. This is consistent with the view that high-on-private-self-consciousness individuals, who reflect more about the nature of their behavior, are more likely to know how often they watch television (Schwarz et al., 1985).

Comparable results were obtained by Joyce and Biddle (1981). They showed that trained accountants were not subject to anchoring effects on an auditing task when they themselves generated the anchors. Self-generated anchors cannot provide information about the experimenter's estimate of the frequency of a behavior in the target population. However, trained accountants were still susceptible to anchoring effects on tasks when the experimenter provided the anchors (Joyce and Biddle, 1981).

Similar results were obtained by Sanbonmatsu, Kardes, and Herr (1992), who showed that expertise moderated the effects of incomplete information on preference judgments. Respondents were presented either with four or eight statements about a camera that were uniformly positive (e.g., "The Brand A camera is lighter and more compact than most other

35-mm cameras"). The respondents had been classified as possessing either high, medium, or low knowledge about cameras. Expertise had no effect on preference when the amount of information given was large. However, when the amount of information given was small, high-knowledge respondents were significantly less positive in their evaluations. Presumably, low- and medium-knowledge respondents considered the range of relevant information given to be complete, whether they received four or eight items of information. However, high-knowledge respondents who received four items of information presumably recognized that information about important dimensions of judgment was missing. In the absence of explicitly positive statements about dimensions known by the experts to be relevant, they may have implicitly presumed relatively negative attributes on these dimensions. This would have resulted in the more negative evaluation reported. Sanbonmatsu et al. suggested that these findings are inconsistent with the predictions of the anchoring and adjustment hypothesis, which would predict that the effect of set size on favorability of impressions should generalize across all respondents, regardless of expertise.

In sum, experimental results suggest that when respondents do not have direct access to the frequency information required, they use the frequency range provided by the experimenter to estimate the likely frequency of a behavior in the population, which they then use to calculate their response, for example, their position on that scale. Respondents seem to be guided by a strategy of guessing on the basis of the response scales that had been provided by a cooperative experimenter who did not wish to mislead the respondent about the likely range of responses in the population studied. Cognitive explanations based on anchoring and adjustment cannot explain why self-provided anchors are ineffective, why experimenter-provided anchors are most effective in domains about which the respondent knows little, or why set size effects on preference judgment are most pronounced for experts.

Relevance of the Range and Phrasing of Response Sets: A Reexamination of Attribution Experiments

It is often claimed that respondents underuse consensus information, a form of base-rate information referring to how other people would have behaved in the target situation (Alloy

and Tabachnik, 1984; Higgins and Bargh, 1987; Kassin, 1979; McArthur, 1972, 1976; Nisbett and Borgida, 1975; Nisbett, Borgida, Crandall, and Reed, 1976; Ross and Fletcher, 1985). One reason for this claim is that in an influential study, McArthur found little influence of consensus information on attributions. However, Hilton (1990b) suggested that this pattern may be the result of methodological artifacts. One factor of key importance is McArthur's failure to specify interactional attributions in her response format. In such studies, respondents are given a target event such as "Sue is afraid of the dog" and three items of covariation information: consensus, indicating covariation of the target behavior over other persons (whether other people are afraid of the dog); distinctiveness, indicating covariation of the target behavior over other stimuli (whether Sue is afraid of other dogs); and consistency, indicating covariation of the target behavior over other times (whether Sue has been afraid of this dog on other occasions). A representative information pattern that respondents might receive in such studies is the low-consensus, high-distinctiveness, low-consistency information configuration below:

Sue is afraid of the dog.
 Hardly anyone else is afraid of the dog.
 Sue is afraid of hardly any other dog.
 In the past, Sue has hardly ever been afraid of this dog.

In McArthur's (1972, 1976) original tests of Kelley's (1967) model, respondents were given main effect attributions to the person, stimulus, or circumstances to select or were asked to write any interactional attributions in a space provided.

Please circle the cause of the event.

- Something about Sue caused her to be afraid of the dog.
- Something about the dog caused her to be afraid of it.
- Something about the circumstances caused Sue to be afraid of the dog.
- Some combination of these causes. (please write your answer in the space below)

The attribution predicted by the application of Mill's (1872/1973) method of difference is the combination of the person, the stimulus, and the circumstances (Jaspars, Hewstone, and Fincham, 1983). However, McArthur (1972, 1976) found a strong preference to attribute this configuration to a single effect,

the circumstances (cf. Orvis, Cunningham, and Kelley, 1975).

This attributional pattern could reflect a bias produced by the response set. This set of response alternatives, in combination with the use of the ambiguous term *the circumstances*, may have caused respondents not to make predicted interactional attributions to combinations of factors (e.g., the person and stimulus and the occasion). Respondents may have taken the lack of interactional attributions explicitly specified in the response format as a cue not to produce them and may have also used *the circumstances* to indicate interactional attributions. This supposition is supported by results obtained by studies that used a full set of response alternatives:

Please circle the cause of the event.

- a. Something about Sue caused her to be afraid of the dog.
- b. Something about the dog caused her to be afraid of it.
- c. Something about the circumstances caused Sue to be afraid of the dog.
- d. Some combination of Sue and the dog caused her to be afraid of it.
- e. Some combination of Sue and the circumstances caused her to be afraid of the dog.
- f. Some combination of the dog and the circumstances caused Sue to be afraid of it.
- g. Some combination of Sue, the dog, and the circumstances caused her to be afraid of it.

With this format, the most favored response is the predicted interactional attribution to the combination of the person, the stimulus, and the circumstances (Jaspars, 1983). More generally, studies that did give a full range of interactional attributions in the response format found 61% (Jaspars, 1983) and 47% (Hilton and Jaspars, 1987) interactional attributions, whereas studies that did not use such response formats found only 37% (McArthur, 1972) and 35% (Hewstone and Jaspars, 1983) interactional attributions. Thus, the data collected by McArthur may have been systematically biased (Hilton, 1990b). Studies that used full-response formats show the predicted effect of consensus information on person attribution (Cheng and Novick, 1990; Försterling, 1989; Hilton and Jaspars, 1987; Iacobucci and McGill, 1990; Jaspars, 1983). Consequently, the original finding that consensus information is underused may be attributable to methodological problems, in part caused by

how respondents interpreted the response sets that they were given (Hilton, 1990b).

Another explanation for the apparent underuse of consensus information may have been the failure of earlier research to take into account the role of respondents' pragmatic presuppositions about event base rates in causal inference (Cheng and Novick, 1990; Försterling, 1989). In addition, actor – observer differences (Jones and Nisbett, 1972) and success – failure asymmetries in explanation (Weiner et al., 1972) are amenable to explanation in terms of pragmatic question focus (McGill, 1989). Interested readers are referred to Hilton (1990a, 1991) for a detailed discussion.

Pragmatic Inferences and Stimulus Vocabulary Choice

Some pragmatic phenomena are not determined by inferences about the speaker's intended meaning derived through application of Grice's (1975) principles (Levinson, 1983). These include inferences about focus determined through *pragmatic particles*. Pragmatic particles – such as *but*, *few*, *a few*, *occasionally*, and *seldom* – conventionally determine the interpretation of words with which they are conjoined, as well as having truth values that determine their own range of applicability. For example, *seldom* and *occasionally* indicate approximately the same frequency of occurrence of a behavior and thus have the same truth values. However, although similar in semantic terms, they have different pragmatic properties. Thus, they focus attention on different aspects of the behavior (Moxey and Sanford, 1987). If one is asked to explain why John seldom walks the dog, one is apt to come up with reasons for the nonoccurrence of the behavior (e.g., because he is always busy), whereas if one is asked to explain why he occasionally walks the dog, one tends to give reasons that account for the occurrence of the behavior (e.g., because he likes the exercise).

Experimental psychologists and survey researchers who are not aware of the functions of pragmatic particles are liable to produce unintended effects or to misattribute effects that they obtain. An example can be found in the stimulus material used by Kahneman and Miller (1986) to test norm theory. Kahneman and Miller argued that unusual events are more likely to activate counterfactual alternatives in which the nonoccurrence of the target event is brought to mind. However, if an experimenter describes an event as *seldom* rather than *occasionally* happening,

then this would serve as a cue to the respondent to focus on why the event did not happen rather than why it did happen, regardless of the actual normality of the event. Such is the case in one of the stimulus passages used by Kahneman and Miller: "On the day of the accident, Mr. Jones left the office earlier than usual, to attend to some household chores at his wife's request. He drove home along his regular route. Mr. Jones occasionally chose to drive along the shore, to enjoy the view on exceptionally clear days, but that day was just average" (p. 143). Hence, one cannot be sure whether the effects obtained (e.g., events undone by counterfactual reasoning) are attributable to the normality of the events described or to the focus indicated by the experimenter's choice of temporal quantifier.

A related effect may be the *forbid-allow* asymmetry studied by Hippler and Schwarz (1986). Forbidding something and not allowing something appear to be semantically similar; they would seem to be true of the same kind of event. However, survey respondents are much more likely to agree, for example, that peep-shows should not be allowed than that they should be forbidden (Hippler and Schwarz, 1986). Although it is not altogether clear why the forbid-allow asymmetry should exist, it is clear that seemingly irrelevant changes in phrasing that appear to preserve the literal meaning of the target stimulus, nevertheless, change the meaning conveyed to the respondent.

Transparency of Reference and Use of Base-Rate Information

Grice's (1975) maxim of manner exhorts speakers to be clear and unambiguous. Using methods similar to those of Dulany and Hilton (1991), Macchi (1991) showed that respondents use base-rate information in response to questions that clarify the nature of the judgment required. In one of Macchi's experimental tasks, adapted from the suicide problem of Tversky and Kahneman (1980), respondents were informed that 80% of a population of young adults were married, whereas 20% were single. They were also told that the percentage of deaths is three times higher among single individuals than among married individuals. Macchi suggested that the phrasing "three times higher" is ambiguous between the percentage of all suicides (implying that 75% of deaths are singles, whereas 25% are marrieds) and the percentage among singles as opposed to the per-

centage among marrieds. It is an empirical question as to the interpretation that is more likely to be preferred here and a normative question for the rules of conversation to decide which is more rational. In any case, respondents' median response (3:1) is entirely consistent with the former interpretation. Thus, respondents appear not to use the base-rate information about the proportion of marrieds and singles in the population in making their judgments.

Noting that this effect may be due to a misunderstanding, Macchi (1991) rephrased this item of information as "30% of single individuals and 10% of married individuals commit suicide" (p. 9), which has the merit of being unambiguous, clear, and coherent with the manner of describing the base-rate information, which was also expressed in percentage. In this condition, respondents used the base-rate information appropriately.

Macchi (1991) also showed that similar changes in discourse structure that add no information but simply clarify the relationship between supersets and subsets produce similar variations in use of base-rate information in Tversky and Kahneman's (1980) suicide problem. In particular, she showed that the manipulation of causal relevance that induced use of base-rate information may have done so because it manipulated discourse structure by explicitly mentioning both the superset (young adults) and the subset (suicides) in the same question. A similar superset-subset phrasing of a logically similar but noncausal problem involving books and paperbacks likewise induced use of base-rate information, whereas a question that referred explicitly to the subset but not to the superset did not induce corresponding use of base-rate information. As has been noted above with other paradigms, an effect (the use of base-rate information) may have been misattributed to a cognitive factor (causal relevance) when in fact it is attributable to discourse processes.

Implications of Conversational Inference for the Attribution of Rationality

The larger issue addressed in this review has been the attribution of rationality or irrationality to human judgments. I have argued that in many cases judgments that have been or could be considered irrational may in fact be considered rational if prior processes of conversational inference are taken into account. These shape the representation of the task used by the experimental or survey respondent. Moreover, these

processes of conversational inference are not ad hoc or defective in some way but reflect the rationality of social interaction and communication, where trade-offs have to be made, for example, between explicitness and economy in communication. Consequently, as in everyday communication, respondents may transform the information given explicitly by the experimenter by adding information they assume to be relevant but omitted by a cooperative experimenter who assumed that such information was implicitly shared. Alternatively, they may assume that all the information given by the experimenter must be relevant, otherwise why mention it? Or, they may assume that the order in which the information is presented indicates its degree of importance or relevance to the judgment task.

In each case, the respondent goes beyond the information given (or intended to be given) by the experimenter. Such departures from the explicit reasoning task may not be so much the result of an individual's failure to apply normative rules of inference properly to the information given (the cognitive bias explanation) but to the socially skilled application of shared rules of message interpretation (the conversational inference interpretation). These rules of inference have a quite general application. Thus, undermining the assumption of intentionality reduces biases in such diverse tasks as Piagetian conservation tasks, the engineers-and-lawyers task of Tversky and Kahneman (1974), and the leading questions paradigm of Loftus and Palmer (1974). Another example is the similar kinds of experimental demands created by juxtaposing questions comparing specific and general quantities in tasks involving conservation, object naming, probability judgments, and survey judgments of life satisfaction. Conversational inference thus has general features that emerge in a wide range of tasks.

In particular, I have argued that two important features of conversational inferences are their ampliativeness and their defeasibility. Like good inductions, good conversational inferences go beyond the information given and can be corrected by empirical evidence. However, these general properties of conversational inference are in direct conflict with basic assumptions of much judgment research, as is discussed below.

Implications of Conversational Inference for the Thesis of Negative Rationality

According to the logic of conversation, respondents may interpret what is said to them in

particular ways and be justified in adding extra premises that seem to be relevant in interpreting what is said. The inductive nature of conversational inference poses a general problem for the metaphysical assumptions of workers interested in assessing errors in human judgment. This is because such workers normally assume that the correct answer can be determined by applying a normative model to the explicitly given data set, such as Bayes' rule for probabilistic inference tasks (Tversky and Kahneman, 1974) or the assumption of reversibility of logical operations for conservation tasks (Inhelder and Piaget, 1958).

In the negative rationality perspective (Rometveit, 1978), errors are defined by deviations from the predictions of the normative model. The inference task is thus essentially deductive in nature; given the premises, the correct answer can be deduced. However, according to conversational inference, it is rational to add to, elaborate, or reinterpret the information given, subject to Gricean assumptions. Consequently, the overall experimental task of forming a representation of the information given and of reasoning from that representation also becomes inductive in nature. In assessing the overall rationality of the participant's response, the experimenter has to take the rationality of his or her interpretation of the task into account, as well as the rationality of his or her reasoning processes.

The inductive nature of conversational inference suggests that many of the experimental results that have been attributed to faulty reasoning may be reinterpreted as being due to rational interpretations of experimenter-given information. However, the attributional model of conversational inference does not imply that respondents never make bona fide errors of reasoning. Rather, better specification of these inference processes should enable researchers to identify cases in which mistakes may be attributable to conversationally guided interpretations of the judgment task, as opposed to cases in which mistakes are due to genuine errors of reasoning. Below, I consider how the present framework can help classify errors more clearly, by either explicitly controlling respondents' assumptions about the conversational relevance of information or assessing the representations built on the basis of such assumptions.

Controlling for Conversational Inference: Methodological Implications

The present framework suggests that the interpretation of experimenter-given information

should be systematically investigated and controlled for in experimental and survey research. Although the research reported in this review gives support to the attributional model of conversational inference, much of it was not conducted with this model in mind and therefore did not examine variables that would enable a full test of the model. Below, I suggest some general methodological procedures that can aid in this task.

First, as suggested by the attributional model of conversational inference, assumptions about the source of a message can be manipulated or otherwise controlled. For example, the basic assumption of conversational inference that the source is intentional can be undermined by persuading the respondent that the information provided has been randomly generated (e.g., by computer) or has been generated by the respondent (e.g., through the respondent's own search efforts).

Second, even where the source is intentional, the respondent's perception of the reliability of the source may be affected by the cooperativeness or knowledgeability of the source. As argued above (e.g., Dulany and Hilton, 1991), the inference that what is left unsaid did not in fact happen because it would otherwise have been mentioned by a cooperative and knowledgeable speaker rests on attributions about the speaker. These attributions can be measured and manipulated. For example, the intuition that a witness who gives more details is more credible (although precise descriptions must necessarily have less chance of being true than vague ones, see Macdonald, 1986) may rest on the assumption that detailed testimony indicates a clear mind, attentiveness, and first-hand experience of the event in question. However, where detailed testimony indicates unreliability (e.g., when it seems improbable that any witness could form a coherent and detailed impression of the scene, for example, in the seconds after the assassination of President John F. Kennedy), it may be perceived as less probable than a fleeting description of the scene. Such questions are open to empirical verification.

Third, key words should be checked for conventional implicatures. Words such as *but* and *although* suggest an adversative relation between items of information and signal the experimenter's expectancies. Likewise, quantifiers such as *a few* and *few*, and adverbs such as *occasionally* and *seldom*, signal the speaker's focus of interest (e.g., on reasons for doing or not doing, respectively). Although words signaling

conventional implicatures are few (Grice, 1968), they are frequently used. Consequently, where their use may signal the experimenter's hypothesis, they should be suppressed, or alternatively, dual versions of the task should be created that signal both the hypothesis and its contrary (e.g., the use of *occasionally* in tests of the norm theory, Kahneman and Miller, 1986, p. 143). For example, Krosnick et al. (1990) made use of this technique in comparing the effects of *but* and *although* on the integration of base-rate and diagnostic information.

Fourth, experimenters need to be fully sensitive to conversational implicatures. For example, Tversky and Kahneman (1983) were quite aware of conversational explanations of the conjunction fallacy and tried to rebut these with a direct phrasing of the conjunction. However, their extensional phrasing "Linda is a bank teller whether or not she is a feminist" (the intended meaning is "bank teller and either feminist or not a feminist") can be rationally understood as "Linda is a bank teller even if she is a feminist" (the conveyed meaning is "bank teller and feminist"), just as the everyday phrase "Let's go to the zoo whether or not it rains" conveys "Let's go to the zoo even if it does rain." Such examples suggest that even those psychologists sensitive to conversational processes may benefit from a deeper consideration of the nature of conversational implicature (cf. Adler, 1991).

Fifth, respondents' interpretations of experimenter-given information can be checked by either multiple-choice check methods or analysis of open-ended protocols (e.g., Dulany and Hilton, 1991; Macchi, 1991). Of course, to be effective, the coding of such data needs to be in terms of categories that can be justified on theoretical grounds.

Sixth, the production of open-ended responses may be controlled by explicitly instructing respondents to maximize the maxim of either quality or quantity. Such variation in instructions has been shown to affect respondents' verbal protocols (Fiedler, Semin, and Bolten, 1989) and may be a useful technique in exploring respondents' representations of their task. For example, respondents may be more likely to include inferred conversational implicatures in a verbal protocol when told to be as informative as possible, but less so if instructed to stick as close as possible to the truth.

Seventh, researchers need to test for evidence supporting the implication of any nonconversational variables they hypothesize as causing a pattern of judgment. For example, theorists have

sometimes made claims about the role of cognitive variables in judgment such as salience (Trope and Ginosar, 1988) or causal relevance (Tversky and Kahneman, 1980), without collecting relevant recall, recognition, and belief measures. That they have not felt the need to do so perhaps testifies to a perception shared by editors and reviewers that a plausible alternative position does not exist. In the future, more studies should include measures that test for the operation of both cognitive biases and conversational inference processes.

Eighth, if changes with age in performance on various reasoning tasks are due to development of conversational inference strategies, then such changes should appear simultaneously on several tasks. For example, if young children's failure in the conservation task and their use of the mutual exclusivity assumption in word learning are both dependent on their assumption that the experimenter is respecting the given-new contract, then an ability to recognize that the given-new contract is not being respected should lead to simultaneous changes on both tasks.

Finally, data should be sought that distinguishes conversational and cognitive bias explanations. For example, Bar-Hillel and Neter (1993) reported an experiment in which monetary incentives failed to remove a misinterpretation of a reasoning task (cf. Wolford et al., 1990). However, it is not clear why increasing the financial stakes in an experiment should cause respondents to abandon an interpretation that is pragmatically correct and rational. Recall that Tetlock and Boettger (1991) manipulated their respondents' conversational interpretations of the judgment task by undermining the respondents' assumption of intentionality. Respondents then rejected or used nondiagnostic information on the basis of its perceived conversational relevance. Then they found that accountability manipulations, which, like monetary incentives, should accentuate the value of getting a right answer, simply amplified the effect of conversational relevance, suggesting that incentives simply made respondents adhere more strongly to the answer that seemed conversationally rational. Incentives are not going to make respondents drop a conversationally rational interpretation in favor of a less plausible one in the context.

The above issue highlights a difference between the conversational inference approach to rationality and others that argue that a larger

context than the experiment should be taken into account in establishing rational judgment. For example, one approach has been to accept that heuristics or logically suboptimal rules of thumb are used, but they are used flexibly and rationally with an eye to the costs and benefits of accurate inference and are thus normative (Payne, Bettman, and Johnson, 1993). However, when the decision is important, respondents use more accurate but resource-expensive strategies. Like Tetlock's (1992) accountability approach, this perspective therefore predicts that performance becomes more accurate where the decision outcomes become more important. However, as noted above, the conversational inference approach does not predict that increased incentives lead respondents to change an interpretation that seems rational in the context.

A clear list of criteria and methods for specifying and controlling conversational inference will also enable conversational absolutions of errors to be distinguished from others. For example, Fiedler (1988) showed a dramatic reduction in Tversky and Kahneman's (1983) conjunction effect by framing the task in terms of frequencies rather than probabilities. If the frequentist frame changed the way respondents interpreted the task (cf. Dulany and Hilton, 1991), then this effect could fairly be considered conversational, if not then another presumably cognitive bias explanation of this improved performance should be considered.

In some cases, investigators have used multiple methods to evaluate claims about biases. For example, in a variant of the engineer-and-lawyer study, Kahneman and Tversky (1973) not only gave respondents personality descriptions and then asked them to estimate the probability that the person described would major in a number of subjects but also to give the base rate of people majoring in that subject. They found that respondents underused their own base-rate information – an error that cannot be attributed to conversational inference processes as defined in this article. Although underuse of base-rate information may occur in certain conditions, this should not be taken as invalidating the current perspective. Understanding how the conversational factors reviewed earlier, such as source characteristics, information order, and question-phrasing, influence use of base-rate information help us better understand when its underuse is truly due to cognitive shortcomings rather than to communicational factors.

Controlling for Conversational Inference in the Identification of Errors of Reasoning

It may therefore be that many patterns of judgment that have been classified as errors appear quite rational when systematic and normal processes of conversational inference are taken into account. However, the approach also allows us to deem as irrational errors that cannot be explained by processes of conversational inference. For example, Tversky and Kahneman (1974) reported that numerical anchors produced randomly by a roulette wheel biased subsequent estimates of the number of African countries in the United Nations. Because randomness prevents the attribution of intentionality to the number given as an anchor, such an effect can only be the result of a cognitive bias. Likewise, Tetlock's (1985) finding that anchoring effects are reduced by making respondents accountable for their judgments are consistent with the heuristics view that the effect can be reduced with incentives inducing more cognitive effort.

However, other effects attributable to anchoring with insufficient adjustment may in fact be the result of conversational factors (e.g., a tendency to treat early information as more important) if presented in conversational form (e.g., Krosnick et al., 1990). For example, R. Brown (1986) gave an insightful analysis of Asch's (1946) impression formation paradigm that suggests that both the primacy and centrality effects can be attributed to the operation of a principle of information gain consistent with that of the maxim of quantity. According to R. Brown, traits that come later in a description of a person's character (e.g., kind) are likely to have less effect if they are redundant with earlier traits (e.g., honest) that are used to predict them. For this primacy effect to be classified as nonconversational in nature, for example, it should be shown to be reduced by accountability instructions (Tetlock, 1985) and also to occur in conditions where respondents have been made to believe that the information was presented in random order.

Conclusions

Judgments about the intended meaning of utterances are themselves judgments under uncertainty. The likely intended meaning is likely to be affected by the hearer's perceptions about the speaker. The implication for psychological

experiments on rationality is that respondents' answers may not deviate from what might be expected from a normative model because of an individual's cognitive shortcomings, but because of the application of consensually shared rules of conversational inference.

Like previous work on experimental demand effects, the attributional model of conversational inference predicts that source characteristics affect the experimental respondent's performance. However, previous work on source effects has focused on how respondents comply with experimental demands, for example, by detecting the experimenter's hypothesis and producing the desired behavior (Orne, 1962; Rosenthal and Rubin, 1978). The present approach focuses on how respondents deviate from the judgments predicted by the normative model considered relevant by the experimenter by using rules of conversational inference very different than those assumed by the experimenter.

Understanding conversational inference may help clarify the question as to which normative model is appropriate in a given situation. Thus, various writers have addressed the question of whether the experimental tasks used are truly representative of real-life decision tasks (e.g., Funder, 1987; Hogarth, 1981; Tetlock, 1985). Sometimes it can be suggested that an alternative normative model of judgment can describe respondents' patterns of reasoning, as when Cohen (1979) suggested a Baconian model of judgment as an alternative to the Bayesian model used by Tversky and Kahneman (1974). One advantage of the conversational framework is, of course, that it can help identify how responses reflect one reasoning process more so than another by better specifying the implicit premises that the respondent derives from the information explicitly given. For example, Hilton (1990a, 1991) showed how laypeople's causal attributions can be seen to follow a normative model of causal inference, namely, the analysis of variance, when the role of presupposed knowledge in completing the data matrix necessary for the computation of an analysis of variance or its equivalent is taken into account.

Recognition of the conversational context of the psychology experiment thus may enable researchers to better recognize the rationality of respondents' judgments. However, it is also important to recognize how processes of conversational inference may produce errors in

real-world settings. This could happen in several ways. First, hearers may be inaccurate in their perceptions of speakers, thus causing them to misinterpret utterances. Although this is a common source of miscommunication, it may be that some errors in social perception are systematic. For example, Fussell and Krauss (1992) suggested that hearers overestimate the mutual knowledge they share with speakers because of the false consensus effect. Second, as Levinson (1995) suggested, many reasoning heuristics may have evolved because they are adaptive in contexts of social interaction. For example, the expectation that errors of interpretation will be quickly repaired may be correct when we are interacting with a human being but incorrect when managing a complex system such as an aircraft, a nuclear power plant, or an economy. The evolutionary adaptiveness of such an expectation to a conversational setting may explain why people are so bad at dealing with lagged feedback in other settings.

Recognition of linguistic and conversational factors may also have practical implications for facilitating statistical reasoning. Presentations of numerical information in terms of frequencies rather than probabilities (Fiedler, 1988) or that make set – superset relations clear (Macchi, 1991) are likely to facilitate correct understanding of statistical problems. Clearly, newspapers and other media should take advantage of this.

Thus, the attributional model of conversational inference introduces a social dimension to the study of reasoning and inference. It suggests that no utterance is depersonalized, that all messages have a source, and that reasoning and inference processes typically operate on socially communicated information. However, it does by no means deny the importance of cognitive processes. Rather, it argues that the processes of inference, reasoning, and understanding are shaped by interpersonal assumptions, even in supposedly neutral settings such as the laboratory experiment or survey questionnaire. As such it offers a view of social cognition other than the application of cognitive psychology to the understanding of how information is processed about social objects, important though this enterprise is (see Fiske and Taylor, 1991, for a review). Instead, by locating reasoning and inference processes in communicative settings, the attributional model of conversational inference offers another view of social cognition, namely, the social psychology of higher mental processes.

Appendix: Grice's (1975) Cooperative Principle and the Maxims of Conversation

The Cooperative Principle

Make your contribution such as is required, at the stage at which it occurs, by the accepted purpose or direction of the talk exchange in which you are engaged.

The Maxims of Quality

Try to make your contribution one that you believe to be true, specifically:

- (a) Do not say what you believe to be false.
- (b) Do not say that for which you lack adequate evidence.

The Maxims of Quantity

- (a) Make your contribution as informative as is required for the current purposes of the exchange.
- (b) Do not make your contribution more informative than is required.

The Maxim of Relation

Make your contributions relevant.

The Maxims of Manner

- (a) Avoid obscurity.
- (b) Avoid ambiguity.
- (c) Be brief.
- (d) Be orderly.

Notes

- 1 Sperber and Wilson (1986), while acknowledging the importance of inductive inference in comprehension, also considered that deductive inference plays an important role.
- 2 Grice (1989) himself was quite categorical about the centrality of attribution in the calculation of implicatures and indeed in his last writings defined implicatures in terms of attributed mental states: "Implicatures are thought of as arising in the following way; an implicatum (factual or imperatival) is the content of that psychological state or attitude which needs to be attributed to a speaker to secure one or another of the following results: (a) that a violation on his

part of conversational maxim is in the circumstances justifiable, at least in his eyes, or (b) that what appears to be a violation by him of a conversational maxim is only a seeming, not a real violation; the spirit, though perhaps not the letter, of the maxim is respected" (p. 370).

- 3 Dulany and Hilton (1991) also studied empirical possibility implicatures, such as "Linda is a bank teller who is probably active in the feminist movement." They also treat these as interpretations that absolve conjunction effects of being fallacies.

Section 10: Domain-Specific, Goal-Based, and Evolutionary Approaches

Chapter 39: Domain-Specific Knowledge and Conceptual Change

SUSAN CAREY AND ELIZABETH SPELKE

Overview

We argue that human reasoning is guided by a collection of innate domain-specific systems of knowledge. Each system is characterized by a set of core principles that define the entities covered by the domain and support reasoning about those entities. Learning, on this view, consists of an enrichment of the core principles, plus their entrenchment, along with the entrenchment of the ontology they determine. In these domains, then, we would expect cross-cultural universality: cognitive universals akin to language universals.

However, there is one crucial disanalogy to language. The history of science and mathematics demonstrates that conceptual change in cognitive domains is both possible and actual. Conceptual change involves overriding core principles, creating new principles, and creating new ontological types. We sketch one potential mechanism underlying conceptual change and motivate a central empirical problem for cognitive anthropology: To what extent is there cross-cultural universality in the domains covered by innate systems of knowledge?

Domain-Specific Cognition

The notion of domain-specific cognition to be pursued here is articulated most clearly by Chomsky (1980a). Humans are endowed with domain-specific systems of knowledge such as

knowledge of language, knowledge of physical objects, and knowledge of number. Each system of knowledge applies to a distinct set of entities and phenomena. For example, knowledge of language applies to sentences and their constituents; knowledge of physical objects applies to macroscopic material bodies and their behavior; knowledge of number applies to sets and to mathematical operations such as addition. More deeply, each system of knowledge is organized around a distinct body of core principles. For language, these are the principles of universal grammar; for physical objects, the principles might include Newton's axioms and the principles of continuity and solidity; for number, they might include the principles of one-one correspondence and succession.

This notion of domain specificity provides a basis for determining, and distinguishing among, the domains of human knowledge: Two systems of knowledge are distinct just in case they center on distinct principles. For example, if knowledge of language and knowledge of number were found to center on the same core principles, psychologists should conclude that they constitute a single system of knowledge, despite the many obvious differences between the abilities that knowledge of language and knowledge of number support. Indeed, Chomsky (1980b) has suggested that language and number are connected in this way. This notion similarly provides a basis for distinguishing the genuine cognitive domains

from more trivial collection of beliefs: Only genuine domains are characterized by distinct sets of core principles. In particular, reasoning about material bodies, about persons and about sets may well depend on distinct systems of knowledge of physics, psychology, and number. In contrast, reasoning about billiard balls, about bricks, and about plates probably depends on a single knowledge system: The core principles underlying reasoning about one of these collections of objects probably apply to the other collections as well (Carey, 1985).

Domain-Specific Perception

If human reasoning depends on domain-specific knowledge systems, then reasoners face a crucial task: They must single out the entities to which each system of knowledge applies. For example, a well-developed system of knowledge of psychology is useless unless a reasoner can determine when he or she is faced with a person. Similarly, systems of knowledge of physics and number can function only insofar as a reasoner can single out material bodies and sets. The mechanisms that single out such entities need not be (and never are) flawless: It is sufficient for the reasoner to pick out some of the persons, some of the material bodies, and the like. Without some mechanisms for singling out entities within a domain, however, reasoning cannot proceed. A domain-specific reasoner cannot simply ask of some part of the layout, "How does this thing behave?" The reasoner also must ask, "What kind of thing is this?" (see Wiggins, 1980).

We will call the processes that single out material bodies, persons and sets *domain-specific perception*. These processes may not be perceptual, however in a narrow sense. Most of the processes studied in psychophysics, sensor physiology, and computational vision do not function to single out the entities about which one reasons but rather they function to construct representations of the continuous surrounding surface layout. Vision, for example, appears to culminate in representations of the distances, orientations, colors, textures, and motions of light-reflecting surfaces (Gibson, 1950; Marr, 1982). These representations are not sufficient for the operation of domain-specific reasoning. To reason about material bodies, one must carve the surface layout into unitary, bounded, and persisting things (Spelke, 1988). To reason about number, one must represent a collection of bod-

ies, surfaces, or other entities as a set (Gelman & Gallistel, 1978; also see Shipley & Shepperson, 1990; Wynn, 1992). To reason about human action and mental life, one must represent a portion of the surface layout as a sentient, purposive being. The processes that culminate in such representations are our focus here.

There are two general ways in which the task of apprehending the entities in a domain could be accomplished: Domain-specific perception either could depend on principles that are distinct from the principles guiding domain-specific reasoning, or domain-specific perception and reasoning could depend on a single set of principles. Consider, for example, the domain of reasoning about human action and experience. It is possible that perceivers single out human beings by virtue of a face-recognizer, a voice-recognizer, a gait-recognizer, and the like. Whenever the perceiver is confronted by eyes, hair, and other features in the proper configuration, his or her face-recognizer would signal the presence of a person. This signal would then trigger the operation of the processes of psychological reasoning, whereby the actions of the person are understood in terms of the person's goals and feelings. On this view, apprehending persons and reasoning about human actions depends on distinct principles: principles governing the physical arrangement of eyes, noses, and so forth, on one hand, and principles concerning the relation among purposes, perceptions, and the like, on the other. Psychological reasoning would proceed appropriately, because the mechanisms that embody these distinct principles would be suitably linked together.

Alternatively, perceivers may single out persons by analyzing the behavior of entities, asking whether an entity's behavior appears to be directed to some goal, to be guided by perceptions of its environment, to be colored by emotions, and so on. Entities would be perceived as persons insofar as their behavior was consistent with such an analysis. On the second account, processes of perceiving and reasoning about psychological beings are intimately connected: They are guided by the same system of knowledge.

In human infancy, we suggest, perception and reasoning are guided by a single knowledge system in at least three domains: physics, psychology, and number. We begin with the case of physics by reviewing the findings of studies of object perception and physical reasoning in infancy (see Spelke, 1990, or Spelke & Van de Walle, 1999, for a more extensive review).

Perceiving and Reasoning about Physical Objects

Research on object perception provides evidence that young infants can perceive the unity, boundaries, complete shapes, and persistence of objects under some conditions. Object perception appears to depend on amodal mechanisms that divide the surface layout into bodies in accordance with a small number of principles, each of which reflects constraints on object motion.

Consider first young infants' perception of the unity of a visible object. Experiments using preferential looking methods, which rely on infants' well-documented tendency to look longer at displays that they perceive to be novel, provide evidence that infants as young as 3 months of age perceive a three-dimensional object presented against a uniform background as a connected body that will maintain its connectedness as it moves. For example, infants who were familiarized with a cohesive object subsequently looked longer at the outcome of an event in which the object broke in two than at the outcome of an event in which the object moved as a whole (Spelke, Breinlinger, & Jacobson, 1992). Infants' preference for the former outcome reliably exceeded that of infants in a baseline condition who viewed the same outcome displays with no preceding events. The experiment provides evidence that infants perceived the original object as a connected body that should maintain its connectedness over motion.

Further experiments focusing on infants' preferential looking or object-directed reaching provide evidence that young infants perceive the distinctness of adjacent objects if the objects undergo different rigid motions (Hofsten & Spelke, 1985; Spelke, Hofsten, & Kestenbaum, 1989). Infants also perceive the distinctness of stationary objects if the objects are spatially separated: Spatially separated objects are perceived as distinct units even if they are separated only in depth such that the gap between them is not directly visible (von Hofsten & Spelke, 1985; Kestenbaum, Termine, & Spelke, 1987; Spelke, von Hofsten, & Kestenbaum, 1989).

The above findings suggest that infants perceive objects in accord with two constraints on object motion. First, objects are connected bodies that maintain their connectedness as they move: Two spatially separated objects, or two adjacent objects that slide with respect to one another, are therefore perceived as distinct. Sec-

ond, objects are not connected to other objects and retain their separateness as they move: Two stationary and adjacent objects, lacking any spatially or spatiotemporally specified boundary, are therefore perceived as one connected body. These two constraints can be captured by a single *principle of cohesion*: Surfaces in the layout lie on a single object if and only if they are connected.

Now consider infants' perception of the unity of an object whose ends are visible or tangible but whose center is hidden. Four-month-old infants have been familiarized with such an object and then presented with a fully visible complete object or with two objects separated by a gap where the original object had been hidden. If infants perceived the original object as a connected body, then they should look longer at the two-object test display, relative to infants in a baseline condition who viewed the same test displays with no previous familiarization.

Such experiments provide evidence that 4-month-old infants perceive a visible, center-occluded object as a connected body if the ends of the object undergo a common rigid motion (Kellman & Spelke, 1983; Slater, Morison, Somers, Mattock, Brown, & Taylor, 1990; Craton & Baillargeon, personal communication, 1991). Rigid motion in any direction, including motion in depth, specifies the connectedness of the object (Kellman, Spelke, & Short, 1986); a pattern of common retinal displacement in the absence of true motion does not (Kellman, Gleitman, & Spelke, 1987). Studies in the haptic mode provide evidence that infants perceive the unity of objects whose ends are tangible under the same conditions as they perceive the unity of objects whose ends are visible (Streri & Spelke, 1988, 1989; Streri, Spelke, & Rameix 1992). Infants aged 4½ months held the two ends of a haptic assembly in their two hands, without visual or haptic access to the full assembly. They perceived the assembly as one connected body when the ends moved together and as two spatially separated bodies when the ends moved independently.

The findings of these studies suggest that infants perceive objects in accordance with two further constraints on object motion. First, surfaces move together only if they are in contact: The two rigidly moving ends of a center-occluded visible object or of a haptic assembly are therefore connected. Second, surfaces move independently only if they are spatially separated: Two independently movable seen or

felt objects are therefore separated by a gap. These two constraints can be encompassed by a single *principle of contact*: Surfaces move together if and only if they are in contact.

Finally, consider infants' perception of objects that move fully out of view. Experiments using visual preference methods provide evidence that young infants perceive the persisting identity or distinctness of objects over successive encounters in accordance with the principle of contact (discussed earlier) and the principle of continuity: An object moves on exactly one connected path over space and time. First, Van de Walle and Spelke (1993) presented infants with an object that moved back and forth behind an occluder such that its two ends were visible in immediate succession but never simultaneously: The left side of the object moved behind the occluder until the object was fully hidden, and then the right side of the object began to appear from behind the opposite side, moving at the same speed and on the same path. Subsequent looking preferences between nonoccluded complete and broken displays provided evidence that the infants perceived the object as a connected body, in accordance with the contact principle. Second, Spelke and Kestenbaum (1986) and Xu and Carey (1992) presented infants with events in which an object moved out of view behind the first of two spatially separated occluders, and after a pause an object moved into view from behind the second occluder. Subsequent visual preferences between fully visible one- and two-object displays provided evidence that infants perceived two objects in this event in accordance with the continuity principle: Because no object appeared between the two screens, the object moving on the left must have been distinct from that on the right.

In summary, young infants appear to perceive objects in accordance with the principles of cohesion, contact, and continuity. We now consider whether infants respect these principles when they reason about objects that move from view.

A variety of experiments provide evidence that young infants represent the existence of an object that moves from view and make certain inferences about the object's continued motion (e.g., Baillargeon, 1986; Leslie, 1991; Spelke, Breinlinger, Macomber, & Jacobson, 1992). These experiments have used preferential looking methods to assess infants' reactions to an "invisible displacement task" (Piaget, 1954), in which an object moves from view and infants must infer its further motion. The experiments

provide evidence that infants make some, but not all, of the inferences about object motion made by older children and adults. A consideration of infants' successes and failures may thus shed light on the principles guiding infants' inferences.

Experiments from three laboratories offer evidence that infants' inferences accord with two constraints on object motion: continuity (objects move only on connected paths), and solidity (objects move only on unobstructed paths, such that two objects never occupy the same place at the same time) (Baillargeon, 1986; Leslie, 1991; Spelke et al., 1992). In one experiment (Spelke et al., 1992, Exp. 1), 4-month-old infants first were familiarized with an event in which a ball fell behind a screen on an open stage and was revealed on the stage floor. Then a second surface was placed above the stage floor and a test sequence was presented in which the ball fell behind the screen, and the screen was raised to reveal the ball at rest either on the upper surface or on the lower surface. The latter position was inconsistent with the continuity and solidity constraints, because the ball could reach the lower surface only by jumping discontinuously over or by passing through the upper surface. Infants looked longer at the inconsistent than at the consistent test outcome. Their preference for the inconsistent outcome reliably exceeded the preferences of infants in a separate control condition, who viewed the same outcome displays preceded by consistent events. The experiment therefore provides evidence that 4-month-old infants infer that a hidden object will move on a connected and unobstructed path, in accordance with the continuity and solidity constraints. Further experiments provide evidence for the same ability at ages ranging from 2½ months to 10 months, with a variety of displays and events (e.g., Baillargeon, 1986; Baillargeon, Graber, DeVos, & Black, 1990; Leslie, 1991; Spelke et al., 1992).

The continuity and solidity constraints are closely related: Whereas the continuity constraint dictates that an object must move on at least one connected path (i.e., the path of an object can contain no gaps), the solidity constraint dictates that an object must move on at most one connected path (i.e., the paths of two objects cannot intersect in space and time). Both constraints therefore can be captured by the principle of continuity: An object traces exactly one connected path.

Additional experiments provide evidence that infants infer that a hidden object will move in accordance with the principles of cohesion

and contact. Carey, Klatt, and Schlaffer (1992) tested 8-month-old infants with events in which one object was lowered, raised, and lowered again behind a screen, and then the screen was raised to reveal one or two objects on the display floor. Infants looked longer at the two-object event, relative to the length of infants' looks in a baseline control experiment. The experiment provided evidence that infants inferred that the object would move in accordance with the cohesion principle: Unlike nonsolid substances (which were tested in other experiments), moving objects do not leave parts of themselves behind. Ball (1973) familiarized infants with an event in which one object moved out of view behind a screen and then a second object, which was initially half visible and stationary, moved fully into view. Then infants were tested with nonoccluded displays in which the first object either came into contact with the second object or stopped short of the second object. Infants looked longer at the no-contact event, relative to baseline controls. The experiment provides evidence that the infants inferred that the first object contacted the second object, in accordance with the contact principle (for further evidence, see Leslie, 1988).

In summary, infants appear to infer that hidden objects will move in accordance with the principles of cohesion, contact, and continuity. These are the same principles that guide infants' perception of the unity, boundaries, and persistence of the objects they see and feel. A single system of knowledge therefore appears to underlie object perception and physical reasoning in infancy. We now ask briefly whether a single system of knowledge also guides infants' perception and reasoning in the domains of psychology and number.

Perceiving and Reasoning about Persons

The system of knowledge guiding reasoning about human action and mental life is currently a subject of much study and some debate (see Astington, Harris, & Olson, 1988; Leslie, 1987; Perner, 1991; Wellman, 1990). Central to our understanding of other human beings, however, appears to be the notion that people are sentient beings who choose their actions (see Wellman, 1990, for a discussion). If this notion is central to reasoning about human action, then the system of knowledge of psychology is distinct from that of physics. We must ask, therefore, how reasoners single out a person as an entity in the domain of their psychological reasoning.

Babies appear to have an innate representation of the structure of the human face; this representation allows neonates to direct attention to faces that move across the field of view (see Johnson & Morton, 1991, for a review). Perhaps babies use that representation to identify people as entities expected to be capable of perceptions and purposive action. Evidence from a number of sources suggests this is not the case: Infants, children, and adults identify animate, sentient beings by taking account of their actions, not by analyzing their surface appearance.

Consider first young children's reactions to dolls. Many young children are delighted by dolls, with whom they engage in rich pretend interactions. At no age, however, do children appear to be led by dolls' human features to treat dolls as animate, sentient beings (R. Gelman, 1990; R. Gelman, Spelke, & Meck, 1983). Even infants respond differently to dolls and to living faces: A stationary doll's faces is an object of interest or delight, whereas a stationary human face, seen under similar circumstances, can evoke fear or aversion (Tronick, 1982). In addition, young infants appear to respond to object the lack any clearly animate features (e.g., mobiles) as animate and social beings, if the behavior of those objects approximates the behavior of a responsive social agent. These findings, and other findings with adults (Heider & Simmel, 1944), suggest that children and adults use some principles of their intuitive psychology not only to reason about persons but also to perceive persons as persons (for more detailed expositions of this view, see R. Gelman, 1990, and Premack, 1990).¹

Perceiving and Reasoning about Number

The origin and the nature of knowledge of number has been a topic of philosophical debate at least since Hume (e.g., Kitcher, 1983). Psychological research on infants (e.g., Wynn, 1992) and animals (see Gallistel, 1990, for a review) strongly supports the existence of innate knowledge of number that includes core principles of one-to-one correspondence and succession (every number has a unique successor, Gallistel & R. Gelman, 1992). If this view is correct, then number would appear to be a domain of knowledge distinct from physics or psychology. How do reasoners single out the entities in this domain, apprehending sets and their numerosity?

A controversy exists concerning the relations between perceiving and reasoning about small

sets. On one view, perception of small sets depends on a special pattern-recognition process, "subitizing," whereas perception of large sets depends on a counting process (Klahr & Wallace, 1973; Davis & Pérusse 1988). The principles of operation of the subitizing process are unknown, but they are believed to be distinct from the principles governing numerical reasoning. On a different view (Gallistel, 1990; Gallistel & R. Gelman, 1992), sets of all sizes are enumerated by a counting process. Proponents of both views agree that the principles at the core of the counting process include one-to-one correspondence and succession, and that these principles underline not only counting but also the operations of spontaneous arithmetic.

In our terms, the difference between these two views of the process of enumerating small sets is exactly the difference between the thesis that a single system of knowledge underlies number perception and numerical reasoning, and the thesis that distinct systems underlie these abilities. Note that on both views, a single set of principles is thought to enable humans to perceive and reason about large sets.

In summary, domain-specific reasoning and domain-specific perception appear to depend on a single system of knowledge in the domains of physics, psychology, and number (at least for large sets). We now ask how knowledge grows and changes in these domains.

Cognitive Development

It is natural to suppose that humans learn about the world by observing it. We learn that bodies fall by watching them fall; we learn that insults make people angry by watching people react to insults; we learn that $2 + 2 = 4$ by observing two sets of two things combine into one set of four things. Variants of this thesis may be offered. Children may learn through active manipulation (releasing or throwing objects, hitting people, combining sets), or by social interaction (tossing balls around, participating in social exchanges, playing number games).

If any of these proposals is correct, then children and adults will learn only about the things they perceive. A child who cannot perceive any object that falls, any person who is moved to anger, or any sets of two things that combine into a set of four things, will never learn about these entities, however much he or she observes, manipulates, or communicates about the surrounding layout. Perception limits the development of knowledge.

The consequences of this limit depend on the relation between the principles governing perception and those governing reasoning. If perception and reasoning are guided by distinct principles, experience may overturn the original principles governing reasoning. For example, suppose that perception of persons depends on a face-recognizer, whereas initial reasoning about persons depends on notions that action is internally generated in accordance with perceptions and feelings. Encountering a doll, the child would perceive a person. The behavior of this person, however, would not appear to result from choices but from the blind operation of the laws of mechanics. Because the doll must be admitted to the class of persons (we are assuming that the face-recognizer, not the psychological reasoner, makes this decision), the child is now in a position to learn that his or her initial psychology is false: Not all persons are purposive, sentient beings. With increased exposure to dolls, stuffed animals, portraits, and the like, this learning will grow and be extended. Learning will therefore bring changes to the child's initial system of knowledge.

If the same system of knowledge guides perception and reasoning, in contrast, it would seem that children *cannot* learn, by observing the world, that their initial system of knowledge is false. For example, suppose that both perception and reasoning about persons are guided by the notion that people are sentient and purposive. When children encounter an entity that looks like a human being but does not engage in self-generated action, they will not conclude that their notion of person is false but rather that this entity does not fall within the domain of their psychology: It is not a person.

In any domain in which perception and reasoning depend on the same system of knowledge, learning from observation, from action, or from social interchange will tend to preserve the initial system of knowledge. Knowledge will grow by a process of enrichment, whereby core principles become further entrenched. The initial system of knowledge will not be overthrown by any process of induction from experience, because only objects that conform to that system are available to be experienced. Cognitive development will result in the enrichment of knowledge around unchanging core principles.

Some aspects of mature, commonsense reasoning appear to support the view that knowledge of physical objects, persons, and number develops by enrichment. In the domain of physics, principles such as cohesion, contact,

and continuity appear to be central to mature intuitions about object persistence (see Hirsch, 1982) and object motion (see Spelke, 1991, for discussion). In the domain of psychology, the notion that people choose their actions appears to be deeply ingrained in mature common-sense reasoning (Wellman, 1990). Finally, in the domain of number, Gallistel and R. Gelman (1992) argue that the most intuitive mature conceptions of number are those that derive from the principles of one-to-one correspondence and succession.

Nevertheless, this reasoning leads to a contradiction. Conceptual change in the domains of physics, psychology, and number is not only possible but actual. In the history of science and mathematics, it has occurred with the development of Newtonian and quantum mechanics, with the attempt to construct a purely behavioristic or mechanistic psychology, and with the discovery of rational, real, and complex numbers. In each of these cases, the development of science has led to the construction of new principles and to the abandonment of principles that formerly were central to knowledge in the domain. In each of these cases, new types of entities were discovered or posited. The existence of conceptual change in science challenges the view that knowledge develops by enrichment around a constant core, and it raises the possibility that there are no cognitive universals: no core principles of reasoning that are immune to cultural variation.

Conceptual Change

The nature and existence of conceptual change has been extensively analyzed and debated since Feyerabend (1962) and Kuhn (1962) independently adopted the mathematical term "incommensurability" (no common measure) to refer to mutually untranslatable theoretical languages (see Suppe, 1977, for a comprehensive critique of the early Kuhn/Feyerabend positions). These debates have led to a softening of Kuhn's and Feyerabend's early claims. In particular, current analyses of conceptual change in science deny that the meanings of all terms in a theory change when some do, that theories completely determine evidence and therefore are unfalsifiable, or that theory change is akin to religious conversion. These analyses nevertheless hold that the core insight of the Kuhn/Feyerabend early work stands: The history of science is marked by transitions across which students of the same phenomena speak incommensurable languages.

Carey (1991) summarizes the recent analyses of conceptual change that have been offered by philosophers of science (Kitcher, 1988; Kuhn, 1982; see also Hacking, 1993; Nersessian, 1992) and by cognitive scientists (Thagard, 1988; see also Chi, 1992; Vosniadou & Brewer, 1992). Conceptual change consists of conceptual differentiations, such that the undifferentiated parent concept plays no role in subsequent theories (Carey, 1991; Kuhn, 1977), and of the creation of new ontological categories (Thagard, 1988; Chi, 1992). Conceptual change involves change in the core principles that define the entities in a domain and govern reasoning about those entities. It brings the emergence of new principles, incommensurable with the old, which carve the world at different joints.

Cognitive Science and the History of Science

Some doubt the relevance of historical analyses of conceptual change to cognitive science and especially to cognitive development. Scientific reasoning and concepts, one might argue, are different from ordinary reasoning and concepts. Only the former undergo changes in core principles.

We consider it a serious empirical question as to whether the core concepts of common-sense reasoning are subject to change. Whatever answer one gives to this question, however, the existence of conceptual change in science challenges the argument for enrichment given above. If the development of domain-specific reasoning is constrained by domain-specific perception, and if the same system of knowledge underlies both reasoning and perception, then no person at any level of expertise is in a position to learn that his or her initial system of knowledge is false. This argument applies to any perceiver and reasoner, whether human or animal, layperson or scientist. The existence of conceptual change in domain-specific core knowledge presents a serious counterexample to the argument for enrichment and needs to be explained (Carey, 1991).

Those who emphasize the differences between intuitive theories and explicit scientific theories often imply that those differences in themselves *explain* conceptual change. In particular, the community of scientists, the self-reflective nature of explicit theory construction, and the instructional institutions that create scientists may be engines of conceptual change (e.g., Spelke, 1991). We grant that developed science differs from intuitive knowledge in these three ways. Nonetheless, communication among

scientists, reflection, and instruction do not in themselves provide a mechanism for conceptual change.

First, processes that occur within an interactive community of scientists cannot, in themselves, bring about conceptual change, because the interactions within a scientific community can only be as effective as the conceptions of its individual members permit. Communication between scientists succeeds only insofar as two scientists can single out the same things to talk about (see Kuhn, 1962). The arguments against the possibility of conceptual change therefore apply to the community of scientists as well as to the individual scientist.

Next, consider the possibility that reasoners use “disciplined reflection” to revise conceptions within a domain. Many have argued that metacognitive abilities enable human intelligence to extend itself beyond its initial limits (e.g., Rozin, 1976; Sperber, 1994). By itself, however, reflection can do nothing to extricate developing conceptions from the self-perpetuating cycle described above. We as humans can only reflect on the entities we perceive. If our initial conceptions determine those entities then we will be able to reflect only on entities whose behavior accords with our initial conceptions. Reflection by itself will not produce conceptual change.

Finally, instructional institutions that create scientists cannot in themselves account for conceptual change, for two reasons. First, instruction cannot account for individual discovery or invention. Second, instruction, like all communication, is limited by the student’s ability to apprehend the objects to which it applies. If a student is not able to apprehend the entities in a to-be-learned theory, he or she may mouth the correct words but will assign to them meanings licensed by his or her own concepts (see the science misconceptions literature reviewed in Carey, 1986, and Vosniadou, 1994).

In sum, we do not dispute that Western science is a social process, the product of self-reflective, metacognitively sophisticated adults, and that systematic instruction is required to form these adults. These facts, however, do not provide an account of conceptual change. We require such an account: an explanation of how a reasoner can move beyond the core principles in a system of knowledge. Once such an account is provided, we may ask how it tempers the generalization that knowledge develops by enrichment around a constant core.

Mechanisms of Conceptual Change

Mappings across Domains

The formal reflections of scientists provide one source of evidence concerning the processes of conceptual change. We begin with the reflections of the physicist, historian, and philosopher of science, Pierre Duhem. Duhem (1949) suggested that scientific physics is not built directly upon commonsense understanding of physical phenomena but depends instead on translations between the language of ordinary experience and the language of mathematics. According to Duhem, the objects of science are not concrete material bodies but numbers. To provide explanations for physical phenomena, physicists first translate from a physical to a mathematical description of the world, and then they look for generalizations and regularities in the mathematical description. These generalizations, when translated back into the language of everyday objects, are the physicist’s laws.

In our terms, scientists who effect a translation from physics to mathematics are using their innately given system of knowledge of number to shed light on phenomena in the domain of their innately given system of knowledge of physics. Scientists do this by devising and using systems of measurement to create *mappings* between the objects in the first system (numbers) and those in the second (bodies).² Once a mapping is created, the scientists can use conceptions of number to reason about physical objects. They therefore may escape the constraints imposed by the core principles of physical reasoning. In effect, the mapping from physics to number creates a new perceptual system for the domain of physics, centering not on the principles of cohesion, contact, and continuity but on the principles of one-to-one correspondence, succession, and the like. The entities picked out by this new perceptual system need not be commensurable with those picked out by the old.

Duhem focuses exclusively on the construction of a translation, or mapping, from physics to mathematics. Conceptual change may occur as well through mappings across other domains. In particular, conceptual changes in science appear to have resulted from the construction and use of mappings from psychology to physics. By viewing animals and people as complex machines, mechanistic biology and mechanistic psychology aim to explain animal and human action in terms of physical principles. We return to these conceptual changes below.

How do scientists construct mappings across domains? Science's informal documents (lab notebooks, journals) provide an excellent source of data concerning this process. Recently, cognitive scientists as well as historians and philosophers of science have begun to mine this source (e.g., Gruber, 1974, on Darwin; Nersessian, 1992, on Maxwell; Tweney, 1991, on Faraday). Nersessian (1992) concentrates on two interconnected pairs of processes that recur in historical cases of conceptual change: (1) the use of physical analogy, and (2) the construction of thought experiments and limiting case analyses. These processes serve both to reveal tensions and inadequacies within a system of knowledge and to restructure that system through the construction of mappings across knowledge domains.

Physical Analogies

Nersessian's analysis of Maxwell's use of physical analogies provides a worked example of the productive use of such mappings in the process of conceptual change. According to Nersessian, Maxwell himself used the term "physical analogy" in explaining his method. A physical analogy exploits a set of mathematical relationships as they are embodied in a source domain so as to analyze a target domain about which there is only partial knowledge. In Maxwell's case, the source domain was fluid mechanics as an embodiment of the mathematics of continuum mechanics, and the target domain was electromagnetism. By constructing the analogy between these two areas of physics, Maxwell was able ultimately to construct an effective mathematical theory of electromagnetism.

Nersessian notes several important lessons from this case study. First, the analogy from fluid mechanics to electromagnetism did real inferential work: Important mistakes in Maxwell's first characterization of the electromagnetic field are traceable to points at which this analogy breaks down. Second, the process of constructing mappings across domains is difficult: Each mapping must be explored and tested in depth to determine its usefulness. Third, "imagistic representations" play an important part in constructing the mapping from physics to number. They express mathematical relationships in a directly comprehensible way and thus serve as a good bridge between domains. Fourth, the process of constructing a mapping across domains is not one of transferring the relations from source domain to target in one fell swoop by plug-

ging in and testing values. Rather, a scientist explores different possible mappings from the source domain onto the target domain, imposing different conceptualizations of the target domain in so doing. Finally, the mapping thus created can produce conceptual change in both domains. By using the Newtonian mathematics of continuum mechanics to understand electromagnetic fields, Maxwell constructed a mathematics of greater generality than that of his source domain (Nersessian, 1992).

Thought Experiments and Limiting Case Analyses

Another modeling activity is the construction of thought experiments, including limiting case analyses. Philosophers of science have often discussed how (or whether) thought experiments can be *experimental*: Can they have empirical content even though they involve no data? Kuhn (1977), analyzing a thought experiment that figured in the process by which Galileo differentiated instantaneous velocity from average velocity, argued that one function of thought experiments is to show that current concepts cannot apply to the world without contradiction. Nersessian (1992) extended Kuhn's analysis arguing that thought experiments involve mental model simulations, which are part of the source of their empirical content.

Nersessian's example is Galileo's famous thought experiment showing that heavier objects do not fall faster than lighter ones. Galileo imagined two objects, a large heavy one and a small light one, in free fall. According to Aristotelian and scholastic physics, the heavier object should fall faster. He then imagined joining the two objects with an extremely thin rod, creating a composite object. This thought experiment suggests two contradictory outcomes: (1) The composite object is heavier still and therefore should fall even faster, and (2) the slower speed of the smaller object should impede the speed of the larger object, so the composite object should fall more slowly! Galileo went on to construct a limiting case analysis concerning the medium in which objects fall to resolve the contradiction. He concluded that in a vacuum, objects of any weight will fall at the same speed. This thought experiment and limiting case analysis played a role in constructing a differentiated, extensive conception of weight. That conception, in turn, depends on the mathematical distinction between a sum and an average.³

Conceptual Change and Cognitive Universals

If processes such as those discussed by Nersessian are necessary components of the engine for conceptual change, we can account for the plausibility of the intuition that conceptual change results from the cooperative activity of a scientific community, from reflection, and from instruction. Galileo, Maxwell, Faraday, Einstein, and Darwin left writings, diaries, and notebooks showing that they used the heuristic processes Nersessian describes, and that they were fully conscious of doing so. They used these processes in the context of a self-reflective understanding of the goal of constructing new scientific theories. When one constructs a mapping across domains for the first time, one never knows how useful or deceptive it will prove to be. Thought experiments, physical analogies, and limiting case analyses serve as devices to communicate new conceptualizations to the scientific community, but these new conceptualizations will be adopted only insofar as they provide resolutions to standing puzzles and promote a productive research program. The jury is the social institutions of science.

But do heuristic processes of the kind Nersessian describes, and the mappings that result from them, also occur outside of developed science? Do they bring conceptual change to lay adults and children, creating cultural differences in core knowledge systems? The evidence considered thus far is consistent with three different hypotheses concerning conceptual change outside of science, each with different consequences for the existence of cross-cultural cognitive universals.

According to the *strong universality hypothesis*, only metaconceptually sophisticated scientists can overturn the core principles that innately determine ontology and reasoning. If this hypothesis is true, then the intuitive theories of people in all cultures will be enriched versions of those innate principles. The core principles of commonsense reasoning will be universal.

According to the *weak universality hypothesis*, children and lay adults can overturn innate, core principles of reasoning, but only through experience in a culture with a developed science. The source of conceptual change is the assimilation by children of the conceptions of the adults around them as those conceptions are expressed in adult language, in the measurement devices and technology of the culture, and in systematic instruction in school. And the source of the lay

adult's conceptions, in turn, is the cultural assimilation of conceptual changes *originally* made by metaconceptually sophisticated scientists. If the weak universality hypothesis is true, then the intuitive knowledge systems of all cultures will share a common innate core, except in the case of cultures with a developed science.

According to the *no universality hypothesis*, the processes of conceptual change observed in scientists also occur spontaneously in children and lay adults. Although infants the world over share a set of initial systems of knowledge, those systems are spontaneously overturned over the course of development and learning, as children and adults construct, explore, and adopt mappings across knowledge systems. Because of the diversity of the potential mappings across domains, it is unlikely that the knowledge systems of members of different cultures will share a common core.

In the rest of this chapter, we turn to evidence bearing on these hypotheses. Rather than rely on cross-cultural data, we will examine a population that stands outside the cultural institutions of science and that lacks metaconceptual awareness of theory construction and choice: American children. Even though children do not engage in the social process of explicit theory construction and are not self-reflective theorizers, there is ample empirical evidence for conceptual change in childhood. Conceptual change occurs both spontaneously, as the child masters the language and the intuitive knowledge systems of the adult culture, and also as the result of systematic instruction in school. The existence of conceptual change in childhood militates against the strong universality hypothesis.

Conceptual Change in Childhood

Number

The preschool child's concept of number is the *positive integer* (see R. Gelman, 1991), as defined by the core principles of one-to-one correspondence and succession. This core notion changes early in the child's school years as the child constructs the concept of *0* (Wellman & Miller, 1986), the concept of *infinity* (in the form of a realization that there is no highest number; R. Gelman & Evans, 1981), and the concept of *rational number* (R. Gelman, 1991), and as the child becomes explicitly aware of the core principles defining number and thereby becomes able to reason about conservation of number (see R. Gelman & Gallistel, 1978, for a review).

It could be argued that the construction of 0 and no highest number involve change in the concept of number, as both changes begin to separate number from counting. Moreover, the construction of the concept of rational number brings an even deeper conceptual change. Coming to see .5 or 1/3 as numbers requires abandoning the identification of number with counting, abandoning the successor principle, and constructing a new understanding of division (as a different operation from repeated subtraction). The new principles that jointly determine what constitutes a number and that govern reasoning with numbers include closure under division, construed in this new way.

R. Gelman (1991) suggested that changing conceptions of number depend in part on the construction of mappings between number and physical objects (as the child learns measurement) and on the construction of mappings between number and geometry (via devices such as the number line). Children's ability to benefit from these mappings suggests that the strong universality thesis is false for the domain of number. It is not clear, however, whether children or adults would spontaneously devise measurement devices or construct number lines in the absence of a developed science and mathematics. The weak universality hypothesis and the no universality hypothesis are both consistent with the above studies.

Biology and Psychology

The principles determining the entities of the earliest psychology – capacity for self-generated motion and attention and contingent reaction to surrounding events – actually determine the ontological kind *animal*, not just *person*. For this reason, Carey (1985) speculated that young children's intuitive biology is not differentiated from their intuitive psychology. Her claim that 4-year-olds do not have an autonomous domain of intuitive biology has come under much scrutiny (e.g., Inagaki & Hatano, 1988; Springer & Keil, 1989; Wellman & Gelman, 1992). Regardless of whether preschool children should be granted an autonomous biology, however, it is clear that their understanding of biological phenomena differs radically from that of older children. In Hatano and Inagaki's (1987) terms, children progress from a vitalistic biology to a mechanistic biology.

Much of the evidence for this conceptual change was reviewed in Carey (1985, 1988): Evidence for the differentiation of the concepts

dead and *inanimate*, for a change in the status of *person* as *animal*, and for the coalescence of the concepts *animal* and *plant* into a new concept, *living thing*. To that evidence, Keil and his colleagues have added many new phenomena suggesting conceptual change over these years (Keil, 1989; Springer & Keil, 1989). Keil's data serve two important purposes: They provide information concerning the precise characterization of the preschool child's initial biological concepts, and they provide evidence for conceptual change in the concept of *animal* and perhaps the concept of *person*.

Take Keil's transformation studies. Preschool children believe that a skunk can be turned into a raccoon through surgery; by age 9 (and earlier in some studies), children believe that the animal resulting from such a transformation is still a skunk that just looks like a raccoon (Keil, 1989). Preschool children do not think, however, that anything that looks like raccoon is a raccoon: A skunk wearing a raccoon costume and pictured to look identical to a raccoon is judged to be a skunk (Keil, 1989). Similarly a dog with all its insides removed (the blood and bones and stuff like that) is judged not to be a dog any more (Gelman & Wellman, 1991). These data suggest that to preschool children, the core of the notion of *animal kind* includes bodily structure: It is not enough to look just like an animal (e.g., a stuffed dog) or a particular kind of animal (e.g., a raccoon-costumed skunk), in order for an entity to be an animal or a particular kind of animal. Rather, the body of the entity must have the right structure, including internal structure. But these data also show that 9-year-olds have constructed a deeper notion of how that bodily structure must come to be: For 4- to 6-year-olds, surgery will do it; for 9-year-olds, bodily structure must result from a natural growth process. We take this developmental difference to reflect changes in the principles that define the entities in the domain of biology: By age 9, aspects of the life cycle have become part of the core principles. Changes of this sort are typical of historical cases of conceptual change (Kitcher, 1988).⁴

That this change actually reflects conceptual change rather than enrichment is further shown by changes in children's understanding of why children resemble their parents. Both Springer and Keil (1989) and Gelman and Wellman (1991) claim that preschool children understand that babies (including animal babies) inherit an innate potential from their parents to develop certain traits rather than others. However, their

data do not establish that the preschool child has an understanding of the *biological* inheritance of properties.

We take an understanding of inheritance of properties to include, at a minimum, two essential components. First, children resemble their parents: Black parents tend to have black children, blue-eyed parents are more likely to have blue-eyed children than are brown-eyed parents, dogs have baby dogs rather than baby cats, and so on. Second, the *mechanism* underlying this resemblance crucially involves birth. There are many ways children may come to resemble their parents: Curly-haired parents may have curly-haired children because they give them permanents; prejudiced parents may have prejudiced children because they taught them to be so. Such mechanisms are not part of a biological process of inheritance of properties. To be credited with a biological concept of inheritance, children need not understand anything like a genetic mechanism, but they must distinguish the process underlying family resemblance from mechanical or psychological processes. At a minimum, children should realize that the process through which an animal originates – birth – is crucially involved in the process through which animals come to have their specific characteristics.

Without doubt, preschool children understand that offspring resemble their parents. Springer (1992) told 4- to 8-year-olds that a pictured animal had an unusual property (e.g., this horse has hair inside its ears) and then probed for projection of the property to a physically similar horse, described as a friend who is unrelated to the target, and to a physically dissimilar horse, described as the target's baby. At all ages, the property was projected more to the baby than to the friend. This important result confirms the mounting evidence that preschool children are not appearance-bound (S. Gelman, Coley, & Gottfried, 1994) and establishes the family resemblance component of a belief in inheritance of properties. However, because Springer did not probe the mechanism responsible for inheritance, his study does not bear on the second component. Springer distinguished what he considers a biological relationship (parentage) from a social relationship (friendship), but, as Carey (1985, 1988) points out, parentage is also a social relationship. At a minimum, one would like to see biological parentage distinguished from adoptive parentage.

The same issue arises with respect to the data of Springer and Keil (1989). Four- to seven-

year-old children, plus adults, were told that both parents have a particular atypical property (e.g., pink rather than the usual red hearts) and were asked whether an offspring would have that property. They manipulated further information about the unusual property (whether the parents were born with the property or acquired it in an accident, whether the property was internal or external to the body, and whether the property had "biological" functional consequences).⁵ Two important results emerged. First, only adults based their judgments solely on information about how the parents acquired the property: That is, only adults related birth to inheritance. In one study, 7-year-olds were beginning to take this variable into account. Second, even preschool children made systematic judgments, influenced by whether or not the property was described as having biological consequences. From this result, Springer and Keil concluded that preschoolers have a biological concept of inheritance, but that it is different from the adult's concept. Again, a comparison between natural parentage and adoptive parentage is necessary to determine whether preschoolers' concept of inheritance goes beyond an understanding of family resemblance.

S. Gelman and Wellman (1991) specifically contrasted nature versus nurture. For example, they asked whether a cow, Edith, who had been separated from other cows at birth and raised with pigs, would (1) moo or oink and (2) have a straight or curly tail. Even 4-year-olds judged that Edith would moo and have a straight tail. But the story asserts that Edith is a cow, in spite of having been raised in the company of pigs. There is a wealth of evidence, much of it from Gelman herself (S. Gelman, Coley, & Gottfried, 1994), that preschoolers take category membership as predictive of category-relevant properties, even in the face of conflicting information. Furthermore, the task does not stress that the baby cow is raised in a pig family, a child among other children who are pigs. S. Gelman and Wellman also posed a story about a seed from an apple, planted in a flower pot, and found that by age 5, children judged it would come up an apple rather than a flower. This scenario contrasts environment (in the company of flowers) with parentage (seed from an apple) and confirms Springer's (1992) finding that *family* resemblance is crucial. The experiment does not provide evidence, however for an understanding of biological inheritance and a differentiation between biological and adoptive parentage.

Solomon, Johnson, Zaitchik, and Carey (1993) have carried out several studies contrasting adoptive with biological parentage. For example, a story is told about a (tall) shepherd whose son is taken at birth to be adopted by a (short) king and raised as the prince. The child is then asked whether the boy, when he grows up, will be tall like the shepherd or short like the king. Adults project physical properties such as height on the basis of biological parentage. This pattern does not begin to emerge until age 7: the age at which Springer and Keil (1989) begin to see the effect of information as to whether the property of the parent was inborn or acquired. As of now, there is no evidence that preschoolers have a conception of biological inheritance that goes beyond expectations of resemblance between parents and their offspring.

These data are consistent with those reviewed in Carey (1985), indicating changes in children's understanding of reproduction during the early school years. Preschool children do not take reproduction as one of the core principles defining animals and governing inferences about them. By age 10, in contrast, knowledge of reproduction begins to organize children's understanding of animals, as reflected both in the beginning understanding of inheritance and as reflected in judgments of what makes a skunk a skunk (Keil, 1989). This change is part of the construction of the new ontological category, *living thing*, which includes plants as well as animals (Carey, 1985). New core principles and new entities in the domain are hallmarks of conceptual change.

How do these fundamental changes in children's concept of *animal* bear on children's innate concept of *person*? Does the notion of a person as a sentient, freely acting being change once children begin to construct a mechanistic biology? If so, how does this change come about, if the principles at the center of the initial concept of person underlie not only psychological reasoning but also perception of persons?

Although answers to these questions are far from clear, we offer the following observations. First, biological concepts appear to exert some influence on mature, commonsense psychology. For example, Western adults are inclined to consider the living descendant of two persons as a person, even if that person lacks all capacity to act (e.g., while sleeping or in a coma). Adults also are inclined to deny personhood to apes, dolphins, and parrots, however impressive their behavioral accomplishments. *Person* is, at least in part, a species concept (see, e.g., Wiggins, 1980).

Second, the initial conception of a person as a freely acting, sentient being remains a powerful part of Western adults' commonsense understanding of human action, surviving in uneasy coexistence with the later-developing biological conception. Tensions between these conceptions can be found not only in scientific psychology and philosophy of mind but also in everyday life, as current debates over abortion, criminal responsibility, and other topics demonstrate.

Finally, note that the development of mechanistic biology and mechanistic psychology depend in part on the construction of mappings across the domains of psychology and physics. The research reviewed above provides evidence that the construction of these mappings is a difficult and extended process. Insofar as it succeeds, however, there arises the possibility for conceptual change. A person may be viewed not only as a free agent but also as a complex machine and a member of a living kind (see Gentner & Grudin, 1985, for a historical analysis of changes in metaphors for the mind over 90 years of scientific psychology).

Studies of American children's changing biological and psychological conceptions cast doubt on the strong universality hypothesis, but they do not distinguish between the weak and the no universality hypotheses. To explore the conjecture that conceptual change in biology and psychology requires a developed scientific tradition, we need empirical studies of the intuitive biological and psychological theories held by children and adults in a wide range of cultures. Atran (1990) finds evidence for cross-cultural universality of folk taxonomies in biology but does not review research on folk explanations of biological phenomena: disease, reproduction, inheritance, and the functions of body parts. To our knowledge, the only work exploiting recent methodologies to diagnose intuitive biological conceptions is that of Jeyifous (1986), building on the work of Keil (1989). Jeyifous's results suggest that the developing conceptions of biology sketched in this section occur in cultures isolated from Western biological thought. For example, unschooled rural Yoruba children shift from the judgment that an operated-upon raccoon has become a skunk to the judgment that it is still a raccoon at about the same age as their American counterparts. If this shift reflects conceptual change, then Jeyifous's finding suggests two conclusions. First, conceptual change does not require developed scientific institutions. Even though Yoruba biology differs greatly from intuitive American biology, both involve a notion of

animal kind that is deeper than bodily structure, whereas the preschool child's biology (in both cultures) does not. Second, even though conceptual change is seen in both cultures, cross-cultural universality is still observed. Of course, whether intuitive Yoruba biology is commensurable with intuitive American biology is an open empirical question.

Matter and Physical Objects

We have suggested that objects, for babies, are defined by the principles of cohesion, continuity, and contact: Objects are coherent solids that maintain their boundaries as they move along spatiotemporally continuous paths, and that act upon each other only on contact. There are tensions in the baby's application of these principles, however, and these tensions may provide the seeds for future conceptual change. The principles do not apply equally well to persons (who commonly appear to violate the contact principle, while behaving in accord with the principles of cohesion and continuity). Similarly, nonsolid substances such as liquids, gels, and powders obey the principle of continuity (e.g., sand cannot pass through solid barriers) but not the principle of cohesion (e.g., sand can disperse and coalesce as it moves). Although innate principles determine an ontology for the child, they do not define entirely nonoverlapping sets of entities. How do children conceptualize the entities in the overlapping sections of their ontological universe, and how do their conceptions change with development and experience? We focus here on changing conceptions of nonsolid substances and on emerging conceptions of *matter*.

The distinction between objects and nonsolid substances is very salient to young children. Objects are typically quantified as individuals, whereas nonsolid substances are typically not quantified as individuals. This quantificational distinction is marked as the count/mass distinction in the syntax of many of the world's languages, and it conditions 2-year-old children's hypotheses about word meaning (Soja, Carey, & Spelke, 1991). But do young children appreciate that both objects and nonsolid substances are material?

Four-year-old children treat both objects and nonsolid substances as subject to the continuity principle: They judge that it is impossible for water to fill a box if the box is already filled by a steel block of the same dimensions (Carey, 1991). Moreover, 3- and 4-year-olds dis-

tinguish objects from ideas, dreams, and images on the basis of two properties that are relevant to the distinction between material and immaterial entities: objective perceptual access and causal interaction with other material entities (Estes, Wellman, & Woolley, 1989). Children's abilities to distinguish some material entities (i.e., objects) from some immaterial entities (i.e., ideas) on the basis of some properties that for adults are part of the core of the distinction between material and immaterial entities does not show, however, that children draw a material/immaterial distinction. Rather, children might draw a distinction between objects and mental entities, or between real and imaginary entities, on the basis of these properties. Two types of further information are required before we attribute a material/immaterial distinction to the child: We need to probe more widely the entities that fall under the distinction, and we need to analyze the explanatory work the distinction does for the child, in relation to the explanatory work that the material/immaterial distinction does for adults.

Carey (1991) presents such an investigation and concludes that preschool and early elementary-aged children *do* draw a material/immaterial distinction. The child's concept of matter, however, is incommensurable with that of the adult. Conceptual change in the years from 4 to 12 involves each of the interrelated concepts of *matter*, *kind of stuff*, *weight*, *density*, and *air*. The analysis includes two examples of initially undifferentiated concepts that are incommensurable with adult concepts: *weight/density* and *air/nothing*.⁶ The principles that pick out material entities and guide reasoning about them for preschool children include the principle that a given region of space can be occupied by only one portion of matter at a time (the continuity principle), the principle that material entities are publicly observable, and the principle that material entities interact causally with each other (the contact principle). Unlike adults, the young child does not take weight to be a core property of matter. This is seen by the judgment that heat, light, and electricity are "made of some kind stuff," just like cars, trees, and animals and unlike ideas and dreams. More strikingly, weight is viewed as an accidental property of prototypical material entities. For example, most children up through age 10 judge that a pea-sized piece of styrofoam, although material, weighs nothing at all. Weight therefore is not a necessary property of entities judged material.

Because weight is not a necessary property of material entities, it cannot provide a measure of amount of matter. Like the Greeks (Jammer, 1961), young children have no measure of matter (Piaget & Inhelder, 1941; Carey, 1991). For young children, weight (an extensive magnitude) is not differentiated from density (an intensive magnitude) and therefore cannot be an extensive property of matter (Carey, 1991; Smith, Carey, & Wiser, 1985). Children know that if object A weighs 250 grams and if object B weighs less than A, then object B will weigh less than 250 grams. But the same children are perfectly happy to judge that object A can be broken into 10 pieces, each of which weighs 0 grams!

Finally, preschool children, and roughly half of our sample of 6- to 10-year-olds, have not constructed a model of matter as continuous and homogeneous. Asked to imagine cutting a piece of steel in half repeatedly, they claim one finally will arrive at a piece that is so small that it no longer occupies space, and also that one will arrive at a piece of steel in which one could (in principle) see all the steel: There would be no more steel inside. The other half of the elementary schoolchildren, and all the 12-year-olds, judged that steel is continuous, homogeneous, and infinitely divisible: No matter how small the piece, it would still occupy space and would have more steel inside it. (By age 12, in spite of science education, most children have constructed a continuous model of matter.) The continuous model of matter supports the distinction between weight and density, providing the possibility that weight may become one of the core properties of material entities.

How do children come to reconceptualize matter and material objects? Mappings between the domains of physics and number, constructed through the processes described by Nersessian, appear to play a role in this process. Carol Smith and her collaborators (e.g., Smith, Snir, & Grosslight, 1992; Smith, Grosslight, Macklin, & Davis, 1993) have explored the use of physical analogies to drive 11- to 13-year-olds' reconceptualization of matter, especially the differentiation of weight from density and the construction of weight as an extensive quantity. The ideas are tested in the arena of science education. The curriculum that Smith et al. have developed centers around computer implemented, interactive visual models that serve to represent the mathematics of intensive and extensive quantities. For example, in one model, weight is represented by the number of dots, volume by the number of

boxes of a fixed size, and density by the number of dots per box. Students first work with the models, exploring the mathematical relations between the extensive and intensive quantities internal to the models. Then students work on mapping the models to the material world, by exploring such phenomena as the constant ratios of size to weight within each material and the laws of floating and sinking. This mapping is slow and difficult: Without having differentiated weight from density, students cannot readily succeed in mapping number of dots per box to density, rather than to absolute weight or to some other physical variable.

To facilitate this mapping, Smith et al. use the physical analogy of dissolving sugar in water as a source domain (in which sweetness is the intensive quantity and amounts of sugar and water are the extensive quantities) as well as the visual model of the intensive quantity (dot crowdedness). The visual model embodies the mathematics of extensive and intensive quantities, and serves as a bridge between mathematical representations and the target domain. As did Maxwell, students explore the analogy in a piecemeal manner, over time. When they encounter the phenomenon of thermal expansion and attempt to model it, they must change the model (material kinds do not have constant densities). This process consolidates and extends their understanding of the mathematics of intensive and extensive quantities, and it contributes to change in their concept of matter. It results in a mapping between physics and mathematics that gives rise to a new core concept: *quantity of matter*.

Smith et al. also employ thought experiments and limiting case analyses in their curricular intervention. Here we provide one example of a limiting case analysis (concretely exemplified rather than part of a thought experiment). Students who lack an extensive concept of weight maintain that a single grain of rice weighs nothing at all. As a classroom exercise, teams of students discover how many grains of rice placed on one edge of a playing card balanced on a thick fulcrum cause it to topple (around 50). They are asked to explain why the card fell. (Most say, "the rice was heavy.") Then the playing card is balanced on a thinner fulcrum, such that 10 grains of rice suffice, and again students explain that the rice was heavy enough to topple the card. Then the card is balanced on a very very thin fulcrum, and a single grain of rice placed on its edge causes it to fall. Students are asked to reconsider whether a single grain of rice

weighs a tiny amount or nothing at all. Seven-year-olds are unmoved by this experience; they insist that the single grain of rice weighs nothing. A classroom of 10- or 11-year-olds presents a completely different picture. First, they are very interested in the experiment, and a lively discussion ensues, pitting those who now think that a grain of rice weighs a tiny amount against those who still maintain it weighs nothing. In every class observed thus far, the proponents of the former view have spontaneously produced two arguments: (1) a sensitivity of the measuring device argument and (2) the argument that a single grain of rice must weigh something, because if it weighed 0 grams, then 50 grains of rice would weigh 0 grams as well.

Note that these two arguments depend on the mapping from physical objects to number: It is only in the realm of mathematics that repeated division of a positive quantity always yields a positive quantity, and that repeated addition of 0 always yields 0. In the realm of physics, in contrast, every physical interaction has a threshold. Repeated division of an object always results, eventually, in objects that are too small to be detected by any given physical device. Moreover, a collection of objects, each of which falls below the threshold of a given device, may well be detectable by the device. Like the Aristotelian physicists discussed by Jammer (1961, see note 3), 7-year-old children who resist Smith's limiting case analysis and continue to insist that a single grain of rice weighs nothing are not necessarily irrational. Rather, they may be reasoning consistently within the domain of perceivable objects and outside the domain of number. Smith's limiting case analysis forms part of the process of constructing a mapping between weight and number and fosters the development of an extensive concept of weight. It does not, however, guarantee that the mapping will be constructed and used.

Smith et al. (1993) recently documented that their model-based curriculum, including thought experiments and limiting case analyses, is more effective in inducing conceptual change than is a control curriculum that does not involve these heuristics. Wiser (1988) has obtained similar results from the use of physical analogy in inducing conceptual change in high school students' thermal concepts, especially the differentiation of heat and temperature.

These results support Duhem's and Nersessian's proposals concerning the mechanisms effecting conceptual change. In addition, they reveal that meta-conceptually unsophisticated

individuals, who are not part of the social process of scientific theory building, can use the heuristics that scientists use to effect conceptual change. The success of these curricula suggests that conceptual change in childhood is the same sort of process as is conceptual change in the history of science. Studies of conceptual change in physics provide evidence against the strong universality hypothesis.

As in the case of number and psychology, however, the weak universality hypothesis is left untouched. Smith's students did not spontaneously explore the mapping between number and weight, and they did not invent the physical analogy, the thought experiments, or the limiting case analyses. These were constructed to be instructional aids by adults who understood the students' conceptions of matter and who knew what conceptual change they wanted to effect. This demonstration therefore leaves open the possibility that only meta-conceptually aware theory builders invent thought experiments, limiting case analyses, and physical analogies in order to construct and use mappings between different knowledge domains.

In summary, studies of conceptual change in childhood show the strong universality hypothesis to be false. Children and adults, like scientists can bring about changes in their core, domain-specific systems of knowledge by constructing and using mappings across those systems. These studies weaken the expectation of cross-cultural cognitive universals, even in domains supported by innate principles. The personal qualities of mature scientists and the cultural institutions of science are not necessary for conceptual change. Psychologists and anthropologists therefore cannot expect that intuitive theories held by lay people the world over will be enriched versions of the innate principles in these domains.

Conclusions

Studies of conceptual change, both in the history of science and in childhood, suggest that human reasoners go beyond the principles at the core of their initial systems of knowledge. Reasoners do this, in part by constructing mappings across different knowledge domains. Because the possibilities for mapping across different domains of knowledge are vast, there is little reason to expect, a priori, that all adults in all cultures will have commensurable conceptions, even in those domains where humans are endowed with systems of knowledge whose principles both

determine the entities of the domain and support reasoning about those entities.

Still, we do not know whether children or adults spontaneously construct mappings across domains, by means of such heuristics as those described above, in the process of developing systems of culturally constructed knowledge. In the absence of developed science, does cognitive development in all cultures require conceptual change, such that the conceptual systems of the members of distinct cultures are incommensurable with the innately given systems? And does the cultural construction of knowledge in these domains lead to intuitive theories across different cultures that are incommensurable with each other? We offer these two related questions as *the* central problems for cognitive anthropology. At least they are the questions we would most like to have answered.

Notes

- 1 Some researchers take the wide-ranging changes, at about age 4, in children's abilities to reason about false beliefs, about the appearance-reality distinction, and about certain perspective-taking tasks as evidence for conceptual change in the child's theory of mind (e.g., Perner, 1991). Others maintain that the mature psychological conception of a person is an enriched version of the 2-year-old's conception (e.g., Wellman, 1990; Fodor, 1992). We do not take sides in this debate but note that researchers on both sides hold that the child, even the baby, attributes to people the capacity for self-generated action, for contingent reactions to the baby's own reactions, and for attention to entities in the world. The later development of representational theories of mind would appear to preserve this core conception of people as sentient and purposive beings.
- 2 Competing views of analogical reasoning within cognitive science (e.g., Gentner, 1989; Holyoak & Thagard, 1989; Carbonell, 1986) flesh out the details of how such mappings are constructed and used.
- 3 Galileo's thought experiment reveals that the Aristotelian concept of *weight* is undifferentiated between an extensive quantity (the weight of the composite object is additive) and an intensive quantity (the weight of the composite object is an average). According to Jammer (1961), Aristotle's concept of weight was in fact undifferentiated in this way. Indeed, Aristotle considered a version of Galileo's thought experiment and drew the conclusion that the composite object would fall faster, because the weight of any given piece of substance was a function of the totality of which it was part: Both the small

and the large object would be heavier when they became part of a single object! Galileo's thought experiment therefore leads to no contradiction within Aristotelian physics. Thought experiments, like any experiments, depend upon current conceptualizations and do not guarantee conceptual change.

- 4 This deepening continues beyond age 10; ten-year-olds judge that a skunk, accidentally given an injection of a chemical shortly after birth, which caused it to grow into an animal that looks just like a raccoon, has indeed become a raccoon; adults judge it will continue to be a skunk (Keil, 1989).
- 5 Springer and Keil (1989) offer no analysis of what constitutes a "biological" functional consequence and include such examples as "has stretched out eyes which make it easier to see their enemies."
- 6 For example, all 4-year-olds and roughly half of the 6- to 10-year-olds maintained that the box mentioned here could contain both the steel block and an equal volume of air at the same time, "because air isn't anything." The same children also asserted that we need air to breathe, that the wind is made of air, that there is no air in outer space or on the moon. In a different interview of 6-year-olds, in which air had not been mentioned, about one quarter of the children posited air as the material of which dreams and ideas are made!

Chapter 40: Pragmatic Reasoning Schemas

PATRICIA W. CHENG AND KEITH J. HOLYOAK

Reasoning fallacies are apparent in discourse and behavior. Their causes, however, have been as mysterious and elusive as the fallacies themselves are evident. A classic debate among both philosophers and psychologists concerns whether apparent fallacies directly reflect errors in the deductive process or indirectly reflect changes in the interpretation of the material from which one reasons. According to the latter view, “fallacies” in fact stem from interpretational changes such as the addition or omission of premises. It has been claimed that if such changes are taken into account, adults in fact reason in accord with formal logic (Henle, 1962). The above view assumes two components in the reasoning process: a deductive component that has context-free, syntactic rules comparable to those in formal logic and an interpretative component that maps statements in natural language onto syntactic rules in the deductive component.

Despite abundant evidence for such interpretational changes (e.g., Fillenbaum, 1975, 1976; Geis & Zwicky, 1971), they in fact cannot fully account for typical patterns of errors produced by college students in deductive reasoning tasks (see Evans, 1982, for a review). Some of these patterns are inconsistent with any logical interpretation of the materials. One such line of evidence is based on Wason’s (1966) selection task. In this task, subjects are informed that they will be shown cards that have numbers on one side and letters on the other, and are given a rule such as, “If a card has a vowel on one side, then it has an even number on the other.” Subjects are then presented with four cards, which might show an “A,” a “B,” a “4,” and a “7” and are asked to indicate all and only those cards that must be turned over to determine whether the rule is

true or false. The correct answer in this example is to turn over the cards showing “A” and “7.” More generally, the rule used in such problems is a conditional, *if p then q*, and the relevant cases are *p* and *not-q*. When presented in an “abstract” form, such as in the above example, typically less than 10% of college students produce the above answer. Subjects also rarely select in accord with a biconditional interpretation of the rule (i.e., *p if and only if q*), which requires that all four cards be turned over. Instead they often select patterns that are irreconcilable with any logical interpretation, such as “A” and “4” (i.e., *p* and *q*). One of the errors in the above answer is omission of the card showing “7,” indicating a failure to see the equivalence of a conditional statement and its contrapositive (i.e., “If a card does not have an even number on one side, then it does not have a vowel on the other”). Such systematic errors suggest that typical college students do commit fallacies due to errors in the deductive process, at least with “abstract” materials.

Although subjects typically fail to reason correctly with “abstract” materials, they nonetheless seem capable of doing so with materials that have been characterized as “concrete,” “realistic,” or “thematic” (e.g., Johnson-Laird, Legrenzi, & Legrenzi, 1972; Wason & Shapiro, 1971). Reasoning performance has sometimes been shown to dramatically improve when the selection task is recast in such contexts (see Evans, 1982, Griggs, 1983, and Wason, 1983, for reviews). Johnson-Laird et al., for example, asked their subjects to pretend that they were postal workers sorting letters, and had to determine whether rules such as, “If a letter is sealed, then it has a 5d stamp on it,” were violated. The problem was cast in the frame of a selection task. The

percentage of correct responses for this version was 81. In sharp contrast, only 15% of the same subjects produced the correct response when given the “card” version mentioned earlier.

Despite these and other positive results, however, the search for thematic facilitation has also been fraught with failures to replicate. To illustrate, although the postal rule problem mentioned above produced facilitation for British subjects in the 1972 study by Johnson-Laird et al., it produced no facilitation at all for American subjects studied by Griggs and Cox (1982). Golding (1981) found that the postal rule problem produced facilitation for older British subjects who were familiar with a similar but now defunct postal regulation imposed by the British post office, but not for younger British subjects who were not as familiar with this rule. The pattern of replications suggested to some that the source of facilitation was prior experience with a rule, particularly prior experience with counterexamples to the rule. It has been argued that subjects familiar with the postal rule do well because the falsifying instance – a sealed but understamped envelope – would be available immediately in the subjects’ memory, prompting them to inspect the sealed envelope (*p*) and the understamped envelope (*not-q*). Faced with the mass of evidence indicating illogical reasoning, several psychologists have recently hypothesized that people typically are not able to use rules of inference to reason, but instead use their memory of domain-specific experiences (e.g., Griggs & Cox, 1982; Manktelow & Evans, 1979; Reich & Ruth, 1982).

The syntactic view has not been abandoned by all, however. Various theorists have proposed *natural logics* which specify repertoires of inferential rules that people untutored in formal logic naturally use (Braine, 1978; Braine, Reiser, & Romain, 1984; Johnson-Laird, 1975; Osherson, 1975; Rips, 1983). With respect to the connective *if-then*, every one of these repertoires proposed include modus ponens. Only one includes modus tollens (Osherson, 1975); however, others include reductio ad absurdum (an inference method which can be used to derive indirectly the same conclusion as follows from tollens) for some or all people (Braine, 1978; Braine et al., 1984; Johnson-Laird, 1975; Rips, 1983).

A different approach, which can be viewed as an attempt to merge the extreme positions represented by specific knowledge and abstract syntactic rules, has been taken by Johnson-Laird (1982, 1983). He proposed that people possess a set of procedures for “modeling” the relations in

deductive reasoning problems so as to reach conclusions about possible states of affairs given the current model of relations among elements. In Johnson-Laird’s theory, mental models are constructed using both general linguistic strategies for interpreting logical terms such as quantifiers and specific knowledge retrieved from memory. The modeling procedures themselves are formal and domain independent. Although Johnson-Laird’s theory differs from other accounts of reasoning in its performance aspects, it does not introduce novel types of knowledge structures.

Critique of Two Current Theories

To recapitulate, the view that people typically reason in accord with formal logic has been overwhelmingly refuted by evidence based on experiments in conditional reasoning. In its place, two major views have been proposed: the specific-experience view and the natural-logic view. We find neither of these views entirely convincing. The inadequacies of each are discussed in turn.

The specific-experience view faces two difficulties. First, remembered counterexamples do not always facilitate performance. In a series of four experiments, Manktelow and Evans (1979) failed to observe facilitation with conditional rules for which subjects were likely to have experienced counterexamples. The rules were arbitrary combinations of foods and drinks, such as, “If I eat haddock then I drink gin.” It should be noted that although the particular combinations used were arbitrary, the general idea of selecting drinks based on the selection of food would presumably be familiar to most people, as would the foods and drinks themselves. A further problem with the above hypothesis is that prior experience does not seem to be required for facilitation: A version of the selection problem developed by D’Andrade (1982) involves an assistant at a department store who has to check sales receipts to ensure that receipts exceeding a certain value were initialed at the back by a section manager. Few subjects would be expected to have a counterexample to this rule readily available in memory. Yet the problem has reliably produced facilitation. Thus experience with a specific rule appears to be neither necessary nor sufficient to yield facilitation.

A further problem with the specific memory approach is that subjects are prone to different types of errors on different types of problems. Reich and Ruth (1982) reported that with “symbolic” problems subjects tended to match the terms mentioned in the rule with those provided

in the cards (disregarding negatives associated with those terms), whereas with “realistic” problems they tended to verify the rule (i.e., selecting p and q). These two patterns of errors can be explained by neither the specific-experience approach nor the natural-logic approach.

The natural-logic view (as well as the syntactic view in general) assumes that when the invitation to infer the converse is taken into account, rules associated with the connective *if-then* are general across contexts. This assumption implies that any variation in performance that is logically unrelated to the invitation to infer the converse, such as the different patterns of errors just mentioned, either falls outside the scope of the theory, or contradicts it. Another type of variation in performance that is logically unrelated to the invitation to infer the converse is variation in the frequency of selecting the *not-q* case in a selection task. The natural logic view, by positing that some subjects do not have *reductio* or *modus tollens* available, can explain some subjects’ failure to select *not-q*. This view cannot, however, explain why the same subjects who fail to select *not-q* in one context do select it in other contexts.

These problems, and others that are raised in the General Discussion, beset any theory of conditional reasoning that assumes context-free inference rules associated with *if-then*. Therefore, a different approach seems warranted.

Pragmatic Reasoning Schemas

Our own approach is based on a type of knowledge structure qualitatively different from those postulated by other theories of deductive reasoning. We propose that people often reason using neither syntactic, context-free rules of inference, nor memory of specific experiences. Rather, they reason using abstract knowledge structures induced from ordinary life experiences, such as “permissions,” “obligations,” and “causations.” Such knowledge structures are termed *pragmatic reasoning schemas*. A pragmatic reasoning schema consists of a set of generalized, context-sensitive rules which, unlike purely syntactic rules, are defined in terms of classes of goals (such as taking desirable actions or making predictions about possible future events) and relationships to these goals (such as cause and effect or precondition and allowable action). Although context-sensitive, the rules that comprise pragmatic schemas may extend beyond the scope of purely syntactic rules of logic, because they will serve to interpret “nonlogical” terms such

as *cause* and *predict* as well as terms treated by formal logic, such as *if-then* and *only-if*.

Although a syntactically based reasoning system tells us which inferences are valid, it does not tell us which inferences are useful among the potentially many that are valid. Consider, for example, the contrapositive transformation of the material conditional. Given the statement, “If two particles have like electrical charges, then they repel each other,” a logic-based reasoning system lets us infer the potentially useful conclusion, “If two particles do not repel each other, then they don’t have like electrical charges.” In contrast, given the statement, “If I have a headache, then I should take some aspirin,” the same rule will produce the inference, “If it’s not the case that I should take some aspirin, then I don’t have a headache,” which is hardly ever a useful inference to make. More generally, the fact that a problem exists creates the goal of finding a remedy for it; however, the absence of the need for a remedy does not create the goal of inferring the absence of a problem. Since people do not seem to make this type of useless inference, it seems that pragmatic goals must guide the process of inference.

Our theoretical framework assumes that the role of prior experience in facilitation is in the induction and evocation of certain types of schemas. Not all schemas are facilitating, as becomes clear below. Some schemas lead to responses that correspond more closely than others with those that follow from the material conditional in formal logic. Performance as evaluated by the standard of formal logic depends on what type of schema is evoked, or whether any schema is evoked at all.

