REASONING

This interdisciplinary work is a collection of major essays on reasoning: deductive, inductive, abductive, belief revision, defeasible (non-monotonic), cross cultural, conversational, and argumentative. They are each oriented toward contemporary empirical studies. The book focuses on foundational issues, including paradoxes, fallacies, and debates about the nature of rationality, the traditional modes of reasoning, as well as counterfactual and causal reasoning. It also includes chapters on the interface between reasoning and other forms of thought. In general, this last set of essays represents growth points in reasoning research, drawing connections to pragmatics, cross-cultural studies, emotion, and evolution.

Jonathan E. Adler is a professor of philosophy at Brooklyn College and the Graduate School, CUNY. His D. Phil. in philosophy is from Oxford University. His main areas of research and publication are epistemology, philosophy of psychology, informal logic, ethics, and philosophy of education. He is the author of *Belief's Own Ethics*.

Lance J. Rips is a professor of psychology at Northwestern University. He received his Ph.D. from the Psychology Department at Stanford University and has taught at the University of Chicago. He is on the editorial board of the journals *Cognition*, *Public Opinion Quarterly*, and *Informal Logic* and is the author of *The Psychology of Proof* and *The Psychology of Survey Response* (with Roger Tourangeau and Kenneth Rasinski).

Preface

This is a collection of essays on reasoning – deductive, inductive, abductive, belief-revision, defeasible, cross-cultural, conversational, argumentative – oriented toward contemporary empirical research. The study of reasoning is, of course, a major focus of investigation in both philosophy and psychology, and this volume attempts to combine these perspectives. Philosophy, especially logic and philosophy of science, inspired psychology’s interest in deduction, induction, and other forms of inference. In the past thirty years, the focus of common interest has greatly enlarged to include causal reasoning, cross-cultural comparisons, moral reasoning, and argumentation. There is increasing attention to reasoning as a response to new information or change of belief (belief-revision or defeasible reasoning), which is a far-reaching concern in epistemology. These advances, along with the more than twenty-year debate on rationality, have made reasoning a focal point of cognitive science research and reflections.

Three additional paths also are now converging on reasoning as major research interests. The first is a focus on fallacious reasoning and its reduction through education, which usually goes under the banner of informal logic or critical thinking. Second, the development of pragmatics, particularly following Grice’s foundational contribution, has given rise to fruitful applications to traditional reasoning tasks. A number of commentators in the rationality debate have suggested connections between performance on those tasks and conversational expectations. These suggestions are coming in for experimental testing and some corroboration. Third, and last, neuroimaging studies suggest that the contrasts between inductive and deductive reasoning, and, more surprisingly, between thinking about different ethical dilemmas, are realized by distinct areas of brain activity. This volume takes up these issues, along with the more traditional ones.

The idea for this volume began when Adler searched fruitlessly for a collection for a graduate seminar on reasoning. Rips could not do better, because existing anthologies on reasoning were quite out of date. We have tried to choose topics for this book to fill this gap, concentrating on central and emerging issues that are underrepresented elsewhere. We have largely avoided the topic of practical reasoning because it has been much less studied empirically, is more oriented toward philosophical issues, and is well represented in a recent collection (Millgram’s *Varieties of Practical Reasoning*). Similarly, there are excellent collections of work in both decision making and analogical reasoning that allowed us to focus on other topics here.

We hope this volume will interest students of reasoning in philosophy, psychology, and cognitive science and that it will inspire the teaching of interdisciplinary courses on reasoning. Readers will, of course, find their way to those sections of the book most relevant to their interests, but we have planned the sequence of chapters to begin with foundational topics that may illuminate issues in the rest of the book. The introductory chapter and the essays in Part I provide (mostly philosophical) background on the general topic of reasoning and rationality. The remaining two parts of the book more evenly comingle work by psychologists and philosophers. Part II focuses on the traditional “ductions” – deduction, induction, abduction, and a few others – and Part III features new trends or less traditional topics, such as the relation of reasoning to pragmatics, cross-cultural research, modularity, and biology. Readers can concentrate on just the psychological or just the philosophical chapters in Parts II and III, but we sincerely hope they won’t. Part of our own excitement in putting together this book came from juxtaposing work from these fields that we believe deserve closer linkage. To cite just one example, we think there is much to glean by reading Davidson and Williams on relativism alongside Burnett and Medin’s and Nisbett, Peng, Choi, and Norenzayan’s chapters on reasoning across cultures.

We have included previously published papers that we deem of special importance to ongoing work, but many of the chapters (labeled with asterisks in the Table of Contents) appear here for the first time. We feel especially fortunate in being able to persuade some of the leaders in the field to set out their points of view on earlier research and to comment on recent trends. Some of these new contributions are detailed summaries and updates of earlier research; others tackle new problems or outline newly emerging research domains. We thank these contributors for their patience during the preparation of this anthology. Our thanks to Blakely Phillips, as well, for her major assistance with the indexing. And special thanks to our families for not deserting us in what was an unexpectedly lengthy and complicated process.

Introduction: Philosophical Foundations

JONATHAN E. ADLER

1. Reasoned Transitions

Reasoning is a transition in thought, where some beliefs (or thoughts) provide the ground or reason for coming to another. From Jim's beliefs that

(1) Either Bill receives an A or a B on the final.
and

(2) Bill does not receive an A.

he infers that

(3) Bill receives a B.

Assuming that Jim bases his inference on the deductive relation of (1) and (2) to (3), his conclusion is warranted, since the argument is valid. (1) and (2) implies (3), since it is not possible, as contradictory, for (1) and (2) to be true and (3) false. More formally, ϕ is a logical consequence of Γ if and only if there is no interpretation (model) in which all sentences of Γ are true but ϕ is false (Tarski 1983).

Although in reaching (3) Jim comes to a new belief, its information is already entailed by (1) and (2). Unlike deduction, an inductively good argument provides for new beliefs whose information is not already entailed by the beliefs from which it is inferred:

(4) Bill brought his back pack to class every day of the semester.

So, [probably] (5) Bill will bring it to the next class.

The falsity of the conclusion (5) is compatible with the truth of the premises (4). The premises only render the truth of the conclusion more probable (than in their absence). Although this is a good inductive argument, the premises can be true and the conclusion false, so the argument is invalid.

Deductive validity is monotonic: A valid argument cannot be converted into an invalid argument by adding additional premises. But an inductively good argument is nonmonotonic: new premises alone can generate an argument that is not good. If I add to the argument from (4) to (5), a premise that

(4.1) Bill's back pack was stolen,

the conclusion no longer follows.

In either argument, there is a reasoned transition in thought. The person who draws the inference, takes the premises as his reasons to believe the conclusion (or, in the second case, to believe it probable.) By contrast, the transition in thought from the belief that

(6) Joe's cousin drives a BMW.

to

(7) I better call Fred.

is not reasoning because, let's suppose, (6) is merely a cue or stimulus or prompt for the thought that (7) to arise. (6) could not serve as the reason for accepting (believing) (7) as true, as (1) and (2) could for (3). (Another technical use of 'accepting' is for momentary purposes, as, say, when one accepts a supposition for a proof Stalnaker 1987).

Grice (2001) draws the connection between reasons and reasoning by noting that if reason is the faculty which "equips us to recognize and operate with *reasons*" then we should also think of it as the faculty which "empowers us to engage in *reasoning*." Elaborating, he writes

if reasoning should be characterizable as the occurrence or production of a chain of inferences, and if such chains consist in (sequentially) arriving at conclusions which are derivable from some initial set of

premises . . . of which, therefore, these premises are . . . reasons, the connection between the two ideas is not accidental. (5)

Grice's 'not accidental' is, presumably, a cautious expression for a conceptual dependence of reasoning on reasons.

Minimally, to have a reason is to have a favorable consideration. However, a reason to do something as in 'my reason to go to the ice cream store is get a sundae' serves to motivate action, whereas a reason to believe does not serve in a motivational role. You can be indifferent to the grade Bill receives, but not, presumably, to the ice cream sundae. Of course, reasons or evidence are typically uncovered through investigation, as when trying to determine the grade Bill receives. But then the motive to investigate obtains independent of the reason to believe. However, in other cases, and much more typically, we acquire evidence that a statement is true and then we come to believe that statement, like it or not. If you overhear Jim affirm (3) that Bill receives a B, then special circumstances aside (e.g., you do not trust Jim), you will come to the corresponding belief, even if you are indifferent to Bill's grade. There is no gap between judging that there are sufficient reasons to believe p true and judging (accepting) that p is true, nor between judging that p is true and believing it.

What is a favorable consideration? Is (1) and (2) a reason to believe (3) because they constitute a mental state or because they constitute facts which serves as the content of that state? If my wanting the sundae is my reason to go to the store, the mental state is the reason. If, instead, what I want to be the case – the fact that I buy apples – is my reason, it supports the truth of the belief's content that I go to the market. ("Belief" suffers a similar ambiguity. Does it refer to an attitude (believing) or to the content of that attitude? We assume that when disambiguation is needed, context will prove adequate.)

Is the reason (as a proposition) a consideration to hold a certain attitude – believing or desiring – or is it a consideration favoring the truth of the content of that attitude (Parfit 2001)? The mother who learns that her son survived a fire in school will be relieved by coming to the belief that he survived, which is then a reason – a consideration in favor – of her taking the attitude of believing it. But that value or utility to her of holding the belief is not a reason that renders it true that her son did survive. In general, it seems that the utility of believing a statement, since it is never a reason for the statement's truth,

can never serve as a proper reason to believe. Arguably, though, even if utilities can not bear on what to believe, they may enter with the question of whether to hold a belief rather than not to hold any (Nozick 1993 Ch. III).

2. Belief and Truth

Induction and deduction supply reasons to believe, since each seeks to preserve the truth of its premises, while extending them to new truths acquired as beliefs. Beliefs are the product of reasoning since belief aims at truth. The end result in belief explains why reasoning matters so profoundly to us. We care to get correct conclusions both intrinsically, since that is what having a belief claims, but also, and more obviously, extrinsically. Belief guides actions, and actions are expected to succeed (reach their goal) only if the beliefs that guide them are true. If you want an ice cream sundae immediately and you believe that the only near-by place to purchase one is on the corner of Broadway and 110th St., then you are expected to succeed (to satisfy your desire for the sundae) only if your belief as to its location is true.

Both forms of reasoning or inference aim to discern what is the case, and so aim, figuratively, for the mind to fit the world (e.g., that I come to believe that a sundae is produced at the store just because it is). By contrast, to desire the ice cream sundae, which specifies one's goal in action (to acquire and to eat the ice cream sundae), is to desire the world to conform to the mind. Beliefs and desires have opposite "directions of fit" (Anscombe 1957, Searle 1983).

The fundamental notion of belief is that of "believing that", a characteristic propositional attitude. If Jim believes that Mary is in Alaska, Jim believes the proposition Mary is in Alaska to be true. Propositions are the contents of sentences or statements as expressed on an occasion. The sentence 'I like Krispy Kreme donuts' cannot be true or false as it stands, since the 'I' has no definite reference. But, on an occasion of use, the fixed meaning of 'I' (and similarly for other indexicals like 'you' or 'now') will have their reference determined; the reference of 'I' is the speaker on that occasion (Kaplan 1989). When values for all indexical and similarly context-sensitive terms in an assertion are fixed, the statement expresses an abstract entity of a corresponding form, a proposition. (The prominent features of context are speaker, hearer, location, and time.)

What is it we are claiming of a proposition when we attribute to it truth or falsity? There does not seem to be any difference between

(8) John believes that the proposition that the nearest ice cream store is on Broadway and 110th St. is true.

and

(9) John believes that the nearest ice cream store is on Broadway and 110th St.

Both seem to say the same thing – to be true or false under the same circumstances – suggesting the generalization:

(T) The proposition that p is true if and only if p .

The left-hand side of (T) (“The proposition that p is true”) speaks about a proposition. The right-hand side speaks about the world or a fact of the world namely, that the nearest ice cream store is on Broadway and 110th St. The circular appearance does not run deep.

If (T) is correct, there is no further problem about understanding truth than understanding the corresponding proposition. If you understand the proposition that the library is open on Saturday, no special difficulty attends to your understanding the proposition – that the library is open on Saturday – is true (Tarski 1983; Horwich 1990). However, the (T) equivalence does not tell you how to determine or verify or discover whether a proposition is true.

3. Theoretical and Practical Reasoning

Reasoning to how one should act can involve inductive and deductive transitions, but its aim or purpose is distinctive from reasoning whose endpoint is belief:

(10) I want an ice cream sundae.

(11) The closest ice cream store is on Broadway.

(12) There are no barriers to my going there.

So, (13) I should now go to the ice cream store on Broadway.

[Alternatively, (13) I shall/intend to now go . . .]

(10)–(12) constitute good reasons for concluding (believing) that (13) is true. But the ultimate purpose of this reasoning is not to figure out what is the case. Reasoning whose endpoint is belief is referred to as *theoretical reasoning*. Rather, this reasoning (10)–(13) aims to figure

out how one should act or *practical reasoning*. The goal is to figure out what one [I] should do (Millgram 2001). As indicated by the alternative reading, (13) should be viewed not just as a judgment as to what is best for me to do, but the actual intention to so act.

Theoretical reasoning aims to answer whether p is the case, not whether I ought to believe it, whereas practical reasoning is concerned to determine what I ought to do. The structure of theoretical reasoning is obscured if its conclusions are taken to be of the form ‘I ought to believe p .’ What it is best to do is that act which is better than all the alternatives, on the available reasons. But what one can or should believe is only what is genuinely worthy of belief, not what is currently better than the alternatives. (Think here of the difference between poker, where the best hand wins, and rummy, where only the right or proper hand can win Adler 2002).

The end or goal to which practical reasoning is directed is characteristically set by what one wants or desires, expressed in premise (10). (Not that any desire or want specifies a real end or goal – something that you aim to pursue or that even supplies a reason or motive to pursue. You may have a desire to humiliate yourself, which you neither value nor with which you identify.) Practical reasoning aims at figuring out how to go about satisfying a desire, if opportunity permits. When one’s wants or desires set a genuine end or goal, motivation to act according to the conclusion’s directive is built in. It is unremarkable self-interest to attempt to satisfy one’s own ends.

Can one be motivated to act other than internally (from one’s wants or desires)? The Humean ‘internalist’ answers ‘no’, whereas the Kantian and other ‘externalists’ answer ‘yes.’ (Williams this volume). Externalists hold that one can be motivated purely by recognition of a reason (belief) that a rule or principle or duty applies. So, for example, can a child be motivated to visit his grandmother without any desire to do so nor any threat of punishment? Can his recognition that visiting his grandmother is the right thing to do give him a reason to act accordingly, even if he has no internal – desire – motive to do so? Can reason alone, as a source of judgments of truth and falsity, be a source of reasons (motivation) to act?

With slight differences, the internalist answers “no” to these questions, holding that reason is inert. Reason (belief) is only able to guide one to those actions that are likely to

satisfy the motivation that lies elsewhere (in one's desires or wants).

Are one's wants or desires the endpoint to fix one's goal or aims to which practical reasoning is directed? Internalists typically deny that one's ends (or goals) can be rationally altered except on the basis of further desires or wants. One methodological weakness in this instrumentalism is that one's desires are often too unspecific to fix any end. (Richardson 1994; Millgram this volume). Hardly anything is fixed by one's desire to be happily married (to whom?) or to get a good job (which one?). One's ends must be specified to serve as a guide to action, and the specification requires input from beliefs.

Similarly, one's plans need constant updating and modification as they begin to be executed (Bratman 1987). When you learn of a traffic jam further up on the highway, you turn off to the service road. In this way, you fill in your plans, not just modify them. One's plans direct one toward one's goal, but they do so in an open-ended way, leaving room to fill in details and for modifications, as more information is learned.

In theoretical reasoning, motivation is not an ingredient, which is another way to mark its "inertness." Once you judge a conclusion true, based on the reasoning, you thereby believe accordingly, idiosyncratic psychological barriers aside (e.g., distraction). Belief is in one way passive and not subject to choice: Think of all the beliefs you pick up on the way to your morning commuter train to which you are completely indifferent, for example, that your new neighbor is wearing a green jacket today. No motivation is necessary for belief to respond to a convincing argument. It is a heard contradiction, discussed further below, to affirm a statement of the form "*p* is true, but I don't believe it" ("Moore's Paradox").

The objective of theoretical reasoning is to relieve doubt or to satisfy curiosity or to diminish puzzlement by achieving corresponding beliefs, whereas the objective of practical reasoning is to secure the means to realize one's ends. Because practical reasoning is directed toward action it is overtly constrained by time and resources – its objective is to discover which option is best, all available things considered. But the objective of theoretical reasoning is not merely to discover what proposition (option) is best supported by one's available evidence, but what is correct (true). Consequently, to draw a conclusion in theoretical reasoning requires the claim not just that one's evidence is the total relevant evidence available, but that the evidence is

representative, rather than a skewed sample. It follows further that our limits in gathering and assessing evidence contours theoretical reasoning, but, like utilities, our limits cannot play an overt role in drawing a conclusion. You should not – and, perhaps, cannot – believe a conclusion because it is best supported by the evidence so far and that you do not have more time to examine further evidence. (The problems raised here are for assimilating theoretical to practical reasoning. For a discussion of the assimilation of practical to theoretical reasoning, see Velleman 2000.)

4. Theoretical Reasoning: Limits, Closure, and Belief-Revision

Our limits restrict the resources and time to devote to empirical search, testing, and inquiry, as well as to the inferences worth carrying out. The valid and sound argument from "Trump is rich" to "Trump is rich or cousin Harry is in Jamaica" yields no new worthwhile information. Endless such trivial consequences (e.g., *p*, *p* or *q*, *p* or *q* or *r*, . . . ; *p*, *p* & *p*, *p* & *p* & *p* . . .)¹ can be so generated, which will just "clutter" one's memory as explicit beliefs (Harman 1986; Sperber and Wilson 1986). Also, if one "loses" or forgets the origination of the disjunctive belief in the belief that Trump is rich, one will mislead oneself on attending to it that one has special reason to believe Harry is in Jamaica or that it bears a significant connection to the other alternative that Trump is rich.

Theoretical reasoning involves revising beliefs we already hold. Rules of standard logic or implication, however, do not (Harman 1986). Jane believes that if she attends Yale, she'll become an atheist. She believes that she will attend Yale. If she reasons by the impeccable rule of Modus Ponens (MP: *p* and if *p*, *q* implies *q*), she concludes that she will become an atheist. But although she now has a reason to believe that conclusion, logic does not decide that she will or should believe it. Once Jane becomes aware of that conclusion, she also becomes aware of other beliefs, which deny that she will ever be an atheist. Instead of drawing the MP conclusion, Jane ceases to believe the conditional, which served as her main premise. Reasoning that results in modification of beliefs of one's own may be dubbed "self-reductios" (ad absurdum).

Examples such as the previous one show how from deduction we can learn something new about the content of our beliefs, even though, in a figurative way of speaking, deduction only

renders explicit information already in the premises. Briefly, our beliefs are not closed under deduction. (Similar, but distinguishable, worries attend to the requirement that our beliefs at a given time be consistent. The worries are different for failures of closure or consistency that the agent does not recognize and those cases in which the agent does recognize the failure. The latter cases generate more forceful conceptual friction with the concept of belief. For recent treatment of these logical requirements on belief, see Christensen 2004.) One's beliefs are closed just in case if one believes p and p implies q , one believes q . None of us mortals have bodies of beliefs that are deductively, let alone inductively, closed. There are complex tautologies or logical equivalents to what we believe, which we will not believe and may even disbelieve. The failure of deductive closure for belief is a facet again of our limits, including our limited grasp of our own beliefs, our lack of omniscience, and our "inability" to perceive the future. If Socrates believes that no one does wrong knowingly, does Socrates believe that Richard Nixon did no wrong knowingly? (For examples and critical reflection's see Stalnaker 1987: Ch. 5.) Implications or deductions from one's beliefs can yield surprising conclusions. Well before the discovery of penicillin by Fleming, biologists knew that molds cause clear spots in bacteria cultures, and they knew that a clear spot indicates no bacterial growth. Yet, they did not come to realize, or even to hypothesize, that molds release an antibacterial agent. The observations did not render salient the disparate beliefs and place focus on them together (Cherniak 1986).

So, putting aside closure imposed as an idealization for specialized purposes (Hintikka 1962), one can believe, or even know, p , and p imply q , without believing or knowing q . Similarly, it can be the case that $a = b$ and that one believes (and even knows) that a is F , without one believing that b is F , though the embedded argument is valid. So, for example, Lois Lane may know that

(14) Superman flies.

In the tale, it is true that

(15) Superman is Clark Kent.

But Lois Lane does not know (and actually believes false) that

(16) Clark Kent flies.

The fault lies with a lack of knowledge of the middle step – (15). Knowledge or belief is "opaque" – in "S believes that a is F " the position of " a " is not purely referential. (Opacity intrudes on what counts as a reason: If Lois Lane wants to marry only a man who flies, does she have reason to marry Clark Kent?) Consequently, substitution of arbitrary coreferential terms is not truth-preserving. Within the scope of Lois Lane's beliefs or knowledge, "Superman" in (14) does not simply refer to an object (Superman), but to that object as understood by Lois Lane. (The problem originates with Frege [1970]. An alternative account holds that the substitution does go through. The assumption as to how the person [Lois Lane] thinks of the name is only pragmatic. A parallel worry applies to the distinction between attributive and referential meanings of a term [Kripke 1977]. To appreciate this alternative reading substitute for the names a pure pointing device like "this" or "that.")

A much-discussed example takes the problem of closure a step further, because it holds that knowledge is not closed even when the person knows the "middle" step – the relevant implication (Dretske 1970; Nozick 1981). Assume that Tony is looking at an animal behind a cage marked "zebra," which looks like a zebra. Barring any weird circumstances, we would say that Tony knows that

(14) The animal I am looking at is a zebra.

Let's now grant that Tony also knows the implication that

(15) If the animal I am looking at is a zebra, then it is not a mule cleverly disguised to look like a zebra.

(14) and (15) imply

(16) The animal I am looking at is not a mule cleverly disguised to look like a zebra.

Still, we are reluctant to attribute knowledge of (16) to Tony. Those who oppose closure reason that Tony has never checked that the animal he is looking at is not such a cleverly disguised mule. Tony is simply looking at the animal from outside the cage. These theorists reject:

(Epistemic Closure EC) If X knows that p and X knows that p implies q , then X knows that q .

Arguably, this is the principle licensing Descartes' famed sceptical argument: If you know that you are in your office and you know

that if you are in your office, you are not just *dreaming* it, then you know you are not just dreaming it. But you do not know that you are not dreaming it. So you do not know you are in your office.

The rejection of EC fits the previous zebra example, answers Descartes' sceptical argument, and it is explained as due to our not checking on all the implications of propositions that we know. The rejection also follows from analyzing knowledge as involving satisfaction of the following subjunctive or counterfactual conditional:

(Tracking Knowledge TK) Were p false, S would not believe p .

The most likely (or nearest) way for it to be false that you are in your office is for you to be somewhere else, like your kitchen. If so, you would clearly recognize where you were in the other room. Consequently, you would satisfy (TK), because you would not believe that you were in your office. (TK) does not then support (EC). (Contextualists, whose views we return to below, hold that you do know that you are not dreaming, when you are in an ordinary setting. However, when Descartes or a skeptic mentions the possibility that you are dreaming, they alter the context or standards for knowing. Only then you do not know that you are not dreaming. But, in that case and compatible with EC, you do not know that you are in your office either.)

Despite these advantages, the dominant view is that EC cannot be rejected, since deductive implication preserves truth. What better way to know the truth of a proposition but by deducing it from a proposition one does know? (For overview, see Luper 2006). Without pursuing this line, it's worth noting that sometimes (non-trivial) deductions seem not be a way to advance knowledge. From the evidence of (17),

(17) The Smiths are making an extravagant wedding for their daughter,

(18) is concluded:

(18) The Smiths are wealthy.

From (18), (19) follows:

(19) In making the extravagant wedding, the Smiths are not just appearing to be wealthy.

Assume that you are in a discussion with someone who disputes whether the Smiths are really wealthy. Although (18) implies (19), it seems to

beg the question in this context to use (18) as a reason to believe (19). (17) can only provide evidence for (18) if (19) is assumed or presupposed. But (19) is in dispute. If it is presupposed in treating (17) as evidence for (18), then the warrant or support that (17) lends to (18) does not *transmit* to the conclusion (19) (Wright 2000).

5. Belief-Revision, Holism, and the Quine–Duhem Thesis

If a corpus of beliefs is not closed for the reasons suggested, it is likely to be inconsistent. If there are serious implications of one's beliefs that one fails to believe, one is likely to acquire the contrary of some of those beliefs without recognizing the incompatibility. Here's a very ordinary illustration of Lewis's:

I used to think that Nassau Street ran roughly east-west; that the railroad nearby ran roughly north-south; and that the two were roughly parallel. (1982, 436)

Once these beliefs are brought together with the evident tacit belief, Lewis recognizes that the set of beliefs {Nassau Street ran roughly east-west; the railroad nearby ran roughly north-south; Nassau Street and the railroad nearby are roughly parallel; if one path is east-west and another is north-south, they are not parallel} is inconsistent. They cannot be simultaneously true. Once Lewis recognizes the inconsistency, he can no longer hold on to all these beliefs ("I used to think..."). The question that he now confronts – the question of belief-revision – is how he should restore consistency.

Rejecting any one or more of the members of the inconsistent set will restore consistency. Quine (1980) argued that selection to restore consistency depends on extralogical considerations. He made these claims in developing his criticism of the "dogma of empiricism" that statements (hypotheses) can be tested in isolation. Instead, he put forth what is referred to as the "Quine–Duhem Thesis" (Duhem 1954) that hypotheses are never tested in isolation. Hypotheses (or theories) do not entail any observational predictions by themselves. To derive predictions that serve to test a hypothesis, assumptions are required that crucial terms are not empty and that conditions are normal. Newton's enormously successful theory of gravity and mechanics erred in its (pre-1846) prediction of the orbit of Uranus. But Uranus's deviation was treated as an anomaly, rather than

a falsification, because the theory made substantial assumptions about the operative gravitational forces. In the discovery of Neptune, some of those assumptions were abandoned, rather than the Newtonian theory itself. In general, when a well-regarded hypothesis fails, we do not immediately conclude that the hypothesis is false, as the traditional view implies, rather than that some of the conditions assumed normal – the auxilliary assumptions – failed.

The hypothetico-deductive model incorporating the Quine–Duhem thesis is represented schematically as

H and Auxilliary Assumptions (AA) imply O.

If O, then (H and AA) are confirmed.

If not O, then (H or AA) fails.

The latter is the crucial result because consistency does not demand the falsity of H.

The problem of what extralogical principles to apply to belief-revision has generated numerous investigations and constructions of logics of belief revision (Hanson 2006; for an introduction to a computational approach to belief reasoning and revision, see Pollock and Cruz 1999: Ch. 7). A central proposal is that belief revision should be conservative. One revises one's beliefs so that rejection or modification is minimal. You all-out believe that Skinner wrote *Walden II* and that Chaucer wrote the *Canterbury Tales*. But if you discovered that one of these is wrong, you would sooner surrender one rather than both and the latter, rather than the former, which is attested to by a greater variety of good sources. To surrender the belief about Skinner's authorship would require surrendering – nonconservatively – much more information than surrendering the latter.

But conservatism cannot stand alone. Lewis cannot just decide to give up the belief that Nassau Street ran roughly east-west and keep the one that the railroad nearby ran roughly north-south, although that surrenders only one, rather than more, among equally contentful, incompatible, beliefs. Merely his deciding would not be a sufficient reason that the belief retained is true.

Other principles of belief revision include prominently simplicity and coherence. The more a belief coheres, fits, or is explanatorily connected, with others, the more resistant it should be to modification. But some conflictual beliefs may be surrendered (in strain with

conservatism) to increase coherence. You believe that ten-year-old Jim is in good health, that he will be in the tennis tournament tomorrow, and that he will meet you for lunch at noon. You learn that he is not at school today and that his mother is not at her office. You infer that Jim is sick. That best explains the latter two beliefs – unifies them in an explanatory nexus. But as a consequence you surrender other beliefs about Jim (e.g., that he will be at tennis practice later in the afternoon).

Coherence is an internal requirement on one's beliefs. But our belief corpus improves by external input, especially through our senses. The improvement is not just in the addition of new beliefs picked up as we navigate our environment. Perception and other sensory mechanisms provide for ongoing self-correction, which is a hallmark of scientific method (Sellars 1963). If you believe that Lisa is in Alaska and you see her car at the local diner, you surrender – and so correct – your belief. Normally, beliefs operate as a filter on perceptual judgment. If Lisa drives a blue Ford and that was all that was in your perceptual field as you approached the diner, then if you noticed the car, you would not think of it as hers, given that you believe that she is in Alaska.

However, there must be limits to this filtering role, otherwise our beliefs would not be subject to correction. Once you see the car more closely, and observe the familiar dent on the hood, you are compelled to notice that it is Lisa's blue Ford. Your belief is revised. The new perceptual information nullifies your prior belief, evidence that perception can succeed as a self-corrective on reasoning only if it has some independence of operation from belief and reasoning (from one's "central systems," Fodor 1983).

If the formation of perceptual beliefs always had to be first checked (for veracity) by way of one's corpus of beliefs, it would be subject to the "dogmatism paradox." If you know that Lisa is in Alaska, why should you even acknowledge as putative undermining evidence that it is her car at the Brooklyn diner? Shouldn't you rather judge that, say, her husband must have taken her car, because, if you know that she is in Alaska, shouldn't you know that putative evidence against it must be mistaken or misleading? [Think of the tautology: $p \rightarrow ((q \rightarrow \sim p) \rightarrow \sim q)$.]

However, there is something deviant about the conditional "If there is evidence against my knowledge (that Lisa is in Alaska), then that evidence is mistaken or misleading." It does not

seem to be open to modus ponens, just as the following is not:

If my wife cheated on me, I would never know. (Harman 1973; Ginet 1980; Stalnaker 1987)

Were I to discover that my wife cheated on me, I would reject the conditional (or its antecedent), rather than conclude that I would never know that she cheated on me. Similarly, the previous conditional of the dogmatism paradox is to be rejected when the undermining evidence is obtained, rather than rejecting the evidence as misleading or false.

6. Deductive Rules and Deviant Logics

Usually, of course, conclusions drawn from one's beliefs simply form new beliefs. But often conclusions are drawn that cast doubt back on the premises (beliefs) or the inferential transitions from which those conclusions are drawn.

In drawing out conclusions, what rules should be used? Although in the case of induction and especially deduction a core of rules and results are well established, disputes abound about their scope and other putative rules are flat-out contested. After considering some of these rules and disputes, we briefly turn to how the rules are to be justified and selected.

Standard or classical logic is first-order quantification or predicate logic – the logic of the truth-functions (“and,” “or,” “not,” “if, then”) and the quantifiers (“For every . . .,” “For at least one . . .”) The “first-order” implies that the variables of quantification take as values objects or individuals, not names, predicates, propositions, or properties. First-order logic (including identity) is sound: no proof (a syntactic notion) will take one from truths to falsehoods. Every proof corresponds to a valid argument, a semantic notion. But also and more distinctively, first-order logic is complete (every logical truth or valid argument is provable). Once second-order quantification is admitted, particularly to embrace set theory, the extended logic is no longer complete.

Unlike additions to standard logic, as in adding axioms for necessity and possibility to logic, deviant logics deny some basic logical law. Quine's “holism” opened a door to defend deviation from classical logic, which Quine (1970) attempted to quickly shut. The holistic assumption that justification for logical laws, like the justification of empirical claims, is sensitive to the whole body of beliefs provides an opening

for arguing that a logical law is to be rejected because removing it from one's corpus of beliefs increases coherence. But although Quine's opened this door as a theoretical possibility, he argued that the standard logical laws are too useful or indispensable to the progress of science for abandonment.

Additionally, Quine argued that when you try to deny a logical law like the law of non-contradiction (i.e., $\sim(p \ \& \ \sim p)$), your “&” and “ \sim ” no longer translate “and” and “not,” as intended. These operators are fully specified by the truth-tables and the implied laws. They are defined implicitly by their roles in these assignments and laws. (However, we know that unless restraints are imposed on implicit definitions, specifically, that they introduce no new theorems [“conservative”], the introduction of new connectives can generate crazy rules, ones from which anything can be deduced; Prior 1960; Belnap 1962). If someone infers from an utterance of “A or B” to “A,” we can be sure his “A or B” is not the English disjunction. The deviant logician's predicament is that “when he tries to deny the doctrine he only changes the subject” (Quine 1970), p. 81.

Quine's argument opposes the plausible claim that the denial of an operator in some inferential roles is compatible with its playing the appropriate roles in other inferences, sufficiently so as to remain a viable candidate for capturing the basic meaning. Even the denial that all contradictions are false, allows for preserving a good deal of classical logic with suitable adjustments. In classical logic, every sentence follows from a contradiction. However, this trivialization can be excised by denying the rules from p to $p \vee q$ (weakening); and from $p \vee q$ and $\sim p$ to q (disjunctive syllogism). In the former case, the denial is independently motivated by the lack of relevance in subject matter of the premise to the disjunct q . With a number of other adjustments a major portion of basic logic remains in tact, and the resulting logical system can be sound and complete (Priest 1998).

Although most of the alleged examples of contradictions that are candidates for the ascription of truth are rarified, one of them is a resource from which a number of deviant logics draw strength, and it resonates with everyday reasoning. The resource is in the phenomena of vagueness. The vagueness of a term is that while it sorts objects into those to which the term applies and those to which it does not, it leaves undecided many objects. When a teenager's room has no clothes on the floor and dirty dishes

have been removed, but it has not been dusted or swept, it is indeterminate, let's suppose, whether it is clean or not. A defender of the view that there can be true contradictions might say that the room is both clean and not clean. Others may deny the law of excluded middle: that either the room is clean or it is not clean.

A contextualist confronted by an assertion such as "John's room is clean" will respond that for everyday purposes, it is enough that his clothes are off the floor and that the dirty dishes have been removed. But if John develops asthma, you will not count the room as clean until a careful dusting is complete. The proposition expressed by the assertion is false in that context. Outside of any contextual specification, there is no assigning it a truth-value (or assigning it additional truth-values) (Lewis 1983). Contextualism explains how one utterance of "John's room is clean" can be true and another false, when there is no change in John's room. Because contextual variations include variations in the importance of the matter, contextualism also makes sense of why when you inquire as to the truth of a hypothesis, you are bound to investigate harder in one context (where the costs of error are greater) than in another.

Contextualism, however, is a minority view in how to handle the sceptical implications of vagueness that originates from the "sorites paradox." In its historical form, the sorites is presented as the "paradox of the heap" (Sainsbury 1988; this volume). If you have a heap of sand, and you subtract one grain, you still have a heap (one grain cannot make a significant difference). The judgment suggests a principle: if you now subtract one grain from the previous heap, you still have a heap. But repeated applications leaves you with a couple of grains that you are committed to taking to be a heap, even though they obviously do not make a heap.

Intuitionists respond that when there are too few grains in a pile to clearly be a heap and too many grains to clearly not be a heap, it is not true that either that pile is a heap or that it is not a heap, contrary to the law of excluded middle. And if it not clearly either, the failure to not be a heap does not imply that it is a heap, contrary to the law of double-negation.

The sorites is derivable via the impeccable principle of mathematical induction: R_0 is the base case with a certain property P (e.g., That large collection of grains of sand is a heap). And if R_n has P , there is some fraction of it (e.g., one grain of sand) such that if we decrease R_n by that amount, then what results – R_{n-1} – still is P (e.g.,

that 1-less grain collection is a heap). Then any lesser R_i has P (e.g., every collection of grains of sand less than the base case is a heap including a one-grain collection). Alternatively, the paradox can be presented simply as a string of MP arguments, each one yielding a decrement from the previous. Either way, the nonnoticeable difference for any sized heap – the decrement between R_n and R_{n-1} – becomes a marked difference after enough applications.

The sorites paradox is particularly wrenching because it seems to arise merely from the vagueness of terms, which holds of most terms. Most, if not all (nonartificial) terms leave undecided an unlimited range of cases for example, "blue," "happy," "short," "table," "flat," "rich," "child." At what moment does childhood end? The exception would be contrived cases where an exact specification is provided: We could define a U.S. adult citizen as rich* just in case his total wealth is \$484,234.04 or higher. However, to attempt exact replacements for our vague terms would fail to preserve their value or usefulness. (On utility considerations for vagueness, see Parikh 1994.) The contrived precision would require a sharp break in judgments, where a gradation of responses is appropriate (between, e.g., a person who is rich and one who is very well off financially). The vagueness of a term reflects its "tolerance" for certain tiny alterations, which can mount up to significant alterations.

But is this insensitivity in the term or is it merely because of the limits of our discriminatory powers, which are foisted on to the term? "Epistemicists" favor the latter, which allows them to avoid offending against standard logic. They hold that there is an exact boundary for vague terms, but it is unknowable (Williamson 1994; Sorensen 2001). (The previous question suggests another: Is it reality – heaps themselves – that is vague or how we describe it, e.g., some collections of grains of sand are described as "heaps"?)

Among the numerous attempts to solve the problem the dominant view preserves almost all of standard logic, allowing only for truth-value gaps. A "supervaluationist" observes that within the indeterminate cases, we are free, as far as a consistent assignment of truth-values, to decide them as serves our purposes, as contextualists claim, too (Fine 1975). Some will treat a U.S. citizen with total wealth of \$325,683.03 as rich and others not (for purposes of assigning, say, an estate tax), because this amount is clearly between the definitely not rich and the definitely rich. When we so decide cases we

provide “sharpenings.” However, on every sharpening “That citizen is either rich or not rich” will be true, so supervaluationists can accept the logical law of excluded middle (although neither disjunct may be definitely true). Consequently, on a supervaluationist view, a conditional sentence – the second step in the sorites paradox (e.g., if that citizen is rich with \$325,683.03 then he is rich with \$325,683.02) will not come out true for every sharpening of it. There is a sharpening under which the antecedent is true, but the consequent false, so that the conditional is false. Because supervaluationism does not reject logical laws and it does not require powers in our language that supercede our own, it has the advantage of providing for a conservative response to the sorites.

But is the supervaluationist right, to return to the earlier example, that “either that room is clean or not” is definitely true, when the room is clearly a borderline case? Worries like this incline others, although far fewer, to take the route of treating the initial reaction that neither alternative is true at face value. We can say only that John’s room is clean to a certain degree, or to a higher degree than others. The error on this probabilistic approach is to contrive to derive absolute judgments from matters of degree.

7. Ordinary Language Challenges to Logic and the Conversationalist Response

A very different source of doubts about logical reasoning as standard first-order logic derives from alleged deviations from ordinary language. Numerous patterns of inference of ordinary language, as well as straightforward readings of complex statements, *prima facie* do not obey the rules governing deductive logic or the logical operators. Some examples:

(20) John goes drinking and John gets arrested.

(21) John gets arrested and John goes drinking.

If “and” is the “&” of formal logic, it is symmetric, so (20) and (21) should be equivalent. Yet, they do not seem to mean the same, (21) does not follow from (20) (or conversely). Another:

(22) John will order either pasta or steak, but he orders pasta.

So (23) John does not order steak.

The inference seems valid, but fails on the truth-table analysis of “v” (inclusive “or”). Finally for an

example using a conditional to which we devote the next section:

(24) If you tutor me in logic, I’ll pay you \$50.

So (25) if you don’t tutor me, I won’t.

The conclusion seems to follow. However, the straightforward translation of it into logic yields a fallacious form, one that appears valid, but that isn’t.

One reaction to such discrepancies is: so much the worse for ordinary language. It requires formal regimentation to be a satisfactory medium of reasoned argument. The opposed reaction is: so much the worse for logic’s claim to provide a systematic analysis of ordinary reasoning.

The most profound reaction is that of H. P. Grice’s (1989). His account of conversational reasoning opposes both previous ones. Grice’s claim is that the logic of ordinary language is already that of formal logic. However, we impose, without recognition of the imposition, assumptions or expectations on ordinary language because we treat the sentences as assertions or other contributions to a conversation. In (22)–(23), we assume that John could not order both pasta and steak, given our knowledge about eating. The inference from (20) to (21) (or their equivalents) stands. However, the speaker exploits the listing of conjuncts, which is mutual with the hearer, as implicating an ordering (in time). Grice’s account explains these deviations without positing an ambiguity in the relevant logical constant (e.g., “and,” “and then”).

Conversation or social communicational exchanges are facilitated by shared or mutual assumptions that are not part of what is said or its logical implications, but which nevertheless are invited, given the common goals of the cooperative exchange. The fundamental “maxim” (and so expectation or presumption) is that the speaker intends to cooperate to advance the purposes of the conversational exchange. The Cooperative Principle (cp) includes subsidiary maxims. The speaker intends his contribution to be informative, warranted, relevant, and well formed (for brevity, style, politeness, and comprehension). This package of maxims under the cp Grice thought to be justified as principles for rational cooperative arrangements for beneficial ends (of transferring information).

What we mean to communicate typically goes beyond what is said, although calculated on the basis of what is said:

H (hearer): Are you going to Jeff's party?

S (speaker): I have an exam the next day.

S's stated response has nothing to do with H's question. But H presumes that S is following the cp, and that is best explained if S meant to communicate a negative answer, as well as supplying H with further information (as to her reason). S conversationally *implicates*, in Grice's term, that she will not attend. If, however, the assertion's only function was to yield this implicature, then the burden on the hearer of drawing the inference, and the risk that he would not succeed, is not worthwhile: Why not answer the question directly? Consequently, assuming that the cp is in force, the speaker must intend to communicate further thoughts (beliefs) – that the studying is his reason for not attending, and that the activities are incompatible. She efficiently conveys much more information than she would by a mere “no.” (Optimization of costs and inferences is central to the pragmatics of Sperber and Wilson 1986).

The technical term “implicature” is meant to draw a comparison with logical implication, yet to distinguish them. The best, although still imperfect, test for implicatures, as contrasted to logical or semantical implications, is *cancellation*. This speaker could say without contradiction: “I have an exam on the next day, but maybe I'll go to the party anyhow.” The second clause cancels the implicature of the first. In (20)–(21), the ordering is arguably not part of the meaning because we can append to either, without contradiction, a cancellation “. . . but maybe not in that order.”

Cancellation provides a way to establish that the fundamental speech-act of assertion does not merely conversationally implicate that the speaker believes what he asserts. For, again, it is contradictory to assert any statement of the form “*p*, but I do not believe that *p*,” which is the basic form of Moore's Paradox. The paradox is that this sentence is consistent: It can be raining (*p*), say, but I not believe it. Yet, it is inconsistent to assert. The impossibility of canceling the implicature leads Grice to explain the “heard” contradiction as stemming from assertion expressing belief, not merely implicating it.

Because the expectation generated by the maxims are mutually known to speakers and hearers, speakers can exploit them to communicate better. Speakers can overtly violate a maxim as with metaphor or irony. In Plato's *Euthyphro*, when Socrates tells Euthyphro “I should be your

student, Euthyphro,” what he asserted is recognized as blatantly unwarranted by his audience (and it is expected to be so recognized by the speaker), so that Socrates implicates the opposite.

Grice characterizes when *p* conversationally implicates *q* as follows:

He [the speaker] has said that *p*; there is no reason to suppose that he is not observing the maxims, or at least the Cooperative Principle; he could not be doing this unless he thought that *q*; he knows (and knows that I know that he knows) that I can see that the supposition that he thinks that *q* is required . . . he intends me to think . . . that *q*; and so he has implicated that *q*. (31)

These chained inferences require the speaker to assume not just that the hearer knows the maxims under the cp, but that the hearer can work out or calculate the implicature, based on his presumption that the speaker complies with the cp.

Grice's essays on conversational implicatures have given rise to a vast amount of extremely fruitful research on pragmatics, spanning a number of disciplines.

8. Conditionals and Conversation

Of all the originally intended applications of Grice's pragmatics to ordinary language inference, the most promising and the most difficult is to the indicative conditional, such as “If John's car is in his driveway, then he is at home.”² The wide disparities between the ordinary indicative conditional (If A, B) and the material conditional (\supset or ‘hook’) of propositional logic are well known. Aside from the material conditional not requiring any overlap in content between antecedent (A) and consequent (B), counterintuitive results follow when the antecedent is false, because then the material conditional is true. (The only secure row in the truth-table for the material conditional is falsity, when antecedent is true and consequent false.) For one problem case: Assume it is false that Jones fails the final. Then it will be true for the material conditional that if Jones fails the final, she will be overjoyed (and also, of course, that if Jones fails the final, she will not be overjoyed).

Grice's suggestion for the alleged failings of the material conditional is that we confuse whether the conditional is true with whether it is

assertible (without misleading). I know that if it is false that Jones fails the final, it would be misleading to assert the conditional. The conditional is noticeably weaker than the relevant information I could assert instead with no more burden on the hearer namely, Jones will not fail the final. (Compare to: either Jones does not fail the final or she will be overjoyed, which is logically equivalent to the material conditional). So the hearer will take the speaker to have (falsely) implicated that she does not know whether Jones fails the final. To explain away the irrelevance problem, a Gricean proposal is that asserting two sentences close to one another would be confusing (disorderly), unless they enjoy some common relation to the informational purposes of the exchange. In the case of the conditional, the relation would be some reason or ground (expressed in the antecedent) for the consequent.

Jackson (1987) developed a Gricean approach. With qualifications, the conditional is the material conditional. But it is assertible only when the consequent remains highly probable (is “robust”) in the event that the antecedent turns out to be true. That is, not only should the conditional be highly probable in itself, but it should also be highly probable *given* that the antecedent is true. The reason for this is that upon learning that the antecedent is true, we want to be able to proceed with such inferences as *modus ponens*, rather than having to withdraw the (material) conditional. Although it may be true that if Jones fails the final, she will be overjoyed, if it is true only because she will not fail, it is unassertible, since it is not robust with respect to its antecedent.

Grice’s proposal, particularly as developed by Jackson, contains insights that all draw on. Tom believes that his son Joe will get his driver’s license, regardless of whether he takes a driver’s ed course. So it will be misleading for him to assert, even if circumstances are otherwise appropriate, “If Joe takes the driver’s ed class, he will get his driver’s license,” although Tom does believe this. Still, the objections to the Gricean analysis are formidable for thought, not just its home territory of conversation. If you believe it is false that Jones fails the final, you may still disbelieve (and not just refrain from asserting) that if she fails, she will be overjoyed. Or, because the negation of a material conditional implies the antecedent and negation of the consequent, I will disbelieve (believe false) that if I get arrested tonight, I’ll go dancing in the morning, while disbelieving, as well, that I will be arrested tonight.

A widely adopted proposal denies Grice’s argument that the conditional is actually truth-functional. Instead, the “if” directs a supposition of the antecedent. (Bennett 2003 for a survey with references to the main contributors.) If, given that supposition, the consequent holds (or it is highly probable) within one’s corpus of beliefs when the corpus is minimally altered to accommodate to the antecedent, the conditional is assertible. (An alternative formulation is via the similarity of possible worlds.) In short, the assertibility (warrant; acceptability) of “if A, B” equals that of $\text{pr}(B/A)$, where this is the subjective conditional probability of B given A, determined in accord with the suggested procedure.

The ‘suppositional’ proposal follows upon the major discovery of Lewis’s (1986b) that the simple equation of $\text{pr}(A \rightarrow B)$ and $\text{pr}(B/A)$ (when $\text{pr}(A) > 0$) fails. Conditional probabilities cannot, without trivialization, be the probability of the truth of a (conditional) proposition. Consequently, one should not view “if A, B” as a truth-bearing proposition, but as an evaluative procedure whereby the proposition A is supposed and B is evaluated on that supposition. The result of that evaluation is not, however, a proposition that is probably true, when B is probably true, given A.

There have been extensive developments of this framework, and the discovery of a number of sticking points such as how to handle embedded conditionals and cases in which it seems that two persons could each have sufficient reasons to accept conflicting conditionals $A \rightarrow B$; $A \rightarrow \sim B$. (McGee 1985; Gibbard 1981)

9. Foundational Problems of Induction

Gricean implicatures are inductive inferences or inferences to the best explanation (what the speaker meant as the best explanation of why he asserted what he did). Aside from a dominant commitment to the probability calculus, there is no analogue for inductive logic of the basic laws or rules of first-order logic to which deviant inductive logics may dissent. Even so basic a rule as the “straight rule” (if m/n As are Bs infer that the probability that the next A will be a B is m/n) has been questioned (doesn’t it matter under what conditions the As were discovered – a single or varied sample?).

Although it seems evident that positive inductive evidence for a hypothesis provides support for it, does that support actually provide reasons to believe that its claims will continue to hold (in the future)? A negative answer

was offered by Hume, at the launching point for investigations of induction. Hume writes

We have said, that all arguments concerning existence are founded on the relation of cause and effect; that our knowledge of that relation is derived entirely from experience; and that all our experimental conclusions proceed upon the supposition, that the future will be conformable to the past. To endeavour, therefore, the proof of this last supposition by probable arguments, or arguments regarding existence, must be evidently going in a circle, and taking that for granted, which is the very point in question. (Hume 1977: 23)

Nondemonstrative arguments about an unobserved (future) event only work if we assume that “the future will be conformable to the past,” which is referred to as the assumption of the uniformity of nature (UN) – the future will be like the past (at least in respect of the regularity involved). So the argument should really be:

In the past, Fs have been followed by Gs (and never by non-Gs).

This present case is an F.

UN: Nature is uniform (at least in regard to Fs followed by Gs).

So, the present case of an F will be followed by a G.

The cogency of this argument turns on the uniformity supposition. Its defense can not be, again, by demonstrative argument, because it is possible that the future is not like the past in this or any other respect. The laws could break down. (“It’s possible,” in Hume’s weak sense of possibility as logical consistency, that the sun does not rise tomorrow.) So then we need a parallel argument for uniformity:

In the past, nature has been uniform (at least in regard to Fs followed by Gs).

The present case is an instance of that uniformity (of an F).

So, the present case will be followed by a continuation of the uniformity (a G will follow).

Because the premises are all about the past and the conclusion is about the future, what is needed is a past-future linking assumption:

In the past, nature has been uniform (at least in regard to Fs followed by Gs).

The present case is an instance of that uniformity (of an F).

Nature is uniform (at least in regard to the uniformity of Fs followed by Gs).