An arbitrary rule, being unrelated to typical life experiences, will not reliably evoke any reasoning schemas. Subjects confronted with such a rule may attempt to interpret it in terms of a reasoning schema. Failing that, they would have to draw upon their knowledge of formal reasoning to arrive at a correct solution. Only a small percentage of college students apparently know the material conditional or can derive the contrapositive or *modus tollens* using *reductio ad absurdum*. Failing either, some might draw on some nonlogical strategy such as matching, as observed by Reich and Ruth (1982) and Manktelow and Evans (1979), among others.

In contrast, some rules evoke schemas with structures that yield the same solutions as the material conditional (under circumstances explicated below). In particular, most of the thematic problems that have yielded facilitation

fit a *permission* schema. The permission schema describes a type of regulation in which taking a particular action requires satisfaction of a certain precondition.

In standard propositional logic the deductive rules pertaining to *if-then* specify syntactic patterns based on the components *if*, *then*, *not*, and *only if*. For example, one rule states that *if p then q* is equivalent to *if not-q then not-p*, where the symbols *p* and *q* represent any statements. The permission schema, in contrast, contains no context-free symbols such as *p* and *q* above. Instead the inference patterns include as components the concepts of possibility, necessity, an action to be taken, and a precondition to be satisfied. (The deontic concepts of possibility and necessity are typically expressed in English by the modals *can* and *must*, respectively, and various synonyms, such as *may* and *is required to*.)

The core of the permission schema can be succinctly summarized in four production rules, each of which specifies one of the four possible antecedent situations, assuming the occurrence or nonoccurrence of the action and the precondition:

- Rule 1: If the action is to be taken, then the precondition must be satisfied.
- Rule 2: If the action is not to be taken, then the precondition need not be satisfied.
- Rule 3: If the precondition is satisfied, then the action may be taken.
- Rule 4: If the precondition is not satisfied, then the action must not be taken.

To understand when and why the permission schema facilitates selection performance, compare the above rules to the four possible inference patterns of the material conditional. When a situation or problem evokes a permission schema, the entire set of rules comprising the schema becomes available. Suppose the conditional rule in a given selection problem is in the form of Rule 1, such as "If one is to drink alcohol, then one must be over eighteen." Rule 1 has the same effect as modus ponens. Rule 2, because it indicates that the precondition is irrelevant if the action is not taken (the precondition need not be satisfied, but may be anyway), effectively blocks the fallacy of Denying the Antecedent. Similarly, Rule 3 indicates that if the precondition is satisfied, then the action is allowed but not dictated, thus blocking the fallacy of Affirming the Consequent. Finally, Rule 4 explicitly states that fail-

ure to satisfy the precondition precludes taking the action, an inference pattern corresponding to the contrapositive. A rule corresponding to the contrapositive is thus available directly, rather than requiring an indirect derivation by means of reductio ad absurdum. In sum, when a conditional statement in the form of Rule 1 evokes a permission schema, the solution derivable from the permission schema matches that required by the material conditional. Hence, the permission schema should be facilitative.

This does not imply that the permission schema is equivalent to the material conditional in standard propositional logic. The permission schema is context-sensitive. In addition, as is discussed further in Experiment 3, the permission schema is directly related to deontic concepts such as *must* and *may* that cannot be expressed in standard propositional logic. Furthermore, the rules attached to reasoning schemas are often useful heuristics rather than strictly valid inferences. For example, Rule 3 above does not logically follow from Rule 1, since it could yield a false conclusion if the precondition is necessary but not sufficient to render the action permissible (e.g., if a drinking law required drinkers to be both over 18 and free of recent drunk driving violations, then the inference "If a person is over eighteen, then he or she may drink alcohol" would not hold). Because reasoning schemas are not restricted to strictly valid rules, our approach is not equivalent to any proposed formal or natural logic of the conditional.

Not all conditional reasoning schemas suggest the same solution to selection problems as does formal logic. A *causal* schema, for example, will sometimes invite an assumption of the converse of a given conditional statement. (Assumption of the converse is to be distinguished here from the biconditional, which includes assumption of both the converse and its contrapositive.) A conditional, *if p then q*, interpreted in the context of a causal schema may be represented as "If (cause), then (effect)." To the degree that only a single cause is perceived, the effect may be treated as evidence for concluding the presence or prior existence of the cause, yielding an inference in the opposite direction, "If (evidence), then (conclusion)." Since events are sometimes perceived as having a single cause, problems evoking a causal schema are more likely to lead to the fallacy of Affirming the Consequent than problems evoking a permission schema.

Alternative reasoning schemas may account for reported variations in performance on the

selection task. As noted earlier, Reich and Ruth (1982) found that "realistic" sentences such as, "If a fruit is yellow, then it is ripe," tended to lead to verification (selecting p and q), whereas arbitrary "symbolic" problems tended to lead to a matching strategy (also Manktelow & Evans, 1979). It seems that there may be a general "covariation" schema, which can be applied to any situation in which two situations or events are for some reason expected to co-occur, as in Reich and Ruth's "realistic" sentences. The covariation schema, like the causal schema, can be expected to invite an assumption of the converse of a given conditional statement and would lead to selection of p and q , the pattern observed for Reich and Ruth's "realistic" sentences. Arbitrary rules, being unrelated to real-life experiences, may fail to evoke even a covariation schema for some subjects, so that these subjects must resort to an entirely nonlogical strategy. It is therefore possible that evocation of different reasoning schemas can account for variations in performance even among problems in which none of the dominant response patterns are consistent with formal logic.

To summarize, we suggest that many inference schemas are pragmatic in nature, with the purposes of the set of rules being salient features of each schema. Because these purposes differ between schemas, they may serve to discriminate between types of schemas at the interpretative stage. Regulations such as permissions and obligations are imposed typically by an authority to achieve some social purpose. In contrast, causal rules are not imposed by an authority, but simply serve to generate useful predictions about transitions between environmental states. Thus the purposes of the schemas are of different natures. As we see in Experiment 1, provision of the purpose of a regulation constitutes a major cue for evocation of the permission schema.

We propose that people typically make inferences based on pragmatic reasoning schemas. Whereas the logic approach assumes that an interpretative component maps statements onto particular context-free syntactic inference rules comprising the deductive component, the schema approach assumes that the interpretative component maps statements onto a particular set of context-sensitive rules attached to the relevant schema. Such schemas vary in their degree of correspondence with the material conditional. The experiments reported below were designed to provide direct tests of the schema hypothesis.

Experiment 1

According to the schema hypothesis, failure on selection problems is due to failure to evoke a schema that corresponds well with the conditional in formal logic. A possible explanation for the conflicting results obtained with the envelope problem (discussed earlier) is that subjects who have had experience with the postal rule (or one that is highly similar to it) understand the rule in terms of a permission – one is permitted to seal an envelope only if it carries a certain amount of postage. In contrast, subjects who have not had any experience with such rules perceive it as being arbitrary. If people in fact reason using pragmatic reasoning schemas, then it may be possible to improve performance by evoking a facilitating schema, such as the permission schema, without providing subjects with experience on specific rules.

In the present experiment we attempted to evoke a permission schema by providing a rationale for conditional rules that may otherwise appear arbitrary. Two versions of each of two thematic problems were administered to groups of college students: a version with a rationale and a version without it. If provision of a rationale succeeds in evoking a permission schema, then performance should generally be better in the rationale than in the no-rationale condition. The two thematic problems were the envelope problem mentioned earlier, involving the rule: "If an envelope is sealed, then it must have a 20 cent stamp"; and a "cholera" problem, involving the rule: "If a passenger's form says 'Entering' on one side, then the other side must include 'cholera'."

In addition to varying the inclusion of a rationale, we also varied subjects' prior experience with a rule by using subjects in Michigan and in Hong Kong. Whereas subjects in Michigan were not familiar with the postal rule, since no similar rule had been in effect in the United States, subjects in Hong Kong were familiar with it, since a similar rule was in effect until about 6 months before the experiment was run. Few of the subjects in either location would be expected to have had experience with the cholera rule. In general, those who have had experience with the rules should be able to perceive them as permissions, even though they may appear arbitrary to other subjects. The schema hypothesis therefore predicts that for the no-rationale condition only subjects in Hong Kong given the envelope problem would do well, but for the

rationale condition subjects in both Hong Kong and Michigan would do well on both thematic problems.

In contrast, the syntactic view predicts that performance would be similar across all conditions, since the forms of the conditional statements were identical in the rationale and no-rationale versions for subjects in both places. Even allowing for differences in the tendency to invite the converse assumption, the syntactic view would still predict that the frequency of selecting the *not-q* case would be constant across conditions. The domain-specificity view also predicts that the rationale should have no effect. However, it predicts that the performance of Hong Kong subjects on the envelope problem should be superior to performance in all other conditions, since Hong Kong subjects alone were familiar with the postal rule.

Method

Subjects. Eighty-two students who were enrolled in an introductory psychology course at the Chinese University of Hong Kong participated in the experiment as partial fulfillment of the course requirement. Eighty-eight students at the University of Michigan participated in the experiment for the same reason. None of the participants had had any prior experience with the selection task.

Procedure. Subjects at each location were randomly assigned to two equal-sized groups. Each subject received one version of each of two thematic problems: a rationale version of one problem, and a no-rationale version of the other problem. Half of the subjects at each location received the rationale version of a problem, and the other half received the no-rationale version of the same problem. Subjects were run in groups of 8 to 10. All subjects were told to think carefully and solve the problems as best they could. To ensure that subjects arrived at the best answer they were capable of, they were allowed as much time as they needed, and were also allowed to make corrections. Subjects were encouraged to write brief explanations of their responses. As mentioned earlier, the two problems were the envelope problem and the cholera problem. The envelope problem preceded the cholera problem. For the Hong Kong subjects, who were bilingual, the rule in each problem was stated in both English and Chinese.

Materials. The no-rationale version of the envelope problem stated, "You are a postal clerk

working in some foreign country. Part of your job is to go through letters to check the postage. The country's postal regulation requires that *if a letter is sealed, then it must carry a 20-cent stamp*. In order to check that the regulation is followed, which of the following four envelopes would you turn over? Turn over only those that you need to check to be sure."

The above paragraph was followed by drawings of four envelopes, one carrying a 20-cent stamp, a second carrying a 10-cent stamp, a third one labeled "back of sealed envelope," and a fourth one labeled "back of unsealed envelope."

The rationale version of the envelope problem was identical to the no-rationale version, except that the conditional rule (underscored) was immediately followed by the sentences: "The rationale for this regulation is to increase profit from personal mail, which is nearly always sealed. Sealed letters are defined as personal and must therefore carry more postage than unsealed letters."

The no-rationale version of the cholera problem stated "You are an immigration officer at the International Airport in Manila, capital of the Philippines. Among the documents you have to check is a sheet called Form H. One side of this form indicates whether the passenger is entering the country or in transit, while the other side of the form lists names of tropical diseases. You have to make sure that *if the form says 'ENTERING' on one side, then the other side includes cholera among the list of diseases*. Which of the following forms would you have to turn over to check? Indicate only those that you need to check to be sure." The above paragraph was followed by drawings of four cards. One of them carried the word "TRANSIT," another carried the word "ENTERING," a third listed "cholera, typhoid, hepatitis," and a fourth listed "typhoid, hepatitis."

The rationale version of the cholera problem was identical to the no-rationale version except that instead of saying that the form listed names of tropical diseases, it said that the form listed inoculations the passenger had had in the past 6 months. In addition, the conditional rule (underscored) was followed by the sentence. "This is to ensure that entering passengers are protected against the disease."

Results

Figure 1 presents the percentage of subjects who solved the selection problem in each condition.

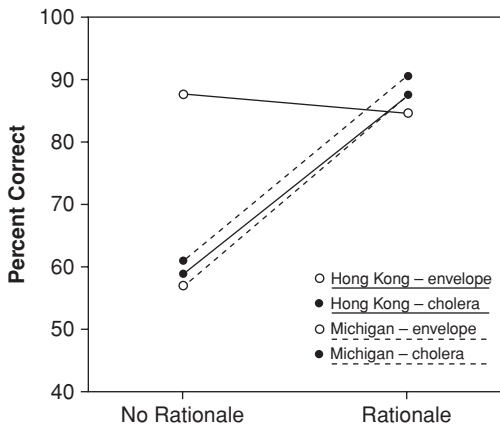

Figure 1. Percentage of subjects who solved the selection task correctly in each condition as a function of provision of a rationale (Experiment 1).

The pattern of results was precisely as predicted by the schema hypothesis. The rationale versions produced uniformly high success rates for subjects at both locations for both thematic problems, whereas the no-rationale versions produced a high success rate only for the envelope problem with Hong Kong subjects. The difference in frequency of correct solutions as a function of provision of a rationale was tested using the χ^2 statistic for each problem and subject group. Except for the envelope problem with the Hong Kong subjects, for whom the rationale was redundant as predicted, all conditions produced a significantly higher success rate for the rationale versions ($p < .01$ for each of the 3 location-problem conditions). The frequency of successfully selecting the *not-q* case reflects the same pattern of performance as the frequency of solving the entire problem correctly.

Performance levels for the no-rationale groups were higher in the present experiment than in other studies using subjects lacking experience with similar rules (Griggs & Cox, 1982). It is difficult to interpret such differences in absolute performance levels across subject populations. It may be that our subjects were sometimes able to provide their own implicit rationales for the stated rules even when none were provided by the experimenter. Our procedure of allowing for corrections might also have contributed to the higher performance level.

The results of Experiment 1 provide clear support for the schema hypothesis. Since experience on the given domains did not differ between the rationale and the no-rationale

groups, the effect of the rationales cannot be due to the amount of specific experience. And since the syntactic form of the *if-then* rules remained constant across all conditions, the effect of the rationales cannot be accounted for by the syntactic view either.

Experiment 2

It might be argued that since the rationales in Experiment 1 were not content free, their introduction might have changed the nature of the relevant experience brought to bear on the problems. For example, although specific experience with the postal rule per se was not affected by introduction of the rationale, the idea of increasing profit – probably familiar to most subjects – may have prompted subjects to check envelopes carrying relatively small amounts of postage to ensure that they did not unduly reduce profit. Similarly, the idea of protection against a disease may prompt subjects to check passengers unprotected against it. In both cases, the rationales may encourage checking the *not-q* case, the omission of which is a frequent error in selection problems. The relevant experience evoked by the rationales would extend beyond the specific conditional statements, but would nonetheless be content specific.

To provide clearcut evidence for abstract schemas that are not bound to any domain-specific content, we tested performance on a selection problem that described a permission situation abstractly, with no reference to any concrete content. Subjects were asked to check regulations that have the general form, "If one is to take action 'A,' then one must first satisfy precondition 'P.'" To demonstrate that concreteness of the *if-then* rule, in the absence of a facilitating schema such as a permission, does not lead to logically correct responses, subjects were also tested on an arbitrary "card" version of the selection problem involving a rule specifying concrete entities.

Method

Subjects. Forty-four University of Michigan undergraduates enrolled in psychology courses volunteered for the experiment. None of the students had had any previous experience with the selection paradigm.

Materials. Each subject was given two selection problems. One was an abstract description of a permission, stating, "Suppose you are an

authority checking whether or not people are obeying certain regulations. The regulations all have the general form, "If one is to take action 'A,' then one must first satisfy precondition 'P.'" In other words, in order to be permitted to do "A," one must first have fulfilled prerequisite "P." The cards below contain information on four people one side of the card indicates whether or not a person has taken action "A," the other indicates whether or not the same individual has fulfilled precondition "P." In order to check that a certain regulation is being followed, which of the cards below would you turn over? Turn over only those that you need to check to be sure."

The above instructions were followed by drawings of four cards stating the four possible cases: "has taken action A," "has not taken action A," "has fulfilled precondition P," and "has not fulfilled precondition P."

The other problem involved an arbitrary card rule stating, "Below are four cards. Every card has a letter on one side and a number on the other. Your task is to decide which of the cards you need to turn over in order to find out whether or not a certain rule is being followed. The rule is: If a card has an 'A' on one side, then it must have a '4' on the other side. Turn over only those cards that you need to check to be sure." Although this rule has often been labeled "abstract" in the literature, we would like to call attention to the distinction between the arbitrariness of the relation and the abstractness of the entities involved in the rule (Wason & Shapiro, 1971). The above rule specifies an arbitrary relation between specific, concrete entities.

Drawings of four cards followed, showing four possible cases: "A," "B," "4," and "7." To more closely match the syntactic form of the cases in the permission problem, cases that negated terms in the *if-then* rule were so indicated explicitly. The card showing "7" carried the caption "i.e., not '4,'" and the card showing "B" carried the caption "i.e., not 'A.'" In addition, the modal *must* was included in the arbitrary version of the rule to match the syntactic form of the permission rule.

Procedure. Subjects were given the same general instructions for solving the problems as in Experiment 1, except that they were not allowed to change answers on a previous problem. Subjects were run in small groups. The ordering of the two problems was counterbalanced across subjects. The four cases to be selected in each problem were either ordered *p*, *not-p*, *q*, *not-q*, or the reverse. Each subject received a different ordering of the cases in each problem. The

ordering of the cases was counterbalanced across problems.

Results and Discussion

In order to assess performance on the permission and card problems independently of any transfer from one to the other, an analysis was performed on data from just the first problem solved by each subject. Although the permission problem was more abstract than the card problem, 61% of the subjects solved the permission problem correctly, whereas only 19% solved the card problem correctly, $\chi^2(1) = 7.76, p < .01$. Since the permission problem made no reference to any domain-specific content, and the syntactic form of the *if-then* rules was matched across the permission and card problems, superior performance on the permission problem provides strong evidence for the existence of an abstract permission schema.

The effect of the ordering of the two problems did not approach significance; however, the card problem was more often solved correctly when it followed the permission problem (39%) than when it preceded it (19%), suggesting possible positive transfer. In contrast, the permission problem was less often solved correctly when it followed the card problem (48%) than when it preceded it (61%), suggesting possible negative transfer. Collapsing over the two orders of the problems, 55% of the subjects solved the permission problem correctly, whereas only 30% of the same subjects solved the card problem correctly. This difference was significant when tested with a binomial test of symmetry ($p = .01$). The order of the four alternative choices had no significant effect on the frequency of solving a problem correctly. The frequency of successfully selecting the *not-q* case reflects the same pattern of performance as the frequency of solving the entire problem correctly.

Experiment 3

The knowledge contained in the permission schema should affect performance in other tasks besides the selection paradigm. For example, since rules in the schema govern and aid the rephrasing of sentences from *if-then* into *only-if* form and vice versa, such rephrasings of permission statements should follow certain consistent patterns, some of which correspond well with formal logic. In contrast, since transformations of arbitrary conditional statements are not guided by any rule that corresponds well with formal

logic, performance on such rephrasings should be no different from chance.

According to standard logic a conditional of the form *if p then q* is equivalent to *p only if q*, in the sense that the two statements have identical truth tables. As Evans (1977) has noted, the *only-if* form stresses the necessity of the consequent – i.e., the fact that *q* must hold in order for *p* to be the case. The *only-if* form is thus closely related to the contrapositive of the *if-then* form (i.e., *if not-q then not-p*), which also emphasizes the necessity of *q*.

Because people do not in general use an inference rule equivalent to the contrapositive, we would expect them to have great difficulty in rephrasing between *if-then* and *only-if* forms for arbitrary statements (Braine, 1978). There will be no rules to help them decide whether a statement in the form *if p then q* should be rephrased into *p only if q* or its converse, *q only if p* (and vice versa).

In contrast, such rephrasings of permission statements should follow certain consistent patterns. Consider the following two possible rephrasings into *only-if* form of an *if-then* permission statement, “If the action is to be taken, then the precondition must be satisfied”:

- (5) The action is to be taken only if the precondition is satisfied.
- (6) The precondition must be satisfied only if the action is to be taken.

Although only (5) is a valid rephrasing ((6) would be false if there were some other reason for the precondition being necessary), both are plausible inferences. Nonetheless, (5) is a more natural and direct inference than (6). A possible reason is that a statement in the form *p only if q* carries the connotation that *q* is necessary for *p* as well as prior to it in time (Evans, 1977; Evans & Newstead, 1977), both aspects of which are central to what it means to constitute a precondition or prerequisite. Hence, the form is highly compatible with the content in Statement (5), whereas Statement (6) carries the implication that taking the action is the prerequisite for the necessity of satisfying the precondition, which is a very circuitous way of saying, “If the action is not to be taken, then the precondition need not be satisfied.” There seems to be no natural way of stating a permission in an *only-if* form in which the precondition precedes the action. It follows that subjects are more likely to produce Statement (5) than Statement (6) (or corresponding variants) when asked to phrase a per-

mission statement in an *only-if* form. Since (5) is the strictly valid inference, it follows that subjects will appear to follow the dictates of formal logic in rephrasing a permission statement from *if-then* into *only-if* form.

Such a difference in naturalness will not guide the rephrasing of permission statements in the reverse direction, from *only-if* form as in (5) into *if-then* form. Either the action or the precondition can be the antecedent of a permission statement in an *if-then* form without any awkwardness. Rules 1 and 3 of the permission schema described in the introduction are examples of the two orderings,

- (1) If the action is to be taken, then the precondition must be satisfied.
- (3) If the precondition is satisfied, then the action may be taken.

According to formal logic only (1) is a valid rephrasing of (5) (with the caveat that a deontic logic is required to account for the introduction of *must* in (1); see below); as noted in the introduction, (3) could be false if the stated precondition were necessary but not sufficient for the action. Nonetheless, both (1) and (3) are pragmatically plausible and natural inferences in most permission contexts. We therefore do not expect any difference in subjects' propensity to produce the two forms of *if-then* sentences in our rephrasing task. It follows that for permission statements, subjects' rephrasings will appear to follow the dictates of formal logic more closely when the direction is from *if-then* into *only-if* form rather than vice versa. This asymmetry is only apparent, however, in that the entire predicted response pattern follows from the nature of the information contained in the permission schema.

The schema hypothesis also generates predictions about the introduction of modals into rephrasings. The concept of permission is based on the deontic concepts of “possibility” and “necessity.” The modals that express these concepts allow inference patterns beyond the scope of standard propositional logic. For example, applying a rule of standard propositional logic to the permission statement, “A customer is to drink an alcoholic beverage only if she is at least eighteen,” we obtain the supposedly equivalent statement, “If a customer is to drink an alcoholic beverage, then she is at least eighteen.” However, this rephrasing is quite unnatural because it tends to be interpreted as a claim that drinking an alcoholic beverage *causes* the person to

be 18. To maintain the sense of permission, it is much more natural to introduce the modal *must* into the consequent: "If a customer is to drink an alcoholic beverage, then she *must* be at least eighteen." In contrast, introduction of the modal is not dictated for arbitrary statements, which are not interpreted deontically. For example, the statement, "A card has an 'A' on one side only if it has a '4' on the other" can be rephrased as, "If a card has an 'A' on one side, then it has a '4' on the other." In this case introduction of *must* ("then it *must* have a '4' on the other") is unnecessary, since the original statement has no deontic implications. Accordingly, the schema hypothesis predicts that *must* will be introduced in rephrasing from *only-if* to *if-then* form for permission statements but not for arbitrary statements.

Similarly, *can* or its synonyms will be introduced in rephrasing from *if-then* to *only-if* form more often for permission than for arbitrary statements. For example, the alcohol rule discussed in the last paragraph is more naturally stated as, "A customer *can* drink alcohol only if she is at least eighteen," rather than, "A customer drinks alcohol only if she is at least eighteen." The modal *can*, or its synonyms such as *may*, *is to*, or *is allowed to*, serves to retain the sense of a social regulation. In contrast, arbitrary statements do not require any modal (e.g., "A card has an 'A' on one side only if it has a '4' on the other").

Method

Subjects. Fifty-two undergraduates at the University of Michigan, none of whom had prior experience with the selection task, served as subjects.

Procedure. All subjects received four problems, two based on permission statements and two on arbitrary statements. One statement of each type was presented in *if-then* form and one in *only-if* form. For each statement subjects first performed the standard selection task and then attempted to rephrase the statement into an alternative form (i.e., *if-then* into *only-if* or vice versa).

Materials. In addition to the usual selection-task instructions, the first page of the booklet given to subjects explained that *if-then* statements can be rephrased into *only-if* form and vice versa. An arbitrary statement was used as an example: "If the tablecloth is brown, then the wall is white" corresponds to "The tablecloth is brown only if the wall is white."

The two permission statements were the "cholera" rule used in Experiment 1 (the ratio-

Table 1: Percentage Correct on Selection Task (Experiment 3)

Given Form	Rule Type		Mean
	Permission	Arbitrary	
If-then	67	17	42
Only-if	56	4	30
Mean	62	11	

nale version), and the "alcohol" rule used above as an example. The arbitrary statements were the card problem and a "bird" problem, which in *if-then* form involved the statement, "If a bird has a purple spot underneath each wing, then it must build nests on the ground." As this example illustrates, all statements included *must* in their *if-then* forms in order to equate the syntactic structure of the permission and arbitrary statements.¹

Each problem was presented on a separate page of the booklet. The selection task was presented at the top of each page. The basic statement was then repeated below, and subjects were asked to write the equivalent rephrasing in either *if-then* or *only-if* form. Which statements were presented in which form, and the order of the problems, were counterbalanced across subjects.

Results and Discussion

Selection task. Table 1 presents the percentage of subjects who gave logically correct responses in the selection task as a function of the type of rule (permission and arbitrary) and the form of the rule (*if-then* or *only-if*). The data were analyzed using analysis of variance. We will report the results collapsed across the two problems of each type, since the overall pattern held for the individual problems.

As Table 1 indicates, subjects were far more accurate in choosing the two correct alternatives, *p* and *not-q*, for permission statements (62%) than for arbitrary statements (11%), $F(1, 51) = 131, p < .001$. This result is of course predicted by the hypothesis that people are able to apply a specialized schema to reason about permission statements. In addition, performance was more accurate, when the rules were stated in *if-then* rather than *only-if* form, $F(1, 51) = 5.22, p < .05$. These two factors, the type and form of the rule, did not significantly interact.

Rephrasing. According to the schema hypothesis, modals should be systematically introduced

Table 2: Percentage "Correct" Rephrasings, Including and Excluding Modals (Experiment 3)

Given Form	Permission			Arbitrary		
	Modal	No Modal	Total	Modal	No Modal	Total
If-then	42 ^a	29	71	4 ^a	33	37
Only-if	31 ^b	11	42	6 ^b	42	48

^a Can *p* only if *q*.

^b If *p* then must *q*.

into rephrased permission statements to preserve their deontic sense, whereas modals will not be introduced into arbitrary statements. Moreover, whereas permission statements of the form *if p then must q* should be readily rephrased into the form *p only if q* (or *can p only if q*), permission statements of the form *p only if q* would likely be rephrased into two modal forms: *if p then must q* or *If q then can p*. Only the first of the two modal forms is a strictly valid inference from the original statement.

Table 2 reports the percentage of subjects who rephrased rules of each type and form into forms in which *p* was ordered before *q*, with or without the inclusion of modals. This ordering of *p* and *q* corresponds to that dictated by formal logic, and hence will be referred to as "correct," although we emphasize that within our schema framework certain forms that reverse the order of *p* and *q* also constitute pragmatically appropriate inferences. Two transformations form a statement in the form *if p then q* were scored as correct: *p only if q* (no modal) and *can p only if q* (with modal). Similarly, two transformations from a statement in the form *p only if q* were scored as correct: *If p then q* (no modal) and *if p then must q* (with modal). A response was thus scored as correct if the propositions *p* and *q* were placed as the antecedent and the consequent, regardless of the insertion or omission of the appropriate modal. Since there are only two possible permutations of *p* and *q*, subjects would be expected to achieve 50% accuracy if they ordered the propositions randomly.

As Table 2 indicates, the rephrasing results were entirely in accord with the schema hypothesis. Arbitrary statements in either the *if-then* or the *only-if* form were not rephrased correctly with a frequency significantly different from the chance level of 50%. The interaction between the form of the given statement (*if-then* versus *only-if*) and its content (permission versus arbitrary) was highly significant, $F(1, 51) = 19.2, p < .001$. Permission state-

ments in *if-then* form were rephrased correctly significantly more often than arbitrary *if-then* statements, $F(1, 51) = 21.6, p < .001$, whereas permission statements in *only-if* form were not rephrased correctly more often than arbitrary statements.² As predicted, *only-if* permission statements were often rephrased into the alternative form *if q then can p*. This alternative rephrasing was produced in 38% of the cases for *only-if* permission statements versus only 2% of the *only-if* arbitrary statements.

The data in Table 2 also reveal that among the correct rephrasings, modals tended to be introduced for permission but not for arbitrary statements. For *if-then* permission statements there was a nonsignificant tendency to introduce *can* or a synonym (i.e., *can p only if q*) more often than not, whereas for *if-then* arbitrary statements the correct rephrasings were much more likely to omit any modal, $\chi^2(1) = 11.8, p < .001$. Similarly, for *only-if* permission statements correct rephrasings included a modal (i.e., *if p then must q*) more often than not, $\chi^2(1) = 4.55, p < .05$, whereas for *only-if* arbitrary statements correct rephrasings more often omitted any modal, $\chi^2(1) = 14.4, p < .001$. Thus for both correct and incorrect rephrasings, modals were consistently inserted into transformations of permission statements but not of arbitrary statements.

General Discussion

The present results support the view that people typically reason using schematic knowledge structures that can be distinguished both from representations of specific experiences and from context-free syntactic inference rules. In Experiment 1, a rationale designed to evoke a permission schema facilitated performance on selection problems for which subjects lacked specific experience. Indeed, provision of a rationale raised performance to the same level of accuracy as did prior experience with the rule. Neither the specific-experience view nor the

syntactic view can account for the observed performance pattern.

Experiment 2 demonstrated that a selection problem based on an abstract statement of a permission rule, totally devoid of concrete content, produced substantially more accurate performance than did an arbitrary rule. This result is damaging to both the syntactic and the specific-experience view. Finally, Experiment 3 provided evidence that evocation of a permission schema affects not only performance on the selection task, but also how subjects rephrased sentences from *if-then* into *only-if* forms and vice versa. In particular, statements in the form *if p then q* were rephrased into the form *p only if q* much more frequently for permission than for arbitrary statements, and rephrasings of permission statements produced a pattern of introduction of modals (*must, can*) totally unlike that observed for arbitrary conditional statements that lack a deontic context. Again, neither of the alternative views can account for the observed pattern of results.

Comparison with Other Approaches

Our results thus speak strongly for the existence of pragmatic schemas; the findings are inexplicable according to either the specific-experience view or the syntactic view. Nonetheless, our findings need not be interpreted as evidence against the very possibility of the two extreme modes of reasoning. It is conceivable that alternative knowledge structures relevant to deductive reasoning coexist within a population and even within an individual. Cheng, Holyoak, Nisbett, and Oliver (1985) propose a possible set of relations between logical rules, specific experience, and pragmatic schemas. Although the three levels of knowledge structures may coexist, the apparent priority of the pragmatic level in reasoning has important implications for attempts to alter performance on reasoning tasks by direct instruction. Cheng et al. (1985) compared the impact on selection-task performance of purely formal logic training with that of training based on a pragmatic schema for obligation. They found that purely formal training was quite ineffectual, whereas instruction in the nature of obligations improved performance on a range of conditional rules that could be interpreted as expressing obligations.

Other theorists have suggested that schemas (Rumelhart, 1980; Wason, 1983) or scenarios (Pollard, 1982) play a role in deductive reasoning; however, previous discussions have said lit-

tle about the types and nature of the information that might be included in such schemas or scenarios. One suggestion related to the present proposal is that performance on the selection task is facilitated if subjects are oriented toward checking for violations, rather than testing a hypothesis (see Griggs, 1983; Yachanin & Tweney, 1982). The core of the permission schema, as well as of similar schemas for other types of regulations, indeed consists of procedural knowledge for assessing whether a type of rule is being followed or violated. However, the schema approach predicts that violation checking will only lead to accurate performance if the problem evokes a schema specifying those situations that in fact constitute violations. Asking subjects to check for violations in an otherwise arbitrary problem would not suffice, as Griggs (1984) and Yachanin (1985) have shown. In addition, the pattern of selections will only correspond to that required by formal logic if the schema yields the same solution as does the formal conditional. Although the permission schema does so when the given *if-then* statement is in the form of Rule 1, other regulation schemas have a different structure. For example, many obligations are pragmatically biconditional. Thus the rule, "If a child has reached age six, then he or she must enter school" may be given an "if and only if" interpretation, in which case the pattern of choices on a selection task will not correspond to that specified by the formal conditional, even if the subject checks for violations.

It is also clear from the results of Experiment 3 that the impact of the permission schema on performance is broader than simply encouraging violation checking. The rephrasing results indicate that evocation of the schema has consequences for a linguistic task involving declarative knowledge. Even if such declarative knowledge is derived from more basic procedural knowledge, performance on the linguistic task certainly goes beyond what could be described as orientation toward violation checking.

We do not claim, however, that all variations in performance on reasoning problems can be accounted for solely in terms of variations in the reasoning schemas evoked by different problems. For example, Wason and Green (1984) demonstrated that more accurate performance is observed when the selection task is simplified by only offering the subject alternatives based on the consequent (i.e., *q* and *not-q*), omitting those based on the antecedent. Wason and Green also found that subjects were more accurate when the rule related properties of a unitary object

(e.g., “If the figure on the card is a triangle then it has been colored red”), rather than properties of disjoint objects (e.g., “All the triangles have a red patch above them”). The positive effects of such task manipulations are most likely due to decreases in the overall cognitive load imposed by the task.

Causal Schemas and Linguistic Anomalies

Although this chapter dealt most directly with the permission schema, we expect that a number of other schemas are used to reason about conditional rules. We have already mentioned schemas for obligations. An obligation is very similar to a permission except that the temporal direction is reversed. In a permission, performing an action requires satisfaction of a precondition, whereas in an obligation, a certain situation requires execution of a subsequent action.

Outside of the realm of social regulations, the concept of “causation” appears to correspond to a family of reasoning schemas (Kelley, 1972, 1973). There are very likely several subtypes of causal schemas, varying on such basic dimensions as whether the causal relation is deterministic or probabilistic and whether single or multiple causes are believed to produce the effect. In addition, as we noted earlier, schemas relating causes and their effects are closely related to schemas for “evidence” (e.g., an observed effect is evidence for the operation of its known cause).

Schematic knowledge about causation and evidence can account for anomalies sometimes created by the contrapositive transformation (which changes statements in the form *if p then q* into the form *if not-q then not-p*). Note the transformations of the following two sentences:

- (7) If the bomb explodes, then everyone will die.
- (8) If one takes proper care of a plant, then it grows.

They result in the following pragmatically anomalous contrapositives:

- (7a) If not everyone will die, then the bomb does not explode.
- (8a) If a plant does not grow, then one does not take proper care of it.

In contrast, the transformations of the following two sentences,

- (9) If there is smoke, then there is fire.

- (10) If one has been inoculated against cholera, then one is immune to it.

result in meaningful contrapositives:

- (9a) If there is no fire, then there is no smoke.
- (10a) If one is not immune to cholera, then one has not been inoculated against it.

No syntactic interpretation of the connective *if-then* in terms of either standard or natural logic can account for the difference in acceptability between (7a) and (8a) on the one hand, and (9a) and (10a) on the other.³ The temporal direction of *if-then* statements hypothesized by Evans and Newstead (1977) – although a factor in determining acceptability, as we shall see – also cannot fully account for the difference. Sentences (10) and (10a), for example, are both acceptable, despite the antecedent and the consequent being ordered temporally in opposite directions.

But let us consider the transformations in terms of pragmatic knowledge about causation, which could be represented by rules attached to a causal schema. The contrapositive transformation reverses the antecedent and the consequent of a conditional. The inference, “If (cause), then (effect),” in a causal schema has the contrapositive, “If (absence of effect), then (absence of cause),” where the absence of the effect serves as evidence for concluding the absence of the cause. The above two conditionals have a common temporal restriction involving the relative temporal order of cause and effect. When the cause and the effect are temporally ordered by world knowledge, as in Sentences (7), (8), and (10), the event interpreted as the cause (or its absence) must temporally precede the effect (or its absence). Notice that this temporal restriction hinges on the semantic content of the events, regardless of which event is logically the antecedent or the consequent. Whereas the antecedent should be prior to the consequent in the conditional, “If (cause), then (effect),” the consequent should be prior to the antecedent in the conditional, “If (evidence: absence of effect), then (conclusion: absence of cause).”

If the temporal order of a causal relation expressed in a conditional sentence violates the above restriction, the sentence will sound anomalous. This may occur in the contrapositive transformation of conditionals in which the antecedent and consequent are not temporally ordered by tense. In such cases, the *if-then* frame imposes a forward temporal direction on them

(Evans & Beck, 1981; Evans & Newstead, 1977). Thus, the meaningful temporal order in Sentence (8), "If one takes proper care of a plant, then it grows," becomes anomalously reversed upon transformation into Sentence (8a), "If the plant does not grow, then one does not take proper care of it." Sentence (8a) suggests that the plant's lack of growth (the supposed effect) precedes one's failure to take proper care of it (the supposed cause). A similar anomalous reversal occurs in Sentence (7a). Notice that the anomalousness of Sentence (7a) disappears when the priority of the absence of the cause (the consequent) is specified by tense: "If not everyone will die, then the bomb is not exploding."

The remaining examples do not violate the above restriction. In the case of Sentence (9), "If there is smoke, then there is fire," both tense and world knowledge indicate that the evidence and conclusion are continuous and contemporaneous states. Since the events are contemporaneous, the contrapositive transformation causes no change in the temporal order, therefore yielding a meaningful Sentence in (9a). Sentence (10a), "If one is not immune to cholera, then one has not been inoculated against it," also does not violate the temporal restriction mentioned above, despite the events being temporally ordered by world knowledge. In this case explicit tense markers indicate that the conclusion temporally precedes the evidence, rendering the sentence meaningful.

The above examples illustrate how pragmatic knowledge of causation can account for the differing effects of the contrapositive transformation. It is not the case that p must occur prior to q for statements in the form *if p then q* in order to be acceptable. Rather, when the conditional expresses a temporally ordered causal relation, p must occur prior to q if p expresses the cause (or its absence), and the reverse if p expresses the effect (or its absence). This restriction does not apply when the events are contemporaneous. And as noted earlier, different temporal restrictions apply if an *if-then* statement is interpreted in terms of a noncausal schema such as permission or obligation (also see Cheng et al., 1985).

Conclusion

In this chapter, we have applied the concept of pragmatic reasoning schemas to explain three different types of phenomena: the complex patterns of performance observed in Wason's selection task, patterns of rephrasing between state-

ments in *if-then* and *only-if* forms (including introduction of modals), and linguistic anomalies involving the contrapositive transformation of certain causal statements. Our theoretical approach has other potential directions for development. In other work (Cheng et al., 1985), we have interpreted the effects of alternative methods of training on deductive reasoning in terms of the pragmatic-schema hypothesis.

Another direction that bears mention because of its perennial interest is the relationship between reasoning and language. Our approach to reasoning implies that the schematic structures that guide everyday reasoning are primarily the products of induction from recurring experience with classes of goal-related situations. Reasoning rules are fundamentally based on our pragmatic interpretations of situations, rather than on the syntactic interpretation of sentences. Our view thus diverges from the Whorfian hypothesis that thought is shaped by the language one speaks, particularly, it has been argued (Bloom, 1981), for such abstract concepts as the conditional. The results of Experiment 1 (as well as of the experiment mentioned in Footnote 2) in fact provide suggestive evidence in favor of our position. The Hong Kong subjects received conditional rules in Chinese, a language which (unlike English) has distinct colloquial connectives corresponding to the concepts *if* and *if and only if* (*ruguo jui* and *ruguo cai*, respectively). A Whorfian might suppose that these expressions would allow Chinese speakers to distinguish more readily between these two confusable senses of *if-then*, and therefore perform more accurately on selection problems. However, no such advantage was detected in our experiments. Although these null results are far from conclusive, there is certainly no convincing evidence that cross-linguistic syntactic differences in expression of conditionals have any impact on reasoning performance (Au, 1983; Cheng, 1985). Our framework implies that if reasoning performance is found to vary across populations, the explanation will lie not in linguistic differences, but rather in cultural differences regarding pragmatically important goals and situations.

Notes

- 1 In a further experiment we compared selection-task performance for an arbitrary rule (the card problem) with or without *must* in the consequent. Performance did not differ across the alternative versions.

- 2 In an earlier experiment, essentially the same pattern of results for rephrasing from *if-then* into *only-if* forms was obtained with subjects at the Chinese University of Hong Kong.
- 3 The anomalousness of (7a) and (8a) can be avoided by changes of tense. For example (7a) can be changed into "If not everyone dies, then the bomb did not explode." Such adjustments, however, still cannot circumvent the issue of *differences* in acceptability, which can simply be rephrased as: Why do some contrapositive transformations require tense adjustment whereas others do not?

Chapter 41: Beyond Intuition and Instinct Blindness: Toward an Evolutionarily Rigorous Cognitive Science

LEDA COSMIDES AND JOHN TOOBY

Nothing in biology makes sense except in the light of evolution.

Theodosius Dobzhansky

Is it not reasonable to anticipate that our understanding of the human mind would be aided greatly by knowing the purpose for which it was designed?

George C. Williams

The cognitive sciences have reached a pivotal point in their development. We now have the opportunity to take our place in the far larger and more exacting scientific landscape that includes the rest of the modern biological sciences. Every day, research of immediate and direct relevance to our own is being generated in evolutionary biology, behavioral ecology, developmental biology, genetics, paleontology, population biology, and neuroscience. In turn, many of these fields are finding it necessary to use concepts and research from the cognitive sciences.

But to benefit from knowledge generated in these collateral fields, we will have to learn how to use biological facts and principles in theory formation and experimental design. This means shedding certain concepts and prejudices inherited from parochial parent traditions: the obsessive search for a cognitive architecture that is general purpose and initially content-free; the excessive reliance on results derived from artificial “intellectual” tasks; the idea that the field’s scope is limited to the study of “higher” mental processes; and a long list of

false dichotomies reflecting premodern biological thought – evolved/learned, evolved/developed, innate/learned, genetic/environmental, biological/social, biological/cultural, emotion/cognition, animal/human. Most importantly, cognitive scientists will have to abandon the functional agnosticism that is endemic to the field (Tooby & Cosmides, 1992).

The biological and cognitive sciences dovetail elegantly because in evolved systems – such as the human brain – there is a causal relationship between the adaptive problems a species encountered during its evolution and the design of its phenotypic structures. Indeed, a theoretical synthesis between the two fields seems inevitable, because evolutionary biologists investigate and inventory the set of adaptive information-processing problems the brain evolved to solve, and cognitive scientists investigate the design of the circuits or mechanisms that evolved to solve them. In fact, the cognitive subfields that already recognize and exploit this relationship between function and structure, such as visual perception, have made the most rapid empirical progress. These areas succeed because they are guided by (1) theories of adaptive function, (2) detailed analyses of the tasks each mechanism was designed by evolution to solve, and (3) the recognition that these tasks are usually solved by cognitive machinery that is highly functionally specialized. We believe the study of central processes can be revitalized by applying the same adaptationist program. But for this to happen, cognitive scientists

will have to replace the intuitive, folk psychological notions that now dominate the field with evolutionarily rigorous theories of function.

It is exactly this reluctance to consider function that is the central impediment to the emergence of a biologically sophisticated cognitive science. Surprisingly, a few cognitive scientists have tried to ground their dismissal of functional reasoning in biology itself. The claim that natural selection is too constrained by other factors to organize organisms very functionally has indeed been made by a small number of biologists (e.g., Gould & Lewontin, 1979). However, this argument has been empirically falsified so regularly and comprehensively that it is now taken seriously only by research communities too far outside of evolutionary biology to be acquainted with its primary literature (Clutton-Brock & Harvey, 1979; Daly & Wilson, 1983; Dawkins, 1982, 1986; Krebs & Davies, 1987; Williams, 1966; Williams & Nesse, 1991).¹ Other cognitive scientists take a less ideological, more agnostic stance; most never think about function at all.

As a result, cognitive psychology has been conducted as if Darwin never lived. Most cognitive scientists proceed without any clear notion of what "function" means for biological structures like the brain, or what the explicit analysis of function could teach them. Indeed, many cognitive scientists think that theories of adaptive function are an explanatory luxury – fanciful, unfalsifiable speculations that one indulges in at the end of a project, after the hard work of experimentation has been done.

But theories of adaptive function are not a luxury. They are an indispensable methodological tool, crucial to the future development of cognitive psychology. Atheoretical approaches will not suffice – a random stroll through hypothesis space will not allow you to distinguish figure from ground in a complex system. To isolate a functionally organized mechanism within a complex system, you need a theory of what function that mechanism was designed to perform.

This article is intended as an overview of the role we believe theories of adaptive function should play in cognitive psychology. We will briefly explain why they are important, where exactly they fit into a research program, how they bear on cognitive and neural theories, and what orthodoxies they call into question. (For a more complete and detailed argument, see Tooby & Cosmides, 1992.)

I. Function Determines Structure

Explanation and Discovery in the Cognitive Sciences

... trying to understand perception by studying only neurons is like trying to understand bird flight by studying only feathers: it just cannot be done. In order to understand bird flight, we have to understand aerodynamics; only then do the structure of feathers and the different shapes of birds' wings make sense. (Marr, 1982, p. 27)

David Marr developed a general explanatory system for the cognitive sciences that is much cited but rarely applied. His three-level system applies to any device that processes information – a calculator, a cash register, a television, a computer, a brain. It is based on the following observations:

- (1) Information-processing devices are designed to solve problems.
- (2) They solve problems by virtue of their structure.
- (3) Hence to explain the structure of a device, you need to know
 - (a) *what* problem it was designed to solve, and
 - (b) *why* it was designed to solve that problem and not some other one.

In other words, you need to develop a task analysis of the problem, or what Marr called a *computational theory* (Marr, 1982). Knowing the physical structure of a cognitive device and the information-processing program realized by that structure is not enough. For human-made artifacts and biological systems, form follows function. The physical structure is there because it embodies a set of programs; the programs are there because they solve a particular problem. A computational theory specifies what that problem is and why there is a device to solve it. It specifies the *function* of an information-processing device. Marr felt that the computational theory is the most important and the most neglected level of explanation in the cognitive sciences.

This functional level of explanation has not been neglected in the biological sciences, however, because it is essential for understanding how natural selection designs organisms. An

Table 1: Three Levels at Which Any Machine Carrying Out an Information-Processing Task Must Be Understood (from Marr, 1982, p. 25)

-
1. Computational theory
What is the goal of the computation, why is it appropriate, and what is the logic of the strategy by which it can be carried out?
 2. Representation and algorithm
How can this computational theory be implemented? In particular, what is the representation for the input and output, and what is the algorithm for the transformation?
 3. Hardware implementation
How can the representation and algorithm be realized physically?

In evolutionary biology:

Explanations at the level of the computational theory are called *ultimate* level explanations.

Explanations at the level of representations and algorithm, or at the level of hardware implementation, are called *proximate* levels of explanation.

organism's phenotypic structure can be thought of as a collection of "design features" – micro-machines, such as the functional components of the eye or liver. Over evolutionary time, new design features are added or discarded from the species' design because of their consequences. A design feature will cause its own spread over generations if it has the consequence of solving adaptive problems: cross-generationally recurrent problems whose solution promotes reproduction, such as detecting predators or detoxifying poisons. Natural selection is a feedback process that "chooses" among alternative designs on the basis of how well they function. By selecting designs on the basis of how well they solve adaptive problems, this process engineers a tight fit between the function of a device and its structure.² To understand this causal relationship, biologists had to develop a theoretical vocabulary that distinguishes between structure and function. Marr's computational theory is a functional level of explanation that corresponds roughly to what biologists refer to as the "ultimate" or "functional" explanation of a phenotypic structure.

A computational theory defines what problem the device solves and why it solves it; theories about programs and their physical substrate specify *how* the device solves the problem. "How" questions – questions about programs and hardware – currently dominate the research agenda in the cognitive sciences. Answering such questions is extremely difficult, and most cognitive scientists realize that groping in the dark is not a productive research strategy. Many see the need for a reliable source of theoretical guidance. The question is, what form should it take?

Why Ask Why? – or – How to Ask How

It is currently fashionable to think that the findings of neuroscience will eventually place strong constraints on theory formation at the cognitive level. Undoubtedly they will. But extreme partisans of this position believe neural constraints will be *sufficient* for developing cognitive theories. In this view, once we know enough about the properties of neurons, neurotransmitters and cellular development, figuring out what cognitive programs the human mind contains will become a trivial task.

This cannot be true. Consider the fact that there are birds that migrate by the stars, bats that echolocate, bees that compute the variance of flower patches, spiders that spin webs, humans that speak, ants that farm, lions that hunt in teams, cheetahs that hunt alone, monogamous gibbons, polyandrous seahorses, polygynous gorillas... There are millions of animal species on earth, each with a different set of cognitive programs. *The same basic neural tissue embodies all of these programs*, and it could support many others as well. Facts about the properties of neurons, neurotransmitters, and cellular development cannot tell you which of these millions of programs the human mind contains.

Even if all neural activity is the expression of a uniform process at the cellular level, it is the arrangement of neurons – into birdsong templates or web-spinning programs – that matters. The idea that low-level neuroscience will generate a self-sufficient cognitive theory is a physicalist expression of the ethologically naive associationist/empiricist doctrine that all animal brains are essentially the same.

Table 2: Why Cash Registers Add (Adapted from Marr, 1982, pp. 22–23)

<i>Rules Defining Addition</i>	<i>Rules Governing Social Exchange in a Supermarket</i>
1. There is a unique element, “zero”; Adding zero has no effect: $2 + 0 = 2$	1. If you buy nothing, it should cost you nothing; and buying nothing and something should cost the same as buying just the something. (The rules for zero.)
2. Commutativity: $(2 + 3) = (3 + 2) = 5$	2. The order in which goods are presented to the cashier should not affect the total. (Commutativity.)
3. Associativity: $(2 + 3) + 4 = 2 + (3 + 4)$	3. Arranging the goods into two piles and paying for each pile separately should not affect the total amount you pay. (Associativity; the basic operation for combining prices.)
4. Each number has a unique inverse that when added to the number gives zero: $2 + (-2) = 0$	4. If you buy an item and then return it for a refund, your total expenditure should be zero. (Inverses.)

In fact, as David Marr put it, a program’s structure “depends more upon the computational problems that have to be solved than upon the particular hardware in which their solutions are implemented” (1982, p. 27). In other words, knowing *what* and *why* places strong constraints on theories of *how*.

For this reason, a computational theory of function is not an explanatory luxury. It is an essential tool for discovery in the cognitive and neural sciences. A theory of function may not determine a program’s structure uniquely, but it reduces the number of possibilities to an empirically manageable number. Task demands radically constrain the range of possible solutions; consequently, very few cognitive programs are capable of solving any given adaptive problem. By developing a careful task analysis of an information-processing problem, you can vastly simplify the empirical search for the cognitive program that solves it. And once that program has been identified, it becomes straightforward to develop clinical tests that will target its neural basis.

To figure out how the mind works, cognitive scientists will need to know what problems our cognitive and neural mechanisms were designed to solve.

Beyond Intuition: How to Build a Computational Theory

To illustrate the notion of a computational theory, Marr asks us to consider the what and why of a cash register at a check-out counter in a grocery store. We know the what of a cash register: it adds numbers. Addition is an operation that maps pairs of numbers onto single numbers, and

it has certain abstract properties, such as commutativity and associativity (see Table 2). How the addition is accomplished is quite irrelevant: any set of representations and algorithms that satisfy these abstract constraints will do. The input to the cash register is prices, which are represented by numbers. To compute a final bill, the cash register adds these numbers together. That’s the what.

But *why* was the cash register designed to add the prices of each item? Why not multiply them together, or subtract the price of each item from 100? According to Marr, “the reason is that the rules we *intuitively feel to be appropriate* for combining the individual prices in fact define the mathematical operation of addition” (p. 22, emphasis added). He formulates these intuitive rules as a series of constraints on how prices should be combined when people exchange money for goods, then shows that these constraints map directly onto those that define addition (see Table 2). On this view, cash registers were designed to add because addition is the mathematical operation that realizes the constraints on buying and selling that our intuitions deem appropriate. Other mathematical operations are inappropriate because they violate these intuitions; for example, if the cash register subtracted each price from 100, the more goods you chose the less you would pay – and whenever you chose more than \$100 of goods, the store would pay *you*.

In this particular example, the buck stopped at intuition. But it shouldn’t. Our intuitions are produced by the human brain, an information-processing device that was designed by the evolutionary process. To discover the structure of the brain, you need to know *what* problems it

was designed to solve and *why* it was designed to solve those problems rather than some other ones. In other words, you need to ask the same questions of the brain as you would of the cash register.

Cognitive science is the study of the design of minds, regardless of their origin. Cognitive psychology is the study of the design of minds that were produced by the evolutionary process. Evolution produced the what, and evolutionary biology is the study of why.

Most cognitive scientists know this. What they don't yet know is that understanding the evolutionary process can bring the architecture of the mind into sharper relief. For biological systems, the nature of the designer carries implications for the nature of the design.

The brain can process information because it contains complex neural circuits that are functionally organized. The only component of the evolutionary process that can build complex structures that are functionally organized is natural selection. And the only kind of problems that natural selection can build complexly organized structures for solving are adaptive problems, where "adaptive" has a very precise, narrow technical meaning (Dawkins, 1986; Pinker & Bloom, 1990; Tooby & Cosmides, 1990a, 1992; Williams, 1966). Bearing this in mind, let's consider the *source* of Marr's intuitions about the cash register.

Buying food at a grocery store is a form of social exchange – cooperation between two or more individuals for mutual benefit. The adaptive problems that arise when individuals engage in this form of cooperation have constituted a long-enduring selection pressure on the hominid line. Paleoanthropological evidence indicates that social exchange extends back at least 2 million years in the human line, and the fact that social exchange exists in some of our primate cousins suggests that it may be even more ancient than that. It is exactly the kind of problem that selection can build cognitive mechanisms for solving.

Social exchange is not a recent cultural invention, like writing, yam cultivation, or computer programming; if it were, one would expect to find evidence of its having one or several points of origin, of its having spread by contact, and of its being extremely elaborated in some cultures and absent in others. But its distribution does not fit this pattern. Social exchange is both universal and highly elaborated across human cultures, presenting itself in many forms: reciprocal gift-

giving, food-sharing, marketing-pricing, and so on (Cosmides & Tooby, 1992; Fiske, 1991). It is an ancient, pervasive and central part of human social life.

In evolutionary biology, researchers such as George Williams, Robert Trivers, W. D. Hamilton, and Robert Axelrod have explored constraints on the evolution of social exchange using game theory, modeling it as a repeated Prisoner's Dilemma. These analyses have turned up a number of important features of this adaptive problem, a crucial one being that social exchange cannot evolve in a species unless individuals have some means of detecting individuals who cheat and excluding them from future interactions (e.g., Axelrod, 1984; Axelrod & Hamilton, 1981; Boyd, 1988; Trivers, 1971). One can think of this as an *evolvability constraint*. Selection cannot construct mechanisms in any species – including humans – that systematically violate such constraints. Behavior is generated by computational mechanisms. If a species engages in social exchange behavior, then it does so by virtue of computational mechanisms that satisfy the evolvability constraints that characterize this adaptive problem.

Behavioral ecologists have used these constraints on the evolution of social exchange to build computational theories of this adaptive problem – theories of what and why. These theories have provided a principled basis for generating hypotheses about the phenotypic design of mechanisms that generate social exchange in a variety of species. They spotlight design features that any cognitive program capable of solving this adaptive problem must have. By cataloging these design features, animal behavior researchers were able to look for – and discover – previously unknown aspects of the psychology of social exchange in species from chimpanzees, baboons and vervets to vampire bats and hermaphroditic coral-reef fish (e.g., Cheney & Seyfarth, 1990; de Waal & Luttrell, 1988; Fischer, 1988; Smuts, 1986; Wilkinson, 1988, 1990).

This research strategy has been successful for a very simple reason: *very few cognitive programs satisfy the evolvability constraints for social exchange*. If a species engages in this behavior (and not all do), then its cognitive architecture must contain one of these programs.

In our own species, social exchange is a universal, species-typical trait with a long evolutionary history. We have strong and cross-culturally reliable intuitions about how this form

of cooperation should be conducted, which arise in the absence of any explicit instruction (Cosmides & Tooby, 1992; Fiske, 1991). In developing his computational theory of the cash register – a tool used in social exchange – David Marr was consulting these deep human intuitions.³

From these facts, we can deduce that the human cognitive architecture contains programs that satisfy the evolvability constraints for social exchange. As cognitive scientists, we should be able to specify *what* rules govern human behavior in this domain, and *why* we humans reliably develop circuits that embody these rules rather than others. In other words, we should be able to develop a computational theory of the organic information-processing device that governs social exchange in humans.

Since Marr, cognitive scientists have become familiar with the notion of developing computational theories to study perception and language, but the notion that one can develop computational theories to study the information-processing devices that give rise to social behavior is still quite alien. Yet some of the most important adaptive problems our ancestors had to solve involved navigating the social world, and some of the best work in evolutionary biology is devoted to analyzing constraints on the evolution of mechanisms that solve these problems. In fact, these evolutionary analyses may be the *only* source of constraints available for developing computational theories of social cognition.

Principles of Organic Design

The field of evolutionary biology summarizes our knowledge of the engineering principles that govern the design of organisms. As a source of theoretical guidance about organic design, functionalism has an unparalleled historical track record. As Ernst Mayr notes, “The adaptationist question, ‘What is the function of a given structure or organ?’ has been for centuries the basis for every advance in physiology” (1983, p. 328).

Attention to function can advance the cognitive sciences as well. Aside from those properties acquired by chance or imposed by engineering constraint, the mind consists of a set of information-processing circuits that were designed by natural selection to solve adaptive problems that our hunter-gatherer ancestors faced generation after generation.⁴ If we know what these problems were, we can seek mechanisms that are well engineered for solving them.

The exploration and definition of these adaptive problems is a major activity of evolu-

tionary biologists. By combining results derived from mathematical modeling, comparative studies, behavioral ecology, paleoanthropology and other fields, evolutionary biologists try to identify what problems the mind was designed to solve and why it was designed to solve those problems rather than some other ones. In other words, evolutionary biologists explore exactly those questions that Marr argued were essential for developing computational theories of adaptive information-processing problems.

Computational theories address *what* and *why*, but because there are multiple ways of achieving any solution, experiments are needed to establish *how*. But the more precisely you can define the goal of processing – the more tightly you can constrain what would count as a solution – the more clearly you can see what a mechanism capable of producing that solution would have to look like. The more constraints you can discover, the more the field of possible solutions is narrowed, and the more you can concentrate your experimental efforts on discriminating between viable hypotheses.

A technological analogy may make this clearer. It is difficult to figure out the design of the object I’m now thinking about if all you know is that it is a machine (toaster? airplane? supercollider?). But the answer becomes progressively clearer as I add functional constraints: (1) it is well designed for entertainment (movie projector, TV, CD player?); it was not designed to project images (nothing with a screen); it is well designed for playing taped music (stereo or Walkman); it was designed to be easily portable during exercise (Walkman).

Knowing the object is well engineered for solving these problems provides powerful clues about its functional design features that can guide research. Never having seen one, you would know that it must contain a device that converts magnetic patterns into sound waves; a place to insert the tape; an outer shell no smaller than a tape, but no larger than necessary to perform the transduction; and so on.

Guessing at random would have taken forever. Information about features that have no impact on the machine’s function would not have helped much either (e.g., its color, the number of scratches). Because functionally neutral features are free to vary, information about them does little to narrow your search.

Functional information helps because it narrowly specifies the outcome to be produced. The smaller the class of entities capable of producing that outcome, the more useful functional

Table 3: Evolutionary Biology Provides Constraints from Which Computational Theories of Adaptive Information-Processing Problems Can Be Built

To build a computational theory, you need to answer two questions:

1. What is the adaptive problem?
2. What information would have been available in ancestral environments for solving it?

Some sources of constraints

1. More precise definition of Marr's "goal" of processing that is appropriate to evolved (as opposed to artificial) information-processing systems
2. Game-theoretic models of the dynamics of natural selection (e.g., kin selection, Prisoner's Dilemma and cooperation – particularly useful for analysis of cognitive mechanisms responsible for social behavior)
3. Evolvability constraints: can a design with properties X, Y, and Z evolve, or would it have been selected out by alternative designs with different properties? (i.e., does the design represent an evolutionary stable strategy? – related to point 2)
4. Hunter-gatherer studies and paleoanthropology – source of information about the environmental background against which our cognitive architecture evolved. (Information that is present now may not have been present then, and vice versa.)
5. Studies of the algorithms and representations whereby other animals solve the same adaptive problem. (These will sometimes be the same, sometimes different.)

information is. This means (1) narrow definitions of outcomes are more useful than broad ones (tape player versus entertainment device), and (2) functional information is most useful when there are only a few ways of producing an outcome (Walkman versus paperweight; seeing versus scratching).

Narrow definitions of function are a powerful methodological tool for discovering the design features of any complex problem-solving device, including the human mind. Yet the definition of function that guides most research on the mind (it "processes information") is so broad that it applies even to a Walkman.

It is possible to create detailed theories of adaptive function. This is because natural selection is only capable of producing certain kinds of designs: designs that promoted their own reproduction in past environments. This rule of organic design sounds too general to be of any help. But when it is applied to real species in actual environments, this deceptively simple constraint radically limits what counts as an adaptive problem and, therefore, narrows the field of possible solutions. Table 3 lists some principles of organic design that cognitive psychologists could be using, but aren't.

Doing experiments is like playing "20 questions" with nature, and evolutionary biology gives you an advantage in this game: it tells you what questions are most worth asking, and what the answer will probably look like. It provides constraints – functional and otherwise – from which computational theories of adaptive information-processing problems can be built.

Taking Function Seriously

We know the cognitive science that intuition has wrought. It is more difficult, however, to know how our intuitions might have blinded us. What cognitive systems, if any, are we *not* seeing? How would evolutionary functionalism transform the science of mind?

Textbooks in psychology are organized according to a folk psychological categorization of mechanisms: "attention", "memory", "reasoning", "learning". In contrast, textbooks in evolutionary biology and behavioral ecology are organized according to adaptive problems: foraging (hunting and gathering), kinship, predator defense, resource competition, cooperation, aggression, parental care, dominance and status, inbreeding avoidance, courtship, mateship maintenance, trade-offs between mating effort and parenting effort, mating system, sexual conflict, paternity uncertainty and sexual jealousy, signaling and communication, navigation, habitat selection, and so on.

Textbooks in evolutionary biology are organized according to adaptive problems because these are the only problems that selection can build mechanisms for solving. Textbooks in behavioral ecology are organized according to adaptive problems because circuits that are functionally specialized for solving these problems have been found in species after species. No less should prove true of humans. Twenty-first-century textbooks on human cognition will probably be organized similarly.

Fortunately, behavioral ecologists and evolutionary biologists have already created a library

of sophisticated models of the selection pressures, strategies and trade-offs that characterize these very fundamental adaptive problems, which they use in studying processes of attention, memory, reasoning and learning in non-humans. Which model is applicable for a given species depends on certain key life-history parameters. Findings from paleoanthropology, hunter-gatherer archaeology, and studies of living hunter-gatherer populations locate humans in this theoretical landscape by filling in the critical parameter values. Ancestral hominids were ground-living primates; omnivores, exposed to a wide variety of plant toxins and having a sexual division of labor between hunting and gathering; mammals with altricial young, long periods of biparental investment in offspring, enduring male–female mateships, and an extended period of physiologically obligatory female investment in pregnancy and lactation. They were a long-lived, low-fecundity species in which variance in male reproductive success was higher than variance in female reproductive success. They lived in small nomadic kin-based bands of perhaps 20–100; they would rarely (if ever) have seen more than 1000 people at one time; they had little opportunity to store provisions for the future; they engaged in cooperative hunting, defense and aggressive coalitions; they made tools and engaged in extensive amounts of cooperative reciprocation; they were vulnerable to a large variety of parasites and pathogens. When these parameters are combined with formal models from evolutionary biology and behavioral ecology, a reasonably consistent picture of ancestral life begins to appear (e.g., Tooby & DeVore, 1987).

In this picture, the adaptive problems posed by social life loom large. Most of these are characterized by strict evolvability constraints, which could only be satisfied by cognitive programs that are *specialized* for reasoning about the social world. This suggests that our evolved mental architecture contains a large and intricate “faculty” of social cognition (Brothers, 1990; Cosmides & Tooby, 1992; Fiske, 1991; Jackendoff, 1992). Yet despite its importance, very little work in the cognitive sciences has been devoted to looking for cognitive mechanisms that are specialized for reasoning about the social world. Nor have cognitive neuroscientists been looking for dissociations among different forms of social reasoning, or between social reasoning and other cognitive functions. The work on autism as a neurological impairment of a “theory of mind” module is a very notable – and very successful –

exception (e.g., Baron-Cohen, Leslie, & Frith, 1985; Frith, 1989; Leslie, 1987).

There are many reasons for the neglect of these topics in the study of humans (see Tooby & Cosmides, 1992), but a primary one is that cognitive scientists have been relying on their intuitions for hypotheses rather than asking themselves what kind of problems the mind was designed by evolution to solve. By using evolutionary biology to remind ourselves of the types of problems hominids faced across hundreds of thousands of generations, we can escape the narrow conceptual cage imposed on us by our intuitions and folk psychology. This is not a minor point: if you don’t think a thing exists, you won’t take the steps necessary to find it. By having the preliminary map that an evolutionary perspective provides, we can find our way out into the vast, barely explored areas of the human cognitive architecture.

II. Computational Theories Derived from Evolutionary Biology Suggest that the Mind is Riddled with Functionally Specialized Circuits

During most of this century, research in psychology and the other biobehavioral and social sciences has been dominated by the assumptions of what we have elsewhere called the Standard Social Science Model (SSSM) (Tooby & Cosmides, 1992). This model’s fundamental premise is that the evolved architecture of the human mind is comprised mainly of cognitive processes that are content-free, few in number and general purpose. These general-purpose mechanisms fly under names such as “learning”, “induction”, “imitation”, “reasoning” and “the capacity for culture”, and are thought to explain nearly every human phenomenon. Their structure is rarely specified by more than a wave of the hand.

In this view, the same mechanisms are thought to govern how one acquires a language and a gender identity, an aversion to incest and an appreciation for vistas, a desire for friends and a fear of spiders – indeed, nearly every thought and feeling of which humans are capable. By definition, these empiricist mechanisms have no inherent content built into their procedures, they are not designed to construct certain mental contents more readily than others, and they have no features specialized for processing particular kinds of content over others. In other words, they are assumed to operate uniformly, no matter what content, subject matter or domain of

life experience they are operating on. (For this reason, such procedures are described as *content-independent*, *domain-general* or *content-free*). The premise that these mechanisms have no content to impart is what leads to the doctrine central to the modern behavioral and social sciences: that all of our particular mental content originated in the social and physical world and entered through perception. As Aquinas put this empiricist tenet a millennium ago, "There is nothing in the intellect that was not first in the senses."

As we will discuss, this view of central processes is difficult to reconcile with modern evolutionary biology.

The Weakness of Content-Independent Architectures

To some it may seem as if an evolutionary perspective supports the case that our cognitive architecture consists primarily of powerful, general-purpose problem-solvers – inference engines that embody the content-free normative theories of mathematics and logic. After all, wouldn't an organism be better equipped and better adapted if it could solve a more general class of problems over a narrower class?

This empiricist view is difficult to reconcile with evolutionary principles for a simple reason: content-free, general-purpose problem-solving mechanisms are extraordinarily weak – or even inert – compared to specialized ones. Every computational system – living or artificial – must somehow solve the frame problem (e.g., Pylyshyn, 1987). Most artificial intelligence programs have domain-specific knowledge and procedures that do this (even those that are called "general purpose"). A program equipped solely with domain-general procedures can do nothing unless the human programmer solves the frame problem for it: either by artificially constraining the problem space or by supplying the program – by fiat – with pre-existing knowledge bases ("innate" knowledge) that it could not have acquired on its own, with or without connections to a perceptual system.

However, to be a viable hypothesis about our cognitive architecture, a proposed design must pass a solvability test. It must, in principle, be able to solve problems humans are known to be able to solve. At a minimum, any proposed cognitive architecture had to produce sufficiently self-reproductive behavior in ancestral environments – we know this because all living species have been able to reproduce themselves in an unbroken chain up to the present. While arti-

ficial intelligence programs struggle to recognize and manipulate coke cans, naturally intelligent programs situated in organisms successfully negotiate through lifetimes full of biotic antagonists – predators, conspecific competitors, self-defending food items, parasites, even siblings. At the same time, these naturally intelligent programs solve a large series of intricate problems in the project of assembling a sufficient number of replacement individuals: offspring. Just as a hypothesized set of cognitive mechanisms underlying language must be able to account for the facts of human linguistic behavior, so too must any hypothetical domain-general cognitive architecture reliably generate solutions to all of the problems that were necessary for survival and reproduction in the Pleistocene. For humans and most other species, this is a remarkably diverse, highly structured and very complex set of problems.

If it can be shown that there are essential adaptive problems that humans must have been able to solve in order to have propagated and that domain-general mechanisms cannot solve them, then the domain-general hypothesis fails. We think there is a very large number of such problems, including inclusive fitness regulation, mate choice, nutritional regulation, foraging, navigation, incest avoidance, sexual jealousy, predator avoidance, social exchange – at a minimum, any kind of information-processing problem that involves motivation, and many others as well. We have developed this argument in detail elsewhere (Cosmides & Tooby, 1987, 1994; Tooby & Cosmides, 1990a, 1992), so we won't belabor it here. Instead, we will simply summarize a few of the relevant points.

(1) *The "Stoppit" problem.* There is a Gary Larson cartoon about an "all-purpose" product called "Stoppit". When sprayed from an aerosol can, Stoppit stops faucet drips, taxis, cigarette smoking, crying babies and charging elephants. An "all-purpose" cognitive program is no more feasible for an analogous reason: *what counts as adaptive behavior differs markedly from domain to domain.* An architecture equipped only with content-independent mechanisms must succeed at survival and reproduction by applying the same procedures to every adaptive problem. But there is no domain-general criterion of success or failure that correlates with fitness (e.g., what counts as a "good" mate has little in common with a "good" lunch or a "good" brother). Because what counts as the wrong thing to do differs from one class of problems to the next, there must be as many domain-specific

subsystems as there are domains in which the definitions of successful behavioral outcomes are incommensurate.

(2) *Combinatorial explosion*. Combinatorial explosion paralyzes even moderately domain-general systems when encountering real-world complexity. As generality is increased by adding new dimensions to a problem space or new branch points to a decision tree the computational load increases with catastrophic rapidity. A content-independent, specialization-free architecture contains no rules of relevance, procedural knowledge or privileged hypotheses, and so could not solve any biological problem of routine complexity in the amount of time an organism has to solve it (for discussion see, for example, Carey, 1985; Gallistel, Brown, Carey, Gelman, & Keil, 1991; Keil, 1989; Markman, 1989; Tooby & Cosmides, 1992). The question is not "How much specialization does a general purpose system require?" but rather "How many degrees of freedom can a system *tolerate* – even a specialized, highly targeted one – and still compute decisions in useful, real-world time?" Combinatorics guarantee that real systems can only tolerate a small number. (Hence this problem cannot be solved by placing a few "constraints" on a general system.)

(3) *Clueless environments*. Content-free architectures are limited to knowing what can be validly derived by general processes from perceptual information. This sharply limits the range of problems they can solve: when the environment is clueless, the mechanism will be too. Domain-specific mechanisms are not limited in this way. They can be constructed to embody clues that fill in the blanks when perceptual evidence is lacking or difficult to obtain.

Consider the following adaptive problem. All plants foods contain an array of toxins. Ones that your liver metabolizes with ease sometimes harm a developing embryo. This subtle statistical relationship between the environment, eating behavior and fitness is ontogenetically "invisible": it cannot be observed or induced via general-purpose processes on the basis of perceptual evidence.⁵ It can, however, be "observed" phylogenetically, by natural selection, because selection does not work by inference or simulation. Natural selection "counts up" the actual results of alternative designs operating in the real world, over millions of individuals, over thousands of generations, and weights these alternatives by the statistical distribution of their consequences: those design features that statistically lead to the best available outcome

are retained. In this sense it is omniscient – it is not limited to what could be validly deduced by one individual, based on a short period of experience, it is not limited to what is locally perceivable, and it is not confused by spurious local correlations. As a result, it can build circuits – like those that regulate food choice during pregnancy – which embody privileged hypotheses that reflect and exploit these virtually unobservable relationships in the world. For example, the embryo/toxin problem is solved by a set of functionally specialized mechanisms that adjust the threshold on the mother's normal food aversion system (Profet, 1992). They lower it when the embryo is most at risk – thereby causing the food aversions, nausea and vomiting of early pregnancy – and raise it when caloric intake becomes a priority. As a result, the mother avoids ordinarily palatable foods when they would threaten the embryo: she responds adaptively to an ontogenetically invisible relationship. Functionally specialized designs allow organisms to solve a broad range of otherwise unsolvable adaptive problems. (For discussion of this design principle, see Cosmides & Tooby, 1987, 1994; Shepard, 1981, 1987; Tooby & Cosmides, 1990a.)

In sum, architectures that do not come factory-equipped with sufficiently rich sets of content-specific machinery fail the solvability test. They could not have evolved, survived or propagated because they are incapable of solving even routine adaptive problems (Cosmides & Tooby, 1987, 1994; Tooby & Cosmides, 1992).

Natural Selection, Efficiency and Functional Specialization

Some researchers accept the conclusion that the human mind cannot consist solely of content-independent machinery, but nevertheless continue to believe that the mind needs very little content-specific organization to function. They believe that the preponderance of mental processes are content-independent and general purpose. Moreover, they believe that the correct null hypothesis – the parsimonious, prudent scientific stance – is to posit as few functionally specialized mechanisms as possible.

This stance ignores what is now known about the nature of the evolutionary process and the types of functional organization that it produces. Natural selection is a relentlessly hill-climbing process which tends to replace relatively less efficient designs with ones that perform better. Hence, in deciding which of two

alternative designs is more likely to have evolved, their comparative performance on ancestral adaptive problems is the appropriate standard to use. Given this standard, positing a preponderance of general-purpose machinery is neither prudent nor parsimonious.⁶ General-purpose mechanisms can't solve most adaptive problems at all, and in those few cases where one could, a specialized mechanism is likely to solve it more efficiently. The reason why is quite straightforward.

A general engineering principle is that the same machine is rarely capable of solving two different problems equally well. We have both cork-screws and cups because each solves a particular problem better than the other. It would be extremely difficult to open a bottle of wine with a cup or to drink from a cork-screw.

This same principle applies to the design of the human body. The heart is elegantly designed for pumping blood, but it is not good at detoxifying poisons; the liver is specialized for detoxifying poisons, but it cannot function as a pump. Pumping blood throughout the body and detoxifying poisons are two very different problems: consequently, the human body has a different machine for solving each of them. In biology, machines like these – ones that are specialized and functionally distinct – are called *adaptive specializations* (Rozin, 1976). Specialization of design is natural selection's signature and its most common result (Williams, 1966).⁷ In fact, the more important the adaptive problem, the more intensely natural selection tends to specialize and improve the performance of the mechanism for solving it.

There is no reason to believe that the human brain and mind are any exception. The cognitive programs that govern how you choose a mate should differ from those that govern how you choose your dinner. Different information-processing problems usually have different solutions. Implementing different solutions requires different, functionally distinct mechanisms (Sherry & Schacter, 1987). Speed, reliability and efficiency can be engineered into specialized mechanisms, because they do not need to engineer a compromise between mutually incompatible task demands: a jack of all trades – assuming one is possible at all – is necessarily a master of none. For this reason, one should expect the evolved architecture of the human mind to include many functionally distinct *cognitive* adaptive specializations.

And it does. For example, the learning mechanisms that govern language acquisition are dif-

ferent from those that govern the acquisition of food aversions, and both of these are different from the learning mechanisms that govern the acquisition of snake phobias (e.g., Cook, Hodes, & Lang, 1986; Cook & Mineka, 1989; Garcia, 1990; Mineka & Cook, 1988; Pinker, 1994; Ohman, Dimberg, & Ost, 1985; Ohman, Eriksson, & Olofsson, 1975). These adaptive specializations are *domain-specific*: the specialized design features that make them good at solving the problems that arise in one domain (avoiding venomous snakes) make them bad at solving the problems that arise in another (inducing a grammar). They are also *content-dependent*: they are activated by different kinds of content (speech versus screams), and their procedures are designed to accept different kinds of content as input (sentences versus snakes). A mind that applied relatively general-purpose reasoning circuits to all these problems, regardless of their content, would be a very clumsy problem-solver. But flexibility and efficiency of thought and action can be achieved by a mind that contains a battery of special-purpose circuits. The mind is probably more like a Swiss army knife than an all-purpose blade: competent in so many situations because it has a large number of components – bottle opener, cork-screw, knife, toothpick, scissors – each of which is well designed for solving a different problem.

The functional architecture of the mind was designed by natural selection; natural selection is a hill-climbing process which produces mechanisms that solve adaptive problems well; a specialized design is usually able to solve a problem better than a more generalized one. It is unlikely that a process with these properties would design central processes that are general purpose and content-free. Consequently, one's default assumption should be that the architecture of the human mind is saturated with adaptive specializations.

How to Find a Needle in a Haystack

The human brain is the most complex system scientists have ever tried to understand; identifying its components is enormously difficult. The more functionally integrated circuits it contains, the more difficult it will be to isolate and map any one of them. Looking for a functionally integrated mechanism within a multimodular mind is like looking for a needle in a haystack. The odds you'll find one are low unless you can radically narrow the search space. Marr's central insight was that you could do this by developing

computational theories of the problems these mechanisms were designed to solve – for the human brain, the adaptive problems our hunter-gatherer ancestors faced.

The only behavioral scientists who still derive their hypotheses from intuition and folk psychology, rather than an evolutionary based theory, are those who study humans.⁸ The empirical advantages of using evolutionary biology to develop computational theories of adaptive problems have already been amply demonstrated in the study of non-human minds (e.g., Gallistel, 1990; Gould, 1982; Krebs & Davies, 1987; Real, 1991). We wanted to demonstrate its utility in studying the human mind. We thought an effective way of doing this would be to use an evolutionarily derived computational theory to discover cognitive mechanisms whose existence no one had previously suspected. Because most cognitive scientists still think of central processes as content-independent, we thought it would be particularly interesting to demonstrate the existence of central processes that are functionally specialized and content-dependent: domain-specific reasoning mechanisms.

Toward this end, we have conducted an experimental research program over the last 10 years, exploring the hypothesis that the human mind contains specialized circuits designed for reasoning about adaptive problems posed by the social world of our ancestors: social exchange, threat, coalitional action, mate choice, and so on. We initially focused on social exchange because (1) the evolutionary theory is clear and well developed, (2) the relevant selection pressures are strong, (3) paleoanthropological evidence suggests that hominids have been engaging in it for millions of years – more than enough time for selection to shape specialized mechanisms – and (4) humans in all cultures engage in social exchange. By starting with an adaptive problem hunter-gatherers are known to have faced, we could proceed to design experiments to test for associated cognitive specializations.

The evolutionary analysis of social exchange parallels the economist's concept of trade. Sometimes known as "reciprocal altruism", social exchange is an "I'll scratch your back if you scratch mine" principle (for evolutionary analyses see, for example, Axelrod, 1984; Axelrod & Hamilton, 1981; Boyd, 1988; Trivers, 1971; Williams, 1966.). Using evolvability constraints that biologists had already identified (some involving the Prisoners' Dilemma), we devel-

oped a computational theory of the information-processing problems that arise in this domain (Cosmides, 1985; Cosmides & Tooby, 1989). This gave us a principled basis for generating detailed hypotheses about the design of the circuits that generate social exchange in humans. Some of the design features we predicted are listed in Table 4.

For example, mathematical analyses had established cheater detection as a crucial adaptive problem. Circuits that generate social exchange will be selected out unless they allow individuals to detect those who fail to reciprocate favors – cheaters. This evolvability constraint led us directly to the hypothesis that humans might have evolved inference procedures that are specialized for detecting cheaters. We tested this hypothesis using the Wason selection task, which had originally been developed as a test of logical reasoning (Wason, 1966; Wason & Johnson-Laird, 1972).

A large literature already existed showing that people are not very good at detecting logical violations of "if-then" rules in Wason selection tasks, even when these rules deal with familiar content drawn from everyday life (e.g., Manktelow & Evans, 1979; Wason, 1983). For example, suppose you are skeptical when an astrologer tells you, "If a person is a Leo, then that person is brave," and you want to prove him wrong. In looking for exceptions to this rule, you will probably investigate people who you know are Leos, to see whether they are brave. Many people also have the impulse to investigate people who are brave, to see if they are Leos. Yet investigating brave people would be a waste of time; the astrologer said that all Leos are brave – not that all brave people are Leos – so finding a brave Virgo would prove nothing. And, if you are like most people, you probably won't realize that you need to investigate cowards. Yet a coward who turns out to be a Leo would represent a violation of the rule.

If your mind had reasoning circuits specialized for detecting logical violations of rules, it would be immediately obvious to you that you should investigate Leos and cowards. But it is not intuitively obvious to most subjects. In general, fewer than 10% of subjects spontaneously realize this. Despite claims for the power of culture and "learning", even formal training in logical reasoning does little to boost performance (e.g., Cheng, Holyoak, Nisbett, & Oliver, 1986; Wason & Johnson-Laird, 1972).

However, we found that people who ordinarily cannot detect violations of "if-then" rules

Table 4: Reasoning About Social Exchange: Evidence of Special Design^a

<i>(a) The Following Design Features Were Predicted and Found</i>	<i>(b) The Following By-Product Hypotheses Were Empirically Eliminated</i>
1. The algorithms governing reasoning about social contracts operate even in unfamiliar situations.	1. Familiarity cannot explain the social contract effect.
2. The definition of cheating that they embody depends on one's perspective.	2. It is not the case that social contract content merely facilitates the application of the rules of inference of the propositional calculus.
3. They are just as good at computing the cost-benefit representation of a social contract from the perspective of one party as from the perspective of another.	3. Social contract content does not merely "afford" clear thinking.
4. They embody implicational procedures specified by the computational theory.	4. Permission schema theory cannot explain the social contract effect; in other words, application of a generalized deontic logic cannot explain the results.
5. They include inference procedures specialized for cheater detection.	5. It is not the case that any problem involving payoffs will elicit the detection of violations.
6. Their cheater detection procedures cannot detect violations of social contracts that do not correspond to cheating.	
7. They do not include altruist detection procedures.	
8. They cannot operate so as to detect cheaters unless the rule has been assigned the cost-benefit representation of a social contract.	

^a To show that an aspect of the phenotype is an adaptation to perform a particular function, one must show that it is particularly well designed for performing that function, and that it cannot be better explained as a by-product of some other adaptation or physical law.

can do so easily and accurately when that violation represents cheating in a situation of social exchange. This is a situation in which one is entitled to a benefit only if one has fulfilled a requirement (e.g., "If you are to eat these cookies, then you must first fix your bed" or "If you are to eat cassava root, then you must have a tattoo on your face"). In these situations, the adaptively correct answer is immediately obvious to almost all subjects, who commonly experience a "pop out" effect. No formal training is needed. Whenever the content of a problem asks subjects to look for cheaters on a social exchange – even when the situation described is culturally unfamiliar and even bizarre – subjects experience the problem as simple to solve, and their performance jumps dramatically. Seventy to 90% of subjects get it right, the highest performance ever found for a task of this kind.

From a domain-general, formal view, investigating people eating cassava root and people without tattoos is logically equivalent to investigating Leos and cowards. But everywhere it has been tested, people do not treat social exchange problems as equivalent to other kinds of rea-

soning problems. Their minds distinguish social exchange contents, and apply domain-specific, content-dependent rules of inference that are adaptively appropriate only to that task. (For a review of the relevant experiments, see Cosmides & Tooby, 1992. For more detailed descriptions, see Cosmides, 1985, 1989; Cosmides & Tooby, 1989; Gigerenzer & Hug, 1992.)

We think that the goal of cognitive research should be to recover, out of carefully designed experimental studies, high-resolution "maps" of the intricate mechanisms that collectively constitute the cognitive architecture. Our evolutionarily derived computational theory of social exchange allowed us to construct experiments capable of detecting, isolating and mapping out previously unknown cognitive procedures. It led us to predict a large number of design features in advance – features that no one was looking for and that most of our colleagues thought were outlandish (Cosmides & Tooby, 1989). Experimental tests have confirmed the presence of all the predicted design features that have been tested for so far. Those design features that have been tested and confirmed are

listed in Table 4, along with the alternative by-product hypotheses that we and our colleagues have eliminated. So far, no known theory invoking general-purpose cognitive processes has been able to explain the very precise and unique pattern of data that experiments like these have generated. The data seem best explained by the hypothesis that humans reliably develop circuits that are complexly specialized for reasoning about reciprocal social interactions.

Parallel lines of investigation have already identified two other domain-specialized reasoning mechanisms: one for reasoning about aggressive threats and one for reasoning about protection from hazards (e.g., Manktelow & Over, 1990; Tooby & Cosmides, 1989). We are now designing clinical tests to identify the neural basis for these mechanisms. By studying patient populations with autism and other neurological impairments of social cognition, we should be able to see whether dissociations occur along the fracture lines that our various computational theories suggest.

Reasoning Instincts

In our view, a large range of reasoning problems (like the astrological one) are difficult because (1) their content is not drawn from a domain for which humans evolved functionally specialized reasoning circuits, and (2) we lack the content-independent circuits necessary for performing certain logical operations ("logical reasoning"). In contrast, social exchange problems are easy because we do have evolved circuits specialized for reasoning about that important, evolutionarily long-enduring problem in social cognition. The inferences necessary for detecting cheaters are obvious to humans for the same reason that the inferences necessary for echolocation are obvious to a bat.

Instincts are often thought of as the polar opposite of reasoning. Non-human animals are widely believed to act through "instinct", while humans "gave up instincts" to become "the rational animal". But the reasoning circuits we have been investigating are complexly structured for solving a specific type of adaptive problem, they reliably develop in all normal human beings, they develop without any conscious effort and in the absence of any formal instruction, they are applied without any conscious awareness of their underlying logic, and they are distinct from more general abilities to process information or to behave intelligently. In other words, they have all the hallmarks of what one usually thinks of as

an "instinct" (Pinker, 1994). Consequently, one can think of these specialized circuits as *reasoning instincts*. They make certain kinds of inferences just as easy, effortless and "natural" to us as humans, as spinning a web is to a spider or dead-reckoning is to a desert ant.

Three decades of research in cognitive psychology, evolutionary biology and neuroscience have shown that the central premise of the SSSM – that the mind is general purpose and content-free – is fundamentally misconceived. An alternative framework – sometimes called evolutionary psychology – is beginning to replace it (Tooby & Cosmides, 1992). According to this view, the evolved architecture of the human mind is full of specialized reasoning circuits and regulatory mechanisms that organize the way we interpret experience, construct knowledge and make decisions. These circuits inject certain recurrent concepts and motivations into our mental life, and they provide universal frames of meaning that allow us to understand the actions and intentions of others. Beneath the level of surface variability, all humans share certain views and assumptions about the nature of the world and human action by virtue of these universal reasoning circuits (Atran, 1990; Boyer, 1994; Brown, 1991; Carey & Gelman, 1991; Gelman & Hirschfeld, 1994; Keil, 1989; Leslie, 1987; Markman, 1990; Spelke, 1990; Sperber, 1985, 1990, 1994; Symons, 1979; Tooby & Cosmides, 1992).

III. Intuition is a Misleading Source of Hypotheses Because Functionally Specialized Mechanisms Create "Instinct Blindness"; Computational Theories are Lenses that Correct for Instinct Blindness

Intuitions About Cognition: The Limitations of an Atheoretical Approach

The adaptationist view of a multimodular mind was common at the turn of the century. Early experimental psychologists, such as William James and William McDougall, thought the mind is a collection of "faculties" or "instincts" that direct learning, reasoning and action (James, 1890; McDougall, 1908). These faculties were thought to embody sophisticated information-processing procedures that were domain-specific. In James's view, human behavior is so much more flexibly intelligent than that of other animals because we have *more* instincts than they do – not fewer (James, 1890).

The vocabulary may be archaic, but the model is modern. With every new discovery, it becomes more apparent that the evolved architecture of the human mind is densely multimodal – that it consists of an enormous collection of circuits, each specialized for performing a particular adaptive function. The study of perception and language has provided the most conspicuous examples, but evidence for the existence of learning instincts (Marler, 1991) and reasoning instincts is pouring in from all corners of the cognitive sciences (for examples, see Atran, 1990; Barkow, Cosmides, & Tooby, 1992; Baron-Cohen, Leslie, & Frith, 1985; A. Brown, 1990; D. E. Brown, 1991; Carey & Gelman, 1991; Cosmides & Tooby, in press; Daly & Wilson, 1988, 1994; Frith, 1989; Gelman & Hirschfeld, 1994; Gigerenzer, Hoffrage, & Kleinbolting, 1991; Leslie, 1988; Pinker, 1994; Rozin, 1976; Spelke, 1988; Sperber, 1994; Symons, 1979; Wilson & Daly, 1992; Wynn, 1992).

In spite of this consistent pattern, however, most cognitive scientists balk at the model of a brain crowded with specialized inference engines. Even Fodor, who has championed the case for modular processes, takes the traditional view that “central” processes are general purpose (Fodor, 1983). The notion that learning and reasoning are like perception and language – the complex product of a large collection of functionally specialized circuits – is deeply at war with our intuitions.

But so is the inherent indeterminacy in the position of electrons. It is uncomfortable but scientifically necessary to accept that common sense is the faculty that tells us the world is flat.⁹ Our intuitions may feel authoritative and irresistibly compelling, and they may lead us to dismiss many ideas as ridiculous. But they are, nevertheless, an untrustworthy guide to the reality of subatomic particles or the evolved structure of the human mind.

In the case of central processes, we think human intuition is not merely untrustworthy: it is systematically misleading. Well-designed reasoning instincts should be invisible to our intuitions, even as they generate them – no more accessible to consciousness than retinal cells and line detectors, but just as important in creating our perception of the world.

Intuitively, we are all naive realists, experiencing the world as already parsed into objects, relationships, goals, foods, dangers, humans, words, sentences, social groups, motives, artifacts, animals, smiles, glares, relevances and saliences, the known and the obvious. This automati-

cally manufactured universe, input as toy worlds into computers, seems like it could almost be tractable by that perennially elusive collection of general-purpose algorithms cognitive scientists keep expecting to find. But to produce this simplified world that we effortlessly experience, a vast sea of computational problems are being silently solved, out of awareness, by a host of functionally integrated circuits. These reasoning instincts are powerful inference engines, whose automatic, non-conscious operation creates our seamless experience of the world. The sense of clarity and self-evidence they generate is so potent it is difficult to see that the computational problems they solve even exist. As a result, we incorrectly locate the computationally manufactured simplicity that we experience as a natural property of the external world – as the pristine state of nature, not requiring any explanation or research.

Thus the “naturalness” of certain inferences acts to obstruct the discovery of the mechanisms that produced them. Cognitive instincts create problems for cognitive scientists. Precisely because they work so well – because they process information so effortlessly and automatically – we tend to be blind to their existence. Not suspecting they exist, we do not conduct research programs to find them.

To see that they exist, you need to envision an alternative conceptual universe. But these dedicated circuits structure our thought so powerfully that it can be difficult to imagine how things could be otherwise. As William James wrote:

It takes . . . a mind debauched by learning to carry the process of making the natural seem strange, so far as to ask for the *why* of any instinctive human act. To the metaphysician alone can such questions occur as: why do we smile, when pleased, and not scowl? Why are we unable to talk to a crowd as we talk to a single friend? Why does a particular maiden turn our wits so upside-down? The common man can only say, *Of course* we smile, *of course* our heart palpitates at the sight of the crowd, *of course* we love the maiden, that beautiful soul clad in that perfect form, so palpably and flagrantly made for all eternity to be loved!

And so, probably, does each animal feel about the particular things it tends to do in the presence of particular objects. . . . To the lion it is the lioness which is made to be loved; to the bear, the she-bear. To the broody hen the notion would probably seem monstrous

Table 5: Inferences that Violate a Grammar of Social Reasoning

(a)	I want to help him because he has helped me so often in the past. I don't want to help him because whenever I'm in trouble he refuses to help me. *I want to help him because whenever I'm in trouble he refuses to help me. *I don't want to help him because he has helped me so often in the past.
(b)	I love my daughter. If you hurt her, I'll kill you. *I love my daughter. If you hurt her, I'll kiss you.
(c)	If I help you now, then you must promise to help me. *If I help you now, then you must promise to never help me.
(d)	He gave her something expecting nothing in return; she was touched. *He gave her something expecting nothing in return; she was enraged.
(e)	She paid \$5 for the book because the book was more valuable to her than \$5. *She paid \$5 for the book because the book was less valuable to her than \$5.

that there should be a creature in the world to whom a nestful of eggs was not the utterly fascinating and precious and never-to-be-too-much-sat-upon object which it is to her. (James, 1890)

For exactly this reason, intuition is an unreliable guide to points of interest in the human mind. Functionally specialized reasoning circuits will make certain inferences intuitive – so “natural” that there doesn't seem to be any phenomenon that is in need of explanation.

Consider, for example, sentences (1) and (2):

- (1) If he's the victim of an unlucky tragedy, then we should pitch in to help him out.
- (2) If he spends his time loafing and living off of others, then he doesn't deserve our help.

The inferences they express seem perfectly natural; there seems to be nothing to explain. They may not always be applicable, but they are perfectly intelligible.

But consider sentences (3) and (4):

- *(3) If he's the victim of an unlucky tragedy, then he doesn't deserve our help.
- *(4) If he spends his time loafing and living off of others, then we should pitch in to help him out.

Sentences (3) and (4) sound eccentric in a way that (1) and (2) do not. Yet they involve no *logical* contradictions. The inferences they embody seem to violate a grammar of social reasoning –

in much the same way that “Alice might slowly” violates the grammar of English but “Alice might come” does not (Cosmides, 1985; Cosmides & Tooby, 1989, 1992). If so, then one needs to look for a reasoning device that can reliably generate (1) and (2) without also generating (3) and (4).

Realizing that *not* generating (3) and (4) is a design feature of the mechanism is tricky, however. Precisely because the device in question does not spontaneously generate inferences like (3) and (4), we rarely notice their absence or feel the need to explain it. And that is the root of the problem. There is a complex pattern to the inferences we generate, but seeing it requires a contrast between figure and ground; the geometry of a snowflake disappears against a white background. “Unnatural” inferences form the high contrast background necessary to see the complex geometry of the inferences that we do spontaneously generate. Yet these “unnatural” inferences are exactly the ones we don't produce. Without this background, the pattern can't be seen. As a result, we look neither for the pattern, nor for the mechanisms that generate it. And no one guesses that our central processes instantiate domain-specific grammars every bit as rich as that of a natural language (for more examples, see Table 5).

Hidden Grammars

In the study of language, a grammar is defined as a finite set of rules that is capable of generating all the sentences of a language without generating any non-sentences; a sentence is defined as

a string of words that members of a linguistic community would judge as well formed. In the study of reasoning, a grammar is a finite set of rules that can generate all appropriate inferences while not simultaneously generating inappropriate ones. If it is a grammar of social reasoning, then these inferences are about the domain of social motivation and behavior; an “inappropriate” inference is defined as one that members of a social community would judge as incomprehensible or nonsensical.¹⁰

The cornerstone of any computational theory of the problem of language acquisition is the specification of a grammar. Discovering the grammar of a human language is so difficult, however, that there is an entire field – linguistics – devoted to the task. The task is difficult precisely because our linguistic inferences are generated by a “language instinct” (Pinker, 1994). One thing this set of specialized circuits can do is distinguish grammatical from ungrammatical sentences. But the rules that generate sentences – the grammar itself – operate effortlessly and automatically, hidden from our conscious awareness. Indeed, these complex rules are so opaque that just 40 years ago most linguists thought each human language – English, Chinese, Setswana – had a completely different grammar. Only recently have these grammars been recognized as minor variants on a Universal Grammar (UG): an invariant set of rules embodied in the brains of all human beings who are not neurologically impaired (Chomsky, 1980; Pinker, 1994).¹¹

Universal grammars of social reasoning are invisible to cognitive scientists now for the same reason that UG was invisible to linguists for such a long time. The fact that the internal operations of the computational machinery in question are automatic and unconscious is a contributing factor; but the causes of invisibility go even deeper.

Instinct Blindness

UG is a small corner of hypothesis space; there are an indefinitely large number of grammars that are *not* variants of UG. To explain the fact that all natural languages fall within the bounds of UG, one must first realize that UG exists. To realize that it exists, one must realize that there are alternative grammars.

But this last step is where our imagination stumbles. The language instinct structures our thought so powerfully that alternative grammars are difficult to imagine. This is not an incidental

feature of the language instinct; it is the language acquisition device’s (LAD) principal adaptive function.¹² Any set of utterances a child hears is consistent with an infinite number of possible grammars, but only one of them is the grammar of its native language. A content-free learning mechanism would be forever lost in hypothesis space. The LAD is an adaptation to combinatorial explosion: by restricting the child’s grammatical imagination to a very small subset of hypothesis space – hypotheses consistent with the principles of UG – it makes language acquisition possible. Its function is to generate grammatical inferences consistent with UG *without simultaneously* generating inconsistent ones. To do this, the LAD’s structure must make alternative grammars literally unimaginable (at least by the language faculty).