So, the present case will be followed by a continuation of the uniformity (a G will follow).

But the premise affirmed is effectively the conclusion itself or a proposition that implies it. The reasoning is circular in a way that would be found for any inductive or nondemonstrative argument, since they all require the uniformity assumption.³ In brief, even if induction has worked in the past to infer that it will continue to work in the future would itself presuppose the validity of inductive inference, which is what we were supposed to prove.

Karl Popper (1959) champions Hume’s inductive scepticism, stressing that Hume’s doubts or scepticism apply even if the inductive conclusion is to follow only with high probability. Deduction is really the only kind of reasoning. Even if no amount of evidence can increase the inductive probability of any statement, one negative instance is enough to falsify it conclusively.

Popper’s falsificationism claims that scientists should aim only to falsify, not confirm, hypotheses and so they should express hypotheses in as strong a form as possible. Falsificationism runs up against many technical hurdles. Most relevant is a nontechnical problem. Because a strict falsificationist denies any inductive inference, he cannot make sense of the relation between finding positive evidence and rational increases in confidence.

Other responses to Hume’s problem include the proposal to vindicate induction, showing that even if induction cannot be justified, it is the best or the only method that works if anything does (i.e., if nature is uniform) (Reichenbach 1961) and the “Oxford” position that it is a conceptual truth that an empirical statement is justified by positive evidence (Strawson 1952). The latter, however, seems to only push the problem back to determining what counts as positive evidence. Bayesian views, discussed below, hold that opinions or subjective judgments are free for the asking. Conformity with the axioms of probability is the only constraint. But with new evidence our confidence in those opinions and judgments, as hypotheses, are rationally alterable according to a probabilistic analogue of logical consistency and a rule for learning (or updating values). Together these equate the new

probability with the old conditional probability of a hypothesis on that new evidence. The justification of inductive judgments should be viewed diachronically, not synchronically.

We know that overwhelmingly inductive inferences do work. They must or else our success in action, and that of other animals, makes no sense, since induction is our guide to forming expectations and to the future. This is not an answer to Hume's sceptical argument, but only a way to clarify its scope. Even if we cannot demonstrate that inductive arguments must be reliable, it is enough for our confidence in induction that it regularly succeeds. The possibility that the future is unlike the past is not often realized and the world is by-and-large lawful, even if neither observation can be massaged into a justification of induction.

10. Qualitative Confirmation and Its Paradoxes

Although Hume's analysis of induction is the background to the development of an inductive logic, its nearer roots are the project of articulating a logic of scientific method. The project takes off from the failure of Positivist or Logical Empiricist attempts to provide a criterion to demarcate science from metaphysics or nonsense, or, less tendentiously, nonscience. Because scientific hypotheses are typically in the form of generalizations – for example, “ $F = ma$ ” – whose scope is unlimited, and because our evidence for any hypothesis at any time is finite, hypotheses could not be established deductively with premises that only report the evidence.

Our hypotheses are highly underdetermined by the evidence in their favor. Developing a confirmation theory or inductive logic was aimed at the fundamentals of epistemology – to provide standards of rational belief. Initially, the attempt was to propose and examine rules of qualitative confirmation, whose findings were expected to be incorporated into a quantitative account (Hempel 1965).

An attractive starting point is that a generalization of the form “All As are Bs” should be confirmed by all positive instances of it. So a basic rule would be:

(IC) A hypothesis is of the form “All As are Bs” is confirmed by any positive instance “Aa & Ba.”⁴

A second principle is that logical equivalence preserves confirmation, which is recommended

if logical equivalence, as mutual implication, is sameness of content:

(EQ) If H and H' are logically equivalent, then if e confirms H, e confirms H'.

(For development and refinement, the classic is Hempel 1965)

However, a problem was quickly recognized, referred to as the “raven paradox.” The hypothesis

All ravens are black

is logically equivalent to

All nonblack things are nonravens.

According to (IC), the latter hypothesis is confirmed by positive instances, which include blue shoes, a red jacket, yellow baskets, and the noncolorable number 33. So by (EQ) these each confirm H. The result is supposed to be paradoxical because IC and EQ are individually credible, yet they allow that finding a red jacket confirms that all ravens are black.

But is it a real paradox? The basic notion – confirmation itself – is not quantitative. Perhaps, the blue shoe does provide confirmation, only very little. Hempel also observed that simply to reject the EQ is questionable because hypotheses are involved in deductive arguments (for explanations and predictions), and validity does not vary with logically equivalent sentences.

The raven paradox has structural analogies with the Wason selection task – with “vowel” for “raven”; “consonant” for “black”; “even” for “nonraven”; and “odd” for “nonblack.” The well-known findings are that to test the conditional “if there is a vowel on one side then there is an even number on the other” with cards A, D, 4, 7, subjects turn over the A card, but not the 7, and many the 4. The results, originally explained as a result of a bias in search for confirming (positive) to falsifying instances, provides insight into our response to the raven paradox: we think of looking for ravens to observe whether they are black, but not of looking for nonblack things to test for whether they are nonravens.

However, the analogy breaks down at two junctures: First, our response is presumably influenced by the background information of both the relative frequency of the different classes and of the underlying explanatory connections (a genetic account of the original hypothesis (positive) to falsifying instances, provides insight into our response to the raven paradox: we think of looking for ravens to observe whether they are black, but not of looking for nonblack things to test for whether they are nonravens). However, the analogy breaks down at two junctures: First, our response is presumably influenced by the background information of both the relative frequency of the different classes and of the underlying explanatory connections (a genetic account of the original hypothesis (positive) to falsifying instances, provides insight into our response to the raven paradox: we think of looking for ravens to observe whether they are black, but not of looking for nonblack things to test for whether they are nonravens). However, the analogy breaks down at two junctures: First, our response is presumably influenced by the background information of both the relative frequency of the different classes and of the underlying explanatory connections (a genetic account of the original hypothesis (positive) to falsifying instances, provides insight into our response to the raven paradox: we think of looking for ravens to observe whether they are black, but not of looking for nonblack things to test for whether they are nonravens).

Second, in the Wason task, the pairs selected are the unusual ones for which the contradictory is as natural as the original – even-odd; vowel-consonant. But objects that are nonblack are not merely objects with colors other than black, but all manner of objects, like numbers, that could not have a color at all. The Wason task is the specialized one in which the contradictory of a natural category or predicate is itself natural.

Quine (1969) picked up on the unnaturalness of the negation of a natural class to propose that even if the two hypotheses are logically equivalent only the one with the predicate for the natural class is fit for confirmation or projection (to new cases). The notion of projectibility he drew from the far reaching (“grue”) paradox of Goodman (1983). Goodman’s target was a qualitative account of confirmation that attempts to model confirmation (or inductive) arguments on deductive arguments in which validity turns on their form, not their content.

The hypothesis that Goodman selected to formulate his ‘grue’ paradox is:

(Green) All emeralds are green.

He then offered a competing hypothesis:

(Grue) All emeralds are grue.

Something is grue, he proposed, if and only if either it is green and examined before 2050 or blue and examined after 2050. Now take any collection of positive instances of (Green) – for example, the finding of ten green emeralds each confirms, according to IC, (Green). But this same evidence will also be positive instances of (Grue), and so, by IC, confirm it. But this is the ruin of confirmation theory because (Green) and (Grue) compete (they disagree over the color of emeralds discovered after 2050), yet “grue”-type hypotheses can be manufactured for any hypothesis.

The analogy with the “curve fitters” problem is often made. Through any finite set of data points, an infinite number of functions can yield those data points. Which one should be preferred and why? If one of them is near enough a straight line, the others will appear as much more complex, if not bizarre. Still, does this basis for preference correspond to an objective feature of the world or of what we find simple?

Goodman’s Paradox harmonizes with three other important theses about inference and reasoning, noted already: underdetermination, the

Quine–Duhem thesis, and holism. Each of these theses, like Goodman’s Paradox, are extensions of Hume’s insight about induction that the evidence for a hypothesis, however strong, never implies that hypothesis. This much underdetermination is unremarkable. A slightly more exciting thesis is that for any positive evidence for a hypothesis, there are always other competing hypotheses compatible with that evidence. This is only slightly more exciting, because further evidence can be gathered, or tests constructed, to select among the hypotheses at the previous stage. A much stronger and very controversial thesis of underdetermination is that there are sets of hypotheses that are empirically equivalent (sharing the same observational consequences), so that despite their competing or conflicting, no evidence can select between them. Underdetermination has been urged against realist inferences from the confirmation of a scientific theory to either its truth or to the reference of the theoretical terms in it.

These neighboring problems lead to the question of what constraints can be applied to hypotheses so that evidence is a reliable basis to discriminate among hypotheses. In the case of Goodman’s Paradox, a natural thought about “grue” is that it is artificially complex or contrived or that it predicts an arbitrary and radical change in color. Goodman anticipates this worry. He introduces another predicate “bleen”: something is bleen if it is blue and examined before 2050 or green and examined after 2050. For a language with “grue” and “bleen” as primitive or simple as “green” and “blue” in our language, the latter appear complex “x is green if and only if x is grue and examined before 2050 or x is bleen and examined after 2050.” From the point of view of that language, our green hypothesis is complex and it posits a radical change from objects that were grue up to 2050 to their becoming bleen after.

Goodman proposes that “green” is preferable to “grue” because it is projectible, and it is projectible because, in fact, it has been successfully used (projected) in our predictive practices. The solution, as resting projectibility on our successful habits of projection, has struck many as turning on too superficial or accidental a feature. But doubts about Goodman’s solution are not doubts about his paradox as arguing for the need for prior restrictions on the predicates suitable for inductive inference and the confirmation of hypotheses, as well as the formulation of laws of nature.

11. Quantitative Induction and Confirmation

A dominant response to both paradoxes is to give up on qualitative confirmation for a quantitative approach through probability. The basic thought is that probability provides a measure of the degree of inductive support that evidence for a hypothesis transfers to it: If

$$\text{pr}(h | e \& b) > \text{pr}(h | b),$$

where b is the background or previous evidence and e is new evidence, then e is positive evidence or confirms h , and the difference between the two values is the degree of support or confirmation. (For alternative measures of degree of confirmation, see Fitelson 1999, 2003; Kyburg and Teng 2001; Tentori, Crupi, Bonini, and Osherson 2007.)

Because there are hugely many nonblack things, as well as nonravens, especially compared to the class of ravens and the class of black things, the antecedent probability of finding a nonraven among nonblack things is extremely high. Consequently, finding a nonblack nonraven little increases the probability that “All ravens are black.” Understanding confirmation as above, the difference will be very small, the posterior probability becomes only slightly greater. In application to the “grue” paradox, since the prior probability assigned to “All emeralds are green” is significantly higher than to “All emeralds are grue,” the former hypothesis is claimed to be much better supported by a collection of green emeralds than the latter by the same evidence described as grue emeralds. (Is this how the grue-bleen language speakers would describe the difference?)

Goodman originally directed his paradox against the earliest formulations of quantitative confirmation theory in the pioneering work of Carnap (1947; 1962) and Hempel (1965). Carnap began with the specification of a formal language over which a confirmation function was to be defined. Because there were no restrictions beyond coherence on the predicates, Carnap’s formal language was ripe for the “grue” paradox, which demands such prior restrictions.

Carnap’s simplest languages involved one-place predicates and names, and then a state-description is defined as the maximally consistent combination (via negation and conjunction) of all predicates and names.⁵ Each state-description described a complete possible world. How

should an initial probability distribution be set up among these possible worlds? Because there is no basis for taking one world as more likely than another before obtaining evidence, Carnap invoked something like a *principle of indifference* to justify assigning equal probabilities to each state-description. The arresting consequence was that learning from experience – a change in probability values with new evidence – was impossible. Consequently, Carnap proposed a set of inductive method determined by the continuum of ways to reject the assignment of equal weights to each state-description. Of these, one has the philosophical advantage that it is indifferent to bare differences between individuals, but not to kinds or properties. (See Kyburg and Teng 2001; for methods to assess these different inductive strategies see Lewis 1971.) Carnap’s plausible line of reasoning from the assignment of equal weights to state-descriptions converged on the implication of Hume’s and Goodman’s analyses that without prior favoring or biasing toward some “worlds” (state-descriptions) over others induction could not take place.

Conditionalization is the key principle for changing degrees of belief or learning from experience for Bayesians. Given a body of new evidence e , you should adjust your degree of belief in a hypothesis h so that it is now equal to what was (before learning the new evidence) the conditional probability of the hypothesis given the evidence. Conditionalization stipulates that

$$\text{pr}_{\text{new}}(h) = \text{pr}_{\text{old}}(h | e).$$

But how should you compute $\text{pr}_{\text{old}}(h | e)$? Bayesians take their name from Bayes’s Theorem, an elementary consequence of the probability calculus. Bayesians claim that Bayes’s Theorem and its role in conditionalization captures all or just about all that one requires for inductive or statistical inference, including that probabilities can be assigned to all statements. Bayesians have problems with assigning prior probabilities – what is the probability of Newton’s second law before any evidence is in? If the probability is to be assigned objectively, it will have to rely on a principle of indifference. That principle runs into difficulties of conflicting representations of the set of statements to which one’s ignorance is to translate into an equal distribution of probabilities. If wholly subjective, why should the assignments be accorded any respect (Sober 2005)?

In one form (where h and $\neg h$ are the only two hypotheses) Bayes' Theorem states that:

$$\text{pr}(h | e) = \frac{\text{pr}(e | h)\text{pr}(h)}{\text{pr}(e | h)\text{pr}(h) + \text{pr}(e | \neg h)\text{pr}(\neg h)}$$

(Here as elsewhere, it is assumed that denominators do not equal 0.) Where there are n mutually exclusive and exhaustive hypotheses (h_i), the general formula is:

$$\text{pr}(h_j | e_j) = \frac{\text{pr}(e_j | h_j)\text{pr}(h_j)}{\sum_{i=1}^n \text{pr}(e_i | h_i)\text{pr}(h_i)}$$

The main components of Bayes's Theorem are the likelihood $\text{pr}(e | h)$ and the prior probability $\text{pr}(h)$. To know how likely it is that the evidence arose from h requires knowing not only of the connection between e and h , but also how antecedently likely it is that h is true. It is highly likely that if there is a snow storm in Miami that school will be canceled. Yet, the probability that the school was actually canceled because of a snow storm is still quite low. To derive the probability of h on e also requires evaluating the probability that h actually arose from e compared to the other possible hypotheses that might account for e (the denominator above).

Bayes's Theorem provides good explanations for intuitive judgments about induction such as the value of evidence that is surprising or diverse (Bovens and Hartmann 2003: Ch. 4). The posterior conditional probability of h on e , $\text{pr}(h | e)$, expresses how much more expected h is were e true. Assume that finding e is very unexpected (its prior probability is low) (e.g. Alfred E. Neumann receives an A in his logic final). However, were h true (e.g., he had a copy of the exam earlier), e would not be surprising. So $\text{pr}(\text{AEN gets an A} | \text{AEN has the exam in advance})$ is high. In that case, e greatly confirms h [i.e. $\text{pr}(\text{AEN has the exam} | \text{AEN gets an A})$ is also high]. (This pattern of reasoning is common in inference to the best explanation discussed in the next section.)

When we move from Bayes's Theorem to Bayesianism, which restricts probability to degrees of belief or subjective probabilities, we move from the taken-for-granted to the controversial. A major advantage claimed for Bayesianism is theoretical minimalism: No claims or assumptions are made as to the basis for the initial assignment of probabilities beyond what follows from one's degrees of belief (with prior

probabilities, before any learning, problematically dependent on a principle of indifference, as noted earlier). The only demand on those degrees of belief is consistency or coherence.

The minimalism is one source of criticism: any assignment of probabilities is as good as any other provided only that they are coherent (i.e., conform to the axioms of probability). Conditionalization provides for the response that if individuals assign similar values to the likelihood and conditionalize, then with new information there will be convergence on assignments of probability. But only if there is uniformity in how to judge the new information as evidence. (Another problem is how to treat old evidence newly discovered to be implied by a long-standing hypothesis or theory, so that there is no change in the probability of the evidence; Glymour 1980.)

Bayesians tend to treat all learning from experience as changes in probability by conditionalization. The treatment is in opposition to construing theoretical reasoning as aiming at the all-out acceptance (or rejection) of a hypothesis as true, detaching it from its evidential base. The Bayesians worry that the detachment is in conflict with a recognition of our fallibility, discussed later, and related problems like the dogmatism paradox mentioned in Section 5 (Levi 1980; Jeffrey 1983; Kaplan 1996).

The possibility of detachment is one way to understand a difference between probability and inductive inference. Think of a simple inductive inference, for example, Alice is an academic whose library is filled with books on early American history, so she is [probably] a historian. Strong detachment marks the end of an inquiry. The judgment or hypothesis is separated from its evidential base with all-out acceptance. Detachment implies a claim that the evidence is sufficient or representative enough for drawing a conclusion, rather than just assigning a probability on that evidence. Detachment is a risk, requiring an underlying pattern or law or regularity that is indicated by the evidence. But without taking that risk, an inquiry would never terminate, so long as the evidence leaves open the possibility of error (i.e., does not establish the hypothesis as certainly correct). The underlying regularity allows for the detached judgment, since it allows us to project from, but to go well beyond, the evidence.

By contrast, consider a fair lottery with one thousand tickets of which you own one. The probability of your losing is very high: .999. It

is reasonable to assume that this probability of your losing is higher than the probability that Alice is a historian, based on your knowledge and observation (maybe the library is simply an inheritance from her parents who bequeathed her the house?). Yet you cannot detach – all-out believe – that you will lose the lottery. Otherwise, purchasing a ticket would be worse than merely incurring a high negative expected utility. It would be to throw away money, since there is a cost without prospect of gain. Still, you can all-out believe or come to know that Alice is a historian. How come? The answer resides in the assumed underlying regularity or law in the historian case, but not for the lottery. Only the former then permits projection beyond the evidence.

An alternative explanation is that in the former case (that Alice is a historian) there is an implicit deductive argument, yielding a probability of 1, but not in the latter (that you will lose the lottery). However, even if the generalizations, regularities, and other assumptions, which underlie the inference, would, if stated explicitly, yield a deductive argument, it does not follow that the original argument is only an enthymeme for (i.e., an abbreviated version of) that deductive argument. The presumed generalization includes that conditions are normal and that in such conditions, if one is an academic and one's library is dominated by books in a certain field, then the field is one's profession. If the normalcy condition is understood to exclude all ways that the conclusion could be false, not already excluded by the explicit premise, we have a formula to convert any inductive argument into a deductive one (see Smith, Shafir, and Osherson 1993). But this does not explain the difference between the historian and the lottery arguments, any more than if we add a conditional whose antecedent is the conjunction of premises and the consequent is the conclusion, as a way to turn any argument into a modus ponens deductive one. For these additional assumptions, which are unnecessary for the high probability of the lottery cases, are themselves not backed by any grounds additional to the premises. The risk – that is, the inductive gap between premises and conclusion – is the same as the gap between the premises and these assumptions. Nothing is advanced in the argument, but only in the recognition of its basis.

If there is all-out acceptance, how should it be based on probability? A simple proposal for

relating probability to acceptance (one that we have just implicitly rejected) is

(ACC) $\text{Acc}(p)$ if and only if $\text{pr}(p | e) > r$, r is some suitably large value – certainly greater than .5.

But for acceptance (or detachment) more is needed. The evidence e must constitute representative evidence. Its weight of evidence – the proportion of the evidence – must be high or maximal (Keynes 1952, Cohen 1977).

Regardless of the value selected for r , Kyburg (1961) showed that a paradox follows if a conjunction principle holds:

(CR) $\text{Acc}(q_1), \dots, \text{Acc}(q_n) \implies \text{Acc}(q_1 \& \dots \& q_n)$.

To make it clear that the “Lottery Paradox” is indifferent to values of r (less than 1), let's set the criterion very high, say, .95. Kyburg asks us to imagine that there is a fair lottery with one thousand tickets. You have one ticket t_{123} . The probability that you will lose the lottery with that ticket is .999, which exceeds the criterion. So, in accord with (ACC), you accept the statement that you will lose the lottery. But now for each of the other 999 tickets, the probability that each of them will lose is also .999. So each of them satisfies the condition for acceptance. Because, by (ACC) you accept, for each of the one thousand tickets, the statement that it will lose, (CR) tells us that the conjunction of those one thousand statements is likewise accepted. It follows that you have accepted that all the tickets will lose. But it is impossible for every ticket to lose, if it is a fair lottery.

Both (ACC) and (CR) have come in for rejection as a basis to resolve the lottery paradox. (CR) is disputed (and here is where the Bayesian attacks) because when probabilities are multiplied (in non-extreme cases), the result is necessarily a diminution in probability. (The probability of $q_1 \& \dots \& q_{1000}$ will typically be far below the acceptance threshold, r .) However, if acceptance is all-out, the truth of a conjunction is logically equivalent to the truth of its individual conjuncts, and so (CR) seems another expression of the basic idea of acceptance. This defense of (CR) goes along with a challenge to (ACC): probability alone is never sufficient for acceptance. As noted earlier, in distinguishing the assignment of probability from genuine inference (and detachment), no one can all-out believe that they will lose a lottery with a single ticket in contrast to the more precise assignment

of a high degree of belief. The contrast between the lottery case and genuine inductive inferences provides for an answer to the lottery paradox that is different from the one Bayesians offer, when they allow for acceptance at all (Kaplan 1996). What more than high probability (and high weight of evidence) is required for acceptance is a lingering question.

12. Inference to the Best Explanation

A natural form of inference is to infer the hypothesis that best explains the data. Sherlock Holmes infers that the owner of the dog committed the crime because this is the best explanation of why the dog did not bark when the crime was committed nearby. The data of the dog's not barking confirms the hypothesis that the owner committed the crime, and the hypothesis is introduced to explain why the dog did not bark. Inference and explanation implicate each other. Inference to the best explanation is at work where observable events, like John's rude behavior at a party, are explained by the hypothesis of an unobserved (and sometimes unobservable) cause (e.g., John was just fired from his job). (For criticisms, see van Fraassen 1980.)

Inference to the best explanation offers a promising approach to the confirmation paradoxes. The best explanation of why nonblack things are nonravens will *not* be that all ravens are black, or even that all nonblack things are nonravens. The finding of nonravens among nonblack things is best explained by the fact that nonblack things are just such a numerous and heterogeneous collection that it is unsurprising that we should find some, and so it calls for no further explanation. Similarly, that the observed emeralds have been green is well explained if all emeralds are green, which, as well, give us reason to expect the next observed emerald to be green. But the grueness of the observed emerald is not well explained by the hypothesis that all emeralds are grue, because that implies that unobserved emeralds will be blue. (For advances along these lines, see Jackson 1975; White 2005.)

Inference to the best explanation captures Peirce's (1931) "abduction," whereby plausibility accrues to a hypothesis – it is worth taking seriously. When you meet someone at a party who dresses in a similar slightly off-beat way of another acquaintance, you might think that they share political or cultural views. Although the

off-beat dress is a reason to take seriously the hypothesis that the two share political or cultural views, it is hardly much of a reason to actually believe it. Suggestive or analogical reasons are important in view of the underdetermination problem of the unlimited number of hypotheses to fit any data, as well as the problem of coming up with credible hypotheses to explain complex data or observations.

Inference to the best explanation serves a stronger role as a form of eliminative inductive, whereby evidence is sought to select among rivals:

one infers, from the premise that a given hypothesis would provide a "better" explanation for the evidence than would any other hypothesis, to the conclusion that the given hypothesis is true. (Harman 1965)

Inference to the best explanation is closest to causal explanation, where competitors are specified by contrasts – why p rather than q . When the bank robber Willie Sutton was asked why he robbed banks, he responded "Because that's where the money is." He construed the question as something such as "Why do you rob banks, rather than grocery stores?" Although having lots of money in an accessible location is only one cause for his robbing banks, it is the one that makes the distinctive difference between Sutton's robbing the bank and his robbing the grocery store. However, his questioners actually had in mind a different question, calling for an answer selected from a different contrast class ("rather than"): "Why do you rob banks rather than working a decent job?" (Garfinkel 1981).

If the best explanation is accepted as correct or even as worthy of investigation, it must at least provide a good explanation, not merely the best of a lousy lot. Criteria for the best explanation include that the hypothesis is simple, conservative, and unifying. However, the criteria should not include an explicitly truth relevant property such as high probability. That is the conclusion to be reached not assumed. The hypothesis that yields the most understanding must prove itself to be the likeliest (Lipton 2004).

Inference to the best explanation is at the center of the "miracle argument" from the success of science to a realist view of science, which hold that scientific theories are at least approximately true and that its theoretical terms genuinely refer, rather than merely serving as useful posits. The question is whether these realist claims are the best explanation for the success

of science, whose success would otherwise be a “miracle” (a grand coincidence).

13. Foundational Justification: Coherence and Reflective Equilibrium

How at the most basic level should the putative rules or principles of logic (inductive, deductive, practical) be justified?

Earlier, we noted that Bayesianism’s admirable minimalism invites the criticism that it allows one to believe almost anything, so long as one conforms to the axioms of probability. It is evident that logical consistency is much too weak a criterion for rational belief – the belief that Santa Claus brings presents or that there are an even number of stars are both logically consistent. But, recall, Bayesians have a distinctive consistency requirement – coherence – which they offer to justify the probability axioms as representations of degrees of belief and preferences, and this notion they think is sufficient (with conditionalization) to represent rational belief.

The coherence arguments for commitment to the probability calculus are known as “Dutch Book Arguments.” These arguments claim that if your preferences or degrees of belief do not conform to the probability calculus then a set of bets (a “book”) can be designed that you are committed to regarding individually as fair, because fitting your preferences. (For references and presentation, see Hacking 2001; van Fraassen, this volume.) The bets, however, guarantee that you cannot win or that you must lose. (Conversely, if your degrees of belief do conform to the probability axioms, no “book” can be made against you.) The argument requires an idealization away from influences on betting besides an interest in winning, like the pleasure of gambling. A more problematic assumption is that logical omniscience (deductive closure) is needed, because the probability of deductive truths must be assigned the value 1.

The “sure loss” or “Dutch Book” argument can be extended to justify a principle for changing one’s degree of belief by conditionalization (see Section 11). Conditionalization, recall, assigns a new probability when evidence is obtained as the old conditional probability on that evidence:

$$pr_{\text{new}}(h) = pr_{\text{old}}(h | e).$$

(Teller 1973; Lewis 1999; for a more general form of conditionalization, see Jeffrey 1983).

If coherence is an extension of consistency, it provides a model for the justification of the axioms of probability as representing degrees of belief that is *a priori* (not dependent on experience or sense perception). It remains an open question as to how successful are the Dutch Book Arguments and how general a model for justifying principles they provide. They do not pretend to answer Hume’s problem, but they do claim to mitigate it. A principle for learning from experience is justifiable as a way to protect against a self-defeating set of preferences or degrees of belief, even if it cannot guarantee success.

Can this model be generalized to justify rules of logic (inductive, deductive, practical)? A familiar problem is that consistency or coherence is too weak, since plausible rules that are incompatible with one another can form internally consistent systems. Once substantive principles are offered besides consistency, the evident problem is a version of Hume’s circularity problem (see Section 9): To establish the rules of logic requires reasoning, and how can one reason without logic (Boghossian 2000)? However, certain kinds of circularity are not a failing or not a decisive one. Proofs of the soundness of a logical principle, like the rule of conjunction simplification (“ $p \& q$ ” implies “ p ”), use an analogue of that principle in the proof. But the analogue – the soundness proof – is not syntactic or at the object level, but at the meta-level or the semantics (Dummett 1978).

A traditional view is that logic is established *a priori*. We have already noted that the Dutch Book Arguments aspire to an *a priori* justification for inductive principles. But Dutch Book Arguments do not reach to the foundations, since they presuppose a particular view of consistency. For logic, one approach is to claim that from reflection on, or analysis of, concepts such as “if, then,” we can validate laws like *modus ponens*. Reflection on the concept of negation is supposed to show that instances of the $p \& \sim p$ must be false. This view is an advance on the one that claims that we have a faculty of intuition to discern logical laws, which merely pushes the problem back to validating the faculty of intuition. *A priori* knowledge is knowledge that is not based on experience, and since on traditional views they are necessary truths, such knowledge is indefeasible (no empirical findings could count as evidence against a genuine logical law).

Strict empiricists – stricter even than Hume – are not satisfied with the claimed power of reflection. They attempt a straightforward a posteriori or inductive approach to logical laws as

generalizations from observations of uniformly successful inferences. These laws are subject to hypothesis testing akin to any empirical claim (Mill 1963).

The strict empiricist approach is unpopular on Kantian grounds that observations or related evidential considerations can never establish the necessity of logical laws. An improvement over empiricism on this count is that with a logical law we cannot conceive of its failing. But what is the relation between conceivability or imaginability and real possibility (Yablo 1993)? As Putnam (1975) noted, our ability to conceive that water is not H_2O does not entail that it is really possible that water is not H_2O .

A more recent approach is to seek reflective equilibrium between principles (or rules) and judgments (or intuitions). Earlier, we noted how a soundness proof justifies a particular rule by showing that it generates only valid arguments. The semantic version of the rule is legitimate if its use is only to explain why the rule is endorsed. But for ultimate justification of a rule or principle, this explanation, which takes a lot of standard semantics for granted, is not sufficient. The justification of any set of principles eventually confronts two horns of an ancient dilemma. Either the justification process relies on further principles to justify others, which must finally be exhausted, and so return – circularly – to principles already used or, and this is the other horn, the process never exhausts itself. The process never stops. Each new principle requires a further and different principle to justify it in turn. There is an infinite regress, because these different principles must themselves be justified. The rules for, say, the derivation of excluded middle – that is, $p \vee \sim p$ – are justified by the truth-table for “ \sim ” and “ \vee .” But what justifies the truth-table (as corresponding to “not” and “or”)?

Reflective equilibrium answers the latter horn by claiming that there is a starting point, rather than a regress, in the judgments of validity we already accept. It answers the former, circularity, horn by conceiving some circularities as an acceptable matter of accommodation or balance. In the richly suggestive passage that launched the reflective equilibrium model, Goodman explicitly compared the justification of inductive and deductive rules:

How do we justify a *deduction*? Plainly, by showing that it conforms to the general rules of deductive inference. . . . Analogously, the basic task in justifying an inductive inference

is to show that it conforms to the general rules of *induction*.

. . . Principles of deductive inference are justified by their conformity with accepted deductive practice. . . . Justification of general rules thus derives from judgments rejecting or accepting particular deductive inferences.

This looks flagrantly circular. . . . But this circle is a virtuous one. The point is that rules and particular inferences alike are justified by being brought into agreement with each other. *A rule is amended if it yields an inference we are unwilling to accept; an inference is rejected if it violates a rule we are unwilling to amend.* The process of justification is the delicate one of making mutual adjustments between rules and accepted inferences; and in the agreement achieved lies the only justification needed for either. (Goodman 1965: 63–64)

Reflective equilibrium is intended as an alternative to a purely a priori justification of logical principles. Reflective equilibrium embraces neither a crude inductive justification (as just a generalization from successful instances) nor a “foundational” one, which treats some principles as sacrosanct.

In this respect, reflective equilibrium is closely aligned with coherentism in epistemology, the view that justification is holistic (Elgin 1996): A principle is justified to the extent that it coheres within one’s corpus of beliefs. However, if the coherence is only within one’s current corpus of beliefs, it is a narrow reflective equilibrium. It lacks the justificatory force of a wide reflective equilibrium, where one’s judgments (intuitions) and principles are evaluated against alternative principles and they are subjected to extended critical analysis. Although the approach was originally proposed as a guide to generating inductive rules, it has been invoked predominantly as the underlying model for theory construction in moral or political philosophy (Rawls 1971).

As a description of our actual practices in proposing or justifying rules, reflective equilibrium is on target. When it comes to the conditional, for instance, modus ponens and falsity when antecedent is true and consequent false are strong intuitions, with contraposition much less secure, and modus tollens in between. However, reflective equilibrium can provide little further substantive guidance. It does not specify how to balance among principles or judgments when they conflict. So it cannot settle serious disputes.

Recall that Goodman himself rejected an intuition about his “grue” paradox that most others took as a pillar.

What counts as an intuition anyway? Most of us deny the validity of disjunctive weakening (i.e., “ p ” implies “ $p \vee q$ ”) on initial presentation. But students are brought around by the truth-table analysis. Is the former the intuition or the latter, and how do we characterize the difference in a general way? (Is it to be assimilated to the difference between narrow and wide reflective equilibrium?) Systematization pressures intuitions. Given the interconnections that any logical system quickly establishes, principles and rules are not going to be readily adoptable or modifiable piecemeal to capture particular judgments or intuitions. Thus, to use the unintuitive rule of disjunctive weakening again, it follows almost immediately if the rules either of *reductio ad absurdum* or conditional proof are available.⁶ Without further modification, to reject the former requires rejecting the latter. (Intuitionists and their sympathizers, however, treat the additional losses as a bargain.)

14. Paradoxes

Reflective equilibrium is a practical approach to the evaluation of reasoning principles, offering no latitude for sceptical doubts about the ultimate justification of our principles (or intuitions). A search for reflective equilibrium is impatient with paradoxes, like the sorites, because one option in the face of paradoxes is a sceptical or nihilist conclusion that certain basic concepts are ultimately incoherent, even if we seem to make intuitive sense in talking about them.

Paradoxes involve the derivation of either a contradictory or a starkly unacceptable conclusion, like that there are no heaps or rich people, from *prima facie* valid chains of reasoning, derived from apparently sound premises. A solution to a paradox would be to uncover an error either in the premises or in the reasoning. Difficulties in solving the paradoxes, particularly ancient ones like the sorites, raise sceptical prospects.

If not the sorites, then the Liar, is the paradox that has occasioned the most intense investigations. Tarski’s equivalence condition earlier (see Section 2) was formulated in his response to the Liar Paradox:

(A) Sentence A is false.

From an intuitive assumption about any sentence, (A) is either true or false (or expresses a proposition that is either true or false). If it is true, what it claims is correct. But what it claims is that (A) is false, which is, effectively, “I am false.” So, it’s false. If, however, it is false, then what it claims is wrong. So it is true. In short: (A) is true if and only if (A) is false.

Like the sorites, the Liar Paradox encourages suspicion of bi-valence (the thought that every sentence is true or false), while supporting logics allowing for truth-value gaps, as well as gluts (more than two truth-values) However, if you think that this move alone will do the trick, out pops a “strengthened Liar”

(A′) Sentence A′ is not true.

One can claim that denying “Sentence A is false” does not necessarily imply that Sentence A is true. But this is no escape from the strengthened Liar, because even if “not true” is weaker than “false,” as the strategy requires, the contradiction arises when we ask whether (A′) is true.

Focusing on a version like (A), Tarski thought the culprit is that “semantically closed languages” (i.e., those which contain their own truth predicate and a device – like naming – to denote each sentence) are inconsistent. In those languages, not every sentence can be assigned the value *true* or *false*. Part of Tarski’s solution is to define truth only for open languages, establishing a hierarchy: truth for language L is defined in a higher (meta) language, which has the resources to pick out all the sentences of L. Tarski showed how to define truth for a language (in a meta-language) by way of recursive definition. From a finite assignment of truth to atomic sentences, sentences of any complexity can be generated, for example, “A and B” is true if and only if “A” is true and “B” is true. (For critical discussion Field 1972; for applications to natural language Davidson 1984. Kripke (1975) contains both an example of consistent predications of truth that receive contradictory assignments in Tarski’s hierarchy and an alternative way to define truth.)

One problem with Tarski’s approach to our ordinary notion of truth is that we can understand sentences that predicate truth without any knowledge of their truth-level in his hierarchy. A suggestion here is that “true” is implicitly indexical, like “I” or “you,” whose reference is determined within the context of utterance, although the meaning is constant (Kaplan 1989). Thus:

(A) Sentence A is not true₁

and

(A) Sentence A is true_{l+1}

are not contradictory, anymore than “You are a lefty” and “You are a righty” affirmed of different people (Burge 1979).

A paradox of set theory, whose origin lies with Liar-like self-reference, was discovered by Russell – hence, “Russell’s Paradox.” Typically, members of a class, like members of the class of people, are not themselves classes and so they cannot be members of themselves. But some classes are: The class containing as members all classes that have more than five members. Russell asked a question that combined these: Is the class of all classes that are not members of themselves a member of itself? If so, then it meets the defining conditions that it is not a member of itself, so it is not a member of itself. But if it is not a member of itself, then it satisfies the condition, and so must be included as a member of the class of all classes that are not members of itself. In brief, the class of all classes that are members of themselves is a member of itself if and only if it isn’t.

Even though Russell’s Paradox is one of set-theory and the Liar one of semantics, they have striking similarities, which led Russell to compare them. The contradiction yielded by either involves similar reasoning from respective self-referential questions. Both involve extremely plausible existence claims about the universal predication of their respective key notions (truth-value; membership) and invite similar hierarchical restrictions on that predication. The problem is not self-reference alone. Numerous self-referential statements are unproblematically true (“This sentence is in English”) and others unproblematically false (“This sentence is in Russian”). Russell thought that the essential connection was, roughly, that a member of a totality is defined in terms of the totality (the Vicious Circle Principle).

A number of the central paradoxes share a feature close to the fault line that Russell proposed. These paradoxes claim the existence of a meaningful property or term to fit a specified general condition. The sorites requires that to every concept there is a determinate answer to whether the concept applies to an object or not. The very different “grue” paradox still has this feature: It casts doubt on the condition that to every predicate there corresponds a confirmable or projectible property. The Liar Paradox assumes the condition that to every grammatically well-formed sentence there is one of

two truth values. Russell’s Paradox is sometimes illustrated by the Barber Paradox. In a town, where the barber shaves all and only those citizens who do not shave themselves, who shaves the barber? A Russell’s Paradox-like contradiction follows. But the Barber is only a contradiction, no paradox. For no credible principle establishes that there is such a barber. Not so for Russell’s Paradox. Russell originally directed his paradox to an explicit axiom of Frege’s system, which implied the assumption tacitly made in constructing the paradox: To every coherent condition there is a set meeting exactly that condition.

The natural reaction to Russell’s Paradox is to deny that the membership in the set of all sets that are not members of themselves is a coherent condition. But the denial does not sit well with much positive work in set theory and, specifically, if the restriction suggested is not qualified it undermines other fundamental results (e.g., Cantor’s diagonal proof that the power set of a class has more members than the class, a proof that shares structural features with many paradoxes, including the Liar and Russell’s).

15. The Preface Paradox, the First Person, and Fallibility

The Preface Paradox is a paradox of self-reflection that arises naturally from thoughts about one’s fallibility. Its name derives from a typical disclaimer that occurs in prefaces to books (Makinson 1964). The author of a non-fictional work writes something intended to express modesty “Remaining errors in the book are my own.” The author is justified in making this assertion. Given the numerous statements in the book, he is bound to have made some error. Assuming the author is conscientious, however, he believes each sentence he wrote and asserts them to be true. But it is impossible for each statement in the book to be true, if the preface is part of the book.

The bite of the Preface Paradox arises when we realize that fallibility about one’s own beliefs is akin to the modesty expressed in the preface. In taking oneself to be fallible one appears to believe that “at least one of my beliefs is false.” However, for each of one’s beliefs, one does (trivially) believe it. But one’s corpus of beliefs, including the belief in one’s fallibility so expressed, is inconsistent. As standardly presented, the Preface Paradox has the form of “w-inconsistency.” All instances of a generalization are true, but not the generalization itself.

Unlike other paradoxes, the dominant view is that the consequence of the Preface Paradox is acceptable. In maintaining this corpus, a fallible believer is “being rational though inconsistent” (Makinson 1964: 207).

But can we just resign ourselves to this consequence? The result would be a kind of complex Moore’s Paradox: “ $p_1, p_2, \dots p_n$, [are each true] but I believe that not all of $p_1, p_2, \dots p_n$ [are true],” where among the p_i is the quoted sentence itself. A different way out is that even those who admit their fallibility do not really all-out believe that at least one their beliefs is false. Rather, they take it to be only extremely probable in parallel to the impossibility of all-out accepting that one will lose a fair lottery with a single ticket.

How should one factor into any of one’s reasoning (inclusive of that reasoning) one’s belief that one is fallible? Hume (1978) observed that if we incorporate into our judgments an evaluation of those judgments that represents our fallibility, a sceptical regress threatens. Hume writes:

In every judgment, which we can form concerning probability, as well as concerning knowledge, we ought always to correct the first judgment, deriv’d from the nature of the object, by another judgment, deriv’d from the nature of the understanding. . . . In the man of the best sense and longest experience, this authority is never entire; since even such-a-one must be conscious of many errors in the past, and must still dread the like for the future. Here then rises a new species of probability to correct and regulate the first. . . .

Having thus found in every probability, beside the uncertainty inherent in the subject, a new uncertainty deriv’d from the weakness of that faculty, which judges, and having adjusted these two together, we are oblig’d by our reason to add a new doubt deriv’d from the possibility of error in the estimation we make of the truth and fidelity of our faculties. . . . But this decision, tho’ it shou’d be favourable to our preceding judgment, being founded only on probability, must weaken still further our first evidence, and must itself be weaken’d by a fourth doubt of the same kind, and so on *in infinitum*; till at last there remain nothing of the original probability. (182–183)

This argument is puzzling even aside from its skeptical end, because it seems only to require a recognition of one’s fallibility and the willing-

ness to take that into account to qualify one’s judgment. However, once a judgment is made, it is made, and to do it over in light of one’s fallibility is to just double-count. Moreover, why should the correction – representing one’s fallibility – lessen the original probability, rather than raise it? After all, fallibility is about error, and one can err in either of two directions – overestimate, as well as underestimate. Fallibility bears on the weight of evidence, not its force. (In familiar psychological studies, subjects are asked, e.g., “Which is more populous city San Diego or Santa Fe?” After providing that answer, subjects are asked, “How confident are you in your prior judgment?” Hume’s conflated question now is evident: “How probable do you now think it is that Santa Fe is larger than San Diego in light of your prior judgment of fairly high confidence in your even earlier judgment than Santa Fe is larger than San Diego?” [huh?].) Consequently, it does not make sense to calculate the probability of a judgment by an integration (via Bayes’s Theorem) with the weight of evidence, where this is measured in Hume’s terms, by one’s estimate of one’s degree of fallibility for the judgment at hand.

16. Fallacy and Charity

If the objections just given succeed, Hume’s argument is fallacious. A fallacy is an argument that seems to be good, but which isn’t (Hamblin 1970). One is falsely persuaded, unlike the case of crudely bad reasoning (e.g., If John is in Albany, he is in New York. So even if he isn’t in Albany, he is in New York.).

The following is an example of a student committing a fallacy of denying the antecedent (i.e., “If p then q ; not p ; therefore, not q):

(26) If I don’t study, my dad won’t let me go to the party.

So, (27) I’ll study, then he has to let me go out.

More common and seductive are fallacies of scope:

(28) Necessarily, if Jeff is a teenager, he is under twenty.

(29) Jeff is a teenager.

So, (30) Necessarily, Jeff is under twenty [i.e., he cannot become an adult].

Or, (31) Alice does not believe that the library is open on Saturday.

So (32) Alice believes that the library is not open on Saturday.

But are these common fallacies? Would not anyone who reasons to (30), really mean that Jeff must be under twenty only given that he is a teenager? Assumptions about the necessity of human rationality have led to scepticism about whether people ever really commit fallacies or that there really are common fallacies. (A weaker reading is that the attribution of fallacies is never warranted. Problems with the former, which we concentrate on, apply to the latter.) The best defense of this conclusion is that when we understand the speech-acts of others, we must see them as rational, hence, we must interpret their assertions under a *principle of charity* (Davidson 1984). Think of the comprehension of metaphor or hyperbole or similar figurative speech, along lines already suggested by Gricean pragmatics (see Section 7). A recent newspaper column states “Bush is radioactive.” If the political commentator who wrote it really believed that President Bush is subject to radioactive decay, he would have to be so bereft of rational thought that he would be unintelligible, including to himself. Instead, the striking falsity of a literal reading of that utterance is a signal to infer that the best explanation of what is meant is something different, for example, if a political leader associates closely with President Bush, the association immediately taints that leader. Now the speaker can be readily viewed as rational (Davidson 1984) and as speaking in accord with the cooperative principle (Grice 1989).

Because a fallacy is a serious failure of reasoning, the principle of charity, as well as the cp, are alleged to undermine a fallacy reading, especially, where an evident nonfallacious alternative is available. In (26)–(27), the first premise, although stated as a conditional, is reasonably meant as a biconditional and then the inference goes through.

Scepticism about the commission of fallacies is unwarranted. First, when someone commits a fallacy, the person need not, even cannot, recognize it as having a fallacious form (e.g., if A, B; so if not A, not B), let alone being a fallacy (which would be to commit a Moore’s Paradox: “My argument establishes its conclusion, but the argument is fallacious”). Second, the principle of charity, assumptions of rationality, and the cooperative principle assume a background of mostly well-founded beliefs and good reasoning. One can commit many fallacies compatible with this assumption, because the “mostly”

is for a much larger reference class of beliefs and reasoning than the “many” (salient or prominent arguments). The former include such banalities as that: If today is Tuesday, I have class. Today is Tuesday, so I have class. Or, Jim is not in the classroom. So, Jim is somewhere else. You can easily understand and communicate with a person, who commits the above three fallacies, because his reasoning remains predominantly cogent.

In fact, one can readily explain on rational grounds why the above and other seductive fallacies are committed. It is easy enough to construct a reasonable path (from a misunderstanding of the law of large numbers) to the committing of a gambler’s fallacy. Or, take (26)–(27). The student understands the relevant words and sentences he utters, which already presupposes a huge amount of rationality. (The student realizes that his father takes seriously that he should study, that this is a domain of his father’s authority, and that his going to the party depends on his father’s approval.) The student also understands that many times when he has done what the father regarded as his duty, the father allowed him to engage in a desired activity only when the duty was performed. Factor in to this attempt at rational explanation for fallacious thought normal human distraction and indifference, as well as our inclinations to impose contextually invited assumptions. It is not then at all uncharitable to ascribe to the student an inference on these occasions to the belief that whenever he fulfills a necessary condition for gaining his father’s permission, he has thereby fulfilled a sufficient condition, although the student probably would not describe it in these ways (of “necessary” and “sufficient” conditions). Finally, a simple test applies. Would the student who reasons from (26) to (27) be surprised and taken aback, rather than hostile to an unfair accusation, by the following argument as paralleling his own in form and yet clearly (to his mind) fallacious?:

(33) If I don’t study, I won’t get into Yale.

So, (34) I’ll study, then I must get into Yale.

17. Implicitness and Argument

These examples all illustrate one facilitator of fallacies, compatible with our rationality and basic reasoning competence. Much of our reasoning and particularly our ordinary arguments are tacit or implicit as compared to the reconstructions of those arguments, where missing

or hidden assumptions are stated. The student would likely not endorse the abstract logical principle his argument assumes: if p , q . So, if not p , not q .

This observation provides no formula for eliminating common fallacies, because ordinary argument and reasoning cannot aspire to much explicitness. Implicitness is a barrier that can be overcome in specific cases, but it is ineliminable, for reasons of economy and limited grasp of our beliefs. Tacitness or implicitness is evident in the drawing of conversational implicatures, allowing communication of much information with brevity (see Section 7).

The extent of the implicitness even of deductive arguments is obscured when they are reconstructed so that the validity is exhibited in the logical form alone as with the opening example (1)–(3): Either p or q . Not p . So, q . There are valid arguments, whose validity does not reside in their logical form:

(35) John is taller than Jim.

So, (36) Jim is not taller than John.

The argument's validity pivots on the asymmetry of "is taller than." But asymmetry is clearly not a property of all relations or two-place predicates (cf., "as smart as"). To capture the validity of (35)–(36) by logical form, there would need to be a separate premise affirming the asymmetry of "is taller than."

In everyday reasoning rarely would such a premise be explicitly thought. If arguments or inferences are not valid by their logical form alone, then arguments such as (35)–(36) can be valid as they stand (Brandom 1994, Ch. 2; Thomson 1965). It is valid as a result of the content of its substantive or nonlogical vocabulary ("is taller than"), rather than only because of its logical form as with (1)–(3).

Accepting the validity of (35)–(36) as it stands is one way to introduce the implicit nature of much reasoning, though greatly understating it. The following would be quickly recognized as a good argument, although stating the assumptions informing it explicitly would be burdensome:

(37) North Korea successfully tested missiles today.

So, (38) the United States is going to call on the United Nations to impose sanctions.

The argument draws on the audience's vast background knowledge to efficiently – without stating – provide a bridge to the conclusion.

Although brevity and limited knowledge are fundamental reasons for an ineliminable implicitness of argument and reasoning, persuasion is aided by it. The one persuaded will supply without recognition the missing assumptions, and so he commits himself to them. The benefit to persuasion may not be intended, but simply a product of ignorance, because we often do not know what are the assumptions our arguments require. An argument that used to be found persuasive is

(39) Scientists discovered that the Morning Star and the Evening Star are Venus.

So, (40) it is a contingent matter that the Morning Star and the Evening Star are one and the same.

We now realize that the argument rests on an assumption:

If it is an empirical discovery that p (i.e., if from the point of view of the investigators, it might have turned out otherwise), it is contingent that p (i.e., p could actually turn out false).

Once the assumption is stated explicitly, it immediately appears suspect. Our missing the invalidity of the inference is evidence that until Kripke's (1980) discovery we did not even recognize that an assumption was made.

A conceptual basis for implicitness – in particular, that an argument cannot express as premises all the reasons logically involved in deriving its conclusions – is the moral of Lewis Carroll's (1895) parable "Achilles and the Tortoise." Achilles wants to show the Tortoise that anyone who accepts (41) and (42) must accept (43):

(41) Things that are equal to the same are equal to each other.

(42) The two sides of this Triangle are things that are equal to the same.

(43) The two sides of this Triangle are equal to each other.

The Tortoise accepts (41) and (42), but not (43). Achilles agrees that he must now show the Tortoise that

(44) If (41) and (42), then (43)

But what if the Tortoise responds that he accepts (41), (42), and (44), yet he still does not accept (43)? Then Achilles must show him, by parity,

(45) If (41) and (42) and (44), then (43).