This is good for the child learning language, but bad for the cognitive scientist, who needs to imagine these unimaginable grammars. Forming the plural through mirror reversal – so that the plural of “cat” is “tac” – is a rule in an alternative grammar. No child considers this possibility; the LAD cannot generate this rule. The cognitive scientist needs to know this, however, in order to characterize UG and produce a correct theory of the LAD’s cognitive structure. UG is *what*, an algorithm is *how*. A proposed algorithm can be ruled out, for example, if formal analyses reveal that it produces both the mirror reverse rule and the “add ‘s’ to a stem” rule.

Alternative grammars – and hence Universal Grammar – were difficult to discover because circuits designed to generate only a small subset of all grammatical inferences in the child also do so in the linguist. This property of the language instinct is crucial to its adaptive function. But it caused a form of theoretical blindness in linguists, which obstructed the discovery of UG and of the language instinct itself. One can think of this phenomenon as *instinct blindness*.

Discovering a grammar of social reasoning is likely to prove just as difficult as discovering the grammar of a language, and for exactly the same reasons. Yet there is no field, parallel to linguistics, that is devoted to this task; indeed, very few individuals even recognize the need for such a grammar, let alone such a field (for exceptions, see Cosmides, 1985; Cosmides & Tooby, 1989, 1992; Fiske, 1991; Jackendoff, 1992).

Our intuitions blind us not only to the existence of instincts, but to their complexity. The phenomenal experience of an activity as “easy” or “natural” often leads scientists to assume that the processes that give rise to it are simple.

Legend has it that in the early days of artificial intelligence, Marvin Minsky assigned the development of machine vision to a graduate student as a summer project. This illusion of simplicity hampered vision research for years:

... in the 1960s almost no one realized that machine vision was difficult. The field had to go through [a series of fiascos] before it was at last realized that here were some problems that had to be taken seriously. The reason for this misperception is that we humans are ourselves so good at vision. (Marr, 1982, p. 16)

Phenomenally, seeing seems simple. It is effortless, automatic, reliable, fast, unconscious and requires no explicit instruction. But seeing is effortless, automatic, reliable, fast, and unconscious precisely because there is a vast array of complex, dedicated computational machinery that makes this possible.

Most cognitive scientists don't realize it, but they are grossly underestimating the complexity of our central processes. To find someone beautiful, to fall in love, to feel jealous, to experience moral outrage, to fear disease, to reciprocate a favor, to initiate an attack, to deduce a tool's function from its shape – and a myriad other cognitive accomplishments – can seem as simple and automatic and effortless as opening your eyes and seeing. But this apparent simplicity is possible only because there is a vast array of complex computational machinery supporting and regulating these activities, the human cognitive architecture probably embodies a large number of domain-specific “grammars”, targeting not just the domain of social life, but also disease, botany, tool-making, animal behavior, foraging and many other situations that our hunter-gatherer ancestors had to cope with on a regular basis.

Research on the computational machinery responsible for these kinds of inferences, choices and preferences – especially the social ones – is almost totally absent in the cognitive sciences. This is a remarkable omission, from an evolutionary point of view. Instinct blindness is one culprit; extreme and unfounded claims about cultural relativity is another (e.g., Brown, 1991; Sperber, 1982; Tooby & Cosmides, 1992).

Anthropological Malpractice

As a result of the rhetoric of anthropologists, most cognitive researchers have, as part of their standard intellectual furniture, a confidence that cultural relativity is an empirically established

finding of wide applicability (see discussion of the Standard Social Science Model in Tooby & Cosmides, 1992). Consequently, most scientists harbor the incorrect impression that there is no “Universal Grammar” of social reasoning to be discovered. According to this view, a grammar of social reasoning might exist in each culture, but these grammars will differ dramatically and capriciously from one culture to the next. In its most extreme form, the relativist position holds that the grammars of different cultures are utterly incommensurate – that there is no transformation that can map the rules of one onto the rules of another. If so, then these rules cannot be expressions of an underlying UG of social reasoning.

Among anthropologists, however, cultural relativism is an interpretation imposed as an article of faith – not a conclusion based on scientific data (Brown, 1991; Sperber, 1982; Tooby & Cosmides, 1992).¹³ Indeed, Maurice Bloch, a prominent member of the field, has complained that it is the “professional malpractice of anthropologists to exaggerate the exotic character of other cultures” (Bloch, 1977). To some degree, this is a self-legitimizing institutional pressure: why go long distances to study things that could be studied at home (Brown, 1991)? More importantly, however, anthropologists are just as oblivious to what is universally natural for the human mind as the rest of us. Their attention is drawn to what differs from culture to culture, not what is absent from all cultures or what differs from species to species. Drawing on their cognitive instincts, they understand, automatically and without reflection, much of what happens in other cultures. They know they can work out exchanges without language, or see a smile, a shared look, or an aggressive gesture and infer its meaning and its referent. Indeed, they operate within a huge set of implicit panhuman assumptions that allow them to decode the residue of human life that does differ from place to place (Sperber, 1982; Tooby & Cosmides, 1992).

The notion of universal human reasoning instincts – including social reasoning instincts – is completely compatible with the ethnographic record. It is more than empirically reasonable; it is a logical necessity, for the reasons discussed above. Indeed, without universal reasoning instincts, the acquisition of one's “culture” would be literally impossible, because one wouldn't be able to infer which representations, out of the infinite universe of possibilities, existed in the minds of other members of the

culture (Boyer, 1994; Chomsky, 1980; Sperber, 1985, 1990; Tooby & Cosmides, 1992).

Instinct blindness is a side-effect of any instinct whose function is to generate some inferences or behaviors without simultaneously generating others. This is a very general property of instincts, because combinatorial explosion is a very general selection pressure (for discussion, see Tooby & Cosmides, 1992). The fact that human instincts are difficult for human minds to discover is a side-effect of their adaptive function.

Many aspects of the human mind can't be seen by the naked "I" – by intuition unaided by theory. A good theory rips away the veil of naturalness and familiarity that our own minds create, exposing computational problems whose existence we never even imagined. The cognitive sciences need theoretical guidance that is grounded in something beyond intuition. Otherwise, we're flying blind.

Corrective Lenses

There are various ways of overcoming instinct blindness. One of the most common is the study of non-human minds that differ profoundly from our own – animal minds and electronic minds, broody hens and AI programs. Linguists were awakened to the existence of alternative grammars by the creation of computer "languages", which are not variants of UG. These languages "made the natural seem strange", inspiring linguists to generate even stranger grammars. To do this, they had to escape the confines of their intuitions, which they did through the use of mathematical logic and the theory of computation. In William James's terms, they debauched their minds with learning.

The study of animal behavior is another time-honored method for debauching the mind – the one used by William James himself. Hermaphroditic worms, colonies of ant sisters who come in three "genders" (sterile workers, soldiers, queens), male langur monkeys who commit systematic infanticide when they join a troop, flies who are attracted to the smell of dung, polyandrous jacanas who mate with a male after breaking the eggs he was incubating for a rival female, fish who change sex when the composition of their social group changes, female praying mantises who eat their mate's head while copulating with him – other animals engage in behaviors that truly are exotic by human standards. Human cultural variation is trivial in comparison. Observing behaviors

caused by alternative instincts jars us into recognizing the specificity and multiplicity of our own instincts.

Observations like these tell us what we are not, but not what we are. That's why theoretical biology is so important. It provides positive theories of what kinds of cognitive programs we should expect to find in species that evolved under various ecological conditions: theories of what and why. Evolutionary biology's formal theories are powerful lenses that correct for instinct blindness. In their focus, the intricate outlines of the mind's design stand out in sharp relief.

Notes

- 1 Similar results emerge from the cognitive sciences. Although artificial intelligence researchers have been working for decades on computer vision, object recognition, color constancy, speech recognition and comprehension, and many other evolved competences of humans, naturally selected computational systems still far outperform artificial systems on the adaptive problems they evolved to solve – on those rare occasions when artificial systems can solve the assigned tasks at all. In short, natural selection is known to produce cognitive machinery of an intricate functionality as yet unmatched by the deliberate application of modern engineering. This is a far more definable standard than "optimality" – where many anti-adaptationist arguments go awry. There are an uncountable number of changes that could conceivably be introduced into the design of organisms and, consequently, the state space of potential organic designs is infinitely large and infinitely dimensioned. Thus, there is no way of defining an "optimal" point in it, much less "measuring" how closely evolution brings organisms to it. However, when definable engineering standards of functionality are applied, adaptations can be shown to be very functionally designed for solving *adaptive* problems.
- 2 All traits that comprise species-typical designs can be partitioned into adaptations, which are present because they were selected for, by-products, which are present because they are causally coupled to traits that were selected for, and noise, which was injected by the stochastic components of evolution. Like other machines, only narrowly defined aspects of organisms fit together into functional systems: most of the system is incidental to the functional properties. Unfortunately, some have misrepresented the well-supported claim that selection organizes organisms very functionally as the obviously

- false claim that all traits of organisms are functional – something no sensible evolutionary biologist would ever maintain. Nevertheless, cognitive scientists need to recognize that while not everything in the designs of organisms is the product of selection, all complex functional organization is (Dawkins, 1986; Pinker & Bloom, 1990; Tooby & Cosmides, 1990a, 1990b, 1992; Williams, 1966, 1985).
- 3 Had Marr known about the importance of cheating in evolutionary analyses of social exchange, he might have been able to understand other features of the cash register as well. Most cash registers have anti-cheating devices. Cash drawers lock until a new set of prices is punched in; two rolls of tape keep track of transactions (one is for the customer; the other rolls into an inaccessible place in the cash register, preventing the clerk from altering the totals to match the amount of cash in the drawer); and so on.
 - 4 Our ancestors spent the last 2 million years as Pleistocene hunter-gatherers (and several hundred million years before that as one kind of forager or another). The few thousand years since the scattered appearance of agriculture is a short stretch, in evolutionary terms (less than 1% of the past 2 million years). Complex designs – ones requiring the coordinated assembly of many novel, functionally integrated features – are built up slowly, change by change, subject to the constraint that each new design feature must solve an adaptive problem better than the previous design (the vertebrate eye is an example). For these and other reasons, it is unlikely that our species evolved complex adaptations even to agriculture, let alone to post-industrial society (for discussion, see Dawkins, 1982; Tooby & Cosmides, 1990a, 1990b).
 - 5 Women ingest thousands of plant toxins every day; embryos self-abort for many reasons; early term abortions are often undetectable; the best trade-off between calories consumed and risk of teratogenesis is obscure.
 - 6 Parsimony applies to number of principles, not number of entities – physicists posit a small number of laws, not a small number of elements, molecules or stellar bodies. Epicycle upon epicycle would have to be added on to evolutionary theory to create a model in which less efficient designs frequently outcompeted more efficient ones.
 - 7 There are strict standards of evidence that must be met before a design feature can be considered an adaptation for performing function X. (1) The design feature must be species-typical; (2) function X must be an *adaptive* problem (i.e., a cross-generationally recurrent problem whose solution would have promoted the design feature's own reproduction); (3) the design feature must reliably develop (in the appropriate morphs) given the developmental circumstances that characterized its environment of evolutionary adaptedness; and, most importantly, (4) it must be shown that the design feature is particularly *well designed for performing function X*, and that it cannot be better explained as a by-product of some other adaptation or physical law. Contrary to popular belief, the following forms of "evidence" are *not* relevant: (1) showing that the design feature has a high heritability; (2) showing that variations in the environment do not affect its development; (3) showing that "learning" plays no role in its development. (Criteria for frequency-dependent adaptations differ. For refinements and complications, see Dawkins, 1982, 1986; Symons, 1992; Tooby & Cosmides, 1992b, 1992; and, especially, Williams, 1966, 1985).
 - 8 For a detailed analysis of the common arguments against the application of evolutionary biology to the study of the human mind, see Tooby and Cosmides (1992).
 - 9 This should not be surprising. Our intuitions were designed to generate adaptive behavior in Pleistocene hunter-gatherers, not useful theories for physicists and cognitive scientists.
 - 10 The similarities between a grammar of language and a grammar of social reasoning run even deeper. Context can make a seemingly ungrammatical sentence grammatical. To pick a standard linguistic example, "The horse raced past the barn fell" seems ungrammatical when "raced" is categorized as the main verb of the sentence, but grammatical if the context indicates that there are two horses. "Fell" is then *recategorized* as the main verb, and "raced" as a passive verb within a prepositional phrase. Context can have the same effect on statements that seem socially ungrammatical. "I'll give you \$1000 for your gum wrapper" seems eccentric – ungrammatical – because gum wrappers are considered worthless. It violates a grammatical constraint of social contract theory: that (benefit to offerer) > (cost to offerer) (Cosmides & Tooby, 1989). To become grammatical, the context must cause the violated constraint to be satisfied. For example, recategorizing the gum wrapper as something extremely valuable (potentially justifying the \$1000 payment) would do this: the statement seems sensible if you are told that the speaker is a spy who knows the gum wrapper has a microdot with the key for breaking an enemy code.
 - 11 The term "innate" means different things to different scientific communities, but no person who uses the term means "immune to every environmental perturbation". UG is innate in the following sense: its intricate internal organization is the product of our species' genetic

endowment in the same way that the internal organization of the eye is. Its neurological development is buffered against most naturally occurring variations in the physical and social environment. Certain environmental conditions are necessary to trigger the development of UG, but these conditions are not the source of its internal organization. As a result, all normal human beings raised in reasonably normal environments develop the same UG (e.g., Pinker, 1994). For an extensive discussion of how natural selection structures the relationships among genotype, phenotype and environment in development, see Tooby and Cosmides (1992).

- 12 As a side-effect, it can also solve problems that played no causal role in its selective history. For example, the LAD was not designed to support writing, but its properties made the design and spread of this cultural invention possible.
- 13 For a history and discussion of how unsupported relativist claims gained widespread acceptance in the social sciences, see Brown (1991) and Tooby and Cosmides (1992).

Chapter 42: Use or Misuse of the Selection Task?

Rejoinder to Fiddick, Cosmides, and Tooby

DAN SPERBER AND VITTORIO GIROTTO

1. Introduction

Why has Wason's selection task (Wason, 1966)¹ been, for almost 40 years, so extensively used in psychology of reasoning? Because it has a simple, logically compelling solution, and yet, in most versions, most participants fail to solve it. Philosophers have seen this as highly relevant evidence in assessing human rationality (e.g., Stein, 1996). Psychologists have found ways of improving participants' performance, in particular by changing the narrative content of the task, and have offered various interpretations of these results. Selection task data have thus been garnered in support of various general claims about human reasoning.

In particular, Leda Cosmides, John Tooby, and their collaborators have, over the past 20 years, performed a variety of original selection task experiments to establish the existence of evolved domain-specific reasoning mechanisms. Their most famous, best developed hypothesis concerns the existence of a "social contract algorithm," one subcomponent of which is a cheater detection device (Cosmides, 1989; Cosmides & Tooby, 1989, 1992, 1997; Fiddick, Cosmides, & Tooby, 2000). They define a social contract as a situation in which one party is obligated to satisfy a requirement in order to be entitled to receive a benefit from another party, and they define cheating as the taking of the benefit without satisfying the requirement. A social contract situation can be depicted in a selection task by means of cards representing on one side whether or not the benefit has been taken and on the other side whether or not the requirement has

been satisfied. A cheater detection device should favor the selection of the "benefit taken" and of the "requirement not satisfied" cards, either of which could turn out to correspond to a case of cheating. This is indeed what a majority of participants select in the social contract situations used in the experiments of Cosmides, Tooby, and their collaborators. The selection task thus seems to provide crucial data in favor of the evolutionary psychology approach of which Tooby and Cosmides have been the most articulate exponents.

Although many researchers clearly believe that the selection task provides appropriate evidence for general claims about human reasoning, no such claim has ever been accepted by the scientific community on the basis of such evidence. Rather, what seems to drive the continuous production of selection task experiments is that their interpretations can be endlessly contested by means of further experiments with the task. This in itself would be reason enough to question the reasonableness of the proliferation of research based on the selection task of which the work of Cosmides, Tooby, and their collaborators is a striking example. Moreover, Sperber, Cara, and Girotto (1995) (henceforth SCG) have put forward an analysis of the task itself that casts principled doubts on its scientific utility.

SCG argued that, in the selection task, relevance-guided comprehension mechanisms tend to pre-empt the use of whatever domain-general or domain-specific reasoning mechanisms people are endowed with.² In support of this

Reproduced with permission from Sperber, D., and Girotto, V. (2002) Use or misuse of the selection task: Rejoinder to Fiddick, Cosmides, and Tooby. *Cognition*, 85, 277–290.

claim, they showed how to manipulate relevance factors in descriptive versions of the task so as to elicit more than 50% correct responses (a rate of success normally found with deontic rather than descriptive versions). Girotto, Kemelemer, Sperber, and van der Henst (2001) provided further evidence by manipulating relevance factors in deontic versions so as to elicit more than 80% incorrect responses (a rate of failure normally found with descriptive rather than deontic versions). The only challenge to SCG purporting to contain counterevidence has been Fiddick et al. (2000) (henceforth FCT). What we aim to do here is rebut FCT's central theoretical argument (what they call the "principle of pre-emptive specificity") and demonstrate a methodological flaw in their experimental evidence. We hope that this will be enough to vindicate and indeed reinforce our earlier warnings against basing any important claim in the psychology of reasoning on Wason selection task data (other issues raised by FCT are discussed in Sperber & Girotto, in press; see also Atran, 2000).

1.1. Comprehension, Reasoning, and the Order of Pre-emption

According to most modern pragmatics, comprehension is an inferential process that takes as input an utterance and contextual information, and that produces as output an interpretation of the speaker's meaning. Comprehension is an attribution of a mental state to the speaker, a form of mind-reading. According to relevance theory in particular, this comprehension process consists of developing an interpretation that satisfies the expectation of relevance raised by the utterance itself. This process is specific to comprehension. If mind-reading is viewed as a module of the human mind, then comprehension can be viewed as a sub-module (Sperber, 2000; Sperber & Wilson, 2002). Cheater detection too is presented by FCT as a sub-module of the social contract algorithm. Let us accept, for the sake of discussion, that the normally developed human mind is equipped with both a comprehension mechanism and a cheater detection mechanism. What happens when participants in an experiment are verbally presented with a selection task involving a social contract, that is, with an input that could, in principle, activate both the comprehension and the cheater detection mechanisms? This is where SCG and FCT give almost diametrically opposed answers.

SCG argued that, in Wason's selection task, pragmatic comprehension mechanisms tend to pre-empt the use of whatever domain-general or domain-specific reasoning mechanisms people may be endowed with (and this is what makes the selection task an inappropriate tool to study reasoning). FCT claim on the contrary that the more specialized mechanism will pre-empt the less specialized mechanism and in particular cheater detection will pre-empt inferential comprehension.

FCT's (p. 24) main argument is this: "a well-engineered problem-solving system should deploy, to the extent possible, the most specialized problem-solving machinery that is activated by the problem at hand, because on average, it will be more knowledgeable than the alternative, more general problem-solvers that also apply [...] This principle of cognitive design – what we will call the *principle of pre-emptive specificity* – should be expressed in design features throughout the cognitive architecture. It applies to the problems herein. Social contract algorithms and hazard management algorithms are more content-specialized than relevance mechanisms, whose domain is all content that arrives via communication from an agent." While this argument has obvious merits, it ignores essential design factors. Some mechanisms accept as input the output of other mechanisms. Whatever their relative degree of specialization, the receiver mechanism cannot prevent the feeder mechanism from performing its operations. In fact, without the output of the feeder mechanism, the receiver mechanism would have no input to process.

In order to recognize a verbally presented reasoning problem, whatever the domain-general or domain-specific reasoning mechanism they may ultimately bring to bear on its solution, participants must first comprehend the text of the problem and, for this, use their comprehension mechanism. According to relevance theory, comprehending a text involves grasping its intended relevance, and this involves a meaning construction process that often goes beyond or away from strict literal meaning. With standard reasoning problems, participants are presented with verbal premises and are explicitly asked to infer or evaluate conclusions. Their understanding of the premises may be biased by comprehension factors (for a review, see Evans, Newstead, & Byrne, 1993; for illustrations, e.g. Begg & Harris, 1982; Politzer, 1990), but, at least, it is clear that they must engage in a reasoning effort, over and above comprehension proper.

The selection task is not a standard reasoning problem. Participants are not asked to reason from premises to conclusions, and they are not even told that the question they are asked can best be answered by making use of deductive reasoning. Participants are just asked to evaluate the relevance of one part of the problem (the cards) to another part of the problem (the conditional rule). What SCG argued is that the intuitions of relevance arrived at in the process of comprehending a selection task problem provide what looks like an intuitive solution to the problem itself. So, it is not just that comprehension will take place anyhow. It is that, in the particular case of the selection task, there is no incentive, for most participants, to engage in further active reasoning of either a general or a domain-specific kind, in order to find the solution to the problem.

Our answer to FCT is therefore, firstly, that there is no way that a cheater detection mechanism could pre-empt a comprehension mechanism in the processing of a selection task problem, since, anyhow, the problem must first be comprehended. Secondly, the comprehension mechanism automatically provides what looks like a solution to the selection task. It may well – and does for a majority of participants – pre-empt any further reasoning processes.

1.2. *Distinguishing the Wason Selection Task from the FCT Selection Task*

As SCG (p. 42) pointed out, a number of past experiments with deontic tasks (e.g. Cosmides, 1989; Light, Girotto, & Legrenzi, 1990; Manktelow & Over, 1991) suffered from a methodological defect. Participants were simultaneously asked, not one, but two questions: the standard Wason task question of whether the conditional rule had been obeyed or violated and the direct question of whether some cheating had taken place (or worse, they were asked just the question about cheating). Answering correctly the first question is performing successfully on Wason's selection task, but answering correctly the second question is not: it demonstrates just the ability to identify a cheater on the basis of the information provided in the problem narrative. FCT (p. 15) themselves point out the difference. They write: "Note that the definition of cheating *does not map onto the logical definition of violation* (the latter being a true antecedent paired with a false consequent). Cheating is a content-dependent concept: there must be an illicitly taken *benefit*. This, and only this, counts as cheating. Logical categories and definitions of viola-

tion form an orthogonal representational dimension." This should make them wary of using as evidence data obtained with the two questions, that of cheating and that of violation posed simultaneously.

For instance, in one of the problems used in Experiments 2 and 4 in Cosmides (1989), participants were asked "Did Big Kiku get away with cheating any of these four men [a question directly about cheating]? Indicate only those card(s) you definitely need to turn over to see if Big Kiku has broken his word to any of these four men [an indirect question about the respect or violation of the conditional rule uttered by Big Kiku]" (Cosmides, 1989, p. 265). This kind of formulation suggests that both questions have the same correct answer and, in fact, in Cosmides' Experiment 2, where the conditional rule was Big Kiku's statement: "if you get a tattoo on your face, then I'll give you cassava root," they do. Big Kiku got away with cheating a man just in case Big Kiku did not do what he said he would do. This correct answer was given by 71% of the participants, but there is no way to decide whether they based their response on the first question ("Did Big Kiku get away with cheating?"), or the second (is it the case that "Big Kiku has broken his word?"), or paid attention to both questions.

In Experiment 4, however, the conditional rule was "switched" to "If I give you cassava root, then you must get a tattoo on your face" (Cosmides, 1989, p. 217). This time, to begin with, both questions become harder to interpret. Strictly understood, Big Kiku's word expresses not a conditional contractual promise (i.e., a commitment to do something conditional on the other party's action), but a requirement that the other party do something (see Legrenzi, Politzer, & Girotto, 1996). Therefore, Big Kiku is not in a position to either cheat or break his word. However – as has long been known in pragmatics (Geis & Zwicky, 1971) – many conditional statements and in particular conditional promises are commonly understood as implying their converse (see e.g. Fillenbaum, 1975; Newstead, Ellis, Evans, & Dennis, 1997). Here Big Kiku's statement can be understood as implying that, if his interlocutor got a tattoo, then he would give him cassava root, making sense of the narrative and of the ideas that Big Kiku might cheat. At this point, of course, the question about cheating, and the Wason task question about whether the conditional rule was violated or not have different answers (that is, if the conditional rule is strictly understood). The correct

answer to the Wason task question would be, as always, to select the P and not-Q cards, whereas the correct answer to the cheating question would be to select the not-P and Q cards, which 75% of the participants in Cosmides (1989) did. She took this to show that people use a cheater detection Darwinian algorithm to solve such a Wason selection task. We suggest that this shows that participants answered the cheating question and not the Wason task question, or that they reinterpreted Big Kiku's statement as meaning its converse (in which case both questions result in the same answer).

What is it that makes the Wason task question significantly different from the question about cheating? The Wason task question is about the truth or falsity (in the descriptive versions) or the respect or violation (in the deontic versions) of a conditional rule. The only fail-safe way of answering it involves applying conditional reasoning to four hypothetical cases. The cheating question is not a conditional reasoning question but a categorization question. As explained in detail by Cosmides and her collaborators, cheating is commonly understood as the co-occurrence of the taking of a benefit and the failure to fulfill a requirement, in particular of paying a cost. It is, in other terms, characterized by the conjunction of these two features. In order to answer the cheating question, then, all that participants have to do is select the cards that exhibit one of these two features (and that might have the other characteristic feature on the other side).

More generally, one could devise a categorization task that would use material similar to that used in the Wason selection task, and in particular cards exhibiting one of two possible values for a pair of traits (e.g., *benefit taken* vs. *benefit not taken*, and *requirement fulfilled* vs. *requirement not fulfilled*; or *flying vehicle* vs. *non-flying vehicle*, and *has an engine* vs. *does not have an engine*). Out of the four possible combinations of such trait values, one and only one would determine a given category. For instance the combination *benefit taken* + *requirement not fulfilled* would determine the category of cheaters, or the combination *flying vehicle* + *does not have an engine* would determine the category of gliders. Participants would then be asked which of the four cards could turn out to represent an instance of the category. This is what FCT have actually done, devising a task that is superficially similar to the Wason selection task, but that tests for a different cognitive capacity. As we indicated above, in order to distinguish it from the gen-

uine Wason task – something that FCT totally failed to do – we will call this categorization task the “FCT selection task.” When both the Wason and the FCT questions are posed in the same problem, as in the Big Kiku example, we speak of a Wason/FCT task.

Is there any reason to think that the FCT selection task is of particular psychological interest? Should we expect people to generally fail at the FCT task, as they do with the Wason task, and to succeed when the material used activates domain-specific evolved mechanisms? We believe not. The FCT task is quite trivial. As we will show, participants perform it without difficulty, even with totally artificial material. It looks interesting only when it is confused with the Wason task, and used without adequate control conditions. As with the Wason selection task, the FCT selection task is inadequate to test the interesting Cosmides (1989) hypothesis that humans are endowed with an evolved mental module to reason about social contracts, or other similar evolutionary psychology hypotheses.

2. Experiment 1

The goal of our first experiment was to check whether the FCT selection task is, as we claimed, trivially easy. Can individuals, if asked to do so, correctly select the cards that might represent an instance not just of cheating, but of any category defined by the combination of a positive and a negative trait?

We devised three conditions: a first condition where the relevant category was explicitly that of cheating defined by the combination of “cost paid” and “benefit not received”; a second condition, with material strictly parallel to the first condition but where the relevant category was an arbitrary one called “Wason's selection” defined by the combination of “food item” and “non-Italian”; and a third condition where the relevant category was that of a glider. Whereas, in the two former conditions, the relevant categories were explicitly defined as the combination of a positive and a negative trait, participants did not receive the definition of “glider.” In this experiment, we were comparing a condition of a kind assumed by FCT to provide evidence for the existence of an evolved mental cheating detector, with two conditions where what had to be “detected” was either a made-up arbitrary category, or an ordinary language category of no evolutionary significance and the relevant properties of which were not even mentioned in the

text. We predicted that participants would do well in all conditions.

2.1. Method

2.1.1. PARTICIPANTS

A total of 100 humanities undergraduates at Trieste University (Italy) participated in the experiment voluntarily. They were randomly assigned to one of three groups: "look for cheater," "look for Wason's selection," and "look for glider."

2.1.2. PROCEDURE AND MATERIALS

The study was carried out in Italian with native speakers of the language. The participants were tested in groups, but they worked on the problems individually, at their own pace. In the "look for cheater" condition, the problem read as follows:

Paolo often buys things through the Internet, but he is fearful of being cheated. For each order, he fills a card. On one side of the card, he indicates whether he has received the item ordered. On the other side of the card, he indicates whether he has paid for the item ordered.

Paolo puts in a box labeled "Risk of cheating" the cards indicating that he has paid for the item and has not received the item.

Below are four cards, each of which represents a different order. Two cards show the side that indicates whether Paolo has received the item ordered. The two other cards show the side that indicates whether Paolo has paid for the item.

7th December 2000: Item paid for

14th December 2000: Item not paid for
--

29th October 2000: Item received

21st November 2000: Item not received
--

Indicate only the card or cards you definitely need to turn over to see whether, among these cards, there are some cards that Paolo should put in the "Risk of cheating" box.

In the "look for Wason's selection" condition, the problem read as follows:

Paolo often buys things through the Internet. For each order, he fills a card. On one side of the card, he indicates whether the item ord-

ered is food. On the other side of the card, he indicates whether the item ordered is Italian. Paolo puts in a box labeled "Wason's selection" the cards indicating a food item that is not Italian.

Below you find four cards, each of which represents a different order. Two cards show the side that indicates whether the items ordered are food or not. The two other cards show the side that indicates whether the items are Italian or not.

7th December 2000: Food item

14th December 2000: Non food item

29th October 2000: Italian item

21st November 2000: Non Italian item

Indicate only the card or the cards you definitely need to turn over to see whether, among these cards, there are some cards that Paolo should put in the "Wason's selection" box.

In the "look for gliders" condition, the problem read as follows:

Paolo collects pictures of vehicles. For each vehicle, he fills a card. On one side, he indicates where the vehicle movements take place. On the other side, he indicates whether the vehicle has an engine or not.

Paolo puts in a box labeled "Gliders" the cards representing a glider. Below are four cards, each of which represents a different vehicle. Two cards show the side that indicates where the vehicle movements take place. The two other cards show the side that indicates whether the vehicle has an engine or not.

Vehicle 15 Where does it move? In the air

Vehicle 8 Where does it move? On rails
--

Vehicle 34 Does it have an engine? Yes
--

Vehicle 27 Does it have an engine? No

Indicate only the card or cards you definitely need to turn over to see whether, among these cards, there are some cards that Paolo should put in the "Gliders" box.

Table 1: Percentage of the Selection Patterns in the Three Conditions of Experiment 1

Pattern	Condition (N)		
	Look for Cheater (35)	Look for Wason (35)	Look for Glider (30)
P, not-Q	68	91	73
P	6	3	–
P, Q	–	–	13
Not-Q	20	–	10
Not-P, Q	–	3	3
P, not-P, not-Q	6	–	–
All	–	3	–

2.2. Results and Discussion

Table 1 reports the percentages of the selection patterns obtained in the three conditions. As predicted, participants performed well in all conditions. In particular, in the condition in which they were required to look, not for cheaters, but for the arbitrary category of Wason's selection, 91% of them selected the cards corresponding to the P and not-Q features. This rate of correct performance is significantly higher than the one (68%) obtained in the "look for cheater" condition ($\chi^2(1, N = 70) = 4.37, p < 0.05$), and marginally higher than in the "look for glider" condition ($\chi^2(1, N = 65) = 2.7, p < 0.10$).

The fact that the participants' performance is lower in the "look for glider" than in the "look for Wason's selection" condition is readily explained by the fact that the two defining traits of a "Wason's selection" were mentioned in the text of the problem, whereas participants had to know and remember that a glider is a vehicle that moves in air without an engine. This interpretation was confirmed by a replication of the "look for glider" condition, in which we asked participants (20 humanities undergraduates at Trieste University) to justify their selections. The rate of correct performance (65%) was similar to the one obtained in the previous "look for glider" condition, and significantly lower than the one obtained in the "look for Wason" condition ($\chi^2(1, N = 55) = 4.33, p < 0.05$). All but one participant who failed selected only the P card ("vehicle moving on air"). All of them explained that they did not select the not-Q card ("engineless vehicle") because they were not sure whether a glider has an engine or not. Presumably, then, if we had mentioned in the text of the problem the two defining traits of

the relevant category, the performance in the "look for glider" condition would have been higher.

On the other hand, the fact that the participants' performance is lower in the "look for cheater" than in the "look for Wason's selection" condition and is similar to that in the "look for glider" condition is somewhat puzzling, since in the "cheater" condition the two defining traits were mentioned. Whatever the explanation of this less-than-perfect performance in the "look for cheater" condition, and whatever the remedies that could be found to improve this performance, the fact remains that, in an FCT task, cheaters are not more easily detected than arbitrary items such as Wason's selections, or items devoid of evolutionary significance such as gliders. As we predicted, participants did well in all three conditions. We would expect participants to do well with any category whatsoever, provided that they knew or were told its defining traits.

3. Experiment 2

Experiment 1 showed that the FCT selection task is trivially easy, and therefore is quite unlike the Wason selection task, in spite of being modeled on it. In their Experiment 1, FCT argue that, in the Wason selection task, people do not reason from the logical form expressed in the conditional rule, as shown by the fact that they perform as well when the logical connective "if... then" is removed. From a pragmatic point of view, we would anyhow agree that logical connectives are not necessary for people to give a conditional interpretation to a text or dialogue. For instance in a dialogue such as:

Child: I want to go out and play!

Mother: You must put on your coat!

the mother's reply is normally understood as meaning implicitly: *If* you want to go out and play, *then* you must put on your coat. The logical form of an utterance need not be wholly explicit, and there is no reason why a proper Wason selection task could not be performed with an implicit rather than an explicit conditional rule. This, however, was not FCT's point.

FCT assumed that if people, in a task describing a social exchange, performed equally well with or without an explicit conditional, this showed that they didn't reason on the conditional logical form, but just on the "logic of social exchange." However, FCT used as evidence not

a Wason selection task but an FCT selection task. We would argue that the conditional form, whether it is implicitly retrieved by the participants or not, is anyhow irrelevant to successful performance of an FCT selection task. More specifically, FCT asked participants to indicate the cards they had to turn over “to see whether any of these people [represented by the cards] have cheated you.” They compared two conditions, one where the exchange was explicitly described in conditional form, the other where it was not. Since this is an FCT task, we would have predicted that participants would perform equally well in both conditions, as indeed they did. Our claim is that when people are explicitly instructed to identify possible cheaters, they have no problem understanding the instruction and following it. FCT do not consider this simple possibility and argue that when people recognize an exchange situation, and moreover adopt the perspective of one of the two parties to the exchange, then they automatically look for cheaters. If FCT are so confident that this is so, it is hard to understand why they mar their experimental evidence by explicitly asking participants to look for cheaters.

To help decide whether people look for cheaters because they are asked to look for cheaters, or because they are asked to reason about an exchange situation, we performed an FCT experiment with two conditions replicating FCT’s own and two other conditions identical in every point, except that participants were not asked to look for instances of cheating, but for instances of exchange. If it is the exchange situation that triggers the selection of the P and not-Q cards representing a possible instance of cheating, then this modification should have little or no effect. If, as we claim, participants in an FCT task trivially do just what they are asked to do, then we should expect participants in the new conditions to select the P and Q cards, which represent possible instances of exchange, more often than the P and not-Q cards, which represent possible instance of cheating.

3.1. Method

3.1.1. PARTICIPANTS

The participants were 120 humanities undergraduates from Trieste University. They were randomly assigned to one of four equal-sized groups: “look for exchange (conditional),” “look for exchange (want),” “look for cheater (conditional),” and “look for cheater (want)” ($N = 30$).

3.1.2. PROCEDURE AND MATERIALS

The same procedure as in Experiment 1 was used. Each participant had to solve one problem. The “look for cheater (conditional)” and “look for cheater (want)” conditions replicated, respectively, the “conditional” and “want” problems of FCT Experiment 1. They read as follows:

You are a South American farmer. At the end of the harvest you find you have more potatoes than you need so you pack up some of them and travel to the neighboring village. When you get to the village four different people approach you, and though you don’t speak the same dialect, you recognize that each of them is telling you:

“If you give me some potatoes, then I will give you some corn.” [conditional version] “I want some potatoes.” You, in turn, know a little bit of their dialect, and tell them “I want some corn.” [want version]

The cards below represent four people who approached you. One side of the cards tells whether or not you gave the person any potatoes and the other side of the cards tells whether or not that person gave you any corn.

You gave this person potatoes	You gave this person nothing
This person gave you corn	This person gave you nothing

Indicate only the card or the cards you definitely need to turn over to see whether any of these people have cheated you.

The “look for exchange (conditional)” and “look for exchange (want)” conditions presented exactly the same problems, except that the final instruction read as follows:

Indicate only the card or the cards you definitely need to turn over to see whether any of these people have made an exchange with you.

3.2. Results and Discussion

Table 2 presents the percentages of the main selection patterns in the four versions. In both “look for cheater” conditions, the most frequently selected pattern was the correct P and not-Q pattern. In the want version, the proportion of participants who made such a selection

Table 2: Percentage of the Main Selection Patterns in the Four Conditions of Experiment 2 (N = 30)

Pattern	Condition			
	<i>Look for Cheater (Conditional)</i>	<i>Look for Cheater (Want)</i>	<i>Look for Exchange (Conditional)</i>	<i>Look for Exchange (Want)</i>
P, not-Q	33	43	10	0
P, Q	7	13	33	53
P	30	10	30	20
Not-Q	13	17	13	0
Other ^a	17	17	13	27

^a Each of the patterns indicated in the "Other" cells was produced by fewer than four participants.

was similar to the one obtained in FCT's study (43% vs. 50%, respectively), and significantly higher than the one obtained in the corresponding "look for exchange" condition, in which no participant made this selection ($\chi^2(1, N = 60) = 14.14, p < 0.001$). In the conditional version, however, our participants made this selection less often than FCT's ones (33% vs. 66%, respectively). We have no confident explanation for this failure to replicate their results. As we predicted, in both "look for exchange" conditions the most frequently selected pattern was the correct P and Q pattern. Participants produced more such P and Q selections than in the "look for cheater" conditions (conditional versions: $\chi^2(1, N = 60) = 5.10, p < 0.05$; want versions: $\chi^2(1, N = 60) = 9.07, p < 0.01$).

These results confirm our main claim that, in an FCT task, people do as they are told and, in particular, look for a cheater when they are told to do so, just as they look for an exchange when this is what they are told to do. They disconfirm FCT's claim that when people recognize a situation as an exchange and moreover take the perspective of a party, they automatically look for cheaters.

4. Conclusion

Let us be quite clear: nothing we have said and none of the evidence we have mustered implies that the Cosmides (1989) hypothesis about the existence of a specific competence to deal with social exchanges is wrong. What we have tried to show is that this hypothesis, in spite of having been at the center of heated debates in the past 12 years, has not yet been properly experimentally tested, since almost all the evidence is based on the Wason or the FCT selection task, which are inappropriate for this purpose, or on

a mixed Wason/FCT task, which is methodologically unsound. Incidentally, using patients with brain lesions (see Adolphs, 1999) with Wason or FCT selection tasks to test hypotheses about specialized mechanisms for social information processing is just further and more costly use of an inappropriate methodology. In no ways does this constitute independent evidence for the claims based on standard uses of the tasks. There is a variety of methods by means of which Cosmides' hypothesis might be seriously tested (see Sperber & Girotto, in press). Experimenting with the Wason or the FCT selection task is not one of them.

More generally, much of the work done with the selection task should be considered a sunk cost in the history of the psychology of reasoning and further investments of research effort and journal pages in uses of the task should be discouraged.

Notes

- 1 In the Wason selection task, participants are presented with a conditional rule of the form: If an item has the feature P, then it has the feature Q (descriptive versions) or If an item has the feature P, then it should have the feature Q (deontic versions), and with four cards representing individual items. Only half of the information these four cards contain is visible, showing that the four items represented have respectively the P, not-P, Q, and not-Q feature (the cards are accordingly called the P, not-P, Q, and not-Q cards). The full information can be made visible by turning over the card in order to find out whether or not the P and not-P cards also have feature Q, and whether or not the Q and not-Q cards also have feature P. Participants are asked which cards it is necessary to turn over to determine whether the rule is true or false (descriptive version) or obeyed or disobeyed

(deontic versions). Since, as far as these four cards are concerned, the rule is true (or obeyed) unless there are cards combining the P and the not-Q features, the logically correct selection is that of the P and the not-Q cards, either of which could turn out to provide a counterexample to (or a violation of) the rule.

- 2 See also Evans (1989) for an earlier and different relevance-based account of the task, and Sperber and Wilson (1995) for relevance theory.

Chapter 43: Why We Are So Good at Catching Cheaters

JERRY A. FODOR

There is robust experimental evidence that Ss who are required to check whether $P \rightarrow Q$ regularly overlook the relevance of $\sim Q$ s. So, Ss asked to verify (1), though they routinely want to know what the under-18s are drinking, only rarely remember to ask the non-Coke drinkers whether they are under 18 (Wason 1966).

- (1) If someone is under 18 (s)he is drinking Coke.
- (2) It's required that if someone is under 18 (s)he drinks Coke.¹

By contrast, Ss who are told that (2) is a regulation and asked to check whether everyone is in compliance reliably remember to ask anyone not drinking Coke how old (s)he is. It appears that what sort of drinking is going on is somehow more salient if you're evaluating (2) than if you're evaluating (1). Why on earth is that?

One explanation, recently widely bruited, is that we are innately equipped with special, domain-specific, modular mechanisms for cheater detection, and that these mechanisms are better at their job than the other circuits we use for coping with hypotheticals. (See Cosmides and Tooby [1992] and references therein.) The reason we have this high-performance equipment available, it is further explained, is that it would have been useful for us to have it back when we were heavily into hunting and gathering. (A similar theory would account for our uncanny innate ability to navigate according to the earth's magnetic field – *such* a comfort if you're driving home late from a hunt or a gather – except that we haven't got one.) This putative selectional explanation of the data about cheater detection is among the very

small number of flagship results that are supposed to provide experimental support for a neo-Darwinian account of the evolution of cognition. So it's of some polemical significance whether it can be sustained.

In fact, there would seem to be a perfectly plausible, if less imaginative, synchronic explanation of the asymmetry between (1) and (2). The key, I think, is the following intuition, which you are hereby encouraged to share: (1) asserts that there's a conditional relation between P and Q (namely, that Q is true if P is). P is thus one of the relata between which (1) says that this conditional relation obtains (the other being, of course, Q). By contrast, what (2) prohibits isn't anything conditional at all. Rather, (2) categorically prohibits Q , though, to be sure, it imposes its categorical ban on Q only in case that P . It's thus the whole symbol " $P \rightarrow Q$ " that expresses what is asserted by (1). But it's only the " Q " part that expresses what is prohibited by (2). All P does in (2) is determine *on whom the prohibition falls*. If this intuition about the parsing of (2) is correct, then it's hardly surprising that Ss who fail to see non-Coke drinkers as ipso facto prospective falsifiers of (1), are perfectly able to see non-Coke drinkers as ipso facto prospective violators of (2). It is, to repeat, precisely non-Coke drinking that (2) prohibits.

So the mystery about cheater detecting vanishes if we can make it plausible that, whereas in some sense (1) is about its being the case that if P then Q , (2) is about Q 's being mandatory. And it is, in fact, plausible that (1) and (2) differ in just this way. That they do so is built into a difference between the logic of indicative and deontic conditionals; that is, between conditionals that assert truths and those that impose obligations.

Here's a sketch of an argument showing that, whereas it's common ground that "if P then Q " asserts $P \rightarrow Q$, "it's required that if P then Q " requires Q rather than $P \rightarrow Q$.²

- I. Assume, for reductio, that "it's required that if P then Q " is equivalent to *required* ($P \rightarrow Q$).
- II. Assume (*required* $P \rightarrow Q$) & $\sim Q$
- III. The inference scheme ((A & (*required* $A \rightarrow B$)) \rightarrow (*required* B)) is valid. (If it weren't, *Sam is under 18* & (*required* (*if under 18* \rightarrow *drinks coke*)) wouldn't entail *required* (*Sam drinks coke*)).
- IV. *Required* ($P \rightarrow Q$) \rightarrow *required* ($\sim Q \rightarrow \sim P$). Contraposition is valid in the scope of "required." ("Required A " is closed under A 's entailments.)
- V. ($\sim Q$ & (*required* ($\sim Q \rightarrow \sim P$))) \rightarrow *required* ($\sim P$) (by iii and iv, putting $\sim Q$ for A , and putting *required* $\sim Q \rightarrow \sim P$ for *required* $A \rightarrow B$). This says that if it's required that $P \rightarrow Q$, and it's the case that $\sim Q$, then it's required that $\sim P$.

But (see below) there are counterexamples to (v), so the argument that leads to it must be unsound. And, since the only tendentious premise the argument employs is (i), it follows that we should not read "it's required that if P then Q " as *required* ($P \rightarrow Q$).

Here's a case where (ii)–(iv) are true but (v) is false.³ Suppose everyone under 18 is obliged to drink Coke. Then if Sam is under 18, he is prohibited from drinking whiskey. But *it does not follow* that if Sam is drinking whiskey, he is then obliged to be over 18. In fact, Sam *can't* be obliged to be over 18 because he can't be obliged to do *anything* that he is unable to do. And with Sam, as with the rest of us, there's nothing much that he can do about how old he is (in, alas, either direction). I conclude that Authority cannot mandate the conditional (Sam drinks Coke if he is under 18). The only course it can coherently pursue, having taken note of Sam's being under 18, is to mandate categorically that he drink Coke.

So, then, we have an argument that, although *it's true that if $P \rightarrow Q$* is, as it were, really about $P \rightarrow Q$ being true, *it's required that $P \rightarrow Q$* isn't really about $P \rightarrow Q$ being required. *It's required that $P \rightarrow Q$* is about Q being required (in a certain case; viz., in the case that P). Since S s know all this, they hear (2) as *mandating Coke drinking* (in a certain case, viz., when the drinker is

under 18); and since they hear (2) as mandating Coke drinking, they see, straight off, that if (2) is being flouted, whiskey drinkers are among the likely suspects.⁴ That they do see this straight off should hardly be surprising; if the mandate is "drink only Coke," whiskey drinkers are *on the face of it* not in compliance (though, as a lawyer might say, the ones over 18 have secured a variance).⁵

You can assert that $P \rightarrow Q$ or you can assert that Q , whichever you prefer. But since you can't *require* that $P \rightarrow Q$, you likewise can't *cheat* on $P \rightarrow Q$; the best you can do is cheat on Q in case it's the case that P . But that $\sim Q$ s may be cheating on Q should, on anybody's story, be more obvious than that $\sim Q$ s may contradict $P \rightarrow Q$ since, on any reasonable way of counting, $\sim(Q \& \sim Q)$ is more obvious than $((P \rightarrow Q) \& \sim Q) \rightarrow \sim P$. It's plausibly these logical truisms, and not whatever it was that happened to Granny and Gramps on their way to the savannah, that explain why we are so good at detecting cheaters (compared, anyhow, with how bad we are on the standard Wason task).

The received view has it that cheater detection data show that we reason about sentences like (1) and (2) *with different parts of our minds*. The present proposal, not nearly so glamorous, is that we reason about sentences like (1) and (2) *along different inferential routes*. We could hardly do otherwise, considering the structural disanalogies between them that I've just been expounding. In effect, I claim that much, quite possibly all, of the putative experimental evidence for a cheater detection effect on the Wason task conflates the distinction *reasoning with the Law of Contraposition/reasoning with the Law of Contradiction* with the distinction *reasoning about indicative conditionals/reasoning about deontic conditionals*; and is therefore null and void.

Methodological moral: When subjects appear to behave peculiarly in an experimental task, this is not infrequently because they are sensitive to a materials variable that the experimenter has failed to notice.⁶

Notes

- 1 "P" and "Q" correspond, respectively, to "someone is under 18" and "(s)he drinks/is drinking coke." The examples may seem less forced if you add "(rather than whiskey)" as a codicil throughout, and stipulate that "drinks whiskey iff doesn't drink Coke" is true of everybody involved.

- 2 For the record: I think what's in the text is an ok argument and that it does indeed strongly suggest that *P* doesn't belong to the content of what's required in "it's required that if *P* then *Q*." But explaining the cheater detection effect in the Wason task, which is the main point of the discussion, doesn't actually need this argument to be sound. All it needs is the truth of the conclusion, namely, that *Q* is what is required by "it's required that if *P* then *Q*."
- 3 That (v) is invalid doesn't, of course, mean that every inference of that form is unsound. Inferences of an invalid form may nonetheless be sound in light of entailments carried by the *non*logical vocabulary. I'm grateful to Alan Leslie for examples like: "if you borrow my trumpet, you should give me some tomatoes," from which it does follow that if you don't give me the tomatoes, you shouldn't borrow my trumpet. I take it, however, that it's the meaning of "borrow," rather than the logic of conditional deontic inferences per se, that supports contraposition in such cases. Compare "if I sell you my trumpet, you should be grateful," from which it doesn't follow that if you're not grateful I ought not sell you my trumpet.
- 4 The other likely suspects being, of course, drinkers who are under 18. Unsurprisingly, *Ss* evaluating sentences like (1) in the Wason selection task practically always understand that the *P*-card is germane. (The *P*-card is the one that asserts the antecedent of the hypothetical to be verified.) *S* contemplates modus ponens on "If you're under 18, you're required to drink Coke"; so, if you're under 18, *S* wants to know what you're drinking.
- 5 I have, however, encountered an evolutionary psychology enthusiast who did find surprising my claim that if *Ss* construe deontic conditionals in the way I've suggested, then they should see "straight off" that whiskey drinkers are potential violators of "if you're under 18, drink Coke." He held, indeed, that if they did so, that would be as much in need of explanation as the original finding that the Wason task is easier in the cheater-detection version. If he was right, then of course my labor's been in vain; I've only explained one mystery by invoking another. But I suspect him of a merely tactical bemusement. Imagine an experiment in which *S* is told about a party where some are drinking and some are not. *S* is offered for verification "at this party, they are drinking only Coke" and asked whom he'd prefer to interview, the drinkers or the others. Which do you suppose he'll choose?
- 6 Many thanks to David Rosenthal for helping me to sort out all this stuff. He does *Ps* and *Qs* much better than I do.

Chapter 44: The Modularity of Mind: An Essay on Faculty Psychology

JERRY A. FODOR

A Functional Taxonomy of Cognitive Mechanisms

I want to argue that the current best candidates for treatment as *modular* cognitive systems share a certain functional role in the mental life of organisms; the discussion in this section is largely devoted to saying which functional role that is. As often happens in playing cognitive science, it is helpful to characterize the functions of psychological systems by analogy to the organization of idealized computing machines. So, I commence with a brief digression in the direction of computers.

When philosophers of mind think about computers, it is often Turing machines that they are thinking about. And this is understandable. If there is an interesting analogy between minds qua minds and computers qua computers, it ought to be possible to couch it as an analogy between minds and Turing machines, since a Turing machine is, in a certain sense, as general as any kind of computer can be. More precisely: if, as many of us now suppose, minds are essentially symbol-manipulating devices, it ought to be useful to think of minds on the Turing-machine model since Turing machines are (again “in a certain sense”) as general as any symbol-manipulating device can be.

However, as we have already had reason to observe, Turing machines are also very simple devices; their functional architecture is exhaustively surveyed when we have mentioned a small number of interacting subsystems (tape, scanner, printer, and executive) and a small inventory of primitive machine operations (stop, start, move

the tape, read the tape, change state, print). Moreover – and this is the point of present concern – Turing machines are *closed* computational systems; the sole determinants of their computations are the current machine state, the tape configuration, and the program, the rest of the world being quite irrelevant to the character of their performance; whereas, of course, organisms are forever exchanging information with their environments, and much of their psychological structure is constituted of mechanisms which function to mediate such exchanges. If, therefore, we are to start with anything like Turing machines as models in cognitive psychology, we must think of them as embedded in a matrix of subsidiary systems which affect their computations in ways that are responsive to the flow of environmental events. The function of these subsidiary systems is to provide the central machine with information about the world; information expressed by mental symbols in whatever format cognitive processes demand of the representations that they apply to.

I pause to note that the format constraint on the subsidiary systems is vital. *Any* mechanism whose states covary with environmental ones can be thought of as registering information about the world; and, given the satisfaction of certain further conditions, the output of such systems can reasonably be thought of as *representations* of the environmental states with which they covary. (See Dretske, 1981; Stampe, 1977; Fodor, 1987.) But if cognitive processors are *computational* systems, they have access to such information solely in virtue of the *form* of

the representations in which it is couched. Computational processes are, by definition, *syntactic*; a device which makes information available to such processes is therefore responsible for its format as well as its quality. If, for example, we think of such a device as writing on the tape of a Turing machine, then it must write *in a language that the machine can understand* (more precisely, in the language in which the machine computes). Or, to put it in a psychological-sounding way, if we think of the perceptual mechanisms as analogous to such devices, then we are saying that *what perception must do is to so represent the world as to make it accessible to thought*. The condition on appropriateness of format is by way of emphasizing that not every representation of the world will do for this purpose.

I wish that I knew what to call the “subsidiary systems” that perform this function. Here are some possibilities that I have considered and – with varying degrees of reluctance – decided to reject:

– ‘Perceptual systems’ would be the obvious choice except that, as we shall presently see, perception is not the only psychological mechanism that functions to present the world to thought, and I would like a term broad enough to embrace them all. Moreover, as will also become apparent, there are important reasons for not viewing the subsidiary systems as effecting the fixation of belief. By contrast, perception is a mechanism of belief fixation par excellence: the normal consequence of a perceptual transaction is the acquisition of a perceptual belief. (Having entered this caveat, I shall nevertheless often speak of the subsidiary systems as mechanisms of perceptual analysis. For most purposes it is harmless to do so and it does simplify the exposition.)

– I have sometimes thought of calling these subsidiary systems ‘compilers’, thereby stressing that their output consists of representations that are accessible to relatively central computational processes. But that way of talking leads to difficulties too. Real compilers are functions from programs onto programs, programs themselves being (approximately) sequences of instructions. But not much of what perception makes available to thought is plausibly viewed as a program. Indeed, it is partly the attempt to force perceptual information into that mold which engenders procedural semantics, the identification of perceptual categories with action schemes, and other such aberrations of theory. (For discussion, see Fodor, 1981, chapter 8.)

– One could try calling them ‘transducers’ except that, on at least one usual under-

standing (see Lowenstein, 1960), transducers are analog systems that take proximal stimulations onto more or less precisely covarying neural signals. Mechanisms of transduction are thus *contrasted* with computational mechanisms: whereas the latter may perform quite complicated, inference-like transformations, the former are supposed – at least ideally – to preserve the informational content of their inputs, altering *only* the format in which the information is displayed. We shall see, however, that representations at the interface between (what I have been calling) ‘subsidiary’ and ‘central’ systems exhibit levels of encoding that are quite abstractly related to the play of proximal stimulation.

Pylshyn and I (1981) have called these subsidiary systems ‘compiled transducers’, using the ‘compiled’ part to indicate that they have an internal computational structure and the ‘transducer’ part to indicate that they exhibit a certain sort of informational encapsulation that will presently loom large in this discussion. I think that usage is all right given the explication, but it admittedly hasn’t much to do with the conventional import of these terms and thus probably produces as much confusion as it avoids.

It is, perhaps, not surprising that computer theory provides no way of talking that does precisely the job I want to do. Computers generally interface with their environments *via some human being* (which is what makes them computers rather than robots). The programmer thus takes on the function of the subsidiary computational systems that I have been struggling to describe – viz., by providing the machine with information about the world in a form in which the machine can use it. Surprising or not, however, it is a considerable nuisance. Ingenuity having failed me completely, I propose to call them variously ‘input systems’, or ‘input analyzers’ or, sometimes, ‘interface systems’. At least this terminology emphasizes that they operate relatively early on. I rely on the reader to keep it in mind, however, that input systems are *post*-transductive mechanisms according to my usage. Also that switches from one of the epithets to another usually signify no more than a yen for stylistic variation.

So, then, we are to have a trichotomous functional taxonomy of psychological processes; a taxonomy which distinguishes transducers, input systems, and central processors, with the flow of input information becoming accessible to these mechanisms in about that order. These categories are intended to be exclusive but not,

of course, to exhaust the types of psychological mechanisms that a theory of cognition might have reason to postulate. Since the trichotomy is not exhaustive, it is left wide open that there may be modular systems that do not subserve any of these functions. Among the obvious candidates would be systems involved in the motor integration of such behaviors as speech and locomotion. It would please me if the kinds of arguments that I shall give for the modularity of input systems proved to have application to motor systems as well. But I don't propose to investigate that possibility here.

Input systems function to get information into the central processors; specifically, they mediate between transducer outputs and central cognitive mechanisms by encoding the mental representations which provide domains for the operations of the latter. This does not mean, however, that input systems *translate* from the representations that transducers afford into representations in the central code. On the contrary, translation preserves informational content and, as I remarked above, the computations that input systems perform typically do not. Whereas transducer outputs are most naturally interpreted as specifying the distribution of stimulations at the 'surfaces' (as it were) of the organism, the input systems deliver representations that are most naturally interpreted as characterizing the arrangement of *things in the world*. Input analyzers are thus inference-performing systems within the usual limitations of that metaphor. Specifically, the inferences at issue have as their 'premises' transduced representations of proximal stimulus configurations, and as their 'conclusions' representations of the character and distribution of distal objects.

It is hard to see how a computer could fail to exhibit mechanisms of transduction if it is to interface with the world at all. But it is perfectly possible to imagine a machine whose computations are appropriately sensitive to environmental events but which does *not* exhibit a functional distinction between input systems and central systems. Roughly, endorsing this computational architecture is tantamount to insisting upon a perception/cognition distinction. It is tantamount to claiming that a certain class of computational problems of 'object identification' (or, more correctly, a class of computational problems whose solutions consist in the recovery of certain proprietary descriptions of objects) has been 'detached' from the domain of cognition at large and handed over to functionally distinguishable psychological mechanisms. Perceptual

analysis is, according to this model, not, strictly speaking, a species of thought. (The reader is again reminded, however, that the identification of input processing with perceptual analysis is itself only approximate. This will all presently sort itself out; I promise.)

Given the possibility in principle that the perceptual mechanisms could be continuous with the higher cognitive processes, one is tempted to ask what the point of a trichotomous functional architecture could be. What, teleologically speaking, might it buy for an organism that has transducers and central cognitive processors to have input analyzers as well? I think there probably is an answer to this question: Implicit in the trichotomous architecture is the isolation of perceptual analysis from certain effects of background belief and set; and, as we shall see, this has implications for both the speed and the objectivity of perceptual integration. It bears emphasis, however, that putting the teleological issues in the way I just did involves some fairly dubious evolutionary assumptions. To suppose that the issue is *Why, given that there are central processors, should there be input systems as well?* is to take for granted that the former should be viewed as phylogenetically prior to the latter. However, an equally plausible story might have it the other way 'round – viz., that input analyzers, with their (as I shall argue) relatively rigid domain specificity and automaticity of functioning, are the aboriginal prototypes of inference-making psychological systems. Cognitive evolution would thus have been in the direction of gradually freeing certain sorts of problem-solving systems from the constraints under which input analyzers labor – hence of producing, as a relatively late achievement, the comparatively domain-free inferential capacities which apparently mediate the higher flights of cognition. (See Rozin, 1976, where the plausibility of this picture of cognitive phylogeny is impressively defended.)

In any event, the justification for postulating a functionally individuated class of input analyzers distinct from central cognitive mechanisms must finally rest on two sorts of evidence: I have to show that there are interesting things that the input analyzers have in common; and I have to show that there are interesting respects in which they differ from cognitive processes at large. The second of these burdens will be taken up in [the third part of this chapter]. For now, I am going to argue that the functionally specified class *input system* does pick out a "natural kind" for purposes of psychological theory construction; that there

are, in fact, lots of interesting things to say about the common properties of the mechanisms that mediate input analysis.

There is, however, one more preliminary point to make before getting down to that business. To claim that the functional category *input system* picks out a natural kind is to endorse an eccentric taxonomy of cognitive processes. Eyebrows should commence to be raised starting here. For, if you ask “which *are* the psychological mechanisms that can plausibly be thought of as functioning to provide information about the distal environment in a format appropriate for central processing?” the answer would seem to be “the perceptual systems *plus language*.” And this is, from the point of view of traditional ways of carving things up, an odd category.

The traditional taxonomy goes something like this: perception (vision, audition, or whatever) on the one side, and thought-and-language (the representational processes) on the other. Now, the representational character of language is self-evident, and I don’t doubt the theoretical importance of the representational character of thought. (On the contrary, I think that it is *the* essential fact that an adequate theory of the propositional attitudes would have to account for. (See Fodor, 1981, chapter 7.)) But we’re not, of course, committed to there being only one right way of assigning psychological mechanisms to functional classes. The present claim is that, for purposes of assessing the issues about modularity, a rather different taxonomy proves illuminating.

Well then, what precisely *is* the functional similarity between language mechanisms and perceptual mechanisms in virtue of which both count as ‘input systems’? There is, of course, the obvious point that utterances (e.g., sentence tokens) are themselves objects to be perceptually identified, just as mountains, teacups, and four-alarm fires are. Understanding a token sentence presumably involves assigning it a structural description, this being part and parcel of computing a token-to-type relation; and that is precisely the sort of function we would expect an input system to perform. However, in stressing the functional analogy between language and perception, I have something more in mind than the fact that understanding utterances is itself a typical perceptual process.

I’ve said that input systems function to interpret transduced information and to make it available to central processes; and that, in the normal case, what they provide will be information about the “layout” (to borrow a term of

Gibson’s) of distal stimuli. How might such a system work? Heaven knows there are few harder questions; but I assume that, in the case of perception, the answer must include some such story as the following. The character of transducer outputs is determined, in some lawful way, by the character of impinging energy at the transducer surface; and the character of the energy at the transducer surface is itself lawfully determined by the character of the distal layout. Because there are regularities of this latter sort, it is possible to infer properties of the distal layout from corresponding properties of the transducer output. Input analyzers are devices which perform inferences of this sort.

A useful example is Ullman’s (1979) algorithm for inferring “form from motion” in visual perception. Under assumptions (e.g., of rigidity) that distal stimuli usually satisfy, a specific sequence of transformations of the energy distributions at the retina will be reliably interpretable as having been caused by (and hence as specifying) the spatial displacement of a distal object of determinate three-dimensional shape. A device that has access to the transducer outputs can infer this shape by executing Ullman’s (or some equivalent) algorithm. I assume that performing such computations is precisely the function of input systems, Ullman’s case being unusual primarily in the univocality with which the premises of the perceptual inference warrant its conclusion.

Now about language: Just as patterns of visual energy arriving at the retina are correlated, in a complicated but regular way, with certain properties of distal layouts, so too are the patterns of auditory energy that excite the tympanic membrane in speech exchanges. With, of course, this vital difference: What underwrites the correlation between visual stimulations and distal layouts are (roughly) the laws of light reflectance. Whereas, what underwrites the correlation between token utterances and distal layouts is (roughly) a convention of truth-telling. In the root case, the convention is that we say of x that it is F only if x is F . Because that convention holds, it is possible to infer from what one hears said to the way that the world is.¹

Of course, in neither the linguistic nor the perceptual case is the information so provided infallible. The world often isn’t the way it looks to be or the way that people say it is. But, equally of course, input systems don’t have to deliver apodictic truths in order to deliver quite useful information. And, anyhow, *the operation of the input systems should not be identified with the*

fixation of belief. What we *believe* depends on the evaluation of how things look, or are said to be, *in light of background information* about (inter alia) how good the seeing is or how trustworthy the source. Fixation of belief is *just* the sort of thing I have in mind as a typical *central* process.

So much, then, for the similarity of function between the linguistic and the perceptual systems: both serve to get information about the world into a format appropriate for access by such central processes as mediate the fixation of belief. But now, is there anything to be said for exploiting this analogy? What, from the point of view of psychological theory, do we gain by postulating a functional class of perceptual-and-linguistic processes? Clearly, the proof of this pudding is *entirely* in the eating. I'm about to argue that, if we undertake to build a psychology that acknowledges this functional class as a natural kind, we discover that the processes we have grouped together do indeed have many interesting properties in common – properties the possession of which is not entailed by their functional homogeneity. (I take it that that is what a natural kind is: a class of phenomena that have many scientifically interesting properties in common over and above whatever properties define the class.) In the present case, what the input systems have in common besides their functional similarities can be summarized in a phrase: *input systems are modules*. A fortiori, they share those properties that are characteristic of vertical faculties. Input systems are – or so I'll argue – what Gall was right about.

What follows is the elaboration of that claim, together with an occasional glimpse at the state of the evidence. I should say at the outset that not every psychologist would agree with me about what the state of the evidence is. I am arguing well in advance of (and, in some places, a little in the face of) the currently received views. So, perhaps one should take this exercise as in part a thought experiment: I'll be trying to say what you might expect the data to look like if the modularity story is true of input systems; and I'll claim that, insofar as any facts are known, they seem to be generally compatible with such expectations.

Input Systems as Modules

The modularity of the input systems consists in their possession of most or all of the properties now to be enumerated. If there are other psychological systems which possess most or all of these properties then, of course, they are modular too.

It is, however, a main thesis of this work that the properties in virtue of which input systems are modular are ones which, in general, central cognitive processes do not share.

Input Systems are Domain Specific

Let's start with this: how many input systems are there? The discussion thus far might be construed so as to suggest an answer somewhere in the vicinity of six – viz., one for each of the traditional sensory/perceptual 'modes' (hearing, sight, touch, taste, smell) and one more for language. This is *not*, however, the intended doctrine; what is proposed is something much more in the spirit of Gall's bumps. I imagine that within (and, quite possibly, across)² the traditional modes, there are highly specialized computational mechanisms in the business of generating hypotheses about the distal sources of proximal stimulations. The specialization of these mechanisms consists in constraints either on the range of information they can access in the course of projecting such hypotheses, or in the range of distal properties they can project such hypotheses about, or, most usually, on both.

Candidates might include, in the case of vision, mechanisms for color perception, for the analysis of shape, and for the analysis of three-dimensional spatial relations.³ They might also include quite narrowly task-specific 'higher level' systems concerned with the visual guidance of bodily motions or with the recognition of faces of conspecifics. Candidates in audition might include computational systems that assign grammatical descriptions to token utterances; or ones that detect the melodic or rhythmic structure of acoustic arrays; or, for that matter, ones that mediate the recognition of the *voices* of conspecifics. There is, in fact, some evidence for the domain specificity of several of the systems just enumerated, but I suggest the examples primarily by way of indicating the levels of grain which input systems might be modularized.

What, then, are the arguments for the domain specificity of input systems? To begin with, there is a sense in which input systems are ipso facto domain specific in a way in which computational systems at large are not. This is, however, quite uninteresting, a merely semantic point. Suppose, for example, that the function of the mechanisms of visual perception is to map transduced patterns of retinal excitation onto formulas of some central computational code. Then it follows trivially that their computational domain *qua mechanisms of visual perception* is specific to

the class of possible retinal outputs. Correspondingly, if what the language-processing mechanisms do is pair utterance tokens with central formulas, then their computational domains *qua mechanisms of language processing*, must be whatever encodings of utterances the auditory transducer produce. In similar boring fashion, the psychological mechanism that mediate the perception of cows are ipso facto domain specific *qua mechanisms of cow perception*.

From such truisms, it goes without saying, nothing useful follows. In particular, the modularity of a system cannot be inferred from this trivial kind of domain specificity. It is, for example, entirely compatible, with the cow specificity of cow perception that the recognition of cows should be mediated by precisely the same mechanisms that effect the perception of language, or of earth quakes, or of three-masted brigantines. For example, all four could perfectly well be accomplished by one and the same set of horizontal faculties. The interesting notion of domain specificity, by contrast, is Gall's idea that there are distinct psychological mechanisms – *vertical* faculties – corresponding to distinct stimulus domains. It is this latter claim that's now at issue.

Evidence for the domain specificity of an input analyzer can be of a variety of different sorts. Just occasionally the argument is quite direct and the demonstrations correspondingly dramatic. For example, there are results owing to investigators at the Haskins Laboratories which strongly suggest the domain specificity of the perceptual systems that effect the phonetic analysis of speech. The claim is that these mechanisms are different from those which effect the perceptual analysis of auditory nonspeech, and the experiments show that how a signal sounds to the hearer does depend, in rather startling ways, on whether the acoustic context indicates that the stimulus is an utterance. Roughly, the very same signal that is heard as the onset of a consonant when the context specifies that the stimulus is speech is heard as a "whistle" or "glide" when it is isolated from the speech stream. The rather strong implication is that the computational systems that come into play in the perceptual analysis of speech are distinctive in that they operate *only* upon acoustic signals that are taken to be utterances. (See Liberman et al., 1967; for further discussion, see Fodor, Bever, and Garrett, 1974.)

The Haskins experiments demonstrate the domain specificity of an input analyzer by showing that only a relatively restricted class of stim-

ulations can throw the switch that turns it on. There are, however, other kinds of empirical arguments that can lead to the same sort of conclusions. One that has done quite a lot of work for cognitive scientists goes like this: If you have an *eccentric* stimulus domain – one in which perceptual analysis requires a body of information whose character and content is specific to that domain – then it is plausible that psychological processes defined over that domain may be carried out by relatively special purpose computational systems. All things being equal, the plausibility of this speculation is about proportional to the eccentricity of the domain.

Comparing perceiving cows with perceiving sentences will help to show what's going on here. I really have no idea how cow perception works, but let's follow the fashions and suppose, for purposes of discussion, that we use some sort of prototype-plus-similarity-metric. That is, the perceptual recognition of cows is effected by some mechanism which provides solutions for computational problems of the form: how similar – how 'close' – is the distal stimulus to a prototypical cow? My point is that if that's the way it's done, then cow perception might be mediated by much the same mechanisms that operate in a large variety of other perceptual domains as well – in fact, in any domain that is organized around prototypes. This is because we can imagine a quite general computational system which, given a specification of a prototype and a similarity metric for an arbitrary domain of percepts, will then compute the relevant distance relations in that domain. It seems plausible, that is to say, that procedures for estimating the distance between an input and a perceptual prototype should have pretty much the same computational structure wherever they are encountered.

It is, however, most unlikely that the perceptual recognition of sentences should be mediated by such procedures, and that is because sentence tokens constitute a set of highly *eccentric* stimuli: All the available evidence suggests that the computations which sentence recognizers perform must be closely tuned to a complex of stimulus properties that is quite specific to sentences. Roughly, the idea is that the structure of the sentence recognition system is responsive to universal properties of language and hence that the system works only in domains which exhibit these properties.

I take it that this story is by now pretty well known. The argument goes like this: Consider the class of *nomologically possible human*

languages. There is evidence that this class constitutes quite a small subset of the logically possible linguistic systems. In particular, the nomologically possible human languages include only the ones that satisfy a set of (contingent) generalizations known as the 'linguistic universals.' One way to find out something about what linguistic universals there are is by examining and comparing *actual* human languages (French, English, Urdu, or whatever) with an eye to determining which properties they have in common. Much work in linguistics over the last twenty-five years or so has pursued this strategy, and a variety of candidate linguistic universals have been proposed, both in phonology and in syntax.

It seems quite unlikely that the existence of these universals is merely fortuitous, or that they can be explained by appeal to historical affinities among the languages that share them or by appeal to whatever pragmatic factors may operate to shape communication systems. (By pragmatic factors, I mean ones that involve general properties of communication exchanges as such, including the utilities of the partners to the exchanges. So, for example, Putnam (1961) once suggested that there are grammatical transformations because communicative efficiency is served by the deletion of redundant portions of messages, etc.) The obvious alternative to such accounts is to assume that the universals represent biases of a species-specific language-learning system, and a number of proposals have been made about how, in detail, such systems might be pretuned. It is assumed, according to all these accounts, that the language-learning mechanisms 'know about' the universals and operate only in domains in which the universals are satisfied. (For a review, see Pinker, 1979.)

Parity of argument suggests that a similar story should hold for the mechanisms of language *perception*. In particular, the perceptual system involved is presumed to have access to information about how the universals are realized in the language it applies to. The upshot of this line of thought is that the perceptual system for a language comes to be viewed as containing quite an elaborate theory of the objects in its domain; perhaps a theory couched in the form of a grammar of the language. Correspondingly, the process of perceptual recognition is viewed as the application of that theory to the analysis of current inputs. (For some recent work on the parsing of natural language, see Marcus, 1977; Kaplan and Bresnan, 1982; and Frazier and Fodor, 1978. All these otherwise quite different

approaches share the methodological framework just outlined.)

To come to the moral: Since the satisfaction of the universals is supposed to be a property that distinguishes sentences from other stimulus domains, the more elaborate and complex the theory of universals comes to be the more eccentric the stimulus domain for sentence recognition. And, as we remarked above, the more eccentric a stimulus domain, the more plausible the speculation that it is computed by a special-purpose mechanism. It is, in particular, very hard to see how a device which classifies stimuli in respect of distance from a prototype could be recruited for purposes of sentence recognition. The computational question in sentence recognition seems to be not "How far to the nearest prototype?" but rather "How does the theory of the language apply to the analysis of the stimulus now at hand?"

There are probably quite a lot of kinds of relatively eccentric stimulus domains – ones whose perceptual analysis requires information that is highly specific to the domain in question. The organization of sentence perception around syntactic and phonological information does not exhaust the examples even in the case of language. So, for a further example, it is often and plausibly proposed that the processes that mediate phone recognition must have access to an internal model of the physical structure of the vocal apparatus. The argument is that a variety of constancies in speech perception seem to have precisely the effect of undoing garble that its inertial properties produce when the vocal mechanism responds to the phonetic intentions of the speaker. If this hypothesis is correct, then phone recognition is quite closely tuned to the mechanisms of speech production (see note 2). Once again, highly tuned computations are suggestive of special-purpose processors. Analogous points could be made in other perceptual modes. Faces are favorite candidates for eccentric stimuli (see Yin, 1969, 1970; Carey, 1978); and as I mentioned above, Ullman's work has made it seem plausible that the visual recognition of three-dimensional form is accomplished by systems that are tuned to the eccentricities of special classes of rigid spatial transformations.

From our point of view, the crucial question in all such examples is: how good is the inference from the eccentricity of the stimulus domain to the specificity of the corresponding psychological mechanisms? I am, in fact, not boundlessly enthusiastic about such inferences; they are clearly a long way from apodictic. Chess

playing, for example, exploits a vast amount of eccentric information, but nobody wants to postulate a chess faculty. (Well, *almost* nobody. It is of some interest that recent progress in the artificial intelligence of chess has been achieved largely by employing specialized hardware. And, for what it's worth, chess is notably one of those cognitive capacities which breeds prodigies; so it is a candidate for modularity by Gall's criteria if not by mine.) Suffice it, for the present to suggest that it is probably characteristic of many modular systems that they operate in eccentric domains, since a likely motive for modularizing a system is that the computations it performs are idiosyncratic. But the converse inference – from the eccentricity of the domain to the modularity of the system – is warranted by nothing stronger than the maxim: specialized systems for specialized tasks. The most transparent situation is thus the one where you have a mechanism that computes an eccentric domain and is also modular by independent criteria; the eccentricity of the domain rationalizes the modularity of the processor and the modularity of the processor goes some way towards explaining how the efficient computation of eccentric domains is possible.

The Operation of Input Systems is Mandatory

You can't help hearing an utterance of a sentence (in a language you know) as an utterance of a sentence, and you can't help seeing a visual array as consisting of objects distributed in three-dimensional space. Similarly, *mutatis mutandis*, for the other perceptual modes: you can't, for instance, help feeling what you run your fingers over as the surface of an object.⁴ Marslen-Wilson and Tyler (1981), discussing word recognition, remark that "... even when subjects are asked to focus their attention on the acoustic-phonetic properties of the input, they do not seem to be able to avoid identifying the words involved. ... This implies that the kind of processing operations observable in spoken-word recognition are mediated by automatic processes which are obligatorily applied. ..." (p. 327).

The fact that input systems are apparently constrained to apply whenever they can apply is, when one thinks of it, rather remarkable. There is every reason to believe that, in the general case, the computational relations that input systems mediate – roughly, the relations between transducer outputs and percepts – are quite remote. For example, on all current theories, it requires elaborate processing to get you from the repre-

sentation of a proximal stimulus that the retina provides to a representation of the distal stimuli as an array of objects in space.⁵ Yet we apparently have no choice but to take up this computational burden whenever it is offered. In short, the operation of the input systems appears to be, in this respect, inflexibly insensitive to the character of one's utilities. You can't hear speech as noise *even if you would prefer to*.

What you can do, of course, is choose not to hear it at all – viz., not attend.⁶ In the interesting cases – where this is achieved without deactivating a transducer (e.g., by sticking your fingers in your ears) – the strategy that works best is rather tortuous: one avoids attending to x by deciding to concentrate on y , thereby taking advantage of the difficulty of concentrating on more than one thing at a time. It may be that, when this strategy is successful, the unattended input system does indeed get selectively 'switched off', in which case there is a somewhat pickwickian sense in which voluntary control over the operation of an input system is circuitously achieved. Or it may be that the unattended input systems continue to operate but lose their access to some central processes (e.g., to those that mediate storage and report). The latter account is favored, at least for the case of language perception, in light of a fair number of results which seem to show relatively high-level processing of the unattended channel in dichotic listening tasks (Lackner and Garrett, 1973; Corteen and Wood, 1972; Lewis, 1970). But since the experimental results in this area are not univocal perhaps the most conservative claim is this: input analysis is mandatory in that it provides the *only* route by which transducer output can gain access to central processes; if transduced information is to affect thought at all, it must do so via the computations that input systems perform.

I suppose one has to enter a minor caveat. Painters, or so I'm told, learn a little to undo the perceptual constancies and thus to see the world in something like the terms that the retina must deliver – as a two-dimensional spread of color discontinuities varying over time. And it is alleged that phoneticians can be taught to hear their language as something like a sound-stream – viz., as something like what the spikes in the auditory nerves presumably encode. (Though, as a matter of fact, the empirical evidence that phoneticians are actually able to do this is equivocal; see, for example, Lieberman, 1965.) But I doubt that we should take these highly skilled phenomenological reductions very seriously as counterexamples to the

generalization that input processes are mandatory. For one thing, precisely because they *are* highly skilled, they may tell us very little about the character of normal perceptual processing. Moreover, it is tendentious – and quite possibly wrong – to think of what painters and phoneticians learn to do as getting access to, as it were, raw transducer output. An at least equally plausible story is that what they learn is how to ‘correct’ perceptually interpreted representations in ways that compensate for constancy effects. On this latter view, “seeing the visual field” or “hearing the speech stream” are *supersophisticated* perceptual achievements. I don’t know which of these stories is the right one, but the issue is clearly empirical and oughtn’t to be prejudged.

Anyhow, barring the specialized achievements of painters and phoneticians, one simply cannot see the world under its retinal projection and one has practically no access to the acoustics of utterances in languages that one speaks. (You all know what Swedish and Chinese sound like; what does *English* sound like?) In this respect (and in other respects too, or so I’ll presently argue) the input mechanisms approximate the condition often ascribed to reflexes: they are automatically triggered by the stimuli that they apply to. And this is true for both the language comprehension mechanisms and the perceptual systems traditionally so-called.

It is perhaps unnecessary to remark that it does *not* seem to be true for nonperceptual cognitive processes. We have only the narrowest of options about how the objects of perception shall be represented, but we have all the leeway in the world as to how we shall represent the objects of *thought*; outside perception, the way that one deploys one’s cognitive resources, is, in general, rationally subservient to one’s utilities. Here are some exercises that you can do if you choose: think of *Hamlet* as a revenge play; as a typical product of Mannerist sensibility; as a pot-boiler; as an unlikely vehicle for Greta Garbo. Think of sixteen different ways of using a brick. Think of an utterance of “All Gaul is divided into three parts” as an acoustic object. Now try *hearing* an utterance of “All Gaul is divided into three parts” as an acoustic object. Notice the difference.

No doubt there are *some* limits to the freedom that one enjoys in rationally manipulating the representational capacities of thought. If, indeed, the Freudians are right, more of the direction of thought is mandatory – not to say obsessive – than the uninitiated might suppose. But the quantitative difference surely

seems to be there. There is, as the computer people would put it, “executive control” over central representational capacities; and intellectual sophistication consists, in some part, in being able to exert that control in a manner conducive to the satisfaction of one’s goals – in ways, in short, that seem likely to get you somewhere. By contrast, perceptual processes apparently apply willy-nilly in disregard of one’s immediate concerns. “I couldn’t help hearing what you said” is one of those clichés which, often enough, expresses a literal truth; and it is what is *said* that one can’t help hearing, not just what is *uttered*.

There is Only Limited Central Access to the Mental Representations That Input Systems Compute

It is worth distinguishing the claim that input operations are mandatory (you can’t but hear an utterance of a sentence *as* an utterance of a sentence) from the claim that what might be called ‘interlevels’ of input representation are, typically, relatively inaccessible to consciousness. Not only must you hear an utterance of a sentence as such, but, to a first approximation, you can hear it *only* that way.

What makes this consideration interesting is that, according to all standard theories, the computations that input systems perform typically proceed via the assignment of a number of intermediate analyses of the proximal stimulation. Sentence comprehension, for example, involves not only acoustic encoding but also the recovery of phonetic and lexical content and syntactic form. Apparently an analogous picture applies in the case of vision, where the recognition of a distal array as, say, a-bottle-on-a-table-in-the-corner-of-the-room proceeds via the recovery of a series of preliminary representations (in terms of visual frequencies and primal sketches *inter alia*. For a review of recent thinking about interlevels of visual representation, see Zucker, 1981).

The present point is that the subject doesn’t have equal access to all of these ascending levels of representation – not at least if we take the criterion of accessibility to be the availability for explicit report of the information that these representations encode. Indeed, as I remarked above, the lowest levels (the ones that correspond most closely to transducer outputs) appear to be completely *inaccessible* for all intents and purposes. The rule seems to be that, even if perceptual processing goes from ‘bottom to top’ (each level of representation of a stimulus

computed being more abstractly related to transducer outputs than the one that immediately preceded), still *access* goes from top down (the further you get from transducer outputs, the more accessible the representations recovered are to central cognitive systems that presumably mediate conscious report).

A plausible first approximation might be that only such representations as constitute the *final* consequences of input processing are fully and freely available to the cognitive processes that eventuate in the voluntary determination of overt behavior. This arrangement of accessibility relations is reasonable enough assuming, on the one hand, that the computational capacities of central cognitive systems are not inexhaustible in their ability to attend to impinging information and, on the other, that it is the relatively abstract products of input-processing that encode most of the news that we are likely to want to know. I said in [the previous] section that the operation of input systems is relatively insensitive to the subject's utilities. By contrast, according to this account, the architectural arrangements that govern exchanges of information between input systems and other mechanisms of cognition do reflect aspects of the organism's standing concerns.

The generalization about the relative inaccessibility of intermediate levels of input analysis is pretty rough, but all sorts of anecdotal and experimental considerations suggest that something of the sort is going on. A well known psychological party trick goes like this:

E: Please look at your watch and tell me the time.

S: (Does so.)

E: Now tell me, without looking again, what is the shape of the numerals on your watch face?

S: (Stumped, evinces bafflement and awe.) (See Morton, 1967)

The point is that visual information which specifies the shape of the numerals must be registered when one reads one's watch, but from the point of view of access to later report, that information doesn't take. One recalls, as it were, pure position with no shape in the position occupied. There are analogous anecdotes to the effect that it is often hard to remember whether somebody you have just been talking to has a beard (or a moustache, or wears glasses). Yet visual information that specifies a beard must be registered and processed whenever you recognize a bearded face. More anecdote: Almost nobody can tell you how the letters and numbers are grouped on a telephone dial, though you use this information

whenever you make a phone call. And Nickerson and Adams (1979) have shown that not only are subjects unable to describe a Lincoln penny accurately, they also can't pick out an accurate drawing from ones that get it grossly wrong.

There are quite similar phenomena in the case of language, where it is easy to show that details of syntax (or of the choice of vocabulary) are lost within moments of hearing an utterance, only the gist being retained. (Which did I just say was rapidly lost? Was it the syntactic details or the details of syntax?) Yet it is inconceivable that such information is not registered somewhere in the comprehension process and, within limits, it is possible to enhance its recovery by the manipulation of instructional variables. (For edifying experiments, see Sachs, 1967; Wanner, 1968.)

These sorts of examples make it seem plausible that the relative inaccessibility of lower levels of input analysis is at least in part a matter of how priorities are allocated in the transfer of representations from relatively short- to relatively long-term memory.⁷ The idea would be that only quite high-level representations are stored, earlier ones being discarded as soon as subsystems of the input analyzer get the goodness out of them. Or, more precisely, intermediate input representations, when not discarded, are retained only at special cost in memory or attention, the existence of such charges-for-internal-access being itself a prototypical feature of modular systems.

This is, no doubt, part of the story. Witness the fact that in tasks which minimize memory demands by requiring comparison of *simultaneously* presented stimuli, responses that are sensitive to stimulus properties specified at relatively low levels of representation are frequently *faster* than responses to properties of the sort that high-level representations mark. Here, then, the ordering of relative accessibility reverses the top-to-bottom picture proposed above. It may be worth a digression to review some relevant findings.

The classical experimental paradigm is owing to Posner (1978). S's are required to respond 'yes' to visually presented letter pairs when they are *either* font identical (t,t; T,T) *or* alphabetically identical (t,T; T,t). The finding is that when letters in a pair are presented *simultaneously*, response to alphabetically identical pairs that are also font identical is faster than response to pairs that are identical alphabetically but not in font. This effect diminishes asymptotically with increase in the interstimulus interval when the letters are presented *sequentially*.

A plausible (though not mandatory) interpretation is that the representation that specifies the physical shape of the impinging stimulus is computed earlier than representations that specify its alphabetic value. (At a minimum, *some* shape information must be registered prior to alphabetic value, since alphabetic value depends upon shape.) In any event, the fact that representations of shape can drive voluntary responses suggests that they must be available to central processes at *some* point in the course of S's interaction with the stimulus. And this suggests, in turn, that the inaccessibility of font- as compared with alphabetic-information over the relatively long term must be a matter of how memory is deployed rather than of the intrinsic opacity of low-level representations to high-level processes. It looks as though, in these cases, the relative unavailability of lower levels of input analysis is primarily a matter of the way that the subsystems of the input processors interface with memory systems. It is less a matter of information being unconscious than of its being unrecalled. (See also Crowder and Morton, 1969.)

It is unlikely, however, that this is the whole story about the inaccessibility of interlevels of input analysis. For one thing, as was remarked above, some very low levels of stimulus representation appear to be absolutely inaccessible to report. It is, to all intents and purposes (i.e., short of extensive training of the subject) impossible to elicit voluntary responses that are selectively sensitive to subphonetic linguistic distinctions (or, in the case of vision, to parameters of the retinal projection of distal objects) even though we have excellent theoretical grounds for supposing that such information must be registered somewhere in the course of linguistic (/visual) processing. And not *just* theoretical grounds: *we can often show that aspects of the subject's behavior are sensitive to the information that he can't report.*

For example, a famous result on the psychophysics of speech argues that utterances of syllables may be indistinguishable despite very substantial differences in their acoustic structure *so long as these differences are subphonetic*. When, however, quantitatively identical acoustic differences happen to be, as, linguists say, 'contrastive' – i.e., when they mark distinctions between phones – they will be quite discriminable to the subject; as distinguishable, say, as "ba" is from "pa". It appears, in short, that there is a perceptual constancy at work which determines, in a wide range of cases, that only such acoustic differences as have linguistic value are

accessible to the hearer in discrimination tasks. (See Liberman, et al., 1967.) What is equally striking, however, is that these 'inaccessible' differences *do affect reaction times*. Suppose a/a and a/b are utterance pairs such that the members of the first pair are literally acoustically identical and the members of the second differ only in *noncontrastive* acoustic properties – i.e., the acoustic distinction between a and b is subphonetic. As we have seen, it is possible to choose such properties so that the members of the a/b pair are perceptually indistinguishable (as are, of course, the members of the pair a/a). Even so, in such cases reaction times to make the 'same' judgment for the a/a pair are reliably faster than reaction times to make the 'same' judgment for the a/b pair. (Pisoni and Tash, 1974.) The subject can't report – and presumably can't hear – the difference between signal a and signal b, but his behavior is sensitive to it all the same.

These kinds of cases are legion in studies of the constancies, and this fact bears discussion. The *typical* function of the constancies is to engender perceptual similarity in the face of the variability of proximal stimulation. Proximal variation is very often misleading; the world is, in general, considerably more stable than are its projections onto the surfaces of transducers. Constancies correct for this, so that in general percepts correspond to distal layouts *better than* proximal stimuli do. But, of course, the work of the constancies would be undone unless the central systems which run behavior were required largely to ignore the representations which encode *unconnected* proximal information. The obvious architectural solution is to allow central systems to access information engendered by proximal stimulation *only after* it has been run through the input analyzers. Which is to say that central processes should have free access only to the *outputs* of perceptual processors, interlevels of perceptual processing being correspondingly opaque to higher cognitive systems. This, I'm claiming, is the architecture that we in fact do find.

There appears, in short, to be a generalization to state about input systems as such. Input analysis typically involves *mediated* mappings from transducer outputs onto percepts – mappings that are effected via the computation of interlevels of representation of the impinging stimulus. These intermediate representations are sometimes absolutely inaccessible to central processes, or, in many cases, they are accessible at a price: you can get at them, but only by imposing special demands upon memory or attention. Or,

to put it another way: To a first approximation, input systems can be freely queried by memory and other central systems only in respect of *one* of the levels of representation that they compute; and the level that defines this interface is, in general, the one that is most abstractly related to transduced representations. This claim, if true, is substantive; and if, as I believe, it holds for input systems at large, then that is another reason to believe that the construct *input system* subsumes a natural kind.

Input Systems are Fast

Identifying sentences and visual arrays are among the fastest of our psychological processes. It is a little hard to quantify this claim because of unclarity about the individuation of mental activities. (What precisely are the boundaries of the processes to be compared? For example, where does sentence (*scene*) *recognition* stop and more central activities take over? [...]) Still, granting the imprecision, there are more than enough facts around to shape one's theoretical intuitions.

Among the simplest of voluntary responses are two-choice reactions (push the button if the left-hand light goes on). The demands that this task imposes upon the cognitive capacities are minimal, and a practiced subject can respond reliably at latencies on the low side of a quarter of a second. It thus bears thinking about that the recovery of semantic content from a spoken sentence can occur at speeds quite comparable to those achieved in the two-choice reaction paradigm. In particular, appreciable numbers of subjects can 'shadow' continuous speech with a quarter-second latency (shadowing is repeating what you hear as you hear it) and, contrary to some of the original reports, there is now good evidence that such 'fast shadowers' understand what they repeat. (See Marslen-Wilson, 1973.) Considering the amount of processing that must go on in sentence comprehension (unless all our current theories are *totally* wrongheaded), this finding is mind-boggling. And, mind-boggling or otherwise, it is clear that shadowing latency is an extremely conservative measure of the speed of comprehension. Since shadowing requires *repeating* what one is hearing, the 250 msec. of lag between stimulus and response includes not only the time required for the perceptual analysis of the message, but also the time required for the subject's integration of his verbalization.

In fact, it may be that the phenomenon of fast shadowing shows that the efficiency of lan-

guage processing comes very close to achieving theoretical limits. Since the syllabic rate of normal speech is about 4 per second, the observed 250 msec. latency is compatible with the suggestion that fast shadowers are processing speech in syllable-length units – i.e., that the initiation of the shadower's response is commenced upon the identification of each syllable-length input. Now, work in the psychoacoustics of speech makes it look quite likely that the syllable is the shortest linguistic unit that *can* be reliably identified in the speech stream (see Liberman et al., 1967). Apparently, the acoustic realizations of shorter linguistic forms (like phones) exhibit such extreme context dependence as to make them unidentifiable on a unit-by-unit basis. Only at the level of the syllable do we begin to find stretches of wave form whose acoustic properties are at all reliably related to their linguistic values. If this is so, then it suggests the following profoundly depressing possibility: the responses of fast shadowers lag a syllable behind the stimulus *not* because a quarter second is the upper bound on the speed of the mental processes that mediate language comprehension, but rather because, if the subject were to go any faster, he would overrun the ability of the speech stream to signal linguistic distinctions.⁸

In the attempt to estimate the speed of computation of visual processing, problems of quantification are considerably more severe. On the one hand, the stimulus is not usually spread out in time, so it's hard to determine how much of the input the subject registers before initiating his identificatory response. And, on the other hand, we don't have a taxonomy of visual stimuli comparable to the classification of utterance tokens into linguistic types. Since the question what type a linguistic token belongs to is a great deal clearer than the corresponding question for visual arrays, it is even less obvious in vision than in speech what sort of response should count as indicating that a given array has been identified.

For all of which there is good reason to believe that given a motivated decision about how to quantify the observations, the facts about visual perception would prove quite as appalling as those about language. For example, in one study by Haber (1980), subjects were exposed to 2,560 photographic slides of randomly chosen natural scenes, each slide being exposed for an interval of 10 seconds. Performance on recognition recall (ability to correctly identify a test slide as one that had been seen previously) approached 90 percent one hour after the original exposure. Haber remarks that the results

“suggest that recognition of pictures is essentially perfect.” Recent work by Potter (personal communication) indicates that 10 seconds of exposure is actually a great deal more than subjects need to effect a perceptual encoding of the stimulus adequate to mediate this near-perfect performance. According to Potter, S’s performance in the Haber paradigm asymptotes at an exposure interval of about 2 seconds per slide.

There are some other results of Potter’s (1975) that make the point still more graphically. S is shown a sequence of slides of magazine photographs, the rate of presentation of the slides being the experimentally manipulated variable. Prior to each sequence, S is provided with a brief description of an object or event that may appear in one or another slide – e.g., a boat, two men drinking beer, etc. S is to attend to the slides, responding when he sees one that satisfies the description. Under these conditions, S’s respond with better than 70 percent accuracy when each slide is exposed for 125 msec. Accuracy asymptotes (at around 96 percent) at exposure times of 167 msec, per slide. It is of some interest that S’s are as good at this task as they are at recognition recall (i.e., at making the global judgment that a given slide is one that they have seen before).

Two first-blush morals should be drawn from such findings about the computational efficiency of input processes. First, it contrasts with the relative slowness of paradigmatic central processes like problem-solving; and, second, it is presumably no accident that these very fast psychological processes are mandatory.

The first point is, I suppose, intuitively obvious: one can, and often does, spend hours thinking about a problem in philosophy or chess, though there is no reason to suppose that the computational complexity of these problems is greater than that of the ones that are routinely solved effortlessly in the course of perceptual processing. Indeed, the puzzle about input analysis is precisely that the computational complexity of the problem to be solved doesn’t seem to predict the difficulty of solving it; or, rather, if it does, the difference between a ‘hard’ problem and an ‘easy’ one is measured not in months but in milliseconds. This dissimilarity between perception and thought is surely so adequately robust that it is unlikely to be an artifact of the way that we individuate cognitive achievements. It is only in trick cases, of the sorts that psychologists devise in experimental laboratories, that the perceptual analysis of an utterance or a visual scene is other than effectively instan-

aneous. What goes on when you parse a standard psycholinguistic poser like “the horse raced past the barn fell” is, almost certainly, *not* the same sort of processing that mediates sentence recognition in the normal case. They even *feel* different.

Second, it may well be that processes of input analysis are fast *because* they are mandatory. Because these processes are automatic, you save computation (hence time) that would otherwise have to be devoted to deciding whether, and how, they ought to be performed. Compare: eye-blink is a fast response *because* it is a reflex – i.e., because you don’t have to *decide* whether to blink your eye when someone jabs a finger at it. Automatic responses are, in a certain sense, deeply unintelligent; of the whole range of computational (and, eventually, behavioral) options available to the organism, only a stereotyped subset is brought into play. But what you save by indulging in this sort of stupidity is *not having to make up your mind*, and making your mind up takes time. Reflexes, whatever their limitations, are not in jeopardy of being sicklied o’er with the pale cast of thought. Nor are input processes, according to the present analysis.

There is, however, more than this to be said about the speed of input processes. We’ll return to the matter shortly.

Input Systems are Informationally Encapsulated

Some of the claims that I’m now about to make are in dispute among psychologists, but I shall make them anyway because I think that they are true. I shall run the discussion in this section largely in terms of language, though, as usual, it is intended that the morals should hold for input systems at large.

I remarked above that, almost certainly, understanding an utterance involves establishing its analysis at several different levels of representation: phonetic, phonological, lexical, syntactic; and so forth. Now, in principle, information about the probable structure of the stimulus at any of these levels could be brought to bear upon the recovery of its analysis at any of the others. Indeed, in principle *any* information available to the hearer, including meteorological information, astrological information, or – rather more plausibly – information about the speaker’s probable communicative intentions could be brought to bear at any point in the comprehension process. In particular, it is entirely possible that, in the course of computing

a structural description, information that is specified only at relatively high levels of representation should be 'fed back' to determine analyses at relatively lower levels.⁹ But though this is possible in principle, the burden of my argument is going to be that the operations of input systems are in certain respects unaffected by such feedback.

I want to emphasize the 'in certain respects'. For there exist, in the psychological literature, dramatic illustrations of the effects of information feedback upon some input operations. Consider, for example, the 'phoneme restoration effect' (Warren, 1970). You make a tape recording of a word (as it might be, the word "legislature") and you splice out one of the speech sounds (as it might be, the 's'), which you then replace with a tape recording of a cough. The acoustic structure of the resultant signal is thus /legi(cough)lature/. But what a subject will *hear* when you play the tape to him is an utterance of /legislature/ with a cough 'in the background'. It surely seems that what is going on here is that the perceived phonetic constituency of the utterance is determined not just by the transduced information (not just by information specified at *sub*-phonetic levels of analysis) but also by higher-level information about the probable lexical representation of the utterance (i.e., by the subject's guess that the intended utterance was probably /legislature/).