Clearly, Achilles has been persuaded to enter an infinite regress. The moral of the story or one moral, anyway, is that Achilles should have balked at the first step: (41) and (42) already imply (43), so that no further premise is necessary to justify that inference. For the Tortoise to claim that he accepts the conditional (41), as well as (42), but that he does not accept (43) is to contradict himself (the validity of the inference is implicit in the meaning of the conditional). He is committed to (43), even if he lacks any specific belief in *modus ponens* as a valid argument form.

Despite the essential benefits to reasoning of implicitness, the reconstruction of arguments in which assumptions are stated and terms and statements are standardized is central for purposes of the critical analysis of arguments. By rendering these assumptions visible and as entering claims to truth, burdens of proof are imposed on the claimant. Explicitness renders bad reasoning and confabulation more difficult.

Explicitization is a natural consequence of argumentation as a dialectical exchange. Because argumentation is social – ideally, public – to engage in it is to impose a questioner or critic or interlocutor on oneself, and so a device of self-correction. If the interlocutor is not under the arguer's control, if he does not share the same biases as the arguer, he is thereby an obstacle to bending argument to favor the arguer's own position. Socratic questioning compels focus by interlocutors on crucial consequences or implications, keeping the dialectical exchange on target. Of course, explicitization can also add biased information. It can overload and distract one's thoughts. Interlocutors may be heavily self-selected. But these are interferences with argumentation, and our purpose here is to highlight its potential value functioning optimally for reasoning (Adler 2006).

Argumentation involves moving one's argument from its inchoate form to an articulate one. For complex arguments, argumentation almost certainly calls for written formulation, which is characterized by greater explicitness, since addressed to a more impersonal audience (than in casual thought or conversation). In articulate forms, the social activity of argumentation can become public, with unrestricted access. In argumentation, participants attempt to render explicit implicit assumptions, inferences, qualifications, and so on. Explicitization brings forth the basic structures or generalizations that constitute the underlying warrants for inferences. (On warrants, see Toulmin 1958: Ch. III; this

volume) It facilitates reconstruction of the argument with variables, which encourages testing in disparate domains, through diverse substitutions for the variables.

18. Social Reasoning and Oneself Over Time

Argumentation is a form of social or dialectical exchange. In one form, close to Socratic dialogue, one agent acts as questioner of another's claim or thesis and elicits his reasons for that claim or thesis. The objective is to test whether that claim or thesis and the reasons for it are consistent, including with other claims (beliefs).

Besides its value for self-correction and learning, argumentation and social reasoning, more generally, foster coordination with others or oneself in the future and they exploit a division of epistemic or cognitive labor. In argumentation, we take turns as questioners and claimants (arguers) and by presenting arguments to others we automatically draw on information and skills that they have, which we do not.

Although we cannot draw on information that we will obtain only in the future, we can alter beliefs as new information comes in, which improves the beliefs of our later self. Recall that conditionalization is a primary mechanism for updating probabilities with new information, generating a rational connection between earlier and later stages of oneself (see Section 11). An analogue of conditionalization in practical reasoning does not appear as secure. Suppose the deterrence of a nuclear war is expected to succeed if the United States provides evidence that it will retaliate. Then the deterrence effect is a reason to intend to retaliate. However, this reason, though sufficient to justify the attitude, may not be a reason sufficient to render it true that one will retaliate. Were the deterrence to fail, it might be better to enter negotiation rather than engage in all-out nuclear retaliation (Gauthier 1986; Kavka 1983). The transition from the conditional intention to the all-out intention, when the condition is realized, ought not to be taken for granted. Is conditionalization subject to anything like this gap?

The gap involves how one's present self seeks to guide itself over time. The future self subject to the conditional intention does not regard itself as bound by it. Surely, I am not bound now to agree with what I regard as my earlier foolishness. (However, the earlier judgment could be a strategic one, adopted with the intention that one's later self should not be faithful to it.

More on this strategic explanation later.) Conditionalization seems applicable. I may recognize a continuous chain via conditionalization to my present position. But I may now regard the limited information and foolishness of my earlier self as implying that my past assignment of probabilities places no restrictions on my present self. I do not conditionalize from the position of (what I now believed are) earlier immature thoughts.

However, when we turn to our understanding of ourselves in the future – our future selves – a surprising principle has, like conditionalization, also been defended by a Dutch Book (or “sure loss”) Argument. This is van Fraassen’s “Reflection Principle,” which says, informally, that if your probability now that A at some later time is r , then right now the probability that you assign to A should be r . More formally:

$$\text{Pr}_t(A \mid \text{pr}_{t+x}(A) = r) = r \text{ (van Fraassen 1984).}$$

The principle implies a commitment to consistency with one’s later self, not merely an expectation that one’s later self will be more informed or mature. The commitment holds even if one regards one’s later self as subject to prejudices or biases (e.g., one’s present youthful liberal self anticipates that with middle age one will become, unfortunately, less liberal and more politically conservative), unless one ceases to identify with one’s later self.

This principle seems to say that I cannot regard my future self as foolish as I can my past self. Can’t I, and if not, why? (It does not seem to be a Moore’s Paradox to affirm “Taxes to support welfare is just, but *I will* (in my conservative middle age) not believe it.”) (Bovens 1995) Is this a problem for the Reflection Principle? Alternatively, does it show that “sure loss” arguments, which turn on preferences as fixed only by one’s judgments of what is likely, are not applicable to all-out beliefs or acceptance? All-out acceptance is responsive to our need to economize – to end inquiry in a finite amount of time, despite the possibility of acquiring further evidence.

The hold of my present self on my future self is central to practical reasoning – one’s present self determines how one’s future self should act. Once a goal or end is fixed for practical reasoning, though, what form do the conclusions take? When a student reasons about whether she should talk to a teacher to question a low grade, her conclusion is not merely that on the evidence, she should go to talk to him. That does not yet determine how she should act – perhaps,

she should find more evidence? Her conclusion is a commitment or intention to act accordingly – to speak to him (or not) – akin to all-out acceptance. Although sometimes practical reasoning does not reach a terminus and further inquiry is called for, the aim is a decision to act, when feasible.

A natural principle of rationality is that if I conclude that I ought to A (e.g., floss my teeth), all things considered, then I form the intention to A or I act to A. But this natural principle is one we often disobey. My concluding that I ought to floss tonight is a far cry from my deliberately forming the intention to floss. When I judge that I ought to floss all things considered (including my laziness and displeasure with flossing), but I do not intend to floss or I deliberately or intentionally do not floss, I suffer weakness of will or *akrasia*. Because weakness of will smacks of irrationality, perhaps the cases that seem to fit it are really ones where at the moment of action, I change my judgment to a denial that I ought to floss, rather than just relax in bed. Attributions of irrationality are hard to square with actions that appear to make sense. There is then a drive to avoid the attribution by redescribing what is going on as a change in judgment (a form of the “principle of charity”). Still, not all cases can be redescribed in this way. When I do not floss, I have not changed my mind that I am really better off not flossing. I suffer weakness of will, allowing laziness to thwart good judgment (Davidson 1980).

But there are some cases in which the conclusion of practical reasoning does not yield the corresponding intention or action, and there is no irrationality. A teenager reasons that because a teacher purposely embarrassed him in class, he should get even by puncturing the tire on the teacher’s car. The student reaches this conclusion, yet when the moment of truth comes he does not act. Nevertheless, his weakness of will is not irrational, given the teenager’s overall values, beliefs, and interests. His practical reasoning simply did not comprehend all his genuine reasons for actions in the circumstance, some of which provide forceful resistance to the teenager’s proposed action.

What force is there then in speaking of commitments, decisions, or intentions, over and above (detached from) the relation of the evidence or reasons to the conclusions as to how one ought to act? In either case one ends inquiry with a judgment and sets up a barrier to reconsideration. When one commits oneself, however, one takes a stance that one will not act

otherwise, regardless of what one learns in the interim except in extreme cases. That stance goes beyond merely drawing a conclusion as to how one should act. A promise is the most familiar example: If I promise to meet you for lunch next Tuesday and in the interim I receive another invitation, I will not accept it. Of course, if an emergency comes up in the interim, then I do legitimately break the engagement (Raz 1990).

When promising, as when one forms an intention or commitment, one's present self generates reasons that bind one's later self from acting otherwise. Given that one's later self will acquire further information, unavailable to one's present self, including detailed information about the current circumstances, how can it be rational to so bind oneself in the future? Answers to this question, which also go a good way to answering an analogous question for why we should ever adopt rules, center on coordination with oneself and with others and anticipated limits on rational judgment. If I decide that I will be in London in June, rather than merely regarding that as my best option so far, I can form plans around that trip (e.g., to purchase tickets to a London play). More important, if I commit myself to act in certain ways, others can coordinate their plans with me. We can arrange for a meeting on the presumption that we will all attend, which we could not do if inquiry or options remain open.

In binding one's future self, one forecloses one's later self from exercising its will. Most vividly and with highly variable success, we commit ourselves to diets that deny our later self from acting deliberately on its own. How is the binding to work, because at that later time, I can simply decide to follow my current judgment, rather than my past one?

One famous model for these problems is the tale of Ulysses and the Sirens (Elster 1984). Ulysses wants to hear the song of the Sirens, but he wants to avoid the dangerous madness that hearing their song is known to induce. His solution is to have his men tie him to the mast as they pass the Sirens' island, and to stuff their ears so that they can hear neither his cries for release nor, more importantly, the Sirens' song, as he can.

However, the irreversible binding is risky. What would happen if Ulysses' sailors spy a storm or an enemy ship, while he is bound? They acquire information unavailable to Ulysses' present deciding self. They need Ulysses' guidance, but only if the sailors release him, could he provide it. If the sailors follow the earlier command, it will be to the ship's detriment. Alter-

natively, the new determination counts as an emergency circumstance cuing them to release Ulysses and to unstuff their ears. But this alternative reintroduces a role for his sailors' judgment and thus the original problem of how to maintain the decision of the earlier self.

Irreversible or absolute binding does not, in fact, cover many realistic cases where the binding is porous (e.g., "controlled cheating" in diets: you can occasionally eat a sweet for dessert) and we add incentives to lessen the benefits of the immediate reward (e.g., if you lose a certain amount of weight, your family takes you on a vacation) (Ainslie 1992).

Commitments that are less binding than that of Ulysses are often made to avoid temptations that one judges overall worse for oneself. You purchase a subscription to the theater, even when you believe, let us assume, that you will have no problem purchasing a ticket for performances on the selected evenings. You do so because you value going to the theater and you know that your own laziness on the night of the performance will lead you just stay home and watch TV. The subscription pressures you to go because otherwise you will have wasted money, and so you are very likely, as you anticipate, to go to far more plays with the subscription than without it.

But wait: If on a given night, you genuinely prefer to stay home, why should it make any difference whether you have a subscription or not? The money is spent in any case, and since without the subscription you would not have gone, why should you allow the past to force you to do what you currently disprefer? Economists refer to these past investments as "sunk costs," and they recommend that we do not honor them. It is irrational to do so, if our only goal is to maximize profits. In that case, future return is all.

But is maximizing profit all? We value committing ourselves to a plan and sticking to it. For others to trust us, requires that when we enter a commitment to another – say to meet them for lunch – we honor it. In this way, one gains a reputation for trustworthiness, which invites others to continue to cooperate, an invitation that is foregone if one regularly subjects one's commitments to the test of better offers and future returns (Nozick 1993).

The honoring of commitments and the maintenance of trust are necessary for stable solutions in "Prisoner's Dilemma" (PD) situations. In a standard example, we agree to a long-distance trade – your \$1,000 for my stereo – and we will realize the trade by your sending a check

to me and my shipping the stereo to you. If the trade goes through, we are both better off, since I value your \$1,000 more than my stereo and you value my stereo more than your \$1,000.

There are, however, two contrary pulls: fear of being a sucker and the prospect of far greater gain. If you do not hold up your end of the bargain and I do, I am out a stereo without compensation; and if you hold up your end of the bargain, I realize far more if I do not send you my stereo. Now if the trade is made through any legal institution, like e-Bay, each participant has a legitimate fear of punishment if he reneges. However, the recourse to an external authority, which Hobbes took as the only way to resolve the dilemma, should be unnecessary. Isn't rationality enough to allow us to realize the mutual, if second-best, gain of cooperation?

The problem is represented vividly in the following matrix:

		You	
		Cooperate	Not Cooperate
Me	Cooperate	A. Me: + 100; You: + 100	B. Me: -100; You: + 200
	Not Cooperate	C. Me + 200; You: - 100	D. Me: 0; You: 0

Except in special cases, these numbers, which are to represent utilities, not monetary value, do not matter only the ordering:

For me: $C > A > D > B$
 For you: $B > A > D > C$

Our best and worst outcomes are opposites; and our second and third best match. As a consequence there is a "Dominance" argument not to cooperate. From my point of view, C is better than A and D is better than B. Although the Dominance argument is strictly rational, its Achilles Heel is that if you reason as I do, we both wind up at D, which is worse for both than if we cooperated (A). These two opposed arguments – for and against cooperation – are what make the PD a dilemma.

The problem arises as well in many person PDs, for those who would "free ride" – gain the benefits of the cooperation of others without sharing the sacrifices. A large community is conserving water in order to avoid a drought. (Another obvious example is voting.) You know that most others will conserve, and that if most others do, there will be no need for rationing water, which will be far worse for all. Because there are so many persons who are involved,

if you defect by taking an extra long shower, that will not be noticed, so you free-ride. As long as few of you defect, the community does stave off the drought. In fact, if few defect this is presumably better overall, because it is sufficient for conserving that most, not all, cooperate, even if the really cooperative result would be to rotate opportunities for longer showers. Free-riding will only succeed for you however if not only does it remain fairly secret that you defect, but it remains secret that any group or collection is free-riding. However, the pull toward free-riding is available to anyone who reasons as the defectors do. The conservation policy will then be undermined and all will be worse off.

The cooperative solution, whether in the two-person or the many-person PD, is a case where self-interest and ethics harmonize, giving a positive answer to the ancient question "Why

should I be ethical?," treating cooperation as the ethical result. Cooperation benefits each cooperator. It's in their interest to do what is ethical. In a two-person PD, we are both better off cooperating than if, instead, neither of us do, both acting on behalf of immediate, rather than enlightened, self-interest.

Outside the bounds of an external authority, realizing the cooperative result depends on trusting other participants, which thereby leaves us vulnerable if another is untrustworthy or chooses to defect. In a repeated Prisoner's Dilemma, as with ongoing trades or meetings, there is much greater prospects for trust and so the cooperative option. We each know what the other did previously, giving each the power to retaliate or to defect on the next round. Each of us recognizes the benefits of maintaining our cooperative practice for which either one can opt out, as well as defect. The strategy that is overall most successful is "tit-for-tat." If you play tit-for-tat you start off by cooperating and continue to cooperate unless the other party defects. After which you defect in retaliations, but then return to cooperating, rather than holding a grudge. The strategy is simple and it is easy for others to recognize that you are playing it, which are among the main reasons for its success (Axelrod 1984).

The Prisoner’s Dilemma in its one-shot form bears unexpected affinities to another dilemma that Nozick (1969) introduced: Newcomb’s Problem. In Newcomb’s Problem, the Superior Being, whose predictions have always come to pass over many trials, offers you a choice to be made one week later between taking the contents of Box 1, which contains 0 or \$1,000,000 only or taking as well the contents of Box 2, which contains \$1,000. If the Superior Being predicts that you will take the contents only of Box 1, he places \$1,000,000 in it; otherwise, if he predicts that you will take the contents of both boxes, he does not put anything in Box 1, and you wind up with only \$1,000. The argument to take only the contents of Box 1 is evident enough: you secure \$1,000,000. The argument to take the contents of both boxes is also evident: Because the being has already placed the money in Box 1 or not, you have nothing to lose now – one week later – in taking the contents of both boxes.

In Newcomb’s Problem, your action of selecting a box is causally independent of what the Superior Being does (assuming no reverse causal process). But there is a probabilistic dependence, since what you now do affects the probability of the reward that you will receive. (In the PD, the actions of each party is assumed causally and probabilistically independent of the other. Were there probabilistic dependence, the PD gives rise to a similar conflict.) Then there is a dominance argument to take both boxes:

		Superior Being	
		Predicts One	Predicts Take Both
You	Take One	\$1 million	\$0
	Take Two	\$1 million + \$1000	\$1000

Taking the contents of both boxes dominates for you over just taking the contents of Box 1 (the box, which you cannot see into, that has \$1 million or \$0).

However, assuming that the probability of the Superior Being is very high (e.g., .95) and that your utility is roughly the same as the dollar rewards, you maximize expected utility by taking only Box 1:

$$EU(\text{Box 1 only}) = (1,000,000) (.95) + (0) (.05) = 950,000$$

$$EU(\text{Box 1 and 2}) = (1,001,000) (.05) + (1,000) (.95) = 51,000.$$

Another twist, which favors a two-box choice, is to limit the expected utilities to causal

dependencies of the action taken and the results, which, again, is assumed not to operate backward in time. For a typical application: Assume that smoking and lung cancer have a genetic base, but that the only cause of lung cancer is genetic. Smoking and lung cancer remain probabilistically dependent. Then it would seem that one should not quit smoking to avoid lung cancer, assuming that smoking is pleasurable. Yet to do so does lower the probability that one has lung cancer (Gibbard and Harper 1978; Lewis 1986a; for a collection on the Newcomb Problem and the Prisoner’s Dilemma with an excellent introduction, see Campbell and Sowden 1985; also Sainsbury 1988, this volume).

Earlier, we mentioned a strategy that you would like to adopt here. You would like to intend to take the contents of only Box 1, up to the moment when the Superior Being makes his prediction. But then, when your moment of decision comes (one week later), you actually do not follow through on that intention. You then take the contents of both boxes. You secure the prediction you seek from the Superior Being without the real commitment to it. However, this strategy confronts the obstacle that the Superior Being may see through your facade. So you have a new version of the old conflict: a dominance argument to take both boxes and an expected utility argument to take only the contents of the million dollar box. What should you do?

Notes

- 1 In this chapter, we use the symbols “&” (and), “∨” (inclusive or), “~” (not), and “⊃” (the material conditional) was the meanings given in standard texts on classical logical logic.
- 2 A nice example to distinguish indicative from counterfactual (subjunctive) conditionals is from Adams 1970: on our current understanding, the indicative that if Oswald did not kill Kennedy, someone else did, is true, but the counterfactual that if Oswald hadn’t killed Kennedy, someone else would have, is false.
- 3 On this reading, Hume’s argument is a far-reaching scepticism:
Even after the observation of the frequent or constant conjunction of objects, we have no reason to draw any inference concerning any object beyond those of which we have had experience. (1978: 139)
- 4 There are examples that violate IC e.g., the hypothesis is that ravens are under 5’ long, and you find a raven that is 4’10”. This and similar examples depend, however, on background

- information, which the original presentation of confirmation theory attempts to abstract from.
- 5 For example, suppose that there are just two predicates in our universe, Red and Square, and just three names, Huey, Dewey, and Louie. Then a state description is an assignment of each predicate or its negation to each of the individuals. For example:
- Square(Huey) & not-Red(Huey) & not-Square(Dewey) & not-Red(Dewey) & Square(Louie) & Red(Louie)
- In general, if there are n logically independent predicates, then there are 2^n possible combinations of predicates that could be assigned to an individual. If there are m names, each of which could have any of the 2^n combinations, then there are $(2^n)^m$ state descriptions in all.
- 6 Here's a simple reductio proof: We're given p . Suppose, for the sake of the reductio, that $\sim(p \vee q)$. By DeMorgan's Law, this last sentence implies $\sim p$ & $\sim q$, from which $\sim p$ follows. But $\sim p$ contradicts the premise p . Hence, the assumption $\sim(p \vee q)$ is false, and $p \vee q$ is true.
- 7 Thanks to Lance Rips for his valuable comments.

PART I: FOUNDATIONS OF REASONING

Section 1: Some Philosophical Viewpoints

Chapter 1: Change in View: Principles of Reasoning

GILBERT HARMAN

BELIEF AND DEGREE OF BELIEF

Probabilistic Implication

We have a rule connecting implication and reasoning:

Principle of Immediate Implication That P is immediately implied by things one believes can be a reason to believe P .

Is there also a weaker probabilistic version of this rule?

Hypothetical Principle of Immediate Probabilistic Implication That P is obviously highly probable, given one's beliefs, can be a reason to believe P .

Suppose Mary purchases a ticket in the state lottery. Given her beliefs, it is obviously highly probable that her ticket will not be one of the winning tickets. Can she infer that her ticket will not win? Is she justified in believing her ticket is not one of the winning tickets?

Intuitions waver here. On the one hand, if Mary is justified in believing her ticket is not one of the winning tickets, how can she be justified in buying the ticket in the first place? Furthermore, it certainly seems wrong to say she can *know* that her ticket is not one of the winning tickets if it is really a fair lottery. On the other hand the probability that the ticket is not one of the winning tickets seems higher than the probability of other things we might easily say Mary knows. We ordinarily allow that Mary can come

to know various things by reading about them in the newspaper, even though we are aware that newspapers sometimes get even important stories wrong.

This issue is one that I will return to several times, but I want to begin by considering a suggestion which I think is mistaken, namely, that the trouble here comes from not seeing that belief is a matter of degree.

All-or-Nothing Belief

I have been supposing that for the theory of reasoning, explicit belief is an all-or-nothing matter. I have assumed that, as far as principles of reasoning are concerned, one either believes something explicitly or one does not; in other words an appropriate "representation" is either in one's "memory" or not. The principles of reasoning are principles for modifying such all-or-nothing representations.

This is not to deny that in some ways belief is a matter of degree. For one thing implicit belief is certainly a matter of degree, since it is a matter of how easily and automatically one can infer something from what one believes explicitly. Furthermore, explicit belief is a matter of degree in the sense that one believes some things more strongly than others. Sometimes one is only somewhat inclined to believe something, sometimes one is not sure what to believe, sometimes one is inclined to disbelieve something, sometimes one is quite confident something is not so, and so forth.

How should we account for the varying strengths of explicit beliefs? I am inclined to suppose that these varying strengths are implicit in a system of beliefs one accepts in a yes/no fashion. My guess is that they are to be explained as a kind of epiphenomenon resulting from the operation of rules of revision. For example, it may be that P is believed more strongly than Q if it would be harder to stop believing P than to stop believing Q , perhaps because it would require more of a revision of one's view to stop believing P than to stop believing Q .

In contrast to this, it might be suggested that principles of reasoning *should* be rules for modifying explicit *degrees of belief*. In this view, an account of reasoning should be embedded in a theory of subjective probability, for example, as developed by Jeffrey (1983), not that Jeffrey himself accepts this particular suggestion. In fact, this suggestion cannot really be carried out. People do not normally associate with their beliefs degrees of confidence of a sort they can use in reasoning. It is too complicated for them to do so. Degrees of belief are and have to be implicit rather than explicit, except for a few special cases of beliefs that are explicitly beliefs about probabilities.

Let me say why this is so. To begin with, Kyburg (1961) observes that the Immediate Implication and Inconsistency Principles would not be right even as approximations if belief were a matter of degree.

Immediate Implication Principle The fact that one's view immediately implies P can be a reason to accept P .

Immediate Inconsistency Principle Immediate logical inconsistency in one's view can be a reason to modify one's view.

Propositions that are individually highly probable can have an immediate implication that is not. The fact that one assigns a high probability to P and also to *if P then Q* is not a sufficient reason to assign a high probability to Q . Each premise of a valid argument might be probable even though the conclusion is improbable. Since one might assign a high degree of belief to various propositions without being committed to assigning a high degree of belief to a logical consequence of these propositions, Kyburg argues that the Logical Implication Principle is mistaken.

Similarly, each of an inconsistent set of beliefs might be highly probable. To take Kyburg's lottery example, it might be that the proposition,

"one of the N tickets in this lottery is the winning ticket" is highly probable, and so is each proposition of the form, "ticket i is not the winning ticket," for each i between 1 and N . So one might believe each of these propositions to a high degree while recognizing that they are jointly inconsistent. Kyburg argues there is nothing wrong with this, so the Logical Inconsistency Principle is mistaken.

It is not just that these principles have exceptions. We have seen that they are defeasible and hold only other things being equal. But if belief were always a matter of degree the principles would not even hold in this way as defeasible principles. They would not hold at all.

It would be odd for someone to take this seriously in a routine matter. It is contrary to the way we normally think. Imagine arguing with such a person. You get him to believe certain premises and to appreciate that they imply your conclusion, but he is not persuaded to believe this conclusion, saying that, although you have persuaded him to assign a high probability to each of your premises, that is not enough to show he should assign a high probability to the conclusion! This is not the way people usually respond to arguments.

Or consider the following attitude toward contradiction. As Jack asserts several things, you observe that he has contradicted himself. His response is that he sees nothing wrong, since all the things he has asserted are highly probable. This is comprehensible, but it is again different from the normal way of doing things.

A normal reaction to someone's refusal to accept the conclusion of a clearly valid argument after he says he has been persuaded to accept the premises, if he gives Kyburg's reason, is to suppose that he does not really accept the premises after all, but only believes of each that it is probable. Similarly, we suppose that a person who says at least one ticket will win and also says of each ticket that it will not win does not really believe of each ticket that it will not win but merely believes of each ticket that it is unlikely that that ticket will win. We do not ordinarily think of this as like the case in which an author believes each of the things he or she says in a book he or she has written and also believes that, given human fallibility, at least one of the things he or she has said in the book must be false. Such a person is justified in having inconsistent beliefs, but that does not show that the Recognized Inconsistency Principle is incorrect. It only shows that the principle is defeasible.

Of course, to say one normally thinks of belief in an all-or-nothing way is not to deny one sometimes has beliefs about probabilities. More important, one often manifests a varying degree of confidence in this or that proposition as revealed in one's willingness to *act*, for example, to bet. But this does not show one normally or usually assigns *explicit* levels of confidence or probability to one's beliefs. The degree of confidence one has might be merely implicit in one's system of beliefs. Subjective probability theory can give an account of one's dispositions without being an account of the psychological reality underlying those dispositions.

It might be said one *ought* to operate using explicit degrees of belief. This would imply one should make much more use of probability theory than one does.

Similarly, it might be said that one's goals should be treated as matters of degree. Since different prospects are more or less desirable, one ought to assign them different degrees of "subjective utility." In acting, one should act so as to maximize expected utility.

I argue [in Chapter 9 of *Change in View*] that this is not right. But even if it were right, such an appeal to probability theory would not eliminate the need for reasoning in the sense of change in view. One's subjective probability assignments would never be complete. They would often have to be extended. To some extent they could be extended by means of the Principle of Immediate Implication by considering the immediate implications of one's current probability assignments and by allowing for clutter avoidance and other relevant considerations. Furthermore, there would also often be cases in which current subjective probability assignments would have to be changed, for example because they were not consistent with each other. The Principle of Immediate Inconsistency then has a role to play. And there are other cases in which one will want to modify such assignments, for example, when one discovers that a current theory would explain old evidence one had not realized it would explain (Glymour 1980, chap. 3). And whatever principles are developed for changing all-or-nothing belief will apply to changing degrees of belief, treating these as all-or-nothing beliefs about probabilities.

Conditionalization

Some probability theorists appear to deny these obvious points. They seem to suppose that reasoned revision is or ought always to be in accor-

dance with a special principle of "conditionalization" that applies when one comes to treat evidence E as certain. The claim is that in such a case one is to modify one's other degrees of belief so that the new probability one assigns to any given proposition P is given by the following formula:

$$\text{new prob } (P) = \frac{\text{old prob } (P \& E)}{\text{old prob } (E)}$$

The quotient on the right-hand side is sometimes called the conditional probability of P given E , which is why the principle is called conditionalization.

R. C. Jeffrey (1983, chap. 11) shows how this formula can be generalized to allow for the case in which evidence propositions change in probability without becoming certain. Suppose that there are n relevant atomic evidence propositions E_1, \dots, E_n , so that there are 2^n strongest conjunctions C_i , each containing E_i , or its denial. Then the new probability one assigns to any given proposition P is the sum of all the quantities of the following form:

$$\text{new prob } (C_i) \times \frac{\text{old prob } (P \& C_i)}{\text{old prob } (C_i)}$$

So, let us consider the following hypothesis, which is widely accepted by subjective probability theorists:

Reasoning is conditionalization The updating of probabilities via conditionalization or generalized conditionalization is (or ought to be) the only principle of reasoned revision.

One way to argue for this is to try to show that various intuitively acceptable principles of reasoning from evidence can be accounted for if this hypothesis is accepted (e.g., Dorling 1972; Horwich 1982).

However, there is a problem with making extensive use of this method of updating. One can use conditionalization to get a new probability for P only if one has already assigned a prior probability not only to E but to $P \& E$. If one is to be prepared for various possible conditionalizations, then for every proposition P one wants to update, one must already have assigned probabilities to various conjunctions of P together with one or more of the possible evidence propositions and/or their denials. Unhappily, this leads to a combinatorial explosion, since the number of such conjunctions is an exponential function of the number of possibly relevant evidence propositions. In other words, to be prepared for

coming to accept or reject any of ten evidence propositions, one would have to record probabilities of over a thousand such conjunctions for each proposition one is interested in updating. To be prepared for twenty evidence propositions, one must record a million probabilities. For thirty evidence propositions, a billion probabilities are needed, and so forth.

Clearly, one could not represent all the needed conjunctions explicitly. One would have to represent them implicitly using some sort of general principle. Given such a general principle, one's total probability distribution would then be determined, by either (1) the total evidence one accepts as certain (using conditionalization) or (2) the various new probabilities assigned to the C_i , (using Jeffrey's generalization of conditionalization). But neither (1) nor (2) is feasible. Consider what is involved in each case.

The idea behind (1) is to represent the degrees of belief to which one is presently committed by means of some general principle, specifying an initial probability distribution, together with a list of all the evidence one has come to treat as certain. Such evidence will include all immediate perceptual evidence – how things look, sound, smell, etc., to one at this or that moment. One will have to remember all such evidence that has influenced one's present degrees of belief. But in fact one rarely remembers such evidence beyond the moment in which one possesses it (a point I return to [in the following part of this chapter]). So (1) is not a usable approach.

On the other hand, (2) requires that one keep track of one's current degree of belief in each of the relevant conjunctions C_i , of evidence propositions and/or their denials. These are things one does not have to be certain about, so the relevant propositions need not be for the most part about immediate perceptual experience, as in (1). So the objection that one hardly ever remembers such propositions does not apply to (2). But (2) is also unworkable, since the number of relevant conjunctions C_i is an exponential function of the number of atomic evidence propositions.

These objections assume one sticks with one's original general principle describing one's initial degrees of belief and records one's present degrees of belief by representing the new evidence accepted as certain or the new probabilities of the various conjunctions C_i .

Alternatively, one might try each time to find a new principle describing one's updated degrees of belief in a single general statement. But the problem of finding such a general principle is

intractable, and anyway there will normally be no simpler way to describe one's new probability distribution than the description envisioned in (1) or (2), so this will not normally be feasible either.

Doing extensive updating by conditionalization or generalized conditionalization would be too complicated in practice. Therefore one must follow other principles in revising one's views. It is *conceivable* that all or some of these principles might refer to strength or degree of belief and not just to whether one believes something in a yes/no fashion. But the actual principles we follow do not seem to be of that sort, and it is unclear how these principles might be modified to be sensitive to degree or strength of belief. In the rest of this book I assume that, as far as the principles of revision we follow are concerned, belief is an all-or-nothing matter. I assume that this is so because it is too complicated for mere finite beings to make extensive use of probabilities.

POSITIVE VERSUS NEGATIVE UNDERMINING

I now want to compare two competing theories of reasoned belief revision, which I will call the foundations theory and the coherence theory since they are similar to certain philosophical theories of justification sometimes called foundations and coherence theories (Sosa 1980; Pollock 1979). But the theories I am concerned with are not precisely the same as the corresponding philosophical theories of justification, which are not normally presented as theories of belief revision. Actually, I am not sure what these philosophical theories of "justification" are supposed to be concerned with. So, although I will be using the *term* "justification" in what follows, as well as the terms "coherence" and "foundations," I do not claim that my use of any of these terms is the same as its use in these theories of justification. I mean to be raising a new issue, not discussing an old one.

The key issue is whether one needs to keep track of one's original justifications for beliefs. What I am calling the *foundations* theory says yes; what I am calling the *coherence* theory says no.

The foundations theory holds that some of one's beliefs "depend on" others for their current justification; these other beliefs may depend on still others, until one gets to foundational beliefs

that do not depend on any further beliefs for their justification. In this view reasoning or belief revision should consist, first, in subtracting any of one's beliefs that do not now have a satisfactory justification and, second, in adding new beliefs that either need no justification or are justified on the basis of other justified beliefs one has.

On the other hand, according to the coherence theory, it is not true that one's ongoing beliefs have or ought to have the sort of justificational structure required by the foundations theory. In this view ongoing beliefs do not usually require any justification. Justification is taken to be required only if one has a special reason to doubt a particular belief. Such a reason might consist in a conflicting belief or in the observation that one's beliefs could be made more "coherent," that is, more organized or simpler or less ad hoc, if the given belief were abandoned (and perhaps if certain other changes were made). According to the coherence theory, belief revision should involve minimal changes in one's beliefs in a way that sufficiently increases overall coherence.

In this chapter I elaborate these two theories in order to compare them with actual reasoning and intuitive judgments about such reasoning. It turns out that the theories are most easily distinguished by the conflicting advice they occasionally give concerning whether one should *give up* a belief *P* from which many other of one's beliefs have been inferred, when *P*'s original justification has to be abandoned. Here a surprising contrast seems to emerge – "is" and "ought" seem to come apart. The foundations theory seems, at least at first, to be more in line with our intuitions about how people *ought* to revise their beliefs; the coherence theory is more in line with what people *actually do* in such situations. Intuition seems strongly to support the foundations theory over the coherence theory as an account of what one is *justified* in doing in such cases; but *in fact* one will tend to act as the coherence theory advises.

After I explain this I consider how this apparent discrepancy can be resolved. I conclude that the coherence theory is normatively correct after all, despite initial appearances.

The Foundations Theory of Belief Revision

The basic principle of the foundations theory, as I will interpret it, is that one must keep track of one's original reasons for one's beliefs, so that one's ongoing beliefs have a justificational struc-

ture, some beliefs serving as reasons or justifications for others. These justifying beliefs are more basic or fundamental for justification than the beliefs they justify.

The foundations theory rejects any principle of *conservatism*. In this view a proposition cannot acquire justification simply by being believed. The justification of a given belief cannot be, either in whole or in part, that one has that belief. For example, one's justification for believing something cannot be that one already believes it and that one's beliefs in this area are reliable.

Justifications are *prima facie* or defeasible. The foundations theory allows, indeed insists, that one can be justified in believing something *P* and then come to believe something else that undermines one's justification for believing *P*. In that case one should stop believing *P*, unless one has some further justification that is not undermined.

I say "unless one has some further justification," because in this view a belief can have more than one justification. To be justified, a belief must have *at least* one justification. That is, if a belief in *P* is to be justified, it is required either that *P* be a foundational belief whose intrinsic justification is not defeated or that there be at least one undefeated justification of *P* from other beliefs one is justified in believing. If one believes *P* and it happens that all one's justifications for believing *P* come to be defeated, one is no longer justified in continuing to believe *P*, and one should subtract *P* from one's beliefs.

Furthermore, and this is important, if one comes not to be justified in continuing to believe *P* in this way, then not only is it true that one must abandon belief in *P* but justifications one has for other beliefs are also affected if these justifications appeal to one's belief in *P*. Justifications appealing to *P* must be abandoned when *P* is abandoned. If that means further beliefs are left without justification, then these beliefs too must be dropped along with any justifications appealing to them. So there will be a chain reaction when one loses justification for a belief on which other beliefs depend for their justification. (This is worked out in more detail for an artificial intelligence system by Doyle (1979, 1980).)

Now, it is an important aspect of the foundations theory of reasoning that justifications cannot legitimately be circular. *P* cannot be part of the justification for *Q* while *Q* is part of the justification for *P* (unless one of these beliefs has a different justification that does not appeal to the other belief).

The foundations theory also disallows infinite justifications. It does not allow P to be justified by appeal to Q , which is justified by appeal to R , and so on forever. Since justification cannot be circular, justification must eventually end in beliefs that either need no justification or are justified but not by appeal to other beliefs. Let us say that such basic or foundational beliefs are intrinsically justified.

For my purposes it does not matter exactly which beliefs are taken to be intrinsically justified in this sense. Furthermore, I emphasize that the foundations theory allows for situations in which a basic belief has its intrinsic justification defeated by one or more other beliefs, just as it allows for situations in which the justification of one belief in terms of other beliefs is defeated by still other beliefs. As I am interpreting it, foundationalism is not committed to the *incorrigibility* of basic beliefs.

A belief is a basic belief if it has an intrinsic justification which does not appeal to other beliefs. A basic belief can also have one or more nonintrinsic justifications which do appeal to other beliefs. So, a basic belief can have its intrinsic justification defeated and still remain justified as long as it retains at least one justification that is not defeated.

The existence of basic beliefs follows from the restrictions against circular and infinite justifications. Infinite justifications are to be ruled out because a finite creature can have only a finite number of beliefs, or at least only a finite number of *explicit beliefs*, whose content is explicitly represented in the brain. What one is justified in believing either implicitly or explicitly depends entirely on what one is justified in believing explicitly. To consider whether one's implicit beliefs are justified is to consider whether one is justified in believing the explicit beliefs on which the implicit beliefs depend. A justification for a belief that appeals to other beliefs must always appeal to things one believes explicitly. Since one has only finitely many explicit beliefs, there are only finitely many beliefs that can be appealed to for purposes of justification, and so infinite justifications are ruled out.

The Coherence Theory of Belief Revision

The coherence theory is *conservative* in a way the foundations theory is not. The coherence theory supposes one's present beliefs are justified just as they are in the absence of special reasons to change them, where changes are allowed only to the extent that they yield sufficient increases in

coherence. This is a striking difference from the foundations theory. The foundations theory says one is justified in continuing to believe something only if one has a special reason to continue to accept that belief, whereas the coherence theory says one is justified in continuing to believe something as long as one has no special reason to stop believing it.

According to the coherence theory, if one's beliefs are incoherent in some way, because of outright inconsistency or simple *ad hocness*, then one should try to make minimal changes in those beliefs in order to eliminate the incoherence. More generally, small changes in one's beliefs are justified to the extent these changes add to the coherence of one's beliefs.

For present purposes, I do not need to be too specific as to exactly what coherence involves, except to say it includes not only consistency but also a network of relations among one's beliefs, especially relations of implication and explanation.

It is important that coherence competes with conservatism. It is as if there were two aims or tendencies of reasoned revision, to maximize coherence and to minimize change. Both tendencies are important. Without conservatism a person would be led to reduce his or her beliefs to the single Parmenidean thought that all is one. Without the tendency toward coherence we would have what Peirce (1877) called the method of tenacity, in which one holds to one's initial convictions no matter what evidence may accumulate against them.

According to the coherence theory, the assessment of a challenged belief is always holistic. Whether such a belief is justified depends on how well it fits together with everything else one believes. If one's beliefs are coherent, they are mutually supporting. All one's beliefs are, in a sense, equally fundamental. In the coherence theory there are not the asymmetrical justification relations among one's ongoing beliefs that there are in the foundations theory. It can happen in the coherence theory that P is justified because of the way it coheres with Q and Q is justified because of the way it coheres with P . In the foundations theory, such a pattern of justification is ruled out by the restriction against circular justification. But there is nothing wrong with circular justification in the coherence theory, especially if the circle is a large one!

I turn now to testing the foundations and coherence theories against our intuitions about cases. This raises an apparent problem for the coherence theory.

An Objection to the Coherence Theory: Karen's Aptitude Test

Sometimes there clearly are asymmetrical justification relations among one's beliefs.

Consider Karen, who has taken an aptitude test and has just been told her results show she has a considerable aptitude for science and music but little aptitude for history and philosophy. This news does not correlate perfectly with her previous grades. She had previously done well not only in physics, for which her aptitude scores are reported to be high, but also in history, for which her aptitude scores are reported to be low. Furthermore, she had previously done poorly not only in philosophy, for which her aptitude scores are reported to be low, but also in music, for which her aptitude scores are reported to be high.

After carefully thinking over these discrepancies, Karen concludes that her reported aptitude scores accurately reflect and are explained by her actual aptitudes; so she has an aptitude for science and music and no aptitude for history and philosophy; therefore her history course must have been an easy one, and also she did not work hard enough in the music course. She decides to take another music course and not to take any more history.

It seems quite clear that, in reaching these conclusions, Karen bases some of her beliefs on others. Her belief that the history course was easy depends for its justification on her belief that she has no aptitude for history, a belief which depends in turn for its justification on her belief that she got a low score in history on her aptitude test. There is no dependence in the other direction. For example, her belief about her aptitude test score in history is not based on her belief that she has no aptitude for history or on her belief that the history course was an easy one.

According to the coherence theory, the relevant relations here are merely *temporal* or *causal* relations. The coherence theory can agree that Karen's belief about the outcome of her aptitude test precedes and is an important cause of her belief that the history course she took was an easy one. But the coherence theory denies that a relation of dependence or justification holds or ought to hold between these two beliefs as time goes by, once the new belief has been firmly accepted.

In order to test this, let me tell more of Karen's story. Some days later she is informed that the report about her aptitude scores was

incorrect! The scores reported were those of someone else whose name was confused with hers. Unfortunately, her own scores have now been lost. How should Karen revise her views, given this new information?

The foundations theory says she should abandon all beliefs whose justifications depend in part on her prior belief about her aptitude test scores. The only exception is for beliefs for which she can now find another and independent justification which does not depend on her belief about her aptitude test scores. She should continue to believe only those things she would have been justified in believing if she had never been given the false information about those scores. The foundations theory says this because it does not accept a principle of conservatism. The foundations theory does not allow that a belief can acquire justification simply by being believed.

Let us assume that, if Karen had not been given the false information about her aptitude test scores, she could not have reasonably reached any of the conclusions she did reach about her aptitudes for physics, history, philosophy, and music; and let us also assume that without those beliefs Karen could not have reached any of her further conclusions about the courses she has already taken. Then, according to the foundations theory, Karen should abandon her beliefs about her relative aptitudes for these subjects, and she should give up her belief that the history course she took was easy as well as her belief that she did not work hard enough in the music course. She should also reconsider her decisions to take another course in music and not to take any more history courses.

The coherence theory does not automatically yield the same advice that the foundations theory gives about this case. Karen's new information does produce a loss of overall coherence in her beliefs, since she can no longer coherently suppose that her aptitudes for science, music, philosophy, and history are in any way responsible for the original report she received about the results of her aptitude test. She must abandon that particular supposition about the explanation of the original report of her scores. Still, there is considerable coherence among the beliefs she inferred from this false report. For example, there is a connection between her belief that she has little aptitude for history, her belief that her high grade in the history course was the result of the course's being an easy one, and her belief that she will not take any more courses in history. There are similar connections between her beliefs about her aptitudes

for other subjects, how well she did in courses in those subjects, and her plans for the future in those areas. Let us suppose that from the original report Karen inferred a great many other things that I haven't mentioned; so there are many beliefs involved here. Abandoning all these beliefs is costly from the point of view of conservatism, which says to minimize change. Suppose that there are so many of these beliefs and that they are so connected with each other and with other things Karen believes that the coherence theory implies Karen should retain all these new beliefs even though she must give up her beliefs about the explanation of the report of her aptitude scores. (In fact, we do not really need to suppose these beliefs are intricately connected with each other or even that there are many of them, since in the coherence theory a belief *does* acquire justification simply by being believed.)

The foundations theory says Karen should give up all these beliefs, whereas the coherence theory says Karen should retain them. Which theory is right about what Karen ought to do? Almost everyone who has considered this issue sides with the foundations theory: Karen should not retain any beliefs she inferred from the false report of her aptitude test scores that she would not have been justified in believing in the absence of that false report. That does seem to be the intuitively right answer. The foundations theory is in accordance with our intuitions about what Karen *ought* to do in a case like this. The coherence theory is not.

Belief Perseverance

In fact, Karen would almost certainly keep her new beliefs! That is what people actually do in situations like this. Although the foundations theory seems to give intuitively satisfying advice about what Karen *ought* to do in such a situation, the coherence theory is more in accord with what people actually do.

To document the rather surprising facts here, let me quote at some length from a recent survey article (Ross and Anderson 1982, pp. 147–149), which speaks of

the dilemma of the social psychologist who has made use of deception in the course of an experiment and then seeks to debrief the subjects who had been the target of such deception. The psychologist reveals the totally contrived and inauthentic nature of the information presented presuming that

this debriefing will thereby eliminate any effects such information might have exerted upon the subjects' feelings or beliefs. Many professionals, however, have expressed public concern that such experimental deception may do great harm that is not fully undone by conventional debriefing procedures. . . .

Ross and Anderson go on to describe experiments designed to "explore" what they call "the phenomenon of belief perseverance in the face of evidential discrediting." In one experiment.

Subjects first received continuous false feedback as they performed a novel discrimination task (i.e., distinguishing authentic suicide notes from fictitious ones). . . . [Then each subject] received a standard debriefing session in which he learned that his putative outcome had been predetermined and that his feedback had been totally unrelated to actual performance. . . . [E]very subject was led to explicitly acknowledge his understanding of the nature and purpose of the experimental deception. Following this total discrediting of the original information, the subjects completed a dependent variable questionnaire dealing with [their] performance and abilities. The evidence for postdebriefing impression perseverance was unmistakable. . . . On virtually every measure . . . the totally discredited initial outcome manipulation produced significant "residual" effects upon [subjects'] . . . assessments. . . .

Follow-up experiments have since shown that a variety of unfounded personal impressions, once induced by experimental procedures, can survive a variety of total discrediting procedures. For example, Jennings, Lepper, and Ross . . . have demonstrated that subjects' impressions of their ability at interpersonal persuasion (having them succeed or fail to convince a confederate to donate blood) can persist after they have learned that the initial outcome was totally inauthentic. Similarly, . . . two related experiments have shown that students' erroneous impressions of their "logical problem solving abilities" (and their academic choices in a follow-up measure two months later) persevered even after they had learned that good or poor teaching procedures provided a totally sufficient explanation for the successes or failures that were the basis for such impressions.

. . . [Other] studies first manipulated and then attempted to undermine subjects'

theories about the functional relationship between two measured variables: the adequacy of firefighters' professional performances and their prior scores on a paper and pencil test of risk performance. . . . [S]uch theories survived the revelations that the cases in question had been totally fictitious and the different subjects had, in fact, received opposite pairings of riskiness scores and job outcomes. . . . [O]ver 50% of the initial effect of the "case history" information remained after debriefing.

In summary, it is clear that beliefs can survive . . . the total destruction of their original evidential bases.

It is therefore quite likely that Karen will continue to believe many of the things she inferred from the false report of her aptitude test scores. She will continue to believe these things even after learning that the report was false.

The Habit Theory of Belief

Why is it so hard for subjects to be debriefed? Why do people retain conclusions they have drawn from evidence that is now discredited? One possibility is that belief is a kind of habit. This is an implication of behaviorism, the view that beliefs and other mental attitudes are habits of behavior. But the suggestion that beliefs are habits might be correct even apart from behaviorism. The relevant habits need not be overt behavioral habits. They might be habits of thought. Perhaps, to believe that *P* is to be disposed to *think* that *P* under certain conditions, to be disposed to use this thought as a premise or assumption in reasoning and in deciding what to do. Then, once a belief has become established, considerable effort might be needed to get rid of it, even if the believer should come to see that he or she ought to get rid of it, just as it is hard to get rid of other bad habits. One can't simply decide to get rid of a bad habit; one must take active steps to ensure that the habit does not reassert itself. Perhaps it is just as difficult to get rid of a bad belief.

Goldman (1978) mentions a related possibility, observing that Anderson and Bower (1973) treat coming to believe something as the establishing of connections, or "associative links," between relevant conceptual representations in the brain. Now, it may be that, once set up, such connections or links cannot easily be broken unless competing connections are set up that overwhelm the original ones. The easiest case

might be that in which one starts by believing *P* and then comes to believe *not P* by setting up stronger connections involving *not P* than those involved in believing *P*. It might be much harder simply to give up one's belief in *P* without substituting a contrary belief. According to this model of belief, in order to stop believing *P*, it would not be enough simply to notice passively that one's evidence for *P* had been discredited. One would have to take positive steps to counteract the associations that constitute one's belief in *P*. The difficulties in giving up a discredited belief would be similar in this view to the difficulties envisioned in the habit theory of belief.

But this explanation does not give a plausible account of the phenomenon of belief perseverance. Of course, there are cases in which one has to struggle in order to abandon a belief one takes to be discredited. One finds oneself coming back to thoughts one realizes one should no longer accept. There are such habits of thought, but this is not what is happening in the debriefing studies. Subjects in these studies are not struggling to abandon beliefs they see are discredited. On the contrary, the subjects do not see that the beliefs they have acquired have been discredited. They come up with all sorts of "rationalizations" (as we say) appealing to connections with other beliefs of a sort that the coherence theory, but not the foundations theory, might approve. So the correct explanation of belief perseverance in these studies is not that beliefs which have lost their evidential grounding are like bad habits.

Positive versus Negative Undermining

In fact, what the debriefing studies show is that people simply do not keep track of the justification relations among their beliefs. They continue to believe things after the evidence for them has been discredited because they do not realize what they are doing. They do not understand that the discredited evidence was the *sole* reason why they believe as they do. They do not see they would not have been justified in forming those beliefs in the absence of the now discredited evidence. They do not realize these beliefs have been undermined. It is this, rather than the difficulty of giving up bad habits, that is responsible for belief perseverance.

The foundations theory says people should keep track of their reasons for believing as they do and should stop believing anything that is not associated with adequate evidence. So the foundations theory implies that, if Karen has not kept track of her reason for believing her history

course was an easy one, she should have abandoned her belief even before she was told about the mix-up with her aptitude test scores. This seems clearly wrong.

Furthermore, since people rarely keep track of their reasons, the theory implies that people are unjustified in almost all their beliefs. This is an absurd result! The foundations theory turns out not to be a plausible normative theory after all. So let us see whether we cannot defend the coherence theory as a normative theory.

We have already seen how the coherence theory can appeal to a nonholistic *causal* notion of local justification by means of a limited number of one's prior beliefs, namely, those prior beliefs that are most crucial to one's justification for adding the new belief. The coherence theory does not suppose there are *continuing* links of justification dependency that can be consulted when revising one's beliefs. But the theory can admit that Karen's coming to believe certain things depended on certain of her prior beliefs in a way that it did not depend on others, where this dependence represents a kind of local justification, even though in another respect whether Karen was justified in coming to believe those things depended on everything she then believed.