It is not difficult to imagine how this sort of feedback might be achieved. Perhaps, when the stimulus is noisy, the subject's mental lexicon is searched for a 'best match' to however much of the phonetic content of the utterance has been securely identified. In effect, the lexicon is queried by the instruction 'Find an entry some ten phones long, of which the initial phone sequence is /legi/ and the terminal sequence is /lature/.' The reply to this query constitutes the lexical analysis under which the input is heard.

Apparently rather similar phenomena occur in the case of visual scotoma (where neurological disorders produce a 'hole' in the subject's visual field). The evidence is that scotoma can mask quite a lot of the visual input without creating a phenomenal blind spot for the subject. What happens is presumably that information about higher-level redundancies is fed back to 'fill in' the missing sensory information. Some such process also presumably accounts for one's inability to 'see' one's retinal blind spot.

These sorts of considerations have led some psychologists (and many theorists in AI) to pro-

pose relentlessly top-down models of input analysis, in which the perceptual encoding of a stimulus is determined largely by the subject's (conscious or unconscious) beliefs and expectations, and hardly at all by the stimulus information that transducers provide. Extreme examples of such feedback-oriented approaches can be found in Schank's account of language comprehension, in Neisser's early theorizing about vision, and in 'analysis by synthesis' approaches to sentence parsing. Indeed, a sentimental attachment to what are known generically as 'New Look' accounts of perception (Bruner, 1957) is pervasive in the cognitive science community. It will, however, be a main moral of this discussion that the involvement of certain sorts of feedback in the operation of input systems would be incompatible with their modularity, at least as I propose to construe the modularity thesis. One or other of these doctrines will have to go.

In the long run, which one goes will be a question of how the data turn out. Indeed, a great deal of the empirical interest of the modularity thesis lies in the fact that the experimental predictions it makes tend to be diametrically opposed to the ones that New Look approaches license. But experiments to one side, there are some *prima facie* reasons for doubting that the computations that input systems perform could have anything like unlimited access to high-level expectations or beliefs. These considerations suggest that even if there are *some* perceptual mechanisms whose operations are extensively subject to feedback, there must be others that compute the structure of a percept largely, perhaps solely, in isolation from background information.

For one thing, there is the widely noted persistence of many perceptual illusions (e.g., the Ames room, the phi phenomenon, the Muller-Lyer illusion in vision; the phoneme restoration and click displacement effects in speech) even in defiance of the subject's explicit knowledge that the percept is illusory. The very same subject who can tell you that the Muller-Lyer arrows are identical in length, who indeed has seen them measured, still finds one looking longer than the other. In such cases it is hard to see an alternative to the view that at least *some* of the background information at the subject's disposal is inaccessible to at least some of his perceptual mechanisms.

An old psychological puzzle provides a further example of this kind. When you move your head, or your eyes, the flow of images across the retina may be identical to what it would be were

the head and eyes to remain stationary while the scene moves. So: why don't we experience apparent motion when we move our eyes? Most psychologists now accept one or other version of the "corollary discharge" answer to this problem. According to this story, the neural centers which initiate head and eye motions communicate with the input analyzer in charge of interpreting visual stimulations (see Bizzi, 1968). Because the latter system knows what the former is up to, it is able to discount alterations in the retinal flow that are due to the motions of the receptive organs.

Well, the point of interest for us is that this visual-motor system is informationally encapsulated. Witness the fact that, if you (gently) push your eyeball with your finger (as opposed to moving it in the usual way: by an exercise of the will), you *do* get apparent motion. Consider the moral: when you voluntarily move your eyeball with your finger, you certainly are possessed of the information that it's your eye (and not the visual scene) that is moving. This knowledge is absolutely explicit; if I ask you, you can *say* what's going on. But this explicit information, available to you for (e.g.) report, is *not* available to the analyzer in charge of the perceptual integration of your retinal stimulations. That system has access to corollary discharges from the motor center *and to no other information that you possess*. Modularity with a vengeance.

We've been surveying first blush considerations which suggest that at least some input analyzers are encapsulated with respect to at least some sorts of feedback. The next of these is a point of principle: feedback works only to the extent that the information which perception supplies is redundant; and it is possible to perceptually analyze arbitrarily unredundant stimulus arrays. This point is spectacularly obvious in the case of language. If I write "I keep a giraffe in my pocket," you are able to understand me despite the fact that, on even the most inflationary construal of the notion of context, there is nothing in the context of the inscription that would have enabled you to predict either its form or its content. In short, feedback is effective only to the extent that, *prior* to the analysis of the stimulus, the perceiver knows quite a lot about what the stimulus is going to be like. Whereas, the *point* of perception is, surely, that it lets us find out how the world is even when the world is some way that we *don't* expect it to be. The teleology of perceptual capacities presupposes a considerably-less-than-omniscient-organism; they'd be no use to

God. If you already *know* how things are, why look to *see* how things are?¹⁰

So: The perceptual analysis of *unanticipated* stimulus layouts (in language and elsewhere) is possible only to the extent that (a) the output of the transducer is insensitive to the beliefs/expectations of the organism; and (b) the input analyzers are adequate to compute a representation of the stimulus from the information that the transducers supply. This is to say that the perception of novelty depends on bottom-to-top perceptual mechanisms.

There is a variety of ways of putting this point, which is, I think, among the most important for understanding the character of the input systems. Pylyshyn (1980) speaks of the "cognitive impenetrability" of perception, meaning that the output of the perceptual systems is largely insensitive to what the perceiver presumes or desires. Pylyshyn's point is that a condition for the *reliability* of perception, at least for a fallible organism, is that it generally sees what's there, not what it wants or expects to be there. Organisms that don't do so become deceased.

Here is another terminology for framing these issues about the direction of information flow in perceptual analysis: Suppose that the organism is given the problem of determining the analysis of a stimulus at a certain level of representation – e.g., the problem of determining which sequence of words a given utterance encodes. Since, in the general case, transducer outputs underdetermine perceptual analyses,¹¹ we can think of the solution of such problems as involving processes of nondemonstrative inference. In particular, we can think of each input system as a computational mechanism which projects and confirms a certain class of hypotheses on the basis of a certain body of data. In the present example, the available hypotheses are the word sequences that can be constructed from entries in the subject's mental lexicon, and the perceptual problem is to determine which of these sequences provides the right analysis of the currently impinging utterance token. The mechanism which solves the problem is, in effect, the realization of a *confirmation function*: it's a mapping which associates with each pair of a lexical hypothesis and some acoustic datum a value which expresses the degree of confirmation that the latter bestows upon the former. (And similarly, *mutatis mutandis*, for the nondemonstrative inferences that the other input analyzers effect.) I emphasize that construing the situation this way involves no commitment to a detailed theory of the operation of perceptual

systems. *Any* nondemonstrative inference can be viewed as the projection and confirmation of a hypothesis, and I take it that perceptual inferences must in general be nondemonstrative, since their underdetermination by sensory data is not in serious dispute.

Looked at this way, the claim that input systems are informationally encapsulated is equivalent to the claim that the data that can bear on the confirmation of perceptual hypotheses includes, in the general case, considerably less than the organism may know. That is, the confirmation function for input systems does not have access to all of the information that the organism internally represents; there are restrictions upon the allocation of internally represented information to input processes.

Talking about the direction of information flow in psychological processes and talking about restrictions upon the allocation of information to such processes are thus two ways of talking about the same thing. If, for example, we say that the flow of information in language comprehension runs directly from the determination of the phonetic structure of an utterance to the determination of its lexical content, then we are saying that only phonetic information is available to whatever mechanism decides the level of confirmation of perceptual hypotheses about lexical structure. On that account, such mechanisms are encapsulated with respect to *nonphonetic* information; they have no access to such information; not even if it is *internally represented, accessible to other cognitive processes* (i.e., to cognitive processes other than the assignment of lexical analyses to phone sequences) and *germane* in the sense that if it *were* brought to bear in lexical analysis, it would affect the confirmation levels of perceptual hypotheses about lexical structure.

I put the issue of informational encapsulation in terms of constraints on the data available for hypothesis confirmation because doing so will help us later, when we come to compare input systems with central cognitive processes. Suffice it to say, for the moment, that this formulation suggests another possible reason why input systems are so fast. We remarked above that the computations that input systems perform are mandatory, and that their being so saves time that would otherwise have to be used in executive decision-making. We now add that input systems are bull-headed and that this, too, makes for speed. The point is this: to the extent that input systems are informationally encapsulated, of all the information that might *in principle* bear

upon a problem of perceptual analysis only a portion (perhaps only quite a small and stereotyped portion) is actually admitted for consideration. This is to say that speed is purchased for input systems by permitting them to ignore lots of the facts. Ignoring the facts is not, of course, a good recipe for problem-solving in the general case. But then, as we have seen, input systems don't function in the *general* case. Rather, they function to provide very special kinds of representations of very specialized inputs (to pair transduced representations with formulas in the domains of central processes). What operates in the general case, and what is sensitive, at least in principle, to *everything* that the organism knows, are the central processes themselves. Of which more later.

I should add that these reflections upon the value of bull-headedness do not, as one might suppose, entirely depend upon assumptions about the speed of memory search. Consider an example. Ogden Nash once offered the following splendidly sane advice: "If you're called by a panther/don't anther." Roughly, we want the perceptual identification of panthers to be very fast and to err, if at all, only on the side of false positives. If there is a body of information that must be deployed in such perceptual identifications, then we would prefer not to have to recover that information from a large memory, assuming that the speed of access varies inversely with the amount of information that the memory contains. This is a way of saying that we do not, on that assumption, want to have to access panther-identification information from the (presumably *very* large) central storage in which representations of background-information-at-large are generally supposed to live. Which is in turn to say that we don't want the input analyzer that mediates panther identification to communicate with the central store on the assumption that large memories are searched slowly.

Suppose, however, that random access to a memory is *insensitive* to its size. *Even so* panther-identification (and, *mutatis mutandis*, other processes of input analysis) had better be insensitive to much of what one knows. Suppose that we can get at *everything* we know about panthers *very fast*. We still have the problem of deciding, for each such piece of information retrieved from memory, *how much inductive confirmation it bestows upon the hypothesis that the presently observed black-splotch-in-the-visual-field is a panther*. The point is that in the rush and scramble of panther identification, there are many things I

know about panthers whose bearing on the likely pantherhood of the present stimulus *I do not wish to have to consider*. As, for example, that my grandmother abhors panthers; that every panther bears some distant relation to my Siamese cat Jerrold J.; that there are no panthers on Mars; that there is an Ogden Nash poem about panthers . . . etc. Nor is this all; for, in fact, the property of being 'about panthers' is not one that can be surefootedly relied upon. Given enough context, practically everything I know can be construed as panther related; and, *I do not want to have to consider everything I know* in the course of perceptual panther identification. In short, the point of the informational encapsulation of input processes is not – or not solely – to reduce the memory space that must be searched to find information that is perceptually relevant. The primary point is to so restrict the number of *confirmation relations* that need to be estimated as to make perceptual identifications fast. (I am indebted to Scott Fahlman for raising questions that provoked the last two paragraphs.)¹²

The informational encapsulation of the input systems is, or so I shall argue, the essence of their modularity. It's also the essence of the analogy between the input systems and reflexes; reflexes are informationally encapsulated with bells on.

Suppose that you and I have known each other for many a long year (we were boys together, say) and you have come fully to appreciate the excellence of my character. In particular, you have come to know perfectly well that under no conceivable circumstances would I stick my finger in your eye. Suppose that this belief of yours is both explicit and deeply felt. You would, in fact, go to the wall for it. Still, if I jab my finger near enough to your eyes, and fast enough, you'll blink. To say, as we did above, that the blink reflex is mandatory is to say, *inter alia*, that it has no access to what you know about my character or, for that matter, to any other of your beliefs, utilities and expectations. For this reason the blink reflex is often produced when sober reflection would show it to be uncalled for; like panther-spotting, it is prepared to trade false positive for speed.

That is what it is like for a psychological system to be informationally encapsulated. If you now imagine a system that is encapsulated in the way that reflexes are, but also computational in a way that reflexes are not, you will have some idea of what I'm proposing that input systems are like.

It is worth emphasizing that being modular in this sense is not quite the same thing as being

autonomous in the sense that Gall had in mind. For Gall, if I read him right, the claim that the vertical faculties are autonomous was practically equivalent to the claim that there are no horizontal faculties for them to share. Musical aptitude, for example, is autonomous *in that* judging musical ideas shares no cognitive mechanisms with judging mathematical ideas; remembering music shares no cognitive mechanisms with remembering faces; perceiving music shares no cognitive mechanisms with perceiving speech; and so forth.

Now, it is unclear to what extent the input systems are autonomous *in that* sense. We do know, for example, that there are systematic relations between the amount of computational strain that decoding a sentence places on the language handling systems and the subject's ability to perform simultaneous nonlinguistic tasks quickly and accurately. 'Phoneme monitor' (Foss, 1969) techniques, and others, can be used to measure such interactions, and the results suggest a picture that is now widely accepted among cognitive psychologists: Mental processes often compete for access to resources variously characterized as attention, short-term memory, or work space; and the result of allocating such resources to one of the competing processes is a decrement in the performance of the others. How general this sort of interaction is is unclear in the present state of the art (for contrary cases, suggesting isolated work spaces for visual imagery on the one hand and verbal recall on the other, see Brooks, 1968). In any event, where such competition does obtain, it is a counterexample to autonomy in what I am taking to be Gall's understanding of that notion.¹³

On the other hand, we can think of autonomy in a rather different way from Gall's – viz., in terms of informational encapsulation. So, instead of asking what access language processes (e.g.) have to *computational resources* that other systems also share, we can ask what access they have to the *information* that is available to other systems. If we do look at things this way, then the question "how much autonomy?" is the same question as "how much constraint on information flow?" In a nutshell: one way that a system can be autonomous is by being encapsulated, by not having access to facts that other systems know about. I am claiming that, whether or not the input systems are autonomous in Gall's sense, they are, to an interesting degree, autonomous in this informational sense.

However, I have not yet given any arguments (except some impressionistic ones) to show that

the input systems actually are informationally encapsulated. In fact, I propose to do something considerably more modest: I want to suggest some caveats that ought to be, but frequently aren't, observed in interpreting the sorts of data that have usually been alleged in support of the contrary view. I think that many of the considerations that have seemed to suggest that input processes are cognitively penetrable – that they are importantly affected by the subject's belief about context, or his background information, or his utilities – are, in fact, equivocal or downright misleading. I shall therefore propose several ground rules for evaluating claims about the cognitive penetrability of input systems; and I'll suggest that, when these rules are enforced, the evidence for 'New Look' approaches to perception begins to seem not impressive. My impulse in all this is precisely analogous to what Marr and Poggio say motivates their work on vision: "... to examine ways of squeezing the last ounce of information from an image before taking recourse to the descending influence of high-level interpretation on early processing" (1977, pp. 475–476).

(a) Nobody doubts that the information that input systems provide must somehow be reconciled with the subject's background knowledge. We sometimes know that the world can't really be the way that it looks, and such cases may legitimately be described as the correction of input analyses by top-down information flow. (This, ultimately, is the reason for refusing to identify input analysis with perception. The point of perception is the fixation of belief, and the fixation of belief is a *conservative* process – one that is sensitive, in a variety of ways, to what the perceiver already knows. Input analysis may be informationally encapsulated, but perception surely is not.) However, to demonstrate that sort of interaction between input analyses and background knowledge is not, in and of itself, tantamount to demonstrating the cognitive penetrability of the former; you need also to show that the locus of the top-down effect is *internal* to the input system. That is, you need to show that the information fed back interacts with interlevels of input-processing and not merely with the final results of such processing. The penetrability of a system is, by definition, its susceptibility to top-down effects at stages *prior* to its production of output.

I stress this point because it seems quite possible that input systems specify only relatively shallow levels of representation (see section [III.6 of the original work]). For example,

it is quite possible that the perceptual representation delivered for a token sentence specifies little more than the type to which the token belongs (and hence does *not* specify such information as the speech act potential of the token, still less the speech act performed by the tokening). If this is so, then data showing effects of the hearer's background information on, e.g., his estimates of the speaker's communicative intentions would *not* constitute evidence for the cognitive penetration of the presumptive language-comprehension module; by hypothesis, the computations involved in making such estimates would not be among those that the language-comprehension module *per se* performs. Similarly, *mutatis mutandis*, in the case of vision. There is a great deal of evidence for context effects upon certain aspects of visual object recognition. But such evidence counts for nothing in the present discussion unless there is independent reason to believe that these aspects of object recognition are part of visual input analysis. Perhaps the input system for vision specifies the stimulus only in terms of "primal sketches" for whose cognitive impenetrability there is, by the way, some nontrivial evidence. (See Marr and Nishihara (1978).) The problem of assessing the degree of informational encapsulation of input systems is thus not independent of the problem of determining how such systems are individuated and what sorts of representations constitute their outputs. I shall return to the latter issue presently; for the moment, I'm just issuing caveats.

(b) Evidence for the cognitive penetrability of some computational mechanism that does what input systems do is not, in and of itself, evidence for the cognitive penetrability of input systems.

To see what is at issue here, consider some of the kinds of findings that have been taken as decisively exhibiting the effects of background expectations upon language perception. A well known way of estimating such expectations is the use of the so-called Cloze procedure. Roughly, S is presented with the first *n* words of a sentence and is asked to complete the fragment. Favored completions (as, for example, "salt" in the case of the fragment "I have the pepper, but would you please pass the —") are said to be "high Cloze" and are assumed to indicate what the subject would expect a speaker to say next if he had just uttered a token of the fragment. An obvious generalization allows the estimation of the Cloze value at each point in a sentence, thereby permitting experiments in which the

average Cloze value of the stimulus sentences is a manipulated variable.

It is quite easy to show that relative Cloze value affects S's performance on a number of experimental tasks, and it is reasonable to infer from such demonstrations that whatever mechanisms mediate the performance of these tasks must have access to S's expectations about what speakers are likely to say, hence not just to the 'stimulus' (e.g., acoustic) properties of the linguistic token under analysis. (For an early review of the literature on redundancy effects in sentence processing, see Miller and Isard, 1963.) So, for example, it can be shown that the accuracy of S's perception of sentences heard under masking noise is intimately related to the average Cloze value of the sentences: high Cloze sentences can be understood under conditions of greater distortion than the perception of low Cloze sentences tolerates. (Similarly, high Cloze sentences are, in general, more easily remembered than low Cloze sentences; recognition thresholds for words that are high Cloze in a context are lower than those for words that are low Cloze in that context; and so forth.)

The trouble with such demonstrations, however, is that although they show that there exist *some* language-handling processes that have access to the hearer's expectations about what is likely to be said, they do *not* show that the input systems enjoy such access. For example, it might be argued that, in situations where the stimulus is acoustically degraded, the subject is, in effect, encouraged to guess the identity of the material that he can't hear. (Similarly, *mutatis mutandis*, in memory experiments where a reasonable strategy for the subject is to guess at such of the material as he can't recall.) Not surprisingly, in such circumstances, the subject's background information comes into play with measurable effect. The question, however, is whether the psychological mechanisms deployed in the slow, relatively painful, highly attentional process of reconstructing noisy or otherwise degraded linguistic stimuli are the same mechanisms which mediate the automatic and fluent processes of normal speech perception.

That this question is not merely frivolous is manifested by results such as those of Fishler and Bloom (1980). Using a task in which sentences are presented in clear they found only a marginal effect of high Cloze on the recognition of test words, and such effects vanished entirely when the stimuli were presented at high rates. (High presentation rates presumably discour-

age guessing; guessing takes time.) By contrast, words that are 'semantically anomalous' in context showed considerable inhibition in comparison with neutral controls. This last finding is of interest because it suggests that at least some of the effects of sentence context in speech recognition must be, as psychologists sometimes put it, 'post-perceptual'. In our terminology, these processes must operate *after* the input system has provided a (tentative) analysis of the lexical content of the stimulus. The point is that even if the facilitation of redundant items is mediated by predictive, expectation-driven mechanisms, the inhibition of contextually anomalous items cannot be. It is arguable that, in the course of speech perception, one is forever making such predictions as that 'pepper' will occur in 'salt and —'; but surely one can't also be forever predicting that 'dog', 'tomorrow', and all the other anomalous expressions will *not* occur there.¹⁴ The moral is: some processes which eventuate in perceptual identifications are, doubtless, cognitively penetrated. But this is compatible with the informational encapsulation of the input systems themselves. Some traditional enthusiasm for context-driven perceptual models may have been prompted by confusion on this point.

(c) The claim that input systems are informationally encapsulated must be very carefully distinguished from the claim that there is top-down information flow *within* these systems. These issues are very often run together, with consequent exaggeration of the well-groundedness of the case against encapsulation.

Consider, once again, the phoneme restoration effect. Setting aside the general caution that experiments with distorted stimuli provide dubious grounds for inferences about speech perception in clear, phoneme restoration provides considerable *prima facie* evidence that phone identification has access to what the subject knows about the lexical inventory of his language. If this interpretation is correct, then phoneme restoration illustrates top-down information flow in speech perception. It does *not*, however, illustrate the cognitive penetrability of the language input system. To show that that system is penetrable (hence informationally unencapsulated), you would have to show that its processes have access to information that is not specified at any of the levels of representation that the language input system computes; for example, that it has generalized access to what the hearer knows about the probable beliefs and

intentions of his interlocutors. If, by contrast, the 'background information' deployed in phoneme restoration is simply the hearer's knowledge of the words in his language, then that counts as top-down flow within the language module; on any remotely plausible account, the knowledge of a language includes knowledge of its lexicon.

The most recent work in phoneme restoration makes this point with considerable force. Samuel (1981) has shown that both information about the lexical inventory and 'semantic' information supplied by sentential context affect the magnitude of the phoneme restoration effect. Specifically, you get more restoration in words than in (phonologically possible) nonwords, and you get more restoration when a word is predictable in sentence context than when the context is neutral. This looks like the penetration of phone recognition by both lexical and 'background' information, but the appearance is misleading. In fact, Samuel's data suggest that, of the two effects, *only the former* is strictly perceptual, the latter operating in consequence of a response bias to report predictable words as intact. (Detection theoretically: the word/nonword difference affects d' , whereas the neutral context/predictive context difference affects β .) As Samuel points out, the amount of restoration is inversely proportional to S's ability to distinguish the stimulus word with a phone missing from an undistorted token of the same type; and, on Samuel's data, this discrimination is actually *better* for items that are highly predictable in context than for items that aren't. Another case, in short, where what had been taken to be an example of context-driven prediction in perception is, in fact, an effect of the biasing of post-perceptual decision processes.

The importance of distinguishing cognitive penetration from intramodular effects can be seen in many other cases where predictive analysis in perception is demonstrable. It is, for example, probable (though harder to show than one might have supposed) that top-down processes are involved in the identification of the surface constituent structure of sentences (see Wright, 1982). For example, it appears that the identification of nouns is selectively facilitated in contexts like T A —, the identification of verbs is selectively facilitated in contexts like T N —, and so forth. Such facilitation indicates that the procedures for assigning lexical items to form classes have access to information about the general conditions upon the well-formedness of constituent structure trees.

Now, it is a question of considerable theoretical interest whether, and to what extent, predictive analysis plays a role in parsing; but this issue must be sharply distinguished from the question whether the parser is informationally encapsulated. Counterexamples to encapsulation must exhibit the sensitivity of the parser to information that is not specified internal to the language-recognition module, and constraints on syntactic well-formedness are paradigms of information that does *not* satisfy this condition. The issue is currently a topic of intensive experimental and theoretical inquiry; but as things stand I know of no convincing evidence that syntactic parsing is ever guided by the subject's appreciation of semantic context or of 'real world' background. Perhaps this is not surprising; there are, in general, so many syntactically different ways of saying the same thing that even if context allowed you to estimate the *content* of what is about to be said, that information wouldn't much increase your ability to predict its *form*.¹⁵

These questions about where the interacting information comes from (whether it comes from inside or outside the input system) take on a special salience in light of the following consideration: it is possible to imagine ways in which mechanisms *internal* to a module might contrive to, as it were, mimic effects of cognitive penetration. The operation of such mechanisms might thus invite overestimations of the extent to which the module has access to the organism's general informational resources. To see how this might occur, let's return to the question of contextual facilitation of word recognition; traditionally a parade case for New Look theorizing, but increasingly an area in which the data are coming to seem equivocal.

Here are the bare bones of an ingenious experiment of David Swinney's (1979; for further, quite similar, results, see Tanenhaus, Leiman, and Seidenberg, 1979). The subject listens to a stimulus sentence along the lines of "Because he was afraid of electronic surveillance, the spy carefully searched the room for bugs." Now, we know from previous research that the response latencies for 'bugs' (say, in a word/nonword decision task) will be faster in this context, where it is relatively predictable, than in a neutral context where it is acceptable but relatively low Cloze. This seems to be – and is traditionally taken to be – the sort of result which demonstrates how expectations based upon an intelligent appreciation of sentential context can guide lexical access; the subject predicts 'bugs'

before he hears the word. His responses are correspondingly accelerated whenever his prediction proves true. Hence, cognitive penetration of lexical access.

You can, or so it seems, gild this lily. Suppose that, instead of measuring reaction time for word/nonword decisions on 'bugs', you simultaneously present (flashed on a screen that the subject can see) a different word belonging to the same (as one used to say) 'semantic field' (e.g., 'microphones'). If the top-down story is right in supposing that the subject is using semantic/background information to predict lexical content, then 'microphones' is as good a prediction in context as 'bugs' is, so you might expect that 'microphones', too, will exhibit facilitation as compared with a neutral context. And so it proves to do. Cognitive penetration of lexical access with bells on, or so it would appear.

But the appearance is misleading. For Swinney's data show that if you test with 'insects' instead of 'microphones', you get the same result: facilitation as compared with a neutral context. Consider what this means. 'Bugs' has two paraphrases: 'microphones' and 'insects'. But though only one of these is contextually relevant, *both are contextually facilitated*. This looks a lot less like the intelligent use of contextual/background information to guide lexical access. What it looks like instead is some sort of associative relation among lexical forms (between, say, 'spy' and 'bug'); a relation pitched at a level of representation sufficiently superficial to be *insensitive* to the semantic content of the items involved. This possibility is important for the following reason: If facilitation is mediated by merely interlexical relations (and not by the interaction of background information with the semantic content of the item and its context), then the information that is exploited to produce the facilitation can be represented *in the lexicon*; hence *internal to the language recognition module*. And if that is right, then contextual facilitation of lexical access is *not* an argument for the cognitive penetration of the module. It makes a difference, as I remarked above, where the penetrating information comes from.

Let's follow this just a little further. Suppose the mental lexicon is a sort of connected graph, with lexical items at the nodes and with paths from each item to several others. We can think of accessing an item in the lexicon as, in effect, exciting the corresponding node; and we can assume that one of the consequences of accessing a node is that excitation spreads along the path-

ways that lead from it. Assume, finally, that when excitation spreads through a portion of the lexical network, response thresholds for the excited nodes are correspondingly lowered. Accessing a given lexical item will thus decrease the response times for items to which it is connected. (This picture is familiar from the work of, among others, Morton, 1969, and Collins and Loftus, 1975; for relevant experimental evidence, see Meyer and Schvaneveldt, 1971.)

The point of the model-building is to suggest how mechanisms internal to the language processor could mimic the effects that cognitive penetration would produce if the latter indeed occurred. In the present example, what mimics the background knowledge that (roughly) spies have to do with bugs is the existence of a connection between the node assigned to the word 'spy' and the node assigned to the word 'bug'. Facilitation of 'bug' in spy contexts is affected by the excitation of such intralexical connections.

Why should these intralexical connections exist? Surely not just in order to lead psychologists to overestimate the cognitive penetrability of language-processing. In fact, if one works the other way 'round and assumes that the input systems are encapsulated, one might think of the mimicry of penetration as a way that the input processors contrive to make the best of their informational isolation. Presumably, what encapsulation buys is speed; and, as we remarked above, it buys speed at the price of unintelligence. It would, one supposes, take a lot of time to make reliable decisions about whether there is the kind of relation between spies and bugs that makes it on balance likely that the current token of 'spy' will be followed by a token of 'bug'. But that is precisely the kind of decision that the subject would have to make if the contextual facilitation of lexical access were indeed an effect of background knowledge interacting with the semantic content of the context. The present suggestion is that no such intelligent evaluation of the options takes place; there is merely a brute facilitation of the recognition of 'bug' consequent upon the recognition of 'spy'. The condition of this brute facilitation buying anything is that it should be possible, with reasonable accuracy, to mimic what one knows about connectedness *in the world* by establishing corresponding connections among entries in the mental lexicon. In effect, the strategy is to use the structure of interlexical connections to mimic the structure of knowledge. The mimicry won't be precise (a route from 'spy' to 'insect' will be generated as a

by-product of the route from 'spy' to 'bug'). But there's no reason to doubt that it may produce savings over all.

Since we are indulging speculations, we might as well indulge this one: It is a standing mystery in psychology why there should be interlexical associations at all; why subjects should exhibit a reliable and robust disposition to associate 'salt' with 'pepper', 'cat' with 'dog', 'mother' with 'father', and so forth. In the heyday of associationism, of course, such facts seemed quite *unmysterious*; they were, indeed, the stuff of which the mental life was supposed to be made. On one account the utterance of a sentence was taken to be a chained response, and associations among lexical items were what held the links together. According to still earlier tradition, the postulation of associative connections between Ideas was to be the mechanism for reconstructing the notion of degree of belief. None of this seems plausible now, however. Belief is a matter (not of association but) of *judgment*; sentence production is a matter (not of association but) of *planning*. So, what on earth are associations for?

The present suggestion is that associations are the means whereby stupid processing systems manage to behave as though they were smart ones. In particular, interlexical associations are the means whereby the language processor is enabled to act as though it knows that spies have to do with bugs (whereas, in fact, it knows no such thing). The idea is that, just as the tradition supposed, terms for things frequently connected in experience become themselves connected in the lexicon. Such connection is *not* knowledge; it is not even judgment. It is simply the mechanism of the contextual adjustment of response thresholds. Or, to put the matter somewhat metaphysically, the formation of interlexical connections buys the synchronic encapsulation of the language processor at the price of its cognitive penetrability *across time*. The information one has about how things are related in the world is inaccessible to modulate lexical access; that is what the encapsulation of the language processor implies. But one's experience of the relations of things in the world does affect the structure of the lexical network – viz., by instituting connections among lexical nodes. If the present line of speculation is correct, these connections have a real, if modest, role to play in the facilitation of the perceptual analysis of speech. The traditional, fundamental, and decisive objection to association is that it is too stupid a relation

to form the basis of a mental life. But stupidity, when not indulged in to excess, is a virtue in fast, peripheral processes; which is exactly what I have been supposing input processes to be.

I am not quite claiming that all the putative effects of information about background (context, etc.) on sentence recognition are artifacts of connections in the lexical network (though, as a matter of fact, such experimental attempts as I've seen to demonstrate a residual effect of context after interlexical/associative factors are controlled for strike me as not persuasive). I am claiming only that the possibility of such artifacts contaminates quite a lot of the evidence that is standardly alleged. The undoubted fact that "semantically" coherent text is relatively easy to process does not, in and of itself, demonstrate that the input system for language has access to what the organism knows about how the world coheres. Such experimental evidence as supported early enthusiasms for massively top-down perceptual models was, I think, sexy but inconclusive; and the possibility of a modular treatment of input processes provides motivation for its reconsideration. The situation would seem to be paradigmatically Kuhnian: the data look different to a jaundiced eye.

Consider the provenance of New Look theorizing. Cognitive psychologists in the '40s and '50s were faced with the proposal that perception is *literally* reflexive; for example, that the theory of perception is reducible without residue to the theory of discriminative operant response. It was natural and admirable in such circumstances to stress the 'intelligence' of perceptual integration. However, in retrospect it seems that the intelligence of perceptual integration may have been seriously misconstrued by those who were most its partisans.

In the ideal condition – one approached more frequently in the textbooks than *in rerum naturae*, to be sure – reflexes have two salient properties. They are computationally simple (the stimulus is "directly connected" to the response), and they are informationally encapsulated (see above). I'm suggesting that New Look theories failed to distinguish these properties. They thus assumed, wrongly, that the disanalogy between perceptual and reflexive processes consisted in the capacity of the former to access and exploit background information. From the point of view of the modularity thesis, this is a case of the right intuition leading to the wrong claim. Input systems *are* computationally elaborated. Their

typical function is to perform inference-like operations on representations of impinging stimuli. Processes of input analysis are thus unlike reflexes in respect of the character and complexity of the operations that they perform. But this is quite compatible with reflexes and input processes being similar in respect of their informational encapsulation; in this latter respect, both of them contrast with “central processes” – problem-solving and the like – of which cognitive penetrability is perhaps the most salient feature, or so I shall argue below. To see that informational encapsulation and computational elaboration are compatible properties, it is only necessary to bear in mind that unencapsulation is the exploitation of information from outside a system; a computationally elaborated system can thus be encapsulated if it stores the information that its computations exploit. Encapsulation is a matter of foreign affairs; computational elaboration begins at home.

It may be useful to summarize this discussion of the informational encapsulation of input systems by comparing it with some recent, and very interesting, suggestions owing to the philosopher Stephen Stich (1978). Stich's discussion explores the difference between belief and the epistemic relation that is alleged to hold between, for example, speaker/hearers and the grammar of their native language (the relation that Chomsky calls ‘cognizing’). Stich supposes, for purposes of argument, that the empirical evidence shows that speakers *in some sense* ‘know’ the grammar of their native language; his goal is to say something about what that sense is.

Let us call the epistemic relation that a native speaker has to the grammar of his language *subdoxastic* belief.¹⁶ Stich suggests that there are two respects in which subdoxastic beliefs differ from beliefs strictly so-called. In the first place, as practically everybody has emphasized, subdoxastic beliefs are *unconscious*. But, Stich adds, subdoxastic beliefs are also typically “inferentially unintegrated.” The easiest way to understand what Stich means by this is to consider one of his examples.

If a linguist believes a certain generalization to the effect that no transformation rule exhibits a certain characteristic, and if he comes to (nonsubdoxastically) believe a given transformation which violates the generalization, he may well infer that the generalization is false. But merely having the rule stored (in the way that we are assuming all speakers of the language do) does not enable the linguist to draw

the inference. . . . Suppose that for some putative rule, you have come to believe that if *r* then Chomsky is seriously mistaken. Suppose further that, as it happens, *r* is in fact among the rules stored by your language processing mechanism. The belief along with the subdoxastic state will not lead to the belief that Chomsky is seriously mistaken. By contrast, if you believe (perhaps even mistakenly) that *r*, then the belief that Chomsky is seriously mistaken is likely to be inferred. [pp. 508–509]

Or, as Stich puts the argument at another point, “It is characteristic of beliefs that they generate further beliefs via inference. What is more, beliefs are inferentially promiscuous. Provided with a suitable set of supplementary beliefs, almost any belief can play a role in the inference to any other. . . . (However) subdoxastic states, as contrasted with beliefs, are largely inferentially isolated from the large body of inferentially integrated beliefs to which a subject has (conscious) access.”

Now, as Stich clearly sees, the proposal that subdoxastic states are typically both unconscious and inferentially unintegrated raises a question – viz., *Why should these two properties co-occur?* Why should it be, to put it in my terminology, that subdoxastic states are typically encapsulated with respect to the processes which affect the inferential integration of beliefs?

Notice that there is a kind of encapsulation that follows from unconsciousness: an unconscious belief cannot play a role as a premise in the sort of reasoning that goes on in the conscious drawing of inferences. Stich is, however, urging something more interesting than this trivial truth. Stich's claim is that subdoxastic beliefs are largely inaccessible even to *unconscious* mental processes of belief fixation. If this claim is true, the question does indeed arise why it should be so.

I want to suggest, however, that the question doesn't arise because, as a matter of fact, subdoxastic beliefs are not in general encapsulated; or, to put it more precisely, they are not in general encapsulated *qua* subdoxastic. Consider, as counterexamples, one's subdoxastic views about inductive and deductive warrant; for example, one's subdoxastic acquiescence in the rule of *modus ponens*. On the sort of psychological theory that Stich has in mind, subdoxastic knowledge of such principles must be accessible to practically all mental processes, since practically all inferential processes exploit them in

one way or another. One's subdoxastic beliefs about validity and confirmation are thus quite unlike one's subdoxastic beliefs about the rules of grammar; though both are unconscious, the former are paradigms of promiscuous and unencapsulated mental states. So the connection between unconsciousness and encapsulation cannot be *intrinsic*.

Nevertheless, I think that Stich is onto something important. For, though much unconscious information must be widely accessible to processes of fixation of belief, it is quite true that very many of the examples of unconscious beliefs for which there is currently good empirical evidence are encapsulated. This is because most of our current cognitive science is the science of input systems, and, as we have seen, *informational encapsulation is arguably a pervasive feature of such systems*. Input systems typically do not exchange subdoxastic information with central processes or with one another.

Stich almost sees this point. He says that "subdoxastic states occur in a variety of separate, special purpose cognitive systems" (p. 508). True enough; but they must also occur in integrated, general purpose systems (in what I'm calling "central" systems), assuming that much of the fixation of belief is both unconscious and subserved by inferential mechanisms of that kind. The point is: subdoxastic states are informationally encapsulated *only* insofar as they are states of special purpose systems (e.g., states of input analyzers). Practically all psychologically interesting cognitive states are unconscious; but it is only the beliefs accessible to modules that are subdoxastic by the second of Stich's criteria as well.

Central Systems

Vertical faculties are domain specific (by definition) and modular (by hypothesis). So the questions we now want to ask can be put like this: *Are there psychological processes that can plausibly be assumed to cut across cognitive domains?* And, if there are, is there reason to suppose that such processes are subserved by nonmodular (e.g., informationally unencapsulated) mechanisms?

The answer to the first of these questions is, I suppose, reasonably clear. Even if input systems are domain specific, there must be some cognitive mechanisms that are not. The general form of the argument goes back at least to Aristotle: *the representations that input systems deliver have to interface somewhere, and the computational mechanisms that effect the interface*

must ipso facto have access to information from more than one cognitive domain. Consider:

- (a) We have repeatedly distinguished between what the input systems compute and what the organism (consciously or subdoxastically) believes. Part of the point of this distinction is that input systems, being informationally encapsulated, typically compute representations of the distal layout on the basis of less information about the distal layout than the organism has available. Such representations want correction in light of background knowledge (e.g., information in memory) and of the simultaneous results of input analysis in other domains (see Aristotle on the 'common sense'). Call the process of arriving at such corrected representations "the fixation of perceptual belief." To a first approximation, we can assume that the mechanisms that effect this process work like this: they look simultaneously at the representations delivered by the various input systems and at the information currently in memory, and they arrive at a best (i.e., best available) hypothesis about how the world must be, given these various sorts of data.¹⁷ But if there are mechanisms that fix perceptual belief, and if they work in anything like this way, then these mechanisms are not domain specific. Indeed, the point of having them is precisely to ensure that, wherever possible, what the organism believes is determined by all the information it has access to, regardless of which cognitive domains this information is drawn from.
- (b) We use language (*inter alia*) to communicate our views on how the world is. But this use of language is possible only if the mechanisms that mediate the production of speech have access to what we see (or hear, or remember, or think) that the world is like. Since, by assumption, such mechanisms effect an interface among vertical faculties, they cannot themselves be domain specific. More precisely, they must at least be *less* domain specific than the vertical faculties are.¹⁸
- (c) One aspect of the 'impenetrability' of the input systems is, we assumed, their insensitivity to the utilities of the organism. This assumption was required in part to explain the *veridicality* of perception given that the

world doesn't always prove to be the way that we would prefer it to be. However, an interface between perception and utilities must take place *somewhere* if we are to use the information that input systems deliver in order to determine how we ought to act. (Decision theories are, to all intents and purposes, models of the structure of this interface. The point is, roughly, that wishful seeing is avoided by requiring interactions with utilities to occur *after* – not *during* – perceptual integration.) So, again, the moral seems to be that there must be some mechanisms which cross the domains that input systems establish.

For these and other similar reasons, I assume that there must be relatively nondenominational (i.e., domain-*inspecific*) psychological systems which operate, inter alia, to exploit the information that input systems provide. Following the tradition, I shall call these “central” systems, and I will assume that it is the operation of these sorts of systems that people have in mind when they talk, pretheoretically, of such mental processes as thought and problem-solving. Central systems may be domain specific in *some* sense – we will consider this when we get to the issues about ‘epistemic boundedness’ – but at least they aren't domain specific in the way that input systems are. The interesting question about the central systems is whether, being nondenominational, they are also non-modular in other respects as well. That is, whether the central systems fail to exhibit the galaxy of properties that lead us to think of the input systems as a natural kind – the properties enumerated in [the previous section].

Briefly, my argument is going to be this: we have seen that much of what is typical of the input systems is more or less directly a product of their informational encapsulation. By contrast, I'll claim that central systems are, in important respects, *unencapsulated*, and that it is primarily for this reason that they are not plausibly viewed as modular. Notice that I am not going to be arguing for a tautology. It is perfectly possible, in point of logic, that a system which is *not* domain specific might nevertheless be encapsulated. Roughly, domain specificity has to do with the range of questions for which a device provides answers (the range of inputs for which it computes analyses); whereas encapsulation has to do with the range of information that the device consults in deciding what answers to provide. A system could thus be domain specific but

unencapsulated (it answers a relatively narrow range of questions but in doing so it uses whatever it knows); and a system could be nondenominational but encapsulated (it will give some answer to any question; but it gives its answers off the top of its head – i.e., by reference to less than all the relevant information). If, in short, it is true that only domain-specific systems are encapsulated, then that truth is interesting. Perhaps it goes without saying that I am not about to demonstrate this putative truth. I am, however, about to explore it.

So much for what I'm going to be arguing *for*. Now a little about the strategy of the argument. The fact is that there is practically no direct evidence, pro or con, on the question whether central systems are modular. No doubt it is possible to achieve some gross factoring of “intelligence” into “verbal” versus “mathematical/spatial” capacities; and no doubt there is something to the idea of a corresponding hemispheric specialization. But such dichotomies are *very* gross and may themselves be confounded with the modularity of the input systems – that is to say, they give very little evidence for the existence of domain-specific (to say nothing of modular) systems other than the ones that subservise the functions of perceptual and linguistic analysis.

When you run out of direct evidence, you might just as well try arguing from analogies, and that is what I propose to do. I have been assuming that the typical function of central systems is the fixation of belief (perceptual or otherwise) by nondemonstrative inference. Central systems look at what the input systems deliver, and they look at what is in memory, and they use this information to constrain the computation of ‘best hypotheses’ about what the world is like. These processes are, of course, largely unconscious, and very little is known about their operation. However, it seems reasonable enough that something can be inferred about them from what we know about *explicit* processes of nondemonstrative inference – viz., from what we know about empirical inference in science. So, here is how I am going to proceed. First, I'll suggest that scientific confirmation – the nondemonstrative fixation of belief in science – is typically unencapsulated. I'll then argue that if, pursuing the analogy, we assume that the central psychological systems are also unencapsulated, we get a picture of those systems that is, anyhow, not radically implausible given such information about them as is currently available.

The nondemonstrative fixation of belief in science has two properties which, though widely

acknowledged, have not (so far as I know) yet been named. I shall name them: confirmation in science is *isotropic* and it is *Quineian*. It is notoriously hard to give anything approaching a rigorous account of what being isotropic and Quineian amounts to, but it is easy enough to convey the intuitions.

By saying that confirmation is isotropic, I mean that the facts relevant to the confirmation of a scientific hypothesis may be drawn from anywhere in the field of previously established empirical (or, of course, demonstrative) truths. Crudely: everything that the scientist knows is, in principle, relevant to determining what else he ought to believe. In principle, our botany constrains our astronomy, if only we could think of ways to make them connect.

As is usual in a methodological inquiry, it is possible to consider the isotropy of confirmation either normatively (as a principle to which we believe that rational inductive practice *ought* to conform) or sociologically (as a principle which working scientists actually adhere to in assessing the degree of confirmation of their theories). In neither case, however, should we view the isotropy of confirmation as merely gratuitous – or, to use a term of Rorty's (1979) as merely "optional." If isotropic confirmation 'partially defines the language game that scientists play' (remember when we used to talk that way?), that is because of a profound conviction – partly metaphysical and partly epistemological – to which scientists implicitly subscribe: the world is a connected causal system *and we don't know how the connections are arranged*. Because we don't, we must be prepared to abandon previous estimates of confirmational relevance as our scientific theories change. The points of all this is: confirmational isotropy is a reasonable property for nondemonstrative inference to have because the goal of nondemonstrative inference is to determine the truth about a causal mechanism – the world – of whose workings we are arbitrarily ignorant. That is why our institution of scientific confirmation is isotropic, and it is why it is plausible to suppose that what psychologists call "problem-solving" (i.e., nondemonstrative inference in the service of individual fixation of belief) is probably isotropic too.

The isotropy of scientific confirmation has sometimes been denied, but never, I think, very convincingly. For example, according to some historians it was part of the Aristotelian strategy against Galileo to claim that no data other than observations of the movements of astronomical objects could, in principle, be relevant to the

(dis)confirmation of the geocentric theory. Telescopic observations of the phases of Venus were thus ruled irrelevant a priori. In notably similar spirit, some linguists have recently claimed that no data except certain specified kinds of facts about the intuitions of native speakers could, in principle, be relevant to the (dis)confirmation of grammatical theories. Experimental observations from psycholinguistics are thus ruled irrelevant a priori. However, this sort of methodology seems a lot like special pleading: you tend to get it precisely when cherished theories are in trouble from *prima facie* disconfirming data. Moreover, it often comports with Conventionalist construals of the theories so defended. That is, theories for which nonisotropic confirmation is claimed are often viewed, even by their proponents, as merely mechanisms for making predictions; what is alleged in their favor is predictive adequacy rather than correspondence to the world. (Viewed from our perspective, nonisotropic confirmation is, to that extent, not a procedure for fixation of belief, since, on the Conventionalist construal, the predictive adequacy of a theory is *not* a reason for believing that the theory is *true*.)

One final thought on the isotropy issue. We are interested in isotropic systems because such systems are ipso facto unencapsulated. We are interested in scientific confirmation because (a) there is every reason to suppose that it is isotropic; (b) there is every reason to suppose that it is a process fundamentally similar to the fixation of belief; and (c) it is perhaps the only "global", unencapsulated, holistic cognitive process about which anything is known that's worth reporting. For all that, scientific *confirmation* is probably not the best place to look if you want to see cognitive isotropy writ large. The best place to look, at least if one is willing to trust the anecdotes, is scientific *discovery*.

What the anecdotes say about scientific discovery – and they say it with a considerable show of univocality (see, e.g., papers in Ortony, 1979) – is that some sort of 'analogical reasoning' often plays a central role. It seems to me that we are thoroughly in the dark here, so I don't propose to push this point very hard. But it really does look as though there have been frequent examples in the history of science where the structure of theories in a new subject area has been borrowed from, or at least suggested by, theories *in situ* in some quite different domain: what's known about the flow of water gets borrowed to model the flow of electricity; what's known about the structure of the solar system

gets borrowed to model the structure of the atom; what's known about the behavior of the market gets borrowed to model the process of natural selection, which in turn gets borrowed to model the shaping of operant responses. And so forth. The point about all this is that "analogical reasoning" would seem to be isotropy in the purest form: a process which depends precisely upon the transfer of information among cognitive domains previously assumed to be mutually irrelevant. By definition, encapsulated systems do not reason analogically.

I want to suggest two morals before I leave this point. The first is that the closer we get to what we are pretheoretically inclined to think of as the 'higher,' 'more intelligent', less reflexive, less routine exercises of cognitive capacities, the more such global properties as isotropy tend to show up. I doubt that this is an accident. I suspect that it is precisely its possession of such global properties that we have in mind when we think of a cognitive process as paradigmatically intelligent. The second moral preshadows a point that I shall jump up and down about further on. It is striking that, while everybody thinks that analogical reasoning is an important ingredient in all sorts of cognitive achievements that we prize, nobody knows anything about how it works; not even in the dim, in-a-glass-darkly sort of way in which there are some ideas about how confirmation works. I don't think that this is an accident either. In fact, I should like to propose a generalization; one which I fondly hope will some day come to be known as 'Fodor's First Law of the Nonexistence of Cognitive Science'. It goes like this: the more global (e.g., the more isotropic) a cognitive process is, the less anybody understands it. *Very* global processes, like analogical reasoning, aren't understood at all. More about such matters in the last part of this discussion.

By saying that scientific confirmation is Quineian, I mean that the degree of confirmation assigned to any given hypothesis is sensitive to properties of the entire belief system; as it were, the shape of our whole science bears on the epistemic status of each scientific hypothesis. Notice that being Quineian and being isotropic are not the same properties, though they are intimately related. For example, if scientific confirmation is isotropic, it is quite possible that some fact about photosynthesis in algae should be relevant to the confirmation of some hypothesis in astrophysics ("the universe in a grain of sand" and all that). But the point about being Quineian is that we might have two astrophysical theories,

both of which make the same predictions about algae and about everything else that we can think of to test, but such that one of the theories is better confirmed than the other – e.g., on grounds of such considerations as simplicity, plausibility, or conservatism. The point is that simplicity, plausibility, and conservatism are properties that theories have in virtue of their relation to the whole structure of scientific beliefs *taken collectively*. A measure of conservatism or simplicity would be a metric over *global* properties of belief systems.

Consider, by way of a simple example, Goodman's original (1954) treatment of the notion of projectability. We know that two hypotheses that are equivalent in respect of all the available data may nevertheless differ in their level of confirmation depending on which is the more projectable. Now, according to Goodman's treatment, the projectability of a hypothesis is inherited (at least in part) from the projectability of its vocabulary, and the projectability of an item of scientific vocabulary is determined by the (weighted?) frequency with which that item *has been projected* in previously successful scientific theories. So, the whole history of past projections contributes to determining the projectability of any given hypothesis on Goodman's account, and the projectability of a hypothesis (partially) determines its level of confirmation. Similarly with such notions as simplicity, conservatism, and the rest if only we knew how to measure them.

The idea that scientific confirmation is Quineian is by no means untendentious. On the contrary, it was a legacy of traditional philosophy of science – one of the "dogmas of Empiricism" (Quine, 1953) that there must be *semantic* connections between each theory statement and some data statements. That is, each hypothesis about "unobservables" must *entail* some predictions about observables, such entailments holding in virtue of the meanings of the theoretical terms that the hypotheses contain.¹⁹ The effect of postulating such connections would be to determine a priori that certain data would disconfirm certain hypotheses, *whatever the shape of the rest of one's science might be*. For, of course, if H entails O, the discovery that $\neg O$ would entail that $\neg H$. To that extent, the (dis)confirmation of H by $\neg O$ is independent of global features of the belief system that H and O belong to. To postulate meaning relations between data statements and theory statements is thus to treat confirmation as a *local* phenomenon rather than a global one.

I emphasize this consideration because analogous semantic proposals can readily be found in the psychological literature. For example, in the sorts of cognitive theories espoused by, say, Bruner or Vygotsky (and, more recently, in the work of the “procedural” semanticists), it is taken for granted that there must be connections of meaning between ‘concepts’ and ‘percepts’. Basically, according to such theories, concepts are recipes for sorting stimuli into categories. Each recipe specifies a (more or less determinate) galaxy of tests that one can perform to effect a sorting, and each stimulus category is identified with a (more or less determinate) set of outcomes of the tests. To put the idea crudely but near enough for present purposes, there’s a rule that you can test for *dog* by finding out if a thing barks, and the claim is that this rule is constitutive (though not, of course, exhaustive) of the concept *dog*. Since it is alleged to be a *conceptual* truth that whether it barks is relevant to whether it’s a dog, it follows that the confirmation relation between “a thing is a dog” and “it barks” is insensitive to global properties of one’s belief system. So considerations of theoretical simplicity etc. *could* not, even in principle, lead to the conclusion that whether it barks is *irrelevant* to whether it’s a dog. To embrace that conclusion would be to change the concept.

This sort of example makes it clear how closely related being Quineian and being isotropic are. Since, on the view just scouted, it is a matter of *meaning* that barking is relevant to dogness, it is not possible to discover on empirical grounds that one was wrong about that relevancy relation. But isotropy is the principle that *any* fact may turn out to be (ir)relevant to the confirmation of any other. The Bruner-Vygotsky-procedural semantics line is thus incompatible with the isotropy of confirmation as well as with its Quineianness.

In saying that confirmation is isotropic and Quineian, I am thus consciously disagreeing with major traditions in the philosophy of science and in cognitive psychology. Nevertheless, I shall take it for granted that scientific confirmation is Quineian and isotropic. (Those who wish to see the arguments should refer to such classic papers in the modern philosophy of science as Quine, 1953, and Putnam, 1962.) Moreover, since I am committed to relying upon the analogy between scientific confirmation and psychological fixation of belief, I shall take it for granted that the latter must be Quineian and isotropic too, hence that the Bruner-Vygotsky-procedural semantics tradition in cognitive psychology must

be mistaken. I propose, at this point, to be both explicit and emphatic. The argument is that the central processes which mediate the fixation of belief are typically processes of rational nondemonstrative inference and that, since processes of rational nondemonstrative inference are Quineian and isotropic, so too are central processes. In particular, the theory of such processes must be consonant with the principle that the level of acceptance of any belief is sensitive to the level of acceptance of any other and to global properties of the field of beliefs taken collectively.

Given these assumptions, I have now got two things to do: I need to show that this picture of the central processes is broadly incompatible with the assumption that they are modular, and I need to show that it is a picture that has some plausibility independent of the putative analogy between cognitive psychology and the philosophy of science.

I take it that the first of these claims is relatively uncontroversial. We argued that modularity is fundamentally a matter of informational encapsulation and, of course, informationally encapsulated is precisely what Quineian/isotropic systems are not. When we discussed input systems, we thought of them as mechanisms for projecting and confirming hypotheses. And we remarked that, viewed that way, the informational encapsulation of such systems is tantamount to a constraint on the confirmation metrics that they employ; the confirmation metric of an encapsulated system is allowed to ‘look at’ only a certain restricted class of data in determining which hypothesis to accept. If, in particular, the flow of information through such a system is literally bottom-to-top, then its informational encapsulation consists in the fact that the *ith*-level hypotheses are (dis)confirmed solely by reference to lower-than-*ith* level representations. And even if the flow of data is unconstrained *within* a module, encapsulation implies constraints upon the access of intramodular processes to extramodular information sources. Whereas, by contrast, isotropy is by definition the property that a system has when it can look at anything it knows about in the course of determining the confirmation levels of hypotheses. So, in general, the more isotropic a confirmation metric is, the more heterogeneous the provenance of the data that it accepts as relevant to constraining its decisions. Scientific confirmation is isotropic in the limit in this respect; it provides a model of what the nonmodular fixation of belief is like.

Similarly with being Quineian. Quineian confirmation metrics are ipso facto sensitive to global properties of belief systems. Now, an informationally encapsulated system *could*, strictly speaking, nevertheless be Quineian. Simplicity, for example, could constrain confirmation even in a system which computes its simplicity scores over some arbitrarily selected subset of beliefs. But this is mere niggling about the letter. In spirit, global criteria for the evaluation of hypotheses comport most naturally with isotropic principles for the relevance of evidence. Indeed, it is only on the assumption that the selection of evidence is isotropic that considerations of simplicity (and other such global properties of hypotheses) are *rational* determinants of belief. It is epistemically interesting that H & T is a simpler theory than \neg H & T where H is a hypothesis to be evaluated and T is the rest of what one believes. But there is no interest in the analogous consideration where T is some *arbitrarily delimited* subset of one's beliefs. Where relevance is non-isotropic, assessments of relative simplicity can be gerrymandered to favor any hypothesis one likes. This is one of the reasons why the operation of (by assumption informationally encapsulated) input systems should not be identified with the fixation of perceptual belief; not, at least, by those who wish to view the fixation of perceptual belief as by and large a rational process.

So it seems clear that isotropic/Quineian systems are ipso facto unencapsulated; and if unencapsulated, then presumably nonmodular. Or rather, since this is all a matter of degree, we had best say that *to the extent that* a system is Quineian and isotropic, it is also nonmodular. If, in short, isotropic and Quineian considerations are especially pressing in determining the course of the computations that central systems perform, it should follow that these systems differ in their computational character from the vertical faculties.

We are coming close to what we started out to find: an overall taxonomy of cognitive systems. According to the present proposal, there are, at a minimum, two families of such systems: modules (which are, relatively, domain specific and encapsulated) and central processes (which are, relatively, domain neutral and isotropic/Quineian). We have suggested that the characteristic function of modular cognitive systems is input analysis and that the characteristic function of central processes is the fixation of belief. If this is right, then we have three ways of

taxonomizing cognitive processes which prove to be coextensive:

FUNCTIONAL TAXONOMY: input analysis versus fixation of belief

TAXONOMY BY SUBJECT MATTER: domain specific versus domain neutral

TAXONOMY BY COMPUTATIONAL CHARACTER: encapsulated versus Quineian/isotropic

I repeat that this coextension, if it holds at all, holds contingently. Nothing in point of logic stops one from imagining that these categories cross-classify the cognitive systems. If they do not, then that is a fact about the structure of the mind. Indeed, it is a *deep* fact about the structure of the mind.

All of which would be considerably more impressive if there were better evidence for the view of central processes that I have been proposing. Thus far, that account rests entirely on the analogy between psychological processes of belief fixation and a certain story about the character of scientific confirmation. There is very little that I can do about this, given the current underdeveloped state of psychological theories of thought and problem-solving. For what it's worth, however, I want to suggest two considerations that seem relevant and promising.

The first is that the difficulties we encounter when we try to construct theories of central processes are just the sort we would expect to encounter if such processes are, in essential respects, Quineian/isotropic rather than encapsulated. The crux in the construction of such theories is that there seems to be no way to delimit the sorts of informational resources which may affect, or be affected by, central processes of problem-solving. We can't, that is to say, plausibly view the fixation of belief as effected by computations over bounded, local information structures. A graphic example of this sort of difficulty arises in AI, where it has come to be known as the "frame problem" (i.e., the problem of putting a "frame" around the set of beliefs that may need to be revised in light of specified newly available information. Cf. the discussion in McCarthy and Hayes, 1969, from which the following example is drawn).

To see what's going on, suppose you were interested in constructing a robot capable of coping with routine tasks in familiar human environments. In particular, the robot is presented with the job of phoning Mary and finding out whether she will be late for dinner. Let's assume

that the robot 'knows' it can get Mary's number by consulting the directory. So it looks up Mary's number and proceeds to dial. So far, so good. But now, notice that commencing to dial has all sorts of direct and indirect effects on the state of the world (including, of course, the internal state of the robot), and some of these effects are ones that the device needs to keep in mind for the guidance of its future actions and expectations. For example, when the dialing commences, the phone ceases to be free to outside calls; the robot's fingers (or whatever) undergo appropriate alterations of spatial location; the dial tone cuts off and gets replaced by beeps; something happens in a computer at Murray Hill; and so forth. Some (but, in principle, not all) such consequences are ones that the robot must be designed to monitor since they are relevant to "updating" beliefs upon which it may eventually come to act. Well, *which* consequences? The problem has at least the following components. The robot must be able to identify, with reasonable accuracy, those of its previous beliefs whose truth values may be expected to alter as a result of its current activities; and it must have access to systems that do whatever computing is involved in effecting the alterations.

Notice that, unless these circuits are arranged correctly, things can go absurdly wrong. Suppose that, having consulted the directory, the robot has determined that Mary's number is 222-2222, which number it commences to dial, pursuant to instructions previously received. But now it occurs to the machine that *one of the beliefs that may need updating in consequence of its having commenced dialing is its (recently acquired) belief about Mary's telephone number*. So, of course, it stops dialing and goes and looks up Mary's telephone number (again). Repeat, *da capo*, as many times as may amuse you. Clearly, we have here all the makings of a computational trap. Unless the robot can be assured that some of its beliefs are invariant under some of its actions, it will never get to *do* anything.

How, then, does the machine's program determine which beliefs the robot ought to reevaluate given that it has embarked upon some or other course of action? What makes this problem so hard is precisely that it seems unlikely that any *local* solution will do the job. For example, the following truths appear to be self-evident: First, that there is no fixed set of beliefs such that, for any action, those and only those beliefs are the ones that require reconsideration. (That is, which beliefs are up for grabs depends inti-

mately upon which actions are performed and upon the context of the performances. There are *some* – indeed, indefinitely many – actions which, if performed, *should* lead one to consider the possibility that Mary's telephone number has changed in consequence.) Second, new beliefs don't come docketed with information about which old beliefs they ought to affect. On the contrary, we are forever being surprised by the implications of what we know, including, of course, what we know about the actions we perform. Third, the set of beliefs apt for reconsideration cannot be determined by reference to the recency of their acquisition, or by reference to their generality, or by reference to merely semantic relations between the contents of the beliefs and the description under which the action is performed... etc. Should any of these propositions seem *less* than self-evident, consider the special case of the frame problem where the robot is a mechanical scientist and the action performed is an experiment. Here the question 'which of my beliefs ought I to reconsider given the possible consequences of my action' is transparently equivalent to the question "What, in general, is the optimal adjustment of my beliefs to my experiences?" This is, of course, exactly the question that a theory of confirmation is supposed to answer; and, as we have been at pains to notice, confirmation is not a relation reconstructible by reference to local properties of hypotheses or of the data that bear upon them.

I am suggesting that, as soon as we begin to look at cognitive processes other than input analysis – in particular, at central processes of nondemonstrative fixation of belief – we run into problems that have a quite characteristic property. They seem to involve isotropic and Quineian computations; computations that are, in one or other respect, sensitive to the whole belief system. This is exactly what one would expect on the assumption that nondemonstrative fixation of belief really is quite like scientific confirmation, and that scientific confirmation is itself characteristically Quineian and isotropic. In this respect, it seems to me, the frame problem is paradigmatic, and in this respect the seriousness of the frame problem has not been adequately appreciated.

For example, Raphael (1971) comments as follows: "(An intelligent robot) will have to be able to carry out tasks. Since a task generally involves some change in the world, it must be able to update its model (of the world) so it remains as accurate during and after the

performance of a task as it was before. Moreover, it must be able to *plan* how to carry out a task, and this planning process usually requires keeping 'in mind' simultaneously a variety of possible actions and corresponding models of hypothetical worlds that would result from those actions. The bookkeeping problems involved with keeping track of these hypothetical worlds account for much of the difficulty of the frame problem" (p. 159). This makes it look as though the problem is primarily (a) how to notate the possible worlds and (b) how to keep track of the *demonstrative* consequences of changing state descriptions. But the deeper problem, surely, is to keep track of the *nondemonstrative* consequences. Slightly more precisely, the problem is, given an arbitrary belief world *W* and a new state description 'a is F', what is the appropriate successor belief world *W'*? What ought the device to believe, given that it used to believe *W* and now believes that a is F? But this isn't just a bookkeeping problem; it is the general problem of inductive confirmation.²⁰

So far as I can tell, the usual assumption about the frame problem in AI is that it is somehow to be solved 'heuristically'. The idea is that, while nondemonstrative confirmation (and hence, presumably, the psychology of belief fixation) is isotropic and Quineian *in principle*, still, given a particular hypothesis, there are, in practice, heuristic procedures for determining the range of effects its acceptance can have on the rest of one's beliefs. Since these procedures are by assumption merely heuristic, they may be assumed to be local – i.e., to be sensitive to less than the whole of the belief systems to which they apply. Something like this may indeed be true; there is certainly considerable evidence for heuristic short-cutting in belief fixation, deriving both from studies of the psychology of problem-solving (for a recent review, see Nisbett and Ross, 1980) and from the sociology of science (Kuhn, 1970). In such cases, it is possible to show how potentially relevant considerations are often systematically ignored, or distorted, or misconstrued in favor of relatively local (and, of course, highly fallible) problem-solving strategies. Perhaps a bundle of such heuristics, properly coordinated and rapidly deployed, would suffice to make the central processes of a robot as Quineian and isotropic as yours, or mine, or the practicing scientist's ever actually succeed in being. Since there are, at present, no serious proposals about what heuristics might belong to such a bundle, it seems hardly worth arguing the point.

Still, I am going to argue it a little.

There are those who hold that ideas recently evolved in AI – such notion as, e.g., those of 'frame' (see Minsky, 1975)²¹ or 'script' (see Schank and Abelson, 1975) – will illuminate the problems about the globality of belief fixation since they do, in a certain sense, provide for placing a frame around the body of information that gets called when a given sort of problem is encountered. (For a discussion that runs along these optimistic lines, see Thagard, 1980.) It seems to me, however, that the appearance of progress here is entirely illusory – a prime case of confusing a notation with a theory.

If there were a principled solution to the frame problem, then no doubt that solution could be expressed as a constraint on the scripts, or frames, to which a given process of induction has access. But, lacking such a solution, there is simply no content to the idea that only the information represented in the frame (/script) that a problem elicits is computationally available for solving the problem. For one thing, since there are precisely no constraints on the individuation of frames (/scripts), *any* two pieces of information can belong to the same frame (/script) at the discretion of the programmer. This is just a way of saying that the solution of the frame problem can be accommodated to the frame (/script) notation *whatever that solution turns out to be*. Which is just another of saying that the notation does not constrain the solution. Second, it is a widely advertised property of frames (/scripts) that they can cross-reference to one another. The frame for Socrates says, among other things, 'see Plato' . . . and so forth. There is no reason to doubt that, in any developed model, the system of cross-referencing would imply a graph in which there is a route (of greater or lesser length) from each point to any other. But now we have the frame problem all over again, in the form: Which such paths should actually be traversed in a given case of problem-solving, and what should bound the length of the trip? All that has happened is that, instead of thinking of the frame problem as an issue in the logic of confirmation, we are now invited to think of it as an issue in the theory of executive control (a change which there is, by the way, no reason to assume is for the better). More of this presently.

For now, let's summarize the major line of argument. If we assume that central processes are Quineian and isotropic, then we ought to predict that certain kinds of problems will emerge when we try to construct psychological theories which simulate such processes or

otherwise explain them; specifically, we should predict problems that involve the characterization of nonlocal computational mechanisms. By contrast, such problems should not loom large for theories of psychological modules. Since, by assumption, modular systems are informationally encapsulated, it follows that the computations they perform are relatively local. It seems to me that these predictions are in reasonably good accord with the way that the problems of cognitive science have in fact matured: the input systems appear to be primarily stimulus driven, hence to exploit computational processes that are relatively insensitive to the general structure of the organism's belief system. Whereas, when we turn to the fixation of belief, we get a complex of problems that appear to be intractable precisely because they concern mental processes that aren't local. Of these, the frame problem is, as we have seen, a microcosm.

I have been marshaling considerations in favor of the view that central processes are Quineian/isotropic. That is what the analogy to scientific confirmation suggests that they ought to be, and the structure of the problems that arise in attempts to model central processes is quite compatible with that view of them. I now add that the view of central processes as computationally global can perhaps claim some degree of neurological plausibility. The picture of the brain that it suggests is a reasonably decent first approximation to the kind of brain that it appears we actually have.

When we discussed input analyzers, I commented on the natural connection between informational encapsulation and fixed neural architecture. Roughly, standing restrictions on information flow imply the option of hardwiring. If, in the extreme case, system B is required to take note of information from system A and is allowed to take note of information from nowhere else, you might as well build your brain with a permanent neuroanatomical connection from A to B. It is, in short, reasonable to expect biases in the distribution of information to mental processes to show up as structural biases in neural architecture.

Consider, by contrast, Quineian/isotropic systems, where more or less any subsystem may want to talk to any other at more or less any time. In this case, you'd expect the corresponding neuroanatomy to be relatively diffuse. At the limit, you might as well have a random net, with each computational subsystem connected, directly or indirectly, with every other; a kind of wiring in which you get a minimum of sta-

ble correspondence between neuroanatomical form and psychological function. The point is that in Quineian/isotropic systems, it may be *unstable, instantaneous* connectivity that counts. Instead of hardwiring, you get a connectivity that changes from moment to moment as dictated by the interaction between the program that is being executed and the structure of the task in hand. The moral would seem to be that computational isotropy comports naturally with neural isotropy (with what Lashley called "equipotentiality" of neural structure) in much the same way that informational encapsulation comports naturally with the elaboration of neural hardwiring.

So, if input analysis is modular and thought is Quineian/isotropic, you might expect a kind of brain in which there is stable neural architecture associated with perception-and-language but not with thought. And, I suggest, this seems to be pretty much what we in fact find. There is, as I remarked above, quite a lot that can be said about the neural specificity of the perceptual and linguistic mechanisms: at worst we can enumerate in some detail the parts of the brain that handle them; and at best we can exhibit characteristic neural architecture in the areas where these functions are performed. And then there are the rest of the higher brain systems (cf. what used to be called "association cortex"), in which neural connectivity appears to go every which way and the form/function correspondence appears to be minimal. There is some historical irony in all this. Gall argued from a (vertical) faculty psychology to the macroscopic differentiation of the brain. Flourens, his archantagonist, argued from the unity of the Cartesian ego to the brain's equipotentiality (see Bynum, 1976.). The present suggestion is that they were *both* right.²²

I am, heaven knows, not about to set up as an expert on neuropsychology, and I am painfully aware how impressionistic this all is. But while we're collecting impressions, I think the following one is striking. A recent issue of *Scientific American* (September, 1979) was devoted to the brain. Its table of contents is quite as interesting as the papers it contains. There are, as you might expect, articles that cover the neuropsychology of language and of the perceptual mechanisms. But there is nothing on the neuropsychology of thought – presumably because nothing is known about the neuropsychology of thought. I am suggesting that there is a good reason why nothing is known about it – namely, that there is nothing to know about it. You get form/function correspondence for the modular processes (specifically, for

the input systems); but, in the case of central processes, you get an approximation to universal connectivity, hence no stable neural architecture to write *Scientific American* articles about.

To put these claims in a nutshell: there are *no* content-specific central processes for the performance of which correspondingly specific neural structures have been identified. Everything we now know is compatible with the claim that central problem-solving is subserved by equipotential neural mechanisms. This is precisely what you would expect if you assume that the central cognitive processes are largely Quineian and isotropic.

Notes

- 1 Strictly speaking, I suppose, a convention must be something one can adhere to if one chooses; so perhaps the principle at issue is not "Say only what is true" but rather "Say only what you believe." General adherence to the latter injunction will license inferences from utterances to how the world is, given the assumption (which is, anyhow, in all sorts of ways epistemologically indispensable) that much of what people believe is true.
- 2 The "McGurk effect" provides fairly clear evidence for cross-modal linkages in at least one input system for the modularity of which there is independent evidence. McGurk has demonstrated that what are, to all intents and purposes, hallucinatory speech sounds can be induced when the subject is presented with a visual display of a speaker making vocal gestures appropriate to the production of those sounds. The suggestion is that (within, presumably, narrowly defined limits) mechanisms of phonetic analysis can be activated by – and can apply to – *either* acoustic or visual stimuli. (See McGurk and MacDonald, 1976). It is of central importance to realize that the McGurk effect – though cross-modal – is itself domain specific – viz., specific to language. A motion picture of a bouncing ball does not induce bump, bump, bump hallucinations. (I am indebted to Professor Alvin Liberman both for bringing McGurk's results to my attention and for his illuminating comments on their implications.)
- 3 Generally speaking, the more peripheral a mechanism is in the process of perceptual analysis – the earlier it operates, for example – the better candidate for modularity it is likely to be. In the limit, it is untendentious – even traditional – to view the functioning of psychophysical (/sensory) mechanisms as largely autonomous with respect to central processes and largely parallel with respect to one another. There is recent, striking evidence owing to Treisman and her colleagues that the detection of such stimulus "features" as shape and color is typically parallel, preattentive, and *prior* to the identification of the object in which the features, as it were, inhere: "... features are registered early, automatically, and in parallel across the visual field, while objects are identified separately only at a later stage, which requires focused attention" (Treisman and Gelade, 1980, p. 98). There is analogous evidence for the modularity of phonetic feature detectors that operate in speech perception (see Eimas and Corbet, 1973), though its interpretation is less than univocal (see Ganong, 1977).
- 4 I won't, in general, have much to say about input processes other than those involved in vision and language, since these are by far the areas in which the available psychology is most developed. But I hope, and believe, that the points I'll be making apply pretty well to all of the perceptual mechanisms.
- 5 Strictly speaking, I suppose I should say that this is true according to all current non-Gibsonian accounts. For reasons given elsewhere, however (see Fodor and Pylyshyn, 1981), I am deeply unmoved by the Gibsonian claim to have devised a noncomputational theory of perception. I propose simply to ignore it in this discussion.
- 6 Also, given that you hear it as speech, you may have some (surely very limited) options as to which speech you hear it as. For a demonstration of instructional effects in phone recognition, see Carden, Levitt, Jusczyk, and Walley (1981). In somewhat similar fashion: it's hard to see the Necker cube in anything but three-dimensional projection; but you do have some control over which three-dimensional projection you see.
- 7 Pedantic footnote: To the best of my knowledge, the suggestion that what seems to be the inaccessibility of information to *consciousness* is in fact just its inaccessibility to *recall* was first made by William James in the *Principles of Psychology*. James, in his enthusiasm, takes this claim to be quite general. If he'd been right, then the specific inaccessibility of intermediate input representations to report would be a relatively uninteresting epiphenomenon of the subject's allocation of memory resources. However, as we shall see, James's story won't wash; there is clearly more to unconsciousness than he supposed.
- 8 A similar moral is suggested by studies of 'compressed' speech, in which signals presented at input rates much in excess of normal are apparently quite intelligible so long as the increased speed is not achieved at the price of acoustic degradation of the signal. (See Foulke, 1971.)
- 9 A sufficient, but not a necessary, condition for the level of representation *n* being 'higher' than

- the level of representation m is that the entities specified at n contain the entities specified at m as constituents (in the way that words have syllables as constituents, for example). It would be nice if there proved to be a well-ordering of the interlevels of representation computed by each input system, but nothing in the present discussion depends on assuming that this is so. Still less is there reason to assume, in cases where the computations that a system performs are affected by data fed into it from outside, that the exogenous information can always be ordered, with respect to abstractness, relative to the levels of representation that the system computes. I shall conform to the prevalent usage in which *all* effects of background beliefs and expectations in perceptual processing are described as the feedback of information from 'higher levels'. But it is far from clear that either 'higher' or 'level' should be taken very seriously when so employed.
- 10 A corollary consideration is that, if the argument for expectation-driven processes in perception is to be made on teleological grounds, their putative advantages must be carefully weighed against their likely costs. In cases where the environment does *not* exhibit the expected redundancy, the typical effect of predictive error will be to *interfere with* the correct analysis (see Posner, 1978). It is thus by no means a trivial matter to show – even in cases like language processing where quantitative estimates of redundancy can, in some respects, be achieved – that the balance of payoffs favors predictive mechanisms over ones that are data driven. (See Gough, Alford, and Haley-Wilcox, 1978.)
 - 11 That is, perceptual categories are not, in general, *definable* in terms of transducer outputs; phenomenologists, operationalists, Gibsonians, and procedural semanticists to the contrary notwithstanding. (See Fodor, 1981, chap. 7; Fodor and Pylyshyn, 1981.)
 - 12 A plausible inference from this discussion is that lots of information to which input analyzers do have access must be stored twice; once internal to the input analyzers and once in the (putative) central memory where it is accessible to non-modular cognitive processes. This seems natural enough: when you learn about English syntax (e.g., in a linguistics course), what you are learning is something that, in some sense, you already knew. See the discussion of 'subdoxastic' belief at the end of this section.
 - 13 It might be suggested that the impressive consideration is not that there is sometimes measurable competition between input systems, but that the decrements in performance that such competition produces are so small. Given the amount of processing that each must involve, the very fact that we can speak and see at the same time is, arguably, enough to vindicate Gall. But nobody knows what the null hypothesis would look like here, and given the impossibility of serious quantitative estimates, I don't propose to press the point.
 - 14 Recent experiments increasingly suggest that the effects of contextual variables upon the identification of words in sentences are far more fragile than psychologists of the top-down persuasion used to suppose. For example, if you ask a subject to decide, at his best speed, whether a stimulus item is a word (i.e., as opposed to a phonologically licit nonsense syllable), then he will be faster for a word that is highly predictable in context than for that same word in a neutral context. In effect, 'salt' is faster in 'pepper and —' than in 'cheese and —'. This makes it look as though contextual predictability is facilitating 'lexical decision' and is just the sort of result that is grist for the New Look psychologist's mill. It turns out, however, that if you compare reaction times for a highly-predictable-in-context word with reaction times for that same word *in isolation*, you find no facilitation at all when the Cloze probability of the former stimulus is less than 90 percent (Fishler and Bloom, 1979). It appears, in light of such findings, that previous claims for the cognitive penetration of lexical access by contextual information may have been considerably exaggerated. At best, the phenomenon seems to be sensitive to the choice of experimental paradigm and of baseline.
 - 15 A proposal currently in the air is to split the difference between strictly encapsulated parsers and contextually driven ones, as follows: semantic information is never used to predict syntactic structure, but a line of analysis on which the parser is engaged can be aborted whenever it produces structures that resist contextual integration. Boxologically, this means that the parser feeds information freely to the context analyzer, but all that the context analyzer is allowed to say to the parser is either 'yes' (continue with the present line of analysis) or 'no' (try something else, I can't fit what you're giving me to the context). What the context analyzer is *prohibited* from doing is telling the parser *which* line of analysis it ought to try next – i.e., semantic information can't be used predictively to guide the parse. (For a discussion of this model, see Crain and Steedman, 1981.) All the results I know on context effects in parsing are compatible with this account; I'm inclined to bet (small denominations) that something of the sort will prove to be true.
 - 16 Stich himself speaks not of subdoxastic beliefs but of subdoxastic *states*, not only to avoid etymological solecism, but also to emphasize that the subdoxastic lacks some of belief's paradigm properties. Granting Stich's point, the present

- terminology is nonetheless convenient and I shall adhere to it.
- 17 This is, of course, an idealization; decisions about what to believe (subdoxastically or otherwise) do not, in general, succeed in making the optimal use of the available data. This consideration does not, however, affect the present point, which is just that such decisions must, of necessity, be sensitive to information from many different sources.
- 18 There is an assumption underlying this line of argument which the reader may not wish to grant: that the mechanisms that interface between vertical faculties have to be *computational* rather than, as one might say, merely mechanical. Old views of how language connects with perception (e.g., percepts are pictures and words are their associates) implicitly deny this assumption. It seems to me, however, that anyone who thinks seriously about what must be involved in deciding (e.g.) how to say what we see will accept the plausibility of the view that the mental processes that are implicated must be both computational and of formidable complexity.
- 19 Stronger versions had it that each theory statement must be logically equivalent to some (finite?) conjunction of observation statements. For a sophisticated review of this literature, see Glymour, 1980. Glymour takes exception to some aspects of the Quineian account of confirmation, but not for reasons that need concern us here.
- 20 It is often proposed (see, e.g., McCarthy, 1980) that a logic capable of coping with the frame problem will have to be 'nonmonotonic'. (Roughly, a logic is monotonic when the addition of new postulates does *not* reduce the set of previously derivable theorems; nonmonotonic otherwise.) The point is that new beliefs don't just get *added on* to the old set; rather, old beliefs are variously altered to accommodate the new ones. This is, however, hardly surprising on the analysis of the frame problem proposed in the text. For, on that account, the frame problem is not distinguishable from the problem of nondemonstrative confirmation, and confirmation relations are themselves typically nonmonotonic. For example, the availability of a new datum may necessitate the assignment of new confirmation levels to indefinitely many previously accepted hypotheses. Hence, if we think of the confirmation system as formalized, indefinitely many previously derivable formulas of the form 'the level of H is L' may become nontheorems whenever new data become available.
- 21 Since there is no particular relation between *the frame problem* and *frames-cum-data* structures, the nomenclature in this area could hardly be more confusing.
- 22 The localization dispute didn't, of course, end with Gall and Flourens. For a useful, brief survey of its relatively modern history (since Wernicke), see Eggert (1977). It is of some interest – in passing – that Wernicke, committed localizationalist though he was in respect of the language mechanisms, held that only "primary functions . . . can be referred to specific areas. . . . All processes which exceed these primary functions (such as the synthesis of various perceptions into concepts and the complex functions such as thought and consciousness) are dependent upon the fiber bundles connecting different areas of the cortex" (p. 92). Barring the associationism, Wernicke's picture is not very different from the one that we've been developing here.

Chapter 45: Commitment¹

BRIAN SKYRMS

Modular Rationality

In Stanley Kubrick's 1963 film, *Dr. Strangelove, or How I Learned to Stop Worrying and Love the Bomb*,² the USSR has built a doomsday machine – a device that, when triggered by an enemy attack or when tampered with in any way, will set off a nuclear explosion potent enough to destroy all human life. The doomsday machine is designed to be set off by tampering, not to guard it from the enemy but to guard it from its builders having second thoughts. For surely if there were an attack, it would be better for the USSR to suffer the effects of the attack than to suffer the combined effects of the attack and the doomsday machine. After an attack, if they could, they would disable the doomsday machine. And if their enemies could anticipate this, the doomsday machine would lose its power to deter aggression. For this reason, the commitment to retaliate had been built into the doomsday machine. Deterrence requires that all this be known. There is a memorable scene in the film in which Peter Sellers as Dr. Strangelove shouts over the hotline: "You fools! A doomsday machine isn't any good if you don't tell anyone you have it!"

Hollywood is not that far from Santa Monica, where cold war strategies were analyzed at the RAND Corporation. Hermann Kahn reports a typical beginning to a discussion of the policy of massive retaliation:

One Gedanken experiment that I have used many times and in many variations over the last twenty-five or thirty years begins with the statement: "Let us assume that the president of the United States has just been informed

that a multimegaton bomb has been dropped on New York City. What do you think that he would do?" When this was first asked in the mid-1950s, the usual answer was "Press every button for launching nuclear forces and go home." The dialogue between the audience and myself continued more or less as follows:

Kahn: What happens next?

Audience: The Soviets do the same!

Kahn: And then what happens?

Audience: Nothing. Both sides have been destroyed.

Kahn: Why then did the American President do this?

A general rethinking of the issue would follow, and the audience would conclude that perhaps the president should not launch an immediate all-out retaliatory attack.³

In his story, Kahn has led his audience to the point at which the policy of massive retaliation and the supposed equilibrium in deterrence by mutually assured destruction begins to unravel. They have begun to see that the policy is based on a threat that would not be rational to carry out if one were called upon to do so.

The fundamental insight is not new. My friend Bill Harper likes to use Puccini's opera *Gianni Schicchi*⁴ as an illustration.⁵ The plot is based on an old story; the title character can be found in Dante's *Inferno*.⁶ Buoso Donati has died and his will leaves his fortune to a monastery. His relatives call in a noted mimic, Gianni Schicchi. After first explaining the severe penalties for tampering with a will, which include having one's hand cut off, he offers to impersonate Buoso on his deathbed and dictate a new will to a

notary. The relatives accept, but on the occasion Schicchi names himself rather than the relatives as the heir. At this juncture, the relatives have no recourse but to remain silent, for to expose Schicchi would be to expose themselves.⁷

There is a clear folk moral here. A strategy that includes a threat that would not be in the agent's interest to carry out were she called upon to do so, and which she would have the option of not carrying out, is a defective strategy. The point is not really confined to threats. In a credible contingency plan for a situation in which an agent faces a sequence of choices, her plan should specify a *rational* choice at each choice point, relative to her situation at that choice point. Such a contingency plan exhibits *modular rationality* in that it is made up of modules that specify rational choices for the constituent decisions.

Kahn led his audiences into a realization that *peace by mutually assured destruction* is a doctrine that fails the test of modular rationality. Building a doomsday machine preempts the question of modular rationality by removing a choice point. In strategic interactions where the agents' contingency plans and continuing rationality are common knowledge, folk wisdom tells us that modular rationality of strategies is a necessary condition for a credible equilibrium.

It should come as no surprise that this principle is also to be found in contemporary game theory. In 1965, Reinhard Selten⁸ argues that a credible equilibrium in a game should be *subgame perfect*. That is to say that the players' strategies restricted to any subgame should be an equilibrium of that subgame. The mutually assured destruction equilibrium, MAD, is not subgame perfect because the decision problem in which country A has been attacked and must decide for or against mutual destruction counts as a (degenerate) subgame, and in the subgame, MAD prescribes a non-optimal, non-equilibrium action. Subgame imperfect equilibria always reflect failures of modular rationality, but some failures of modular rationality do not show up in subgames in this way.⁹ Modularity rationality is the fundamental general principle.¹⁰

Empirical Justice

To say that a principle is part of folk wisdom is not the same as to say that it is part of common practice. Experiments devised to test bargaining theory have been interpreted to show that modular rationality is routinely violated in practice.

In 1982, Güth, Schmittberger, and Schwartz investigated behavior in a bargaining game that brings the question of modular rationality into play. [...] There] is a good – here a sum of German marks – to be divided. But now player one – the ultimatum giver – gets to make an opening proposal and player two can only accept or reject the offer. If player two rejects the offer, neither player gets anything; otherwise player one gets what he proposes and player two gets what is left. This game is known as *The Ultimatum Game* or *Take It or Leave It!*

Under the assumption that utility here is equal to money, this game has an infinite number of game theoretic equilibria. A version of fair division is one of them. If player one has a strategy of proposing equal division, and player two has a strategy of accepting an offer of at least half, but rejecting any offer of less, the players are at a Nash equilibrium of the game – that is to say, for each player that given the other player's strategy, she is doing as well as possible. But there are also similar Nash equilibria in which the split is 40 percent–60 percent, 10 percent–90 percent, or whatever you please.

Most of these equilibria, however, fail the Gianni Schicchi test. Supposing that player two prefers more to less and acts on her preferences, she will not carry out the threat to refuse a positive offer less than 50 percent (or 40 percent or ...). If the threat is not credible, player one need not worry about it and would do better asking for more. We are left with a subgame perfect equilibrium in which player one offers player two one pfennig and proposes to keep the rest, and player two the strategy of accepting one pfennig but rejecting an offer of nothing. But this modular-rational behavior is not what the experimenters find.

Güth, Schmittberger, and Schwarze tried the ultimatum game on graduate students in economics at the University of Cologne.¹¹ A round of twenty-one games was played. A week later, the experiment was repeated with different random matching of subjects. The modular-rational equilibrium behavior described above was not played in any of these games. In the first experiment, the most frequent offer¹² was equal division. Other subjects in the role of player one tried to exploit their strategic advantage a bit, but not to the point of claiming almost all of the money. The mean demand was just under 2/3. In two cases, quite greedy demands¹³ were rejected. When the same subjects played the game again after having a week to think about it,

the ultimatum givers were slightly more greedy with a mean demand of 69% and more of those asked to “take it or leave it” left it, with 6 offers declined. One subject attempted to implement our modular-rational solution by demanding 4.99 out of 5 marks but that offer was rejected (as were three offers that would have left player two with only 1 mark).¹⁴

The pattern of most naive subjects making an offer at an equal split or close to it, when in the role of player one, and punishing low offers at their own expense by rejection as player two has been widely observed. Roth, Prasnikar, Okuno-Fujiwara, and Zamir¹⁵ ran ultimatum game experiments at their respective universities in the United States, Yugoslavia, Japan and Israel. The experimenters were interested in the effect of learning when subjects repeatedly played the game over ten rounds. (In the context of a somewhat different bargaining game, Binmore, Shaked, and Sutton¹⁶ had suggested that learning from experience would turn “fairmen” into modular-rational “gamesmen”.) In all countries the modal initial offer was an even split, and a substantial number of low offers were rejected. In round ten, this is still true in the United States and Yugoslavia but the modal offer in Israel has fallen to 40 percent. In Japan, there are modes at 40 percent and 45 percent. In some cases, experience has led to an attempt to exploit the strategic advantage of the first move, but nowhere are the experienced players close to being gamesmen. A 60–40 split is closer to 50–50 than to 99–1. One might speculate whether 100 or 1,000 rounds would have moved the players close to subgame perfect equilibrium behavior. However that may be, we want to focus here on the initial behavior exhibited by naive subjects. Why do they do it?

It will come as no surprise that the most widely suggested hypothesis is simply that many subjects, rather than maximizing their expected monetary payoff, are implementing norms of fairness. It is important to keep in mind that these must include not only norms for making fair offers in the role of player one, but also norms for punishing unfair offers in the role of player two – provided the cost of punishment is not too high. None of the punishers is risking having his hands cut off. None is launching all ICBS. But many are willing to give up a dollar or two to punish a greedy proposer who wanted eight or nine.

Richard Thaler chooses the ultimatum game as the subject for the initial article in a series on anomalies in economics – an anomaly being

“an empirical result which requires implausible assumptions to explain within the rational choice paradigm.” But we have a clear violation of the rational choice paradigm here only on the assumption that, for these subjects, utility = income. From the standpoint of rational choice theory, the subjects’ utility functions are up to them. There is no principled reason why norms of fairness cannot be reflected in their utilities in such a way as to make their actions consistent with the theory of rational choice.¹⁷

Appeal to norms of fairness, however, hardly constitutes an explanation in itself. Why do we have such norms? Where do they come from? If they are modeled as factors in a subjective utility function, how do such utility functions come to be so widespread? An explanation might be attempted at the psychological level. Here it may be natural to appeal to the phenomenon of generalization. The sequential problem of dividing a cake in ultimatum bargaining may not seem to subjects much different than the problem where claims are simultaneous and submitted independently. In the latter case, fair division is a perfectly acceptable game theoretic solution. Perhaps subjects generalize from the simultaneous case to the sequential case. That would explain the equal-split offers on the part of player one, but leave unexplained the rejection of low offers on the part of player two. Perhaps punishing behavior could be explained by generalization from some different context. But even if that were the case, we would still be left with the evolutionary question: Why have norms of fairness not been eliminated by the process of evolution? An increase in income of real goods usually translates into an increase in evolutionary fitness.¹⁸ How then could norms of fairness, of the kind observed in the ultimatum game, have evolved?

Evolution of an Anomaly

Of course, generalization can play a role in evolutionary theory. Just as an organ that evolves for one function may be used for another, so a behavioral rule that evolves in the context of one sort of encounter may well be triggered by a similar encounter. Ultimatum game behavior did not evolve solely in a context of ultimatum games. Nevertheless, it may be instructive to build and study a model in which it does. We will see that under favorable conditions, standard evolutionary game dynamics allows the anomalous behavior observed in experiments to evolve.

Table 1: Rule-Based Strategies

	<i>If Player One</i>	<i>If Player Two</i>
S1: Gamesman	Demand 9	Accept All
S2	Demand 9	Reject All
S3	Demand 9	Accept 5, Reject 9
S4: Mad Dog	Demand 9	Accept 9, Reject 5
S5: Easy Rider	Demand 5	Accept All
S6	Demand 5	Reject All
S7: Fairman	Demand 5	Accept 5, Reject 9
S8	Demand 5	Accept 9, Reject 5

We will begin with a simplified ultimatum game, in which each player has only two choices. The cake is divided into ten pieces, and player one can either demand five pieces or nine pieces. Player two either accepts or rejects the proposal as before.¹⁹ We will analyze this game within the context of standard evolutionary game theory.

First, we have to determine the evolutionary strategies at issue in this game. Player one has only two strategies: Demand 9; Demand 5. Player two has four strategies, as evolution must tell her what to do in each contingency. Her strategies are: Accept All; Reject All; Accept if 5 is demanded, but Reject if 9 is demanded; Accept if 9 is demanded but Reject if 5 is demanded.

Next we have to decide between two evolutionary stories. According to the first story, there are two different populations: The Proposers and the Disposers. Those who take the role of player one come from the proposers and those who take the role of player two come from the disposers. According to the second story, there is one population, and individuals from that population sometimes play one role and sometimes another. The two-population model has recently been investigated by Binmore, Gale, and Samuelson (1995). They reach the conclusion that, under certain conditions regarding relative amounts of "noise" in the two populations, the anomalous behavior can evolve. This raises the question whether that behavior can evolve in a single population. The single-population story, after all, seems more relevant to the phenomena under discussion. Here each individual must have as a strategy a rule that tells her what to do in each role, so there are now eight strategies to consider. The strategies are listed in Table 1. I have given names to strategies that are of special interest. In particular, we have two strategies on which most of the game theoretical literature is focused: S1 = *Gamesman* and S7 = *Fairman*. (Note that

"reject 9" means "reject a demand by the first player for 9" or equivalently "reject an offer of 1 to you.") The role of the other two named strategies will emerge in the following discussion.

We assume that individuals are randomly paired from the population; that the decision as to which individual is to play which role is made at random; and that the payoffs are in terms of evolutionary fitness. Because a strategy determines what a player will do in each role, we can now calculate the expected fitness for any of the eight strategies that results from an encounter with any of the eight strategies.²⁰ The assumption of random pairing from a large population, together with the payoffs being in terms of fitness, leads to the replicator dynamics of evolutionary game theory. You can program your computer to simulate this dynamics and observe how populations with various proportions of these strategies will evolve.

Suppose we start with a population with equal proportions of the strategies. Fairmen (S7) go extinct and Gamesmen (S1) persist. But Gamesmen do not take over the entire population. Rather, the population evolves to a polymorphic state composed of about 87 percent Gamesmen and about 13 percent Mad Dogs. The surprise here is the persistence of the rather odd strategy, Mad Dog, which rejects fair offers and accepts unfair ones. Mad Dogs do worse against S5, S6, S7, and S8 than Gamesmen do, but S5, S6, S7, and S8 die off more rapidly than Mad Dogs. When they are extinct, and only greedy first moves are made, Mad Dogs do exactly as well as Gamesmen.

Not every initial mixed population, however, will lead to the extinction of Fairmen. Suppose we start with 30 percent of the population using the Fairman strategy S7 with the remaining strategies having equal proportions of the rest of the population. Then Gamesmen, Mad Dogs, and several other types are driven to extinction. The dynamics carries the population to a state composed of about 64 percent Fairmen and about 36 percent Easy Riders. Let us try a somewhat more plausible initial point, where the population proportions of S1-S8 are, respectively, $\langle .32, .02, .10, .02, .10, .02, .40, .02 \rangle$. The replicator dynamics carries this population to a state of 56.5 percent Fairmen and 43.5 percent Easy Riders.²¹ Again, the "anomalous" Fairman strategy has survived.

Again, it is accompanied by Easy Rider. This is a strategy which makes fair offers but accepts all offers. It free rides on Fairman during the period it takes to drive the greedy S1-S4 to extinction.

As long as some of these greedy strategies are around, Easy Riders do strictly better than Fairmen; but when greedy strategies have been driven to extinction, Fairmen and Easy Riders do exactly as well as each other.

Notice that it is also true that, in the scenario where Gamesmen and Mad Dogs win out, the Gamesmen are free riding on the Mad Dogs in exactly the same way during the extinction of those who make fair offers. It is not usual to think of punishing those who make fair offers, but this is exactly what Mad Dogs do. Gamesmen do strictly better than Mad Dogs as long as there are some fair offer makers in the population, and exactly as well as Mad Dogs when the fair offer makers have gone extinct. In the terminology of game theory, the “free rider” in each of the scenarios *weakly dominates* its partner. That is to say that it does better against some strategies, but worse against none. One interesting thing about the replicator dynamics is that it need not carry weakly dominated strategies, such as our “anomalous” Fairman strategy, to extinction.²²

This is closely related to the fact that the replicator dynamics need not respect modular rationality.²³ Fairman is not modular rational because, if confronted with an unfair offer, it requires choosing a payoff of 0 rather than 1. If Fairman is modified by reversing just that choice, we get a strategy that weakly dominates it, Easy Rider. Some types of inductive learning rules do eliminate weakly dominated strategies. It is the special kind of dynamics induced by replication that allows the evolution of strategies that are not modular rational.²⁴

In this ultimatum game, when we choose the initial conditions at random, the evolutionary dynamics *always* carries us to a polymorphism that includes weakly dominated, modular-irrational strategies. We either get some Fairmen or some Mad Dogs. The same is true if we analyze the evolutionary dynamics of this ultimatum game when played between two populations. This is not evident from the paper of Binmore, Gale, and Samuelson only because they do not admit Mad Dog as a possible strategy. If you put it in, you find Gamesman-Mad Dog polymorphisms just as in the one-population model. Our general conclusion does not depend on having only two possible demands in our game. If you allow more possible demands, you typically end up with a more complicated polymorphism that contains several weakly dominated, modular-irrational strategies.²⁵ As we increase the options, the evolutionary dynamics generates a richer set of anomalies.

The Trembling Hand

There is another aspect of modular rationality that we have yet to explore. To introduce it, we return to *The Divine Comedy*. In the *Paradiso*, Dante explains how imperfection arises in the sublunar realm:

If the wax were exactly worked and the heavens were at the heights of their power, the light of the whole seal would be apparent. But nature always gives it defectively, like an artist who in the practice of his art has a hand that trembles.²⁶

Failures of execution are a problem even for God. Although the Divine plan is perfect, the imperfection of the matter on which it is imposed persists. If God’s strategies cannot be executed without mistakes, how can we ignore the possibility of mistakes in the execution of human strategies? This raises a problem for the theology of commitment.

As Selten showed, strategies that fail to be modular rational are not robust with respect to considerations of the “trembling hand.” For an illustration, let us return to *Dr. Strangelove*. Suppose that you build a doomsday machine and the other side follows a policy of not attacking but, as in the film, an insane field commander attacks anyway. Then you will suffer from the execution of that part of your policy that failed the test of modular rationality. If one factors in some small probability of attack by computer or human error, building a perfect doomsday machine would no longer be optimal. It would be better to construct one that doesn’t work. The point is quite general for strategic situations of the kind under consideration. Robustness of a strategic equilibrium with respect to considerations of the trembling hand implies that equilibrium passes the test of modular rationality.²⁷

How does this apply in the ultimatum game? In a population of Fairmen it would be a “mistake” to make a greedy offer, but if those mistakes are made Easy Riders do strictly better than Fairmen. Should we worry about the trembling hand when we think about the evolution of strategies in the ultimatum game? Indeed we should, for evolution involves its own kind of trembles. Evolution is the result of the interplay of two processes: variation and differential reproduction. The replicator dynamics we used in the last section models only differential reproduction. What about variation?