Given this point, I suggest the coherence theory can suppose it is incoherent to believe both *P* and also that all one's reasons for believing *P* relied crucially on false assumptions. Within the coherence theory, this implies, roughly, the following:

Principle of Positive Undermining One should stop believing *P* whenever one positively believes one's reasons for believing *P* are no good.

This is only roughly right, since there is also the possibility that one should instead stop believing that one's reasons for *P* are no good, as well as the possibility that one cannot decide between that belief and *P*. In any event, I want to compare this rough statement of the principle with the corresponding principle in a foundations theory:

Principle of Negative Undermining One should stop believing *P* whenever one does not associate one's belief in *P* with an adequate justification (either intrinsic or extrinsic).

The Principle of Positive Undermining is much more plausible than the Principle of Negative Undermining. The Principle of Negative Undermining implies that, as one loses track of the justifications of one's beliefs, one should give up

those beliefs. But, if one does not keep track of one's justifications for most of one's beliefs, as seems to be the case, then the Principle of Negative Undermining says that one should stop believing almost everything one believes, which is absurd. On the other hand the Principle of Positive Undermining does not have this absurd implication. The Principle of Positive Undermining does not suppose that the absence of a justification is a reason to stop believing something. It only supposes that one's belief in *P* is undermined by the *positive* belief that one's reasons for *P* are no good.

It is relevant that subjects *can* be successfully debriefed after experiments involving deception if they are made vividly aware of the phenomenon of belief perseverance, that is, if they are made vividly aware of the tendency for people to retain false beliefs after the evidence for them has been undercut, and if they are also made vividly aware of how this phenomenon has acted in their own case (Nisbett and Ross 1980, p. 177). It might be suggested that this shows that under ideal conditions people really do act in accordance with the foundations theory after all, so that the foundations theory is normatively correct as an account of how one ideally ought to revise one's beliefs. But in fact this further phenomenon seems clearly to support the coherence theory, with its Principle of Positive Undermining, and not the foundations theory, with its Principle of Negative Undermining. The so-called process debriefing cannot merely undermine the evidence for the conclusions subjects have reached but must also directly attack each of these conclusions themselves. Process debriefing works not just by getting subjects to give up beliefs that originally served as evidence for the conclusions they have reached but by getting them to accept certain further positive beliefs about their lack of good reasons for each of these conclusions.

What about Our Intuitions?

It may seem to fly in the face of common sense to suppose that the coherence theory is normatively correct in cases like this. Remember that, after carefully considering Karen's situation, almost everyone agrees she should give up all beliefs inferred from the original false report, except those beliefs which would have been justified apart from any appeal to evidence tainted by that false information. Almost everyone's judgment about what Karen ought to do coincides with what the foundations theory

says she ought to do. Indeed, psychologists who have studied the phenomenon of belief perseverance in the face of debriefing consider it to be a paradigm of irrationality. How can these strong normative intuitions possibly be taken to be mistaken, as they must be if the coherence theory is to be accepted as normatively correct?

The answer is that, when people think about Karen's situation, they ignore the possibility that she may have failed to keep track of the justifications of her beliefs. They imagine Karen is or ought to be aware that she no longer has any good reasons for the beliefs she inferred from the false report. And, of course, this is to imagine that Karen is violating the Principle of Positive Undermining. It is hard to allow for the possibility that she may be violating not that principle but only the foundationalist's Principle of Negative Undermining.

Keeping Track of Justification

People do not seem to keep track of the justifications of their beliefs. If we try to suppose that people do keep track of their justifications, we would have to suppose that either they fail to notice when their justifications are undermined or they do notice but have great difficulty in abandoning the unjustified beliefs in the way a person has difficulty abandoning a bad habit. Neither possibility offers a plausible account of the phenomenon of belief perseverance.

It stretches credulity to suppose people always keep track of the sources of their beliefs but often fail to notice when these sources are undermined. That is like supposing people always remember everything that has ever happened to them but cannot always retrieve the stored information from memory. To say one remembers something is to say one has stored it in a way that normally allows it to be retrieved at will. Similarly, to say people keep track of the sources of their beliefs must be to say they can normally use this information when it is appropriate to do so.

I have already remarked that the other possibility seems equally incredible, namely, that people have trouble abandoning the undermined beliefs in the way they have trouble getting rid of bad habits. To repeat, participants in belief perseverance studies show no signs of knowing their beliefs are ungrounded. They do not act like people struggling with their beliefs as with bad habits. Again, I agree it sometimes happens that one keeps returning to thoughts after one has seen there can be no reason to accept those

thoughts. There are habits of thought that can be hard to get rid of. But that is not what is going on in the cases psychologists study under the name of belief perseverance.

This leaves the issue of whether one should *try* always to keep track of the local justifications of one's beliefs, even if, in fact, people do not seem to do this. I want to consider the possibility that there is a good reason for not keeping track of these justifications.

Clutter Avoidance Again

We have seen there is a practical reason to avoid too much clutter in one's beliefs. There is a limit to what one can remember, a limit to the number of things one can put into long-term storage, and a limit to what one can retrieve. It is important to save room for important things and not clutter one's mind with a lot of unimportant matters. This is an important reason why one does not try to believe all sorts of logical consequences of one's beliefs. One should not try to infer all one can from one's beliefs. One should try not to retain too much trivial information. Furthermore, one should try to store in long-term memory only the key matters that one will later need to recall. When one reaches a significant conclusion from one's other beliefs, one needs to remember the conclusion but does not normally need to remember all the intermediate steps involved in reaching that conclusion. Indeed, one should not try to remember those intermediate steps; one should try to avoid too much clutter in one's mind.

Similarly, even if much of one's knowledge of the world is inferred ultimately from what one believes oneself to be immediately perceiving at one or another time, one does not normally need to remember these original perceptual beliefs or many of the various intermediate conclusions drawn from them. It is enough to recall the more important of one's conclusions. This means one should not be disposed to try to keep track of the local justifications of one's beliefs. One could keep track of these justifications only by remembering an incredible number of mostly perceptual original premises, along with many, many intermediate steps which one does not want and has little need to remember. One will not want to link one's beliefs to such justifications because one will not in general want to try to retain the prior beliefs from which one reached one's current beliefs.

The practical reason for not keeping track of the justifications of one's beliefs is not as severe

as the reason that prevents one from trying to operate purely probabilistically, using generalized conditionalization as one's only principle of reasoned revision. The problem is not that there would be a combinatorial explosion. Still, there are important practical constraints. It is more efficient not to try to retain these justifications and the accompanying justifying beliefs. This leaves more room in memory for important matters.

Chapter 2: Belief and the Will

BAS C. VAN FRAASSEN

Can we rationally come to believe a proposition that is entailed neither by those we have believed heretofore nor by our previous opinions conjoined to the evidence before us? Discussing this question, William James quoted W. K. Clifford's statement (in "Ethics of Belief") that it is wrong always, everywhere, and for everyone to believe anything on insufficient evidence.¹ Arguing against this, James claimed that, in forming beliefs, we pursue two aims: to believe truth and to avoid error, and argued that the extent to which we pursue either at the cost of the other is a matter of choice: "he who says 'Better go without belief forever than believe a lie!' merely shows his own preponderant private horror of becoming a dupe. He may be critical of many of his desires and fears, but this fear he slavishly obeys . . . a certain lightness of heart seems healthier than this excessive nervousness [about error]. At any rate, it seems the fittest thing for the empiricist philosopher."²

In philosophy of science, until recently, something of this sort was regarded as part of the received view: general theories, such as Darwin's, Einstein's, or Bohr's, cannot be established on the basis of the evidence, but we may rationally come to believe that they are true. In addition, what we take as evidence itself is not indubitable, and we may later come to regard it as having been false. We regard ourselves as infallible neither with respect to what we take as evidence nor with respect to our extrapolation beyond the evidence, but neither do we think ourselves irrational for engaging in this cognitive enterprise.

The situation is *prima facie* not affected by the replacement of undogmatic, full belief by gradations of partial belief. Perhaps when I pro-

cess belief or acceptance, I merely indicate that the proposition seems highly likely to me. But the evidence at hand, especially if itself not fully believed, plus our opinions heretofore, generally does not entail a high probability of truth for general hypotheses or theories – especially not for the sort studied by scientists, which have empirical consequences for all past and future. Only recently have these views come under attack, by writers inspired by Bayesian foundations of statistics.

My strategy in this paper will be first to submit the traditional epistemological views to a critique along Bayesian lines (without claiming to be a Bayesian of any sort). Then I shall show the implications of that critique for those ways of changing one's opinions which Bayesians have generally admitted as rational. The result will be, I think, a puzzle for all concerned. Indeed, this puzzle suggests that we must obey a principle (which I shall call *Reflection*), going beyond the simple laws of probability, which looks *prima facie* quite unacceptable. I selected James's essay to introduce the topic because I wish to propose a solution to the puzzle along the broadly voluntarist lines of the views he defended. I hope that by consistently carrying through the voluntarist point of view we can, without sacrificing the theory of personal probability as a logic of epistemic judgment, nevertheless maintain the traditional epistemology.³

I. To Believe a Theory

Imagine that today I do not profess total certainty about whether the basic theory of evolution is true nor about whether I shall be sure of its truth next year. It does seem quite possible to

me that I shall become sure of its truth, but also, unfortunately, somewhat possible that I shall form this belief although it is in fact false. Does the state of opinion I have just described seem totally absurd or irrational to you? If not, this section may convince you otherwise.

The critique I am about to offer is along Bayesian lines, though not exactly standard ones, nor perhaps uncontroversial: I request the reader to bear with my rather informal and naive presentation here; in the next section I shall make the argument at once more general and more precise. As described, my present state of opinion is one of uncertainty. The degrees of uncertainty about the different propositions are not the same; it is common today to describe them in terms of subjective or personal probability.⁴ In Bayesian eyes, personal probability is the guide to life. The simplest cases we find are in buying contracts, insurance policies, and wagers. Without going into the details, I shall take the following as paradigm: if a contract is worth 1 to me if A be the case, and nothing otherwise, then its present value for me equals my personal probability for A . More generally,

if it is worth z to me if A and nothing otherwise and if my personal probability that A is the case equals $P(A)$, then the value of this contract for me (fair in buying or selling) equals $zP(A)$.

That is all we shall need for our discussion.

So let H be the hypothesis under discussion – say, the theory of evolution – and let E be the proposition that Bas van Fraassen will fully believe that H (say, one year from today). For definiteness, suppose that $P(E)$ – my degree of belief that E will be the case – equals 0.4 and $P(\sim H \& E)$ – my degree of belief that I will mistakenly come to bestow full belief on H – equals 0.2. For now I shall assume that full belief entails personal probability equal to 1. The argument would go through for a degree very close to 1 as well, but I shall in any case consider more explicitly the case of non-full-belief formation below.

At this point we may introduce into the story a Dutch bookie.⁵

He elicits all the above information from me, and he decides on a secret strategy for betting with me. As a first step, he offers me three bets. I call him Dutch, because what he has offered me is what is called a *Dutch book*, a set of bets such that, no matter what happens, I will lose money. And the unfortunate fact is that each of the bets is fair, according to my own state of opinion.

Because I will describe his betting scheme in full generality in the next section. I ask the reader to consider the present figures only cursorily. The trick up his sleeve is that (a) if I do not come to fully believe H , I win only the second bet, and (b) if I do come to fully believe H , then I lose the second bet, but I also tell the bookie myself that I have lost the first bet as well. At this point he takes the second step in his strategy, which is in effect to buy back the ticket for the first bet, for a pittance. (He can do this by formally offering to buy from me a bet that H is false; since I am sure that H is true, any price at all for that new bet will be more than fair in my opinion.) In either case I will have a net loss.

Here are the bets: the first pays 1 if I come to believe H and H is really false – he asks 0.2 for it. The second will pay 0.5 if I do not come to believe H , and he asks me 0.3 for that one. The third pays 0.5 if I really do come to believe H ; that one costs 0.2. All these prices are fair, given my state of opinion. (I leave out units of value; so they can be adjusted for inflation and the like.) None of the bets pay anything if they are not won. My total cost is 0.7 for all three.

On one scenario I do not embrace H ; I win the second bet and lose the other two. On the other scenario I do embrace the hypothesis; now I lose the second bet, tell him myself that H is true, so I get nothing for the first bet (though I receive a pittance when I sell him back a bet on $\sim H$ for next to nothing), and I win the third. On either scenario I get at most a little more than 0.5, and I have a net loss. This bookie had a strategy which he knew beforehand would allow him to offer me only bets that would be fair by my lights, and yet necessarily give him a net profit. He devised this strategy without any special knowledge either of whether Darwin was right or of whether I would come to believe that hypothesis.

All this may look like so much *léger-de-main* at this point. Suppose for a moment, however, that I have not pulled any tricks. In that case whoever is as I described myself, hypothetically, at the beginning of this section, is in a state of opinion which the Bayesian calls incoherent (a polite word for irrational). Whether or not I actually bought the bets does not matter, of course: my incoherence consists in regarding them as fair.

Unhappy mortal! I found myself in this incoherence merely by contemplating that I could do what James said I could – without even actually deciding to believe Darwin's theories, or anything like it. Not only people so rash as actually to come to believe theories on less than totally

compelling evidence, but anyone who does not, with Clifford, reject such a new belief as utterly irrational, is caught in the trap. Who, upon seeing this Bayesian refutation, does not immediately find himself in full flight from voluntarism and pragmatism, toward the imitation of Carnap's robot?

II. To Raise One's Opinion of a Matter of Fact

The preceding argument gives rise to three initial suspicions. The first is that bets cannot sensibly be made on propositions, like Darwin's hypothesis, which cannot be verified or falsified in a finite amount of time. The second is that it is irrational to become fully certain of any propositions except tautologies. The third suspicion one may have is that it is irrational to change one's mind in any way except by what the Bayesians call "conditionalization on one's evidence." [Roughly speaking, this means that one becomes fully certain of the proposition(s) one takes as evidence, and makes only the minimal adjustments to the rest of one's opinions needed to accommodate this new certainty. We may think of this as Clifford's position, updated to accommodate degrees of belief.] Note well that the second and third suspicion cannot be jointly entertained unless evidence is always tautological. So we must confront the second and third separately, but I think we can show the irrelevance of the first along the way. Later on we shall turn to still further suspicions, for example, about the suitability of one's own future opinions as a subject for prevision.

Before going on to examples, we should look at what exactly is involved in Dutch book arguments. In the simple or *synchronic* case, the bookie is able (without having knowledge superior to the agent's) to offer the agent several bets, which demonstrably have the following features: (a) each bet taken individually looks fair to the agent at this time, and (b) taken together the bets are such that, no matter what happens, the agent will suffer a net loss. The expression 'looks fair' is explicated by the Bayesians in terms of the agent's personal probability P and utility evaluations, following the paradigm that $zP(A)$ is the exact value of a bet on proposition A with payoff z . In the case described, the bets in question constitute a Dutch book, and the agent's vulnerability brands his state of opinion as *incoherent* (and indeed, it can be deduced that P violates the probability calculus).

In the *diachronic* case we should speak of a *Dutch strategy* rather than a Dutch book. The bookie is able (without superior knowledge of present or later circumstances) to devise a strategy for offering bets to the agent which is demonstrably to the agent's disadvantage. This strategy is demonstrably such that, under all eventualities, the agent will be offered bets with two features: (a) individually, each bet will look fair to the agent at the time of the offer, and (b) taken together, the bets offered will be such that, whatever happens, the agent will suffer a net loss. Let us emphasize especially that these features are demonstrable *beforehand*, without appeal to any but logical considerations, and the strategy's implementation requires no information inaccessible to the agent himself. The general conclusion must be that an agent vulnerable to such a Dutch strategy has an initial state of opinion or practice of changing his opinion, which together constitute a demonstrably bad guide to life. In this paper, success of the strategies discussed will be independent of the agent's practices for changing opinion, and hence any blame must attach to his initial state of opinion – his vulnerability reveals an initial incoherence.

It is now time to describe the exact betting strategy used by our Dutch bookie. We have two propositions, H (the hypothesis) and E , a proposition about the customer's future attitude to the hypothesis. The customer has degrees of belief $P(E)$ and $P(\sim H \& E)$, neither of which is 0 or 1. The three bets are:

- (i) The bet which pays 1 if $(\sim H \& E)$ and which costs $P(\sim H \& E)$
- (ii) The bet which pays x if $\sim E$ and which costs $xP(\sim E)$
- (iii) The bet which pays y if E and which costs $yP(E)$

Here the probability of $\sim E$ equals 1 minus the probability of E . The number x is the usual conditional probability of $\sim H$ given E ; that is, $P(\sim H \& E) \div P(E)$. And finally y is x minus the subjective probability the customer will have for the hypothesis, when and if E becomes true. It helps to observe that I and II together form in effect a *conditional bet* on $\sim H$ on the supposition that E , which bears the cost x and has prize 1, with the guarantee of your money back should the supposition turn out to be false.⁶ So the total cost of all the bets together must equal $x + yP(E)$.

Let us now consider an example in which all propositions will have their truth value settled

by a certain definite time and in which it is not strictly implied that anyone is fully certain of the truth of any nontautology. Since we are now on the attack, the example should be made as simple and hygienic as possible. Let it be a race, at Hollywood Park, tomorrow at noon. The proposition H is that the horse Table Hands will run in that race and win it. The bookie now asks me seriously to consider the possibility that tomorrow morning, at 8 A.M., I shall consider fair a bet on this proposition at odds 2 to 1. I say I do not know if that will happen – my personal probability for that eventuality, call it E , is $P(E) = 0.4$. Next he elicits my opinion about how reliable I think I am as a handicapper of horses. What is my subjective probability that E will indeed be true but that the hypothesis that Table Hands will win, is false? Suppose I answer that this degree of belief of mine, $P(\sim H \& E)$, equals 0.3. The exact numbers do not matter here too much, except that they indicate a certain lack of confidence in my own handicapping skill. In this case they entail that my present conditional probability for Table Hands' winning, on the supposition that tomorrow morning I will have subjective probability $1/3$ for it, is only $1/4$. The calculation is simple.⁷

What the bookie does now, if I buy the bets, is also simple. He approaches me at 8 A.M. the next morning. If I do not consider odds of 2 to 1 on Table Hands fair, he pays me off on the second bet, but he has won (I) and (III). On the other hand, if I do call those odds fair, he first of all pays me for bet (III). But then he buys from me a bet, with prize 1, against Table Hands' winning, at my newly announced odds. The result of this is, of course, that whether or not Table Hands wins at noon, no money need change hands between us – he has, so to say, bought (I) back from me. So we can now tally up our prospective losses and gains, and again it turns out that I shall have been the loser come what may.⁸

I chose this example to disarm both the first two initial suppositions at once. For there is no implication, in the description of this case, that anyone ever raises the probability of any nontautology to *one* (though in that case the bookie is being quite agreeable about paying me off before he is totally certain that he has heard me correctly). On the other hand, every proposition becomes settled in a certain finite amount of time. The disaster – which consists of course in my present vulnerability to his strategy, not in any actual bets made or lost – happened again because I profess some doubts today about my judgment of tomorrow.

Let us therefore not think about gambling anymore, and turn to the scientist in his lair, Clifford's ideal who (according to James's quotation) "will guard the purity of his belief with a very fanaticism of jealous care, lest at any time it should rest on an unworthy object, and catch a stain which can never be wiped away" and who, therefore, never believes anything upon insufficient evidence (James, *op. cit.*, p. 92). He is then just like Carnap's robot: his senses bring him propositions that he takes as evidence, and his total response to this consists in *conditionalizing* his present state of opinion on these propositions.⁹ To conditionalize on a proposition X taken as evidence means this: your odds for various eventualities on the supposition that X are still the same, but that supposition you now regard as certainly true.

Well suppose that e is the sort of proposition that I typically do take as evidence. We need not decide here exactly what sort that is. Perhaps it is the sort of report that comes from Mount Wilson observatory, after having been checked and verified numerous times. Or perhaps it is simple everyday propositions like "That rose is red" or "That is a rose." In any of these cases, the example is decided on the basis of perception. Now let me give the reins over to you, reader: do you think that I am infallible when it comes to perception? Do you think that I shall certainly not take a rose to be red if it is not? Or that a needle will never turn out to have been to the left of the number 7 on a dial, when I said it was to the right? All right, you have convinced me: my subjective probability that e is false, on the supposition that I shall take it as evidence, is not zero.

It is not difficult to see that, formally speaking, I am now in exactly the same position as I was when I thought that I might come to believe a false hypothesis of Darwin's. (Let E be the proposition that I shall take e as evidence, and H the hypothesis that e is true.) Merely by contemplating this eventuality and admitting that I am not sure it cannot happen, I imply that I regard as fair each of three bets which together form the basis for a Dutch strategy. Even if I insist that my epistemic life is lived in the Imitation of Carnap's Robot, mere admission of my fallibility, it seems, makes me diachronically incoherent.

III. Prevision of Our Own Previsions

When we begin to think about the laws and sources of our own epistemic judgments and states of opinion, we are automatically led to

deal with them as facts in the world and to consider them in general: that is, with no regard to persons, treating others' no differently from our own. Yet a closer reading of the preceding arguments, once the initial suspicions have been disarmed, presents us with only two possible ways out. The first is that we should have no opinion at all concerning the reliability of our own future judgments; the second, to form as a matter of principle an exceptionally high opinion of their reliability in our own case.¹⁰

The first may claim precedent in the discussions of de Finetti and Savage themselves, rejecting the intelligibility of higher-order degrees of belief. Their reasons have been incisively criticized by Brian Skyrms.¹¹ As I shall explain later, I think there is something to the view that the statement that my opinion is such and such "is not a proposition." But we can, I think, quickly dismiss the simpler objections along this line. First of all, whatever is done by the person who says "It seems as likely to me as not that today will be rainy," we do have a proposition that is true if and only if he is at the moment in the psychological state of considering rain as likely as not, being as willing to bet on rain as on the toss of a coin, and so forth. Psychological studies of this subject are well known and we do not think them, surely, to be of an illusory or non-existent phenomenon.

More important is the worry that, in asking us to consider our own states of opinion, we may be led into the vagaries and paradoxes of self-reference. It would be no surprise if the attempt to assign degrees of credence or credibility to self-referential statements generally were as beset with paradox as the attempt to assign them all truth values. But actually the puzzles or arguments I have presented do not presuppose that degrees of belief are accorded to self-referential statements at all. Suppose that "Cicero" and "D-Day" are context-independent rigid designators referring to a person and a time, respectively, and that p is a function defined on some set of propositions such that $p(A) = r$ if and only if Cicero has on D-Day subjective probability r for proposition A . For definiteness, suppose that the domain of p contains only propositions of an extremely simple sort, such as that Table Hands wins the race or that a certain coin lands heads up or that a certain rose is red. There can surely be no difficulty in anyone's having at any time a degree of belief for the proposition that $p(A) = r$. Hence Cicero may have exactly that the day before D-Day. In addition, there is (independent of these considerations) surely no prob-

lem about Cicero's being able to know that he is Cicero or to know that the day in question is in fact the day before D-Day. If there are difficulties with any of these suppositions, they must be deep skeptical problems concerning the very coherence (in the nontechnical sense) of the concept of subjective probability and the concept of knowledge about who we are and what time it is. This coherence is all our arguments required. At no point did we need to assume that anyone's degrees of belief were accorded to any but time and context-independent propositions.

We come therefore finally to the last way out, which is to say that all three examples were cases in which I made the agent out to be genuinely irrational. This could only be because in each case his degree of belief about what would happen, on the supposition that he would have a certain opinion about that in the future, differed from *that* opinion. The principle we are thereby led to postulate as a new requirement of rationality, in addition to the usual laws of probability calculation is this:

$$\text{(Reflection)} \quad P_t^a(A | p_{t+x}^a(A) = r) = r$$

Here P_t^a is the agent a 's credence function at time t , x is any nonnegative number, and $p_{t+x}^a(A) = r$ is the proposition that at time $t + x$, the agent a will bestow degree r of credence on the proposition A . To satisfy the principle, the agent's present subjective probability for proposition A , on the supposition that his subjective probability for this proposition will equal r at some later time, must equal this same number r . It is tempting to call this principle of reflection by some more memorable name, such as 'Self-confidence', 'Optimism', or perhaps 'EST', or even 'Self-deception', but I have chosen a more neutral name because I propose to examine, and indeed advocate, serious attempts to defend the principle.¹²

Since none of us is willing to adopt a similar principle governing our own opinion concerning the reliability of others' opinions – or the corollary that they will never take as evidence something that is in fact false – justification of this principle can follow no ordinary route! Indeed, it would seem that we already believe that most people whose credence function obeys this principle of Reflection are by that very fact mistaken about themselves.

At the same time we can give independent or indirect reasons to think that criteria of coherence, concerning degrees of belief that are guides for action, will require this Reflection principle

for their satisfaction. To show this I must first briefly outline another justification for the additivity of synchronic degrees of belief, a sort of dual to the Dutch book argument.¹³

To explain the idea of *calibration*, consider a weather forecaster who says in the morning that the probability of rain equals 0.8. That day it either rains or does not. How good a forecaster is he? Clearly to evaluate him we must look at his performance over a longer period of time. Calibration is a measure of agreement between judgments and actual frequencies. Without going into detail, it is still easy to explain perfect calibration. This forecaster was perfectly calibrated over the past year, for example, if, for every number r , the proportion of rainy days among those days on which he announced probability r for rain, equalled r .