In a species like ours that reproduces sexually, there are two sources of variation: mutation

and recombination. In a species that reproduces asexually all variation is due to mutation. Mutations are rare and only make a significant contribution in the long run. Sexual reproduction vastly increases the amount of variation. There is a Mendelian shuffling of the genome at the conception of each individual. Consequently, sex speeds up the process of evolution.²⁸ Cultural evolution has its own kinds of recombination and mutation.

Recombination

In evolutionary game theory there has been considerable recent interest in modeling mutation,²⁹ but less attention has been paid to recombination.³⁰ The theme of recombination has been pursued in computer science by John Holland and his students under the appellation "genetic algorithms."³¹ Replication is governed by success, judged by some standards appropriate to the problem. Recombination is implemented by "crossover." Once in a while, the code for programs is cut into two pieces, and the first and last pieces are swapped between programs, creating new programs. Most of these new programs will be useless and will die out due to the dynamics of replication. But over many cycles, useful programs are created. The most successful applications of the genetic algorithm approach have been to problems of optimization against a fixed environment. How should the idea of recombination be applied in the context of game theory?

How one cuts and recombines depends on how one parses the underlying structure. In the kind of extensive games that we have been considering, the strategies have a natural structure. We can use this structure, and implement recombination at the level of strategy substructures rather than at the level of strings in some programming language. Thus the strategy: *If player one demand 9; If player two accept a demand of 5 but reject a demand of 9* has as large substrategies: *If player one demand 9* and *If player two then accept a demand of 5 but reject a demand of 9* and as smaller substrategies: *If player two and confronted with a demand of 5 accept it* and *If player two and confronted with a demand of 9 reject it*. The idea to cut and recombine at the level of strategy substructures is put forward in the context of sequential decision problems by John Koza,³² in his book on genetic programming. It is applied to the computer modeling of games by Peter Danielson.³³ Related techniques are used in Axelrod's³⁴ latest work on iterated

Prisoner's Dilemma. I do not want to explore any of these models in detail here, but rather to make a general point about the kind of variation they introduce.

Let us return to the ultimatum game and to the polymorphic equilibrium states discussed in the last section. What is the effect of the trembling hand in the form of recombination on these equilibria? Consider the state of 64 percent Fairmen and 36 percent Easy Riders. Both strategies demand 5. So recombination between them can only produce a strategy that demands 5. Both accept a demand of 5, so recombination between them can only produce a strategy that accepts a demand of 5. Recombination between Fairmen and Easy Riders can only produce Fairmen and Easy Riders. Likewise, recombination will not introduce any new strategies into a population of only Gamesmen and Mad Dogs.

This contrasts with a population composed of players playing S3 and S8. First, notice that each of these strategies does badly against itself but better against the other. If only these two strategies are represented in the population, the replicator dynamics carries the population to a polymorphic equilibrium state where 70 percent of the population plays S3 and 30 percent plays S8. Next, notice that S3 and S8 each have three minimal modules, which are:

S3:	S8:
Demand 9	Demand 5
If 9 demanded, reject	If 9 demanded, accept
If 5 demanded, accept	If 5 demanded, reject

Any of the eight possible strategies can arise from S3 and S8 by recombination. But now against a population consisting of almost all S3 and S8, Gamesmen do better than S3 and Easy Riders do better than S8, so even a little bit of recombination causes the S3–S8 equilibrium to unravel.

The variation introduced here by recombination is a rather special kind of variation. Some population equilibria of the process of differential reproduction represented by the replicator dynamics are more robust to a bit of recombination than others. In particular, the persistence of the weakly dominated and modular-irrational Fairmen strategy is quite consistent with this version of Mother Nature's trembling hand.

Mutation

Mutation is a different process. Unlike recombination, mutation can take any strategy into any other. There is no reason to suppose, however, that every transformation is equiprobable.

Depending on how the mutation mechanism works, some transformations may be more probable than others. We will assume, however, that all transformations have positive probability, so that over the long run no strategy remains extinct. It might seem, at first glance, that weakly dominated strategies could not survive forever in such an environment. Those strategies against which the dominating strategies do better keep popping up, so that differential reproduction must favor the dominating strategies. Is it not simply a matter of time before the dominating strategies take over?

This conclusion may seem plausible, but it does not follow from the stated assumptions. It is correct that the play against mutant strategies of all kinds must give the dominating strategy some reproductive advantage over the dominated one. But it is quite possible that, at the same time, the mutation process creates enough extra individuals using the dominated strategy to counterbalance this effect. Whether these small pressures balance each other or not depends on the proportions of the population playing various strategies, on the mutation rate and on the transition probabilities for mutations.³⁵ There are values for these parameters for which Fairman–Easy Rider polymorphisms persist and for which Gamesman–Mad Dog polymorphisms do. But the Gamesman–Mad Dog polymorphisms do have more modest requirements: And in some plausible scenarios, Easy Riders slowly take over more and more of a Fairman–Easy Rider polymorphism until greedy strategies can profitably invade by exploiting the Easy Rider's accommodating nature.

Could strategies that fail the Gianni Schicchi test survive the trembling hand of evolution? The evolutionary process incorporates two kinds of variation, neither of which corresponds exactly to the metaphor of the trembling hand. Recombination and mutation do not create a mere momentary lapse in behavior, but rather a new individual playing a new strategy. Thus they alter not only the distribution of behaviors determining average fitness, but also the composition of the population. They do so in different ways, with mutation making possible transitions of a type not possible with recombination, but doing so on a much longer time scale. Neither source of variation is guaranteed to eliminate strategies that are not modular rational. Recombination might not even make those strategies that exploit the defect. Mutation introduces all strategies and exploits all defects, although the effect may be very small. However it may also have a

dynamic effect favorable to the strategy in question that counterbalances the weak selection pressure against it. Evolution does not respect modular rationality.

The Theology of Commitment

Folk wisdom recognizes that there can be a conflict between commitment and modular rationality. This happens when an agent commits to a strategy like massive retaliation, which would not be in the agent's interest to carry out if the contingency arose. Nevertheless, we find what appear to be violations of modular rationality in experiments, and we find the persistence of such behavior to be consistent with simple models of the evolutionary process. Should we simply conclude that we have here the evolution of irrationality?

Two philosophers, David Gauthier and Edward McClennen, have taken the opposite point of view – that where commitment conflicts with modular rationality, it is committed behavior that should be called rational. The concept of modular rationality is to be relegated to the intellectual junk pile. This is McLennen's doctrine of "resolute choice"³⁶ and (part of) Gauthier's doctrine of "constrained maximization."³⁷ In opposition to both folk wisdom and game theory, McClennen and Gauthier are promulgating a new theology of commitment.

This movement to "reform" rationality is supported by a consistency argument and an ulterior motive. The consistency argument is put as a question: *Would it not be inconsistent to judge it optimal to have a disposition and yet to judge it suboptimal to carry out the act specified by that disposition?* The ulterior motive is the possibility of deriving ethics from the bare postulates of rational behavior.

Suppose you take it to be rational to build a doomsday machine for its deterrent effect, and you build one and announce it. The other side launches a first strike. If the doomsday machine works, you have no choice, but it malfunctions. You now have a choice of whether to launch all missiles. You decide not to. Are you inconsistent? I do not see an inconsistency. The judgment not to launch all missiles was made in a different state than the judgment that it was optimal to construct the doomsday machine. The decision against massive retaliation was made with the knowledge that a first strike had indeed been launched. The decision to build the doomsday machine was made without that knowledge and in the belief that building the machine would

prevent the first strike. There is nothing very surprising here, and certainly no inconsistency.

Suppose Buoso's relatives had written a letter to be opened if the will came out wrong and let Schicchi know about it. Suppose that, without Schicchi's knowledge, the letter was accidentally destroyed. Suppose that Schicchi names himself as heir anyway – for whatever reason. Would the relatives then be *irrational* not to have their hands cut off in order to carry out their threat? Here I find myself more comfortable with folk wisdom than with philosophical innovation.³⁸

Now for the ulterior motive. Let me start with some history. In 1980 John Harsanyi wrote an important paper on *rule utilitarianism*. Harsanyi argued that the moral behavior of rule utilitarians can be gotten from two assumptions:

1. They play a cooperative game in normal form. In choosing a strategy, they solve the *constrained maximization*³⁹ problem of choosing rules that maximizes social utility subject to the constraint that everyone chooses the same rules.
2. They commit to these rules and follow them no matter what.

Rule utilitarianism is in many ways an attractive ethical position. Rule utilitarians cooperate to their mutual benefit in situations in which *act utilitarians* do not. Harsanyi argues that rule utilitarians can make sense of rights and obligations in a way that act utilitarians cannot.

If you could build 1 and 2 into the meaning of individual rationality, you could derive morality from rationality! Something like this is, I believe, what both Gauthier and McClennen have in mind. The first thing to say about the ulterior motive is that it is an ulterior motive. The project of deriving morality from rationality loses much of its interest when it becomes clear that the first step of the derivation is a redefinition of rationality. The second thing to say is that it is not so clear that commitment, by itself, always leads to a kind of behavior that is morally desirable. The examples we have already discussed illustrate this point. Robert Frank⁴⁰ uses the feud between the Hatfield and McCoy families as an opening illustration of a book whose theme is commitment. Commitment can lead to endless chains of retribution. As a model illustration, consider a strategy that has gotten remarkably good press recently – that of Tit-for-Tat in repeated Prisoner's Dilemma. On each round, each player can either cooperate or defect.

Tit-for-tat begins by cooperating and then does to the other player whatever the other did to him in the last round. Suppose both players adopt a strategy of Tit-for-tat and both players know it, but that at some point one player "trembles" and defects by mistake. The other player will punish him in the next round, and he will punish the other player in the subsequent round, and so on ad infinitum.⁴¹ In this situation each of these players would be better off doing what was necessary to restore mutual cooperation. They are not acting in accordance with modular rationality.⁴² Moral and political philosophers should be aware of the dark side of commitment.

Of course whether we look on the dark side or the sunny side of commitment has little to do with the substantive issue of the relation of rationality to commitment. Rationality is not just a word to play with. There is a *theory* of rational decision, due to Ramsey, de Finetti, and Savage, which is an important part of our intellectual heritage. The theory shows that an agent who has a rich, coherent system of choice-dispositions can be endowed with subjective utilities and subjective probabilities such that choice maximizes expected utility. Suppose we are really talking about such an agent's subjective expected utility. A strategy that is not modular rational in these terms is just one that in certain circumstances would require such a rational agent to choose what she would not choose. Credible implementation requires removing the possibility of choice – as when one builds the Doomsday Machine.

If expected utility theory is kept in mind, the idea of modifying the normative theory by somehow building in commitment appears quixotic. Instead of tilting at subjected expected utility theory, moral theorists could more profitably study the conditions under which moral behavior is consistent with it. This is possible when sympathy and justice are reflected in an agent's utilities and when these operate through good habits, whose maintenance carries high utility for her.⁴³

It is also clear that there is a large gap between the results of ultimatum game experiments and the falsification of subjective expected utility as a descriptive theory. Some players may like to make fair offers and to punish those who don't make fair offers. Why shouldn't they? Who presumes to tell them that utility should equal monetary income? Considerations of fairness could be reflected in utilities.⁴⁴

In contrast with subjective expected utility theory, both evolution and experimentation

share an interest in tangible income. It is for this reason that evolutionary dynamics has some relevance to experimental results. We have seen that strategies that are not modular rational in payoffs in evolutionary fitness may evolve. It remains to be seen how useful it is to conceptualize these strategies within the framework of subjective expected utility theory. If they are treated in this way, one could think of evolution as generating bounds on utility functions for the species. The alchemy of the endocrine system and the emotions can be thought of as a powerful tool in this work.⁴⁵ There is no conflict between subjective utility theory and David Hume's famous rejoinder to Spinoza: "Reason is and ought to be the slave of the passions."

Modularity in Evolution and in Choice

Evolution may – if the conditions are right – favor commitment over modular rationality. Mixed populations that include individuals using strategies that are not modular rational in Darwinian fitness can evolve according to the replicator dynamics. They may not be eliminated in the long run even when we take into account the variation due to both recombination and mutation. We should not be surprised to observe some modest implementation of such strategies, as we do in the ultimatum game experiments.

These strategies need not even fail the test of modular rationality in the subject's own terms, providing we construe the subject's own utility function according to Davidson's principle of charity: "Charity in interpreting the words and thoughts of others is unavoidable in another direction as well: just as we must maximize agreement, or risk not making sense of what the alien is talking about, so we must maximize the self-consistency that we attribute to him, on pain of not understanding him."⁴⁶ A pragmatic version of the principle would urge charity in interpreting the *acts* of others so as to maximize coherence.

However, the process of implementing strategies drawn from a stock of evolved behaviors is a process that introduces its own complications. A choice situation may fall under more than one rule, and then which rule that chooser invokes to characterize or "frame" the situation becomes crucial. Thus, in the ultimatum game, player two could see it as a situation in which she was being offered a choice between \$2 or nothing and apply the rule "More is better" or could see it as an ultimatum game in which the other player was trying to take unfair advantage and apply the

rule "Don't accede to unfair offers in the ultimatum game." Both descriptions correctly characterize the situation, but the rules conflict.

The evolution of behavior itself has a modular aspect. It is not possible to have evolved a special rule for every decision situation. Complex problems have to be solved by combining behavioral modules that have evolved separately. The stock of available modules may be rich enough to generate ambiguity in the characterization of the problem. All sorts of cues⁴⁷ may be relevant to how the ambiguity is resolved, and different resolutions may lead to different decisions.⁴⁸ Even if we leave aside the inevitable confusions and errors, we should not be surprised to find a wide range of behavior in situations like the ultimatum game.

The considerations brought forward in this chapter do not pretend to be a full evolutionary explanation of the fairness effect. Rather, we raise the prior question as to how it might be possible for such behavior to survive in the struggle for existence. In the ultimatum game, this becomes the question of whether a strategy of commitment that fails the test of modular rationality can persist. It can. Evolution does not respect modular rationality.

Notes

- 1 More technical details regarding this chapter may be found in my forthcoming "Evolution of an Anomaly."
- 2 Screenplay by Stanley Kubrick, Peter George, and Terry Southern.
- 3 Kahn (1984), p. 59.
- 4 Premier performance at the Metropolitan Opera, Dec. 14, 1918.
- 5 See Harper (1991).
- 6 Dante, *Paradiso*, Canto XXX.
- 7 If the relatives had devised a doomsday machine – perhaps a letter in the hands of a suitable third party to be delivered to the authorities just in case they are not named as heirs – and if Schicchi had known about it, then he would have had no recourse but to abide by his agreement.
- 8 Selten (1965).
- 9 For examples, see Selten (1975).
- 10 This is the position taken by Kreps and Wilson (1982). Modular rationality is the same as their "sequential rationality."
- 11 The students were not familiar with game theory. Forty-two students were divided equally into player one and player two groups. Subjects did not know which member of the other group they were matched against. The amount to be distributed ranged from 4 to 10 marks.

- 12 Seven of 21 games.
- 13 Demands of all of 4 marks and of 4.80 of 6 marks.
- 14 Subsequently, a third experiment was performed in which 37 new subjects were asked to play both roles in the game by submitting a proposal as player one, and a minimal acceptable share as player two. Notice that *this is not an ultimatum game*. Player one does not deliver an ultimatum, and player two does not decide after receiving one. Rather, they simultaneously make actions that determine their payoffs [. . .]. The questions of modular rationality and of subgame perfection do not arise. The same point applies to the experiments of Kahneman, Knetsch, and Thaler (1986). However the considerations of weak dominance and the trembling hand raised in this chapter are relevant to these games.
- 15 Roth, Prasnikar, Okuno-Fujiwara, and Zamir (1991).
- 16 Binmore, Shaked, and Sutton (1985).
- 17 For an attempt to account for the experimental literature on the ultimatum game in this way, see Bolton (1991). On the other hand, there is already a large body of other experimental literature that raises much more fundamental problems for the descriptive validity of expected utility theory. Against this background, one might try to model the experimental results directly in terms of systems of normative rules of behavior. For this approach, see Güth (1988) and Güth and Teitz (1990).
- 18 It is sometimes objected that rich families now have fewer children than poor families. The comment is directed toward biological evolution rather than cultural evolution. Even there the objection can hardly be taken seriously. Does the objector imagine yuppie *Homo erectus* driving BMWs on the savannah? Through most of evolutionary time, payoff in real goods means the difference between nutrition and starvation, and it correlates very well with Darwinian fitness.
- 19 A variant of this simplified game was used in an experiment by Kahneman, Knetsch, and Thaler (1986).
- 20 Here is the resulting fitness matrix:

	S1	S2	S3	S4	S5	S6	S7	S8
S1	5	.5	.5	5	7	2.5	2.5	7
S2	4.5	0	0	4.5	4.5	0	0	4.5
S3	4.5	0	0	4.5	7	2.5	2.5	7
S4	5	.5	.5	5	4.5	0	0	4.5
S5	3	.5	3	.5	5	2.5	5	2.5
S6	2.5	0	2.5	0	2.5	0	2.5	0
S7	2.5	0	2.5	0	5	2.5	5	2.5
S8	3	.5	3	.5	2.5	0	2.5	0

- 21 This state is dynamically stable in the replicator dynamics – that is to say, that any state close to it remains close to it. But it is not asymptotically stable. It is not true that any state close to it is carried to it by the dynamics. It is not evolutionarily stable in the sense of Maynard Smith and Price (1973).
- 22 That replicator dynamics need not eliminate weakly dominated strategies was, to my knowledge, first noted in Samuelson (1988).
- 23 They are equivalent in the kind of game under discussion here. It is an extensive form two-person game in which each person has exactly one move. See van Damme (1987).
- 24 See Samuelson (1988) and Skyrms (1991).
- 25 William Harms (1994) has investigated a game in which one may demand .2, .4, .6, .8, or 1.0 of the pie. Choosing initial population proportions at random, most of the runs (408 of 500) ended up at populations that demand .8, with a polymorphism in the response strategies that accept that demand.
- 26 Dante, *Paradiso*, Canto XIII. The whole passage is an exposition of Aristotelian doctrine.
- 27 The idea is formally introduced into game theory by Selten (1975) in the concept of a (trembling hand) perfect equilibrium, and elaborated by Myerson (1978) in his more stringent concept of a proper equilibrium. Every proper equilibrium is perfect and every perfect equilibrium uses only undominated strategies. An equilibrium in hardwired (committed) strategies that is robust to trembles in the sense of Myerson’s proper equilibrium is modular rational in the sense of Kreps and Wilson’s “sequential equilibrium” and Selten’s “subgame perfect equilibrium.” For details, see van Damme (1987).
- 28 There is a large literature on the question of how recombination itself evolved. For a sampling of important work, see Muller (1932, 1964), Maynard Smith (1978), and Hamilton (1980).
- 29 Starting with the seminal paper of Foster and Young (1990).
- 30 There are two studies that incorporate recombination into the dynamics: Robert Axelrod (1992), a political scientist, and Peter Danielson (1992), a philosopher. There are also recombination models in Hofbauer and Sigmund (1988).
- 31 See Holland (1975).
- 32 Koza (1992).
- 33 Danielson (1992).
- 34 Axelrod (1997).
- 35 Notice that, even if the transition probabilities are taken to be all equal, mutation may favor the dominated strategy in a given state of the population. Consider the equilibrium of the replicator dynamics with $pr(S1) = .948$ and $pr(S4) = .052$. If a transition in either direction is equally likely, mutation will turn many more S1s into S4s than conversely.
- 36 McClennen (1990).
- 37 Gauthier (1986); but see Gauthier (1990) for second thoughts.

- 38 For philosophical defense of folk wisdom, see Kavka (1978, 1983a, 1983b, 1987) and Lewis (1984).
- 39 Harsanyi's terminology.
- 40 Frank (1988).
- 41 Or until another tremble either has them both cooperate and sets them right or has them both defect and sets them on a path of unrelieved vengeance.
- 42 Thus Tit-for-Tat against Tit-for-Tat is not a subgame perfect equilibrium in repeated Prisoner's Dilemma.
- 43 See the discussion of Good Habits in chapter 6 of my 1990 book.
- 44 As in the model proposed by Bolton (1991).
- 45 As Hirshliefer and Frank point out.
- 46 From "Truth and Meaning" (1967), reprinted in Davidson (1984), p. 27. In the introduction, Davidson attributes the basic idea to Neil Wilson and points out that Quine, in *Word and Object*, applies the principle to logical constants.
- 47 Including the importance of what is at stake.
- 48 This is the approach I would take to the Dictator game of Kahneman, Knetsch, and Thaler (1986). Here the subjects were psychology students at Cornell University. Each subject was asked to divide \$20 between herself and an anonymous student in the same class. She could choose either \$18 for herself and \$2 to the other participant or an even split. There was no possibility of rejection of the offer by the recipient. Some subjects may have seen the dictator game as tantamount to an ultimatum game played against a player who accepts all offers. If such a subject had a generous strategy for the ultimatum game, she might simply apply that and choose an even split. If such a subject had a greedy strategy for the ultimatum game, she would choose the \$18. Some subjects may have framed the problem as simply a choice between \$18 and \$10. In fact, 76 percent of the students divided the money equally. These striking results for the dictator game are somewhat controversial. Other investigators find much lower proportions of subjects offering an equal split in the dictator game. See Forsythe, Horowitz, Savin, and Sefton (1988) and Hoffman, McCabe, Shachat, and Smith (1991). The magnitude of the "fairness factor" is controversial, but its existence is not. That robust phenomenon is consistent with the approach advocated here.

Chapter 46: Evolution of Inference

BRIAN SKYRMS

Philosophical Skepticism

Jean-Jacques Rousseau begins his discussion of the origin of language in *A Discourse on Inequality* by toying with a paradox:

[A] substitution of voice for gesture can only have been made by common consent, something rather difficult to put into effect by men whose crude organs had not yet been exercised; something indeed, even more difficult to conceive of having happened in the first place, for such a unanimous agreement would need to be proposed, which means that speech seems to be absolutely necessary to establish the use of speech.¹

Rousseau moves on without taking the problem seriously, but the paradox echoes through modern philosophy of language. How can we explain the genesis of speech without presupposing speech, reference without presupposing reference, meaning without presupposing meaning? A version of this paradox forms the basis of Quine's attack on the logical empiricist doctrine that logic derives its warrant from conventions of meaning – that logical truths are true and logical inferences are valid by virtue of such conventions. Quine raised the general skeptical question of how conventions of language could be established without preexisting language, as well as calling attention to more specific skeptical circularities. If conventions of logic are set up by explicit definitions, or by axioms, must we not presuppose logic to unpack those conventions?

Convention According to David Lewis

David Lewis (1969) sought to answer these skeptical doubts within a game theoretical framework in his book *Convention*. This account contains fundamental new insights, and I regard it as a major advance in the theory of meaning. Lewis sees a convention as being a special kind of strict Nash equilibrium in a game that models the relevant social interaction. To say that a convention is a Nash equilibrium is to say that if an individual deviates from a convention that others observe, he is no better off for that. To say that it is a *strict* Nash equilibrium is to say that he is actually worse off. To this, Lewis adds the additional requirement that an individual unilateral deviation makes *everyone* involved in the social interaction worse off, so that it is in the common interest to avoid such deviations.

A theory of convention must answer two fundamental questions: How do we arrive at conventions? And by virtue of what considerations do conventions remain in force? Within Lewis's game-theoretic setting, these questions become, respectively, the problems of *equilibrium selection* and *equilibrium maintenance*.

On the face of it, the second problem may seem to have a trivial solution – the equilibrium is maintained because it is an equilibrium! No one has an incentive to deviate. In fact, since it is a strict equilibrium, everyone has an incentive not to deviate. This is part of the answer, but Lewis shows that this is not the whole answer.

There is an incentive to avoid unilateral deviation, but, for example, if you expect me to deviate, you might believe you would be better off

Reproduced with permission from Skyrms, B. (2004) *The Stag Hunt and the Evolution of Social Structure* (chapter 4). Cambridge, UK: Cambridge University Press.

deviating as well. And if I believe that you have such beliefs, I may expect you to deviate and by virtue of such expectations deviate myself. It is when I believe that others will not deviate that I must judge deviation to be against my own interest. The self-reinforcing character of a strict Nash equilibrium must be backed by a hierarchy of appropriate interacting expectations.

These considerations lead to Lewis's introduction of the concept of *common knowledge*. A proposition, P, is common knowledge among a group of agents if each of them knows that P, and each of them knows that each of them knows that P, and so forth for all finite levels. To the requirement that a convention must be the appropriate kind of strict Nash equilibrium, he adds the additional requirement that it be backed by the appropriate kind of common knowledge. The game being played must be common knowledge to the players, along with the fact that their actions are jointly at the equilibrium of the game that constitutes the convention.

Considerations of common knowledge are thus at the center of Lewis's theory of equilibrium maintenance. What about equilibrium selection? A convention is typically an equilibrium in an interaction, which admits many different equilibria. That is what makes conventions conventional. An alternative equilibrium might have done as well. How, then, do the agents involved come to coordinate on one of the many possible equilibria involved? Lewis, following Thomas Schelling, identifies three factors that may affect equilibrium selection: prior agreement, precedent and salience. A *salient* equilibrium (Schelling's focal equilibrium) is one that "stands out" to the agents involved for some reason or another. Salience is a psychological property, and the causes of salience are not restricted in any way. Prior agreement and precedent can be viewed as special sources of salience.

Lewis's Signaling Games

Lewis discusses the conventionality of meaning in the context of signaling games.² We suppose that one player, the Sender, comes into possession of some private knowledge about the world and wishes to share it with another player, the Receiver, who could use that knowledge to make a more informed decision. The decision has payoff implications for both Sender and Receiver, and their interests in this decision are common, which is why both wish the decision to be an informed one.

The Sender has a number of potential messages or signals that he can send to the Receiver to convey that information, the only hitch being that the "messages" have no preexisting meaning. The model that Lewis considers has an equal number of states of the world, S, messages, M, and acts, A. The payoffs for both players make the game a game of common interest. For example, where the number of states, messages, and acts is three, we might have payoffs

	Act 1	Act 2	Act 3
State 1	1,1	0,0	0,0
State 2	0,0	1,1	0,0
State 3	0,0	0,0	1,1

(where payoffs are entered as sender payoff, receiver payoff). We will assume in this example that states are equiprobable.

A *Sender's strategy* in this game is a rule that associates each state with a message to be sent in that state; a *Receiver's strategy* associates each message with an act to be taken if the message has been received. Sender's strategy and Receiver's strategy taken together associate an act taken by the Receiver with each state of the world. If, for every state, the act taken is optimal for that state, the combination of Sender's strategy and Receiver's strategy is called a *signaling system*. For example, for three states, messages, and acts, the following is an example of a signaling system:

<i>Sender's Strategy</i>	<i>Receiver's Strategy</i>
$S_1 \rightarrow M_1$	$M_1 \rightarrow A_1$
$S_2 \rightarrow M_2$	$M_2 \rightarrow A_2$
$S_3 \rightarrow M_3$	$M_3 \rightarrow A_3$

It is evident, however, that this is not the only signaling system for this game. If we take it, and permute the messages in any way, we get another equally good signaling system, for example:

<i>Sender's Strategy</i>	<i>Receiver's Strategy</i>
$S_1 \rightarrow M_3$	$M_3 \rightarrow A_1$
$S_2 \rightarrow M_1$	$M_1 \rightarrow A_2$
$S_3 \rightarrow M_2$	$M_2 \rightarrow A_3$

Thus, the meaning of a message is a function of which signaling system is operative. Meaning emerges from social interaction.

Signaling systems are clearly Nash equilibria of the sender-receiver game. They are not the only Nash equilibria of the game. There are totally noncommunicative equilibria, where the Sender always sends the same message and the

Receiver performs the same action regardless of the message received, such as

Sender's Strategy	Receiver's Strategy
$S_1 \rightarrow M_1$	$M_3 \rightarrow A_2$
$S_2 \rightarrow M_1$	$M_1 \rightarrow A_2$
$S_3 \rightarrow M_1$	$M_2 \rightarrow A_2$

This is an equilibrium, no matter how inefficient it is, since neither player can improve a payoff by unilaterally switching strategies. There are equilibria in which partial information is transmitted, such as

Sender's Strategy	Receiver's Strategy
$S_1 \rightarrow M_1$	$M_1 \rightarrow A_1$
$S_2 \rightarrow M_1$	$M_2 \rightarrow A_1$
$S_3 \rightarrow M_3$	$M_3 \rightarrow A_3$

These games contain many equilibria, some of which are signaling systems and some of which are not.

But signaling systems are special. They are not only Nash equilibria but also strict Nash equilibria. (And they are the kind of strict Nash equilibria that are *conventions* in Lewis's general theory of convention.) The other non-signaling system equilibria do not come up to these standards. Unilaterally changing a potential response to an unsent message, or unilaterally changing the circumstance in which you send a message that will be ignored, is of no consequence. It does not make one better off, but it does not make one worse off either. So signaling systems are conventions, and the only conventions, in the kind of sender-receiver game that has been described.³

Lewis's account is a fundamental advance in the philosophy of meaning. It focuses attention on social interaction and information transmission. And it provides an account of how conventions of meaning can be maintained. Still, it does not appear that Lewis's account has completely answered the skeptical doubts with which we began.

Where did all the common knowledge come from? The skeptic is certainly entitled to ask for the origin of the common knowledge invoked by the account of equilibrium maintenance. And the skeptic can also ask for a noncircular account of equilibrium selection for equilibria that constitute conventions of meaning. Prior agreement and precedent can hardly be invoked to explain the genesis of meaningful signals. And where is the salience in Lewis's models of signaling games? All signaling system equilibria are equally good. None seems especially salient. Per-

haps some sort of salience extrinsic to the model might get us off the ground, but we lack any explicit theory of such salience.

Bacteria Do It

Wait a minute! Before we let ourselves become too confused by philosophical skepticism, we should remember that bacteria have developed and maintain effective signaling systems. They do this without benefit of common knowledge, intentionality, or rational choice. Perhaps we have not been looking at the problem in the right way.

In fact, signaling systems are ubiquitous at all levels of biological organization.⁴ The honeybee has a signaling system that successfully encodes and transmits information regarding the location and quality of a food source. Birds use signals for warning, indicating territory, and mating. The species-specific alarm calls of the vervet monkeys, which are the focus of D. Cheney and R. M. Seyfarth's delightful book *How Monkeys See the World*, give us a particularly nice example. Vervets are prey to three main kinds of predator: leopards, snakes, and eagles. For each there is a different alarm call, and each alarm call elicits a different action, appropriate to the type of predator that triggers the call. The situation is remarkably close to that modeled in a Lewis sender-receiver game. Other nonprimate species, such as meerkats and some birds, also instantiate a similar game structure in their alarm calls.

Let us see what happens if we approach Lewis signaling games from the point of view of the evolutionary process – presupposing nothing that could not in principle apply at the level of bacteria, or below. If we start in this way we do not cut ourselves off from the rest of the biological world, and the theory can be augmented as appropriate when applied to organisms with intelligence, knowledge, intentionality, or rationality.

Evolution

J. Maynard Smith and G. Price (1973) introduced a notion of equilibrium maintenance into evolutionary theory, that of an *evolutionarily stable strategy*. The leading idea is that an evolutionarily stable strategy must be able to resist invasion by a small number of mutants. Applying this in a plain-vanilla, large-population, random-encounter evolutionary model, this yields the definition of Maynard Smith and G. Parker

(1976) – in a population playing the strategy, either the natives do better against themselves than a mutant, or both do equally well against the natives, but the natives do better against the mutant.

Suppose we have a species in which an individual sometimes finds herself or himself in the role of Sender, sometimes in the role of Receiver. Individuals have “strategies” (or rules or routines) that determine how they play the game in each role. Suppose that a population consists of individuals who all have the same strategy, which is a signaling system in a Lewis signaling game. If you consider potential mutations to other strategies in the game, you will see that a signaling system is here an evolutionarily stable strategy.

If we look for evolutionarily stable strategies of the signaling game other than signaling systems, we find that they do not exist. The other Nash equilibria of the game correspond to strategies that fail the test of evolutionary stability. For example, consider a population with the noninformative strategy of always sending the same signal, regardless of the state observed, and always taking the same act, regardless of the signal received. That population can be invaded by a mutant playing a signaling system. When playing against natives, both types do equally badly. But when playing against mutants, mutants rather than natives do the best.⁵ Evolutionary stability gives a qualitative account of equilibrium maintenance with no presuppositions of common knowledge or rationality.

But how do we get to a particular equilibrium in the first place? We find one attractive suggestion in a remarkable passage from Darwin’s (1898) *Descent of Man*:

Since monkeys certainly understand much that is said to them by man, and when wild, utter signal cries of danger to their fellows; and since fowls give distinct warnings for danger on the ground, or in the sky from hawks (both, as well as a third cry, intelligible to dogs), may not an unusually wise ape-like animal have imitated the growl of a beast of prey, and thus have told his fellow-monkeys the nature of the expected danger? This would have been the first step in the formation of language.⁶

Darwin knows of species-specific alarm calls. Modern studies support his remarks about the alarm calls of fowl.⁷ He knows that one species may be able to use the information in another

species’ alarm call. Cheney and Seyfarth found that vervets use the information in the alarm calls of the Superb starling. Darwin also has a hypothesis about the genesis of animal signaling.

Darwin’s hypothesis is that the crucial determinant of the signaling system selected is *natural salience*. The prey imitate the natural sounds of the predator to communicate the presence of the predator to their fellows. The only problem with this suggestion is that there seems to be no empirical evidence in support of it. For other kinds of animal signals, such as threat displays, natural salience provides a plausible explanation for the origin of the signal. Baring of teeth in dogs retains its natural salience. But species-specific alarm calls do not resemble the sounds made by the type of predator that they indicate. Of course, it is still possible that they began in the way suggested by Darwin, and that the course of evolution so modified them that their origins are no longer discernible. But in the absence of evidence to this effect, we are led to ask whether signaling systems could evolve without benefit of natural salience.

We can approach this question by applying a simple model of large-population, random-mixing differential reproduction, *replicator dynamics*,⁸ to a Lewis sender-receiver game. We can let all kinds of combinations of Sender and Receiver strategies arise in the population, and run the replicator dynamics. Signaling systems *always* evolve. This can be shown both by computer simulation, and – in simple cases – analytically.⁹

The signaling system that evolves is not always the same. Each possible signaling system evolves for some initial population proportions. But the equilibria that are not signaling systems never evolve. The reason for this is that they are dynamically unstable. Only signaling systems are attractors in the evolutionary dynamics.

If natural salience had been present at the start of the process, it could have had the effect of constraining initial conditions so as to fall within the basin of attraction of a “natural signaling system.” In the absence of natural salience, where meaning is purely conventional, signaling systems arise spontaneously, but which signaling system is selected depends on the vagaries of the initial stages of the evolutionary process.

Evolutionary dynamics has provided a remedy for our skepticism. We have an account of the spontaneous emergence of signaling systems that does not require preexisting common knowledge, agreement, precedent, or salience.

Learning

Is the point confined to strictly evolutionary settings? Adam Smith (1761), in *Considerations Concerning the First Formation of Languages*, suggested a different approach:

Two savages, who had never been taught to speak, but had been bred up remote from the societies of men, would naturally begin to form that language by which they would endeavor to make their mutual wants intelligible to each other, by uttering certain sounds, whenever they meant to denote certain objects.¹⁰

Smith is suggesting that, given the proper incentives, signaling systems can arise naturally from the dynamics of *learning*.

It is not feasible to carry out Smith's thought experiment exactly, but A. Blume, D. V. deJong, Y.-G. Kim, and G. B. Sprinkle (2001) saw whether undergraduates at the University of Iowa would spontaneously learn to play some signaling system in a Sender-Receiver game of the kind discussed by Lewis. They take extraordinary precautions to exclude natural salience from the experimental setting. Sender and Receiver communicate to each other over a computer network. The messages available to the Sender are the asterisk and the pound sign, {*,#}. These are identified to the players as possible messages on their computer screens. The order in which they appear on a given player's screen is chosen at random to control for the possibility that order of presentation might function as the operative salience cue. Then players repeatedly play a Lewis signaling game. They are kept informed of the history of play of the group. Under these conditions, the players rapidly learn to coordinate on one signaling system or another.

The result might be expected, because the qualitative dynamical behavior of the replicator dynamics that explain evolutionary emergence of signaling systems is shared by a wide range of adaptive dynamics.¹¹ In Lewis signaling games, which are games of common interest, evolutionary dynamics, learning dynamics, and almost any reasonable sort of adaptive dynamics lead to successful coordination on a signaling system equilibrium. In the absence of natural salience, which signaling system emerges depends on the vicissitudes of initial conditions and chance aspects of the process. But some signaling system does

evolve because signaling systems are powerful attractors in the dynamics, and other Nash equilibria of the game are dynamically unstable.

Logic?

The dynamics of evolution and learning show us how signaling systems can emerge spontaneously. The skeptical questions concerning equilibrium selection and equilibrium maintenance are completely answered by the dynamical approach. But we should remember that the thrust of Quine's skepticism was directed at conventionalist accounts of logic. And although our account of the dynamics of Lewis signaling games has given us an account of the emergence of a kind of meaning, it has not given us an account of logical truth or logical inference based on that meaning.

Pursuit of such a theory would have to take on some of the complexity of thought that I have deliberately excluded from the basic model. We are still very far from an account of the evolution of logic, and I do not have any general account to offer here. I would like only to indicate a few small steps that we can take in the desired direction.

Proto-Truth Functions

As a first step, I propose that we modify Lewis signaling games to allow for the possibility that the Sender's observation gives less than perfect information about the relevant state of the world. For example, suppose that a vervet Sender could sometimes determine the exact kind of predator, but sometimes tell only that it is a leopard or a snake.

It may well be that the optimal evasive action, given that a leopard or snake is present, is different from either the optimal act for leopard or the optimal act for snake. One would not want to stumble on the snake while running for the nearest tree to escape the leopard. One would not want to draw a leopard's attention by standing up straight and scanning the ground for snakes.¹² A new message should not be hard to come by. (In fact, vervets that have migrated to new localities where they are faced with new predators that call for new evasive action have developed new messages and the appropriate signaling system.)¹³

So we now have a model with four types of knowledge that Senders may have, four messages, and four states with a common interest

payoff structure as before. Then, the evolutionary (or learning) dynamics is no different than the one we would have if we had four predators, four messages, and four appropriate evasive actions in the original setting. The story is the same. A signaling system will emerge with signals for eagle, snake, leopard, and *leopard or snake*. The last signal I call a *proto-truth function*. The truth function “or” is a sentence connective which forms a compound sentence that is true just in case at least one of its constituent simple sentences is true. The last signal need not be a complex sentence with meaningful parts, one of which is the truth function “or,” but one way of giving its meaning is as such a truth function.¹⁴

More generally, we can modify the Lewis model by letting nature decide randomly the specificity with which the Sender can identify the state of nature.¹⁵ Then, given the appropriate common interest structure, we have the conditions for the emergence of a rich signaling system with lots of proto-truth functional signals.

We are now well out of the vervets’ league, and perhaps into the province of “an unusually wise ape-like animal,” but I will continue to frame my example in terms of the vervets for the sake of narrational continuity. Our Sender may now have proto-truth functional signals for both “snake or leopard” and for “not-leopard.”

Inference

Now I would like to complicate the model a little more. Most of the time, one member of the troop detects a predator, gives the alarm call appropriate to his or her state of knowledge, and everything goes as in the last section. This predominant scenario is sufficiently frequent to fix a signaling system, which includes proto-truth functions.

Occasionally, two members of the troop detect a predator at the same time, and both give alarm calls. Sometimes they both have maximally specific information, and both give the alarm call for the specific predator. Sometimes, however, they will have complementary imprecise information as, for example, when one signals *snake or leopard* and the other signals *not-leopard*.

Since the Senders detect the presence of a predator independently and at approximately the same time, they just use their strategies in the signaling game of the last section. What do the Receivers do? Initially, some will do one thing and some will do another. Those who take the evasive action appropriate to snakes will, on

average, fare better than those who don’t. Over time, evolution, learning, or any reasonable adaptive dynamics will fix this behavior. Here we have a kind of evolution of inference, where the inference is based on the kind of meaning explicated by Lewis signaling games.

The setting need not be the Amboseli forest preserve, and the signaling game need not involve alarm calls. The essential points are that a signaling system evolves for communicating partial information, that the Receiver may get multiple signals encoding various pieces of information, and that it is in the common interest of Sender and Receiver that the latter takes the action that is optimal in light of all the information received. When these conditions are realized, adaptive dynamics favors the emergence of inference.

Notes

- 1 Rousseau (1984: 94).
- 2 A more general model of sender-receiver games was introduced and analyzed by Crawford and Sobel (1982).
- 3 This striking result depends to a certain extent on the modeling decision to make the number of states, messages, and actions equal. Suppose that we add a fourth message to our three-state, three-act game and extend a signaling system equilibrium of the original game by extending the Receiver’s strategy to take act 1 if message 4 were received. According to the Sender’s strategy, message 4 is never sent, so what the Receiver would do if she received that message is of no consequence. Thus, we do not have a strict equilibrium, and we do not have a Lewis convention of the game with the enlarged message space. This is perhaps not as serious a difficulty as it may at first seem. Let us bracket these concerns for now. We will return to this matter later in a different context.
- 4 See, for instance, Hauser (1997) and England et al. (1999).
- 5 This striking conclusion, like Lewis’s result that signaling systems are conventions, depends on our modeling assumption that the number of states, messages, and acts are equal. If we add some extra messages to the model, then signaling systems will not be evolutionarily stable strategies in the sense of Maynard Smith and Parker. The reason, as before, is that we can consider a mutant whose strategy specifies a different strategy to a message that is never sent. Such a mutant will not be eliminated. The difficulty, however, does not seem so serious, since the mutant *behaves* just like the native in sending signals and in reacting to signals actually sent. We can shift our attention to classes of behaviorally

equivalent strategies and consider evolutionarily stable classes as ones such that in a population using members of that class, any mutant strategy outside the class will be eliminated. Then the connection between evolutionary stability and signaling systems can be recaptured. The interested reader can find this worked out in Wärneryd (1993).

Section 11: Reasoning and Cultures

Chapter 47: Reasoning across Cultures

RUSSELL C. BURNETT AND DOUGLAS L. MEDIN

In 1931, A. R. Luria traveled to rural Uzbekistan with a question: Is thinking influenced by the social and cultural environment? The fieldwork he did there (Luria 1976) was likely the first attempt to answer this question using methods of experimental psychology. Rural folk in Uzbekistan were at that time in the midst of a socioeconomic transition that involved, among other things, the collectivization of agriculture and the growth of schools and literacy. Luria saw in this a natural experiment. He found groups of participants with different levels of involvement in this transition – including different levels of schooling and literacy – and gave them a variety of cognitive tasks. Some of these were designed to elicit deductive inferences from premises like “precious metals don’t rust” and “gold is a precious metal.” Luria found that subjects with no formal schooling often balked at such problems, rejecting the premises and saying, for example, that “one can speak only of what one has seen.” In contrast, subjects who had been to school were more likely to use the hypothetical premises to draw conclusions (e.g., “gold doesn’t rust”) with no obvious basis in personal experience. Luria also exercised some experimental control, manipulating whether the content of an argument was familiar or unfamiliar to participants. Participants who had not been to school treated the two kinds of content differently, drawing conclusions from premises more often when the content was familiar than when it was unfamiliar. Schooled participants tended to reason from the premises regardless of content.

We revisit Luria’s work because it illustrates two challenges in comparative cultural research. First, there is the natural confounding of numerous factors that might constitute “culture,” and various other factors besides. Luria favored the theory that literacy enables “verbal-logical” rea-

soning, but his groups differed in countless other ways, including general schooling, “practical activities,” “modes of communication,” “cultural outlooks,” “access to a technological culture,” “social relations,” and “life principles” (Luria 1976: 15). Which of these, or what other factors, caused the groups to respond differently? Second, even if the practical problem of confounding could be solved (and nature may sometimes disentangle such factors for us), there is a theoretical problem: Which factors should be understood as constituting culture? Or should culture be thought of as an irreducible construct, something that would remain even after one has controlled for “practical activities,” “social relations,” and so on? Any empirical demonstration of cultural differences presupposes some definition, however vague, of culture, but without a suitably specific theory of culture comparative research has no basis for causal analysis and is capable of little more than cataloging phenomena or disproving their universality.

In evidence of these difficulties, there has been a good deal of disagreement over which social or cultural factors were responsible for the group difference Luria (1976) observed. Cole and Scribner (1974) suggested that this difference was due not to literacy but to schooling or involvement in “complex acts of social planning.” This interpretation found some support in work by Scribner and Cole (1981), who capitalized on a partial disentangling of literacy and schooling among the Vai, a people of Liberia who employed a system of writing apart from formal education. Yet Scribner and Cole’s own findings have been interpreted as due to literacy, where literacy is defined in functional context (e.g., literacy for formal education; Greenfield 1983). Distinguishing between these theories would require finding a case of formal schooling without literacy, which seems unlikely.

The cognitive causes of the group difference are also unclear. Cole and Scribner (1974) argued against a qualitative difference in methods of reasoning: "There is no evidence for different *kinds* of reasoning processes such as the old classic theories alleged – we have no evidence for a 'primitive' logic" (p. 170). Scribner (1977) proposed that schooling promotes a shift from an "empirical bias," or a bias to draw on personal experience, to a more "theoretical" approach to reasoning that allows greater use of hypothetical premises. More recently, Dias, Roazzi, and Harris (2005) found that whereas both schooled and unschooled participants could be prompted to reason from unfamiliar premises (by a suggestion that the premises described a distant planet), there was a persistent gap between schooled and unschooled participants, as in Luria's studies. This suggests that reasoning from novel or hypothetical information does not require schooling, but also that schooling (or one of its correlates) does promote something like a stable orientation or stance that facilitates such reasoning (see also Harris 2000).

In this chapter we will review recent research on reasoning and culture that differs from Luria's (1976) work in an important respect. Whereas Luria's probes were designed to elicit abstract reasoning, guided by content-free principles like class inclusion and entailment, the work we will describe focuses on reasoning that makes greater use of a knowledge base. We will suggest that culture-related variations in knowledge are an important source of differences in reasoning. Of course, differences attributable to the mere presence or absence of relevant knowledge might be fairly uninteresting from a theoretical point of view. Our story will be more interesting. We will suggest that knowledge is often organized according to culture-related framework theories or expectations and that graded differences in the organization or accessibility of knowledge are reflected in reasoning.

That culture influences reasoning by way of such things as framework theories and expectations is consistent with the epidemiological view of culture, or the idea that culture can be understood as socially distributed mental representations, as well as expressions of these representations and behaviors associated with them in given ecological contexts (Atran, Medin, and Ross, 2005; Sperber 1996). The epidemiological approach leads naturally to treating within-culture variation not as noise, but rather as important information that may be used to identify paths of cultural transmission and relevant

correlates of within- and between-culture differences (Medin, Ross, and Cox 2006). To be sure, we are far from a full understanding of the sources of the kinds of representations we will describe in this chapter and the modes by which they are transmitted – we will return to this topic later. Nonetheless, the work reviewed in this chapter benefits from a theory of culture that is specific enough to move us beyond a simple catalog of group differences in reasoning, to hypotheses about proximal causes of these differences in individual minds.

We begin with a distinction that is slippery but still useful. Reasoning can be a tool for understanding cultural differences, or cultural comparisons can be a tool for understanding reasoning. As an example of the former, Choi, Nisbett, and Smith (1997) investigated the suggestion that Westerners (undergraduates at a university in the United States) are more likely to encode examples into categories than Easterners (undergraduates at a Korean university) by giving participants inductive reasoning tests where they might spontaneously generate categories, according to the similarity-coverage model of Osherson, Smith, Wilkie, López, and Shafir (1990). We will describe this model in a moment, but for now the point is that the reasoning task was used as a tool to make observations about a cultural difference in propensity for categorizing. As an example of the latter, López, Atran, Coley, Medin, and Smith (1997) gave Itza' Maya agroforesters and University of Michigan undergraduates the same sorts of reasoning probes as a test of the generality of the similarity-coverage model. They failed to find evidence for one of the reasoning phenomena predicted by the model, and in this way the cross-cultural comparison revealed something about the limits of the model.

Of course, no strict principle distinguishes these two types of studies. Choi et al. (1997) were also, implicitly or explicitly, testing the generality of the similarity-coverage model, and a different pattern of results could have led to changes in the model. Furthermore, as we have said, an observed cultural difference tells us little about reasoning if we do not understand the source of the difference. Nonetheless, the distinction is important for present purposes, because our focus will be on what comparative research tells us about theories of reasoning and not vice versa.

We will focus on two kinds of reasoning. The first is inductive reasoning about categories and their properties (what is often called category-based induction), especially in the biological

domain. Cultural research has shown the importance of framework theories and the organization of knowledge to this kind of reasoning. The second is causal reasoning, where interesting cross-cultural research is being done and where, at the same time, a promising new body of theory has been adopted by cognitive scientists. In this case, the cross-cultural findings and their implications are less clear, but we can begin to see how they might inform the new theory. In trading breadth for depth, we will not discuss some other kinds of reasoning that have been topics of recent cross-cultural research. For recent reviews of other research on culture and cognition, see Cohen (2001); Medin and Atran (2004); Medin, Unsworth, and Hirschfeld (2007); Nisbett and Norenzayan (2002); and Norenzayan and Heine (2005).

Inductive Generalization of Properties over Categories

One form of reasoning studied extensively in cultural research involves the inductive generalization of properties over objects or, more typically, over categories of objects. A fisherman who learns that brown trout are affected by a certain disease might infer, with some degree of confidence, that rainbow trout, or all trout, or catfish, or fish in rivers, or even all fish are affected by this disease. Each of these inferences can be thought of as an argument in which the premise doesn't guarantee the truth of the conclusion but provides some support for it. From this perspective, understanding knowledge generalization involves understanding how reasoners judge the support that a premise like "brown trout have a certain disease" lends to a conclusion like "rainbow trout have this disease."

Reasoning from Similarity and Taxonomic Relationships

Rips (1975) gave undergraduates at Stanford University premises like "all of the robins on an island have a certain disease" and asked them to judge what proportion of, say, the geese on the island are affected by the disease. It was found that judgments were well explained as a function of two constructs. The first was the similarity between the premise category and the conclusion category (the similarity between robins and geese); all else equal, diseases associated with robins generalized to sparrows more strongly than to geese. The second construct was the typicality of the premise category with respect to a

salient category that included both the premise and the conclusion (the typicality of robins with respect to the bird category); for generalizing to other birds, robins were a better premise category than were geese, all else equal. As Rips noted, participants reasoned as if they expected the novel property (the disease) to be distributed over categories in a way that mirrored the distributions of known properties. That robins and sparrows are similar is a consequence (or restatement) of the fact that they share many known properties, and because they share many known properties they are likely to share a novel one, too.

These ideas were elaborated by Osherson et al. (1990) in their *similarity-coverage model*. Consider the following inferences, each of which involves projecting a novel property from a specific category to a more general, inclusive category.

Sparrows have a certain enzyme; therefore, all birds have it. (1)

Penguins have a certain enzyme; therefore, all birds have it. (2)

Osherson et al. and many others have found a *typicality effect* in inferences like these. Sparrows are deemed more typical of birds than are penguins, and (1) is deemed a stronger inference than (2). The similarity-coverage model explains this effect and others as due to (a) similarities among categories and (b) the degree to which small categories "cover" inclusive categories. (1) is better than (2) because sparrows provide better coverage of the bird category, in the sense that they have higher average similarity to other birds. The model also predicts the *similarity effect* found by Rips (1975), in which similar kinds are better bases for inferences about each other than are dissimilar kinds, and a *diversity effect*, in which multiple kinds jointly form a better basis for inferences about an inclusive category if they are more dissimilar and therefore more diverse (less redundant) in their coverage. For example:

Robins and sparrows have a certain enzyme; therefore, all birds have it. (3)

Robins and hawks have a certain enzyme; therefore, all birds have it. (4)

According to the similarity-coverage model, (4) is better than (3) because robins and hawks are more diverse in their coverage of the bird category than are robins and sparrows.

The similarity-coverage model, like Rips's (1975) account, assumes two kinds of knowledge: (a) knowledge of similarity relationships among categories and (b) knowledge of class-inclusion relationships—for example, knowledge that bird is the relevant category that includes robins and geese, so that robin's coverage of the bird category (or the average similarity of robins to other birds, or the typicality of robins with respect to the bird category) can be assessed. Another well-known model, Sloman's (1993) *feature-based model*, does away with the latter component and works just on the similarities between premises and conclusions. This buys some flexibility, as the model applies even in domains that lack clear class-inclusion relationships, but the driving principle is the same: A novel property is likely to cluster with known properties, so categories are likely to share a novel property to the extent that they are similar in their known properties. This model makes many of the same predictions as the similarity-coverage model, including typicality, similarity, and diversity effects.

Insofar as these models work on the general assumption that novel properties mirror known properties, they are *similarity-based*.¹ Studies of cognitive psychology's standard participants (undergraduates at research universities) have found that similarity-based reasoning—including the similarity, typicality, and diversity effects—is quite robust (López et al. 1997; Osherson et al. 1990; Rips 1975; Sloman 1993; and many others).

Studies of culture and expertise have revealed a very different picture. First, reasoners with even moderate knowledge of the domain often employ other strategies; only research subjects with impoverished knowledge consistently reason in line with the similarity-based models. Second, even among reasoners with equal knowledge of the domain, cultural differences in the organization of this knowledge may influence the strategies that are used. Third, even when reasoning is similarity based, culture-related beliefs or theories may influence how broadly properties are generalized from different premise categories. In the sections that follow, we first describe these findings in some detail and then explore their implications for models of reasoning.

A Focus on Biology

Before proceeding, we should explain that most studies of this sort of reasoning have focused on

biology. Participants are usually asked to generalize properties like a disease, an enzyme, or “sesamoid bones” over kinds of animals. Biology is an especially informative domain for several reasons. First, it is a domain in which all cultures have some knowledge, and so it constitutes a common ground for cultural comparisons. Second, as a domain, biology has an abstract structure that all cultures seem to recognize (Atran 1998; Berlin 1992; Medin and Atran 2004). This abstract structure involves clusters of properties that travel together (for example, things that have wings tend to fly, to build nests, and so on) and are distributed systematically through downward-branching taxonomies in which nonoverlapping categories are nested under higher-level categories. Importantly, and not accidentally, this structure is just what is required by the similarity-coverage model. Clusters of co-occurring properties tend to provide clear similarity relationships among categories, and taxonomies yield clear class-inclusion relationships. Note also that the mere fact of property clustering fits the very principle behind similarity-based reasoning: All else equal, a novel property is likely to be distributed along with known properties. Since what the feature-based model requires is just a subset of what is required by the similarity-coverage model (namely, similarity relationships among categories), the abstract structure of the biological domain suits it, as well. In short, if similarity-based models apply anywhere, they should apply in biology. Moreover, since the understood structure of biology is largely invariant across cultures, these models tend to predict invariance in reasoning.

Third, however, biological entities are often the objects of people's goals, theories, beliefs, and practices. If reasoning is sensitive to such factors, then we might expect differences in these factors to be reflected in reasoning. Fourth, biology is an information-rich domain where a lot is hidden even from experts, and so there is room for biases or framework theories to guide the interpretation of experience (Keil 1995; Keil, Levin, Richman, and Gutheil 1999), highlight certain types of information over others, and promote certain inferences over others. In short, people's relationships with plants and animals often involve many of the factors that one might take to constitute or be related to culture. Focusing on biology allows us to test hypotheses about whether and how such factors influence reasoning.

To begin to see how the complexity of biology might play into reasoning, consider that not all

of the properties that one might want to reason about participate in the abstract similarity-based structure of the domain, and that similarity-based reasoning might therefore work better for some properties than for others (cf. Heit and Rubinstein 1994). If one interprets the abstract domain structure as a consequence of progressive speciation via natural selection, then similarity-based reasoning should tend to work for properties that “load” heavily on genes. Other properties are likely to be distributed in ways that are less closely related, or perhaps completely unrelated, to the similarity-and-taxonomy structure of the domain. Take, for example, diseases, which have been used as novel properties in many studies. Some diseases may have little basis in genes or innate potential. Whether an organism or a population is affected by such a disease may have mostly to do with whether it is exposed to a pathogen, and intrinsic susceptibility to the pathogen may be relatively independent of genes, at least in the population of organisms under consideration. (Of course, many other diseases are species-specific.) Other properties might have some basis in innate potential, but it might also be clear that these properties don’t travel with other large bundles of features. For example, flying-related properties in bats do not generalize outward through taxonomic space or its associated similarity space very well. Simply put, there is reason to expect that similarity-based models work only for certain properties. Indeed, Osherson et al. (1990) emphasized that the similarity-coverage model is meant to apply to “blank” properties, or properties for which the reasoner has little prior knowledge about their distribution. In practice, experimenters have tended to use properties, like “sesamoid bones,” that have a “biological flavor” (Rips 2001) and more than a hint of genes or innate potential.

Reasoning from Causal-Ecological Knowledge

The first finding from studies of culture and expertise is that even in biology, with its structure involving similarity and taxonomic relationships, reasoners often prefer inductive strategies that have little to do with this structure – that is, strategies that are not similarity based at all. Knowledgeable reasoners often prefer to project properties like diseases and enzymes on the basis of specific causal mechanisms by which these properties might have arisen in both the premise and the conclusion, and these causal

mechanisms often involve ecological interactions between members of the different categories. For example, in judging which of two kinds of trees was more likely to share a disease with all other trees, three different groups of Chicago-area tree experts preferred the tree with wider geographic distribution or greater intrinsic susceptibility to disease (Proffitt, Coley, and Medin 2000). In the former case, the idea is that trees with wider geographic distribution have greater potential to pass the disease to other species. In the latter case, the rationale is that the disease will spread more easily among trees of the susceptible species, which renders the disease widely distributed and more likely to spread to other species. These experts tended not to invoke similarity or taxonomic strategies.

Similarly, in reasoning about diseases and enzymes (or “little things inside”) in birds, both North American birdwatchers and Itza’ Maya farmers in Guatemala tended to base their inferences on causal-ecological interactions, often focusing on geographic distribution (Bailenson, Shum, Atran, Medin, and Coley 2002). They tended to prefer, as premises, birds that were rich in known ecological associations with other birds. Similarly, in a study that involved reasoning about diseases among mammals, Itza’ Maya tended to focus on geographic range and ecological diversity (López et al. 1997).

In a recent study, conducted in collaboration with Norbert Ross, we asked fishermen of two cultural groups in northern Wisconsin to reason about diseases and enzymes in fish. Most of the probes lent themselves to reasoning by typicality, similarity, or diversity. For example, in one item river shiners were said to have one enzyme (or disease), and sunfish another. Participants were asked which enzyme was more likely to be found in (or which disease was more likely to affect) smallmouth bass. Sunfish are more similar to smallmouth bass than are river shiners, and in taxonomies reported by members of the same populations (including many of the same participants) smallmouth bass tended to be closer to sunfish than to river shiners. Similarity-based reasoning thus predicts that sunfish are the better premise. Nonetheless, a great majority of participants chose river shiners and explained this choice by saying either that smallmouth bass eat river shiners or that smallmouth bass and river shiners are found in the same waters. More generally, over twenty items, participants tended to focus on ecological interactions or associations through which the novel property might be transmitted among fish. In many cases,

participants reasoned upward through the food chain from premise to conclusion; that is, they chose the premise fish that was more likely to transmit the property to the conclusion fish by being eaten (for a similar result, see Shafto and Coley 2003). But food chain knowledge was used in other ways, too. Participants sometimes reasoned downward through the food-chain, choosing the premise that was more likely to have “caught” the property by eating the conclusion fish. In still other cases, participants chose the premise that shared with the conclusion a common food source, the idea being that both fish might have gotten the property from this source. Overall, only 9 percent of inferences were based on similarity and/or taxonomic relationships. Fully 90 percent were based on transmission of the property through ecological interactions (Burnett, Medin, and Ross 2004).

These various groups of participants differ in many ways, of course, and we will turn to cultural differences in a moment. For now, a reasonable generalization is that participants with normal levels of experience with plants and animals often invoke causal knowledge and reason about the mechanisms by which properties might come to be distributed in different ways across categories. For properties like diseases and enzymes (even enzymes), these causal mechanisms often involve ecological interactions that are more or less unrelated to the similarity-and-taxonomy structure of the domain.

Flexibility in Reasoning

The above findings on causal-ecological reasoning notwithstanding, knowledgeable reasoners almost surely prefer similarity-based strategies for properties that (they believe) participate in the similarity-based structure of the domain. What knowledge provides is flexibility, in the form of a variety of strategies that allow the reasoner to project different properties in different ways. In evidence of this flexibility, Shafto and Coley (2003) found that whereas fishermen projected diseases according to food chain relations among marine animals, they projected more abstract or ambiguous properties like “a property called sarca” among the same animals according to similarity or taxonomic relatedness, as did domain novices.

Even novices show some flexibility when stimuli tap their knowledge. Using ecological contrasts that even undergraduates often know (e.g., jungle creatures versus desert creatures), Shafto, Coley, and Baldwin (2005) found that,

against a background preference for reasoning according to taxonomic relatedness, undergraduates showed a tendency to distinguish between properties, such that participants with greater knowledge of the ecological groups were more likely to project diseases and toxins, but not abstract properties like “a property called sarca,” among ecologically related animals. (For other examples of relative novices basing inferences on causal considerations instead of, or in addition to, similarity, see Gelman and Markman 1986; Hadjichristidis, Sloman, Stevenson, and Over 2004; Heit and Rubinstein 1994; and Ross and Murphy 1999. For reviews, see Heit 2000 and Rips 2001.)

An interesting question is how reasoning by causal mechanisms or ecological interactions relates to similarity-based reasoning. On the one hand, there are reasons to think of similarity-based reasoning as simpler or more basic. Similarity and taxonomic relationships are often available even to extreme novices. They seem to be at the core of folk/biological knowledge, robust even under devolution in knowledge (Medin and Atran 2004). Furthermore, reasoners who employ ecological knowledge under normal conditions may abandon this knowledge and fall back on similarity under time pressure (Shafto et al. 2005; see also Coley, Shafto, Stepanova, and Baraff 2005).

On the other hand, causal reasoning and similarity-based reasoning are not mutually exclusive, and reasoning based on similarity and taxonomic relatedness may itself involve or interact with causal considerations. Hadjichristidis et al. (2004) found that similarity had a greater influence on inference when the property in question was more causally central to the category in which it appeared (i.e., when more of the category’s other properties depended on it).² This suggests that similarity-based reasoning is invoked to the degree that causal considerations support it – that is, to the degree that the property in question is involved in the causal mechanisms that give rise to the similarity-and-taxonomy structure of the domain in the first place.

Or consider a related task: inferring whether an individual category member has some property that is associated with the category. Rehder and Burnett (2005) found that inferences were stronger when the individual was known to have other category-associated features. Importantly, results suggested that this was not because the known features made the individual a better or more typical member of the category, as

a similarity-based account might suggest, but because they indicated that the individual possessed some underlying cause or causes of the category's other features. Although known features did tend to boost the individual's typicality, their importance for reasoning lay not in this, but in their relevance to causal considerations.

Of course, this point is meaningful only if people do actually have beliefs about causal structure even in cases where they appear to invoke similarity-based strategies. Other work has suggested that they often do. Even young children and domain novices have intuitions about what properties, or what kinds of properties, of biological organisms are due to intrinsic causes or innate potential (Keil, Smith, Simons, and Levin 1998; Medin and Atran 2004). As for the finding that reasoners fall back on similarity under time pressure, this effect has been most clearly demonstrated in relative novices (Shafto et al. 2005), and it is possible that more knowledgeable reasoners are often as fluent with causal strategies as with similarity.

In general and in short, it is difficult to distinguish (a) true similarity-based reasoning from (b) causal reasoning based on causes that participate in the similarity-and-taxonomy structure of the domain. For example, consider two interpretations of Shafto and Coley's (2003) finding that fishermen reason (as if) from similarity or taxonomic relatedness for properties like "sarca" but from foodchain relationships for diseases. One possibility is that, given an ambiguous or abstract property, these experts fell back on similarity-based reasoning as a default strategy. The other is that these experts assumed that ambiguous properties were causally related to innate potential—for example, properties grounded in genes—and projected them accordingly. As Rips (2001) observed, studies showing that relative novices override similarity in cases where causal considerations provide better bases for reasoning (e.g., Gelman and Markman 1986; Heit and Rubinstein 1994; Ross and Murphy 1999) suggest that, even in novices, inferences consistent with similarity may conceal an influence of causal considerations.

Cultural Factors

We have explained the first of three findings: Knowledgeable reasoners use similarity and taxonomic relationships only some of the time; even for properties like enzymes, which are plausibly related to the similarity-and-taxonomy structure of the domain, knowledgeable reasoners

often invoke causal-ecological strategies instead. In itself this finding concerns the importance of the reasoner's knowledge base, but it also sets the stage for culture. We turn now to two ways in which cultural factors might influence reasoning.

DIFFERENCES IN ORGANIZATION OR ACCESSIBILITY OF KNOWLEDGE

Knowledgeable reasoners often have many bases for generalization available to them. Causal-ecological reasoning is not one strategy but rather a potentially large set of strategies that draw on various causal mechanisms and ecological interactions known by the reasoner. In generalizing diseases, reasoners with knowledge of trees sometimes prefer premise categories with great geographic range or ecological diversity, the idea being that widely or diversely distributed trees will have greater opportunity to transmit the disease to other trees. Sometimes they prefer premises with greater intrinsic susceptibility to disease; here the rationale is that the disease will spread more easily among trees of the susceptible kind, which renders the disease widely distributed and more likely to spread to other kinds. Sometimes they seem to go in the opposite direction, preferring a premise with greater intrinsic resistance to diseases, the idea being that the disease itself must be highly infectious if it managed to spread to an intrinsically resistant kind of tree. Of course, such reasoners also have similarity-based strategies available to them.

Cultural beliefs, values, goals, and attitudes might influence the contents of a person's knowledge base by constraining the practices that he or she undertakes with respect to plants and animals. If a group abhorred trout and avoided catching or touching them, then members of this group would likely know less about trout than if they regarded trout as ideal or desirable. Here we focus on a somewhat more interesting possibility: that even among reasoners with the same knowledge, cultural factors may influence how this knowledge is organized, or the relative accessibility of different pieces of the knowledge base (e.g., Hong, Morris, Chiu, and Martinez 2000; Medin, Ross, Atran, Burnett, and Blok 2002; Medin, Ross, Atran, Cox, Coley, Proffitt, and Blok 2006). Differences in organization or accessibility may, in turn, be reflected in how reasoning strategies are derived from the knowledge base. That is, a single knowledge base may be organized so as to make different reasoning strategies more or less fluent (see also Higgins 1996). In what follows we will first describe

recent studies of cultural differences in the organization or accessibility of folkbiological knowledge and then consider how these differences play into reasoning.

One way of assessing organization of knowledge is to ask participants to sort biological kinds into hierarchies that have the structure characteristic of folkbiological taxonomies. The participant is presented with a set of cards. On each card is printed the name of a kind (e.g., "rainbow trout"), and the participant is asked to sort these kinds into groups "that go together by nature." This instruction is accompanied by telling informants that they should create groups that make sense to them. After this initial sort, the participant is given opportunities to join these groups into progressively more inclusive categories, and then to split the groups into progressively smaller, more specific categories. The result is a downward-branching hierarchy of biological kinds.

This task has revealed differences among various groups of participants in various subdomains of biology (e.g., Bailenson et al. 2002; López et al. 1997; Medin, Lynch, Coley, and Atran 1997; Proffitt et al. 2000; Shafto and Coley 2003). One recent study is especially interesting in that it has shown cultural differences in the organization of knowledge that cannot be reduced to differences in raw experience or practices, but rather seem to arise from differences in what might be called framework theories (Medin, Ross, Atran et al. 2006). This case involves fishermen of two groups in northern Wisconsin: Native American Menominee Indians and a nearby majority-culture (European-American) community. These groups allow a close comparison because they are similar in many ways. They fish in similar waters and are familiar with the same fish. Though they do differ slightly in some of their practices – for example, Menominee put somewhat more emphasis on fishing for food (versus for sport) and are less likely to practice catch and release – these differences in themselves have small, if any, consequences for knowledge acquired through experience.

Whereas these groups showed substantial overall agreement in their sortings of local fish, they also showed some reliable differences. Multidimensional scaling revealed that Menominee sorts, but not majority-culture sorts, tended to express a dimension related to habitat or ecological niche. This difference was also evident in participants' explanations of their sorts. Majority-culture participants gave many taxo-

nomic or morphological justifications such as "bass" and few ecological justifications such as "lake fish" or "fish you find in cool, fast-moving water." In contrast, Menominee participants gave fewer taxonomic or morphological justifications and more ecological ones. In short, Menominee participants seem to organize their knowledge somewhat more around ecological considerations, whereas majority-culture participants seem to focus more on taxonomic and morphological characteristics of fish. This was also reflected in a "species interactions" task, where participants were asked to say how various kinds of fish affect one another. In this task, Menominee participants reported more causal interactions among kinds of fish than did majority-culture participants (Medin, Ross, Atran et al. 2006).

Just as these differences in organization cannot be explained by group differences in practices, neither can they be explained by differences in mere possession of knowledge. When members of the same groups were asked to sort fish according to ecological relatedness, there were no significant group differences. Likewise, when the stimuli used in the "species interactions" task were pared down so that participants spent more time thinking about each response, group differences disappeared (Medin, Ross, Atran et al. 2006). In short, it is not that Menominee participants know more ecological relations; rather, ecological relations seem to play a greater role in organizing their knowledge of fish and are more accessible. The differential importance of ecological relations in organizing knowledge of biological kinds has also been seen in studies with other cultural groups (e.g., Atran et al. 1999, 2002; López et al. 1997).

A significant challenge is to understand how these differences arise. Ross, Medin, Coley, and Atran (2003) reported parallel differences between young rural Euro-American children and young Menominee children – Menominee children were more likely to give ecological justifications on a reasoning task – and so the difference in emphasis on ecological relationships seems to be present early. One possibility is that the mediating factor is cultural differences in skeletal principles or framework theories. Several Menominee participants commented that "every fish has a role to play," and in the "species interaction" task several Menominee participants made explicit mention of the idea that, in general, any two fish are likely to affect each other somehow. In interviews, majority-culture parents often said that they wanted their

children to learn to take care of nature, whereas Menominee parents said they wanted their children to see themselves as part of nature (Bang, Medin, Unsworth, and Townsend 2005). Such ideas might function like framework theories to guide the interpretation of experience, but just how this happens remains a challenging question.

Are differences in organization or accessibility of knowledge reflected in reasoning? One fairly direct way of addressing this question is to measure reasoning and organization of knowledge separately and compare the results. López et al. (1997) asked Itza' Maya farmers in Guatemala and undergraduates at the University of Michigan to both sort and reason about mammals. Not surprisingly, the groups differed in their sorts. Itza' tended to draw finer distinctions among mammals based on more detailed knowledge of morphology, behavior, and ecological associations. Some of the reasoning probes tapped specific differences in the two groups' sorts, and in these cases the groups diverged in reasoning in ways that mirrored their differences in sorting. For example, in their sorts the undergraduates tended to group foxes with dogs, whereas the Itza' grouped foxes with cats. Both groups were given a forced-choice reasoning item in which foxes were said to have some disease, and the task was to generalize this disease to either dogs or cats. Consistent with their respective sorts, undergraduates preferred dogs, and Itza' preferred cats. In short, each group presumably used its relevant knowledge, and the knowledge differences led to group differences in induction. Also, as we have seen, there is some evidence of a relationship between reasoning and organization of knowledge among Menominee and majority-culture participants in Wisconsin, although in this case the relevant pieces of evidence come from different age groups. In sorting, Menominee adults tend to emphasize ecological relationships more than do majority-culture adults. In reasoning, Menominee children invoke ecological mechanisms more than do majority-culture children.

The previous method is correlational, and it would be nice to show the influence of accessibility on reasoning by controlled experimentation. Accessibility itself is difficult to manipulate (it is unclear how to prime, say, ecological relations without introducing a task demand to use these relations in reasoning), but an indirect way to get at accessibility is to manipulate the amount of time the reasoner has to access knowledge. Shafto et al. (2005) observed that under-

graduate participants knew certain ecological associations (e.g., jungle animals, desert animals) but, when forced to choose between ecological and taxonomic relations, tended to generalize novel properties according to taxonomic relatedness. (This was true even for diseases.) To test whether this was due to poor accessibility of ecological relations, they ran speeded and unspeeded versions of another task, in which undergraduates did show evidence of reasoning from the ecological relations. In this task a novel property was attributed to a premise category (e.g., tigers) and the participant rated the likelihood that the property was also present in a conclusion category (e.g., anacondas). In the unspeeded version of the task, ratings were highest for taxonomically related animals, intermediate for ecologically related animals, and lowest for animals that had no close taxonomic or ecological relation. Under time pressure, however, ratings for ecologically related animals dropped to roughly equal those given to unrelated animals. Ratings given to taxonomically related animals were unaffected. This is consistent with the idea that graded differences in accessibility are reflected in reasoning; present but relatively inaccessible knowledge is sometimes invoked in reasoning but in a way that is sensitive to processing costs (Shafto et al. 2005; see also Coley et al. 2005).

In this case, the relevant distinction was between similarity-based reasoning and causal-ecological reasoning, but causal-ecological reasoning consists of a potentially large set of strategies that draw on various causal mechanisms and ecological interactions known by the reasoner. Do different kinds of causal-ecological knowledge vary in accessibility, and are these variations reflected in reasoning? Bailenson et al. (2002) found that in reasoning U.S. experts relied on geographic distribution, whereas Itza' used specific causal-ecological interactions as well as geographic distribution. It remains to be seen whether this difference reflects knowledge accessibility.

ASYMMETRIES AND OTHER DIFFERENCES IN BREADTH OF GENERALIZATION

Similarity-based reasoning itself is subject to variability in how broadly one generalizes from a given premise category. Similarity and taxonomic relationships specify ordinal relationships among categories – a property should generalize outward like a ripple through similarity space or through the taxonomy – but these ordinal

relationships do not in themselves say how far the ripple should travel.

Breadth of generalization has been a focus of developmental research since Carey (1985) argued that young children's understanding of biology is organized around humans. She gave children a reasoning task in which a novel property was said to be true of one biological kind (e.g., "Humans have a little green thing inside them called an omentum") and the child was asked whether that property was true of other biological kinds (e.g., "Do you think that dogs also have an omentum?"). Her participants tended to treat humans as a privileged base for inferences. In general, inferences from humans to nonhuman biological kinds were stronger than (a) from these same nonhuman kinds to humans and (b) from nonhuman kinds to other nonhuman kinds. In some cases this meant that children violated similarity; inferences from humans to bugs were stronger than from bees to bugs. In short, reasoning was anthropocentric.

One interpretation is that Carey's (1985) participants – mostly urban children – knew more about humans than about other kinds, and that better known or more richly represented categories are better premises for generalization. In support of this interpretation, Inagaki (1990) compared two groups of urban children, one group who had raised goldfish at home and another group who had not. Children who had raised goldfish were more likely to draw inferences from both goldfish and humans than were children who had not raised goldfish; the latter group reasoned more like Carey's participants, treating humans as a uniquely privileged premise category. Likewise, Atran et al. (2001) studied Yukatek Maya children and adults in southern Mexico and found no evidence of systematic anthropocentrism. Instead they found a pattern of age- and gender-related differences that were consistent with familiarity effects. For example, girls knew less about the peccary than did boys and also treated the peccary as a weaker premise category. In related work, Tarlowski (2006) has demonstrated that children's patterns of inductive generalization are influenced both by urban versus rural status and by parents' knowledge of the domain.

The finding that better-known kinds make for better premises is problematic but not fatal for the similarity-based models; they can accommodate the finding but have trouble explaining it. For example, the similarity-coverage model can handle the finding by (a) putting much greater weight on the coverage component (e.g., the

degree to which "human" covers "living thing") than on the similarity component (e.g., the similarity of "human" to "bug") and (b) assuming that the representations of the various categories are such that the privileged premise category ("human") covers the relevant inclusive category ("living thing") better than do other, nonprivileged categories. Still, the model provides no reason why coverage should be weighted so much more heavily than similarity (Rips, 2001).

A bigger problem comes from recent cross-cultural work which suggests that richness of knowledge of the premise category is not all that matters. Ross et al. (2003; see also Medin and Atran 2004) studied three groups of children: Menominee children in rural Wisconsin, majority-culture children in rural Wisconsin, and majority-culture children in (urban) Boston. Rural children of both cultural groups have similar levels of experience with animals and plants, and so if amount of knowledge were the only strong determinant of breadth of generalization, then we would expect these two groups to be similar. However, Ross et al. found different developmental trajectories in all three groups.

The rural majority-culture children treated humans as a privileged base at an early age; this anthropocentrism waned with age. When they declined to generalize from nonhuman animals to humans, children in this group (at all ages) often explained that "people aren't animals." In contrast, Menominee children showed no reliable anthropocentrism at any age. Also, they showed less differentiation between "higher" animals and "lower" animals when generalizing from humans, as if humans are intimately related to all other animals.³ In interpreting this finding, Medin and Atran (2004) note that "the Menominee origin myth has people coming from the bear, and even the youngest children are familiar with the animal-based clan system. In short, there is cultural support for a symmetrical relation between humans and other animals" (p. 967).

Interpreting asymmetries is difficult. Medin and Waxman (2007) propose that they often reflect not just richness of knowledge of the premise kind but also the distinctive features of both premise and conclusion kinds and also the higher-level categories that these kinds belong to. In many cases the properties and higher-level categories of the *conclusion* kind seem to matter more than properties and categories of the *premise* kind. Thus, when children fail to generalize a property of peccaries to a target

like humans, this may be not because peccaries are unfamiliar or atypical but rather because humans have distinctive properties that limit generalization to them. In other cases, asymmetries may be due to ecological reasoning, where some kinds are seen as more active ecological agents than others. Until we have a better understanding of the cognitive mechanisms that underlie asymmetries, interpretations should be made with caution. For now, a reasonable conclusion is that at least some asymmetries are due to (culture-related) knowledge of the properties of the relevant kinds and also to (culture-related) tendencies to think of certain kinds as belonging to certain higher-level categories (e.g., a tendency to think of humans as a kind of animal or as a kind distinct from other animals; Anggoro, Waxman, and Medin 2005). Such tendencies are problematic for the similarity-based models.

Implications for Models of Reasoning

To summarize, cross-cultural and other studies have revealed the following.

- (1) Reasoners with domain knowledge flexibly invoke a variety of strategies – including, but not limited to, the similarity-based strategies described by the similarity-coverage model (Osherson et al. 1990) and the feature-based model (Slovan 1993).
- (2) Reasoning favors causal knowledge. Of course, the strategies we have called causal-ecological involve causal knowledge directly (e.g., reasoning about how a property might be transmitted through ecological interactions), and knowledgeable reasoners seem to prefer these to similarity-based strategies even for properties that might plausibly be generalized according to similarity (e.g., enzymes). But even similarity-based reasoning might sometimes involve causal considerations indirectly. Although it may sometimes serve as a mere fallback or default strategy, at other times similarity is invoked just because the property in question is understood to be involved in the causal mechanisms that underlie the similarity-and-taxonomy structure of the domain (Hadjichristidis et al. 2004; Rips 2001).
- (3) Taxonomic relations matter, and they may differ, at least in salience, across cultures. For example, some cultures do not have a superordinate term for animals, and cultures that do have such a term do not always include humans in it (see Anggoro et al. 2005, for evidence and implications). This may mean that, for example, generalization from a given premise category will be broader when the superordinate category that supports broad generalization is more salient (say, because it is named rather than covert).
- (4) When various similarity-based and causal-ecological strategies are available to the reasoner, which strategy is invoked depends in part upon the organization or relative accessibility of different pieces of the reasoner's knowledge base (e.g., Shafto et al. 2005). Or, to put it differently, a single knowledge base can be organized in different ways that render different reasoning strategies more or less fluent. The organization of the knowledge base, in turn, is sensitive not just to the practices or experiences through which people acquire domain knowledge but also to cultural milieu (perhaps in the form of framework theories) (e.g., Medin et al. 2002; Medin, Ross, Atran et al. 2006).
- (5) Even similarity-based reasoning, which one might expect to be well constrained by the intrinsic structure of the domain (taxonomic relationships, clusters of related features, and so on), is sensitive to cultural milieu. Even at early ages, cultural beliefs or framework theories seem to influence how broadly reasoners generalize from different premise categories (Ross et al. 2003; see also Medin and Atran 2004).

What are the implications of these findings for models of reasoning? That reasoners often abandon similarity in favor of causal-ecological strategies (findings 1, 2, and 4) represents a serious limitation of the similarity-coverage and feature-based models, because they seem to predict that similarity-based reasoning will be universal. Of course, one might argue that these models are only meant to apply to truly blank properties – that is, properties for which the reasoner has absolutely no prior belief about their distribution – and that people with some domain knowledge interpret almost any property in such a way that, functionally, it is not blank. There are two problems with this counterargument. One is that it restricts the applicability of such models to the point of irrelevance. The second is that

it is not the case that knowledgeable reasoners never show similarity-based reasoning; rather, similarity-based reasoning is one strategy among many.

Indeed, the similarity-based models seem to emerge from this analysis as good accounts of one strategy that is invoked when knowledge is sparse or when the reasoner believes that the property in question is related to other properties that determine the similarity-and-taxonomy structure of the domain. Still, how can models of reasoning handle findings 1, 2, and 4? We turn now to three alternative theories, each of which addresses some part of these findings.

McDonald, Samuels, and Rispoli (1996) presented a *hypothesis-assessment model* of inductive reasoning. On this model, generalization of properties over categories can be viewed as a form of hypothesis assessment in which the conclusion is the relevant hypothesis and the premise is some evidence for this hypothesis. A general prediction of this model is that inferences will be sensitive to the same sorts of factors that influence hypothesis assessment in other contexts – especially the number of competing hypotheses. McDonald et al. provide support for this prediction by asking people to generate hypotheses or explanations and showing that confidence in inferences decreases when there are competing hypotheses (i.e., other candidates for a conclusion category). The hypothesis-assessment model places no constraints on the hypotheses or explanations that a reasoner might consider, and so in principle it is consistent with a variety of strategies (finding 1). However, it has trouble with finding 2, in that it gives no special status to causal factors. As for knowledge accessibility (finding 4), the model as initially described has little to say, but McDonald et al. discussed this. In their data, judgments of argument strength seemed to be sensitive to how accessible the corresponding conclusion categories were (as measured by the number of participants who, given the premises, spontaneously generated the conclusion category). McDonald et al. noted that adding accessibility to the model as a predictor would be reasonable, given that the influence of accessibility on hypothesis strength has been shown in other contexts.

Heit (1998, 2000) proposed a *Bayesian model* that works more or less as follows. If the task is to generalize a novel property from cows to sheep, then various known properties of cows and sheep are called to mind. Of these, some are likely shared by cows and sheep, and others

distinctive to cows. From the numbers of properties that are shared and distinctive, the reasoner computes the likelihood that the novel property belongs to one group or the other. (If known properties tend to be shared, then it's likely that the novel property is shared. If known properties tend to be distinctive, then it's likely that the novel property is distinctive.) To the extent that the novel property is likely to belong to the shared group, the inference from cows to sheep is strong. In one important respect, this model is like the similarity-based models (and especially the feature-based model): It works on the assumption that the novel property is associated with known properties, and larger clusters of known properties carry more weight in reasoning. Yet the Bayesian model allows flexibility in just which of the known properties of sheep and cows are considered. In this way the model explains, for example, Heit and Rubinstein's (1994) finding that anatomical properties were generalized according to animals' anatomical similarity, whereas behavioral properties were generalized according to behavioral similarity. On the Bayesian model, this is because a novel anatomical property calls to mind known anatomical properties, and these dominate in the inference process. In contrast, a novel behavioral property calls to mind known behavioral properties.

Because the Bayesian model is similarity based (i.e., works on the assumption that the novel property is associated with known properties), it has trouble with findings 1 and (especially) 2. As for finding 4, the Bayesian model allows that different bits of knowledge are called to mind in different contexts, and this can be seen as reflecting context-specific differences in knowledge accessibility. Still, the model's ability to account for finding 4 in this way is limited. First, it relies on an independent theory to explain which bits of knowledge – that is, which known properties of the premise and conclusion categories – are called to mind. Second, and more importantly, the relevant bits of knowledge are always known properties of the premise and conclusion categories; they are not causal mechanisms by which properties are acquired or transmitted. This is another way of saying what has already been said, namely, that the model is similarity based and does not predict causal-ecological reasoning.⁴

A theory better suited to finding 4 is the *relevance framework* outlined by Medin, Coley, Storms, and Hayes (2003). One way to motivate this framework is to consider some responses

that a tree expert gave to Proffitt et al. (2000). The expert was given probes such as the following: "Suppose we know that river birch get disease X and that white oaks get disease Y. Which disease do you think is more likely to affect all trees?" In this case, the expert said disease X, noting that river birches are very susceptible to disease (so that "if one gets it they all get it"). The very next probe involved the ginkgo tree, and the expert chose the disease associated with it as more likely to affect all trees on the grounds that "ginkgos are so resistant to disease that if they get it, it must be a very powerful disease." He then said that he felt as if he had just contradicted himself, but that nonetheless these seemed like the right answers.

Normatively, this expert's answers do not represent a contradiction. Instead, he appeared to be using the information that was most salient and accessible to guide his reasoning (birches are notoriously susceptible to, and ginkgos notoriously resistant to, diseases). Simply put, the expert was using the knowledge that he considered most relevant. Medin et al. (2003) suggested that Sperber and Wilson's (1986) relevance theory provides a good framework for understanding these and related patterns of responding. One motivation for this view is the fact that experiments take place in a social context and participants reasonably infer that the experimenter is being relevant and informative with respect to the inductive argument forms (cf. Grice 1975). Furthermore, this view leads to a number of novel predictions that contrast with those of other models.

In relevance theory, relevance is seen as a property of inputs to cognitive processes:

An input is relevant to an individual at a certain time if processing this input yields cognitive effects. Examples of cognitive effects are the revision of previous beliefs, or the derivation of contextual conclusions, that is, conclusions that follow from the input taken together with previously available information. Such revisions or conclusions are particularly relevant when they answer questions that the individual had in mind (or in an experimental situation, was presented with)... Everything else being equal, the greater the cognitive effects achieved by processing an input, the greater its relevance. On the other hand, the greater the effort involved in processing an input, the lower the relevance. . . . One implication of the definition of relevance in terms of effect and

effort is that salient information, everything else being equal, has greater relevance, given that accessing it requires less effort. (Van der Henst, Sperber, and Politzer 2002: 4)

In support of this approach, Medin et al. (2003) experimentally manipulated effort and effect to determine whether they have the sorts of consequences predicted by relevance theory. Undergraduates contrast with experts in having little background knowledge to bring to bear on these sorts of reasoning tasks, and consequently it is not surprising that they rely heavily on more abstract reasoning strategies. In their studies with undergraduates, Medin et al. were able to identify accessible background knowledge to bring out the effect side of relevance and manipulated the premise and conclusion categories to show consequences on the effort side. As an example of the former, they found that the argument "bananas have enzyme X, therefore monkeys have Enzyme X" was rated stronger than the argument "mice have enzyme X, therefore monkeys have Enzyme X." In this case-relevant background knowledge that monkeys like bananas leads to a violation of similarity.

As an example of varying effort, Medin et al. (2003) showed that undergraduates rate the inductive strength of the argument "grass has enzyme Y, therefore humans have enzyme Y" to be less strong than the argument "grass has enzyme Y, therefore cows and humans have enzyme Y." (The arguments were not juxtaposed but rather were used in a between-subjects design.) In this case, the data yield a "conclusion conjunction fallacy" since, normatively, the former argument's conclusion cannot be less likely than the conclusion of the latter argument. From a relevance perspective, the addition of cows to the conclusion made it easier for the participants to access a sensible causal pathway between grass and humans.

In other conditions, Medin et al. demonstrated premise nonmonotonicity, that is, a drop in argument strength with the addition of premises. For example, "white oaks get disease X, therefore sugar maples do" was rated stronger than "white oaks, red oaks, and burr oaks get disease X, therefore sugar maples do." In this case the idea is that multiple premises involving oaks make "oaks" salient and relevant and reinforce the idea that disease X is specific to oaks.

Of the other models we have described, the relevance framework is most closely related to the hypothesis-assessment model, in that one

could see the relevance framework as a basis for predicting which hypotheses people will tend to generate. Importantly, due to its emphasis on effort, the relevance theory explains differences due to knowledge accessibility (finding 4) in a natural way: Greater accessibility means less effort, and more accessible pieces of knowledge are therefore favored in reasoning. We readily concede that relevance theory seems vague, especially in relation to computational models like the similarity-coverage model. But a theory must also be judged on its ability to generate novel predictions, and relevance theory fares well by this standard.

Although there are numerous other studies looking at inductive reasoning in a cultural context, their primary focus is on induction informing culture rather than vice versa. We now turn to a more speculative consideration of how culture may inform theories of causal reasoning.

Culture and Causal Reasoning

Psychologists have recently begun to explore a theory of learning and reasoning about systems of causal relationships. At the same time, cross-cultural work has revealed ways in which reasoning is guided by abstract expectations or understandings of causal structure. Both lines of work are young (consequently, this section will be shorter and more speculative than the previous one), yet both are far enough along that we can begin to see tensions between them and ways in which the cultural research might inform the new theory.

Causal Bayes Net Theory

The use of causal knowledge to predict and control events is a form of reasoning that is ubiquitous both in everyday life and in more formal contexts like science and medicine. Causal knowledge enables us to discern with some precision whether, or to what degree, variables are relevant to predictions about one another, or to interventions to control one another. When we know causal relationships, we tend to base our predictions on factors that are causally relevant, and to focus our interventions on factors that will in fact transmit influence to the things we wish to control. For example, if we knew that two variables X and Y were associated just because they had a common cause C , and if we wanted to make a prediction about Y , we would rather base this prediction on C than on X . If we wished to exercise control over Y by manipulating one

of the other variables, we would manipulate C , not X .

A detailed account of how causal knowledge can be used to make predictions and exercise control has been developed in philosophy, statistics, and computer science (Pearl 2000; Spirtes, Glymour, and Scheines 2000) and is known as causal Bayes net theory, or causal graphical model theory. There has recently been a good deal of interest in using this theory as a basis of psychological accounts (e.g., Glymour 2001; Gopnik et al. 2004; Lagnado and Sloman 2004; Rehder and Hastie 2001; Sloman and Lagnado 2005; Steyvers, Tenenbaum, Wagenmakers, and Blum 2003; Waldmann and Martignon 1998). Briefly, causal Bayes net theory specifies mappings between causation and correlation (where we use *correlation* broadly, to refer to statistical relationship of any form). Causal knowledge is represented as graphs in which variables (events, states, and so on) appear as nodes, and causal relationships as directed links between nodes. The heavy explanatory work is done by a principle called the *causal Markov assumption*: Any variable is uncorrelated with, or statistically independent of, all variables that are not its descendants in causal structure – that is, not its direct or indirect effects – conditional on its immediate cause(s).

Given a causal graph, the Markov assumption says just which variables are relevant to any instance of prediction or control. For example, suppose that a certain virus, V , causes two symptoms, A and B , by different mechanisms. In graphical form: $A \leftarrow V \rightarrow B$. According to the Markov assumption, A and B should be correlated in general but uncorrelated conditional on V , that is, when V is controlled for. (Neither is a descendant of the other, and each has V as its sole immediate cause.) A reasoner who respects the Markov assumption should treat A as predictive of B except when there is information about V , in which case a prediction about B should be based on V alone. If it is known that a patient has (or does not have) the virus, then the appearance of symptom A should not be predictive of the appearance of B . Interventions to control variables are represented as surgeries on graphs (Pearl 2000), in which the links leading into an intervened-upon variable are broken, and the intervention itself becomes the sole cause of the variable. The Markov assumption can then be applied to determine how relevance flows through the new graph. For example, intervening to control symptom B (by means of a perfectly effective drug, say) breaks the influence of

the virus V on this symptom; consequently, B is no longer predictive of V or A .

The causation-correlation mappings specified by the Markov assumption can also be applied in the other direction, to learn causal models from correlational evidence. If X and Y are correlated in general but uncorrelated when Z is controlled for, then, given a few additional assumptions, there are three ways in which these variables might be related: $X \rightarrow Z \rightarrow Y$, $X \leftarrow Z \leftarrow Y$, and $X \leftarrow Z \rightarrow Y$. Other models, like $Z \rightarrow X \rightarrow Y$, can be ruled out. Though the details are beyond the scope of this chapter, causal Bayes net theory also provides leverage for understanding some seemingly more complicated tasks, including (a) learning causal models by intervening to manipulate variables and (b) inferring the presence of hidden causes.⁵

Several features of causal Bayes net theory are pertinent:

- (1) The theory requires that causal knowledge be *complete*, in two respects. First, there can be no unknown cause of any combination of known variables; this requirement has been called *causal sufficiency* (Spirtes et al. 2000). Second, there can be no unknown paths of influence between variables. If causal knowledge is not complete in these ways, then the Markov assumption does not apply. To see why, suppose there were an unknown common cause of symptoms A and B that did not act via the virus V , or an unknown path of influence between A and B (perhaps A promotes B independently of their joint dependence on V). In these cases A and B would be relevant to predictions about one another (and perhaps to interventions to control one another) even conditional on V .
- (2) Causal knowledge is *concrete*, in two senses. First, causal graphs are made of relationships among specific variables, by which we mean variables encoded with enough specificity to map onto the events and states that we make predictions about, base predictions on, manipulate, and so on. There is (as yet) no place in the formalism for more abstract notions about what *kinds* of variables might be related or relevant to one another. Second, the mechanisms underlying causal relationships must often be understood in some detail if causal knowledge is to be properly complete (Hausman and Woodward 1999). For example, in cases of a single

cause with multiple effects, it is often difficult to tell whether the effects come about by truly distinct mechanisms or by way of a single unseen mechanism. If virus V gave rise to symptoms A and B by way of a single hidden variable (say, lack of a certain enzyme), then A and B would have an unknown common cause, completeness would be violated, and the Markov assumption would not apply. Such arrangements have been called *interactive forks* (Salmon 1984; on the failure of the Markov assumption to apply in these cases, see Sober 1988).

- (3) There are two general approaches to learning causal models from correlational evidence: (a) a bottom-up or “constraint-based” approach, in which learning is primarily a matter of using the causation-correlation mappings specified by the Markov assumption to work backwards, from patterns of correlation to causal models consistent with these patterns (e.g., Spirtes et al. 2000); and (b) a top-down Bayesian approach, in which learning begins with a set of candidate causal models and evaluates these models for their likelihood of having generated the correlational evidence (e.g., Heckerman, Meek, and Cooper 1999). The bottom-up view ties causal structure closely to the correlational input. This view suggests that, in cases where causal knowledge is acquired from correlational evidence, there should be little cultural variation in the understood causal structure of the world (unless, of course, there is corresponding variation in the correlational evidence available to learners in different cultures). If there *were* cultural variation in the interpretation of correlational evidence, this would favor the top-down approach, where culture-related expectations of causal structure might guide the construction of the initial set of candidate structures.

Culture-Related Understandings of Causation

Recent cross-cultural research suggests that causal reasoning is often guided by abstract expectations or understandings of the causal structure of the world. Consider the theory that Easterners and Westerners have holistic and analytic theories, respectively, about causation

(Nisbett 2003; Nisbett, Peng, Choi, and Norenzayan 2001). The idea is that Westerners (roughly, Europeans and European Americans) think of the world as partitionable into causally unrelated objects. When reasoning about the behavior of an object, they tend to look for causes in the intrinsic disposition or attributes of the object itself (e.g., an object falls to earth because of its weight). In contrast, Easterners (roughly, east and central Asians) are thought to have a more holistic view of the causal structure of the world, which can be characterized (or perhaps caricatured) as "everything affects everything else." They tend to consider multiple, perhaps interactive causes and, when reasoning about the behavior of an object, to look outside of the object to situational or environmental influences (e.g., an object falls because of an external force) (Choi, Nisbett, and Norenzayan 1999; Morris and Peng 1994; Nisbett 2003; Nisbett et al. 2001; Peng and Knowles 2003).

The evidence for this view is mostly in the social domain (for a review, see Choi et al. 1999). Miller (1984) found that, in explaining a person's behavior, participants in India invoked more contextual or situational factors than did Americans, who spoke to a greater extent about the person's disposition. Similarly, Morris and Peng (1994) asked graduate students to explain the behavior of a murderer and found that Americans favored dispositional factors and Chinese situational factors. These findings have been echoed in studies of attributions made in print by American and Chinese journalists (Lee, Hallahan, and Herzog 1996; Morris and Peng 1994). When asked to explain the behavior of a cartoon fish which moved in various ways relative to a group of other fish, Americans showed a greater tendency than did Chinese to rate internal causes as more important than the other fish (Morris and Peng 1994).

Predictions in other domains have found less support. Morris and Peng (1994) asked participants about the causes of movements of physical objects (in animated depictions). Participants were asked to rate the relative importance of internal and external causes. This revealed only one difference between American and Chinese participants, and it was in the direction opposite what one might have predicted. Given an animated depiction of an "entraining" event in which one object collides with another and then continues on its path, pushing the second object before it, Americans seemed to favor external over internal causes for the second object's motion, whereas Chinese showed no preference.

Ji, Peng, and Nisbett (2000) used a contingency learning task in which the goal was to judge the strength of a relationship between which of two abstract shapes appeared on the left side of a screen and which of two other shapes appeared on the right. Whereas there were differences in the judgments made by American and Chinese participants, these differences can be explained largely as reflecting a group difference in response bias.⁶

Peng and Knowles (2003) found some suggestive differences in how American and Chinese participants explained abstract, seemingly physical events. When participants' explanations were classified as either dispositional (e.g., referring to a target object's weight or composition) or contextual (e.g., referring to another object or a surrounding medium), American college students showed a bias, relative to Chinese college students, toward dispositional explanations on a few items. Still, this trend was not statistically reliable over the whole set of items, and large differences between items suggest that a considerable part of the story is yet unexplained.

Our belief is that there is something right about the idea that cultures differ in understandings of causal structure, but that these understandings have sometimes been theorized too abstractly.⁷ They are probably bound up with beliefs, habits, goals, and ideals in particular domains. On this view, the robust findings in the social domain are the result not of domain-general stances like holism but of more specific theories of personal behavior and social interaction. Such theories were measured directly by Norenzayan, Choi, and Nisbett (2002), who asked Korean and American participants to rate their agreement with each of three general explanations of human behavior: a dispositional theory, a situational theory, and an interactionist theory (according to which dispositional and situational factors interact to yield behavior). Compared to Americans, Koreans reported reliably greater agreement with situationism in two studies and with interactionism in one. We suspect that theories at this level of abstraction are likely guides of causal reasoning.⁸

Research in folkbiology has revealed other cases in which cultural groups seem to differ in (domain-specific) understandings of causal structure. This work involves the "species interaction" task described earlier. Atran et al. (1999, 2002) asked participants in three cultural groups in Guatemala to say whether and how various kinds of plants and animals affect each other. It was found that the groups differed in the

numbers of interactions they reported and, in particular, in the numbers of helpful effects of animals on plants. In short, the groups seemed to have different understandings of the kinds of causal relationships in the ecosystem. As we noted earlier, Medin, Ross, Atran et al. (2006) found that Menominee and majority-culture fishermen in Wisconsin also have different views of causal structure, such that reciprocal relationships among fish are more salient to Menominee participants. Informally, Menominee participants have sometimes articulated framework theories of causal interaction like “every fish has a role to play” and “all in all, living things affect each other.”

In sum, cross-cultural research suggests that causal reasoning is often guided by understandings of causal structure that are more abstract than causal Bayes nets (although probably not as abstract as domain-general stances like holism). It is too early to say just what these understandings are – perhaps they are skeletal framework theories (Keil 2003a, 2003b) or “causal grammars” (Tenenbaum, Griffiths, and Niyogi 2007) – but in at least some cases they seem to vary along a dimension that runs from *autonomy* (things in a domain tend not to affect each other) to *influence* (things tend to affect each other).

Bringing the Cultural Research to Bear on Causal Bayes Net Theory

These two lines of work are young, and the tasks they involve are quite different – for example, learning whether a certain object causes a machine to light up (Gopnik et al. 2004) versus explaining a murder (Morris and Peng 1994). Yet we can begin to see tensions between them that are similar to the tensions between similarity-based models of inductive reasoning and cross-cultural research on reasoning about plants and animals.

Recall that the principal way in which causal Bayes net theory explains prediction and control is to specify the relevance of variables to one another, based on their relative positions in causal structure. It does this by applying a general principle, the causal Markov assumption, to causal models that are complete and concrete. There are no representational tools for accommodating abstract beliefs about relevance in a domain, and the Markov assumption fails if causal knowledge is incomplete in certain ways. These limitations should be taken seriously in building psychological accounts of reasoning on causal Bayes net theory, because

natural causal knowledge, knowledge that supports reasoning, is often abstract and incomplete (Keil 2003b; Rozenblit and Keil 2002). Indeed, it is often abstract and incomplete in just the ways that invalidate the causal Markov assumption (interactive forks, etc.; Hausman and Woodward 1999). In these cases (and they may be the norm), the lack of complete, concrete knowledge makes room for abstract understandings of relevance and causal relatedness to guide learning and reasoning. Cultural research shows that learning and reasoning are indeed guided by abstract expectations – and, more specifically, expectations that may vary along a continuum from autonomy to influence.

Expectations of autonomy are roughly consistent with the causal Markov assumption, which has the form “variables are irrelevant to one another unless proven otherwise.” Proving otherwise requires knowing just how variables are related in a complete, concrete causal graph, with the result that relevance is assigned to variables conservatively. In contrast, expectations of influence seem to run against the Markov assumption, as they assign relevance more liberally. For a reasoner who knows the model $A \rightarrow B \rightarrow C$, the causal Markov assumption dictates that a prediction about C , given information about A and B , should be based on B alone. But if this reasoner has an expectation of influence, then their prediction might be based also on A . This can be seen as allowing for the possibility that A and C are related in some unknown way. We know of no cross-cultural research on this question, but within-culture work has shown that both undergraduates and domain experts do tend to deviate from the Markov assumption in this way (Burnett 2005; Rehder and Burnett 2005). There is also some tentative evidence that scientists in different fields override the causal Markov assumption to different degrees, consistent with abstract expectations in their respective fields (Burnett 2004). The clear prediction for cultural comparisons is that reasoners with a greater expectation of influence in a given domain will go farther in assigning relevance or predictive value to variables which, according to the causal Markov assumption, should be irrelevant or non-predictive. We might make similar predictions about active intervention. Consider again a reasoner who knows the model $A \rightarrow B \rightarrow C$. If B is manipulated as a way of controlling C , the Markov assumption says there is no additional benefit to manipulating A . Reasoners with an expectation of influence might see additional

benefit and, when given the option, might manipulate *A* as well as *B* in order to control *C*.

Cultural research also has implications for the learning of causal systems from correlational evidence. In the bottom-up or constraint-based approach, where learning is driven mainly by the Markov assumption, there is no room for abstract expectations of influence or autonomy. Furthermore, because an infinity of causal structures involving latent variables are (according to the Markov assumption) consistent with any pattern of correlational evidence, the bottom-up approach requires additional assumptions that favor causal structures that are parsimonious in some respect(s) (e.g., having the fewest latent variables). Cultural research suggests that learning is guided by abstract expectations about causal structures in different domains, and this argues in favor of the top-down approach, where abstract knowledge may influence the causal models that a learner considers (e.g., Tenenbaum and Griffiths 2003; Tenenbaum et al. 2007). Furthermore, when expectations favor influence instead of autonomy, learning may deviate from the parsimony assumptions used in the bottom-up approach. Learners with expectations of influence may infer causal structures that are more than minimally elaborate, perhaps with more latent variables than are necessary to account for observed correlations.

Conclusion

In both of the cases we have discussed, models have been proposed which ground reasoning in concrete knowledge. In the case of inductive reasoning about biological properties, the similarity-based models explain reasoning in terms of that aspect of the domain that is most readily detected: clusters of correlated features and the taxonomies that form around these clusters. In the case of causal reasoning, causal Bayes net theory explains reasoning (i.e., prediction and control) in terms of graphical models of causal systems that are complete and concrete. In both cases, one can imagine how the relevant knowledge might be acquired by an individual learner exploring the world independently of any cultural influence.

In both cases, cultural research suggests that reasoning is guided by more abstract knowledge that is less constrained by the observable structure of the world and more culturally variable. Reasoning about biological properties draws preferentially on an aspect of the domain that is less easily detected than feature clusters

and taxonomies, namely, causal mechanisms by which properties arise and by which properties are transmitted among categories. Furthermore, the knowledge base that supports reasoning – which may include feature clusters, taxonomic relationships, causal-ecological relationships, and more – may be organized according to different framework theories, so as to render different kinds of knowledge more or less accessible. These differences are reflected in reasoning. As for causal reasoning, in at least some domains it draws not only on concrete knowledge but also on abstract theories or expectations of causal structure.

This is not to say that framework theories and expectations of the kinds described in this chapter are the only paths through which culture influences reasoning. It is possible, for example, that cultural factors sometimes promote certain modes of reasoning over others. Furthermore, some cultural differences related to reasoning – for example, differences in typicality among members of biological categories – seem better explained by ideals and goals than by theories and expectations (Burnett, Medin, Ross, and Blok 2005; Lynch, Coley, and Medin 2000).

Given that we take the proximal mechanisms of culture to be cognitive constructs like theories and expectations, one might wonder what is to be gained by studying culture itself. There are several things to be gained. First, in many cases it would be difficult or impossible to identify the relevant cognitive constructs without knowing their sources in culture. Second, the cognitive constructs that depend on culture may be stable or entrenched in ways that cannot be mimicked or modified in laboratory experiments. Finally, the cultural sources of cognitive constructs are interesting in their own right, especially if one wants to predict reasoning in real-world settings.

We have said little about what exactly the operative theories and expectations are, beyond suggesting that they are somewhat domain specific – like the theories of human behavior described by Norenzayan et al. (2002) and the idea that “every fish has a role to play,” mentioned by some Menominee fishermen (Medin et al. 2002). We have said even less about how they are acquired and transmitted. Possibilities include imitation, inference from other people’s behavior, explicit communication of abstract principles (e.g., one Menominee participant explained his bias to see interactions among species by saying that his grandmother had taught him that all living things affect each other), explicit communication of more

concrete facts from which principles can be abstracted, communication of goals and ideals that lead indirectly to differences in knowledge, and so on. As an example of the work that can be done in this area, Atran et al. (2002) employed social network analysis to trace the transmission of mental models of the ecosystem among members of different cultural groups in Guatemala. As this work illustrates, collaboration between psychology and anthropology has the potential to reveal determinants of reasoning that are neither easily detected in the structure of the world nor easily identified without considering the cultural milieu in which individual minds develop and function.

Notes

- 1 Heit (1998, 2000) has proposed a Bayesian model of inductive reasoning based on this same idea. The Bayesian model, however, is somewhat more flexible in its application of the idea that novel properties mirror known properties – as we will discuss later.
- 2 Hadjichristidis et al. distinguish between causal structure and more generic “dependency structure” and draw their conclusions about the latter, but for simplicity we focus here on causal structure.
- 3 Another finding of Ross et al. (2003) and Atran et al. (2001) was that some groups of children – especially Yukatek Maya and Menominee children – showed causal-ecological reasoning even at early ages. Since our focus here is on breadth of generalization by similarity and/or taxonomic relationships, we have disregarded causal-ecological generalizations in our description of the data.
- 4 One might suggest that the Bayesian model handles causal-ecological strategies by computing probabilities over just those properties that are associated with a certain ecological interaction, but here the activation of just those properties is doing most of the explanatory work, and this requires an independent theory. Furthermore, this method of mimicking causal-ecological reasoning is limited to cases where the premise and conclusion categories share some property (e.g., habitat) that can serve as a proxy for the relevant causal mechanism – for example, an inference from one river fish to another might be predicted if “lives in rivers” is called to mind as a shared property – but it is difficult to imagine what shared property might mimic an inference that cows get a property from grass by eating it.
- 5 For applications of these ideas to psychology, see: on reasoning about interventions, Sloman and Lagnado (2005), Waldmann and Hagmayer (2005); on learning causal models by intervention, Gopnik et al. (2004), Lagnado and Sloman (2004), Steyvers et al. (2003); on inferring hidden variables, Gopnik et al. (2004), Kushnir, Gopnik, Schulz, and Danks (2003).
- 6 Ji et al. also reported that Americans but not Chinese showed a primacy effect, in which the judged strength of the relationship was more sensitive to cases presented early in the learning phase than to those presented later. This might have been due to a group difference in level of engagement in the task.
- 7 As a consequence, the mapping between an abstract principle and a particular task typically involves a series of assumptions, often implicit, that themselves may not be straightforward.
- 8 To illustrate how theories and goals might vary by domain, a Korean colleague has suggested that Korean explanations of mental illness or deviant behavior might actually be less holistic than American explanations, precisely because social interconnectedness is valued in Korean culture. A holistic explanation (e.g., society drove him mad) would implicate society, and to avoid this Koreans might prefer analytic explanations (e.g., bad traits or genes).

Chapter 48: Culture and Systems of Thought: Holistic versus Analytic Cognition

RICHARD E. NISBETT, KAIPING PENG, INCHEOL CHOI,
AND ARA NORENZAYAN

The British empiricist philosophers of the 18th and 19th centuries, including Locke, Hume, and Mill, wrote about cognitive processes as if they were the same for all normal adults. This assumption of universality was adopted by mainstream psychology of the 20th century, where it has been predominant from the earliest treatment of cognitive psychology by Piaget, to mid-century learning theorists, to modern cognitive science. The assumption of universality was probably strengthened by the analogy to the computer, which has been implicit and often explicit for the past 30 years (Block, 1995; Shweder, 1991). Brain equals hardware, inferential rules and data processing procedures equal the universal software, and output equals belief and behavior, which can, of course, be radically different given the different inputs possible for different individuals and groups. “Basic” processes such as categorization, learning, inductive and deductive inference, and causal reasoning are generally presumed to be the same among all human groups.

It appears, however, that fairly marked differences in knowledge about and use of inferential rules exist even among educated adults. Work by Nisbett and his colleagues (Larrick, Nisbett, & Morgan, 1993; Nisbett, 1993; Nisbett, Fong, Lehman, & Cheng, 1987; Smith, Langston, & Nisbett, 1992) shows that people can learn statistical, probabilistic, methodological, logical, deontic, cost-benefit, and other quite abstract rule systems and categorization proce-

dures, and that training can affect their reasoning about everyday life events and even their behavior. Significant effects can be obtained not merely by extensive training in formal courses but sometimes even by brief instruction in the laboratory. Given that inferential rules and cognitive processes appear to be malleable even for adults within a given society, it should not be surprising if it turned out to be the case that members of markedly different cultures, socialized from birth into different world views and habits of thought, might differ even more dramatically in their cognitive processes.

In this article, we argue that the considerable social differences that exist among different cultures affect not only their beliefs about specific aspects of the world but also (a) their naive metaphysical¹ systems at a deep level, (b) their tacit epistemologies,² and (c) even the nature of their cognitive processes – the ways by which they know the world. More specifically, we put forward the following propositions, which we develop in more detail later.

1. Social organization directs attention to some aspects of the field at the expense of others.
2. What is attended to influences metaphysics, that is, beliefs about the nature of the world and about causality.
3. Metaphysics guides tacit epistemology, that is, beliefs about what it is important

to know and how knowledge can be obtained.

4. Epistemology dictates the development and application of some cognitive processes at the expense of others.
5. Social organization and social practices can directly affect the plausibility of metaphysical assumptions, such as whether causality should be regarded as residing in the field versus the object.
6. Social organization and social practices can influence directly the development and use of cognitive processes such as dialectical versus logical ones.

First, we review evidence that we find to be a convincing example of the contention that societies can differ markedly in their systems of thought. This evidence concerns a comparison of the societies, philosophical orientations, and scientific outlooks of two highly sophisticated cultures: those of ancient China and Greece. We summarize the views of many historians, philosophers of science, and ethnographers indicating that the two societies differed in marked ways both socially and cognitively, and that the social and cognitive differences were related. We next present a general proposal concerning the relation between social factors and cognition based on an examination of social life and cognitive procedures in the ancient world, deriving a number of quite specific predictions from that formulation. We then present a review of evidence regarding these predictions that comes mostly from our recent research comparing modern individuals raised in societies influenced by ancient Chinese thought with people raised in societies influenced by ancient Greek thought. This research shows that, to a remarkable extent, the social and cognitive differences that scholars have reported about ancient China and Greece find their counterparts among contemporary peoples. Moreover, these are not mere parameter differences, but in many cases differences that are quantitatively very large and even qualitatively distinct. Finally, we speculate on the origins of differences in systems of thought, sketch an analysis of the factors that might sustain "sociocognitive homeostatic systems" over millennia, and present a consideration of the implications of our findings for claims about cognitive universality and for the traditional distinction between cognitive content and cognitive process.

Ancient Greek and Chinese Society

From roughly the 8th to the 3rd century B.C., many civilizations made great strides in philosophical and moral thought and in scientific and technological endeavors, notably Persia, India, the Middle East, China, and Greece. We will examine the differences between the two civilizations that were most distant from one another and probably influenced one another the least: those of Greece and China. In addition, the influence each of these civilizations has had on the modern world is particularly great. Greek civilization gave rise to European civilization and post-Columbian American civilization, and Chinese civilization gave rise to the civilizations of East Asia, including Japan and Korea, and also greatly influenced Southeast Asia.

The Ancient Greeks and Personal Agency

One of the most remarkable characteristics of the ancient Greeks (Jonians and Athenians in particular) was the location of power in the individual. Ordinary people developed a sense of personal agency that had no counterpart among the other ancient civilizations. Indeed, one definition of happiness for the Greeks was "the exercise of vital powers along lines of excellence in a life affording them scope" (Hamilton, 1930/1973, p. 25). Though the Greeks believed in the influence of the gods, "divine intervention and independent human action" were seen to work together (Knox, 1990, p. 39). The daily lives of the Greeks were imbued with a sense of choice and an absence of social constraint that were unparalleled in the ancient world. "The idea of the Athenian state was a union of individuals free to develop their own powers and live in their own way, obedient only to the laws they passed themselves and could criticize and change at will" (Hamilton, p. 144).

Related to the Greek sense of personal freedom is their tradition of debate, which was already well established at least by the time of Homer in the 8th century (Galtung, 1981; Lloyd, 1990; Nakamura, 1964/1985). Homer emphasizes repeatedly that, next to being a capable warrior, the most important skill for a man to have was that of the debater. Even ordinary people participated in the debate of the marketplace and the political assembly and could challenge even a king (Cromer, 1993, p. 65).

An aspect of Greek civilization that had a great effect on posterity was their sense of

curiosity about the world and the presumption that it could be understood by the discovery of rules (Lloyd, 1991; Toulmin & Goodfield, 1961, p. 62). The Greeks speculated about the nature of the objects and events around them and created causal models of them. The construction of these models was done by categorizing objects and events and generating rules about them for the purpose of systematic description, prediction, and explanation. This characterized their advances in, some have said invention of, the fields of physics, astronomy, axiomatic geometry, formal logic, rational philosophy, natural history, history, and ethnography. Whereas many great ancient civilizations, including the earlier Mesopotamian and Egyptian and the later Mayan, made systematic observations in many scientific domains, only the Greeks attempted to model such observations in terms of presumed underlying physical causes (Cromer, 1993; Kane, 2000; Lin, 1936, p. 84; Toulmin & Goodfield, 1961).

The Ancient Chinese and Harmony

The ancient Chinese provide a particularly valuable contrast to the Greeks. The Chinese counterpart to the Greek sense of personal agency was a sense of reciprocal social obligation or collective agency. The Chinese felt that individuals are part of a closely knit collectivity, whether a family or a village, and that the behavior of the individual should be guided by the expectations of the group. The chief moral system of China, Confucianism, was essentially an elaboration of the obligations that obtained between emperor and subject, parent and child, husband and wife, older brother and younger brother, and between friend and friend. Chinese society made the individual feel very much a part of a large, complex, and generally benign social organism in which prescriptive role relations were a guide to ethical conduct (Lin, 1936; Munro, 1985). Individual rights were construed as one's "share" of the rights of the community as a whole. "[R]ole fulfillment in a hierarchical system . . . [took] priority over most other goods" (Munro, p. 19).

Such an emphasis on collective agency resulted in the Chinese valuing in-group *harmony*, "as when the occupants of a social group . . . perform their functions and do not transgress the boundaries of duty or expectations that accompany those functions" (Munro, 1985, pp. 20–21). Within the social group, any form of confrontation, such as debate, was discouraged. Though there was a time, called the period of

the "hundred schools" of 600–200 B.C., during which debate, among philosophers at least, did occur (Yang, 1988), "[t]here never developed a 'spirit of controversial language' nor a 'tradition of free public debate'" (Becker, 1986, p. 78). "In philosophy, in medicine, and elsewhere there is criticism of other points of view . . . [b]ut the Chinese generally conceded far more readily than did the Greeks, that other opinions had something to be said for them" (Lloyd, 1990, p. 550). So far from debate being encouraged in a society with such values, one person could not contradict another without fear of making an enemy (Cromer, 1993, pp. 73–74), and to "be involved in a lawsuit was *ipso facto* ignominious" (Lin, 1936).

Chinese civilization was technologically far advanced beyond that of the Greeks. The Chinese have been credited with the original or independent invention of irrigation systems, ink, porcelain, the magnetic compass, stirrups, the wheelbarrow, deep drilling, the Pascal triangle, pound-locks on canals, fore-and-aft sailing, watertight compartments, the stempost rudder, the paddle-wheel boat, quantitative cartography, immunization techniques, astronomical observations of novae, seismographs, and acoustics (Logan, 1986, p. 51). Many of these technological achievements were in place at a time when the Greeks had none.

But most experts hold that these advances should not be regarded as the result of scientific theory and investigation (Cromer, 1993; Kane, 2000; Logan, 1986). Instead, they are reflective of a Chinese genius for practicality (Nakamura, 1964/1985, p. 189). "In Confucianism there was no thought of *knowing* that did not entail some consequence for action" (Munro, 1969, p. 55; see also On, 1996). The Chinese did not make formal models of the natural world but rather proceeded by intuition and empiricism. Indeed, it has been maintained that the Chinese never developed a concept corresponding to the laws of nature for the sufficient reason that they did not have a concept of "nature" as distinct from human or spiritual entities (Fung, 1983, p. 55; Lloyd, 1991; Logan, 1986, p. 50; Munro, 1969; Zhou, 1990).

Chinese and Greek Science, Mathematics, and Philosophy

The social–psychological aspects of ancient Greek and Chinese life had correspondences in the systems of thought of the two cultures. Their metaphysical beliefs were reflections of their

social existences. And their tacit epistemologies in turn seem to have reflected their different metaphysical beliefs. These resulted in very great differences between Greece and China in their approaches to scientific, mathematical, and philosophical questions.

The cognitive differences between ancient Chinese and Greeks can be loosely grouped under the heading of holistic versus analytic thought (Nisbett, 1998; Peng & Nisbett, 1999). We define holistic thought as involving an orientation to the context or field as a whole, including attention to relationships between a focal object and the field, and a preference for explaining and predicting events on the basis of such relationships. Holistic approaches rely on experience-based knowledge rather than on abstract logic and are dialectical, meaning that there is an emphasis on change, a recognition of contradiction and of the need for multiple perspectives, and a search for the "Middle Way" between opposing propositions. We define analytic thought as involving detachment of the object from its context, a tendency to focus on attributes of the object to assign it to categories, and a preference for using rules about the categories to explain and predict the object's behavior. Inferences rest in part on the practice of decontextualizing structure from content, the use of formal logic, and avoidance of contradiction.

The distinction between holistic and analytic thought rests on a long tradition of theory about reasoning beginning with James and Piaget and continuing to the present. Holistic thought is associative, and its computations reflect similarity and contiguity. Analytic thought recruits symbolic representational systems, and its computations reflect rule structure. Sloman (1996) has recently reviewed evidence for this distinction in the cognitive realm. Witkin and his colleagues (Witkin, Dyk, Faterson, Goodenough, & Karp, 1974; Witkin et al., 1954) have made a similar distinction in the perceptual realm between "field dependence" and "field independence." Our definition encompasses both reasoning aspects and perceptual aspects of the distinction as well as the belief systems that underlie those differences.

Historians and philosophers of science have identified a number of important differences between the Greeks and the Chinese that fit under the definitions above.

CONTINUITY VERSUS DISCRETENESS

A fundamental intellectual difference between the Chinese and the Greeks was that

the Chinese held the "view that the world is a collection of overlapping and interpenetrating stuffs or substances. . . . [This contrasts] with the traditional Platonic philosophical picture of objects which are understood as individuals or particulars which instantiate or 'have' properties" (Hansen, 1983, p. 30) that are themselves universals (e.g., "whiteness," "hardness"). This profound difference in metaphysics had many ramifications. Most fundamentally, the Greeks, unlike the Chinese, were inclined to see the world as a collection of discrete objects which could be categorized by reference to some subset of universal properties that characterized the object. Thus although the Greeks debated whether matter was best understood as waves or particles, the Chinese seem never to have had any doubt about the continuous nature of matter (Needham, 1962, p. 1).

FIELD VERSUS OBJECT

Since the Chinese were oriented toward continuities and relationships, the individual object was "not a primary conceptual starting point" (Moser, 1996, p. 31). Instead, "parts exist only within wholes, to which they have inseparable relations" (Munro, 1985, p. 17). The Greeks, in contrast, were inclined to focus primarily on the central object and its attributes (Hansen, 1983, p. 31). This tendency likely contributed to the Greeks' lack of understanding of the fundamental nature of causality in the physical domain. Aristotle explained a stone's falling through the air as being due to the stone having the property of "gravity" and explained a piece of wood's floating on the surface of water as being due to the wood having the property of "levity." The Chinese, in contrast, recognized that all events are due to the operation of a field of forces. They had knowledge of magnetism and acoustic resonance, for example, and knew the correct explanation for the behavior of the tides (Needham, 1962, p. 60).

RELATIONSHIPS AND SIMILARITIES VERSUS CATEGORIES AND RULES

A consequence of their assumptions about continuity and the importance of the field is that the Chinese were concerned with relationships among objects and events (Zhang, 1985). In contrast, the Greeks were more inclined to focus on the categories and rules that would help them to understand the behavior of the object independent of its context (Nakamura, 1964/1985, pp. 185–186). The Chinese were convinced of the fundamental relatedness of all things and the

consequent alteration of objects and events by the context in which they were located. It is only the whole that exists; and the parts are linked relationally, like “the ropes in a net” (Munro, 1985). Thus any attempt to categorize objects with precision would not have seemed a terribly important epistemic goal (Chan, 1967; Logan, 1986, p. 122; Moser, 1996, p. 116).³

The relationship view versus the rule stance is well illustrated by the difference between the holistic approach to medicine characteristic of the Chinese and the effort to find effective rules and treatment principles in the West. Surgery was common in the West from a very early period because the idea that some part of the body could be malfunctioning was a natural one to the analytic mind. But the idea of surgery was “heretical to ancient Chinese medical tradition, which taught that good health depended on the balance and flow of natural forces throughout the body” (Hadingham, 1994, p. 77).

DIALECTICS VERSUS FOUNDATIONAL PRINCIPLES AND LOGIC

The Chinese seem not to have been motivated to seek first principles underlying their mathematical procedures or scientific assumptions, and, except for the brief “Mohist” period from the end of the 4th to the end of the 3rd century B.C., “the Chinese did not develop any formal systems of logic [or] anything like . . . an Aristotelian syllogism” (Liu, 1974). Indeed, there was an absence “not only of formal logical systems, but indeed of a principle of contradiction” (Becker, 1986, p. 83). It is noteworthy that the Indians did have a strong logical tradition, but the Chinese translations of their texts were full of errors and misunderstandings (Becker, p. 84). It has been argued that the lack of interest in logic accounts for why, although Chinese advances in algebra and arithmetic were substantial, the Chinese made little progress in geometry where proofs rely on formal logic, especially the notion of contradiction (Lloyd, 1990, p. 119; Logan, 1986, p. 48; Needham, 1962, p. 1). (Algebra did not become deductive until the 12th century; Cromer, 1993, p. 89.)

In place of logic, the Chinese developed a dialectic (Lloyd, 1990, p. 119), which involves reconciling, transcending, or even accepting apparent contradictions. In the Chinese intellectual tradition, there is no necessary incompatibility between the belief that *A* and *not A* both have merit. Indeed, in the spirit of the Tao or yin-yang principle, *A* can actually imply that *not A* is also the case – the opposite of a state of

affairs can exist simultaneously with the state of affairs itself (Chang, 1939; Mao, 1937/1962). It is this belief that lies behind much of Chinese thought designed to find the “Middle Way” between extremes – accepting that two parties to a quarrel can both have right on their side or that two opposing propositions can both contain some truth. The Chinese dialectic includes notions resembling the Hegelian dialectic of thesis–antithesis–synthesis and finds its counterpart in modern “post-formal operations” in the Piagetian tradition – for example, understanding of part-whole relations, reciprocal relations, contextual relativism, and self-modifying systems (Baltes & Staudinger, 1993; Basseches, 1984; Riegel, 1973).

EXPERIENCE-BASED KNOWLEDGE VERSUS ABSTRACT ANALYSIS

“The Chinese . . . sought intuitive instantaneous understanding through direct perception” (Nakamura, 1964/1985, p. 171). This resulted in a focus on particular instances and concrete cases in Chinese thought (Fung, 1983; Lloyd, 1990; Nakamura, p. 171). Many Greeks favored the epistemology of logic and abstract principles, and many Greek philosophers, especially Plato and his followers, actually viewed concrete perception and direct experiential knowledge as unreliable and incomplete at best, and downright misleading at worst. Thus they were prepared to reject the evidence of the senses when it conflicted with reason (Lloyd, p. 118).

Ironically, important as the Greek discovery of formal logic was for the development of science, it also impeded it in many ways. After the 6th-century Ionian period, the empirical tradition in Greek science was greatly weakened. It was countered by the conviction on the part of many philosophers that it ought to be possible to understand things through reason alone, without recourse to the senses (Logan, 1986, pp. 114–115). Importantly, there never developed in Greece the critical concept of zero, which is needed for an Arabic-style place number system as well as for algebra. Zero was rejected as an impossibility on the grounds that nonbeing is logically self-contradictory (Logan, p. 115)! Eventual Western understanding of zero, infinity, and infinitesimals required a detour to the East.

Sociocognitive Systems

It is possible to derive the intellectual differences between the ancient Greek and Chinese

approaches to science and philosophy – their differing metaphysics and epistemology – from their differing social psychological attributes. And, more generally, it is possible to build a psychological theory from the historical evidence. We now return to the points sketched in the introduction concerning the links from social organization to cognitive process. We believe that social organization affects cognitive processes in two basic ways: indirectly by focusing attention on different parts of the environment and directly by making some kinds of social communication patterns more acceptable than others.

From Attention to Cognitive Processes

SOCIAL ORGANIZATION, ATTENTION, AND NAIVE METAPHYSICS

If one lives in a complex social world with many role relations, one's attention is likely to be directed outside oneself and toward the social field. The Chinese habit of attending to the social environment might have carried over to the environment in general, allowing, for example, for the discovery of the relevance of the field in understanding physical events. As Markus and Kitayama (1991) put it, "If one perceives oneself as embedded within a larger context of which one is an interdependent part, it is likely that other objects or events will be perceived in a similar way" (p. 246). Attention to the field should foster attempts to understand relations among objects and events in the field and should encourage explanation of events in terms of the relationship between the object and the field. Similarly, the world might naturally seem continuous and interpenetrating to people who view themselves as part of a larger whole and who are motivated to maintain harmony within it.

On the other hand, if one lives in a world with fewer and less significant social relations and role constraints, it may be possible to attend primarily to the object and one's goals with respect to it. The object's properties may thus be salient, and one may be encouraged to use those properties to develop categories and rules that presumably govern the object's behavior. The belief that one knows the rules governing the object's behavior might encourage exclusive focus on the object for explanation and might encourage the belief that the world is a place that is controllable through one's own actions. Moreover, the world is likely to be perceived as discrete and discontinuous by those who regard themselves as fully distinct and autonomous entities having

limited connections to others and possessing the ability to act autonomously.

NAIVE METAPHYSICS AND TACIT EPISTEMOLOGY

Beliefs about the nature of the world can be expected to influence tacit epistemologies or beliefs about how to get knowledge. If the world is a place where relations among objects and events are crucial in determining outcomes, then it will seem important to be able to see all the important elements in the field, to see relations among objects, and to see the relation between the parts and the whole. If the world is a place where the behavior of objects is governed by rules and the categories to which they apply, then it is crucial to be able to isolate the object from its context, to infer category membership of the object from its properties, and to infer how rules apply to categories.

TACIT EPISTEMOLOGY AND COGNITIVE PROCESSES

If it seems important to see relations in the field, then perceptual habits such as deep processing of the environment and covariation-detection skills could be expected to develop as well as cognitive habits such as explaining events with reference to the field. If it is important to find out the object's properties and the categories to which it belongs, then perceptual habits such as decontextualization of the object from the field and cognitive habits such as explaining the object's behavior in terms of the categories and rules that apply to it could be expected to develop. Such differential cognitive habits would, of course, be expected to become largely automatic and unconscious, just as the underlying naive epistemology would be expected to be largely beyond the reach of conscious awareness.

From Social Organization to Cognitive Processes

Social organization can influence cognitive processes without mediation by metaphysical beliefs. Dialectics and logic can both be seen as cognitive tools developed to deal with social conflict. People whose social existence is based on harmony would not be expected to develop a tradition of confrontation or debate. On the contrary, their intellectual goals when confronted with a contradiction in views might be oriented toward resolving the contradiction, transcending it, or finding a "Middle Way" – in short, to exercise a dialectical approach. In contrast, people who are free to contend with their fellows

might be expected to develop rules for the conduct of debate, including the principle of non-contradiction and formal logic (Becker, 1986; Cromer, 1993; Lloyd, 1990, pp. 8–9). Several commentators have maintained that the Greeks brought to the pursuit of science essentially the same principles of rhetoric that governed debate in the marketplace.

Science, in this view, is an extension of rhetoric. It was invented in Greece, and only in Greece, because the Greek institution of the public assembly attached great prestige to debating skill. . . . A geometric proof is . . . the ultimate rhetorical form. (Cromer, 1993, p. 144)

The exact psychological processes by which social organization influences metaphysical beliefs, or metaphysical beliefs affect epistemology, or epistemology governs the development of particular processes cannot, of course, be known at this time. This is true in part because all of these elements are in homeostatic balance, and there is reciprocal influence among all of them. Despite this, it is fruitful to identify the kinds of social practices that tend to be found in conjunction with particular cognitive processes, and we will describe some important ones later. We will also speculate about the ways that the social practices might operate to sustain the cognitive processes.

Contemporary Cognitive Differences?

If the differences in the nature of social life between East and West have been maintained, and if the original differences in cognitive orientations were due to the social psychological ones, then cognitive differences might also be found today and not just among the intelligentsia.

There is substantial evidence that the social psychological differences characteristic of ancient China and Greece do in fact persist. China and other East Asian societies remain collectivist and oriented toward the group, whereas America and other European-influenced societies are more individualist in orientation.⁴ For reviews and general treatments of these differences, see Bond (1996), Fiske, Kitayama, Markus, and Nisbett (1998), Hofstede (1980), Hsu (1981), Markus and Kitayama (1991), Nakamura (1964/1985), and Triandis (1972, 1995). As the psychologist L.-H. Chiu (1972) put it:

Chinese are situation-centered. They are obliged to be sensitive to their environment. Americans are individual-centered. They expect their environment to be sensitive to them. Thus, Chinese tend to assume a passive attitude while Americans tend to possess an active and conquering attitude in dealing with their environment. (p. 236)

[The American] orientation may inhibit the development of a tendency to perceive objects in the environmental context in terms of relationships or interdependence. On the other hand, the Chinese child learns very early to view the world as based on a network of relationships; he is *socio-oriented*, or *situation-centered*. (p. 241)

If the social differences have persisted, and if we are correct in believing that social factors influence metaphysics, epistemology, and ultimately cognitive processes, then several interrelated predictions can be made concerning cognitive differences between contemporary societies that have been influenced by China and those that have been influenced by Greece.

ATTENTION

We believe that attention to the social environment is what underlay ancient Chinese attention to the field in general and accounts in part for metaphysical beliefs such as their recognition of the principle of action at a distance. If this notion is correct, we might find that contemporary Easterners and Westerners attend to different aspects of the environment. East Asians would be expected to attend more to the field than European Americans, who would be expected to attend more to a salient target object. Process implications follow: East Asians should be more accurate at covariation detection than Americans are, that is, the perception of relationships within the field. East Asians should also be more field dependent (Witkin, Dyk et al., 1974); that is, they should find it more difficult than Americans to isolate and analyze an object while ignoring the field in which it is embedded.

CONTROL

If a belief in personal agency underlay Greek curiosity and the invention of science, then Americans might be expected to perceive more control in a given situation than do East Asians and to benefit more from being given control. They might also be more subject to the illusion of control (Langer, 1975), that is, a greater

expectation of success when the self is involved in interaction with the object – even when that interaction could not logically have an effect on the outcome.

EXPLANATION

If East Asians continue to have a metaphysical commitment to the notion that the whole context is relevant for a causal assessment of outcomes, we should find that their explanations of events invoke situational factors more frequently than do those of Americans. East Asians would be expected to explain events, both social and physical, with respect to the field – that is, contexts and situations – more than Americans would, and Americans would be expected to explain events more with respect to a target object and its properties. Thus Americans would be expected to be more prone to the fundamental attribution error – the tendency to attribute behavior to dispositions of the person and to slight the role of situations and contexts (Ross, 1977).

PREDICTION AND “POSTDICTION”

We are proposing that East Asians have always lived in a complex world in which many relevant factors are important to a consideration of outcomes. Thus their predictions about events might cast a wider net among potential causal candidates. They might also be expected to be less surprised by any given outcome because of their ready ability to find some explanation for it in the complex of potentially relevant factors. If explanations come to mind very easily for Asians, we might find that they are more susceptible to hindsight bias, the tendency to regard events as having been inevitable in retrospect (Fischhoff, 1975).

RELATIONSHIPS AND SIMILARITIES VERSUS RULES AND CATEGORIES

If Easterners are oriented toward the field, we would expect that they would organize their worlds in terms of relationships among events in the environment. More concretely, East Asians would be expected to group objects and events on the basis of functional relationships and part-whole relationships; for example, “A is a part of B.” Americans, in contrast, would be expected to group objects more on the basis of category membership; for example, “A and B are both Xs.” Other predictions include the expectations that Americans might learn rule-based categories more readily than East Asians do and

that Americans might rely more on categories for purposes of deduction and induction.

LOGIC VERSUS EXPERIENTIAL KNOWLEDGE

If the scant role played by logic in the history of East Asian mathematics, science, and philosophy has resonance in the thought processes of ordinary people today, and if the sympathy for formal approaches remains in the West, East Asians might be expected to rely more on prior beliefs and experience-based strategies when evaluating the convincingness of formal arguments than do Americans. We might also find that East Asians would be heavily influenced by prior beliefs in judging the soundness of formal arguments. Americans should be more capable of ignoring prior beliefs and setting aside experience in favor of reasoning based on logical rules.

DIALECTICS VERSUS THE LAW OF NONCONTRADICTION

If harmony remains the watchword in social relations for East Asians, and if social needs influence intellectual stances, East Asians would be expected to seek compromise solutions to problems, to prefer arguments based on principles of holism and continuity, and to try to reconcile or transcend seeming contradictions. If the debater’s concern about contradiction continues to affect Western approaches to problems, Americans should be more inclined to reject one or both of two propositions that could be construed as contradicting one another.

As we will see, there is support for each of these hypotheses. In our review, we will not provide details about samples of participants in particular studies. Suffice it to say that we find supportive evidence whether the East Asians studied are ethnic Chinese, Koreans, or Japanese and whether they are living in their own countries or living as foreign students at U.S. universities and whether materials for East Asians are in English or translated into their native languages. Though most of the participants in research to date are students, there is also supportive evidence for nonstudents. It is entirely possible, of course, that there are significant differences among the various East Asian populations with respect to some of the issues we discuss. Certainly there are substantial social and cultural differences, some of which might plausibly affect cognitive processes. It should also be noted that the great majority of people of European culture who have been studied are Americans,

and North Americans may well differ more from East Asians than do Europeans or Latin Americans.

Attention and Control

Work by Meyer and Kieras and their colleagues (Meyer, 1995; Meyer & Kieras, 1997a, 1997b, 1999) suggests that allocation of attention is highly malleable and subject to learned strategic adjustments such that perceptual "bottlenecks" can be ameliorated. Work by Rogoff and her colleagues (Chavajay & Rogoff, 2000; Rogoff, Mistry, Göncü, & Mosier, 1993) indicates that people in some cultures attend to a much wider range of events simultaneously than do people in other cultures. Thus East Asians might be capable of attending to both the object and the field, and to a wider range of objects in the field, than are Americans. We might also expect that, if Westerners attend to the object more, and if they believe that they understand the rules influencing the object's behavior, they might have a greater belief in the controllability of the object than is characteristic of Asians. Several implications follow from these considerations: (a) Easterners should see wholes where Westerners see parts; (b) Easterners should more easily see relationships among elements in the field but (c) find it more difficult to differentiate an object when it is embedded in the field; and (d) Westerners' perceptions and behavior should be more influenced by the belief that they have control over the object or environment.

HOLISTIC VERSUS ANALYTIC RORSCHACH RESPONSES

In an early study by Abel and Hsu (1949), Rorschach cards were presented to European Americans and Chinese Americans. The investigators found that their Chinese American participants were more likely than their European American counterparts to give so-called "whole-card" responses, in which all aspects of the card, or its Gestalt as a whole, was the basis of the response. Their European American participants were more likely to give "part" responses, in which only a single aspect of the card was the basis of the response.

ATTENTION TO THE FIELD

Masuda and Nisbett (2001) presented realistic animated scenes of fish and other underwater objects to Japanese and Americans and asked them to report what they had seen. The

first statement by American participants usually referred to the focal fish ("there was what looked like a trout swimming to the right"), whereas the first statement by Japanese participants usually referred to background elements ("there was a lake or pond"). Although Americans and Japanese were equally likely to mention details about the focal fish, Japanese participants made about 70% more statements about background aspects of the environment. In addition, Japanese participants made about twice as many statements concerning relations involving inanimate aspects of the environment ("the big fish swam past the gray seaweed"). In a subsequent recognition task, Japanese performance was harmed by showing the focal fish with the wrong background, indicating that the perception of the object had been "bound" (Chalfonte & Johnson, 1996) to the field in which it had appeared. In contrast, American recognition of the object was unaffected by the wrong background.

A similar "binding" result was obtained by Hedden and his colleagues (Hedden et al., 2000; Park, Nisbett, & Hedden, 1999). They asked their Chinese and American participants to look at a series of cards having a word printed either on a background of social stimuli (e.g., people at a market) or on no background. The words were unrelated to the pictures. Then participants were asked to recall as many words as they could. Chinese, but not Americans, recalled words better if they had been presented on the background, indicating that recall of the background served as a retrieval cue for the word for them.

DETECTION OF COVARIATION

Ji, Peng, and Nisbett (2000) examined ability to detect covariation among environmental stimuli. Chinese and American participants were asked to judge the degree of association between arbitrary figures. On the left side of a computer screen, one of the two arbitrary figures was shown – for example, a schematic medal or a schematic light bulb. Immediately following that, on the right of the screen, one of another two figures was shown – for example, either a pointing finger or a schematic coin. Actual covariation between figures on the left and those on the right ranged from the equivalent of a correlation of .00 to one of .60. Chinese participants reported a greater degree of covariation than did American participants and were more confident about their covariation

judgments. Their confidence judgments were also better calibrated with actual covariation. In addition, as Yates and Curley (1996) found, American participants showed a strong primacy effect, making predictions about future covariations that were much more influenced by the first pairings they had seen than by the overall degree of covariation to which they had been exposed. Chinese participants, in contrast, showed no primacy effect at all, making predictions about future covariation that were based on the overall covariation they had actually seen.

FIELD DEPENDENCE

Because of their habit of decontextualization and analysis, Americans should find it easier to separate an object from the field in which it is embedded than should East Asians. To examine this possibility, Ji and her colleagues (2000) examined the performance of East Asians and Americans (matched for SAT math score) on the Rod and Frame Test of Witkin and his colleagues (Witkin et al., 1954). In this task, the participant looks into a rectangular box framing a rod that sits inside it. The task is to report when the rod appears to be vertical. Field dependence is indicated by the degree to which judgments about the position of the rod are influenced by the position of the frame. Ji and colleagues found that East Asian participants made more errors on the test than did American participants. East Asian participants were also less confident about the accuracy of their performance than were American participants.⁵

(ILLUSION OF) CONTROL

It seems likely that if Americans believe they have control over events, they might pay more attention to them. Moreover, control is sufficiently important that people often fail to distinguish between objectively controllable events and uncontrollable ones. This "illusion of control" was defined by Langer (1975) as being an expectancy of personal success higher than the objective probability would warrant. The illusion of control can actually result in improvement of some cognitive functions for Americans. For example, participants were found to perform better on routine tasks when they believed mistakenly that they could control a loud noise that occurred periodically during the tasks (Glass & Singer, 1973). Some cross-cultural work suggests that East Asians may not be so susceptible to this illusion. Yamagushi, Gelfand, Miguno, and

Zemba (1997) found that American males were more optimistic in a condition in which they had an illusion of personal control over the environment, whereas American females and Japanese of both genders were not.

As these considerations would suggest, both the covariation detection findings and the field dependence findings just discussed were affected by manipulations intended to give participants a sense of control. In one condition of the covariation-detection task, participants were allowed to push a button to control which stimulus was presented on the left, and they could also control the intertrial interval. Whereas this manipulation could have no effect on the degree of covariation, Americans who were given "control" in this fashion tended to see more covariation and express more confidence in their judgments about covariation, whereas Chinese participants showed the opposite tendencies. Moreover, control actually impaired the calibration of Chinese judgments, whereas this was not true for Americans. Similarly, in the Rod and Frame task, when participants were allowed to control the movement of the rod, the accuracy of American males improved whereas that of the other groups did not. Finally, the confidence of both American males and American females was greater when they had control over the rod, and this was not true for East Asians of either gender.

Thus the attention of East Asians appears to be directed more toward the field as a whole and that of Americans more toward the object. East Asians found it easier to see relationships in the environment but found more difficulty in separating object from field. In addition, Americans and East Asians were affected quite differently by control or the illusion of it: Americans' performance improved and their confidence increased with control, whereas that of East Asians did not.

Explanation and Prediction

It seems reasonable to assume that people attribute causality to the events they attend to. If Westerners attend to the object, we would expect them to attribute causality to the object. If East Asians attend to the field and the object's relations with the field, it seems likely that they would be more inclined to attribute causality to context and situations. Each of these expectations is supported by a substantial amount of evidence.

Dispositions Versus Contexts in Explanation

CAUSAL ATTRIBUTION AND PREDICTION

One of the best established findings in cognitive social psychology concerns the so-called "correspondence bias" (Gilbert & Malone, 1995) or "fundamental attribution error" (FAE; Ross, 1977) – the tendency to see behavior as a product of the actor's dispositions and to ignore important situational determinants of the behavior. If it is really the case that East Asians are more oriented toward contextual factors than are European Americans, then we might expect that they would be less subject to the FAE. I. Choi, Nisbett, and Norenzayan (1999; Norenzayan, Choi, & Nisbett, 1999) have recently reviewed research supporting this contention.

Work by Miller (1984) initially suggested that the FAE might indeed be more characteristic of Western culture than of other cultures. She found that whereas Americans explained another person's behavior predominantly in terms of traits, (e.g., recklessness or kindness), Hindu Indians explained comparable behaviors in terms of social roles, obligations, the physical environment, and other contextual factors. A similar demonstration by Morris and Peng (Morris, Nisbett, & Peng, 1995; Morris & Peng, 1994) showed that causal explanations by Americans of events such as mass murders focused almost wholly on the presumed mental instability and other negative dispositions of the murderers, whereas accounts by Chinese of the same events speculated on situational, contextual, and even societal factors that might have been at work. Lee, Hallahan, and Herzog (1996) found that sports editorial writers in Hong Kong focused on contextual explanations of sports events, whereas American sports writers were more likely to prefer explanations involving the dispositions of individual team members. Norenzayan, Choi, and Nisbett (2001) found that Korean participants were more responsive to contextual factors when making predictions about how people in general would be expected to behave in a given situation and, much more than did American subjects, made use of their beliefs about situational power when making predictions about the behavior of a particular individual. Cha and Nam (1985) also found Koreans to make far more use of situationally relevant information when making causal attributions than Americans did.

Importantly, Norenzayan et al. (2001) found that Koreans and Americans were able to artic-

ulate metatheories of behavior that accorded with their explanations and predictions. Koreans endorsed situational and interactional theories more than did Americans. The East Asian focus on the field and the American focus on the object can be apparent even when the East Asian attributions are dispositional in nature. Menon, Morris, Chiu, and Hong (1999) have found that East Asian dispositional explanations of events (e.g., scandals in organizations) were more likely than those of Americans to refer to *group* dispositions.

The different forms of preferred explanation apparently extend beyond social events. Morris and Peng (1994) and Hong, Chiu, and Kung (1997) showed participants cartoon displays of fish moving in relation to one another in various ways. Chinese participants were more likely to see the behavior of the individual fish as being produced by external factors than Americans were, and American participants were more inclined to see the behavior as being produced by internal ones. Peng and Nisbett (2000) have shown that the physical theories of contemporary Chinese and Americans reflect those of their respective scientific predecessors two-and-a-half millennia ago. For ambiguous physical events involving phenomena that appeared to be hydrodynamic, aerodynamic, or magnetic, Chinese were more likely to refer to the field when giving explanations (e.g., "the ball is more buoyant than the water") than Americans were. (For less ambiguous, lever and "billiard ball" events, the explanations of Americans and Chinese were almost identical.) Thus the attributional differences probably should not be regarded as mere belief differences about local aspects of the world, but rather as deep metaphysical differences not limited to rules about particular domains specifically taught by the culture.

ATTITUDE ATTRIBUTION PARADIGM

One of the first experimental demonstrations of the fundamental attribution error was by Jones and Harris (1967). Participants read an essay, either supporting or opposing some position on an important social question of the day, that allegedly had been written by another student. It was made clear to participants in a "No Choice" condition that the target had no choice about which side to take in the essay. For example, the target had been required to write an essay in favor of Castro's Cuba for a political science exam. Although normatively this information might be expected to eliminate any assumption that the essay reflected anything about the

actual beliefs of the target, participants who read the "Pro" essay reported believing that its writer was probably much more in favor of the question than did participants who read the "Con" essay.

I. Choi and Nisbett (I. Choi, 1998; I. Choi & Nisbett, 1998) duplicated the basic conditions of the Jones and Harris study and added a condition in which, before making judgments about the target's attitude, participants were required to write an essay themselves and allowed no choice about which side to take. It was made clear to participants that the target had been through the same procedure they themselves had been. The American participants in this condition made inferences about the target's attitude that were as strong as those made by participants in the standard "No Choice" condition. Korean participants, in contrast, made much less extreme inferences than did Korean participants in the standard "No Choice" condition. Thus Korean participants, presumably by virtue of seeing the role that the situation played in their own behavior, recognized its power and made attributions about others accordingly. Similar sensitivity to situational constraints in attitude attribution was obtained with Japanese participants by Masuda and Kitayama (Kitayama & Masuda, 1997; Masuda, 1996).

Holistic Prediction and Postdiction

Attention to the field would appear to have clear advantages for explanation of events, inasmuch as it allows for avoidance of the fundamental attribution error. But attention to a broad range of factors might mean that any event can be readily explained – perhaps too readily explained. If a host of factors is attended to, and if naive metaphysics and tacit epistemology support the view that multiple, interactive factors are usually operative in a given outcome, then any outcome may seem to be understandable, even inevitable, after the fact. And indeed, I. Choi, Dalal, and Kim-Prieto (2000) have shown that Koreans regard a larger number of factors as potentially relevant to explaining a given event. They gave European American, Asian American, and Korean participants a detective story and listed a large number of facts. Participants were asked to indicate which of the facts were irrelevant to solving the mystery. Koreans reported believing that far fewer facts were irrelevant than did European Americans. Asian Americans were intermediate between the other two groups.

HINDSIGHT BIAS

An advantage of the more simplistic, rule-based stance of the Westerner may be that surprise is a frequent event. Post hoc explanations may be relatively difficult to generate, and epistemic curiosity may be piqued. The curiosity, in turn, may provoke a search for new, possibly superior models to explain events. In contrast, if Eastern theories about the world are less focused, and a wide range of factors are presumed to be potentially relevant to any given outcome, it may be harder to recognize that a particular outcome could not have been predicted. Hindsight bias (Fischhoff, 1975), or the tendency to assume that one knew all along that a given outcome was likely, might therefore be greater for Easterners.

These notions were tested in a series of experiments by I. Choi and Nisbett (I. Choi, 1998; I. Choi & Nisbett, 2000). One study presented a scenario based on the "Good Samaritan" experiment of Darley and Batson (1973). Participants were told about one particular young seminary student, who, they were assured, was a very kind and religious person. He was headed across campus to deliver a sermon and along the way he encountered a man lying in a doorway asking for help. Participants were also told that the seminarian was late to deliver his sermon. In Condition A, where participants did not know what the target had done, they were asked what they thought was the probability that the target would help and how surprised they would be if they were to find out that he had not helped. Both Koreans and Americans reported about an 80% probability that the target would help and indicated they would be quite surprised if he did not. In Condition B, participants were told the target had helped the victim, and in Condition C they were told he had not helped the victim. Participants in these conditions were asked what they believed they *would* have regarded as the probability that the target would have helped – if, in fact, they had not been told what he did – and also how surprised they were by his actual behavior. Again, both Koreans and Americans in Condition B indicated they would have thought the probability of helping was about 80%, and both groups reported no surprise that he did help. Americans in Condition C, where the target unexpectedly did not help the victim, also reported that they would have thought the probability was about 80% that the target would have helped and reported a great deal of surprise that he did not do so. In contrast, Koreans in Condition C reported that they

would have thought the probability was only about 50% that the target would have helped and reported little surprise that he did not. Thus Americans experienced surprise where Koreans did not, and Koreans showed a very pronounced hindsight bias, indicating that they thought they knew something all along which in fact they did not.

INFLUENCE OF ALTERNATIVE POSSIBILITIES ON SURPRISE AT OUTCOMES

An additional study by I. Choi and Nisbett (2000) indicates that Easterners are not as surprised by unanticipated outcomes as Americans are. We would expect Westerners to regard a scientific finding as more likely if they had previously been presented only with a theory that would lead them to expect that finding than if they had also been presented in addition with a theory that would lead them to expect the opposite. On the other hand, if Koreans are in the habit of regarding outcomes as inevitable, then we would not necessarily expect them to be much more surprised when presented with two opposing theories than when presented only with the theory predicting the actual outcome. And, indeed, this is what was found. Americans reported being more surprised when presented with two strongly competing hypotheses, whereas Koreans were no more surprised when presented with two opposing hypotheses than when presented with only one.

SURPRISE WHEN AN "OUTCOME" IS FOUND NOT TO BE TRUE

In a final study, I. Choi and Nisbett (2000) showed that Koreans expressed little surprise even when an outcome literally contradicted another outcome they had just read about. Participants read either that scientific research had shown that more-optimistic people have better mental health or that more-realistic people do. Participants rated how surprising they found this result to be. Then, under a ruse, the experimenter "discovered" that the materials they had read were mistaken, due to a printing error, and that it was the opposite hypothesis that had been supported. Apologetically, he asked the participants if they would fill out the materials again. Americans reported substantial surprise if they read that it was the less plausible, "realism" hypothesis that, after all, was the correct one. Koreans reported much less surprise than Americans.⁶

The results support the view that East Asians have complicated but underspecified theories

about the world that leave them insufficiently surprised by outcomes that differ from those that are anticipated. Thus, we would maintain that the same cognitive predispositions that make Asians less prone to the fundamental attribution error leave them prey to the hindsight bias and may also reduce their epistemic curiosity.

Relationships and Similarities Versus Rules and Categories

If Westerners attribute causality primarily to objects, it seems likely that they do so on the basis of rules that they presume to govern the behavior of objects. Rules, in turn, are of value to the extent that they apply over a large number and specifiable type of objects, that is, to a category. Thus rules and categories would be expected to be a major basis of organizing events for Westerners. If Easterners attribute causality primarily to the field, then it is relationships between the object and the field, and relationships among events in the field, that might serve as the basis of organization. There is a good deal of evidence supporting these expectations.

RELATIONSHIPS VERSUS CATEGORIES AS THE BASIS FOR GROUPING

Chiu (1972) gave items consisting of three pictures of human, vehicle, furniture, tool, or food categories to American and Chinese children. Children were asked "to choose any two of the three objects in a set which were alike or went together and to state the reason for the choice" (p. 237). The dominant style of the Chinese children was "relational-contextual." For example, shown a picture of a man, a woman, and a child, the Chinese children were likely to group the woman and child together because "the mother takes care of the baby." In contrast, American children were much more likely to group objects on the basis of category membership or shared features, for example, to group the man and the woman because "they are both adults."

RELATIONSHIPS VERSUS CATEGORIES AS THE BASIS FOR JUDGMENTS OF ASSOCIATION

Ji and Nisbett (Ji, 2001; Ji & Nisbett, 2001) obtained the same results as Chiu did with adult Chinese and American college students, who were tested in their native languages. They asked participants to indicate which of two objects out of three, described verbally, were most closely related. In all cases, two of the objects shared

some kind of relationship, either functional (e.g., pencil and notebook) or contextual (e.g., sky and sunshine) and also shared a category (e.g., notebook and magazine) or some feature that would allow them to be categorized together (e.g., sunshine and brightness). Chinese were more likely to group on the basis of relationships, and Americans were more likely to group on the basis of categories or shared object features. Participants were asked to justify their groupings and Chinese were found to be more likely to offer relationships as the justification (“the sun is in the sky”), whereas Americans were more likely to offer category membership as the justification (“the sun and the sky are both in the heavens”).

FAMILY RESEMBLANCE VERSUS RULES AS THE BASIS FOR JUDGMENTS OF SIMILARITY

Norenzayan, Nisbett, Smith, and Kim (2000; Norenzayan, 1999) presented East Asians (Chinese and Koreans), Asian Americans, and European Americans with a series of stimuli on a computer screen in which a simple target object appeared beneath two groups of four similar objects. The groups were always constructed so that the use of a family resemblance strategy and the use of a rule strategy led to different responses (Kemler-Nelson, 1984). The objects in one group had a close family resemblance to one another and to the target object, whereas the objects in the other group did not share a close resemblance with the target object. Instead, the objects of the second group were all describable by a unidimensional, deterministic rule; for example, they all had a curved stem (vs. a straight stem), and the rule was also applicable to the target object. Participants were asked to indicate to which group the target object was most similar. A majority of East Asian participants picked the “family resemblance” group, whereas a majority of the European American participants picked the “rule” group. Asian Americans showed intermediate reasoning, having equal preferences for the rule group and the family resemblance group.

CATEGORIES AND INDUCTION

Osherson, Smith, Wilkie, Lopez, and Shafir (1990) have proposed a theory of inductive inference from categories, which holds that people’s willingness to generalize is in part a function of the extent to which premise categories “cover” the lowest level category that includes all premise categories. Thus, when people are told that lions and giraffes have a particular property, they are more willing to infer that rabbits

have the property than when they are told that lions and tigers have the property (since lions and giraffes provide more coverage of the category *mammal* than do lions and tigers). Work by I. Choi, Nisbett, and Smith (1997) indicates that Koreans make less use of categories for purposes of inductive inference than do Americans. For example, they were less influenced than Americans by coverage of the category – unless the category was made salient in some way. In one manipulation, the category was mentioned in the conclusion (i.e., participants made an inference about “mammals” rather than “rabbits”). This manipulation had no effect on Americans but increased the degree to which Koreans relied on the category. Thus categories are apparently less spontaneously salient for Koreans and, hence, are less available for guiding generalizations.

CATEGORY LEARNING

If East Asians are relatively unlikely to use explicit rules for assigning attributes to objects and objects to categories, then it might be more difficult for them to learn how to classify objects by applying rule systems. Work by Norenzayan et al. (2000) suggests this is the case. Adopting a paradigm of Allen and Brooks (1991), they presented East Asians, Asian Americans, and European Americans with cartoon animals on a computer screen and told them that some of the animals were from Venus and some were from Saturn. Participants in an exemplar-based categorization condition were asked simply to observe a series of animals and make guesses, with feedback, about the category to which each belonged. Other participants were assigned to a rule condition and went through a formal, rule-based category learning procedure. They were told to pay attention to five different properties of the animals – curly tail, knobby antennas, and so forth – and were told that if the animal had any three of these properties it was from Venus; otherwise, it was from Saturn.

Asian and American participants performed equally well at the exemplar-based categorization task with respect both to errors and to speed of response. But in the rule condition, East Asian participants’ response times were slower than those of Americans. Most tellingly, when the test trial in the rule condition presented an animal that met the formal rule criteria for a given category but more closely resembled an animal in the other category – thus placing rule-based and memory-based categorizations in conflict – Asians made more errors of classification

than did Americans. (They did not make more errors when the test animal more closely resembled an instance of the category of which it was also a member in terms of the formal rule, and thus either a rule-based decision or an exemplar-based decision would yield the right answer.) Asian Americans' performance was almost identical to that of European Americans for both speed and accuracy.

Thus the results of several studies indicate that East Asians rely less on rules and categories and more on relationships and similarities in organizing their worlds than do Americans. East Asians preferred to group objects on the basis of relationships and similarity, whereas Americans were more likely to group objects on the basis of categories and rules. Americans were more likely to rely spontaneously on categories for purposes of inductive reasoning than were East Asians and found it easier to learn and use rule-based categories.

Formal Logic Versus Experiential Knowledge

There is a long Western tradition – from the ancient Greeks, to the medieval Scholastics, to the propositional logic theoreticians of the late 19th and early 20th centuries – of analyzing argument structure apart from content and of reasoning on the basis of the underlying abstract propositions alone. Such a tradition has never been common in the East, where instead there has been an explicit disapproval of such decontextualizing practices and an emphasis on the appropriateness of plausibility and sense experience in evaluating propositions. Several studies suggest that East Asians do indeed rely less on formal logic and more on experiential knowledge in reasoning than do Americans – at any rate when logic and experience are in conflict.

TYPICALITY VERSUS LOGIC

Consider the following two deductive arguments. Is one more convincing than the other?

1. All birds have ulnar arteries.
Therefore, all eagles have ulnar arteries.
2. All birds have ulnar arteries.
Therefore, all penguins have ulnar arteries.

One way to measure the extent to which people spontaneously rely on formal logic versus experiential knowledge in reasoning is to exam-

ine how they project properties (the “blank” property “ulnar arteries” in the above example) from superordinate categories (birds) to subordinate categories (eagles, penguins). Notice that the two arguments have identical premises, but their conclusions vary in the typicality of the exemplar. (Eagles are more typical birds than penguins.) Reasoners who apply logic would “see” the implicit middle premises of each argument (“All eagles are birds,” and “all penguins are birds”). Such reasoners would find both deductive valid arguments equally convincing. But people often find typical arguments to be more convincing than atypical ones (Sloman, 1993).

Norenzayan and colleagues (2000) asked Korean, Asian American, and European American participants to evaluate the convincingness of a series of such arguments. The responses of participants who received only typical arguments were compared with those who received only atypical arguments. As expected, Koreans showed a large typicality effect, being more convinced by typical than by atypical arguments. European Americans, in contrast, were equally convinced by typical and atypical arguments. Asian Americans' responses were in between those of European Americans and Koreans. (When an experimental manipulation was introduced that increased the salience of the typicality information, all three groups showed the typicality effect to the same extent.)

KNOWLEDGE VERSUS LOGIC

In another study, Norenzayan and colleagues (2000) presented participants with syllogisms that were either valid or invalid and that had conclusions that were either plausible or implausible. In addition, some arguments were presented in abstract form with no content. Korean and American university students were instructed to evaluate the logical validity of each argument and decide whether the conclusion followed from the premises. Results showed that, overall, there was an effect of logic as well as of knowledge, consistent with past research. Thus, participants correctly judged valid arguments to be more valid than invalid ones, and incorrectly judged arguments with plausible conclusions to be more valid than arguments with implausible conclusions. As predicted, Korean participants showed a stronger “belief bias” for valid arguments than did American students, being more inclined to judge valid arguments as invalid if they had implausible conclusions. Importantly,

this difference cannot be attributed to cultural differences in the ability to reason logically, since both cultural groups showed equal performance on the abstract items. Rather, the results indicate that when logical structure conflicts with everyday belief, American students are more willing to set aside empirical belief in favor of logic than are Korean students.

Dialectics Versus the Law of Noncontradiction

Peng and Nisbett (Peng, 1997; Peng & Nisbett, 1999) have maintained that East Asians do not have the same commitment to avoiding the appearance of contradiction as do Westerners. Examples of rules about contradiction that have played a central role in the Western intellectual tradition include the following:

1. *The law of identity:* $A = A$. A thing is identical to itself.
2. *The law of noncontradiction:* $A \neq \text{not-}A$. No statement can be both true and false.
3. *The law of the excluded middle:* Any statement is either true or false.

Following the proposals of many philosophers of both the East and the West (e.g., Liu, 1974; Needham, 1962, 1978; Zhang & Chen, 1991), Peng and Nisbett argued that there is a tradition in Eastern philosophy that is opposed at its roots to the formal logic tradition, namely the dialectical approach. So-called "naive dialecticism" resembles the dialectic of Hegel and Marx inasmuch as it sometimes involves the creation of a synthesis from a thesis and antithesis. But more commonly it involves transcending, accepting, or even insisting on the contradiction among premises (Huff, 1993; Liu, 1974; Lloyd, 1990; Needham, 1962; Zhang & Chen, 1991; Zhou, 1990). Peng and Nisbett (1999) characterized dialecticism in terms of three principles.

1. *The principle of change:* Reality is a process that is not static but rather is dynamic and changeable. A thing need not be identical to itself at all because of the fluid nature of reality.
2. *The principle of contradiction:* Partly because change is constant, contradiction is constant. Thus old and new, good and bad, exist in the same object or event and indeed depend on one another for their existence.

3. *The principle of relationship or holism:* Because of constant change and contradiction, nothing either in human life or in nature is isolated and independent, but instead everything is related. It follows that attempting to isolate elements of some larger whole can only be misleading.

These principles are, of course, not altogether alien to Western epistemology of either the naive or the professional sort. Indeed, Western developmental psychologists (Baltes & Staudinger, 1993; Basseches, 1980, 1984; Riegel, 1973) have argued that such "post-formal" principles are learned in late adolescence and early adulthood to one degree or another by Westerners and that "wisdom" consists in part of being able to supplement the use of formal operations with a more holistic, dialectical approach to problems. But evidence we now present indicates that Western reliance on dialectical principles is weaker than that of Easterners, and Western reliance on the foundational principles of formal logic, especially the principle of noncontradiction, is stronger.

DIALECTICAL RESOLUTION OF SOCIAL CONTRADICTIONS

Peng and Nisbett (Peng, 1997; Peng & Nisbett, 1999) presented Chinese and American students with contradictions drawn from everyday life. For example, they were asked to analyze a conflict between mothers and their daughters and between having fun and going to school. American responses tended to come down in favor of one side or the other ("mothers should respect daughters' independence"). Chinese responses were more likely to find a "Middle Way," which found merit and fault on both sides and attempted to reconcile the contradiction ("both the mothers and the daughters have failed to understand each other").

DIALECTICISM AND PREFERRED ARGUMENT FORM

Peng and Nisbett (Peng, 1997; Peng & Nisbett, 1999) gave Chinese and American participants, all of whom were graduate students in the natural sciences, two different types of arguments for each of two different propositions and asked them to indicate which argument they preferred. In each case, one of the arguments was a logical one involving contradiction and one was a dialectical one. Thus, in one problem, two arguments for the existence of God

were pitted against one another. One was a variant of the so-called “cosmological” or “first cause” argument. It holds that because everything must have a cause, this creates an infinite regression of cause and effect unless there is a primary cause by an infinite being. The dialectical argument applied the principle of holism, stating that when two people see the same object, such as a cup, from different perspectives, one person sees some aspects of the cup, and the other sees other aspects. But there must be a God above all individual perspectives who sees the truth about the object. Americans preferred the argument based on noncontradiction in each case, and Chinese preferred the dialectic one.

JUDGMENTS ABOUT CONTRADICTORY PROPOSITIONS

One of the strongest implications of the notion that Westerners adhere to a logical analysis of problems is that, when presented with apparently contradictory propositions, they should be inclined to reject one in favor of the other. Easterners, on the other hand, committed to the principle of the Middle Way, might be inclined to embrace both propositions, finding them each to have merit. In one study, Peng and Nisbett (1999) presented participants with either one proposition or two propositions that were, if not outright contradictions, at least very different and on the surface unlikely to both be true. The propositions were presented in the form of social science studies. For example, one proposition was: “A survey found that older inmates are more likely to be ones who are serving long sentences because they have committed severely violent crimes. The authors concluded that they should be held in prison even in the case of a prison population crisis.” Its counterpart was: “A report on the prison overcrowding issue suggests that older inmates are less likely to commit new crimes. Therefore, if there is a prison population crisis, they should be released first.”

Participants read about one of these studies (A or B) or both (A and B) and rated their plausibility. In the case of all five issues presented, Chinese and American participants agreed on which of the two was the more plausible. In the A and B condition, Americans judged the plausibility of the more plausible proposition as greater than did Americans who read only the more plausible assertion by itself. Thus Americans actually found a contradicted assertion to be more plausible than the same proposition when not contradicted, a normatively dubious

tendency that indicates that they felt substantial pressure to resolve the contradiction by butressing their prior beliefs. (This finding is reminiscent of one by Lord, Ross, & Lepper [1979], who found that when people read about two different studies, one supporting their view on capital punishment and one opposing it, they were more convinced of their initial position than if they had not read about any studies.) In contrast, Chinese participants in the A and B condition resolved the contradiction between the two propositions by finding them to be equally plausible, as if they felt obligated to find merit in both the conflicting propositions. They actually found the less plausible proposition to have more merit when it had been contradicted than when it had not – also a normatively dubious inference but utterly different in kind from that of the Americans.

PERSUASION BY STRONG VERSUS WEAK ARGUMENTS

If Westerners respond to apparent contradiction by trying to decide which side is correct, but Easterners respond by yielding points to both sides, then the two groups might respond differently to arguments against an initially held position. Westerners might increase their confidence in their initial position when presented with a weak argument, whereas Easterners might decrease their confidence. This is what was found by Davis and her colleagues (Davis, 2000; Davis, Nisbett, & Schwarz, 2000). They presented groups of Korean, Asian American, and European American participants with a set of strong arguments in favor of funding a particular scientific project. They presented another group with the same set of strong “pro” arguments and an additional set of weak arguments against funding the project. Korean and American participants were equally in favor of funding the project when presented with just the strong “pro” arguments, but the two groups behaved in qualitatively different ways when presented additionally with weak “anti” arguments. Koreans were more unfavorable when weak “anti” arguments were added. But Americans were actually more favorable toward funding the project when presented with the additional weak “anti” arguments than when presented with no “anti” arguments – behavior that is normatively quite suspect.

JUSTIFICATION OF CHOICE

The Western preference for principle-guided decisions and the Eastern preference for the

"Middle Way" appears to apply also for actual choice behavior. Briley, Morris, and Simonson (2000) studied the consumer choices of East Asians and European Americans. All choices were among a triad of objects that differed on two dimensions. Object A was superior to both Object B and C on one dimension, and Object C was superior to both Object A and B on the other dimension. Object B was always intermediate between A and C on both dimensions. On average, across the range of choices, Americans and East Asians in a control condition were about equally likely to choose intermediate Object B. In an experimental condition, Briley et al. had participants give reasons for their choice. They anticipated that this would prompt Americans to look for a simple rule that would justify a given choice (e.g., "RAM is more important than hard drive space") but would prompt people of Asian culture to seek a compromise ("both RAM and hard drive space are important"). This is what was found. Americans in the justification condition moved to a preference for one of the extreme objects whose choice could be justified with reference to a simple rule, whereas Asian culture participants moved to a preference for the compromise object. Justifications given by participants were consistent with their choices, with Americans being more likely to give rule-based justifications and Chinese being more likely to give compromise-based justifications.

Thus, there is substantial evidence to indicate that Easterners are not concerned with contradiction in the same way as are Westerners. They have a greater preference for compromise solutions and holistic arguments; they are more willing to endorse apparently contradictory arguments; and they are more willing to move their beliefs in the direction of an argument, even when it is a weak one. Finally, when asked to justify their choices, they seem to move to a compromise, "Middle Way," instead of referring to a dominating principle. It should be noted that the greater adherence to the principle of noncontradiction on the part of Americans seems to produce no guarantee against normatively questionable inferences. On the contrary, their adherence to the principle of noncontradiction may sometimes cause them to become more extreme in their judgments under conditions in which the evidence indicates they should become less extreme. This tendency mirrors complaints about hyperlogical Western habits of mind often expressed by philosophers and social critics (Korzybski, 1933/1994;

Lin, 1936; Liu, 1974; Nagashima, 1973; Saul, 1992).

Creating and Sustaining Systems of Thought

What produced the differences in ancient times? What sustains them today? These are matters of speculation, of course, so we will confine our response to brief considerations, especially for the first, historical question.

The Origin of Sociocognitive Systems

The explanation for the cognitive differences that we prefer is a distally materialistic but proximally social one that we have put together from the arguments of scholars in a large number of disciplines (Barry, Child, & Bacon, 1959; Berry, 1976; Cromer, 1993; Nakamura, 1964/1985; Needham, 1954; Whiting & Child, 1953; Whiting & Whiting, 1975; Witkin & Berry, 1975).

Chinese civilization was based on agriculture, which entailed that substantial cooperation with neighbors was necessary to carry out economic activities in an effective way. This is especially true of the rice agriculture common in the south of China. China was organized at the level of the large state very early on, and society was complex and hierarchical: The king and later the Emperor and the bureaucracy were ever-present controlling factors in the lives of individual Chinese. Harmony and social order were thus central to Chinese society. Social scientists since Marx have observed that economic and social arrangements such as these are generally associated with "collectivist" or "interdependent" social orientations as distinguished from "individualistic" or "independent" social orientations that are characteristic of societies with economies based on hunting, fishing, trading, or the modern market economy.

In marked contrast to all the other great civilizations of the ancient world, the Greek economy was not completely dependent on agriculture. The Greek ecology conspired against an agrarian base, consisting as it does mostly of mountains descending to the sea. This sort of ecology was more suited to herding and fishing than to large-scale agriculture. The sense of personal agency that characterized the Greeks could have been the natural response to the genuine freedom that they experienced in their less socially complex society.

The politically decentralized Greek cities also provided great scope of action as compared to

Chinese cities. Greeks who wished to leave one city for another were free to do so: The sea provided an escape route for dissidents. In addition, Greeks were involved in trade at one of the crossroads of the world. Thus they would have had plenty to pique their curiosity and much to discuss. The nature of social relations meant that debate would have posed few interpersonal risks, and the authority structure of the city state was too weak to prevent the free expression of opinion. Indeed for Athens and other city states debate was an integral part of the political system.

Speculative as it is, this view has the virtue that it at least is consistent with the economic changes that preceded the Renaissance, namely, the reduced reliance on agriculture and the rise of relatively independent city-states with economies based on crafts and trade. During the Renaissance, the West recapitulated some of the Greek social forms and intellectual traditions, including the rediscovery of science. The invention of the printing press greatly enhanced the conditions of freedom of thought. Ironically, though the Chinese invented movable type before the Europeans did, it was suppressed in China, on the quite correct grounds that the authority of the government would be undermined by it.

Some research by Witkin and his colleagues gives credence to the notion that stronger social networks might produce a more holistic orientation to the world. Berry and Witkin (Berry, 1967, 1976; Witkin & Berry, 1975) showed that farmers in a number of societies are more field dependent than hunters, herders, or industrialized peoples. Witkin and his colleagues (Adevai, Silverman, & McGough, 1970; Dershowitz, 1971; Meizlik, 1973) found that Orthodox Jewish boys, whose families and communities require strict observance of a variety of social rules, were more field dependent than were secular Jewish boys, who in turn were more field dependent than Protestant boys. These differences held even when general intelligence was controlled for. Moreover, individual differences in social orientation within a culture apparently are associated with field dependence. Americans who are more interested in social activities and in dealing with other people are more field dependent (even when intelligence is controlled) than are people with less social interest (Witkin & Goodenough, 1977; Witkin, Price-Williams, et al., 1974).

Finally, Kühnen, Hannover, and Schubert (2000) were able to prime field dependence

on the Embedded Figures Test by a variety of techniques intended to make participants temporarily more collectivist in their orientations. For example, they asked participants to think about what they had in common with family and friends (vs. asking them to think about how they differed from family and friends). The results confirmed that a collectivist prime led to more field dependence.

Sociocognitive Systems in Homeostasis

Mere inertia would not result in contemporary differences in the way people think. We propose that systems of thought exist in homeostasis with the social practices that surround them. We will describe a number of ways in which the social practices and cognitive processes could support or “prime” one another (Y.-y. Hong, Morris, Chiu, & Benet-Martinez, 2000).

HOLISTIC VERSUS ANALYTIC PRACTICES

1. The practice of fêng shui for choosing building sites (even Hong Kong skyscrapers) may encourage the idea that the factors affecting outcomes are extraordinarily complex and interactive, which in turn encourages the search for relationships in the field. This may be contrasted with more atomistic and rule-based approaches to problem-solving characteristic of the West. Consider, for example, the nature of approaches to self-help in the West: “The Three Steps to a Comfortable Retirement” or “Six Ways to Increase Your Word Power.”
2. Employees in the top one third of the Japanese economy are rotated among their company’s divisions frequently, to be able to see the company’s operations from as many viewpoints as possible. A graduate of a top university would be expected to work in the factory for the first year or two of employment and might actually represent union employees to the company (Hampden-Turner & Trompenaars, 1993).
3. The West, beginning in the 18th century and continuing at an increasingly rapid pace into the 20th century, introduced “modularity” – that is, uniform, atomistic, and interchangeable design and production (Shore, 1996). From the introduction of piece good manufacture in English cottages to Henry Ford’s production line

to the chain restaurant, the West – and America in particular – remain the chief innovators and consumers of modular production and products.

4. The most popular game of intellectuals in the East is Go and the most popular in the West is chess. Xia (1997) and Campbell (1983) have pointed out that Go is more complex and holistic than chess, the analytic game par excellence. Go boards have 19×19 spaces whereas chess boards have 8×8 spaces. Go pieces have more variation in possible moves than do chess pieces, which must adhere to a fixed set of rules for movement. Hence, moves in Go are more difficult to predict. The appropriate strategy for Go has been termed dialectic in that the “competition between the black and white is a well calculated trade-off. . . . It is not wise to be greedy and overplay” (Xia, 1997).

ARGUMENT, DEBATE, AND RHETORIC

1. In daily life, East Asians strive to maintain harmony. Ohbuchi and Takahasi (1994) asked Japanese and American businesspeople how they dealt with conflict with their fellow managers. Twice as many Japanese as American respondents reported using avoidance as a means of dealing with a conflict of views, and three times as many Americans as Japanese reported attempting to use persuasion.
2. Decision processes in boardrooms and executive councils in Japan are designed to avoid conflicts. Meetings often consist of nothing more than the ratification of consensus among members obtained by the leader prior to the meeting.
3. Western educators often complain that their Asian students do not participate in class discussions and that they do not follow the requirements of rhetoric in their writings – for example, statement of principles and assumptions, derivations, hypotheses, evidence, argumentation, conclusion. Neither their culture nor their prior educational experience has prepared them for the canonical rhetoric forms that are taken for granted in the West. (See Tweed & Lehman, 2000, for a review.)
4. Galtung (1981) has described the intellectual styles of academics from differ-

ent cultures. The Anglo-American style “fosters and encourages debate and discourse . . . and pluralism is an overriding value” (pp. 823–824). In contrast, for the Japanese, “*the first rule would be not to harm pre-established social relations*” (p. 825).

LAW AND CONTRACTS

1. Although the ancient Chinese had a complex legal system, it was in general not codified in the way it was in the West (Logan, 1986). Today, courts of law are relatively rare in the East, and there is a marked preference for solving conflicts on the basis of the particulars of a specific case and by negotiation through a middleman (Leung & Morris, 2001).
2. Easterners and Westerners have fundamentally different understandings of the nature of contracts. In the West, a contract is unalterable; in the East, a contract is continually renegotiable in the light of changed circumstances (Hampden-Turner & Trompenaars, 1993). This drastic difference of view has often resulted in conflict and bitterness between Eastern and Western negotiators.

RELIGION

1. Some scholars have contended that Christianity has far stronger theological concerns than other religions have, finding it “necessary to formulate elaborately precise statements about the abstract qualities and relations of gods and humans” (Dyson, 1998, p. 8).
2. Religions in East Asia have long been characterized by their interpenetrating and blending qualities. Societies and individuals readily incorporate aspects of several different religions into their worldviews. In contrast, for Christians, there is a strong tendency toward insistence on doctrinal purity. This sometimes results in religious wars in the West, a rarity in East Asia.

LANGUAGE AND WRITING

Perhaps the most pervasive and important of all practices that operate to sustain the cognitive differences are those having to do with language and writing. Indeed, some scholars, notably Logan (1986), have tried to make the case that most of the cognitive differences we have discussed are due primarily to differences in language and writing systems.

1. The basic writing system of Chinese and other East Asian languages has been essentially pictographic. It can be maintained that the Western alphabet is more atomistic and analytic by nature and "is a natural tool for classifying and served as a paradigm for codified law, scientific classification, and standardized weights and measures" (Logan, p. 55).
2. The actual grammar of Indo-European languages encourages thinking of the world as being composed of atomistic building blocks, whereas East Asian languages encourage thinking of the world as continuous and interpenetrating. "[R]ather than one-many, the Chinese language motivates a part-whole dichotomy" (Hansen, 1983, p. vii).
3. East Asian languages are highly contextual in every sense. Because of their multiple meanings, words must be understood in the context of sentences. Because of the minimal nature of syntax in Sinitic languages, context is important to understanding sentences (Freeman & Habermann, 1996). In contrast, Heath (1982) has shown that language socialization for middle-class American children quite deliberately decontextualizes language. Parents try to make words understandable independent of verbal context and utterances understandable independent of situational context.
4. Although Western toddlers learn nouns (i.e., words referring to objects) at a much more rapid rate than they learn verbs (i.e., words referring to relationships), the reverse appears to be true for Chinese (Tardif, 1996) and Koreans (S. Choi & Gopnik, 1995). Moreover, Western toddlers hear more noun phrases from their mothers, whereas East Asian children hear more verbs (Fernald & Morikawa, 1993; Tardif, Shatz, & Naigles, 1997).
5. "Generic" noun phrases – that is, those referring to categories and kinds (e.g., "birds," "tools," as opposed to exemplars such as "sparrow," "hammer") – are more common for English speakers than for Chinese speakers (Gelman & Tardif, 1998), perhaps because Western languages mark in a more explicit way whether a generic interpretation of an utterance is the correct one (Lucy, 1992).
6. Consistent with the above findings about category usage, Ji and Nisbett (Ji, 2001; Ji & Nisbett, 2001) found that English-speaking Chinese used relationships more and categories less when they grouped words in Chinese than when they did so in English.

Thus there are some good reasons to believe that social practices and cognitive ones maintain each other in a state of equilibrium. Cognitive practices may be highly stable because of their embeddedness in larger systems of beliefs and social practices.

Implications for Psychology

Magnitude of Effects

The cognitive differences we have discussed vary in size, but it is important to note that many of them are unusually large, whether the standard is the magnitude of mean or proportion differences (often on the order of 2:1, 3:1, or higher) or effect size (often well in excess of 1.00).

But, in fact, most of the differences we have reported are not merely large. The East Asians and the Americans responded in qualitatively different ways to the same stimulus situation in study after study. For example, American participants showed large primacy effects in judgments about covariation, whereas Chinese participants showed none. "Control" tended to increase the degree of covariation seen and the self-reported accuracy of Americans but tended to have the opposite effect on Chinese, and "control" increased the accuracy and confidence of American participants for the Rod and Frame test but had no effect for Chinese participants (Ji et al., 2000). Similarly, Cha and Nam (1985) and Norenzayan, Choi, and Nisbett (2001) found that Koreans were greatly influenced in their causal attributions by the sort of situational information that has no effect for Americans. I. Choi and Nisbett (2000) found that Koreans showed large hindsight bias effects under conditions where Americans showed none. Peng and Nisbett (1999) found that Americans responded to contradiction by polarizing their beliefs, whereas Chinese responded by moderating their beliefs. Qualitative differences, with Americans responding in one way and East Asians in another, were found in other studies by Briley et al. (2000), I. Choi and Nisbett (1998), Davis et al. (2000), Norenzayan et al. (2000), and Peng and Nisbett

(1999). These qualitative differences indicate that literally different cognitive processes are often invoked by East Asians and Westerners dealing with the same problem.

Universality

The assumption of universality of cognitive processes lies deep in the psychological tradition. We believe that the results discussed here force consideration of the possibility that an indefinitely large number of presumably "basic" cognitive processes may be highly malleable. When psychologists perform experiments on "categorization," "inductive inference," "logical reasoning," or "attributional processes," it does not normally occur to them that their data may apply only rather locally, to people raised in a tradition of European culture. They are, of course, prepared for parameter differences, but parameter differences between populations on the order of 3:1 or more provide an occasion for wondering about universality. It is no exaggeration to state that qualitative differences between populations preempt any claim to universality – unless there is reason to believe that experimental procedures are not comparable across groups.

Just how great the cultural differences can be is unclear at this point, of course. Moreover, although we have looked at tasks that measure important perceptual and cognitive variables, we have no way of knowing what population these variables were selected from. It is possible that the particular variables we have examined exhibit cultural differences that are substantially greater than the differences that might be found in other tasks that are equally good measures of the conceptual variables. But it is equally – if not more – probable that investigators have not been uncannily insightful at this early stage of research and that there are variables and measures that would show even larger differences than the ones we have examined. Moreover, the participant populations, consisting mostly of college students, would be expected to be more similar to one another than to more representative members of their parent populations.

Fixedness of Cognitive Content

It is ironic that, just as our evidence indicates that some cognitive processes are highly susceptible to cultural influence, other investigators are providing evidence that some cognitive content may not be very susceptible to cultural influence. Naive theories of mechanics

and physics (Baillargeon, 1995; Carey & Spelke, 1994; Leslie, 1982; Spelke, 1988, 1990), naive theories of biology (Atran, 1990, 1995; Berlin, 1992; Berlin, Breedlove, & Raven, 1973; Gelman, 1988) and naive theory of mind (Asch, 1952; D'Andrade, 1987; Leslie, 1994; Wellman, 1990) appear so early and are apparently so widespread that it seems quite likely that at least some aspects of them are largely innate and resistant to social modification. Theories of causality – both highly general ones having to do with temporal sequence and spatial contiguity (Seligman, 1970), as well as highly specific ones, such as the link that all omnivorous mammals are likely to make between distinctive-tasting food and gastrointestinal illness experienced many hours later (Garcia, McGowan, Ervin, & Koelling, 1968) – are clearly a part of the organism's biologically given cognitive equipment. Hirschfeld (1996) has argued that "essentialist" beliefs about the nature of the social world are universal, and Sperber (1985) and Boyer (1993) have argued that even religious conceptions such as spirits and superhuman agents are remarkably similar from one culture to another. As Sperber (1996) has written, the human mind is equipped with a set of cognitive properties that make it easier or harder to think certain kinds of thoughts.

Thus, it appears that the assumption that cognitive content is learned and indefinitely malleable and the assumption that cognitive processes are universally the same and biologically fixed may both be quite wrong. Some important content may be universal and part of our biologically given equipment, and some important processes may be highly alterable. The continued existence on the planet of widely different social and intellectual traditions offers an opportunity to learn a great deal more about the fixedness and malleability of both content and process.

The Inseparability of Process and Content

Our theoretical position is at the same time less radical and more radical than the assertion that basic processes differ across cultures. We are urging the view that metaphysics, epistemology, and cognitive processes exist in mutually dependent and reinforcing systems of thought, such that a given stimulus situation often triggers quite different processes in one culture than in another. Thus it is not possible to make a sharp distinction between cognitive process and cognitive content. Content in the form of metaphysical beliefs about the nature of the world determines tacit

epistemology. Tacit epistemology in turn dictates the cognitive procedures that people use for solving particular problems.

People who believe that knowledge about objects is normally both necessary and sufficient for understanding their behavior will believe it is important to find the appropriate categories that apply to the object and the appropriate rules that apply to the categories. The search for categories and rules will dictate particular ways of organizing knowledge as well as procedures for obtaining new knowledge about rules. Such practices in turn are aided by a reliance on formal logic, especially including attention to the specter of contradiction that undermines beliefs about the validity of rules. Abstractions will be a goal because categories and rules will seem to be useful just to the extent that they have wide applicability and because it can be easier to apply formal logic to abstractions than to concrete objects.

Similar points can be made about people who believe that causality is a complex function of multiple factors operating on an object in a field. Complexity indicates dynamism and constant change. A belief in change and instability will tend to make the habits of categorization and of search for universal rules about objects seem dubiously relevant. Rather, an attempt to see the interrelatedness of events will seem important. Contradiction will seem inevitable, since change is constant, and opposing factors always coexist. A concern with concrete objects and events will seem to be more useful than will a search for abstractions. Logic will not be allowed to over-ride sensory experience or common sense.

Thus, without saying that Easterners are unable to make use of categorization or that Westerners are unable to detect covariation, we can see that the differences between cultures can still be very great: (a) The circumstances that prompt the use of one process versus another will differ substantially across cultures; (b) the frequencies with which the very most basic cognitive processes are used will differ greatly; (c) consequently, the degree and nature of expertise in the use of particular cognitive processes will differ; and (d) tacit or even explicit normative standards for thought will differ across cultures (Stich, 1990).

Claude Lévi-Strauss, the great French anthropologist, proposed that, in their attempts to solve the problems of daily life, people might be regarded as bricoleurs – handymen with their bags of cognitive tools. Pursuing this metaphor,

we may say that even if all cultures possessed essentially the same basic cognitive processes as their tools, the tools of choice for the same problem may habitually be very different. People may differ markedly in their beliefs about whether a problem is one requiring use of a wrench or pliers, in their skill in using the two types of tools, and in the location of particular tools at the top or the bottom of the tool kit. Moreover, members of different cultures may not see the same stimulus situation as a problem in need of repair. A seeming contradiction is a problem for Westerners but may not be for Easterners. Indeed, as some of the perceptual work we have reviewed indicates, the different focus of attention of Easterners and Westerners indicates that they may sometimes not be seeing the same stimulus situation at all – even when their heads are immobilized at a fixed distance away from a computer screen.

Another way that cognitive processes can differ is that cultures may construct composite cognitive tools out of the basic universal toolkit, thereby performing acts of elaborate cognitive engineering, as Dennett's (1995) characterization of culture as a "crane-making crane" (p. 338) suggests. Modern statistical, methodological, and cost-benefit rules provide examples of such crane-produced cranes. Nothing like them existed prior to the 17th century, when they were constructed in the West on the basis of rule-based empirical observation, mathematics, and formal logic, and there is great variation among members of Western society today in the degree of understanding and use of these rules. Similar points may be made about the transformation of the ancient Chinese notions about yin and yang into more sophisticated dialectical notions about change, moderation, relativism, and the necessity of multiple viewpoints.

The psychological ideas that our position most closely resembles are those in the tradition of Vygotsky (1978, 1987; e.g., Cole, 1995; Cole & Scribner, 1974; Hutchins, 1995; Lave, 1988; Luria, 1931; Rogoff, 1990), which insists that thought always occurs in a pragmatic problem setting, including the cultural assumptions that are brought to the task. This view, recently referred to as the "situated cognition" view, has been defined by Resnick as the assumption that "the tools of thought . . . embody a culture's intellectual history. . . . Tools have theories built into them, and users accept these theories – albeit unknowingly – when they use these tools" (Resnick, 1994, pp. 476–477).

The particular cognitive orientations we have been discussing have endured for millennia. One of the questions that intrigues us most concerns what it might take to seriously disturb the homeostasis of one of these historically rooted systems of thought. It is not hard to introduce Westerners to cost-benefit rules; these rules can affect their reasoning and their behavior and leave them fully accepted members of their communities. It is far from clear that it would be so easy to introduce East Asians to that rule system, that it would leave members who adopted the rule system so fully accepted by their communities or that it would leave unscathed the sociocognitive homeostasis of their societies if the rule system were to be widely adopted. There seems to be one quite interesting case of resistance to change of a homeostatic system. The introduction of the highly individualistic economic element of capitalism into Japan 130 years ago appears to have had far less effect on either social practices or, as our research indicates, cognitive processes, than might have been anticipated.

It is clear from some of the work summarized in this article that Asians move radically in an American direction after a generation or less in the United States. But it might be a mistake to extrapolate from these facts and assume that it would be an easy matter to teach one culture's tools to individuals in another without total immersion in that culture. It is far from clear that, using normal pedagogical techniques, Americans could be given many of the advantages of a dialectical stance or that East Asians could be taught to experience surprise at outcomes when surprise is warranted.

We hope we have persuaded the reader that the cognitive processes triggered by a given situation may not be so universal as generally supposed, or so divorced from content, or so independent of the particular character of thought that distinguishes one human group from another. Two decades ago, Richard E. Nisbett wrote a book with Lee Ross entitled, modestly, *Human Inference* (Nisbett & Ross, 1980). Roy D'Andrade, a distinguished cognitive anthropologist, read the book and told Richard Nisbett he thought it was a "good ethnography." The author was shocked and dismayed. But we now wholeheartedly agree with D'Andrade's contention about the limits of research conducted in a single culture. Psychologists who choose not to do cross-cultural psychology may have chosen to be ethnographers instead.

Notes

- 1 We use the philosopher's term *metaphysics* rather than *ontology*, which is a more common term for psychologists to use to describe theories about the nature of the world, because we wish to convey concerns with very general notions about the nature of causality and reality, as well as the relationships between substance and attribute, fact and value.
- 2 We use the term *epistemology* to refer to peoples' theory of knowledge, including what counts as knowledge, the degree to which different kinds of knowledge are certain, and the presumed relation between the knower and the object that is known. This definition is probably congenial to both psychologists and philosophers.
- 3 At any rate, the Chinese were not much interested in constructing rigorous classifications of a sort that could make possible scientific rule construction (Atran, 1995).
- 4 We do not wish to imply that Eastern and Western societies have been marked continuously by the sorts of differences found in ancient times. The West during the Middle Ages was similar economically and socially to ancient China in many ways, and one would never characterize the feudal period as being notably individualistic. In contrast, in various periods in China, especially during the late 2nd century to the early 4th century A.D., there were substantial strains of individualism (Yu, 1985). It was probably not until the late Medieval Period that the West began to return to levels of individualism characteristic of ancient Greece. Since that time, however, the West has continued on an ever more individualist trajectory while the East in general has not. It is also important to note that there are marked differences even today within both the societies that we are labeling collectivist and those that we are labeling individualist. While acknowledging these differences, we agree with the mainstream view of historians, ethnographers, sociologists, and cultural psychologists that there are nonetheless broad and deep differences between East and West with respect to the collectivist-individualist dimension.
- 5 Several studies compared the field dependence of East Asians and Westerners using Witkin's Embedded Figures Test (EFT), in which a small figure is shown to participants and they are then asked to find it in a larger, more complicated figure. Typically no difference is found or a slight difference is found favoring East Asians (Bagley, 1995; Huang & Chao, 1995). As Bagley has pointed out, however, this result is ambiguous, because the figures used in the test resemble the characters in Chinese and other East Asian writing systems. To examine if, indeed, writing systems might be responsible for the

lesser field dependence of East Asians examined using the EFT, Kühnen, Hannover, Röder, et al. (2000) compared various Western populations with Malaysians – a highly collectivist East Asian population that, however, has a Latin writing system – and found the Malaysians substantially more field dependent than any of the other three groups.

- 6 When shown only one hypothesis, Koreans and Americans regarded the “optimism” hypothesis as equally likely and the two groups also regarded the “realism” hypothesis as equally likely. Neither Americans nor Koreans expressed much surprise when the more plausible hypothesis replaced the less plausible one.

Chapter 49: On the Very Idea of a Conceptual Scheme

DONALD DAVIDSON

Philosophers of many persuasions are prone to talk of conceptual schemes. Conceptual schemes, we are told, are ways of organizing experience; they are systems of categories that give form to the data of sensation; they are points of view from which individuals, cultures, or periods survey the passing scene. There may be no translating from one scheme to another, in which case the beliefs, desires, hopes and bits of knowledge that characterize one person have no true counterparts for the subscriber to another scheme. Reality itself is relative to a scheme: what counts as real in one system may not in another.

Even those thinkers who are certain there is only one conceptual scheme are in the sway of the scheme concept; even monotheists have religion. And when someone sets out to describe "our conceptual scheme," his homey task assumes, if we take him literally, that there might be rival systems.

Conceptual relativism is a heady and exotic doctrine, or would be if we could make good sense of it. The trouble is, as so often in philosophy, it is hard to improve intelligibility while retaining the excitement. At any rate that is what I shall argue.

We are encouraged to imagine we understand massive conceptual change or profound contrasts by legitimate examples of a familiar sort. Sometimes an idea, like that of simultaneity as defined in relativity theory, is so important that with its addition a whole department of science takes on a new look. Sometimes revisions in the list of sentences held true in a discipline are so central that we may feel that the terms involved have changed their meanings. Languages that have evolved in distant times or

places may differ extensively in their resources for dealing with one or another range of phenomena. What comes easily in one language may come hard in another, and this difference may echo significant dissimilarities in style and value.

But examples like these, impressive as they occasionally are, are not so extreme but that the changes and the contrasts can be explained and described using the equipment of a single language. Whorf, wanting to demonstrate that Hopi incorporates a metaphysics so alien to ours that Hopi and English cannot, as he puts it, "be calibrated," uses English to convey the contents of sample Hopi sentences.¹ Kuhn is brilliant at saying what things were like before the revolution using – what else? – our post-revolutionary idiom.² Quine gives us a feel for the "pre-individuative phase in the evolution of our conceptual scheme,"³ while Bergson tells us where we can go to get a view of a mountain undistorted by one or another provincial perspective.

The dominant metaphor of conceptual relativism, that of differing points of view, seems to betray an underlying paradox. Different points of view make sense, but only if there is a common coordinate system on which to plot them; yet the existence of a common system belies the claim of dramatic incomparability. What we need, it seems to me, is some idea of the considerations that set the limits to conceptual contrast. There are extreme suppositions that founder on paradox or contradiction; there are modest examples we have no trouble understanding. What determines where we cross from the merely strange or novel to the absurd?

We may accept the doctrine that associates having a language with having a conceptual

Reproduced with permission from Davidson, D. (1973–1974) On the very idea of a conceptual scheme. *Proceedings and addresses of the American Philosophical Association*, 47, 5–20.

scheme. The relation may be supposed to be this: if conceptual schemes differ, so do languages. But speakers of different languages may share a conceptual scheme provided there is a way of translating one language into the other. Studying the criteria of translation is therefore a way of focussing on criteria of identity for conceptual schemes. If conceptual schemes aren't associated with languages in this way, the original problem is needlessly doubled, for then we would have to imagine the mind, with its ordinary categories, operating with a language with *its* organizing structure. Under the circumstances we would certainly want to ask who is to be master.

Alternatively, there is the idea that *any* language distorts reality, which implies that it is only wordlessly if at all that the mind comes to grips with things as they really are. This is to conceive language as an inert (though necessarily distorting) medium independent of the human agencies that employ it; a view of language that surely cannot be maintained. Yet if the mind can grapple without distortion with the real, the mind itself must be without categories and concepts. This featureless self is familiar from theories in quite different parts of the philosophical landscape. There are, for example, theories that make freedom consist in decisions taken apart from all desires, habits and dispositions of the agent; and theories of knowledge that suggest that the mind can observe the totality of its own perceptions and ideas. In each case, the mind is divorced from the traits that constitute it; a familiar enough conclusion to certain lines of reasoning, as I said, but one that should always persuade us to reject the premisses.

We may identify conceptual schemes with languages, then, or better, allowing for the possibility that more than one language may express the same scheme, sets of intertranslatable languages. Languages we will not think of as separable from souls; speaking a language is not a trait a man can lose while retaining the power of thought. So there is no chance that someone can take up a vantage point for comparing conceptual schemes by temporarily shedding his own. Can we then say that two people have different conceptual schemes if they speak languages that fail of intertranslatability?

In what follows I consider two kinds of case that might be expected to arise: complete, and partial, failures of translatability. There would be complete failure if no significant range of sentences in one language could be translated into the other; there would be partial failure if some range could be translated and some range could

not (I shall neglect possible asymmetries.) My strategy will be to argue that we cannot make sense of total failure, and then to examine more briefly cases of partial failure.

First, then, the purported cases of complete failure. It is tempting to take a very short line indeed: nothing, it may be said, could count as evidence that some form of activity could not be interpreted in our language that was not at the same time evidence that that form of activity was not speech behavior. If this were right, we probably ought to hold that a form of activity that cannot be interpreted as language in our language is not speech behavior. Putting matters this way is unsatisfactory, however, for it comes to little more than making translatability into a familiar tongue a criterion of languagehood. As fiat, the thesis lacks the appeal of self-evidence; if it is a truth, as I think it is, it should emerge as the conclusion of an argument.

The credibility of the position is improved by reflection on the close relations between language and the attribution of attitudes such as belief, desire and intention. On the one hand, it is clear that speech requires a multitude of finely discriminated intentions and beliefs. A person who asserts that perseverance keeps honor bright must, for example, represent himself as believing that perseverance keeps honor bright, and he must intend to represent himself as believing it. On the other hand, it seems unlikely that we can intelligibly attribute attitudes as complex as these to a speaker unless we can translate his words into ours. There can be no doubt that the relation between being able to translate someone's language and being able to describe his attitudes is very close. Still, until we can say more about *what* this relation is, the case against untranslatable languages remains obscure.

It is sometimes thought that translatability into a familiar language, say English, cannot be a criterion of languagehood on the grounds that the relation of translatability is not transitive. The idea is that some language, say Saturnian, may be translatable into English, and some further language, like Plutonian, may be translatable into Saturnian, while Plutonian is not translatable into English. Enough translatable differences may add up to an untranslatable one. By imagining a sequence of languages, each close enough to the one before to be acceptably translated into it, we can imagine a language so different from English as to resist totally translation into it. Corresponding to this distant language would be a system of concepts altogether alien to us.

This exercise does not, I think, introduce any new element into the discussion. For we should have to ask how we recognized that what the Saturnian was doing was *translating* Plutonian (or anything else). The Saturnian speaker might tell us that that was what he was doing or rather, we might for a moment assume that that was what he was telling us. But then it would occur to us to wonder whether our translations of Saturnian were correct.

According to Kuhn, scientists operating in different scientific traditions (within different "paradigms") "live in different worlds."⁴ Strawson's *The Bounds of Sense* begins with the remark that "It is possible to imagine kinds of worlds very different from the world as we know it."⁵ Since there is at most one world, these pluralities are metaphorical or merely imagined. The metaphors are, however, not at all the same. Strawson invites us to imagine possible non-actual worlds, worlds that might be described, using our present language, by redistributing truth values over sentences in various systematic ways. The clarity of the contrasts between worlds in this case depends on supposing our scheme of concepts, our descriptive resources, to remain fixed. Kuhn, on the other hand, wants us to think of different observers of the same world who come to it with incommensurable systems of concepts. Strawson's many imagined worlds are seen (or heard) – anyway described – from the same point of view; Kuhn's one world is seen from different points of view. It is the second metaphor we want to work on.

The first metaphor requires a distinction within language of concept and content: using a fixed system of concepts (words with fixed meanings) we describe alternative universes. Some sentences will be true simply because of the concepts or meanings involved, others because of the way of the world. In describing possible worlds, we play with sentences of the second kind only.

The second metaphor suggests instead a dualism of quite a different sort, a dualism of total scheme (or language) and uninterpreted content. Adherence to the second dualism, while not inconsistent with adherence to the first, may be encouraged by attacks on the first. Here is how it may work.

To give up the analytic-synthetic distinction as basic to the understanding of language is to give up the idea that we can clearly distinguish between theory and language. Meaning, as we might loosely use the word, is contaminated by

theory, by what is held to be true. Feyerabend puts it this way:

Our argument against meaning invariance is simple and clear. It proceeds from the fact that usually some of the principles involved in the determinations of the meanings of older theories or points of view are inconsistent with the new . . . theories. It points out that it is natural to resolve this contradiction by eliminating the troublesome . . . older principles, and to replace them by principles, or theorems, of a new . . . theory. And it concludes by showing that such a procedure will also lead to the elimination of the old meanings.⁶

We may now seem to have a formula for generating distinct conceptual schemes. We get a new out of an old scheme when the speakers of a language come to accept as true an important range of sentences they previously took to be false (and, of course, vice versa). We must not describe this change simply as a matter of their coming to view old falsehoods as truths, for a truth is a proposition, and what they come to accept, in accepting a sentence as true, is not the same thing that they rejected when formerly they held the sentence to be false. A change has come over the meaning of the sentence because it now belongs to a new language.

This picture of how new (perhaps better) schemes result from new and better science is very much the picture philosophers of science, like Putnam and Feyerabend, and historians of science, like Kuhn, have painted for us. A related idea emerges in the suggestion of some other philosophers, that we could improve our conceptual lot if we were to tune our language to an improved science. Thus both Quine and Smart, in somewhat different ways, regretfully admit that our present ways of talking make a serious science of behavior impossible. (Wittgenstein and Ryle have said similar things without regret.) The cure, Quine and Smart think, is to change how we talk. Smart advocates (and predicts) the change in order to put us on the scientifically straight path of materialism; Quine is more concerned to clear the way for a purely extensional language. (Perhaps I should add that I think our *present* scheme and language are best understood as extensional and materialist.)

If we were to follow this advice, I do not myself think science or understanding would be advanced, though possibly morals would. But the present question is only whether, if such changes were to take place, we should be justified in calling them alterations in the basic

conceptual apparatus. The difficulty in so calling them is easy to appreciate. Suppose that in my office of Minister of Scientific Language I want the new man to stop using words that refer, say, to emotions, feelings, thoughts and intentions, and to talk instead of the physiological states and happenings that are assumed to be more or less identical with the mental ruff and raff. How do I tell whether my advice has been heeded if the new man speaks a new language? For all I know, the shiny new phrases, though stolen from the old language in which they refer to physiological stirrings, may in his mouth play the role of the messy old mental concepts.

The key phrase is: for all I know. What is clear is that retention of some or all of the old vocabulary in itself provides no basis for judging the new scheme to be the same as, or different from, the old. So what sounded at first like a thrilling discovery – that truth is relative to a conceptual scheme – has not so far been shown to be anything more than the pedestrian and familiar fact that the truth of a sentence is relative to (among other things) the language to which it belongs. Instead of living in different worlds, Kuhn's scientists may, like those who need Webster's dictionary, be only words apart.

Giving up the analytic-synthetic distinction has not proven a help in making sense of conceptual relativism. The analytic-synthetic distinction is however explained in terms of something that may serve to buttress conceptual relativism, namely the idea of empirical content. The dualism of the synthetic and the analytic is a dualism of sentences some of which are true (or false) both because of what they mean and because of their empirical content, while others are true (or false) by virtue of meaning alone, having no empirical content. If we give up the dualism, we abandon the conception of meaning that goes with it, but we do not have to abandon the idea of empirical content: we can hold, if we want, that *all* sentences have empirical content. Empirical content is in turn explained by reference to the facts, the world, experience, sensation, the totality of sensory stimuli, or something similar. Meanings gave us a way to talk about categories, the organizing structure of language, and so on; but it is possible, as we have seen, to give up meanings and analyticity while retaining the idea of language as embodying a conceptual scheme. Thus in place of the dualism of the analytic-synthetic we get the dualism of conceptual scheme and empirical content. The new dualism is the foundation of an empiricism shorn of the untenable dogmas of

the analytic-synthetic distinction and reductionism – shorn, that is, of the unworkable idea that we can uniquely allocate empirical content sentence by sentence.

I want to urge that this second dualism of scheme and content, of organizing system and something waiting to be organized, cannot be made intelligible and defensible. It is itself a dogma of empiricism, the third dogma. The third, and perhaps the last, for if we give it up it is not clear that there is anything distinctive left to call empiricism.

The scheme-content dualism has been formulated in many ways. Here are some examples. The first comes from Whorf, elaborating on a theme of Sapir's. Whorf says that:

...language produces an organization of experience. We are inclined to think of language simply as a technique of expression, and not to realize that language first of all is a classification and arrangement of the stream of sensory experience which results in a certain world-order. . . . In other words, language does in a cruder but also in a broader and more versatile way the same thing that science does. . . . We are thus introduced to a new principle of relativity, which holds that all observers are not led by the same physical evidence to the same picture of the universe, unless their linguistic backgrounds are similar, or can in some way be calibrated.⁷

Here we have all the required elements: language as the organizing force, not to be distinguished clearly from science; what is organized, referred to variously as "experience," "the stream of sensory experience," and "physical evidence"; and finally, the failure of intertranslatability ("calibration"). The failure of intertranslatability is a necessary condition for difference of conceptual schemes; the common relation to experience or the evidence is what is supposed to help us make sense of the claim that it is languages or schemes that are under consideration when translation fails. It is essential to this idea that there be something neutral and common that lies outside all schemes. This common something cannot, of course, be the *subject matter* of contrasting languages, or translation would be possible. Thus Kuhn has recently written:

Philosophers have now abandoned hope of finding a pure sense-datum language. . . . but many of them continue to assume that theories can be compared by recourse to a

basic vocabulary consisting entirely of words which are attached to nature in ways that are unproblematic and, to the extent necessary independent of theory... Feyerabend and I have argued at length that no such vocabulary is available. In the transition from one theory to the next words change their meanings or conditions of applicability in subtle ways. Though most of the same signs are used before and after a revolution – e.g. force, mass, element, compound, cell – the ways in which some of them attach to nature has somehow changed. Successive theories are thus, we say, incommensurable.⁸

“Incommensurable” is, of course, Kuhn and Feyerabend’s word for “not intertranslatable.” The neutral content waiting to be organized is supplied by nature.

Feyerabend himself suggests that we may compare contrasting schemes by “choosing a point of view outside the system or the language.” He hopes we can do this because “there is still human experience as an actually existing process”⁹ independent of all schemes.

The same, or similar, thoughts are expressed by Quine in many passages: “The totality of our so-called knowledge or beliefs... is a man-made fabric which impinges on experience only along the edges...”;¹⁰ “... total science is like a field of force whose boundary conditions are experience”;¹¹ “As an empiricist I... think of the conceptual scheme of science as a tool... for predicting future experience in the light of past experience.”¹² And again:

We persist in breaking reality down somehow into a multiplicity of identifiable and discriminable objects... We talk so inveterately of objects that to say we do so seems almost to say nothing at all; for how else is there to talk? It is hard to say how else there is to talk, not because our objectifying pattern is an invariably trait of human nature, but because we are bound to adapt any alien pattern to our own in the very process of understanding or translating the alien sentences.¹³

The test of difference remains failure or difficulty of translation: “... to speak of that remote medium as radically different from ours is to say no more than that the translations do not come smoothly.”¹⁴ Yet the roughness may be so great that the alien has an “as yet unimagined pattern beyond individuation.”¹⁵

The idea is then that something is a language, and associated with a conceptual scheme,

whether we can translate it or not, if it stands in a certain relation (predicting, organizing, facing or fitting) to experience (nature, reality, sensory promptings). The problem is to say what the relation is, and to be clearer about the entities related.

The images and metaphors fall into two main groups: conceptual schemes (languages) either *organize* something, or they *fit* it (as in “he warps his scientific heritage to fit his... sensory promptings”¹⁶ The first group contains also *systematize*, *divide up* (the stream of experience); further examples of the second group are *predict*, *account for*, *face* (the tribunal of experience). As for the entities that get organized, or which the scheme must fit, I think again we may detect two main ideas; either it is reality (the universe, the world, nature), or it is experience (the passing show, surface irritations, sensory promptings, sense data, the given).

We cannot attach a clear meaning to the notion of organizing a single object (the world, nature etc.) unless that object is understood to contain or consist in other objects. Someone who sets out to organize a closet arranges the things in it. If you are told not to organize the shoes and shirts, but the closet itself, you would be bewildered. How would you organize the Pacific Ocean? Straighten out its shores, perhaps, or relocate its islands, or destroy its fish.

A language may contain simple predicates whose extensions are matched by no simple predicates, or even by any predicates at all, in some other language. What enables us to make this point in particular cases is an ontology common to the two languages, with concepts that individuate the same objects. We can be clear about breakdowns in translation when they are local enough, for a background of generally successful translation provides what is needed to make the failures intelligible. But we were after larger game: we wanted to make sense of there being a language we could not translate at all. Or, to put the point differently, we were looking for a criterion of languagehood that did not depend on, or entail, translatability into a familiar idiom. I suggest that the image of organizing the closet of nature will not supply such a criterion.

How about the other kind of object, experience? Can we think of a language organizing *it*? Much the same difficulties recur. The notion of organization applies only to pluralities. But whatever plurality we take experience to consist in – events like losing a button or stubbing a toe, having a sensation of warmth or hearing an oboe – we will have to individuate according

to familiar principles. A language that organizes *such* entities must be a language very like our own.

Experience (and its classmates like surface irritations, sensations and sense data) also makes another and more obvious trouble for the organizing idea. For how could something count as a language that organized *only* experiences, sensations, surface irritations or sense data? Surely knives and forks, railroads and mountains, cabbages and kingdoms also need organizing.

This last remark will no doubt sound inappropriate as a response to the claim that a conceptual scheme is a way of coping with sensory experience; and I agree that it is. But what was under consideration was the idea of *organizing* experience, not the idea of *coping with* (or fitting or facing) experience. The reply was apropos of the former, not the latter, concept. So now let's see whether we can do better with the second idea.

When we turn from talk of organization to talk of fitting we turn our attention from the referential apparatus of language – predicates, quantifiers, variables and singular terms – to whole sentences. It is sentences that predict (or are used to predict), sentences that cope or deal with things, that fit our sensory promptings, that can be compared or confronted with the evidence. It is sentences also that face the tribunal of experience, though of course they must face it together.

The proposal is not that experiences, sense data, surface irritations or sensory promptings are the sole subject matter of language. There is, it is true, the theory that talk about brick houses on Elm Street is ultimately to be construed as being about sense data or perceptions, but such reductionistic views are only extreme, and implausible, versions of the general position we are considering. The general position is that sensory experience provides all the *evidence* for the acceptance of sentences (where sentences may include whole theories). A sentence or theory fits our sensory promptings, successfully faces the tribunal of experience, predicts future experience, or copes with the pattern of our surface irritations, provided it is borne out by the evidence.

In the common course of affairs, a theory may be borne out by the available evidence and yet be false. But what is in view here is not just actually available evidence; it is the totality of possible sensory evidence past, present and future. We do not need to pause to contemplate what this might mean. The point is that for a theory to

fit or face up to the totality of possible sensory evidence is for that theory to be true. If a theory quantifies over physical objects, numbers or sets, what it says about these entities is true provided the theory as a whole fits the sensory evidence. One can see how, from this point of view, such entities might be called posits. It is reasonable to call something a posit if it can be contrasted with something that is not. Here the something that is not is sensory experience – at least that is the idea.

The trouble is that the notion of fitting the totality of experience, like the notions of fitting the facts, or being true to the facts, adds nothing intelligible to the simple concept of being true. To speak of sensory experience rather than the evidence, or just the facts, expresses a view about the source or nature of evidence, but it does not add a new entity to the universe against which to test conceptual schemes. The totality of sensory evidence is what we want provided it is all the evidence there is; and all the evidence there is is just what it takes to make our sentences or theories true. Nothing, however, no *thing*, makes sentences and theories true: not experience, not surface irritations, not the world, can make a sentence true. *That* experience takes a certain course, that our skin is warmed or punctured, that the universe is finite, these facts, if we like to talk that way, make sentences and theories true. But this point is put better without mention of facts. The sentence "My skin is warm" is true if and only if my skin is warm. Here there is no reference to a fact, a world, an experience, or a piece of evidence.¹⁷

Our attempt to characterize languages or conceptual schemes in terms of the notion of fitting some entity has come down, then, to the simple thought that something is an acceptable conceptual scheme or theory if it is true. Perhaps we better say *largely* true in order to allow sharers of a scheme to differ on details. And the criterion of a conceptual scheme different from our own now becomes: largely true but not translatable. The question whether this is a useful criterion is just the question how well we understand the notion of truth, as applied to language, independent of the notion of translation. The answer is, I think, that we do not understand it independently at all.

We recognize sentences like "Snow is white" is true if and only if snow is white" to be trivially true. Yet the totality of such English sentences uniquely determines the extension of the concept of truth for English. Tarski generalized this observation and made it a test of theories

of truth: according to Tarski's Convention T, a satisfactory theory of truth for a language L must entail, for every sentence *s* of L, a theorem of the form "*s* is true if and only if *p*" where "*s*" is replaced by a description of *s* and "*p*" by *s* itself if L is English, and by a translation of *s* into English if L is not English.¹⁸ This isn't, of course, a definition of truth, and it doesn't hint that there is a single definition or theory that applies to languages generally. Nevertheless, Convention T suggests, though it cannot state, an important feature common to all the specialized concepts of truth. It succeeds in doing this by making essential use of the notion of translation into a language we know. Since Convention T embodies our best intuition as to how the concept of truth is used, there does not seem to be much hope for a test that a conceptual scheme is radically different from ours if that test depends on the assumption that we can divorce the notion of truth from that of translation.

Neither a fixed stock of meanings, nor a theory-neutral reality, can provide, then, a ground for comparison of conceptual schemes. It would be a mistake to look further for such a ground if by that we mean something conceived as common to incommensurable schemes. In abandoning this search, we abandon the attempt to make sense of the metaphor of a single space within which each scheme has a position and provides a point of view.

I turn now to the more modest approach: the idea of partial rather than total failure of translation. This introduces the possibility of making changes and contrasts in conceptual schemes intelligible by reference to the common part. What we need is a theory of translation or interpretation that makes no assumptions about shared meanings, concepts or beliefs.

The interdependence of belief and meaning springs from the interdependence of two aspects of the interpretation of speech behavior: the attribution of beliefs and the interpretation of sentences. We remarked before that we can afford to associate conceptual schemes with languages because of these dependencies. Now we can put the point in a somewhat sharper way. Allow that a man's speech cannot be interpreted without knowing a good deal about what he believes (and intends and wants), and that fine distinctions between beliefs are impossible without understood speech; how then are we to interpret speech or intelligibly to attribute beliefs and other attitudes? Clearly we must have a theory that simultaneously accounts for attitudes and

interprets speech – a theory that rests on evidence which assumes neither.

I suggest, following Quine, that we may without circularity or unwarranted assumptions accept certain very general attitudes towards sentences as the basic evidence for a theory of radical interpretation. For the sake of the present discussion at least we may depend on the attitude of accepting as true, directed at sentences, as the crucial notion. (A more full-blooded theory would look to other attitudes towards sentences as well, such as wishing true, wondering whether true, intending to make true, and so on). Attitudes are indeed involved here, but the fact that the main issue is not begged can be seen from this: if we merely know that someone holds a certain sentence to be true, we know neither what he means by the sentence nor what belief his holding it true represents. His holding the sentence true is thus the vector of two forces: the problem of interpretation is to abstract from the evidence a workable theory of meaning and an acceptable theory of belief.

The way this problem is solved is best appreciated from undramatic examples. If you see a ketch sailing by and your companion says, "Look at that handsome yawl," you may be faced with a problem of interpretation. One natural possibility is that your friend has mistaken a ketch for a yawl, and has formed a false belief. But if his vision is good and his line of sight favorable it is even more plausible that he does not use the word "yawl" quite as you do, and has made no mistake at all about the position of the jigger on the passing yacht. We do this sort of off the cuff interpretation all the time, deciding in favor of reinterpretation of words in order to preserve a reasonable theory of belief. As philosophers we are peculiarly tolerant of systematic malapropism, and practised at interpreting the result. The process is that of constructing a viable theory of belief and meaning from sentences held true.

Such examples emphasize the interpretation of anomalous details against a background of common beliefs and a going method of translation. But the principles involved must be the same in less trivial cases. What matters is this: if all we know is what sentences a speaker holds true, and we cannot assume that his language is our own, then we cannot take even a first step towards interpretation without knowing or assuming a great deal about the speaker's beliefs. Since knowledge of beliefs comes only with the ability to interpret words, the only possibility

at the start is to assume general agreement on beliefs. We get a first approximation to a finished theory by assigning to sentences of a speaker conditions of truth that actually obtain (in our own opinion) just when the speaker holds those sentences true. The guiding policy is to do this as far as possible, subject to considerations of simplicity, hunches about the effects of social conditioning, and of course our common sense, or scientific, knowledge of explicable error.

The method is not designed to eliminate disagreement, nor can it; its purpose is to make meaningful disagreement possible, and this depends entirely on a foundation – *some* foundation – in agreement. The agreement may take the form of widespread sharing of sentences held true by speakers of “the same language,” or agreement in the large mediated by a theory of truth contrived by an interpreter for speakers of another language.

Since charity is not an option, but a condition of having a workable theory, it is meaningless to suggest that we might fall into massive error by endorsing it. Until we have successfully established a systematic correlation of sentences held true with sentences held true, there are no mistakes to make. Charity is forced on us; whether we like it or not, if we want to understand others, we must count them right in most matters. If we can produce a theory that reconciles charity and the formal conditions for a theory, we have done all that could be done to ensure communication. Nothing more is possible, and nothing more is needed.

We make maximum sense of the words and thoughts of others when we interpret in a way that optimizes agreement (this includes room, as we said, for explicable error, i.e. differences of opinion). Where does this leave the case for conceptual relativism? The answer is, I think, that we must say much the same thing about differences in conceptual scheme as we say about differences in belief: we improve the clarity and bite of declarations of difference, whether of scheme or opinion, by enlarging the basis of shared (translatable) language or of shared opinion. Indeed, no clear line between the cases can be made out. If we choose to translate some alien sentence rejected by its speakers by a sentence to which we are strongly attached on a community basis, we may be tempted to call this a difference in schemes; if we decide to accommodate the evidence in other ways, it may be more natural to speak of a difference of opinion. But when others think differently from us,

no general principle, or appeal to evidence, can force us to decide that the difference lies in our beliefs rather than in our concepts.

We must conclude, I think, that the attempt to give a solid meaning to the idea of conceptual relativism, and hence to the idea of a conceptual scheme, fares no better when based on partial failure of translation than when based on total failure. Given the underlying methodology of interpretation, we could not be in a position to judge that others had concepts or beliefs radically different from our own.

It would be wrong to summarize by saying we have shown how communication is possible between people who have different schemes, a way that works without need of what there cannot be, namely a neutral ground, or a common coordinate system. For we have found no intelligible basis on which it can be said that schemes are different. It would be equally wrong to announce the glorious news that all mankind – all speakers of language, at least – share a common scheme and ontology. For if we cannot intelligibly say that schemes are different, neither can we intelligibly say that they are one.

In giving up dependence on the concept of an uninterpreted reality, something outside all schemes and science, we do not relinquish the notion of objective truth – quite the contrary. Given the dogma of a dualism of scheme and reality, we get conceptual relativity, and truth relative to a scheme. Without the dogma, this kind of relativity goes by the board. Of course truth of sentences remains relative to language, but that is as objective as can be. In giving up the dualism of scheme and world, we do not give up the world, but reestablish unmediated touch with the familiar objects whose antics make our sentences and opinions true or false.

Chapter 50: The Truth in Relativism

BERNARD WILLIAMS

This chapter tries to place certain issues in the discussion of relativism, rather than to deal with any one of them thoroughly. It is concerned with any kind of relativism, in the sense that the questions raised are ones that should be asked with regard to relativistic views in any area, whether it be the world-views of different cultures, shifts in scientific paradigms, or differences of ethical outlook. A machinery is introduced which is intended to apply quite generally. But the only area in which I want to claim that there is truth in relativism is the area of ethical relativism. This does not mean that I here try to argue against its truth in any other area, nor do I try to pursue any of the numerous issues involved in delimiting the ethical from other areas.

1. Conditions of the Problem

(a) There have to be two or more *systems of belief* (Ss) which are to some extent self-contained. No very heavy weight is put on the propositional implications of the term 'belief', nor, still less, is it implied that all relevant differences between such systems (let 'S1', 'S2', stand for examples from now on) can be adequately expressed in propositional differences: the extent to which this is so will differ with different sorts of examples. Any application of this structure will involve some degree of idealisation, with regard to the coherence and homogeneity of an S. There is more than one way in which these characteristics may be imposed, however, and difference in these affects the way (perhaps, the sense) in which the resultant S is an idealisation.

The characteristics may be involved in the very identification of the Ss: thus two synchronously competing scientific theories may be

picked out in part in terms of what bodies of beliefs hang together. But even in this case the Ss will not just be intellectual items constructed from the outside on the basis of the harmony of their content: there will in fact be bodies of scientists working within these theories (or research programmes) and seeking to impose coherence on them. If failures in imposing coherence were to be regarded as *a priori* impossible, the structure of description in terms of various Ss would lose a great deal of explanatory value.

In the case of alien cultures, the identification of an S may be effected initially through other features (geographical isolation and internal interaction of a group of persons), and the coherence of the S operate rather as an ideal limit for the understanding of the group's beliefs. This idea is in fact problematical, at least if taken as indicative of understanding in any objective sense: one comprehensible, and surely plausible, hypothesis is that no group of human beings will have a belief system which is fully coherent. The demand operates, nevertheless, as a constraint on theory-construction about the group, since the data will even more radically underdetermine theory if room is left for indeterminate amounts of incoherence within the S that theory constructs.

The problems of relativism concern communication between S1 and S2, or between them and some third party, and, in particular, issues of preference between them. It is worth noticing that quite a lot is taken for granted in the construction of the problem-situation already, in the application of the idea of there being a plurality of different Ss. Thus it is presupposed that persons within each S can understand other persons within that S; also that persons

receive information in certain ways and not others, are acculturated in certain ways, etc. It may be that some forms of relativism can be shown to be false by reference to these presuppositions themselves: not on the ground (which would prove nothing) that the *genesis* of ideas such as 'a culture', like that of 'relativism' itself, lies in a certain sort of culture, but on the ground that the *application* of a notion such as 'a culture' presupposes the instantiation in the subject-matter of a whole set of relations which can be adequately expressed at all only via the concepts of one culture rather than another (e.g., certain notions of causality). Any relativism which denied the non-relative validity of concepts involved in setting up its problem at all, would be refuted. This aspect of the matter has received some attention;¹ I shall not try to take it further here.

(b) S1 and S2 have to be *exclusive of one another*. That this should in some sense be so is a necessary condition of the problems arising to which relativism is supposed to provide an answer; indeed, it can itself be seen as a condition of identifying S1 and S2, in any sense relevant to those problems. Suppose for example that two putative Ss constituted merely the history or geography of two different times or places: then evidently they are not Ss in the sense of the problem, because they can merely be conjoined.

A much harder question, however, is raised by asking what are the (most general) conditions of two Ss excluding one another. The most straightforward case is that in which S1 and S2 have conflicting consequences, a condition which I shall first take in the form of requiring that there be some yes/no question to which consequence C1 of S1 answers 'yes' and consequence C2 of S2 answers 'no'. Under this condition, S1 and S2 have to be (at least in the respect in question) *comparable*.

The questions to which relativism is supposed to give an answer may be raised by the case of conflicting consequences, but relativism will not stay around as an answer to them unless something else is also true, namely that the answering of a yes/no question of this sort in one way rather than the other does not constrain either the holder of S1 or the holder of S2 to abandon respectively the positions characteristic of S1 and S2 (and of the difference between them). If this further condition does not hold, there will be a straightforward decision procedure between S1 and S2, and relativism will have been banished. In the scientific case, the possibility of this condition holding, granted that C1 and C2 are consequences of S1 and S2, lies in the possibil-

ity that the consequence follows from the system only using material peripheral to the system and to its most characteristic positions: the situation is the much-discussed one in which theory is underdetermined by observation.

However, if theory is radically underdetermined by observation, can it be required that Ss are even to this modest degree comparable? Thus, in the spirit of one fashionable line of argument, if every observation statement is theory-laden, and all theory-ladenness displays meaning-variance, then it is unclear how there can be one yes/no question which stands in the required relation to S1 and S2. Here it is important to see how little is implied by there being conflicting consequences of S1 and S2. All that is required is that there be *some* description of a possible outcome, which description is acceptable to both S1 and S2, and in terms of which a univocal yes/no question can be formed: it may well be that there are other descriptions of what is (in some sense) the same event which are non-comparable. If this minimal requirement is not satisfied, severe problems are likely to follow, particularly in the case of scientific theories, for the original description of the Ss. We lose control on the notion of observation, concerning which it is said that it underdetermines theory; and we lose the descriptions of certain passages in the history of science which are the subject and in some part the motivation of these accounts (roughly it looks as though not only the choice of a replacement paradigm, but the occasion of that choice, might emerge as entirely socially determined, as though a chief determinant of the alteration of scientific theory were boredom).

However it may be with scientific theories, it would be unwise to exclude the possibility of systems so disparate that they were not, in terms of conflicting consequences, comparable at all. Some social anthropologists have given accounts of the Ss of traditional (pre-scientific) societies in terms which seem to imply that they are quite incommensurable with the Ss of modern, scientific, societies. I shall not go into the question of whether such accounts could be true.² The issue is rather, if such accounts were true, what content could be left to the idea that the traditional and the scientific Ss were exclusive of one another – as surely everyone, including these social anthropologists, would say that they were. Here it looks as though the only thing to be said is that, in ways which need to be analysed, it is impossible to live within both Ss. Accepting this vague idea, we can indeed continue to use, at a different level, the language of conflicting

consequences, since if it is impossible to live within both S1 and S2, then the consequences of (holding) S1 include actions, practices, etc. which are incompatible with those which are consequences of (holding) S2.

I do not take this to be a very illuminating assimilation, since the variation required in the interpretation of 'consequence' remains unexplained. But it does harmlessly help to handle a wider range of cases without constant qualification; and it does, more than that, positively bring out one thing – that even in this limiting case (which I shall call that of *incommensurable exclusivity*), there has to be something which can be identified as the *locus* of exclusivity, and hence the Ss are not entirely incommensurable. This locus will be that of the actions or practices which are the consequences of living within S1 and S2. Another light will be shed on them when we turn, next, to broadly ethical cases.

In ethical cases (taken in a broad sense), the conditions of conflict come out, obviously enough, differently from the form they take with, for instance, scientific theories. The simplest case is that of conflict between answers which are given to yes/no questions which are practical questions, questions about whether to do a certain thing. Now such a question might be a general, or type, action question, asking whether a certain type of thing was to be done in a certain type of situation. In this case, the relevant formulation is that it is possible for S1 to answer 'yes' to such a question while S2 answers 'no' to it; this is parallel to two theories yielding conflicting predictions, but without the question yet being raised of one or the other actually being borne out in fact. We get a structure resembling the occurrence of an actual observation only when we move to the idea of a particular token action question, as asked by a particular agent in a particular situation. Here the practical question *gets answered* in actual fact, and this occurrence of course trivially satisfies the conditions: the fact that a given question gets answered in this sense in a way which conflicts with, say, the consequence if S1 does not constrain a holder of S1 to abandon his position (he may say that the agent was wrong so to decide). What actually is done trivially underdetermines systems of belief about what ought to be done.

Action decisions are not the only possible site of conflicting consequences in the ethical case: various forms of approval, sentiment, etc. can equally come into it. With these, but also with action-descriptions, difficulties can, once more,

arise about the satisfaction of the comparability condition. This condition is easily satisfied under a theory such as Hare's, which is strongly analogous to a positivist philosophy of science, in regarding an ethical outlook or value system (theory) as consisting of a set of principles (laws) whose content is totally characterised by what imperatives (predictions) they generate. But on any more complex view, very severe problems of comparability arise. Here again, we can appeal to the weak requirement which was made in the theory case: that there be some description of the action (say) in terms of which a univocal yes/no question can be formulated. Thus it is certainly true and important that marriage to two persons in a polygamous society is not the same state or action as bigamy in a monogamous society, nor is human sacrifice the same action as murder in the course of armed robbery. But there may well be descriptions such that a univocal yes/no question can be formed for each of these examples, and S1 and S2 differ in their answers. There can be, that is to say, system-based conflict. Two persons can be in a situation of conflict, in which they give opposed answers to the same question of action or approval, and they can be motivated to this by their value system (that is to exclude quarrels inspired by motivations themselves not sanctioned by the value system).

The line I have sketched for describing cases (if there are any) of incommensurable exclusivity implies that for every pair of Ss which are incommensurably exclusive, there must be some action, practice, etc., which under some agreed description will be a locus of disagreement between the holders of the Ss. If this condition is not met, it is unclear what room is left for the notion of exclusivity at all, and hence for the problems of relativism.

2. Variation and Confrontation

With regard to a given kind of S, there can be both diachronic and synchronic variation. In the history and philosophy of science, anthropology, etc., there is room for a great deal of discussion about the interrelations of and the limitations of these kinds of variation. There is for instance the question whether certain synchronic variations represent certain diachronic ones, i.e., whether certain cultural variations in one place are survivals of what was an earlier culture elsewhere (do the Hottentots have a Stone Age culture?). Again, the definition of a certain class of Ss can limit variation: thus the range within which something can count as a *scientific theory* is a

well-known matter of dispute, as is the question whether the use of such restrictions to delimit what is counted as diachronic variation (to constitute, that is, a history of science) is merely a matter of *ex post facto* evaluation. (The matter takes on a different aspect with respect to synchronic variation at the present time, in view of the existence of a unified and institutionalized international scientific culture.)

In many, if not all, cases of diachronic variation, it is an important fact that a later *S* involves consciousness of at least its neighbouring predecessor (though not necessarily, of course, in terms which the predecessor, or again *S*'s successors, would assent to). There are very important issues at this point about the writing of 'objective' cultural history, but I do not intend to take them on. In fact, I propose from this point on to ignore cases in which *S2* arises in a way which involves some conscious relation with *S1*, and to consider only those in which mutual awareness can be regarded as, in principle, a development independent of the existence of *S1* and *S2*. While this simplification is a drastic one, it will do for present purposes.

Under this simplification, let us now consider some possible relations, or lack of them, between *S1* and *S2*. There is, first, the primitive situation in which *S1* and *S2* exist in ignorance of one another. After that, there are cases in which at least one of *S1* and *S2* encounters the other: either directly, in the case in which persons who hold one of the *Ss* encounter persons who hold the other, or indirectly, when persons holding one merely learn of the other.

Some such encounters, I shall call *real confrontations* (the term 'confrontation' is not meant to carry all the implications it has in contemporary politics). For any *S*, there has to be something which counts as assenting to that *S*, fully accepting it or living within it – whatever it is, in each sort of case, for an *S* of that sort to be *somebody's S*. I shall call this relation in general 'holding'. There is a real confrontation between *S1* and *S2* at a given time if there is a group at that time for whom each of *S1* and *S2* is a real option. This includes, but is not confined to, the case of a group which already holds *S1* or *S2*, for whom the question is one of whether to *go over* to the other *S*. We shall come back shortly to the question of what a 'real option' is.

Contrasted with this situation is that of *notional confrontation*.³ Notional confrontation resembles real confrontation in that there are persons who are aware of *S1* and *S2*, and aware of their differences; it differs from it in that at least

one of *S1* and *S2* do not present a real option to them. *S1* and *S2* can of course be in both real and notional confrontation, but not with respect to the same persons at the same time. *S1* and *S2* can be in notional confrontation without ever having been in real confrontation: no one may come to know of both *S1* and *S2* until at least one of them has ceased to present real options. Again, *S1* and *S2* can be in real confrontation without ever being in notional confrontation: no one may ever think of one of them after the hour of its struggle (presumably unsuccessful) with the other.

What is it for an *S* to be a real option? In accordance with the starting-point that *Ss* belong to groups (which is not to deny that they are held by individuals, but to assert that they are held by individuals in ways which require description and explanation by reference to the group), the idea of a real option is meant to be a social notion. *S2* is a real option for a group if either it is their *S* or it is possible for them to go over to *S2*; where going over to *S2* involves, first, that it is possible for them to live within, or hold, *S2* and retain their hold on reality, and, second, to the extent that rational comparison between *S2* and their present outlook is possible, they could acknowledge their transition to *S2* in the light of such comparison.⁴ Both these conditions use concepts which imply that whether a given *S* is a real option to a given group at a given time is, to some extent at least, a matter of degree: this consequence is not unwelcome.

Something must be said in explanation of each of these conditions. Let me take the second first. The purpose of this is to ensure that the question of whether an *S* is a real option is not just (granted the satisfaction of the first condition) a matter of such things as the state of psychological technology. We do not want to say that an eccentric scientific theory is a real option for a group of scientists because they could be drugged or operated upon in such a way that they emerged believing it. To the extent that *S1* and *S2* are comparable, do expose themselves to experiment which can tend to favour one over the other, etc., these methods of assessment are what are to count in the consideration of the accessibility of *S2* from *S1*. Whether something is a real option is a social question, but one rooted in as much rationality as is available on the given type of issue.

In the limiting case of incommensurable exclusivity, this condition will have virtually no effect. There will be little room in such a case for anything except conversion. But even

conversion had better be something which can be lived sanely, and this is the force of the first condition. To speak of people who have accepted S2 'retaining their hold on reality' is to imply such things as that it is possible for S2 to become their S, and for them to live within S2, without their engaging in extensive self-deception, falling into paranoia, and such things. The extent to which that is so depends in turn, to some degree, on what features of their existing social situation are held constant under the assumption of their going over to S2. Thus S2 may not be realistically possible for a group granted features of their present social situation, but it might be if those features were changed. The question of whether S2 is, after all, a real option for them then involves the question of whether those features could be changed.

It is neither a necessary nor a sufficient condition of an S's being a real option for a group that they think that it is a real option. It is not a sufficient condition, because they may be ill-informed, unimaginative, un-self-aware or optimistic about what it would be like for them to try to live within that S (and this may not be just a personal, but a social or political mistake). It is not a necessary condition, because they may not have realised what possibilities going over to that S would offer them: the psychology of conversion of course relates to this matter. I regard the question of whether a given S is a real option for a given group at a given time as basically an objective question. Of course, people may differ about such questions as what is included under 'a hold on reality', and also, notoriously, about what degree of rational comparability can be displayed by Ss of a given kind. In terms of the present structure, such disagreements may well affect what range of Ss those people will regard as real options, for themselves or others.

In this sense many Ss which have been held are not real options now. The life of a Greek Bronze Age chief, or a mediaeval Samurai, and the outlooks that go with those, are not real options for us: there is no way of living them. This is not to say that reflection on those value-systems may not provide inspiration for thoughts about elements missing from modern life, but there is no way of taking on those Ss. Even Utopian projects among a small band of enthusiasts could not reproduce *that* life. Still more, the project of re-enacting it on a societal scale in the context of actual modern industrial life would involve one of those social or political mistakes, in fact a vast illusion. The prospect of removing the conditions of modern industrial life alto-

gether is something else again – another, though different, impossibility.

In this connexion it is important that there are asymmetrically related options. Some version of modern technological life and its outlooks has become a real option for members of some traditional societies, but their life is not, despite the passionate nostalgia of many, a real option for us. The theories one has about the nature and extent of such asymmetries (which Hegelians would ground in asymmetries of both history and consciousness) affect one's views about the objective possibilities of radical social and political action.

3. Relativism

Suppose that we are in real confrontation with some S. Then there will be some vocabulary of appraisal – 'true–false', 'right–wrong', 'acceptable–unacceptable' etc. – which will be deployed, and essentially deployed, in thought and speech about this confrontation. The ways in which it is deployed, and the considerations it is geared into, will of course differ with the type of S in question – for instance, with the degree of comparability that obtains between Ss of this type. Whatever these differences, in speaking of a 'vocabulary of appraisal', I refer only to those expressions which can *at least* be used to express one's own acceptance or rejection of an S or an element of an S. Such a vocabulary is essentially deployed in reflective thought within situations of real confrontation, since in reflection one has to be able to think, and articulate one's feelings, about the different Ss which are a real option for one, and to organise what is to be said in favour or against a given S becoming one's own. Since Ss are things held or accepted, not just conformed to, what has to be said in favour of or against a given S must have some footing in the appraisal of its content.

We can also use this vocabulary about Ss which stand in merely notional confrontation with our own. For some types of S, however, the life of the vocabulary is largely confined to cases of real confrontation, and the more remote a given S is from being a real option for us, the less substantial seems the question of whether it is 'true', 'right', etc. While the vocabulary can no doubt be applied without linguistic impropriety, there is so little to this use, so little of what gives content to the appraisals in the context of real confrontation, that we can say that for a reflective person the question of appraisal does not

genuinely arise for such a type of *S* when it is standing in purely notional confrontation.

We can register that the *S* in question is not ours, and that it is not a real option for us. There is indeed quite a lot we can say about it, and relevantly to our concerns. Thus certain features of an alien way of life, for instance, can stand to us symbolically as emblems of conduct and character to which we have certain attitudes in our own society, in much the same way, indeed, as we can treat works of fiction. The socially and historically remote has always been an important object of self-critical and self-encouraging fantasy. But from the standpoint I am now considering, to raise seriously questions in the vocabulary of appraisal about this culture considered as a concrete historical reality will not be possible for a reflective person. In the case of such *Ss*, to stand in merely notional confrontation is to lack the relation to our concerns which alone gives any point or substance to appraisal. With them, the only real questions of appraisal are about real options.

To think that the standpoint I have just sketched is the appropriate standpoint towards a given type of *Ss* is, in a recognizable sense, to hold a relativistic view of such *Ss*. Relativism, with regard to a given type of *S*, is the view that for one whose *S* stands in purely notional confrontation with such an *S*, questions of appraisal of it do not genuinely arise. This form of relativism, unlike most others,⁵ is coherent. The truth in relativism – which I shall state, not argue for – is that for ethical outlooks at least this standpoint is correct.

This form of relativism (as a structure – its application to any particular type of *S* will always of course be a further question) is coherent because unlike most other forms it manages, in the distinction between real and notional confrontation, to cohere with two propositions both of which are true. The first is that we must have a form of thought not relativized to our own existing *S* for thinking about other *Ss* which may be of concern to us, and to express those concerns. The second is that we can nevertheless recognize that there can be many *Ss* which are related to our concerns too distantly for our judgments to have any grip on them, while admitting that other persons' judgment might get a grip on them, namely, those for whom they were a real option.

Most traditional forms of relativism have paid insufficient respect to the first of these propositions. The simplest form merely seeks to relativize the vocabulary of appraisal, into such phrases as 'true for us', 'true for them'. It is well

known that these formulations do not work, and in particular cannot represent the basic use of the vocabulary in real confrontations. This view could be said to reduce the entire vocabulary of appraisal to expressions for the description of confrontation. Related to this is the view in ethics which I have elsewhere⁶ called 'vulgar relativism', the view which combines a relativistic account of the meaning or content of ethical terms with a non-relativistic principle of toleration. This view is not hard to refute; it was perhaps worth discussing, since it is widely held, but to dispose of it certainly does not take us very far. We can perhaps now see that view more clearly. What vulgar relativism tries to do is to treat real confrontations like notional confrontations, with the result that it either denies that there are any real confrontations at all, or else brings to bear on them a principle which is inadequate to solve them, and is so because while it looks like a principle for deciding between real options, it is really an expression of the impossibility or pointlessness of choosing between unreal options.

Opposed to these kinds of views is that which represents the use of the vocabulary of appraisal as solely that of expressing (not stating) that an *S* is or is not the speaker's own. For such a view (consider for example the pure redundancy or 'speech-act' view of 'true') the issues which have concerned relativists evaporate – there is no way of expressing them. But equally, what has rightly concerned relativists evaporates, and we lose hold on the second truth which the present account is designed to accommodate. The distinction among *Ss*, between that which is and those which are not the speaker's own, is by no means the most significant in this area. The assumption that it is, is something that the discarded forms of relativism, and the evaporating view which apparently stands opposed to them, have in common.

With those types of *S* for which relativism is not true, it is not that there is no distinction between real and notional confrontations, but that questions of appraisal genuinely arise even for *Ss* in notional confrontation. But if that is so, then the status of those *Ss* will reveal itself also in the relevant criteria for distinguishing real and notional confrontations, the considerations that go into determining that a given *S* is or is not a real option for a given group at a given time. This is important for the case of scientific theories. Phlogiston theory is, I take it, not now a real option, but I doubt that this just means that to try to live the life of a convinced phlogiston theorist in the contemporary Royal Society is as

incoherent an enterprise as to try to live the life of a Teutonic knight in 1930s Nuremberg. One reason that phlogiston theory is not a real option is that it cannot be squared with a lot that we know to be true.

These considerations, if pursued, would lead us to the subject of realism. One necessary (but not sufficient) condition of there being the kind of truth I have tried to explain in relativism as applied to ethics, is that ethical realism is false, and there is nothing for ethical Ss to be true of – though there are things for them to be true to, which is why many options are unreal. But scientific realism could be true, and if it is, relativism for scientific theories must be false.

*The unrefined and sluggish mind
of Homo Javanensis
Could only treat of things concrete
and present to the senses*

W. V. Quine

Tropisms and Transitions: Some Leading Questions

Before planning and reasoning, there were tropisms. Tropisms have functions and make use of information detected, but they don't, I assume, involve any actual reasoning. Somewhere along the course of evolution, and at some time in any one of us on the way from zygote to adult, some forms of detection became beliefs, and some tropisms turned into reasoned desires. And at some stage – perhaps, if Quine is right, with *Homo javanensis* – we became adept at processing information, that yet fell short of the power to abstract and generalize. What selective pressures can we then suppose to have effected in our brains, since then, the innovations required to bring us the capacity for fully abstract and general reasoning?

I take for granted that reasoning is something we do; that much or most of what we do is influenced by emotion; that psychology is interested in everything we do; and that psychology is a branch of biology. These breezy premises raise a number of questions.

1. What kind of connection might there be between biology and rationality?
2. More specifically, how does the normativity of logic relate to its biological origins? Is there not, in the very idea of such a connection, something akin to the naturalistic fallacy?

3. If our capacity for inference is in part a legacy of natural selection, are there specific emotional mechanisms that serve to influence reasoning at the proximate level?
4. If so, what is the connection between those means by which our inferences are policed by our emotions, and the formalisms that govern careful reasoning in science and mathematics?

I shall not address these questions directly. By the end of this chapter, however, I hope to have gleaned enough to warrant saying a little about each. On the way there, here is the route I shall follow.

I will begin with *prima facie* distinctions among strategic, epistemic and axiological domains of rationality. The domains soon merge at the edges, and the role of emotions in adjudicating border disputes turns out to be both crucial and equivocal, because of the emotions' ability to function as both cause and effect in all three domains. In addition, emotions are ubiquitous in both of what I shall call the mind's "two tracks": Some emotions were shaped by natural selection long before the invention of language, but the elicitors and very identity of many emotions now commonly rest essentially on explicit linguistic function. In practice, for example, the "feeling of rightness" plays an indispensable role in our assessment of certain basic inferential forms as acceptable or unacceptable. But a striking characteristic of such inferential forms is that they apparently do not, at least in their prelinguistic form, reflect any truly topic-neutral power of logic. That comes only with the contribution of explicit linguistic formulations

of logical rules, and even then the best we can say about our capacities in that department is that they are uneven. This throws some light, I shall suggest, on the “rationality wars” that have pitted “pessimists” about human rationality against both “optimists” and “meliorists.” From those considerations, I will turn to a sampling of cases where inferences appear to be affected not merely by prelinguistic but actually by subpersonal processes, including, in some cases, what appear to be very directly chemical factors affecting belief, desire, or emotion as they affect our disposition to get from one belief to another.

Kinds of Emotional Rationality

A plausible first approach to rationality distinguishes three forms or domains of its application: the *epistemic*, which aims at maximizing true beliefs and minimizing false ones (neither suffices alone, and no easy formula guarantees both); the *strategic* or practical, which aims at success in action in the light of goals and desires; and the *axiological*, which aims at appropriateness of evaluative emotional response. A running theme in the history of philosophy has consisted in attempts by each of the first two to subsume the other. Socrates famously asserted that the true explanation for bad choices invariably lay with a lack of knowledge. That claim rested on the dubious premise that everyone desires the same thing, namely the Good. From that, Socrates inferred that wrong choices reflect not ill-will, but misinformation. If we remove the dubious premise, we can still make a case: If strategic irrationality consists in adopting a counterproductive course of action, it seems reasonable to presume that its counterproductive nature was not known. When I act, I must in some sense believe my action to be the best available. That belief (which doesn't necessarily exclude a simultaneous contrary belief) may be false or irrationally acquired. From that vantage point, epistemic rationality subsumes the strategic.

By contrast, there is a considerable literature on the “ethics” of belief (Adler 2002). And while opinions differ as to whether believing can be done at will, the whole discussion presupposes that it is at least sometimes something that is *done*. As such it must be subject to considerations of strategic rationality (Levi 1967). Viewed thus, the strategic subsumes the epistemic.

Common cases in which the two clash involve self-deception that serve the agent's short- or long-term interests. Self-deception is a good

thing, it is sometimes claimed, when it contributes to self-confidence, encourages effort, or keeps crippling realizations out of consciousness (Taylor 1989).¹ Emotions standardly play a determining role in self-deception, but they need not enter into the reasoning that motivates it. In some grander styles of self-deception, as advocated by Pascal with his famous wager, or in William James's plea for faith (James 1979) as against Clifford's insistence on the requirement of “adequate evidence” (Clifford 1886), emotions only come in at the implementation stage, once self-deception has been chosen by a dispassionate argument as a maximizing policy.

To see this, let us focus on Pascal. Ignoring theological subtleties,² Pascal's wager can be succinctly characterized in Bayesian terms:

The expected utility of believing in God is the weighted sum of the utility of living a life of relative deprivation, followed by eternal bliss, and that of living a life of deprivation followed by nothing. The weights are the probability that God (as conceived by the particular theology in question) actually exists and its converse. Even if the probability of God's existence is tiny (but still finite), the resulting expected utilities – respectively positive and negative – are infinitely large.

It is important to note that while this argument deals with probabilities or Bayesian beliefs, it treats believing or disbelieving themselves as actions. Their expected desirabilities are determined in the same way as that of other actions in terms of their consequences weighted by their likelihoods. And while something like religious terror may well have motivated Pascal's invention of the wager, the argument itself is not overtly driven by emotion. On the contrary, it is a pure calculation of costs and benefits, intended to counter what might be thought of as the greater prima facie emotional weight of the temptation of present earthly pleasures. It is only when Pascal goes on to give advice about how to implement the goal of believing against evidence that he counsels habit-forming behavior, which might in turn bring the emotional tone of conviction. So he seems well aware that concentrating on the expected utilities figuring in the calculation would be ineffectual in changing belief.

But surely, the epistemologist will claim, considerations about heavenly bliss and hellish torment are not relevant to the issue of truth. Truth is by definition the formal object of belief, and therefore the standard of a belief's correctness; and only evidence is relevant to truth (Adler

1999: 268). Therefore, treating practical considerations as bearing on the rationality of belief is simple confusion.

Against this, however, Pascal can insist that the purity of truth can't have been an original virtue of belief. It had to be distilled, as it were, from the soup of overall benefit. Knowing the truth is useful in general, to be sure, but it is hasty to think that practical pursuits will massively fail if concern for truth is not paramount. Indeed, it seems to be strategically rational to lie a certain proportion of the time, both at the level of conscious policy and at the level of phylogenetic strategies. Mimetism, in which the markings of one species have in effect been selected to get a "free ride" on the toxicity of another similar-looking species, is effectively deception at the species level (Sober 1994). Furthermore, as Chris Stephens (2001) as shown, while believing what is true is a good idea in general, there are cases – aptly captured in the slogan "Better safe than sorry," when a signal is wrongly interpreted as indicating the presence of a predator – where the best policy may systematically result in acting on falsehoods as often as on truths.³

In short, the value of truth – telling it, or believing it – should not be exaggerated, and it is only in a context in which one has already agreed to take the purity of epistemic norms for granted that Pascal's wager can be ruled inappropriate.

What then does distinguish those contexts in which epistemic norms are primary, from those which call for more pragmatic criteria?

This question, as I have argued elsewhere, calls for a meta-level judgment of appropriate value: sometimes a value is purely epistemic, at other times, broadly practical. Since that judgment arbitrates between the epistemic and the strategic, neither mode of rationality can make it without begging the question. When each side accuses the other of an *ignoratio elenchi*, the decision between them will inevitably depend on how much one *cares* about one and the other. Emotional endorsement is the only ultimate arbiter of the appropriateness of a standard of rationality (de Sousa 2003).

But if emotions are – in any sense, however perverse – to lord it over logic, what can that mean for the validity of logic? Although an arbitrator is not a dictator, and arbitration is called for only in very special circumstances, it would be paradoxical if the faculty we are accustomed to think most disruptive of Reason were crucially to contribute to the determination of reasons. To resolve that paradox, we should note that at some point in the articulation of the most

basic procedural rules, considerations of normative correctness must merge with certain factual necessities. Correct inference, at the most basic level, consists in the regular functioning of basic psychological mechanisms constrained by the power of social sanctions over individuals.

In a moment, I shall adduce a striking example of the depth of that power, not merely over individual emotions, but over the content of perception. (See "Six Paradigms," later in this chapter.) But it must be acknowledged at the outset that social pressure is sometimes – indeed, perhaps *often* – deplorably wrongheaded. If the power of social influence results from nothing but the random parasitism of memes, this line of thought is unpromising. The key to doing better lies in acknowledging something deeper than social pressure: an original evolutionary basis for some of the "intuitive" judgments that are codified in social consensus.

Evolution and Rational Inference

The need to posit innate predispositions to certain forms of information could be made out with reference to concept acquisition, to classical induction, and to Nelson Goodman's "new" problem of induction (Goodman 1983). But let me illustrate with reference to a narrow and uncontroversial level of rationality: the rationality of logical inference. Clearly, making valid inferences is something we can study to do more effectively but, as famously demonstrated in Plato's *Meno*, it is also something that we know "instinctively." Meno's slave may not know geometry, and he is ever ready to hazard thoughtless answers, but when confronted directly with the consequences of his suggestions he can recognize them as right or wrong – something he could never do with merely empirical information. Similarly, whatever our level of logical sophistication, there are inferences of which we recognize the validity, others which we immediately see as invalid. That fact is no lucky accident. Unless we spontaneously recognized the validity of some basic pattern of inference, such as Modus Ponens or Modus Tollens,⁴ no instruction manual could save our inferences from sinking into logical quicksand. That is the lesson Lewis Carroll's story of Achilles and the Tortoise: if we required every applicable rule of inference to be written down as a premise, we would need another rule to tell that the inference was an instance of it, and so on forever. The simplest inference would require us to endorse an infinite number of finite steps (Carroll 1895).

So it's no mystery that at the most elementary level, the gap closes up between what we do naturally and what valid logical rules prescribe. What does remain unexplained by this, however, is *how* this happy harmony might have come to be preestablished.

This problem is made the more acute, as Mohan Matthen has pointed out, by the fact that most philosophers have given up on the hope of establishing a type-type identity between contentful mental states and neurological ones. So how are we to explain the lucky fact that the causal powers of belief states reflect the logical relations between the propositions believed? If assenting to p , assenting to $(p \rightarrow q)$, and assenting to q are merely token identical to the neurological states that implement them, how does it happen that the conjunction of the first two states tend to cause the third? Perhaps those states are somehow tagged with the right syntactic markers in the brain. But if so, we still need to "show why syntax parallels semantics" (Matthen 1989: 563). He then argues that we have "no choice" about adopting some sort of evolutionary explanation (p. 564), appealing to the now standard notion of an evolutionary function, as arising from selection for some characteristic performance (Millikan 1993). Specifically, Matthen suggests,

we might have a special state that has *if p then q* as content, without its being a special purpose state that brings the q state into being whenever the p state occurs. Such a conditional state would depend for its effectiveness on the existence of higher level modules that were able to execute the logic of conditionals. (Matthen 1989: 567)

This suggestion raises three questions. The first is whether an evolved mechanism such as the one Matthen envisages could be prelinguistic. The second is about the role of emotion in the processes in question. The third, which I shall refer to the *problem of scope*, is whether the mechanisms in question are sufficiently general to cover the full range of possible inferences.

To address the first question, we should first note that logic aspires to operate on topic-neutral form. It presupposes abstraction, requiring some form of representation that is devoid of specific reference. But it is hard to see how a prelinguistic representation might have the required generality. Hence, it may be more promising to reject the question, on the supposition that organisms that do not have language

don't actually ever *need* topic-neutral mechanisms. It may be, as Peter Carruthers among others has suggested, that among the specific virtues of language, is the capacity to bridge and connect information derived from encapsulated prelinguistic modules. On that view, language holds the monopoly on the capacity for abstract or topic neutral reasoning (Carruthers 2002).

This idea fits in with much evidence for a two-tiered organization of our cognitive faculties, a "two-track mind." Track One comprises relatively modular response patterns. The more abstract, language-bound patterns of Track two sometimes supersede the others, but often both remain in competition. Prima facie, it would seem that simply in virtue of involving older structures in the brain, emotions might play an important role in the former but not in the latter. In an early formulation of the hypothesis that brain structures originating at different stages of evolution have overlapping functions, Paul MacLean (1975) identified the limbic system as implicated in both emotional functions and cognitive ones; but only the cortex is involved in language capacity. More recent versions of the view are less cut-and-dried, but there is accumulating evidence for the basic hypothesis of the existence of two systems of mental processing, grounded in structures set up both by evolution and learning on the one hand, and involving explicit linguistic processing on the other. The two systems sometimes compete in generating beliefs, wants, and plans. The idea has appeared many times in psychology (Evans 2003), and its consequences have been most thoroughly explored by Keith Stanovich (2004), who lists twenty-three versions of it. His own version lists "automaticity, modularity, and heuristic processing" as the features characteristic of Track one, while Track two is described as "rule-based, often language based, computationally expensive" (Stanovich 2004: 34–36).

All this suggests, in answer to my second question, that, insofar as emotions can be attributed to beings without language, they belong primarily in Track one. But the two-track mind hypothesis is not committed to drawing the line by opposing the phylogenetic origins of the faculties involved to those that arise by learning, including language learning. Many emotions require language for their full specification, and language reaches deep into the emotional brain. This is obvious from a glance at the power of political rhetoric. Equally obvious, however, is the fact that the emotional power of political rhetoric doesn't work by stimulating our

capacity for logical inference. Instead, such uses of language proceed by triggering what George Lakoff calls “frames” and what I have called “paradigm scenarios” (Lakoff 2002; de Sousa 1987). Frames and paradigm scenarios are fundamentally emotional in their mode of operation, and tend to wrest control from logical reasoning altogether.

The Rationality Debate

It may be objected that the best-known examples of systematic irrationality involve word problems, as detailed by (Kahneman, Slovic, and Tversky 1982), do not appear to involve emotions. How does this square with the idea that the irrationality is explained in part by emotional aspects of the two-track mind?

Let’s look at how this question might apply to one of the best known cases, the Wason test. In the classic version of this, subjects are shown four cards, showing 3, D, 7, K. They are told that all cards have a letter on one side and a number on the other, and they are asked what cards must be turned over to verify that *if a card has D on one side it has 3 on other*. Most people get this wrong, in a puzzling variety of ways. Yet most people can easily solve a problem about how to make sure that underage customers are not drinking alcohol. This latter problem has the same abstract form: in either case, the question can be represented abstractly as requiring verification of a statement of the form “if p then q ,” where the possible moves comprise turning over a p card, a $\sim p$, a q , or a $\sim q$. Given that falsification of “if p then q ” is secured iff $p \ \& \ \sim q$ is true, it should be clear that the actions required are turning over just the p and the $\sim q$ cards. In the case of the drinking problem, that means inspecting the ID of those drinking beer and checking the drinks of those without ID. In the abstract card version, it means turning over the D and the 7. Why does the former seem so much easier than the latter? And what does it have to do with the use of language?

There have been a number of attempts to reject the head the problem off at the pass. One recent argument is made by Jerry Fodor, who denies the basic assumption that the two versions of the problem have the same logical form. Fodor notes that in cheater detection, the subject is charged with conditionally enforcing an imperative, whereas the card-turning version requires verification of a conditional statement (Fodor 2000: 101–104). To be sure, checking on q just in case p is not the same task as checking the truth

of *if p then q* . The former task requires nothing unless p is true. But that accounts only for one typical mistake, which consists in checking only the p card.⁵ But Fodor’s ingenious attempt to pry the two tasks apart is a red herring. For among the vast number of variant experiments to which the Wason test has been submitted, some cases that could be represented as requirements or permissions fail to yield a majority of correct judgments, unless they specifically involve possible violations due to cheating (Cosmides and Tooby 1992: 199–205). Consensus on a clear diagnosis is still lacking; what is clear, however, is that a number of different content-dependent factors appear to be involved in determining whether problems of the same abstract form are more or less easily solved. The difficulty of accessing and applying the purely abstract schema is well established.

We can draw two morals, which at first blush appear somewhat inconsistent. First, that we are sometimes poor at reasoning about abstract problems, compared to our ability to deal with some of their specific concrete instantiations; second, that when we insist on applying formal rules of inference strictly, we can get it right and convincingly expose the error. So is explicit reasoning systematically irrational or not? What seems to be happening in the Wason test is that when the question is posed, it commonly fails to trigger the truth-table for the material conditional even when that schema has been studied in formal logic class. Lacking the clue that will route it to the cheater-detection schema, subjects fall back on some more accessible course, such as attending to the cards mentioned in the problem (“matching bias”), leading to the choice of turning over 3 and D, or confusing “if” with the biconditional. If an emotion is involved, it might come under the heading of intellectual sloth. An abstract word problem requires an analytical Track Two strategy, and that is harder to access if some familiar and more easily available schema appears ready to hand.

Topic-neutrality is a defining characteristic of logic, in which arguments can be assessed independently of the reference of their terms. It is closely related to the idea of universality: for if validity can be assessed without regard to subject matter, then nothing is in principle beyond our comprehension. Yet one might reasonably doubt whether the capacities we now have, even when boosted by language, are able to span topics far removed from those likely to be treated by, or useful to, “the unrefined and sluggish mind of homo Javanensis.” That is the

problem of scope: are there inherent limits to our mental capacities that forever bar us from understanding some things? This idea has taken many forms. Here is a generic version: *Our mental capacities have evolved under the selective pressure of a limited range of practical problems; so we have no good reasons to trust them when we venture beyond that restricted range into theoretical speculation.* The Whorf hypothesis – that a specific language may be equipped to express only a specific range of thoughts (Whorf 1973) – and Colin McGinn’s “mysterian” suggestion that there might be an intrinsic limit to the capacity of the mind to understand itself (McGinn 1982), are well-known variants of the scope problem. But its classic formulation comes from Descartes:

For the proper purpose of the sensory perceptions given me by nature is simply to inform the mind of what is beneficial or harmful. . . . I misuse them by treating them as reliable touchstones for immediate judgments about the essential nature of the bodies located outside us. (*Med. VI*)

The very precision of Descartes’ version of the problem hints at a solution. The answer to the problem of scope lies not in the senses alone, but in our capacity to link sensory data to scientific models and thereby to mathematics. The possibility of discovering or constructing advanced mathematical structures cannot have evolved *as such*. Our remote ancestors are unlikely to have left significantly more offspring on the basis of abilities that could only have been manifested in the past two thousand years. The capacity to think about higher mathematics has to be what Gould called a spandrel or an exaptation (Gould and Lewontin 1979). But then what Eugene Wigner has called “the unreasonable effectiveness of mathematics in the natural sciences” (Wigner 1960) becomes a telling piece of evidence. The success of mathematics in solving problems that have nothing to do with immediate survival, coupled with its applicability in the construction of entirely new technological devices, affords credible support for the view that mathematical inference gives us some access to an objective world. Mathematics and science, however, do not (despite an apparent exception taken up in the next section) progress far without language. This leaves us free to suppose that while our prelinguistic ancestors and cousins mastered an abundance of modular inferences based on analogue computation and applicable in specific domains, they could not mani-

pulate topic-neutral abstractions embodied in digital systems of representation.

That the first track deals in analogue computing, while the second track is the domain of digital representation is strikingly confirmed by work on non verbal counting and calculation in animals and infants, which suggests that animals are capable of primitive forms of ordering, adding, subtracting, and even some forms of multiplication and division (Gallistel and Gelman 2000; Gelman and Cordes 2001). Unsurprisingly, however, there is no evidence for a prelinguistic domain-neutral representation system.

The topic-neutrality of language does not solve the problem of scope. It tells us nothing about the completeness of the potential knowledge to which we could give linguistic expression. The mysterians might still be right about the ultimate limits of knowledge.⁶ But it does lead us to expect a dichotomy between the range of problems that can be expressed and solved in the explicit language of science and mathematics, and those that are best approached in terms of the “intuitive” methods of Track One. The problem of the role of emotions in reasoning is particularly acute here, because it is obviously at the level most relevant to the activities and needs of our ancestors in the environment of evolutionary adaptation (EEA) that emotions are most likely to have preempted, or set up effective precursors to, explicit rational thought. As triggers to fast, prereflective and relatively organized responses to urgent situations, emotions are most likely to be involved in the inferential and decision-making shortcuts that were, at least in the EEA, highly cost-effective if not always such as to guarantee correct answers. That would place them in the domain of Track One. By the same token, emotions are notoriously likely to block rational analysis. They can get in the way of the sort of calculation that might be required to devise more elaborate solutions to problems different in nature from those typically encountered in their contexts of adaptation. By contrast, Antonio Damasio (1999) has described neurological evidence that brain lesions in the frontal lobes, by affecting patients’ capacity for normal emotional responses, result in profound disruptions of practical rationality even while leaving unimpaired the ability to solve Track Two problems on the analytical and verbal level. Just why that is, Damasio leaves unclear; but we can speculate that the emotions are crucial to rational decision making in several ways. They routinely control the agenda of practical reasoning by modifying the salience of different aspects of

life situations; they narrow down to manageable size the unmanageable vastness of our options at any given moment of choice; and they may incline us to one side or another of alternatives that promise comparable expected utilities but different levels of risk (de Sousa 1987). They may also be essential to our ability to commit ourselves to stick with policies that affect our long-term interests (Ainslie 2001). Furthermore, specifically “epistemic” emotions such as wonder, doubt, curiosity, surprise, or the “feeling of rightness” spur the quest for analytic rigor typical of Track two processing.

It is in that light, I suggest, that we should view the “rationality wars” that have opposed, in recent decades, “pessimists” against “Panglossians” about human rationality. These terms are those of Keith Stanovich (2004). Among the pessimists are the contributors (Kahneman, Slovic, and Tversky 1982), who take themselves to have demonstrated a number of ways in which human reasoning is systematically flawed. The best-known Panglossians are the contributors to Gigerenzer, Todd, and ABC Research Group (1999) and Gigerenzer and Selten (2001), who argue that the examples exploited by Tversky, Kahneman, and their colleagues are either artifacts of misleading test conditions, or instances of “fast and frugal” strategies, fine-tuned by natural selection, which are actually superior to those methods thought by the pessimists to embody rational thought.⁷ Against both, Stanovich presents himself as a “meliorist,” advocating an acknowledgment of the shortcomings of ancient and particularly of nonverbal strategies of decision and reasoning, followed by the careful cultivation of improved methods of explicit reasoning that take advantage of the sophisticated language developed for logic, mathematics, and science. This approach is grounded in the acknowledgment of our two-track minds. But the meliorist attitude mustn’t be interpreted as placing emotions exclusively in the first track, nor as requiring that they should play no role in reasoning. On the contrary, that role is deep and pervasive, and by no means limited to the preverbal strategies that might have been selected for us in the course of the EEA.

The difficulty most subjects have in solving abstract word problems such as the Wason test is slight compared to those observed long ago by Aleksander Luriia in conversations with illiterate Russian peasants. What impeded his subjects from performing simple Modus Ponens seemed to be an inability to focus on just the suppositions embodied in the premises of an argument. They always brought more information to the

problem than was contained in the problem they were asked to consider. This prevented them from marshaling the information expressed in the premise of the argument. When presented with *There are no camels in Germany; The city of B. is in Germany, Are there camels there or not?* some subjects reasoned that there probably were camels there if B was a large city, and if not, it was because it was too crowded. When asked for what “didn’t belong,” or was “not alike” in the list of words *saw, hammer, hatchet, and log*, one response was: “They all work together and chop the log.” When Luriia persisted in trying to get them to attend to the fact that all except logs can be called “tools,” the informant replies:

Yes, you could, except a log isn’t a tool. Still, the way we look at it, the log has to be here. Otherwise, what good are the others?⁸

Luriia noted that his informants were apparently incapable of repeating the problems put to them. And yet, as Wilson (unpublished) comments:

An untutored peasant will be perfectly clear in practice that if milk is healthy for humans and this is milk it is healthy for humans, and that if something looks like ordinary milk but is fatal to humans it is not ordinary milk. But she may not be able to repeat the corresponding syllogism or to draw the right inference on command.

It seems that the problems, when stated in words, trigger neither verbal schemata nor situational ones. Luriia’s account doesn’t allow us to judge whether emotions play a role in these difficulties; but it seems to me that it does suggest the power of what (Lakoff 2002) calls “frames” and I have called “paradigm scenarios”: Basic narratives reminiscent of situations and responses experienced in early age, that remain significant in someone’s life, and that typically evoke tendencies to specific sequences of action. The triggering of such a scenario seems to me sufficient, in many circumstances, to warrant speaking of emotion. But it is not entirely clear whether the triggering of such a frame or scenario should be construed as necessarily involving an emotion or not.

Six Paradigms

To try to cast a little light on this question, I shall presently turn to five examples of reasoning or inference in which emotion is somehow involved, but where its exact role is hard to define. They are cases where we can observe, if

not quite understand, the role that subpersonal factors, including chemical agents commonly implicated in emotional states, affect in a surprisingly direct way what we would otherwise regard as inferences driven solely by considerations of validity or evidence. But first, a reminder that nonverbal proto-reasoning is ubiquitous, but that in many forms it needn't involve emotion in any way.

Animal Computation

In the sort of skilled physical activity that we share with other animals, subpersonal computation plays an indispensable role. This does not explicitly involve emotions. A cartoon by Harry Hargreaves, published in *Punch* in 1960, summed this up rather well. A kingfisher looks down at a fish in the water, and the caption records its thoughts: "target in sector 3; speed, 2 knots; angle of deflection, 25°. . . . Who'd be a kingfisher?" Apart from the explicit form of the bird's thought, Hargreaves's cartoon is highly realistic about animals' powers of computation. Studies of ant navigation show that desert ants track their distance from home by means of some sophisticated way of measuring the horizontal ground distance they have traveled even when their actual path involved a hilly journey of greater absolute length (Wohlge-muth, Ronacher, and Wehner 2001). Pharaoh ants appear equally ingenious in their method of reorienting themselves to their nests. They rely on an ability to identify the angle of branching paths out from their nests, typically 60° when facing the nest, but 120° when going the other way (Jackson, Holcombe, and Ratnieks 2004). But such capacities are by no means confined to "lower" species. Humans playing tennis – or more exactly their brains – solve complicated and efficient Bayesian equations, involving both acquired expectations and fast updating of feedback information (Körding and Wolpert 2004). This is done at the subpersonal level, and achieves a precision that couldn't possibly be attained by anyone attempting to solve the problem explicitly without the aid of sophisticated computers. These cases illustrate First Track processing at its most impressive, involving neither explicit reasoning nor emotion, yet producing highly accurate results. Such feats make it irresistible to postulate sophisticated computing mechanisms working at the subpersonal level, deep beneath the level of any consciousness or explicit formulation.

Unlike these first examples, which are intended merely as reminders of the vast terrain of

subpersonal "inference" involved in the ordinary physical motions of humans and other animals, the next series of examples all involve emotion.

The Capgras Syndrome

The first involves the emotion of *feel of familiarity*, or rather a stubborn feeling of *unfamiliarity* that resists ordinary recognition. Typical patients afflicted with the Capgras syndrome persist in believing that a person close to them – wife, or father – is an impostor.⁹

According to Ramachandran, the best explanation for this strange disorder is that a direct link normally exists between the facial recognition mechanism and the areas controlling the appropriate emotional responses (particularly the amygdala). The sight of a close relative – a parent, in the case of Ramachandran's patient Arthur – normally triggers an affective response, which is itself subject to a "familiarity" evaluation. In Arthur's case, the direct link to the area in charge of generating the affective response is missing. As a result, the affective response to his father is not produced. This sets up an incongruity between the strictly cognitive familiarity check that applies to the face and the missing familiarity check applied to the expected affective response. The Capgras delusion can then be construed as the conclusion of a perfectly reasonable inference (though of course one that is neither conscious nor explicit): *I get a characteristic thrill when my father appears; I'm not getting that now; therefore the person before me is not my father. By contrast, he looks exactly like my father. Therefore he is an impostor, a stranger who looks just like my father.* This hypothesis is particularly neat in its capacity to explain why it is that the "impostor" delusion occurs only with persons to whom the person is close: typically parents or spouses. It doesn't occur with mere acquaintances, because in most cases of recognition a more or less indifferent emotional reaction is normal, not aberrant. (It also doesn't normally occur over the telephone, which doesn't implicate the same pathways of facial recognition.) If something like this is correct, it would imply that the emotional aspect of recognition is subject to an independent familiarity marker. Where the person recognized is both familiar and affectively significant, both markers are involved in the required ID check.

Two things are worth noting about this case. First, although we can make sense of it by construing it as a kind of inference, it is not experienced as an inference but as intuitive conviction. Second, while the "feeling of rightness" acts

as a marker, it doesn't present itself as a marker of correct inference *as such*. There are other cases, such as obsessive-compulsive disorder (OCD), however, where the feeling of rightness does just that.

Obsessive-Compulsive Disorder

OCD affects specifically not the sense of familiarity but the feeling of "rightness" itself. OCD may be seen as resulting from some sort of disconnection of the normal emotion of rightness in relation to recent memory of having taken necessary precautions. The relevant emotions here would be specifically *epistemic* emotions. As Chris Hookway has pointed out, epistemic emotions have been almost wholly neglected in the literature but constitute an extremely important aspect of our ability rationally to reason our way to new beliefs. If I didn't experience *doubt*, I wouldn't launch on an inquiry in the first place. If I didn't have the feeling of *rightness* about an inference, I wouldn't rely on it. If I didn't have the feeling of *conviction* about a conclusion, I wouldn't infer it (Hookway 1998). The patient suffering from OCD lacks some of those normal feelings. OCD has traditionally been taken to be a neurotic syndrome calling for psychoanalytic diagnosis and therapy. But the fact that some of these cases are apparently capable of clearing up under the influence of a targeted drug such as Prozac (Kramer 1993) suggests that this apparent complexity is an illusion. As in the case to which I turn in the next paragraph, it seems that the feeling of rightness is an emotion can be triggered or at least facilitated by a simple chemical agent, and in turn determine the presence or absence of conviction in a particular proposition.

The Chemistry of Trust

In a recent article in *Nature* widely reported in the press, researchers at the University of Zurich have shown that "intranasal administration of oxytocin, a neuropeptide that plays a key role in social attachment and affiliation in non-human mammals, causes a substantial increase in trust among humans" (Kosfeld, Heinrichs, Zak et al. 2005). Their results also support the conclusion that "the effect of oxytocin on trust is not due to a general increase in the readiness to bear risks. On the contrary, oxytocin specifically affects an individual's willingness to accept social risks arising through interpersonal interactions" (ibid.). The experimental setup in each run of the experiment involved two subjects, an

"investor" and a "trustee." Both received twelve monetary units, and each unit invested by the investor was tripled by the experimenter. Thus if the investor handed over all of his twelve units, the trustee now had forty-eight, comprising his original twelve plus the tripled investment. He could then return any amount to the investor.

Trust is a nice bridge emotion between the strictly epistemic and the strategic; for it inclines us to believe identifiable propositions – in this case, the proposition that investment in this particular trustee would prove profitable for the investor – but only in the context of a transaction envisaged with a person. A *specific* acceptance of *social* risk was ingeniously distinguished from a *generic* increase in risk tolerance. This was done by comparing the original setup with a situation in which the investor was told that a computer, not a person, would determine what return if any the investor would get. In that situation, the oxytocin had no significant effect. This seems to show that oxytocin didn't simply shift the estimate of risk down a notch; rather, it worked specifically on the emotional component of trust. Another significant control contrasted the effects of oxytocin on the investor with its effect on the trustee: The latter was nil. This showed that the causal factor responsible for the effect wasn't a general increase in benevolence or good feeling. For that would presumably also have led to larger returns from the trustees.

The authors note that there is substantial independent evidence "that oxytocin promotes prosocial approach behaviour by inhibiting defensive behaviours" (p. 675). In the light of this known effect of oxytocin on social approach in other mammals, they tend to minimize its specific effect on belief: "the investors given oxytocin show more trusting behaviour but do not hold significantly different beliefs about the trustworthiness of others." That is paradoxical, if we assume that in either case the behavior of the investor follows a roughly Bayesian strategy. It can be partly though not wholly explained, according to the authors, by appealing to an evaluative rather than a strictly cognitive appraisal: what the chemical has done is help the investors "overcome their betrayal aversion in social interactions." Still, the *consequence* of the diminished "betrayal aversion" is equivalent to a change in the probability measure of the expectation of return. So we have here a kind of primitive, purely causal case of direct biological influence over a process that is, we might

say, functionally equivalent to an inference, even though no explicit inference is made.

If we represent the process in question as a Bayesian calculation,

$$V = \sum_{i=1}^n (P_i \times V_i)$$

the fact that the estimate of risk [p] is not directly affected suggests that “betrayal anxiety” feeds into the desirability factor [v] rather than the probability estimate [p]. Yet there is no explicit inference. We have only the behavioral upshot to go on. So we can think of the emotion as feeding into the practical inference without necessarily assuming that such an “inference” can, like an explicit Bayesian argument, be split into “belief” and “desire” components. Insofar as the Bayesian model fits, however, emotion seems to be targeting the desirability rather than the belief component.

In any case, as might be expected, the effect of the oxytocin is not determining. It may contribute to a Svengali effect, but cannot guarantee its success and could hardly be credited with one all by itself. (Specifically, the median amount entrusted by investors who had absorbed oxytocin was 25 percent higher than those sprayed with a placebo.) So what needs to be made more precise is the nature of the relation between that sort of direct chemical influence on inference, on the one hand, and the influence that common sense attributes to other emotions in cases of bona fide valid inference, on the other.

Cognitive Foraging

One more illustration of the surprisingly direct influence of emotional chemistry on inference is worth noting. In a recent issue of *Nature*, Jonathan Cohen and Gary Aston-Jones (2005) look at some findings by Angela Yu and Peter Dayan (2005) on the application to science of the trade-off between exploration and exploitation. Exploitation of known resources is safe but likely to yield diminishing returns. By contrast, giving up well-trodden paths for the sake of exploration may yield a jackpot of discovery, but is inherently risky.

That trade-off is well known to students of foraging. An ant faced with an established path may either follow it, in the expectation of finding food where many others have already found it, or else strike out in an unexplored direction. The latter option is risky but will pay off, if not for the individual at least for the colony, when the

original sources of food are exhausted (Johnson 2003). This is a good example, then, of a mechanism first instantiated at the most basic level of foraging decisions. What is surprising is that it can be directly applied in the context of sophisticated scientific cognitive strategies, where it appears still to be controlled by a combination of chemical triggers.

Subjectively, the tension between the relative security of “normal science” and the excitement of a potentially fruitful paradigm shift is experienced as an urbane sort of struggle between fear and greed. What Yu and Dayan found is that the balance between the tendency to explore and the tendency to exploit in the cognitive domain are apparently regulated in part by specific neuromodulators, controlling, respectively, the kind of uncertainty that arises from the bearing of a signal and the kind of uncertainty that arises from the reliability of the signal:

Acetylcholine signals expected uncertainty, coming from known unreliability of predictive cues within a context. Norepinephrine signals unexpected uncertainty, as when unsignaled switches produce strongly unexpected observations. These uncertainty signals interact to enable optimal inference and learning in noisy and changeable environments. This formulation is consistent with a wealth of physiological, pharmacological, and behavioral data implicating acetylcholine and norepinephrine in specific aspects of a range of cognitive processes (Yu and Dayan 2005: 681).

They go on to remark that there seem to be “a class of attentional cueing tasks that involve both neuromodulators and shows how their interactions may be part-antagonistic, part-synergistic” (ibid.). And of course those sorts of situations are typically experienced, in humans, as giving rise to emotional states: the “fear” of risk; the “lure” of the unknown; the “disappointment” generated by scientific prospects that don’t pan out. What Yu and Dayan’s discovery seems to be telling us, is that a chemical mechanism underlies, in part, both the phenomenology of emotion and the process of what we assume to be high-level decision making. What they don’t tell us, which raises an intriguing question, is just what relationship there is between those two aspects of brain chemistry and their felt and functional consequences in the subjective experience of the quest for invention and discovery.

The Emotional Price of Nonconformism

In some famous experiments on the power of social conformism done in the 1950s, Solomon Asch had found that when asked to make a judgment of a visual quantity, some 40 percent of subjects went along with the false judgment of stooges posing as fellow subjects (Asch 1962). In a new variant on these experiments, a group of researchers explored “the potency of social pressure in inducing conformity, how information that originates from humans, versus inanimate sources, alters either perception or decision making and the neural basis for such changes” (Berns, Chappelow, Zink et al. 2005: 250). Here again, there are intriguing questions about the role of emotion, and about the precise locus of the inference to the wrong conclusion. Using fMRI data, Berns et al. found a “highly suggestive . . . lack of concomitant activity changes in more frontal areas,” where one might have expected activity if the subject’s judgment had resulted from a decision to override one’s own judgment in favour of that of the majority. The surprising aspect of their findings is that no special cognitive activity was detected in the cortex of those who conformed to others’ false opinion. Instead, “the effects of social conformity are exerted on the very same brain regions that perform the task.” In other words, far from being an inference required by the need to resolve cognitive dissonance (“So many others can’t be wrong, I must revise my verdict”), the influence of others’ judgments seems to act *directly on perception*. The distorting effect of conformity did not require any calculation of costs and benefits: it was those who saw and stood up for an independent truth who endured emotional cost. This finding is as intriguing as it is discouraging, for the emotions involved (though the authors make no attempt to pinpoint these in our repertoire of normal emotions) do not seem to be among those that we would spontaneously label “epistemic emotions.”

Skeptical Concluding Remarks

The mere activation of neuromodulating chemicals, as instantiated in the findings I have sketched, can’t be assimilated to the presence of an emotion. One reason for this is that emotions are phenomena that belong to the *personal* level; the activation of neuromodulators is a *subpersonal* phenomenon. Some of what we are learning about the involvement of specific parts or functions of the brain in reasoning, illustrated above, implicates just such subpersonal factors,

but it is not clear to what extent we are justified in inferring, from the fact that some of the same chemical factors are involved in emotion, that emotions, as commonly conceived, are involved in reasoning. Nevertheless, I shall risk some tentative answers to my leading questions.

1. WHAT KIND OF CONNECTION MIGHT THERE BE BETWEEN BIOLOGY AND RATIONALITY?

Social pressure alone won’t suffice to guarantee the normative correctness of our inclinations to draw inference. A sort of core of basic procedures – perhaps including *Modus Ponens* – had to be installed by natural selection, in the sense that we have a native disposition to effect transitions from one belief to another in accordance with such principles in specific domains. Thus far, only Track One processes need be involved. But when these transitions are codified by rules of language, logic, or mathematics, we can see them in their full generality as well as provide an explicit and conclusive argument for their validity. In practice, however, commonly used inference patterns do not necessarily become more reliable. The reason is that the fit between the “native” dispositions to acquire beliefs and their implementation in explicit language is not itself part of that system of mechanisms on which natural selection has put its certificate of warranty.

2. IS THERE NOT, IN THE VERY SUGGESTION THAT THERE MIGHT BE A CONNECTION BETWEEN LOGIC AND BIOLOGY, SOMETHING AKIN TO THE NATURALISTIC FALLACY?

There is a *prima facie* presumption of functionality to any heritable disposition the complexity of which makes it unlikely to be accidental. But it is crucial to remember that what’s been put in place by natural selection, however useful to our ancestors in the EEA, may be not be worthy now of any evaluative endorsement. Justification can’t be infallibly grounded. It has to run in circles, the capacity of which to inspire respect depends directly on their size. Ultimately, we trust our epistemic emotions to tell us when the circle is big enough for comfort. In that way, Track Two’s analytic mechanisms must submit to the judgment of emotions.

3. IF OUR CAPACITY FOR INFERENCE IS INDEED IN PART A FRUIT OF NATURAL SELECTION, ARE THERE SPECIFIC EMOTIONAL MECHANISMS THAT SERVE TO GUIDE OUR INFERENCE AT THE PROXIMATE LEVEL?

The surprising lesson to be learned from the samples that I have cited from recent

psychological and brain research is that in some cases a relatively abstract inference is triggered by what appears to be a fairly simple chemical agent. It would obviously be greatly exaggerated to conclude from the Zurich experiments that trust was simply triggered by oxytocin, or from those of Yu and Dayan that strategic research decisions were determined by noradrenaline. But these experiments are part of an accumulating body of evidence that suggests that emotional factors, more obviously linked to noncortical brain and hormonal activities, are important to our judgments of what inferences are or are not acceptable.

4. WHAT IS THE CONNECTION BETWEEN THOSE MEANS BY WHICH OUR INFERENCES ARE POLICED BY EMOTIONS, AND THE FORMALISMS THAT GUIDE OUR MOST CAREFUL EXPLICIT INFERENCES IN SCIENCE AND MATHEMATICS?

To answer this question, I have suggested that we must take seriously the two-track hypothesis: We are endowed with two only partly connected and sometimes conflicting levels of processing. Emotions are involved in both; and while it is not surprising to find their role in Track One processes closely tied to the effects of various subpersonal factors, including neuromodulators, what is more surprising is that such factors also appear to be implicated in Track Two reasoning.

In the final analysis, the increasing precision of our understanding of the brain mechanisms underlying the actual and the normatively correct practices studied by psychology and epistemology may blur the image I have sought to sketch. The idea that one should be able to distinguish specific contributions of emotion to inference, and indeed that there is always a clear answer to the question of what inferences have been drawn, presupposes that we can set out clear lines of demarcation between the mind's two tracks, between emotional and merely evaluative determinants of decision making, and between the influence that brain chemicals exert on reasoning and the effects they have on emotions. But the fine-grained picture, when it emerges, may overwrite the lines drawn in the sand by the presuppositions of our questions.

Notes

- 1 I am grateful to Julie Kirsch for this reference.
- 2 Ignore, in particular, the fact that the choice of a faith is not a binary one, so that whichever sect one joins, one risks the fate promised by all the others to those who deny the True Faith.

- 3 As the editors of this volume have pointed out to me, it could be claimed that the belief embedded in the higher level of caution need not be the falsehood that "this is a tiger," but the truth that "this is sufficiently tiger-like not to be worth the risk." But since the belief is bundled into the behavior, it's not clear what evidence could justify one attribution rather than the other. In any case, however the behavior is interpreted, the "better safe than sorry" policy, typically sacrifices high expected utility for a drastic reduction of risk. In the perspective of evolution, that makes it, by definition, a losing strategy in the long run.
- 4 These two patterns are not necessarily on a par as a matter of psychological fact. The point made here, like the point made in the *Meno*, holds a priori: It is that unless some patterns of transition are built into the architecture of the brain, no process of reasoning can get going. What those patterns are is an empirical question: In theory – and sometimes in practice – they might include *believe what you are told*.
- 5 Intriguingly, this mistake is more common among mathematicians, who are much less likely to make the mistake often made by other subjects, which is to turn over both the D and the 3 (Inglis 2005).
- 6 My late Hegelian colleague Emil Fackenheim, puffing on his pipe in the Common Room in the days when North American philosophers were not yet not prosecuted for that egregious crime, once enunciated this Deep Thought: "The aim of philosophy is to find the limits of knowledge . . ." (puff) ". . . and then transcend them."
- 7 A recent best-selling book takes a similar line, although radically downplaying the role of emotion (Gladwell 2005).

Chapter 52: Distinct Brain Loci in Deductive versus Probabilistic Reasoning

DANIEL N. OSHERSON, DANIELA PERANI, STEFANO CAPPÀ,
TATIANA SCHNUR, FRANCO GRASSI, AND FERRUCCIO FAZIO

Introduction

Normative theories of reasoning distinguish two kinds of persuasive arguments depending on the inferential connection between premises and conclusion. If the truth of an argument's premises guarantee that of its conclusion, the argument is called *valid*, whereas if the premises merely enhance the plausibility of the conclusion, the argument is *probabilistically strong*. Human intuition about validity and probability is limited to inferences of moderate size and reveals systematic imperfections even when applied to simple cases. Nonetheless, starting from adolescence both forms of reasoning are recognizable approximations to their normative counterparts [3, 6, 11].

What is the psychological relation between deductive and probabilistic reasoning? One influential theory conceives both kinds of reasoning as involving the manipulation of 'mental models'. In this view, an argument is evaluated by constructing alternative models of its premises, where each model is a representation of potential circumstances that would render the premises true. The argument is then judged to be probabilistically strong in case a large proportion of the models generated for the premises render the conclusion true as well; the intuition of validity arises from the limiting case in which this proportion reaches one. Within epistemology, such an account of the relation between validity and probability was proposed by Wittgenstein [[41], §5.15], and followed up by de Finetti [9] and

others. A psychological version of the same idea has recently been proposed by Johnson-Laird [23], where it receives detailed and persuasive defense.¹ Moreover, the same theory has been claimed to predict right hemispheric predominance in the manipulation of mental models (see [24, 40]). Johnson-Laird writes: "The model theory also makes a critical prediction about the role of the cerebral hemispheres in reasoning. As Whitaker *et al.* [40] first pointed out, the construction of models is likely to depend on the right hemisphere". The mental models perspective on reasoning thus leads to the following theses:

- (1) The brain structures responsible for deductive and probabilistic reasoning are largely the same.
- (2) The brain structures responsible for deductive reasoning are predominantly right hemispheric.

Of course, it follows from identity theses (1) and (2) that:

- (3) The brain structures responsible for deductive and probabilistic reasoning are both predominantly right hemispheric.

Opposing theories conceive deduction as based on mental rules specific to logic [5] and thus envision no particular relation between deductive and probabilistic reasoning. Mental rules for

B was used for test, and thus evaluated on separate occasions for validity, probability and anomaly.

deduction are thought to analyze and transform certain kinds of linguistic structures, namely, the logical forms of sentences. Consequently, such theories would place deductive reasoning in areas involved with linguistic processing, thus principally in the left hemisphere.² It can thus be seen that rule theories suggest the following contrast with thesis (2):

- (4) The brain structures responsible for deductive reasoning are predominantly left hemispheric.

To clarify the empirical status of the foregoing claims, we used positron emission tomography (PET) to examine brain activation during three kinds of reasoning tasks. The three tasks will be called 'logic', 'probability' and 'meaning'. In the logic task, subjects were asked to distinguish valid from invalid arguments. Arguments in the probability and meaning tasks had the same layout as in the logic task, but none were valid. For probability, subjects were asked whether the conclusion had a greater chance of being true than false, supposing the truth of the premises. The meaning task required subjects to examine premises and conclusion individually and determine whether any had anomalous content; it served as a baseline condition since no more than sentence comprehension was involved. As explained below, stimulus presentation was arranged so that during PET scanning identical arguments were evaluated either for validity, probability or anomaly. Sample arguments are presented in Table 1.

Methods

Subjects

Ten right-handed males aged 21–25 years, and recruited from local universities, served as subjects. All claimed to have little or no training in formal logic. The protocol was approved by the Ethics Committee of the San Raffaele Hospital, where the experiment was performed. Subjects provided written consent to participate.

Experimental Tasks

Each of the logic, probability and meaning tasks consisted of four arguments, the first two called 'warm-up', the last two 'test'. The warm-up arguments in a given task varied with respect to possession of the target property (validity, probability or anomaly), and differed across tasks. For example, the warm-up task for logic consisted of one valid and one invalid argument, ordered randomly. Validity is an objective property of arguments, so there was no difficulty distinguishing valid from invalid. Our choice of anomalous statements similarly left little doubt about how to characterize arguments along this dimension. On the other hand, probability is more subjective, so an attempt was made on purely intuitive grounds to select (invalid) arguments that varied in probability.

In contrast to warm-up, the test arguments for all three tasks were identical, namely, a pair of invalid arguments with no anomalous content. Thus, the mental activity required to solve test problems depended only on the kind of reasoning engaged, and practiced during warm-up; the stimuli were identical for the three tasks at the moment of data acquisition. We constructed two other sets of tasks of the same design, using different arguments. The three sets of stimuli yield nine tasks, namely, three each for logic, probability and meaning.

The procedure consisted of a 30-min training session followed by PET scanning within 24 hr. The training session explained the character of the three kinds of reasoning tasks, stated that all arguments concerned a small town in north-eastern Italy, and gave examples (no argument figuring in training appeared later among the experimental stimuli). For the PET session, the nine tasks were individually randomized for each subject with the constraint that successive tasks always differ (for example, two logic tasks could not be given successively). The four arguments

of a given task were presented sequentially, each for 25 sec with no interstimulus interval. They appeared in the center of a 36-cm video monitor placed 60 cm from the subject's eyes. Relevant instructions from the training session were repeated prior to each task in order to ensure that the subject evaluated the succeeding four arguments in terms of the appropriate distinction (valid/invalid, probable/improbable or anomalous/normal). Subjects studied each argument silently, and made no response during the 100 sec of the task. Warm-up stimuli were evaluated for the 50 sec prior to PET acquisition. Then, without alerting the subject, PET scanning began with the first test argument and continued for the 50 sec required to complete the task. The monitor was then blanked, and the subject closed his eyes for 20 sec (this allowed completion of PET acquisition). Subsequently, the four arguments of the task were re-presented and the subject was asked to indicate the evaluation he had made of each argument during its initial presentation. This part of the procedure lasted around 2 min, and was extended to a 10-min pause between tasks (thereby allowing radioactivity to decay to the baseline level).

PET Method and Data Analysis

Subjects were studied in the supine position using a PET tomograph GE-Advance (General Electric Medical System, Milwaukee, WI, U.S.A.) with collimating septa retracted [10]. The system has 18 rings allowing 35 transaxial images with a slice thickness of 4.25 mm, covering an axial field of view of 15.2 cm. Transmission data were acquired using a pair of rotating pin sources filled with ^{68}Ge (10mCi/pin). A filtered back-projection algorithm was employed for image reconstruction, on a 128×128 matrix with pixel size 1.9 mm, using a Hanning filter (cut-off 4 mm width) in the transaxial plane, and a ramp filter (cut-off 8.5 mm) in the axial direction. Regional cerebral blood flow (rCBF) was measured by recording the distribution of radioactivity following intravenous bolus injection of 5 mCi of $^{15}\text{O}\text{-H}_2\text{O}$ through a forearm cannula [15, 28]. The integrated counts, collected for 70 sec, starting 20 sec after injection, were used as an index of rCBF. Image manipulation and statistical analysis were performed in MATLAB 4.2 (Math Works, Natick, MA, U.S.A.) using statistical parametric mapping (SPM95, Wellcome Department of Cognitive Neurology, London, U.K.). Individual PET data were oriented along the intercommisural

line and transformed into a standard stereotactic space. Global differences in cerebral blood flow were covaried out for all voxels and comparisons across conditions were made using *t* statistics with appropriate linear contrasts, and then converted to Z-scores [17, 18]. Only regional activations significant at $P < 0.001$ (thresholding SPM $Z > 3.09$) were considered.

Results

Task Performance

We first consider whether subjects remained focussed on the tasks during PET scanning. The brief period allotted for the evaluation of arguments combined with the long inter-scan interval was expected to promote mental concentration during PET acquisition, and subjects subsequently reported no difficulty in this regard. The subjects' accurate performance on the logic arguments confirms the focussed character of their thought. They averaged 83% correct responses to the logic problems, with range 67–100%. This level of accuracy is equal to that of college students evaluating syllogisms without time stress [[34], pp. 232–234]. For the probability arguments there are no objectively correct answers. That the subjects were able to sustain their attention on the task is nonetheless suggested by their concordant judgment, reflected in a Kuder–Richardson reliability coefficient of 0.87. (Exactly half of the 12 arguments figuring in the probability tasks were judged 'probable' by a majority of subjects.)

PET Data Analysis

Table 2 reports the activation foci and the Z-scores found in the comparison between each experimental condition (logic and probability taken separately) versus the baseline meaning task. The table also shows the foci for the meaning task when compared to the two reasoning conditions pooled. The foci are identified via their stereotactic coordinates, measured in millimeters, relative to the anterior–posterior commissure, corresponding to the Talairach and Tournoux atlas [38].

Consider first the comparison with meaning when the logic and probability tasks are taken separately. We found common foci of activation in the left frontal mesial cortex (dorsal frontal gyrus, BA 6), right and left cerebellar hemisphere, and vermis. We also found common activations for the two reasoning tasks in subcortical

Table 2: Coordinates and Z-Scores for Regions Showing Differential Activation during Logical and Probabilistic Reasoning Compared to the Meaning Task

R sup. temporal gyrus (BA 22)	54	-2	0	3.49
R/L orbitofrontal cortex (BA 11)	0	40	-20	3.99

Coordinates are in millimeter relative to the anterior–posterior commissure, corresponding to the Talairach and Tournoux atlas [38]. SPM $P < 0.001$ throughout.

structures, namely, the left thalamus and right caudate. A distinctive focus of activation for the logic task was found in the left cuneus (BA 18), whereas a distinctive focus for probability appeared in the left anterior cingulate gyrus (BA 24/32).

Now let us consider the activation foci found for the meaning task when compared to the pooled data from the two experimental conditions. The comparison reveals bilateral foci of activation in the temporal poles (BA 38), inferior and middle temporal gyri (BA 20, 21), and in the orbital frontal cortex (BA 11). In addition, there were activations in the superior frontal (BA 9) and fusiform (BA 37) gyri of the left hemi-

sphere, and in the inferior frontal (BA 45, 47) and superior temporal (BA 22) gyri of the right hemisphere.

Table 3 shows the stereotactic coordinates and Z-scores of the activation foci found in direct comparisons of the two experimental conditions (logic and probabilistic reasoning). The same foci are shown in Figure 1. In probabilistic reasoning we found activations in the right insula and in the left prefrontal cortex, specifically, in the middle (BA 10) and the superior frontal (BA 8) gyri. In contrast, deductive reasoning activated the right anterior cingulate gyrus (BA 24/32) and a set of posterior brain regions, prevalently in the right hemisphere, namely: right

Table 3: Coordinates and Z-Scores for Regions Showing Differential Activation during Logical versus Probabilistic Reasoning

Region	Coordinates			Z-score

superior parietal lobule (BA 7), right superior and middle occipital gyri (BA 19), right thalamus, left and right precuneus (BA 7), and left cuneus (BA 18).³

Discussion

The principal result of this study is the difference in brain activity associated with probabilistic and deductive reasoning (Table 3). We discuss these differences first, and then turn to

the differences between the reasoning tasks and the baseline condition. When we write ‘X compared to Y’ we refer to the activation observed in the performance of task X that is observed at a significantly lower level in the performance of task Y.

Probability Compared to Deduction

Compared to deductive reasoning, the probability task produced activation in the left

Figure 1. Activation foci in the direct comparison of logic and probability tasks, superimposed over a magnetic resonance imaging atlas.

dorsolateral frontal cortex (BA 8 and 10), as well as in the right insular cortex. Studies with brain-damaged patients help to explain these findings, even though none appears to have considered probabilistic reasoning *per se*. In a study by Smith and Milner [37], 24 abstract figures were presented various numbers of times to patients with focal cortical ablations for treatment of epilepsy. The subjects were asked to estimate the frequency of appearance of each figure. Only patients with left or right mediolateral frontal corticectomy were impaired, while subjects with temporal and temporo-hippocampal lesions performed comparably to controls. Given that the frontal ablation patients performed normally in recognizing the figures, their disorder was considered to reflect an inability to estimate relative frequency. Since relative frequency is a principal source of information about probability [19], the frontal ablation patients can thus be considered impaired in at least one aspect of probabilistic thought. Another task that may be related to probabilistic reasoning is 'cognitive estimation'. It has been shown that, compared to retro-rolandic damage, frontal lesions on either side of the cortex disturb answers to questions such as 'how fast do race horses gallop?' [35]. In a related study of focal cortical ablations it was found that patients with dorsolateral frontal lesions made more errors in pricing objects (such as a car, a TV set, etc.) than patients with temporal and temporo-hippocampal lesions [36]. Both cognitive estimation and pricing require the selection of a value along a continuous dimension. Chance is likewise a continuous dimension, so determining the probability of a statement might require similar skills. Overall, the foregoing studies provide reason to believe that the dorsolateral frontal cortex is involved in the kind of judgment requested in our probability task.

Deduction Compared to Probability

The prevalent frontal pattern of activation found with probabilistic reasoning can be contrasted with the foci associated with deductive reasoning on identical arguments. For deductive reasoning, the activation was predominantly posterior and bilateral, with a right-side prevalence. There was involvement of the associative visual areas (cuneus, precuneus, middle and superior occipital gyri), as well as the right superior parietal lobule and thalamus. A considerable literature – involving both neuropsychological investigations [39] and PET procedures [8, 21, 22, 27] – implicates these areas in visuo-

spatial processing, including form discrimination and imaginative operations. A relationship between visuo-spatial operations and syllogistic reasoning is suggested by the fact that syllogistic reasoning protocols from naive subjects often involve spatial diagrams resembling Euler circles; the remaining subjects typically connect selected terms of the premises, often using arrows [14]. Both strategies have a geometrical character that would be expected to require visuo-spatial processing. Further evidence comes from clinical and PET studies of deductive reasoning involving spatial-relational terms, like 'taller than'. A study by Caramazza *et al.* [7] reported right brain-damaged, non-aphasic subjects to have difficulty with verbal reasoning tasks involving antonymic contrast ('taller than A but shorter than C'). The findings suggest reliance for such reasoning on visuo-imaginative strategies, involving the right hemisphere. A recent PET study using similar tasks showed significant activation of the right lateral and mesial parietal cortex during reasoning, compared to control conditions in which reasoning could not be initiated [2].

The only significant anterior activation found for logic compared to probability was in the right anterior cingulate cortex. The activation of this area has frequently been observed in PET experiments, and related to attentional processes, in particular to selective or divided attention [8, 29]. In the work of Posner and Petersen [33], the anterior cingulate is conceived as a component of the 'anterior attentional system', devoted to executive control. One aspect of this control function is thought to be the integration of linguistic and spatial processing [32]. Its relative increase in activation during deductive reasoning could thus be due to the greater involvement of spatial processing in logic compared to probability (both tasks obviously presuppose a linguistic component).

The comparisons discussed to this point allow tentative evaluation of the theses formulated in the introductory section. Our data cast doubt on thesis (1), and favor thesis (2) over thesis (4). In other words, the brain structures responsible for deductive and probabilistic reasoning appear to be substantially distinct; moreover, deductive reasoning activates sites predominantly in the right rather than left hemisphere.

Reasoning Compared to Anomaly Detection

Comparison of each reasoning task with the baseline condition (requiring only reading for meaning) revealed common activation in the left

medial frontal cortex (area 6), the cerebellum and in several subcortical structures. Cerebellar activation was particularly extensive. The foregoing structures have been shown to be activated in verbal working memory tasks [12, 30], and are considered to reflect articulatory rehearsal [1]. Cerebellar activation has also been implicated in the manipulation of transient, non-verbal information [26].

The activation of the foregoing structures is consistent with the character of our two reasoning tasks, which require the integration of information in separate premises, and thus probably entail continuous rehearsal of sentences. Indeed, the role of working memory in syllogistic reasoning has been documented via an interference paradigm [20]. In contrast, the meaning task can be performed without integrating information across sentences, since each sentence may be examined separately for anomaly. It is thus likely that the meaning task requires no verbal rehearsal. The activation found in comparing the reasoning tasks with the baseline condition may therefore be explained in terms of the differential requirements for verbal rehearsal in reasoning compared to anomaly detection.

Anomaly Detection Compared to Reasoning

The reverse subtraction (reading for meaning vs reasoning) was associated with activation in a widespread network of cortical areas in both hemispheres. The areas of activation in the left hemisphere included most of the classical perisylvian language areas, as well as the temporal pole. These foci have been shown in PET studies to be involved in processing prose passages [13, 31]. Similar patterns of activation in homologous contralateral hemispheric areas have been reported for comprehending metaphors [4] and 'theory of mind' stories [13].

In summary, the present results suggest that reasoning about syllogisms engages distinct brain mechanisms, depending on the intention to evaluate them deductively versus probabilistically. Likewise, reading the same syllogisms merely for meaning involves a pattern of cortical activation distinct from that obtained during reasoning.

Notes

- 1 For algorithmic simulation of the mental steps presumed to underlie the construction of mental models, see [[25], p. 171 ff.].
- 2 Computer simulation of one version of a mental rule theory is provided in [[34], Ch. 3].

- 3 Principal component analysis [16] of the PET dataset yielded highly similar profiles between tasks belonging to the same kind of reasoning. In particular, the first component (45% of the variance) cleanly separates the neural sites subserving the six reasoning tasks (three each for logic and probability) from the sites subserving the three anomaly detection tasks. The second component (19% of the variance) separates the neural sites for probability from those for logic. This suggests uniform brain activation across each of the three tasks used to induce deductive reasoning, and similarly for probability and anomaly.

Chapter 53: *The Emotional Dog and Its Rational Tail: A Social Intuitionist Approach to Moral Judgment*

JONATHAN HAIDT

Julie and Mark are brother and sister. They are traveling together in France on summer vacation from college. One night they are staying alone in a cabin near the beach. They decide that it would be interesting and fun if they tried making love. At the very least it would be a new experience for each of them. Julie was already taking birth control pills, but Mark uses a condom too, just to be safe. They both enjoy making love, but they decide not to do it again. They keep that night as a special secret, which makes them feel even closer to each other. What do you think about that? Was it OK for them to make love?

Most people who hear the above story immediately say that it was wrong for the siblings to make love, and they then begin searching for reasons (Haidt, Bjorklund, & Murphy, 2000). They point out the dangers of inbreeding, only to remember that Julie and Mark used two forms of birth control. They argue that Julie and Mark will be hurt, perhaps emotionally, even though the story makes it clear that no harm befell them. Eventually, many people say something like, “I don’t know, I can’t explain it, I just know it’s wrong.” But what model of moral judgment allows a person to know that something is wrong without knowing why?

Moral psychology has long been dominated by rationalist models of moral judgment (Figure 1). Rationalist approaches in philosophy stress “the power of a priori reason to grasp substantial truths about the world” (Williams, 1967, p. 69). Rationalist approaches in moral psychology, by extension, say that moral knowledge and

moral judgment are reached primarily by a process of reasoning and reflection (Kohlberg, 1969; Piaget, 1932/1965; Turiel, 1983). Moral emotions such as sympathy may sometimes be inputs to the reasoning process, but moral emotions are not the direct causes of moral judgments. In rationalist models, one briefly becomes a judge, weighing issues of harm, rights, justice, and fairness, before passing judgment on Julie and Mark. If no condemning evidence is found, no condemnation is issued.

This article reviews evidence against rationalist models and proposes an alternative: the social intuitionist model (Figure 2). Intuitionism in philosophy refers to the view that there are moral truths and that when people grasp these truths they do so not by a process of ratiocination and reflection but rather by a process more akin to perception, in which one “just sees without argument that they are and must be true” (Harrison, 1967, p. 72). Thomas Jefferson’s declaration that certain truths are “self-evident” is an example of ethical intuitionism. Intuitionist approaches in moral psychology, by extension, say that moral intuitions (including moral emotions) come first and directly cause moral judgments (Haidt, 2003; Kagan, 1984; Shweder & Haidt, 1993; J. Q. Wilson, 1993). Moral intuition is a kind of cognition, but it is not a kind of reasoning.

The social part of the social intuitionist model proposes that moral judgment should be studied as an interpersonal process. Moral reasoning is usually an *ex post facto* process used to influence the intuitions (and hence judgments) of other people. In the social intuitionist model,

Figure 1. The rationalist model of moral judgment. Moral affects such as sympathy may sometimes be inputs to moral reasoning.

one feels a quick flash of revulsion at the thought of incest and one knows intuitively that something is wrong. Then, when faced with a social demand for a verbal justification, one becomes a lawyer trying to build a case rather than a judge searching for the truth. One puts forth argument after argument, never wavering in the conviction that Julie and Mark were wrong, even after one’s last argument has been shot down. In the social intuitionist model, it becomes plausible to say, “I don’t know, I can’t explain it, I just know it’s wrong.”

The article begins with a brief review of the history of rationalism in philosophy and psychology. It then describes the social intuitionist model and recent relevant findings from a variety of fields. These findings offer four reasons for doubting the causality of reasoning in moral judgment: (a) There are two cognitive processes at work – reasoning and intuition – and the reasoning process has been overemphasized; (b) reasoning is often motivated; (c) the reasoning process constructs post hoc justifications, yet we experience the illusion of objective reasoning;

and (d) moral action covaries with moral emotion more than with moral reasoning. Because much of this evidence is drawn from research outside of the domain of moral judgment, the social intuitionist model is presented here only as a plausible alternative approach to moral psychology, not as an established fact. The article therefore concludes with suggestions for future research and for ways of integrating the findings and insights of rationalism and intuitionism.

It must be stressed at the outset that the social intuitionist model is an antirationalist model only in one limited sense: It says that moral reasoning is rarely the direct cause of moral judgment. That is a descriptive claim, about how moral judgments are actually made. It is not a normative or prescriptive claim, about how moral judgments ought to be made. Baron (1998) has demonstrated that people following their moral intuitions often bring about nonoptimal or even disastrous consequences in matters of public policy, public health, and the tort system. A correct understanding of the intuitive basis of moral judgment may therefore be useful

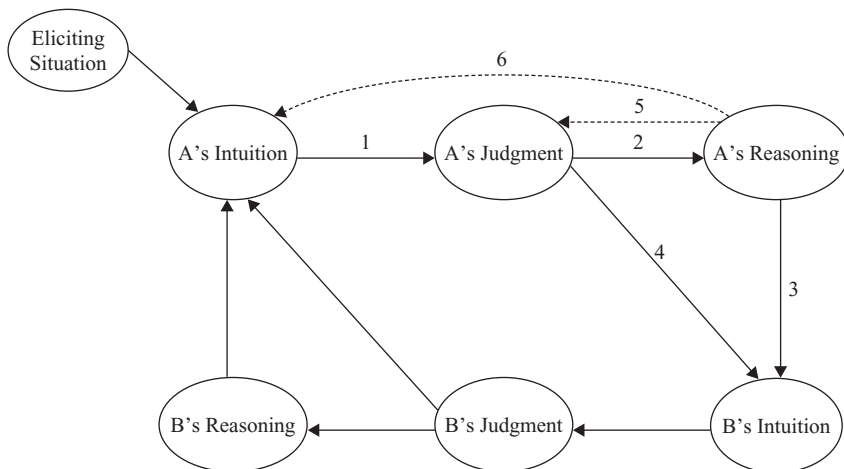

Figure 2. The social intuitionist model of moral judgment. The numbered links, drawn for Person A only, are (1) the intuitive judgment link, (2) the post hoc reasoning link, (3) the reasoned persuasion link, and (4) the social persuasion link. Two additional links are hypothesized to occur less frequently: (5) the reasoned judgment link and (6) the private reflection link.

in helping decision makers avoid mistakes and in helping educators design programs (and environments) to improve the quality of moral judgment and behavior.

Philosophy and the Worship of Reason

Philosophers have frequently written about the conflict between reason and emotion as a conflict between divinity and animality. Plato's *Timaeus* (4th century B.C./1949) presents a charming myth in which the gods first created human heads, with their divine cargo of reason, and then found themselves forced to create seething, passionate bodies to help the heads move around in the world. The drama of human moral life was the struggle of the heads to control the bodies by channeling the bodies' passions toward virtuous ends. The stoic philosophers took an even dimmer view of the emotions, seeing them as conceptual errors that bound one to the material world and therefore to a life of misery (R. C. Solomon, 1993). Medieval Christian philosophers similarly denigrated the emotions because of their link to desire and hence to sin. The 17th century's continental rationalists (e.g., Leibniz, Descartes) worshiped reason as much as Plato had, hoping to model all of philosophy on the deductive method developed by Euclid.

In the 18th century, however, English and Scottish philosophers (e.g., Shaftesbury, Hutcheson, Hume, and Smith) began discussing alternatives to rationalism. They argued that people have a built-in moral sense that creates pleasurable feelings of approval toward benevolent acts and corresponding feelings of disapproval toward evil and vice. David Hume in particular proposed that moral judgments are similar in form to aesthetic judgments: They are derived from sentiment, not reason, and we attain moral knowledge by an "immediate feeling and finer internal sense," not by a "chain of argument and induction" (Hume, 1777/1960, p. 2). His most radical statement of this position was that "we speak not strictly and philosophically when we talk of the combat of passion and of reason. Reason is, and ought only to be the slave of the passions, and can never pretend to any other office than to serve and obey them"¹ (Hume, 1739–1740/1969, p. 462).

The thrust of Hume's attack on rationalism was that reason alone cannot accomplish the magnificent role it has been given since Plato. Hume saw reason as a tool used by the mind to obtain and process information about events in the world or about relations among objects.

Reason can let us infer that a particular action will lead to the death of many innocent people, but unless we care about those people, unless we have some *sentiment* that values human life, reason alone cannot advise against taking the action. Hume argued that a person in full possession of reason yet lacking moral sentiment would have difficulty choosing any ends or goals to pursue and would look like what we now call a psychopath (Cleckley, 1955; Hume, 1777/1960).

Hume's emotivist approach to ethics was not well received by philosophers. Kant's (1785/1959) rationalist ethical theory² was created as an attempt to refute Hume, and Kant has had a much larger impact than Hume on modern moral philosophers (e.g., R. M. Hare, 1981; Rawls, 1971), many of whom have followed Kant in attempting to deduce a foundation for ethics from the meaning of rationality itself.

Psychology and the Focus on Reasoning

Psychologists, however, freed themselves from the worship of reason in the late 19th century, when they abandoned the armchair and went into the laboratory. Until the cognitive revolution of the 1960s, the major schools of psychology did not see reason as the master of anything, and their views on morality were compatible with Hume's emphasis on emotions. Freud (1900/1976) saw people's judgments as driven by unconscious motives and feelings, which are then rationalized with publicly acceptable reasons. The behaviorists also saw moral reasoning as epiphenomenal in the production of moral behavior, explaining morality as the acts that a society happens to reward or punish (Skinner, 1971).

Kohlberg and the Cognitive Revolution

But then came Lawrence Kohlberg. Kohlberg's work was a sustained attack on "irrational emotive theories" (1971, p. 188), and his cognitive-developmental theory was an important part of the cognitive revolution. Kohlberg built on Piaget's (1932/1965) pioneering work, developing an interviewing method that was suitable for use with adults as well as children. Kohlberg presented participants with dilemmas in which moral and nonmoral claims were present on both sides, and he then looked to see how people resolved the conflicts. In his best-known dilemma, a man named Heinz must decide whether he should break into a druggist's shop to steal a drug that may save the life of his dying

wife. Kohlberg found a six-level progression of increasing sophistication in how people handled such dilemmas. He claimed that children start as egoists, judging actions by the good or bad consequences they bring to the self, but as children's cognitive abilities expand they develop the ability to "role-take," or see a situation from other people's perspectives. The experience of role-taking drives the child on to the less egocentric and more powerful conventional and then post-conventional levels of moral reasoning.

Kohlberg's focus was on development, but he often addressed the question of mechanism. He consistently endorsed a rationalist and somewhat Platonic model in which affect may be taken into account by reason (as in Figure 1) but in which reasoning ultimately makes the decisions:

We are claiming... that the moral force in personality is cognitive. Affective forces are involved in moral decisions, but affect is neither moral nor immoral. When the affective arousal is channeled into moral directions, it is moral; when it is not so channeled, it is not. The moral channeling mechanisms themselves are cognitive. (Kohlberg, 1971, pp. 230–231)

Kohlberg was quite explicit that the cognitive mechanisms he discussed involved conscious, language-based thinking. He was interested in the phenomenology of moral reasoning, and he described one of the pillars of his approach as the assumption that "moral reasoning is the conscious process of using ordinary moral language" (Kohlberg, Levine, & Hewer, 1983, p. 69).

After Kohlberg

Kohlberg trained or inspired most of the leading researchers in moral psychology today (see chapters in Kurtines & Gewirtz, 1991; Lapsley, 1996). Rationalism still rules, and there appears to be a consensus that morality lives within the individual mind as a traitlike cognitive attainment, a set of knowledge structures about moral standards that children create for themselves in the course of their everyday reasoning (see Darley, 1993).

The social interactionist perspective (Nucci & Turiel, 1978; Turiel, 1983, 1998; Turiel, Killen, & Helwig, 1987), one of the most widely used approaches at present, can serve as an illustrative model. This research is based on a method developed by Nucci and Turiel (1978) in which children are interviewed about rule violations. After giving an initial judgment, the child is asked to

respond to a series of probe questions designed to assess how the child thinks about the rule in question (e.g., if there were no rule, would the action be OK? Could the rule be changed?). Participants are also asked to provide justifications of their judgments.

In the social interactionist model, people are said to think about the consequences of an action before determining whether the action is a moral violation. Actions that lead to injustice, to harm, or to the violation of rights are recognized as falling within the moral domain and are treated differently from other kinds of rule violations. Rules prohibiting moral violations are judged, even by young children, to be universally applicable and unalterable. Actions that involve no injustice, harm, or rights violations are treated as violations of social conventions (involving locally agreed on uniformities of behavior within social systems) or as personal issues (areas of individual prerogative).

Researchers in this tradition are sensitive to how moral development occurs in a social context, driven forward by children's interactions with peers in such contexts as taking turns, sharing, harming, and responding to harm. This emphasis on social interaction is in harmony with the social part of the social intuitionist model and is not a source of contention in the present article. The central source of contention, and the focus of the present article concerns the causal role of reflective, conscious reasoning.

Questioning the Causality of Reasoning

People undeniably engage in moral reasoning. But does the evidence really show that such reasoning is the cause, rather than the consequence, of moral judgment? Turiel, Hildebrandt, and Wainryb (1991) examined young adults' reasoning about issues of abortion, homosexuality, pornography, and incest. They found that people who judged the actions to be moral violations also talked about harmful consequences, whereas people who thought the actions were not wrong generally cited no harmful consequences. Turiel et al. (1991) interpreted these findings as showing the importance of "informational assumptions"; for example, people who thought that life begins at conception were generally opposed to abortion, whereas people who thought that life begins later were generally not opposed to abortion. In making this interpretation, however, Turiel et al. made a jump from correlation to causation. The correlation they found between judgment and supporting

belief does not necessarily mean that the belief caused the judgment. An intuitionist interpretation is just as plausible: The anti-abortion judgment (a gut feeling that abortion is bad) causes the belief that life begins at conception (an ex post facto rationalization of the gut feeling).

Haidt, Koller, and Dias (1993) found evidence for such an intuitionist interpretation. They examined American and Brazilian responses to actions that were offensive yet harmless, such as eating one's dead pet dog, cleaning one's toilet with the national flag, or eating a chicken carcass one has just used for masturbation. The stories were carefully constructed so that no plausible harm could be found, and most participants directly stated that nobody was hurt by the actions in question, yet participants still usually said the actions were wrong, and universally wrong. They frequently made statements such as, "It's just wrong to have sex with a chicken." Furthermore, their affective reactions to the stories (statements that it would bother them to witness the action) were better predictors of their moral judgments than were their claims about harmful consequences. Haidt and Hersh (2001) found the same thing when they interviewed conservatives and liberals about sexual morality issues, including homosexuality, incest, and unusual forms of masturbation. For both groups, affective reactions were good predictors of judgment, whereas perceptions of harmfulness were not. Haidt and Hersh also found that participants were often "morally dumbfounded" (Haidt et al., 2000); that is, they would stutter, laugh, and express surprise at their inability to find supporting reasons, yet they would not change their initial judgments of condemnation.

It seems, then, that for affectively charged events such as incest and other taboo violations, an intuitionist model may be more plausible than a rationalist model. But can an intuitionist model handle the entire range of moral judgment? Can it accommodate the findings from rationalist research programs while also explaining new phenomena and leading to new and testable predictions? The social intuitionist model may be able to do so.

The Social Intuitionist Model

The central claim of the social intuitionist model is that moral judgment is caused by quick moral intuitions and is followed (when needed) by

slow, ex post facto moral reasoning. Clear definitions of moral judgment, moral intuition, and moral reasoning are therefore needed.

Moral Judgment

Moral philosophers have long struggled to distinguish moral judgments from other kinds of judgments (e.g., aesthetics, skill, or personal taste). Rather than seeking a formal definition that lists the necessary and sufficient features of a moral judgment, the present article takes a more empirical approach, starting from a behavioral fact about human beings: that in every society, people talk about and evaluate the actions of other people, and these evaluations have consequences for future interactions (Boehm, 1999). Many of these evaluations occur against the backdrop of specific cultural practices, in which one praises or criticizes the skills or talents of an individual (e.g., "she is a daring chef"). However, an important subset of these evaluations are made with respect to virtues or goods that are applied to everyone in the society (e.g., fairness, honesty, or piety in some cultures), or to everyone in a certain social category (e.g., chastity for young women in some cultures or generosity for lineage heads). These virtues are obligatory in that everyone (within the relevant categories) is expected to strive to attain them. People who fail to embody these virtues or whose actions betray a lack of respect for them are subject to criticism, ostracism, or some other punishment. It is this subset of evaluations that is at issue in the present article. (For more on moral goods, see Ross, 1930; Shweder & Haidt, 1993.)

Moral judgments are therefore defined as evaluations (good vs. bad) of the actions or character of a person that are made with respect to a set of virtues held to be obligatory by a culture or subculture. This definition is left broad intentionally to allow a large gray area of marginally moral judgments. For example, "eating a low-fat diet" may not qualify as a moral virtue for most philosophers, yet in health-conscious subcultures, people who eat cheeseburgers and milkshakes are seen as morally inferior to those who eat salad and chicken (Stein & Nemeroff, 1995).

Moral Reasoning

Everyday moral reasoners are sometimes said to be like scientists, who learn by forming and testing hypotheses, who build working models of the social world as they interact with it, and

Table 1: General Features of the Two Systems

<i>The Intuitive System</i>	<i>The Reasoning System</i>
Fast and effortless	Slow and effortful
Process is unintentional and runs automatically	Process is intentional and controllable
Process is inaccessible; only results enter awareness	Process is consciously accessible and viewable
Does not demand attentional resources	Demands attentional resources, which are limited
Parallel distributed processing	Serial processing
Pattern matching; thought is metaphorical, holistic	Symbol manipulation; thought is truth preserving, analytical
Common to all mammals	Unique to humans over age 2 and perhaps some language-trained apes
Context dependent	Context independent
Platform dependent (depends on the brain and body that houses it)	Platform independent (the process can be transported to any rule following organism or machine)

Note. These contrasts are discussed in Bruner (1986), Chaiken (1980), Epstein (1994), Freud (1900/1976), Margolis (1987), Metcalfe and Mischel (1999), Petty and Cacioppo (1986), Posner and Snyder (1975), Pyszczynski and Greenberg (1987), Reber (1993), Wegner (1994), T. D. Wilson (2002), and Zajonc (1980).

who consult these models when making moral judgments (Turiel, 1983). A key feature of the scientist metaphor is that judgment is a kind of inference made in several steps. The reasoner searches for relevant evidence, weighs evidence, coordinates evidence with theories, and reaches a decision (Kuhn, 1989; Nisbett & Ross, 1980). Some of these steps may be performed unconsciously and any of the steps may be subject to biases and errors, but a key part of the definition of reasoning is that it has steps, at least a few of which are performed consciously. Galotti (1989), in her definition of everyday reasoning, specifically excludes “any one-step mental processes” such as sudden flashes of insight, gut reactions, or other forms of “momentary intuitive response” (p. 333).

Building on Galotti (1989), *moral reasoning* can now be defined as conscious mental activity that consists of transforming given information about people in order to reach a moral judgment. To say that moral reasoning is a conscious process means that the process is intentional, effortful, and controllable and that the reasoner is aware that it is going on (Bargh, 1994).

Moral Intuition

Commentators on intuition have generally stressed the fact that a judgment, solution, or other conclusion appears suddenly and effortlessly in consciousness, without any awareness by the person of the mental processes that led to the

outcome (Bastick, 1982; Simon, 1992). Bruner (1960) said that intuition does not advance in careful steps; rather, it involves “manoeuvres based seemingly on an implicit perception of the total problem. The thinker arrives at an answer, which may be right or wrong, with little if any awareness of the process by which he reached it” (p. 57). It must be stressed that the contrast of intuition and reasoning is not the contrast of emotion and cognition. Intuition, reasoning, and the appraisals contained in emotions (Frijda, 1986; Lazarus, 1991) are all forms of cognition. Rather, the words *intuition* and *reasoning* are intended to capture the contrast made by dozens of philosophers and psychologists between two kinds of cognition. The most important distinctions (see Table 1) are that intuition occurs quickly, effortlessly, and automatically, such that the outcome but not the process is accessible to consciousness, whereas reasoning occurs more slowly, requires some effort, and involves at least some steps that are accessible to consciousness.

Building on Bastick (1982), Bruner (1960), Simon (1992), and others, *moral intuition* can be defined as the sudden appearance in consciousness of a moral judgment, including an affective valence (good–bad, like–dislike), without any conscious awareness of having gone through steps of searching, weighing evidence, or inferring a conclusion. Moral intuition is therefore the psychological process that the Scottish philosophers talked about, a process akin to aesthetic

judgment: One sees or hears about a social event and one instantly feels approval or disapproval.

The Links in the Model

The social intuitionist model is composed of four principal links or processes, shown as solid arrows in Figure 2. The existence of each link is well established by prior research in some domains of judgment, although not necessarily in the domain of moral judgment. The model is therefore presented as a proposal to spur thinking and new research on moral judgment.

1. THE INTUITIVE JUDGMENT LINK

The model proposes that moral judgments appear in consciousness automatically and effortlessly as the result of moral intuitions. Examples of this link in nonmoral cognition include Zajonc's (1980) demonstrations that affectively valenced evaluations are made ubiquitously and rapidly, before any conscious processing has taken place. More recent examples include findings that much of social cognition operates automatically and implicitly (Bargh & Chartrand, 1999; Greenwald & Banaji, 1995).

2. THE POST HOC REASONING LINK

The model proposes that moral reasoning is an effortful process, engaged in after a moral judgment is made, in which a person searches for arguments that will support an already-made judgment. Nisbett and Wilson (1977) demonstrated such post hoc reasoning for causal explanations. Kuhn (1991), Kunda (1990), and Perkins, Farady, and Bushey (1991) found that everyday reasoning is heavily marred by the biased search only for reasons that support one's already-stated hypothesis.

3. THE REASONED PERSUASION LINK

The model proposes that moral reasoning is produced and sent forth verbally to justify one's already-made moral judgment to others. Such reasoning can sometimes affect other people, although moral discussions and arguments are notorious for the rarity with which persuasion takes place. Because moral positions always have an affective component to them, it is hypothesized that reasoned persuasion works not by providing logically compelling arguments but by triggering new affectively valenced intuitions in the listener. The importance of using affective persuasion to change affectively based attitudes has been demonstrated by Edwards and von Hippel (1995) and by Shavitt (1990).

4. THE SOCIAL PERSUASION LINK

Because people are highly attuned to the emergence of group norms, the model proposes that the mere fact that friends, allies, and acquaintances have made a moral judgment exerts a direct influence on others, even if no reasoned persuasion is used. Such social forces may elicit only outward conformity (Asch, 1956), but in many cases people's privately held judgments are directly shaped by the judgments of others (Berger & Luckman, 1967; Davis & Rus-bult, 2001; Newcomb, 1943; Sherif, 1935).

These four links form the core of the social intuitionist model. The core of the model gives moral reasoning a causal role in moral judgment but only when reasoning runs through other people. It is hypothesized that people rarely override their initial intuitive judgments just by reasoning privately to themselves because reasoning is rarely used to question one's own attitudes or beliefs (see the motivated reasoning problem, below).

However, people are capable of engaging in private moral reasoning, and many people can point to times in their lives when they changed their minds on a moral issue just from mulling the matter over by themselves. Although some of these cases may be illusions (see the post hoc reasoning problem, below), other cases may be real, particularly among philosophers, one of the few groups that has been found to reason well (Kuhn, 1991). The full social intuitionist model therefore includes two ways in which private reasoning can shape moral judgments.

5. THE REASONED JUDGMENT LINK

People may at times reason their way to a judgment by sheer force of logic, overriding their initial intuition. In such cases reasoning truly is causal and cannot be said to be the "slave of the passions." However, such reasoning is hypothesized to be rare, occurring primarily in cases in which the initial intuition is weak and processing capacity is high. In cases where the reasoned judgment conflicts with a strong intuitive judgment, a person usually has a "dual attitude" (T. D. Wilson, Lindsey, & Schooler, 2000) in which the reasoned judgment may be expressed verbally yet the intuitive judgment continues to exist under the surface.

6. THE PRIVATE REFLECTION LINK

In the course of thinking about a situation a person may spontaneously activate a new intuition that contradicts the initial intuitive judgment. The most widely discussed method

of triggering new intuitions is role-taking (Selman, 1971). Simply by putting oneself into the shoes of another person, one may instantly feel pain, sympathy, or other vicarious emotional responses. This is one of the principal pathways of moral reflection according to Piaget (1932/1965), Kohlberg (1969, 1971), and other cognitive developmentalists. A person comes to see an issue or dilemma from more than one side and thereby experiences multiple competing intuitions. The final judgment may be determined either by going with the strongest intuition or by allowing reason to choose among the alternatives on the basis of the conscious application of a rule or principle. This pathway amounts to having an inner dialogue with oneself (Tappan, 1997), obviating the need for a discourse partner.

Rationalist models focus on Links 5 and 6. In the social intuitionist model, in contrast, moral judgment consists primarily of Links 1–4, although the model allows that Links 5 and 6 may sometimes contribute (such as during a formal moral judgment interview). The next section of this article reviews four problems for rationalist models. For each problem, a social intuitionist reinterpretation of the evidence is offered, relying primarily on Links 1–4.

Four Reasons to Doubt the Causal Importance of Reason

1. *The Dual Process Problem: There Is a Ubiquitous and Under-studied Intuitive Process at Work*

It is now widely accepted in social and cognitive psychology that two processing systems are often at work when a person makes judgments or solves problems (see Table 1; see also Chaiken & Trope, 1999). Because these two systems typically run in parallel and are capable of reaching differing conclusions, these models are usually called *dual process* models. Dual process models have thus far had little impact on moral judgment research because most researchers have focused their efforts on understanding the reasoning process (but see Eisenberg, Shea, Carlo, & Knight, 1991; Gibbs, 1991). There is evidence, however, that moral judgment works like other kinds of judgment, in which most of the action is in the intuitive process.

AUTOMATIC EVALUATION

Affective evaluation occurs so quickly, automatically, and pervasively that it is generally

thought to be an integral part of perception. Zajonc (1980) synthesized findings from a variety of fields to create a modern version of Wundt's (1897/1969) affective primacy theory, in which he argued that feeling and thought are to some extent separate systems with separate biological bases. The affective system has primacy in every sense: It came first in phylogeny, it emerges first in ontogeny, it is triggered more quickly in real-time judgments, and it is more powerful and irrevocable when the two systems yield conflicting judgments (see also Reber, 1993). Research on the automatic evaluation effect confirms that very brief or even subliminal presentations of affectively valenced words (Bargh, Chaiken, Raymond, & Hymes, 1996; Fazio, Sanbonmatsu, Powell, & Kardes, 1986), facial expressions (Murphy & Zajonc, 1993), and photographs of people and animals (Hermans, De Houwer, & Eelen, 1994) alter the time it takes to evaluate a target object presented immediately afterward, indicating that affective processing is at work within a quarter second of stimulus presentation.

AUTOMATIC MORAL JUDGMENT

Moral judgments typically involve more complex social stimuli than the simple words and visual objects used in automatic evaluation studies. Could moral judgments be made automatically as well? The emerging view in social cognition is that *most* of our behaviors and judgments are in fact made automatically (i.e., without intention, effort, or awareness of process; Bargh, 1994; Bargh & Chartrand, 1999; Greenwald & Banaji, 1995).

The literature most relevant to moral judgment is the literature on attitudes, where a central question has been how people form attitudes about other people. The evidence indicates that attitude formation is better described as a set of automatic processes than as a process of deliberation and reflection about the traits of a person. People form first impressions at first sight (Albright, Kenny, & Malloy, 1988), and the impressions that they form from observing a "thin slice" of behavior (as little as 5 s) are almost identical to the impressions they form from much longer and more leisurely observation and deliberation (Ambady & Rosenthal, 1992). These first impressions alter subsequent evaluations, creating a halo effect (Thorndike, 1920), in which positive evaluations of non-moral traits such as attractiveness lead to beliefs that a person possesses corresponding moral traits such as kindness and good character (Dion,

Berscheid, & Walster, 1972). People also categorize other people instantly and automatically, applying stereotypes that often include morally evaluated traits (e.g., aggressiveness for African Americans; Devine, 1989). All of these findings illustrate the operation of the intuitive judgment link (Link 1 in Figure 2), in which the perception of a person or an event leads instantly and automatically to a moral judgment without any conscious reflection or reasoning.

Another illustration of automatic moral judgment can be seen in the literature on persuasion. Moral discourse in its natural setting is often a kind of persuasion, in which one person tells others about an event and tries to recruit them to her reading of the event. According to Chaiken's (1987) heuristic-systematic model of persuasion, people are guided in part by the "principle of least effort." Because people have limited cognitive resources, and because heuristic processing is easy and adequate for most tasks, heuristic processing (the intuitive process) is generally used unless there is a special need to engage in systematic processing (see also Simon, 1967). A particularly important heuristic for the study of moral judgment is the "I agree with people I like" heuristic (Chaiken, 1980). If your friend is telling you how Robert mistreated her, there is little need for you to think systematically about the good reasons Robert might have had. The mere fact that your friend has made a judgment affects your own intuitions directly, illustrating the social persuasion link (Link 4). Only if the agreement heuristic leads to other conflicts (e.g., if Robert is a friend of yours) will your sufficiency threshold be raised above your actual level of confidence, triggering effortful systematic processing (Links 5 and 6) to close the gap.

However, the social intuitionist model posits that moral reasoning is usually done interpersonally rather than privately. If Robert is in fact a friend of yours, then you and your friend might present arguments to each other (Link 3, the reasoned persuasion link) in the hope of triggering new intuitions, getting the other to see Robert's actions in a better or worse light. Moral discussions can then be modeled as a repeated cycle through Links 1, 2, and 3 in Person A, then in Person B, then in Person A, and so on. Link 4 would exert a constant pressure toward agreement if the two parties were friends and a constant pressure against agreement if the two parties disliked each other. If at least one of the parties began without a strong initial intuition, then some degree of convergence would be likely. Davis and Rusbult (2001) recently doc-

umented this convergence process, which they called *attitude alignment*. However, if both parties began with strongly felt opposing intuitions (as in a debate over abortion), then reasoned persuasion would be likely to have little effect, except that the post hoc reasoning triggered in the other person could lead to even greater disagreement, a process labeled "attitude polarization" by Lord, Ross, and Lepper (1979).

Petty and Cacioppo's (1986) elaboration-likelihood model gives a similar reading of the standard moral judgment discussion. If you feel a strong identification with the source of the persuasive message (your friend), and you have no conflict motivating elaborated thinking, then a peripheral process is sufficient to lead to an attitude shift, a judgment that Robert is evil. However, if the person talking to you is a stranger (a research psychologist) who challenges your judgment at every turn ("What if Heinz didn't love his wife, should he still steal the drug?"), then you will be forced to engage in extensive effortful, verbal, central processing. Standard moral judgment interviews may therefore create an unnaturally reasoned form of moral judgment, leading to the erroneous conclusion that moral judgment is primarily a reasoning process. Also, because forcing people to introspect to find reasons for their attitudes can change those attitudes temporarily (T. D. Wilson et al., 2000; T. D. Wilson & Schooler, 1991), standard moral judgment interviews might not even provide a valid measure of people's real moral beliefs. (See also Schooler, Fiore, & Brandimonte, 1997, on the impairments caused by forcing people to verbalize what they know intuitively.)

THE SOCIAL INTUITIONIST SOLUTION

The social intuitionist model is fully compatible with modern dual process theories. Like those theories, the model posits that the intuitive process is the default process, handling everyday moral judgments in a rapid, easy, and holistic way. It is primarily when intuitions conflict, or when the social situation demands thorough examination of all facets of a scenario, that the reasoning process is called upon. Reasoning can occur privately (Links 5 and 6), and such solitary moral reasoning may be common among philosophers and among those who have a high need for cognition (Cacioppo & Petty, 1982). Yet ever since Plato wrote his *Dialogues*, philosophers have recognized that moral reasoning naturally occurs in a social setting, between people who can challenge each other's arguments and trigger new intuitions (Links 3 and 4). The social

intuitionist model avoids the traditional focus on conscious private reasoning and draws attention to the role of moral intuitions, and of other people, in shaping moral judgments.

2. The Motivated Reasoning Problem: The Reasoning Process Is More Like a Lawyer Defending a Client Than a Judge or Scientist Seeking Truth

It appears, then, that a dual process model may be appropriate for a theory of moral judgment. If so, then the relationship between the two processes must be specified. Is the reasoning process the "smarter" but more cognitively expensive process, called in whenever the intuitive process is unable to solve a problem cheaply? Or is the relationship one of master and servant, as Hume suggested, in which reason's main job is to formulate arguments that support one's intuitive conclusions? Research on both motivated reasoning and everyday reasoning suggests that the post hoc reasoning link (Link 2) is more important than the reasoned judgment and private reflection links (Links 5 and 6).

Two major classes of motives have been shown to bias and direct reasoning. The first class can be called *relatedness motives*, for it includes concerns about impression management and smooth interaction with other people. The second class can be called *coherence motives*, for it includes a variety of defensive mechanisms triggered by cognitive dissonance and threats to the validity of one's cultural worldview.

RELATEDNESS MOTIVES

From an evolutionary perspective, it would be strange if our moral judgment machinery was designed principally for accuracy, with no concern for the disastrous effects of periodically siding with our enemies and against our friends. Studies of attitudes, person perception, and persuasion show that desires for harmony and agreement do indeed have strong biasing effects on judgments. Chaiken and her colleagues incorporated *impression motivation* into the heuristic-systematic model, which is described as "the desire to hold attitudes and beliefs that will satisfy current social goals" (Chen & Chaiken, 1999, p. 78). Chen, Shechter, and Chaiken (1996) found that people who expected to discuss an issue with a partner whose views were known expressed initial attitudes, before the interaction, that were shifted toward those of their anticipated partner. More broadly, Darley and Berscheid (1967) found that people rate a

description of a person's personality as more likable if they expect to interact with the person than if they do not expect to interact.

The existence of motivations to agree with our friends and allies means that we can be directly affected by their judgments (the social persuasion link). The mere fact that your friend expresses a moral judgment against X is often sufficient to cause in you a critical attitude toward X. Such direct influence, circumventing reasoning entirely, fits with Chartrand and Bargh's (1999) recent demonstration of the "chameleon effect," in which people unconsciously mimic the postures, mannerisms, and facial expressions of their interaction partners. Chartrand and Bargh found that such automatic mimicry is socially adaptive, for people who are "in sync" with another person are liked better by that person.

COHERENCE MOTIVES

Psychologists since Freud have argued that people construct views of themselves and of the world and that they experience potentially crippling anxiety when these constructions are threatened (Moskowitz, Skurnik, & Galinsky, 1999). Research on cognitive dissonance (Festinger, 1957; Wicklund & Brehm, 1976) showed just how readily people change their thinking and beliefs to avoid the threat of internal contradictions. More recently, Chaiken, Giner-Sorolla, and Chen (1996) defined *defense motivation* as "the desire to hold attitudes and beliefs that are congruent with existing self-definitional attitudes and beliefs" (p. 557). Self-definitional attitudes include values and moral commitments. When defense motivation is triggered, both heuristic and systematic thinking work to preserve self-definitional attitudes.

The biasing effects of defense motivation can be seen in studies that challenge participants' moral and political ideology. Lord et al. (1979) found that students with strong opinions about the death penalty, when exposed to research evidence on both sides of the issue, accepted evidence supporting their prior belief uncritically while subjecting opposing evidence to much greater scrutiny. Lerner's (1965) "just world" hypothesis stated that people have a need to believe that they live in a world where people generally get what they deserve. People who suffer for no reason are a threat to this belief, so participants adjusted their moral judgments, derogating or blaming innocent victims (Lerner & Miller, 1978). Tetlock, Kristel, Elson, Green, and Lerner (2000) found that people's willingness to

use relevant base-rate information, or to engage in counterfactual thinking, depended on whether or not their "sacred values" were threatened by doing so. In all of these examples, reasoning is used to defend prior moral commitments.

Moral judgments are also affected by the defensive motivations of terror management (S. Solomon, Greenberg, & Pyszczynski, 1991). When people are asked to think about their own deaths, they appear to suppress a generalized fear of mortality by clinging more tightly to their cultural worldview. Death-primed participants then shift their moral judgments to defend that worldview. They mete out harsher punishment to violators of cultural values, and they give bigger rewards to people who behaved morally (Rosenblatt, Greenberg, Solomon, Pyszczynski, & Lyon, 1989). Death-primed participants have more negative attitudes toward those who do not fully share their worldview (e.g., Jews; Greenberg et al., 1990). From a terror-management perspective, moral judgment is a special kind of judgment, because moral judgments always implicate the cultural worldview. It is plausible to say, "I don't like asparagus, but I don't care if you eat it." It is not plausible to say, "I think human life is sacred, but I don't care if you kill him."

MECHANISMS OF BIAS

Studies of everyday reasoning reveal the mechanisms by which relatedness and coherence motivations make people act like lawyers. Kuhn (1991) found that most people have difficulty understanding what evidence is, and when pressed to give evidence in support of their theories they generally give anecdotes or illustrative examples instead. Furthermore, people show a strong tendency to search for anecdotes and other "evidence" exclusively on their preferred side of an issue, a pattern that has been called the "my-side bias" (Baron, 1995; Perkins et al., 1991). Once people find supporting evidence, even a single piece of bad evidence, they often stop the search, since they have a "makes-sense epistemology" (Perkins, Allen, & Hafner, 1983) in which the goal of thinking is not to reach the most accurate conclusion but to find the first conclusion that hangs together well and that fits with one's important prior beliefs.

Research in social cognition also indicates that people often behave like "intuitive lawyers" rather than "intuitive scientists" (Baumeister & Newman, 1994). Kunda's (1990) review of "motivated reasoning" concludes that "directional goals" (motivations to reach a preor-

ained conclusion) work primarily by causing a biased search in memory for supporting evidence only. However, Pyszczynski and Greenberg (1987) proposed a more comprehensive "biased hypothesis testing" model, in which self-serving motives bias each stage of the hypothesis-testing sequence, including the selection of initial hypotheses, the generation of inferences, the search for evidence, the evaluation of evidence, and the amount of evidence needed before one is willing to make an inference. Research on the "confirmatory bias" (Snyder & Swan, 1978) shows that people do not always seek to confirm their initial hypothesis; sometimes they ask the right questions to get at the truth (Higgins & Bargh, 1987; Trope & Bassok, 1983). However, such demonstrations of truth seeking always involve hypotheses that the participant has no need to defend (e.g., "the person you are about to meet is an extrovert"). When hypotheses involve one's moral commitments (e.g., "the death penalty does not deter murder"), the empirical findings generally show bias and motivated reasoning (Kuhn, 1989; Lord et al., 1979).

This review is not intended to imply that people are stupid or irrational. It is intended to demonstrate that the roots of human intelligence, rationality, and ethical sophistication should not be sought in our ability to search for and evaluate evidence in an open and unbiased way. Rather than following the ancient Greeks in worshipping reason, we should instead look for the roots of human intelligence, rationality, and virtue in what the mind does best: perception, intuition, and other mental operations that are quick, effortless, and generally quite accurate (Gigerenzer & Goldstein, 1996; Margolis, 1987).

THE SOCIAL INTUITIONIST SOLUTION

The reasoning process in moral judgment may be capable of working objectively under very limited circumstances: when the person has adequate time and processing capacity, a motivation to be accurate, no a priori judgment to defend or justify, and when no relatedness or coherence motivations are triggered (Forgas, 1995; Wegner & Bargh, 1998). Such circumstances may be found in moral judgment studies using hypothetical and unemotional dilemmas. Rationalist research methods may therefore *create* an unusual and nonrepresentative kind of moral judgment. However, in real judgment situations, such as when people are gossiping or arguing, relatedness motives are always at work.

If more shocking or threatening issues are being judged, such as abortion, euthanasia, or consensual incest, then coherence motives also will be at work. Under these more realistic circumstances, moral reasoning is not left free to search for truth but is likely to be hired out like a lawyer by various motives, employed only to seek confirmation of preordained conclusions.

3. The Post Hoc Problem: The Reasoning Process Readily Constructs Justifications of Intuitive Judgments, Causing the Illusion of Objective Reasoning

When people are asked to explain the causes of their judgments and actions, they frequently cite factors that could not have mattered and fail to recognize factors that did matter. Nisbett and Schachter (1966), for example, asked participants to take electric shocks, either with or without a placebo pill that was said to produce the same symptoms as electric shock. Participants in the pill condition apparently attributed their heart palpitations and butterflies in the stomach to the pill and were able to take four times as much shock as those who had no such misattribution available for their symptoms. However, when the placebo condition participants were asked if they had made such an attribution, only 25% of them said that they had. The remaining participants denied that they had thought about the pill and instead made up a variety of explanations for their greater shock tolerance, such as, "Well, I used to build radios and stuff when I was 13 or 14, and maybe I got used to electric shock" (Nisbett & Wilson, 1977, p. 237).

Nisbett and Wilson (1977) interpreted such causal explanations as post hoc constructions. When asked to explain their behaviors, people engage in an effortful search that may feel like a kind of introspection. However, what people are searching for is not a memory of the actual cognitive processes that caused their behaviors, because these processes are not accessible to consciousness. Rather, people are searching for plausible theories about why they might have done what they did. People turn first to a "pool of culturally supplied explanations for behavior," which Nisbett and Wilson (1977) refer to as "a priori causal theories" (p. 248). When asked why he enjoyed a party, a person turns first to his cultural knowledge about why people enjoy parties, chooses a reason, and then searches for evidence that the reason was applicable. The search is likely to be a one-sided search of mem-

ory for supporting evidence only (Kunda, 1990; Pyszczynski & Greenberg, 1987).

Additional illustrations of post hoc causal reasoning can be found in studies in which hypnosis (Zimbardo, LaBerge, & Butler, 1993) and subliminal presentation (Kunst-Wilson & Zajonc, 1980) were used to make people perform actions. When asked to explain their actions or choices, people readily made up reasons that sounded plausible but were false. Split-brain patients show this effect in its most dramatic form. When the left hand, guided by the right brain, performs an action, the verbal centers in the left brain readily make up stories to explain it (Gazzaniga, Bogen, & Sperry, 1962). The language centers are so skilled at making up post hoc causal explanations that Gazzaniga (1985) speaks of an "interpreter" module. He argues that behavior is usually produced by mental modules to which consciousness has no access but that the interpreter module provides a running commentary anyway, constantly generating hypotheses to explain why the self might have performed any particular behavior.

POST HOC MORAL REASONING

The idea that people generate causal explanations out of a priori causal theories is easily extended into the moral domain. In a moral judgment interview, a participant is asked to decide whether an action is right or wrong and is then asked to explain why she thinks so. However, if people have no access to the processes behind their automatic initial evaluations then how do they go about providing justifications? They do so by consulting their a priori moral theories. *A priori moral theories* can be defined as a pool of culturally supplied norms for evaluating and criticizing the behavior of others. A priori moral theories provide acceptable reasons for praise and blame (e.g., "unprovoked harm is bad"; "people should strive to live up to God's commandments"). Because the justifications that people give are closely related to the moral judgments that they make, prior researchers have assumed that the justificatory reasons caused the judgments. But if people lack access to their automatic judgment processes then the reverse causal path becomes more plausible.

If this reverse path is common, then the enormous literature on moral reasoning can be reinterpreted as a kind of ethnography of the a priori moral theories held by various communities³ and age groups. Kohlberg's (1969) studies demonstrate that young children

in many cultures hold the a priori moral theory that “acts that get punished are wrong; acts that get rewarded are good” (Stages 1 and 2), but they soon advance to the theory that “acts that others approve of are good; acts that others condemn are bad” (Stage 3). If such statements were the rules that children really used to evaluate actions, then children at Stages 1 and 2 would conclude that actions that are not punished must not be bad, yet Turiel (1983) has shown that young children do not believe this. They say that harmful acts, such as hitting and pulling hair, are wrong whether they are punished or not. They even say that such acts would be wrong if adults ordered them to be done (Damon, 1977; Laupa & Turiel, 1986). Thus, when a child offers the Stage 1 statement that “it’s wrong because she’ll get punished,” the child is not introspecting on the reasoning that led to his condemnation; he is just giving a reason that sounds plausible, perhaps a reason he himself has heard from adults (“if you do that, I will punish you”).

THE ILLUSIONS OF MORAL JUDGMENT

If moral reasoning is generally a post hoc construction intended to justify automatic moral intuitions, then our moral life is plagued by two illusions. The first illusion can be called the *wag-the-dog illusion*: We believe that our own moral judgment (the dog) is driven by our own moral reasoning (the tail). The second illusion can be called the *wag-the-other-dog’s-tail illusion*: In a moral argument, we expect the successful rebuttal of an opponent’s arguments to change the opponent’s mind. Such a belief is like thinking that forcing a dog’s tail to wag by moving it with your hand will make the dog happy.

The wag-the-dog illusion follows directly from the mechanics of the reasoning process described above. Pyszczynski and Greenberg (1987) point out that by going through all the steps of hypothesis testing, even though every step can be biased by self-serving motivations, people can maintain an “illusion of objectivity” about the way they think. The wag-the-dog illusion may therefore be one of the mechanisms underlying naive realism (Griffin & Ross, 1991; Robinson, Keltner, Ward, & Ross, 1995), the finding that people think that they see the world as it is whereas their opponents in a moral dispute are biased by ideology and self-interest.

The bitterness, futility, and self-righteousness of most moral arguments can now be explicated. In a debate about abortion, politics, consensual incest, or what my friend did to your friend, both

sides believe that their positions are based on reasoning about the facts and issues involved (the wag-the-dog illusion). Both sides present what they take to be excellent arguments in support of their positions. Both sides expect the other side to be responsive to such reasons (the wag-the-other-dog’s-tail illusion). When the other side fails to be affected by such good reasons, each side concludes that the other side must be closed minded or insincere. In this way the culture wars over issues such as homosexuality and abortion can generate morally motivated players on both sides who believe that their opponents are not morally motivated (Haidt & Hersh, 2001; Roberson et al., 1995).

THE SOCIAL INTUITIONIST SOLUTION

People have quick and automatic moral intuitions, and when called on to justify these intuitions they generate post hoc justifications out of a priori moral theories. They do not realize that they are doing this, so they fall prey to two illusions. Moral arguments are therefore like shadow-boxing matches: Each contestant lands heavy blows to the opponent’s shadow, then wonders why she doesn’t fall down. Thus, moral reasoning may have little persuasive power in conflict situations, but the social intuitionist model says that moral reasoning can be effective in influencing people before a conflict arises. Words and ideas do affect friends, allies, and even strangers by means of the reasoned-persuasion link. If one can get the other person to see the issue in a new way, perhaps by reframing a problem to trigger new intuitions, then one can influence others with one’s words. Martin Luther King Jr.’s “I Have a Dream” speech was remarkably effective in this task, using metaphors and visual images more than propositional logic to get White Americans to see and thus feel that racial segregation was unjust and un-American (see Lakoff, 1996, on the role of metaphor in political persuasion).

4. The Action Problem: Moral Action Covaries with Moral Emotion More Than with Moral Reasoning

The analysis thus far has focused on moral judgment, not moral behavior, but the debate between rationalism and intuitionism can also be carried out using moral action as the dependent variable. There is a literature that directly examines the relationship between moral reasoning and moral action, and there is a literature that examines what happens when moral reasoning

and moral emotions become dissociated (in the case of psychopaths).

The weak link between moral reasoning and moral action. In a major review of the literature on moral cognition and action, Blasi (1980) concluded that "moral reasoning and moral action are statistically related" (p. 37). But what is the nature of this relationship? Blasi was careful to state that the connection between moral reasoning ability and moral behavior is only a correlation, although later authors in the cognitive developmental tradition read the relationship as causal, stating that higher levels of moral reasoning cause better moral behavior (e.g. Lapsley, 1996). Blasi's review, however, raised the possibility that a third variable caused both better reasoning and better behavior: intelligence. Blasi found that IQ was consistently related to honesty, and he concluded that future investigators must do a better job of controlling for IQ. Kohlberg (1969) reported that scores on his moral judgment interviews correlated with measures of IQ in the .30-.50 range. Rest (1979) reported correlations of .20-.50 between IQ and his Defining Issues Test (DIT).

Intelligence may also be related to better moral behavior by a pathway that does not run through better moral reasoning. Metcalfe and Mischel (1999) proposed a dual process model of willpower in which two separate but interacting systems govern human behavior in the face of temptation. The "hot" system is specialized for quick emotional processing and makes heavy use of amygdala-based memory. The "cool" system is specialized for complex spatiotemporal and episodic representation and thought. It relies on hippocampal memory and frontal lobe planning and inhibition areas. It can block the impulses of the hot system, but it develops later in life, making childhood and adolescence seem like a long struggle to overcome impulsiveness and gain self-control. This theory was proposed in part to explain the astonishing finding that the number of seconds preschoolers were able to delay choosing an immediate small reward (one marshmallow) in favor of a later, bigger reward (two marshmallows) was a powerful predictor of adolescent social and cognitive competence measured about 13 years later, including SAT scores and the ability to exert self-control in frustrating situations (Shoda, Mischel, & Peake, 1990).

The correlation that Blasi (1980) found between moral reasoning and moral behavior may therefore be explained by a third variable, the strength of the cool system. Children start off

with limited ability to resist temptation, but as the hippocampus and frontal cortex finish their development, children become more able to inhibit impulsive behaviors. Some children start off with a more effective cool system (Kochanska, Murray, Jacques, Koenig, & Vandegest, 1996) because of better or faster frontal cortex development. Frontal cortex development makes these children smarter, and they therefore perform better on measures of moral reasoning, but their improved moral behavior comes more from their greater self-regulatory abilities than from their greater moral reasoning abilities. The development of the cool system does not represent the triumph of reasoning over emotion; rather, Metcalfe and Mischel (1999, p. 16) see the successful development and integration of the cool system as an essential feature of emotional intelligence.

This reinterpretation is supported by the fact that moral reasoning ability, in Blasi's (1980) review, was most predictive of negative morality – refraining from delinquent behavior. Criminologists have consistently found an inverse relationship between criminality and IQ. Even after correcting for socioeconomic status, the difference between delinquent and nondelinquent adolescent populations is approximately 8 IQ points (Hirschi & Hindelang, 1977). However, the story for positive morality – directly helping others – is less clear. Blasi found some support for the claim that high scorers on Kohlberg's and Rest's scales were more likely to help other people, but more recent studies have raised doubts. Hart and Fegley (1995) and Colby and Damon (1992) both compared highly prosocial moral exemplars with nonexemplars and found that the groups did not differ in their moral reasoning ability assessed by Kohlbergian techniques. A recent review of evidence supporting the utility of the DIT described three studies that showed a relationship between DIT scores and negative moral behaviors but none showing a relationship between DIT scores and positive morality (Thoma, Narvaez, Rest, & Derryberry, 1999).

The relationship between moral reasoning ability and moral behavior therefore appears to be weak and inconsistent once intelligence is partialled out. Emotional and self-regulatory factors seem to be more powerful determinants of actual behavior (Mischel & Mischel, 1976).

THE STRONG LINK BETWEEN MORAL EMOTIONS AND MORAL ACTION

Further evidence that moral reasoning matters less than moral emotions comes from the

study of psychopaths. Cleckley's (1955) case studies present chilling portraits of people in whom reasoning has become dissociated from moral emotions. Cleckley characterizes psychopaths as having good intelligence and a lack of delusions or irrational thinking. Psychopaths know the rules of social behavior and they understand the harmful consequences of their actions for others. They simply do not care about those consequences. Cleckley's psychopaths show a general poverty of major affective reactions, particularly those that would be triggered by the suffering of others (remorse, sympathy), condemnation by others (shame, embarrassment), or attachment to others (love, grief). (See R. D. Hare, 1993, for a more recent discussion of the emotional deficit.) Psychopaths can steal from their friends, dismember live animals, and even murder their parents to collect insurance benefits without showing any trace of remorse or, when caught, of shame. The very existence of the psychopath illustrates Hume's statement that "'tis not contrary to reason to prefer the destruction of the whole world to the scratching of my little finger" (1739–1740/1969, p. 461). It is not contrary to reason to kill your parents for money unless it is also contrary to sentiment.

Several lines of research are converging on the conclusion that psychopaths and people with antisocial personality disorder differ from normal people in the operation of the frontal cortex. Mednick, Pollock, Volavka, and Gabrielli (1982) reviewed studies of electroencephalogram differences between criminals and noncriminals and concluded that the bulk of the research points to differences in the *anterior regions* of the *brain*. More recent studies using positron emission tomography techniques have narrowed the location of interest to the prefrontal cortex (Raine, 1997). Samples of aggressive offenders show reduced metabolic activity in this area, relative to controls (Raine et al., 1994).

The importance of the prefrontal cortex for moral behavior has been most fully explored by Damasio and his colleagues, who have found a consistent pattern of changes associated with damage to the ventromedial area of the prefrontal cortex (VMPFC, the area behind the bridge of the nose). Patients with damage restricted to the VMPFC show no reduction in their reasoning abilities. They retain full knowledge of moral rules and social conventions, and they show normal abilities to solve logic problems, financial problems, and even hypothetical moral dilemmas (Damasio, 1994). When faced with real decisions, however, they perform disas-

trously, showing poor judgment, indecisiveness, and what appears to be irrational behavior.

Damasio and his colleagues have demonstrated that the central deficit resulting from destruction of the VMPFC is the loss of emotional responsiveness to the world in general and to one's behavioral choices in particular. When shown pictures that arouse strong skin conductance responses in undamaged people (nudity, mutilation, people dying), individuals with VMPFC damage show no response (Damasio, Tranel, & Damasio, 1990), mirroring the lack of autonomic responsiveness of psychopaths (R. D. Hare & Quinn, 1971). The patients know that the images should affect them, but they report feeling nothing. Damasio refers to this pattern of affect loss combined with intact reasoning as "acquired sociopathy." Patients with acquired sociopathy do not generally become moral monsters, perhaps because they have a lifetime of normal emotional learning and habit formation behind them. They do, however, become much less concerned with following social norms, and they sometimes show outrageous and antisocial behavior, as in the case of Phineas Gage (Damasio, 1994). If we imagine a child growing up without a normal VMPFC, who never in his life felt the stings of shame and embarrassment or the pain of emotional loss or empathic distress, then it becomes almost possible to understand the otherwise incomprehensible behavior of Cleckley's psychopaths. With no moral sentiments to motivate and constrain them, they simply do not care about the pain they cause and the lives they ruin.⁴

EMOTIONS LEAD TO ALTRUISM

If reasoning ability is not sufficient to motivate moral action, then what is? Batson and his colleagues have developed the *empathy-altruism hypothesis*, which states that empathy aroused by the perception of someone's suffering evokes an altruistic motivation directed toward the ultimate goal of reducing the suffering (Batson, 1987; see also Hoffman, 1982). Batson, O'Quinn, Fultz, Vanderplass, and Isen (1983) found that participants who experienced empathy while watching a woman receiving (fake) electric shocks generally volunteered to take the shocks in her place, even when they were given the option of leaving the scene. Participants who experienced only nonempathic personal distress about the woman's plight volunteered to trade places with her only when they thought they would have to continue watching the woman receive the shocks. Participants in the first group

seemed to be genuinely motivated to help the distressed woman, not to relieve their own distress.

Cialdini and his colleagues have challenged the empathy–altruism hypothesis, using a variety of experimental designs to show that other motives can often explain seemingly altruistic behavior (Cialdini et al., 1987). Throughout this long debate, however, both sides have consistently agreed that people are often motivated to help others and that the mechanisms involved in this helping are primarily affective, including empathy as well as reflexive distress, sadness, guilt, and shame (Cialdini, 1991).

THE SOCIAL INTUITIONIST SOLUTION

It is easier to study verbal reasoning than it is to study emotions and intuitions, but reasoning may be the tail wagged by the dog. The dog itself may turn out to be moral intuitions and emotions such as empathy and love (for positive morality) and shame, guilt, and remorse, along with emotional self-regulation abilities (for negative morality; see Haidt, in press, for a review and taxonomy of the moral emotions). A dog's tail is worth studying because dogs use their tails so frequently for communication. Similarly, moral reasoning is worth studying because people use moral reasoning so frequently for communication. To really understand how human morality works, however, it may be advisable to shift attention away from the study of moral reasoning and toward the study of intuitive and emotional processes.

The Mechanism of Intuition

Because intuition is the heart of the social intuitionist model, more must be said about exactly how intuitive moral judgments are made (Link 1). Recent work on the importance of bodily experience, as represented in the mind, makes such an account possible.

Gut Feelings in the Mind

The somatic marker hypothesis (Damasio, 1994) states that experiences in the world normally trigger emotional experiences that involve bodily changes and feelings. Once the brain is properly tuned up by repeated experiences of such emotional conditioning (e.g., Pavlov, 1927), the brain areas that monitor these bodily changes begin to respond whenever a similar situation arises. It is then no longer necessary for the rest of the body to be involved. At that point, the mere

thought of a particular action becomes sufficient to trigger an “as if” response in the brain, in which the person experiences in a weaker form the same bodily feelings that she would experience if she performed the action. The critical job of the VMPFC is to integrate these feelings, or “somatic markers,” with the person's other knowledge and planning functions so that the brain can decide quickly on a response. Damasio's work fits well with research in social psychology on the “affect as information” hypothesis, which demonstrates that people frequently rely on their moods and momentary flashes of feeling as guides when making judgments and decisions (Clare, Schwarz, & Conway, 1994; Loewenstein, Weber, Hsee, & Welch, 2001; Schwarz & Clare, 1983; see also an fMRI finding that such flashes help explain people's varying responses to philosophical moral dilemmas in Greene, Sommerville, Nystrom, Darley, & Cohen, 2001).

Two recent studies have directly manipulated moral judgments by manipulating somatic markers. Batson, Engel, and Fridell (1999) used false physiological feedback to tell participants about their emotional reactions when listening to stories in which the values of either freedom or equality were threatened. When later asked to choose which value should be selected as a theme for a weeklong program of events at their university, participants were more likely to choose the value for which they thought they had shown a stronger visceral reaction. Wheatley and Haidt (2001) manipulated somatic markers even more directly. Highly hypnotizable participants were given the suggestion, under hypnosis, that they would feel a pang of disgust when they saw either the word *take* or the word *often*. Participants were then asked to read and make moral judgments about six stories that were designed to elicit mild to moderate disgust, each of which contained either the word *take* or the word *often*. Participants made higher ratings of both disgust and moral condemnation about the stories containing their hypnotic disgust word. This study was designed to directly manipulate the intuitive judgment link (Link 1), and it demonstrates that artificially increasing the strength of a gut feeling increases the strength of the resulting moral judgment.

Metaphor and Embodiment

Whereas Damasio focuses on the role of the autonomic nervous system in thinking, Lakoff and Johnson (1999; Lakoff, 1987) have shown how the entire range of physical and emotional

experience may underlie our “embodied cognition.” By analyzing how people think and talk about love, politics, morality, and other issues, they have shown that nearly all complex thought relies on metaphors, drawn mostly from our experience as physical creatures. For example, because we all have experience with foods that are easily contaminated, we come to equate purity and cleanliness with goodness in the physical domain. We learn from experience that pure substances are quickly contaminated (e.g., by mold, dust, or insects) when not guarded and that once contaminated, it is often difficult to purify them again. These experiences in the physical world then form the basis (in many cultures) of conceptual schemes about moral purity – for example, that children start off in a state of purity and innocence but can be corrupted by a single exposure to sex, violence, drugs, homosexuality, or the devil (Haidt, Rozin, McCauley, & Imada, 1997; Rozin, Haidt, & McCauley, 2000). Some losses of purity can be rectified with great difficulty (e.g., exorcism after exposure to the devil), and others cannot be rectified at all (e.g., the loss of virginity).

Moral intuition, then, appears to be the automatic output of an underlying, largely unconscious set of interlinked moral concepts. These concepts may have some innate basis (to be discussed shortly), which is then built up largely by metaphorical extensions from physical experience. Metaphors have entailments, and much of moral argument and persuasion involves trying to get the other person to apply the right metaphor. If Saddam Hussein is Hitler, it follows that he must be stopped. But if Iraq is Vietnam, it follows that the United States should not become involved (Spellman & Holyoak, 1992). Such arguments are indeed a form of reasoning, but they are reasons designed to trigger intuitions in the listener.

The Origin of Intuitions

Perhaps because moral norms vary by culture, class, and historical era, psychologists have generally assumed that morality is learned in childhood, and they have set out to discover how morality gets from outside the child to inside. The social intuitionist model takes a different view. It proposes that morality, like language, is a major evolutionary adaptation for an intensely social species, built into multiple regions of the brain and body, that is better described as emergent than as learned yet that requires input and shaping from a particular culture. Moral intu-

itions are therefore both innate and enculturated. The present section describes the ways in which moral intuitions are innate; the next section describes the ways in which they are shaped by culture during development.

Primate Protomorality

Darwin (1874/1998) believed that the human moral sense grew out of the social instincts of other animals, and modern primatological research supports him. All species can be said to follow *descriptive* rules for behavior with conspecifics, but it is primarily the primates that show signs of *prescriptive* rules, which de Waal (1991) defines as rules that individuals “have learned to respect because of active reinforcement by others” (p. 338). Chimpanzee groups develop and enforce norms for mating, for playing with or touching infants, and for many other forms of interaction. When one individual violates these norms, others will sometimes look to or even get the attention of the individual whose interests have been violated, who may then take action to punish the transgressor (de Waal, 1991). De Waal’s work indicates that prescriptive behavioral norms can emerge and be understood and enforced by chimpanzees without the benefit of language or language-based reasoning. Language may greatly increase the human use of norms, but the cognitive and emotional machinery of norm creation and norm enforcement was available long before language existed.

It appears, furthermore, that this machinery has been carried forward into the human mind. Alan Fiske (1991, 1992) has identified four underlying models of social cognition that seem to be at work in all human cultures. His first three models fit closely with descriptions of other primates. Fiske’s first model, *communal sharing*, involves the linkage of kindness, kinship, and empathic concern for close others that de Waal describes both for chimpanzees (de Waal, 1996) and for bonobos (de Waal & Lanting, 1997). Fiske’s second model, *authority ranking*, describes the ways that power and rank regulate access to resources but also obligate superiors to protect their subordinates. Such mutual obligations are clear among chimpanzees (de Waal, 1982; Goodall, 1986). Fiske’s third model, *equality matching*, involves the double-edged reciprocal altruism first described by Trivers (1971). Most apes and many monkeys seem remarkably adept at remembering and repaying both favors and slights (de Waal, 1982,

1996). The only model that seems to be uniquely human is Fiske's fourth model, *market pricing*, in which ratio values of goods and services must be computed and aggregated across transactions (Haslam, 1997). Given so many close parallels between the social lives of humans and chimpanzees, the burden of proof must fall on those who want to argue for discontinuity – that is, that human morality arose *ex nihilo* when we developed the ability to speak and reason.

The above considerations are not meant to imply that chimpanzees have morality or that humans are just chimps with post hoc reasoning skills. There is indeed a moral Rubicon that only *Homo sapiens* appears to have crossed: widespread third-party norm enforcement. Chimpanzee norms generally work at the level of private relationships, where the individual that has been harmed is the one that takes punitive action. Human societies, in contrast, are marked by a constant and vigorous discussion of norms and norm violators and by a willingness to expend individual or community resources to inflict punishment, even by those who were not harmed by the violator (Boehm, 1999). Dunbar (1996) has even proposed that language evolved primarily to fulfill the need for gossip. Only with language is it possible to keep track of who did what to whom, who is in, who is out, who can be trusted, and who should be avoided. Although the evolution of language and intelligence may have been driven by the Machiavellian benefits they gave to individuals (Byrne & Whiten, 1988), the combination of language and a full theory of mind (Premack & Premack, 1995) made it possible for large groups of non-kin to reap the benefits of cooperation by monitoring each other's behavior (with gossip), shunning or punishing cheaters, and rewarding team players.

The social intuitionist model fits with this view of the functions of language by including two interpersonal links. Once morality is located in a group's efforts to solve cooperation and commitment problems (Darwin, 1874/1998; Frank, 1988), it becomes clear that individuals must use language to influence others while simultaneously being at least somewhat open to interpersonal influence as specific norms, values, or judgments spread through a community. A group of judges independently seeking truth is unlikely to reach an effective consensus, but a group of people linked together in a large web of mutual influence (an extension of Figure 2 to multiple parties) may eventually settle into a stable configuration, in the same way that a connectionist

network reaches a stable equilibrium after several iterations.

The Externalization of Intuitions

If many moral intuitions (e.g., sympathy, reciprocity, and loyalty) are partially built in by evolution, then the most important developmental question about intuitions is not, "How do they get into the child?" but rather, "How do they get out?" Fiske (1991) argues that social development should be thought of partly as a process of *externalization*, in which innate cognitive models manifest themselves as a part of normal maturation. He reviews evidence (e.g., Damon, 1975) showing that the four models emerge during development in an invariant sequence: communal sharing in infancy, authority ranking by age 3, equality matching around age 4, and market pricing during middle or late childhood. This is the same sequence in which the models appear to have emerged phylogenetically in the mammalian and primate lineages.

The contrast between internalization and externalization is particularly clear for equality matching. Western parents often try to get their young children to share and to play fairly. If moral development were a matter of gradual internalization, or even of reward and punishment, then children's adherence to principles of fairness would show a gradual increase throughout early childhood. Instead, Fiske (1991) argues that children seem relatively insensitive to issues of fairness until around the age of 4, at which point concerns about fairness burst forth and are overgeneralized to social situations in which they were never encouraged and in which they are often inappropriate. This pattern of sudden similarly timed emergence with overgeneralization suggests the maturation of an endogenous ability rather than the learning of a set of cultural norms. Only after the cognitive model has externalized itself can it be shaped and refined by cultural norms about when and how it should be used.

The Development of Intuitions

Even if moral intuitions are partially innate, children somehow end up with a morality that is unique to their culture or group. There are at least three related processes by which cultures modify, enhance, or suppress the emergence of moral intuitions to create a specific morality: by selective loss, by immersion in custom complexes, and by peer socialization.

The Selective Loss of Intuitions

The acquisition of phonology provides a useful analogy for the acquisition of morality. Children are born with the ability to distinguish among hundreds of phonemes, but after a few years of exposure to a specific language they lose the ability to make some unexercised phoneme contrasts (Werker & Tees, 1984). Likewise, Ruth Benedict (1934/1959) suggested, we can imagine a great "arc of culture" on which are arrayed all the possible aspects of human functioning. "A culture that capitalized even a considerable proportion of these would be as unintelligible as a language that used all the clicks, all the glottal stops, all the labials" (Benedict, 1934/1959, p. 24).

Similarly, a culture that emphasized all of the moral intuitions that the human mind is prepared to experience would risk paralysis as every action triggered multiple conflicting intuitions. Cultures seem instead to specialize in a subset of human moral potential. For example, Shweder's theory of the "big three" moral ethics (Shweder, Much, Mahapatra, & Park, 1997; see also Jensen, 1997) proposes that moral "goods" (i.e., culturally shared beliefs about what is morally admirable and valuable) generally cluster into three complexes, or ethics, which cultures embrace to varying degrees: the ethic of autonomy (focusing on goods that protect the autonomous individual, such as rights, freedom of choice, and personal welfare), the ethic of community (focusing on goods that protect families, nations, and other collectivities, such as loyalty, duty, honor, respectfulness, modesty, and self-control), and the ethic of divinity (focusing on goods that protect the spiritual self, such as piety and physical and mental purity). A child is born prepared to develop moral intuitions in all three ethics, but her local cultural environment generally stresses only one or two of the ethics. Intuitions within culturally supported ethics become sharper and more chronically accessible (Higgins, 1996), whereas intuitions within unsupported ethics become weaker and less accessible. Such "maintenance-loss" models have been documented in other areas of human higher cognition. It seems to be a design feature of mammalian brains that much of neural development is "experience expectant" (Black, Jones, Nelson, & Greenough, 1998). That is, there are developmentally timed periods of high neural plasticity, as though the brain "expected" certain types of experience to be present at a certain time to guide its final wiring.

Such sensitive periods are well documented in the development of sensory systems (Hubel & Wiesel, 1970) and language (Johnson & Newport, 1989). Huttenlocher (1994) reports that most synapse selection and elimination in the human cerebral cortex occurs in the first few years but that in the prefrontal cortex the period of plasticity is greatly delayed. Synapse selection in the prefrontal cortex starts later, accelerates in late childhood, and then tails off in adolescence (see also Spear, 2000). Because the prefrontal cortex is the brain area most frequently implicated in moral judgment and behavior (Damasio et al., 1990; Raine, 1997), this suggests that if there is a sensitive period for moral learning it is likely to be later in childhood than psychoanalysts and most American parents suppose. But how exactly does a culture choose and emphasize a subset of the available intuitions?

Immersion in Custom Complexes

The *custom complex* has recently been proposed as the key construct for understanding development within a cultural context (Shweder et al., 1998). The custom complex was originally defined by Whiting and Child (1953) as consisting of "a customary practice and . . . the beliefs, values, sanctions, rules, motives and satisfactions associated with it" (p. 27). The custom complex captures the idea that cultural knowledge is far more than a set of inherited beliefs about the right and wrong ways of doing things. Cultural knowledge is a complex web of explicit and implicit, sensory and propositional, affective, cognitive, and motoric knowledge (D'Andrade, 1984; Shore, 1996).

Custom complexes are easily found in the moral socialization of children. For example, in Orissa, India, many spaces and objects are structured by rules of purity and pollution. Foreigners and dogs may be allowed near the entrance to a temple complex, but only worshipers who have properly bathed may be allowed into the central courtyard (Mahapatra, 1981). In the inner sanctum, where the deity sits, only the Brahmin priest is permitted to enter. Private homes have a similar structure, with zones of high purity (the kitchen and the room where the household deity is kept) and zones of lower purity. The human body has a similar structure, in which the head is the zone of highest purity and the feet are highly polluting.

Children in Orissa constantly encounter spaces and bodies structured by purity, and they learn to respect the dividing lines. They learn

when to remove their shoes and how to use their heads and feet in a symbolic language of deference (as when one touches one's head to the feet of a highly respected person). They develop an intuitive sense that purity and impurity must be kept apart. By participating in these interlinked custom complexes, an Oriya child's physical embodiment comes to include experiences of purity and pollution. When such children later encounter the intellectual content of the ethics of divinity (e.g., ideas of sacredness, asceticism, and transcendence), their minds and bodies are already prepared to accept these ideas, and their truth feels self-evident (see Lakoff, 1987).

American children, in contrast, are immersed in a different set of practices regarding space and the body, supported by a different ideology. When an American adult later travels in Orissa, he may know how rules of purity and pollution govern the use of space, but he knows these things only in a shallow, factual, consciously accessible way; he does not know these things in the deep cognitive, affective, motoric way that a properly enculturated Oriya knows them.

Fiske (1999) reviewed evidence in anthropology that children are taught surprisingly little in most cultures and that they acquire most of their cultural knowledge and expertise by observing and then imitating the practices of older children and adults (see also Bandura & Walters, 1963, on imitation and social learning). Fiske argued that anthropologists have generally underestimated the importance of motor schemas and implicit knowledge, relying instead on the verbal reports of informants as their primary source of ethnographic data. In other words, there is an asymmetry between how culture gets into children and how it gets out to anthropologists. Cultural knowledge gets in largely through nonverbal and nonconscious means, but it gets out through conscious verbal communication. This asymmetry brings the Nisbett and Wilson (1977) problem straight into the heart of anthropology: "Informants pressed to explain practices that they themselves learned by observation, imitation, and participation *generally have to make up concepts* that have very tenuous, often imaginary relations with the manner in which the informants themselves actually acquired or generate the actions in question" (Fiske, 1999, p. 1; emphasis added).

The importance of practice, repetition, and physical movement for the tuning up of cultural intuitions is further demonstrated by Lieberman's (2000) recent review of the neural substrates of intuition. Lieberman finds that social

learning uses some of the same circuits in the basal ganglia that motoric learning does, causing many social skills to become rapid and automatic, like well-learned motor sequences. Social skills and judgmental processes that are learned gradually and implicitly then operate unconsciously, projecting their results into consciousness, where they are experienced as intuitions arising from nowhere (see also Reber, 1993, on implicit learning and Clark, 1999, on the underestimated role of the body in cognition).

The implication of these findings for moral psychology is that moral intuitions are developed and shaped as children behave, imitate, and otherwise take part in the practices and custom complexes of their culture. Participation in custom complexes in this way provides a cultural "front end" for Damasio's (1994) somatic marker hypothesis, and for Lakoff's (1987) embodied cognition. Even though people in all cultures have more or less the same bodies, they have different embodiments, and therefore they end up with different minds.

Peer Socialization

The social intuitionist model presents people as intensely social creatures whose moral judgments are strongly shaped by the judgments of those around them. But whose judgments have the strongest effects on children? Harris (1995) pointed out that children's task in late childhood and adolescence is not to become like their parents but to fit into their peer group, for it is among peers that alliances must be formed and prestige garnered. She therefore proposed a group socialization theory in which children acquire their culture – including moral values – from their peers, just as they acquire their phonology (i.e., children of immigrants copy the accent of their peers, not of their parents).

Harris's (1995) emphasis on peers receives support from a study by Minoura (1992) of Japanese children who spent a few years in California when their fathers were transferred to the United States for work. Minoura found that there was a sensitive period for culture learning between the ages of 9 and 15. When children spent a few years in the United States during this period, they developed American ways of interacting with friends and American ways of feeling about problems in interactions. A few years spent in America before that period led to shallower, nonemotional learning about norms and left no lasting effects. A few years spent in America after the age of 15 led to puzzlement

and culture shock but to little change in the self. These later arrivals, like their parents, knew and could state explicitly the American norms for interpersonal behavior, friendship, and self-promotion, yet these norms did not become internalized. The norms never came to be automatic or to feel self-evidently valid, as intuitive knowledge would be if acquired during the sensitive period.

Putting together all of the developmental theories and findings presented above yields the following expansion of the social intuitionist model: Moral development is primarily a matter of the maturation and cultural shaping of endogenous intuitions. People can acquire explicit propositional knowledge about right and wrong in adulthood, but it is primarily through participation in custom complexes (Shweder et al., 1998) involving sensory, motor, and other forms of implicit knowledge (Fiske, 1999; Lieberman, 2000; Shore, 1996) shared with one's peers during the sensitive period of late childhood and adolescence (Harris, 1995; Huttenlocher, 1994; Minoura, 1992) that one comes to feel, physically and emotionally (Damasio, 1994; Lakoff & Johnson, 1999), the self-evident truth of moral propositions.

Integrating Rationalism and Intuitionism

The debate between rationalism and intuitionism is an old one, but the divide between the two approaches may not be unbridgeable. Both sides agree that people have emotions and intuitions, engage in reasoning, and are influenced by each other. The challenge, then, is to specify how these processes fit together. Rationalist models do this by focusing on reasoning and then discussing the other processes in terms of their effects on reasoning. Emotions matter because they can be inputs to reasoning. Social settings and social interactions matter because they encourage or retard the development of reasoning, in part by providing or blocking opportunities for role-taking. However, if researchers want to get at the heart of the process, the place where most of the variance is located, they should focus on moral reasoning.

The social intuitionist model proposes a very different arrangement, one that fully integrates reasoning, emotion, intuition, and social influence. The discussion thus far may have given the impression that the model dismisses reasoning as post hoc rationalization (Link 2). However, it must be stressed that four of the six links in

the model are reasoning links, and three of these links (Links 3, 5, and 6) are hypothesized to have real causal effects on moral judgment.

Link 3, the reasoned persuasion link, says that people's (ex post facto) moral reasoning can have a causal effect – on *other people's* intuitions. In the social intuitionist view, moral judgment is not just a single act that occurs in a single person's mind but is an ongoing process, often spread out over time and over multiple people. Reasons and arguments can circulate and affect people, even if individuals rarely engage in private moral reasoning for themselves.

Link 6, the reflective judgment link, allows that people may sometimes engage in private moral reasoning for themselves, particularly when their initial intuitions conflict. Abortion may feel wrong to many people when they think about the fetus but right when their attention shifts to the woman. When competing intuitions are evenly matched, the judgment system becomes deadlocked and the "master" (in Hume's metaphor) falls silent. Under such circumstances one may go through repeated cycles of Links 6, 1, and 2, using reasoning and intuition together to break the deadlock. That is, if one consciously examines a dilemma, focusing in turn on each party involved, various intuitions will be triggered (Link 6), leading to various contradictory judgments (Link 1). Reasoning can then be used to construct a case to support each judgment (Link 2). If reasoning more successfully builds a case for one of the judgments than for the others, the judgment will begin to feel right and there will be less temptation (and ability) to consider additional points of view. This is an account of how a "makes sense" epistemology (Perkins et al., 1983) may become a "feels right" ethic. We use conscious reflection to mull over a problem until one side feels right. Then we stop.

Link 5, the reasoned judgment link, recognizes that a person could, in principle, simply reason her way to a judgment that contradicts her initial intuition. The literature on everyday reasoning (Kuhn, 1991) suggests that such an ability may be common only among philosophers, who have been extensively trained and socialized to follow reasoning even to very disturbing conclusions (as in the case of Socrates or the more recent work of Peter Singer [1994]), but the fact that there are at least a few people among us who can reach such conclusions on their own and then argue for them eloquently (Link 3) means that pure moral reasoning can play a causal role in the moral life of a society.

If the social intuitionist model is correct as a description of human moral judgment, it may be possible to use the model to get reasoning and intuition working more effectively together in real moral judgments. One approach would be to directly teach moral thinking and reasoning skills, thereby encouraging people to use Links 5 and 6 more often. However, attempts to directly teach thinking and reasoning in a classroom setting generally show little transfer to activities outside of the classroom (Nickerson, 1994), and because moral judgment involves “hotter” topics than are usually dealt with in courses that attempt to teach thinking and reasoning, the degree of transfer is likely to be even smaller.

A more intuitionist approach is to treat moral judgment style as an aspect of culture and to try to create a culture that fosters a more balanced, reflective, and fair-minded style of judgment. The “just community” schools that Kohlberg created in the 1970s (Power, Higgins, & Kohlberg, 1989) appear to do just that. By making high school students create their own rules, enforce their own discipline, and vote on numerous policies, Kohlberg created an environment where students enacted democracy. By putting students and teachers on an equal footing (all had just one vote; all used first names only; all sat in a circle on the floor at community meetings), Kohlberg created an environment where students and teachers enacted equality. Years of such implicit learning, coupled with explicit discussion, should gradually tune up intuitions (Fiske, 1999; Lieberman, 2000) about justice, rights, and fairness, leading perhaps to an automatic tendency to look at problems from multiple perspectives. By creating a community in which moral talk was ubiquitous (Link 3, reasoned persuasion) and in which adults modeled good moral thinking, Kohlberg may well have strengthened his students’ tendency to use Link 6 (private reflection) on their own. (See Baron, 2000, for more on how cultural beliefs and practices about thinking can help or hinder good thinking.)

The social intuitionist model also offers more general advice for improving moral judgment. If the principal difficulty in objective moral reasoning is the biased search for evidence (Kunda, 1990; Perkins et al., 1991), then people should take advantage of the social persuasion link (Link 4) and get other people to help them improve their reasoning. By seeking out discourse partners who are respected for their wisdom and open-mindedness, and by talking about the evidence, justifications, and mitigating factors

involved in a potential moral violation, people can help trigger a variety of conflicting intuitions in each other. If more conflicting intuitions are triggered, the final judgment is likely to be more nuanced and ultimately more reasonable.

The social intuitionist model, therefore, is not an antirationalist model. It is a model about the complex and dynamic ways that intuition, reasoning, and social influences interact to produce moral judgment.

Testing the Social Intuitionist Model

The social intuitionist model is more complex and comprehensive than most rationalist models. Is the extra complexity necessary? Does the model do a better job of explaining and illuminating human moral life? That is a question that future research must decide. At least three kinds of research may shed light on the relative merits of the model.

1. *Interfering with reasoning.* If reasoning is a slow and effortful process that demands attentional resources, whereas intuition is fast, effortless, and undemanding (see Table 1), then manipulations that interfere with reasoning during a moral judgment interview should affect the quality of the post hoc reasoning produced without affecting the quality of the initial judgment. Rationalist models, in contrast, predict that the quality and speed of a judgment should be heavily dependent on one’s reasoning ability.

2. *Ecological variation.* This article has suggested that standard moral judgment interviews represent unique and ecologically suspect settings in which a variety of factors conspire to maximize the amount and quality of reasoning. If this is true, then the reasoning produced in such interviews is consistent both with rationalist models and with the private reflection loop of the social intuitionist model (Links 1, 2, and 6). However, as the conditions of the interview are gradually changed to increase ecological validity, the social intuitionist model predicts that the reasoning produced should become recognizably post hoc. Alterations that would increase ecological validity include using real (rather than hypothetical) stories, asking about people known to the participant, working questions into a normal conversation (not a formal interview), and conducting the conversation in front of other people (not alone in a private room). Post hoc reasoning can be recognized by three features: (a) attempts to change facts about the story or to introduce new and tangential concerns, (b) a

lack of responsiveness of the judgment to large changes in the facts of the story, and (c) a longer delay between the time the evaluation is made and the time that the first substantive reason is produced.

3. *Consilience*. Edward O. Wilson (1998) resurrected the term *consilience* to refer to the degree to which facts and theories link up across disciplines to create a common groundwork of explanation. He argued that theories that contribute to the unification of the sciences should be preferred to those that contribute to their fragmentation. The present article has tried to show that the social intuitionist model easily links findings in social and developmental psychology to recent findings and theories in neuroscience, primatology, and anthropology, but perhaps a similar case can be made for rationalist models. The debate between rationalism and intuitionism, now over 200 years old, is not just a debate between specific models; it is a debate between perspectives on the human mind. All of the disciplines that study the mind should contribute to the debate.

Conclusion

Rationalist models made sense in the 1960s and 1970s. The cognitive revolution had opened up new ways of thinking about morality and moral development, and it was surely an advance to think about moral judgment as a form of information processing. But times have changed. Now we know (again) that most of cognition occurs automatically and outside of consciousness (Bargh & Chartrand, 1999) and that people cannot tell us how they really reached a judgment (Nisbett & Wilson, 1977). Now we know that the brain is a connectionist system that tunes up slowly but is then able to evaluate complex situations quickly (Bechtel & Abrahamsen, 1991). Now we know that emotions are not as irrational (Frank, 1988), that reasoning is not as reliable (Kahneman & Tversky, 1984), and that animals are not as amoral (de Waal, 1996) as we thought in the 1970s. The time may be right, therefore, to take another look at Hume's perverse thesis: that moral emotions and intuitions drive moral reasoning, just as surely as a dog wags its tail.

Notes

- 1 This is one of Hume's most radical statements, taken from his first book, *A Treatise of Human Nature*. His more mature work, *An Enquiry Con-*

cerning the Principles of Morals, raises reason from a slave to a respected assistant of the moral sense, yet it maintains the basic position that "the ultimate ends of human actions can never... be accounted for by reason, but recommend themselves entirely to the sentiments and affections of mankind" (1777/1960, p. 131).

- 2 Kant responded to Hume's skepticism about the powers of reason. He argued that any rational agent could and should figure out the morally correct thing to do by applying the categorical imperative: "I should never act in such a way that I could not also will that my maxim should be a universal law" (1785/1959, p. 18).
- 3 An ironic example of an a priori moral theory used in a post hoc way is found in Miller's (1999) recent review of the norm of self-interest. Americans strongly embrace the theory that people act, and ought to act, primarily out of self-interest. Americans therefore frequently make up self-interest explanations for their attitudes, votes, and charitable actions, even in cases where they appear to be acting against their self-interest (see also Baron, 1997).
- 4 In fact, two of the only such children ever studied sound uncannily like Cleckley's psychopaths (Anderson, Bechara, Damasio, Tranel, & Damasio, 1999). See also Grandin's (1995) discussion of how the emotional deficits of autism made it difficult for her to understand many social and moral rules, although her feelings of empathy, particularly for animals, and her feelings of social anxiety appear to have been a sufficient foundation for a moral compass.

diachronic, 53, 57
synchronic, 53
- reflective equilibrium, 20–22, 741–742
narrow versus wide, 6–7, 21, 140, 143
- regularities, 83, 589–590
- Reiter's default logic, 293–294
- relativism: conceptual, 986–993, 995–1001
- relevant alternatives, 275
- Rips, Lance, 581–582, 937, 940
- Russell's paradox, 23
- salience: natural, 930
- satisficing, 106, 439
- selective scrutiny model, 441
- self-deception, 1003
- self-defeating arguments, 456–458
- self-perception theory, 551–552
- sentential reasoning; *see* reasoning,
deductive
- sequences, numeric, 282
- signaling games, 928–932
inference and, 932
learning and, 931
logic and, 931
truth functions and, 931–932
- similarity-coverage model, 330–341

- cultural differences in reasoning
 - and, 936–940, 944, 947
- simplicity, 7
- Simpson's paradox, 608
- social norm theory, 107–108
- sociocognitive systems, 973–976
- Solomonic judgments, 101
- somatic marker hypothesis,
 - 553–554, 1039
- sorities paradox, 9–10, 22, 23
- specificationism, 731–743
 - cospecification of ends in,
 - 737–738, 740–741
- Standard Social Science Model (SSSM), 850
- Strawson, P. F., 988
- subjective expected utility (SEU),
 - 437, 438, 446
- subjective motivational set (S),
 - 60–65
- supervaluation, 9–10
- suppression effects, 390
- suppression task, 229–230, 234,
 - 238, 239
- syllogism
 - ambiguities in, 658–661
 - universal premises in, 661–664
- syllogistic reasoning, 249–265
 - logic-based approaches to,
 - 253–255
 - mental models theories of,
 - 255–256
 - natural selection and, 265
- probability-heuristics model (PHM) of, 256
- Tarski, Alfred, 22
- temporal projection, 451, 464–466
 - ultimatum game, 916–923
- theories
 - inadequacy in, 94
 - underdetermination by evidence,
 - 14–15, 19, 996
- thinking dispositions, 416,
 - 422–423, 426
- tit-for-tat, 30
- truncated search strategy, 345
- truth
 - Tarski's theory of, 22, 992
 - in conversations, 772–773
- Turing machines, 878–879
- Tversky, Amos, 384–385, 608, 784,
 - 790–791
- two-track mind hypothesis,
 - 1005–1008, 1012–1013
- undecidability, 288
- undermining: positive versus
 - negative, 43–44, 45
- uncertainty: judgment under,
 - 114–133
- unexpected examination: paradox
 - of, 83–87
- uniformity of nature: assumption
 - of, 13
- universal grammar (UG), 234, 859
- utilitarianism, 94
- vagueness, 8–10
- Vogler, Candace, 738–741
- voluntarism, 47–57
- Wason selection task, 14, 143–145,
 - 202–203, 206–207, 226–228,
 - 234, 383, 384, 422–423, 443,
 - 827–828, 836, 844–848,
 - 866–873, 1006
 - deontic reasoning in, 444–447
 - deontic versus descriptive,
 - 227–228, 443–444,
 - 875–876
 - FCT selection task and, 868
 - weakness of will, 28, 63, 101, 156,
 - 160
 - exponential discounting and,
 - 164–166, 167
 - overcoming, 171–174
 - Whorf, Benjamin, 986, 1007
 - why-questions, 748–749, 761
 - attention and, 756–758
 - attribution theory and, 748–751
 - chance-based explanations and,
 - 751–753
 - consequences of pragmatic
 - norms regarding, 758–762
 - focus of, 748–749
 - pragmatic norms and, 754–756
 - presuppositions of, 748–751
 - reformulations of, 753–754