Although perfect calibration may not be a reasonable aim by itself, and hardly to be expected at the best of times, it certainly looks like a virtue. It would seem to be irrational to organize your degrees of belief in such a way as to ruin, a priori, the possibility of perfect calibration. A few qualifications must at once be introduced: this forecaster would not have been perfectly calibrated over the past year if he had announced irrational numbers, or even numbers not equal to some fraction of form $x/365$. So the only possibility that we should require him not to ruin beforehand is that of arbitrarily close approximation to perfect calibration if he were asked sufficiently often about events that he considers exactly similar to those he was actually asked about during the evaluation period. It can now be proved that satisfaction of this criterion of potential perfect calibration is exactly equivalent to satisfaction of the probability calculus (in exactly the same sense that this equivalence can be claimed for the criterion of invulnerability to Dutch books).

But it is easy to see what will happen if the evaluation is extended to the forecaster's opinions concerning the calibration of his own judgments. For suppose that he is actually perfectly calibrated in his judgments concerning rain over the next year. Then if he has made judgments to the effect that there will be a discrepancy between the actual frequencies and his announced probabilities, *those* judgements will not be perfectly calibrated. Hence by adding such a judgment as "The probability of rain on days on which I announce the probability of rain to be 0.8, equals 0.7" he would automatically ensure that the class of all his judgments was

not perfectly calibrated on any possible scenario. Our criterion accordingly appears to require him to express perfect confidence in the calibration of his own judgments.

Dutch book considerations are of course more familiar; it is interesting to see that the principle of Reflection follows as an immediate corollary to this equivalent, less familiar criterion of coherence. It helps to dispel as vain the small hope that criteria of rationality of this general sort could be satisfied by anyone with doubts that violate Reflection. Yet – and here is the puzzle – we all begin with the intuition that such doubts are not of the radically skeptical kind, but reasonable and rightly common.

IV. Circumventing Moore's Paradox

The main purpose of this section will be to show that certain attempts to defend the principle of Reflection do not work. But at the same time I will attempt to show that even an agent adhering to that principle may have some way to express doubt about the reliability of his own future opinions. Hence the discussion will at least undermine one objection to the principle, even if it does not yet issue in a good defense.

The first proposal to defend (Reflection) is this: to announce my subjective conditional probability for X , on the supposition that Y , is simply to announce what my opinion concerning X would be, should I learn that Y . This thesis implies (Reflection) at once, but the thesis is quite untenable. Richmond Thomason once objected to a similar theory of what it was to believe a conditional, that he believed to be true the proposition that, if his wife were not faithful to him (she being so clever), he would believe that she was. If I go on to reflect on other examples, it is only because I wish to do more than defeat the proposal.¹⁴

Are there propositions that we must admit to be possibly true but could never believe? Hilary Putnam has argued this status for the proposition that we are brains in a vat, and Donald Davidson for the proposition that most of our beliefs are false. These are forms of general and radical skepticism. An older and simpler case is Moore's paradox: "There is a goldfinch in the garden and I do not believe that there is." This statement could of course be true (at the moment I do not believe that there is, yet there might be one) but I could not very well assert it, for this is not a proposition that I can believe. Note, however, that I have just stated parenthetically

that, for all I know or believe, it may be true; so I clearly do not disbelieve it. It is also to be remarked that Moore's paradox does not presuppose that belief is a propositional attitude that we can have toward self-referential propositions. For if Cicero knows himself to be Cicero, he cannot believe that (there is a goldfinch and Cicero does not believe that there is). To consider a somewhat more general version, we must introduce the distinction between probabilities as gradations of belief and as degrees of objective chance.

This distinction is now commonly made, and several recent papers have been devoted to the principles governing their combination.¹⁵ The minimal such principle looks formally similar to the synchronic version of (Reflection):

$$(Miller) = P_t(A | ch_t(A) = r) = r$$

so called because of its role in the (famous but fallacious) argument known as Miller's paradox.¹⁶ To satisfy this principle, the agent's subjective probability for a proposition A , on the supposition that the objective chance that A equals r , must be equal to that same number r . Justification of this principle certainly rests on nontrivial assumptions about what we are like – namely, that we are temporal and finite beings, aware of our temporality and finitude. To see this we deduce that, for an agent whose epistemic history satisfies (Miller), perfect foreknowledge is incompatible with indeterminism. For suppose that such an agent had subjective probability P equalling 1 or 0 for every factual proposition, and indeed, 1 exactly if the proposition is true. Then there is, for each factual proposition A , a number r such that $ch_t(A) = r$ and $P_t(ch_t(A) = r) = 1$. Hence also $P_t(A) = r$, by (Miller); but then it follows that r is 0 or 1; so whether or not A will be the case is already determined with certainty by the facts at this time.¹⁷

If we add to (Miller) the synchronic – I should think, uncontroversial – part of (Reflection) we can now find a proposition which I can admit to be quite possibly true but which I know I could never fully believe. Suppose I have a coin in my hand which I am about to toss and I have picked it at random from a box that contained one fair coin and one magician's coin, the latter having a two-to-one chance of landing heads up. My present subjective probability for the coin in my hand to land heads up is, accordingly, the average of the two objective chances, $1/2(1/2 + 2/3) = 7/12$. So my present subjective

probability for the proposition (the chance of heads equals $1/2$ and my personal probability for it equals $7/12$) equals $1/2$. But of course I could never fully believe that conjunction; for, by (Miller), if I fully believed the first conjunct, my personal probability would automatically equal $1/2$ too. [More rigorously: (Miller) and the synchronic ($x = 0$) part of (Reflection) together entail that if $P_t(ch_t(A) = r \& P_t(A) = s) = 1$ then $r = s$.]

So now we have found a proposition Y to which we can indeed assign a positive subjective probability, but which we cannot conditionalize on. Hence it is clear that $P(X|Y)$ is not to be thought of as the probability we would accord X should we learn that Y . The proposal for defending (Reflection) made at the beginning of this section has failed. But we have learned something useful. Even while adhering to (Reflection) we can to some extent express doubts about the correctness or reliability of our future opinions. For example, without violating (Reflection) I can say: "It does not seem unlikely to me that Table Hands' objective chance of winning tomorrow will be considerably less than my subjective probability for that event tomorrow morning."

Those who believe that we conditionalize on – hence raise to subjective certainty – propositions that we take as evidence, do not have this sort of consolation. For presumably we mean to take as evidence at $t + x$ only propositions A whose truth value becomes settled at or by that time, which implies that A is equivalent to $ch_{t+x}(A) = 1$. To say, therefore, that it is not totally unlikely that tomorrow morning I shall take A as evidence even though its chance is less than 1 is to violate (Reflection) by implication. A simple one-place probability function will never allow us to characterize the epistemic state of someone who says that he may become certain of a proposition but will not reject as absurd the possibility that future evidence will prove him wrong.¹⁸ But it remains that in the preceding paragraphs we have seen considerable leeway for the person who wishes to be diachronically coherent and yet express doubt about the reliability of his future opinions considered as indicators of what will happen.

Leaving this (at least somewhat) happy digression, let us turn to another proposal to defend (Reflection). Could it not be entailed by some more general principle about conveyance of factual information? Perhaps it would not be rational to have a state of opinion that it was not

rational to convey, in so many words, to a suitable audience. But suppose I were to tell you: "If I say tomorrow morning that it will rain, there will still be a 50/50 chance that it will not." You would certainly look at me askance and reply that, in that case, you might as well not listen to me tomorrow morning. But then my assertion just now has taken away all value from my words of tomorrow morning about rain. We can see this as pathological if we take the following point of view: my expressions of opinion make statements about my mental state and, more particularly, about the aspect of my mental state which is meant to be a reliable indicator of relevant facts outside it. The value of these descriptions of my mental state – whether in the terminology of belief or of subjective probability – to my audience lies exactly in the information thus conveyed indirectly about what it is meant to be a reliable indicator of. Hence I have made a statement that cancels the normal conversational force of my statements of that sort.

I do not think that these reflections are entirely without force or relevance to (Reflection), but, as they stand, the rationale is quite wrong, and they do not constitute a defense. There is some ambiguity in the common use of both 'say' and 'there is a chance.' The first can be used to mean "assert" in a sense that implies belief, or requires in some other way that the assertor believes what he asserts; and the terminology of chance is sometimes used simply to express degrees of credence. If we adopt these interpretations when reading the example, it certainly has something putatively wrong with it, but that something is exactly that it implies a violation of (Reflection). Hence it does not manage to point to a more general principle to help us. If on the other hand we understand 'say' as "utter the words" or 'chance' as "objective chance," we have merely a statement that expresses doubt about the reliability of either my mental states or feelings or my words as indicators of rain. Although it is true that the audience is thereafter well advised not to take my words or opinion into account when deciding about the need for umbrellas, no principles or conversational maxims have been contravened. Such statements about my reliability as indicator of rain need no more be logically odd or conversationally pathological than similar statements about the reliability of my watch. The audience is simply, in strict accordance with our conventions of conversational cooperation, advised to listen to the radio weather report (respectively,

time signal) rather than to my guesses about this particular topic.

V. Voluntarism as Solution

for what else is it to believe but to assent to the truth of what is propounded? Consent being a matter of the will. . . .

St. Augustine,
On the Spirit and the Letter, 54

The problem raised by the apparent need for principle of Reflection is, it seems to me, one of interpretation. A tenable interpretation of personal probability must either sever the link between rationality and coherence or else entail that Reflection is a form of epistemic judgment to which we must assent. It seems to me that among the debris in the preceding section there are some usable materials for the construction of an interpretation of the latter sort. The interpretation will first of all consider how the probability calculus can be viewed as a logic of epistemic judgments, and then consider exactly what such judgments are.

Let us begin with two challenges, one very familiar, the other due to Gilbert Harman. The first is that we simply do not have such a finely graded state of opinion as numerically precise subjective probabilities require. This challenge is answered by the admission that our personal probabilities are to some extent vague. Rain tomorrow seems no less likely to me than a tossed coin's coming up heads four times in a row, no more likely than at least one of four tossed coins' coming up heads. My state of opinion is no more precise than this. Harman's challenge goes deeper. Since probabilities, unlike truth values, are not functional – $P(A \& B)$ is not a function of $P(A)$ and $P(B)$ –, storing the information contained in an assignment of probabilities to sentences of even a "small" simple language quickly gets beyond the storage capacity of the mind. With vague probabilities the information storage problem gets worse, because each sentence now has two numbers assigned – a lower and upper probability. To circumvent this information explosion we must characterize a person's opinions as consisting of some which are more or less directly accessible plus all those to which the former commit him, on pain of violation of some higher criteria of rationality to which he subscribes.

No one, we say, has numerically precise degrees of belief. But at a given time I may,

more or less consciously or overtly, make or be committed to a number of judgments of such forms as: it seems likely to rain, it seems as likely as not to snow, it seems likely to me – supposing it rains – that it will be cold, and so forth. These judgments express my opinions on various matters of fact; let us call them *epistemic judgments*. A certain family of these, accordingly, characterize my present state of opinion; they are *mine*. Unless I am very opinionated, they are not many, and they leave gaps: they may for instance not include, either directly or by implication, any judgment nontrivially comparing in such terms as the above, rain and newspaper reports of murder, or Darwin's theories and Einstein's.

It will be clear how an assignment of numbers to propositions could in principle reflect these judgments, because we are all familiar with their counterparts in the terminology of subjective probability. A person has, in the technical sense, a *coherent* state of opinion only if there exists at least one probability function P such that $P(A) > P(B)$ if it seems more likely to him that A than that B , $P(A) \geq P(B)$ if it seems no less likely to him that A than that B , $P(A|C) > P(B|C)$ if on the supposition that C it seems more likely to him that A than that B , and so forth. Let us say that such a function P *satisfies* his judgments. The lack of precision and other gaps in his judgments entail now that, if any one probability function P satisfies his judgments, then so do a number of others. The class of all that do, we may call the *representor* for his state of opinion. Unless that representation contains only a single function, we also say that his degrees of belief, or subjective probabilities, are to some extent vague or indeterminate.¹⁹

We can now introduce a quite exact concept of implication among epistemic judgments for coherent states of opinion: if all probability functions satisfying each of a class X of judgments also satisfy judgment J , then (and only then) does X *coherently entail* J . It is exactly in such a case, when a person overtly makes all the judgments in X , that we say that he is also committed to J , on pain of incoherence.

Obviously a coherent state of opinion can be re-expressed in judgments formulated in the language of vague probability theory. "My subjective probability for A is no less than x , no greater than y " characterizes my state of opinion correctly if and only if, for every member P of my representor, $x \leq P(A) \leq y$. Similarly for subjective conditional probability, subjective odds, and subjective expectation. We see, therefore, that

subjective-probability talk is merely the formulation, in sophisticated and flexible language, of judgments that have exactly the same status as, and indeed are entailed by, the epistemic judgments with which we began our discussion – for coherent states of opinion.

Therefore we must now look closely at exactly what an epistemic judgment is. Suppose I express my opinion as follows: "It seems more likely to me – supposing that it stays this cold – that it will snow than that it will rain." What exactly have I just done? One answer, the answer I wish to dispute, is that I have just made an autobiographical statement, describing my own psychological state.²⁰ Certainly, if you hear me say the above, you will be able to infer something about my psychological state, and perhaps this fact even provided the motive for my utterance. But that is very different from saying that what I did was to make an autobiographical statement of fact. (I belabor the point only because John Austin is not generally discussed in writings on subjective probability.) Consider this story: yesterday morning I said to you "I promise you a horse by nightfall." This morning you point out that I have not got you a horse, and you accuse me of the heinous immorality of breaking my promise. Not at all, I say, I am guilty only of the lesser sin of lying; what I said yesterday morning was only a false autobiographical statement, for I was not in fact promising you a horse.

The sentence "I promised you a horse yesterday" is clearly a statement of fact, the fact that became true yesterday when I made the promise (perhaps by saying "I promise you a horse"). I wish to make the same sort of distinction with respect to the terminology of personal probability. In the preceding sections I already introduced a symbolic distinction, with the capital and lower-case distinction in $P(p_t(A) = r) = s$. If I were to say that, I would be expressing my opinion concerning a factual proposition about what my opinion was (is, will be) at time t . As analogue, consider "I promise you that I will not make you any promises concerning future dividends until I have carefully looked into the chances of success."

I do not mean that to express an opinion is to make a promise. The latter is a sort of ceremony in which I take upon myself, bring into being, an obligation to someone else. Two other alternatives suggest themselves: to express my opinion is to express my feelings, or it is to express an intention or commitment. There is something to be said for the first. A promise properly made

will *follow* the agent's realization that he is willing, and able, to enter the corresponding contract or obligation. But expressing one's feelings generally involves, and may be the only means for, exploration of those feelings – I know that I feel strongly about this subject, but I don't know what I feel until I begin to talk or act or paint or write, and I discover almost as much about what I feel as the onlooker does. In this respect expressing one's opinions is often less like promising and more like emotive expression. But in this respect, expression of intentions is often the same. A difference is that, both in the case of opinion and of intention, and not in the case of feeling, the act of expression does not typically turn from genuine expression into something else, if one deliberately repeats the act.

Suppose, for example, that I have looked at my calibration score, found that I have generally overestimated the chances of rain, and now have exactly the same feelings on the question of rain as I did yesterday. Then my judgment about rain will now be different from what it was yesterday, for this judgment does not have the function of merely expressing my feelings – properly made, formulating my judgment follows deliberation.

It seems then that, of the alternatives examined, epistemic judgments are most like expressions of intention. I may express an intention either by simply stating the outcome of what I have decided upon (“You will be my successor”) or by choosing a form of words traditionally suited to such expression (“You shall be my successor”). In either case, it is conveyed that I have made a decision, have formed an intention, am committed to a certain stance or program or course of action. There is no direct obligation to anyone else to fulfill this intention, but I have, as it were, entered a contract with myself. If I express this intention to an audience, then, just as in the case of a promise, I invite them to rely on my integrity and to feel assured that they now have knowledge of a major consideration in all my subsequent deliberation and courses of action. In this respect, expressing a considered judgment is similar.

Returning now to the principle (Reflection), consider the following analogies. I say, “I promise you a horse,” and you ask, “And what are the chances that you'll get me one”? I say, “I am starting a diet today,” and you ask, “And how likely is it that you won't overeat tomorrow? In both cases, the *first* reply I must give is “You heard me!”. To express anything but a full commitment to stand behind my promises and intentions, is to

undermine my own status as a person of integrity and, hence, my entire activity of avowal. This applies equally in the case of conditional questions. “If you promise to marry me, will you actually do it”? “If you decide to join our crusade, will you really participate”? In the first instance these questions are not invitations to an academic discussion of the objective chances, but challenges or probes of one's avowed intentions and commitments. It is confusing that the same words can be used for either purpose – not confusing in actual dialogue where contextual factors disambiguate, but confusing in written discussion.

Avowal, *qua* avowal, has its own constraints, which affect the logic of expressions of avowal. In none of the above cases do we have a simple way of characterizing what it is to be “false” to one's commitment. Having made a promise, I also have some obligation to prevent circumstances that would make it impossible to keep the promise. Having decided on a program of regular exercise, I have obliged myself to some extent to prevent travel arrangements, hangovers, lack of proper clothes and shoes, and so forth, that would interfere. It may not be easy for the onlooker, or even for me, to allocate blame or to decide whether I was false to myself or merely a victim of circumstances. In the same way, if I express my opinion, I invite the world to rely on my integrity and to infer from this what advice to myself and anyone else in like circumstances, concerning the carrying of umbrellas, purchase of insurance policies, entering wagers, I would presently consider the best. Only in clinically hygienic cases would it be uncontroversially clear whether or not I really stood behind my expressed opinion. But that is so in the case of any expression of commitment or intention.

I conclude that my integrity, *qua* judging agent, requires that, if I am presently asked to express my opinion about whether *A* will come true, on the supposition that I will think it likely tomorrow morning, I must stand by my own cognitive *engagement* as much as I must stand by my own expressions of commitment of any sort. I can rationally and objectively discuss the possibility of a discrepancy between objective chance and my previsions. But I can no more say that I regard *A* as unlikely on the supposition that tomorrow morning I shall express my high expectation of *A*, than I can today make the same statement on the supposition that tomorrow morning I shall promise to bring it about that *A*. To do so would mean that I am now less

than fully committed (a) to giving due regard to the felicity conditions for this act, or (b) to standing by the commitments I shall overtly enter.

VI. Traditional Epistemology Revised

This paper began with a statement of what I regard as a traditional epistemological view in philosophy of science: that we may rationally decide or come to believe propositions, hypotheses, theories which are not entailed by (and which we ourselves do not regard as being made certain by) the evidence at hand. In addition – still spelling out this view – evidence itself is only the body of propositions that we have taken as evidence, and what we take to be evidence on a particular occasion may in fact be false. The refutation, along familiar Bayesian lines, was quick and sure and deadly: anyone who even regards himself as not totally unlikely to do what this view calls rational, is diachronically incoherent: vulnerable in that he implicitly regards as fair, disastrous combinations of wagers.

But then we also saw that the refutation is blocked by adherence to a principle, which goes well beyond the probability calculus, but which is equally required for the diachronic coherence of agents that Bayesian writers regard as rational. So the refutation is no refutation: we need not stop at conditionalization on the evidence on pain of incoherence, as long as we adhere to this principle, which even the strict conditionalizer himself (and also the less committal observer described by Jeffrey) needs equally badly. Of course, the more improbable the proposition we decide to believe, or equivalently, the more we raise our credence in an uncertain proposition, the more risk we take. But that is merely a matter of degree, and there is no violation of coherence or any other criterion of rationality. Any accusation of epistemic extravagance is in any case to be met, by Jamesian and Bayesian alike, with the cool judgment “My credence that *A* is true, on the supposition that tomorrow I shall accord it credence to degree *r*, equals *r*.” We can put the matter in either of two ways, depending on how we value the epithet of “Bayesian.” Either that non-Bayesian epistemic behavior is defensible by exactly the same defense needed for Bayesian behavior; or, if you like, that apparently non-Bayesian behavior described by James and other traditional epistemologists turns out to be, after all, entirely acceptable as far as Bayesian standards go. It may be a bit scary to think that

such leaps of faith as James described in “The Will to Believe” or St. Augustine in “On Belief in Things Unseen” – he included his own belief in the existence of the Ocean – are not ruled out by the Bayesian’s standards of coherence. But it is also a welcome thought, if we regard considerations of coherence as eminently rational, yet hope to find room for independence and enterprise in forming our world picture.

But then there is still the matter of the defense of the defense. I have argued that it is in fact indefensible if we regard the epistemic judgment – whether formulated in probabilistic or more qualitative terms – as a statement of autobiographical fact. The principle (Reflection) can be defended, namely as a form of commitment to stand behind one’s own commitments, if we give a different, voluntarist interpretation of epistemic judgment. I call it “voluntarist,” because it makes judgment in general, and subjective probability in particular, a matter of cognitive commitment, intention, *engagement*. Belief is a matter of the will.

Notes

- 1 “The Will to Believe.” Page references will be to his *Essays in Pragmatism* (New York: Hafner, 1948).
- 2 *Op. cit.* p. 100. Note that on the next page James grants that scientists doing science proceed as Clifford has it. This concession may have been for the sake of argument (for compare the skepticism about the reach of science on pages 23, 25 and 38), rather than a genuine subscription to the objectivity of strict induction from the evidence. Recent philosophy of science has in any case not been so sanguine.
- 3 James’s view may be attacked on the flank by arguing that belief is not a matter of the will at all, not under voluntary control. Voluntarism with respect to belief is usually attacked in its naive versions and defended in more sophisticated formulation; I will of course not suggest that we can believe just any proposition at will. Cf. James. *op. cit.* p. 90; Barbara Winters, “Believing at Will,” *Journal of Philosophy*, LXXVI; 5 (May 1979): 243–256; and Robert Holyer, “Belief and Will Revisited,” *Dialogue*, XXII, 2 (June 1983: 273–290).
- 4 Some common objections, such as that we do not have numerically precise degrees of certainty and uncertainty, are I think, easily met (see, further, Section V-below). But if the reader is willing to conclude that it is the idea of subjective probability that is at fault, he does not need my present defense of traditional epistemology.

- 5 This term is a reference to the so-called “Dutch book theorem.” The usual or synchronic Dutch book argument establishes the obedience of degrees of belief to the probability calculus as a criterion of rationality (“coherence”) for one’s state of opinion at a single time. The betting scheme I am about to describe is part of David Lewis’s diachronic Dutch book argument to justify conditionalization as the correct rule for transforming prior into posterior degrees of belief [see P. Teller, “Conditionalization, Observation, and Change of Preference” in W. L. Harper and C. A. Hooker, *Foundations of Probability Theory*, vol. (Boston: Reidel, 1976)]. Bayes himself had given a similar argument, and a more sophisticated theorem has been proved by Glen Shafer; see his “Bayes’ Two Arguments for Conditioning,” *Annals of Statistics*, x (1982): 1075–1089, and “A Subjective Approach to Conditional Probability,” *Journal of Philosophical Logic*, XII, 3 (November 1983): 453–466.
- 6 To see what the total cost is of I and II together, calculate
- $$P(\sim H \& E) + xP(\sim E) = P(\sim H | E)P(E) + xP(\sim E) \\ = x(P(E)) + P(\sim E) = x$$
- 7 E implies that my probability for H tomorrow morning will be $1/3$, and so my probability for $\sim H$ then is $2/3$. We have $x = 0.3/0.4 = 3/4$ and $y = x - 2/3 = 1/12$. The costs of the bets are 0.3 for (I), $x(1 - P(E)) = (3/4)(0.6) = 0.45$ for bet (II), and $yP(E) = (1/12)(0.4) = (1/30)$ for (III), for a total cost of $(3/4) + (1/30)$.
- 8 From footnote 7 we know that the initial total cost was $(3/4) + (1/30)$. If E is false, I collect only $x = (3/4)$. If E is true, I collect $1/12$ on the third bet, but then I receive in addition only what I then consider a fair price for the bet against Table Hands’ winning, namely $2/3$; so my total return equals $3/4$ again.
- 9 When conditionalized on A , the function P becomes the function P' such that $P'(X) = P(X|A) = P(X \& A) / P(A)$ for all propositions X . This can be done only if $P(A)$ is not zero.
- 10 A third possibility was advocated in discussion by David Lewis: that the standard of rationality exemplified by Dutch-book Invulnerability applies to a certain sort of ideally rational agent, who not only believes himself to be, but is, infallible with respect to perception, and which we explicitly realize ourselves not to be. But this leaves us still with the task of constructing an epistemological theory that does apply to our own case.
- 11 “Higher Order Degrees of Belief” in D. H. Mellor, ed. *Prospects for Pragmatism: Essays in Honour of F. P. Ramsey* (New York: Cambridge, 1980), pp. 109–137, and Appendix 2 of his *Causal Necessity* (New Haven, Conn.: Yale, 1980).
- 12 In Skyrms’s article the synchronic form ($x = 0$) is advocated; the discussion contains diachronic examples as well, but they concern the supposition that the agent *learns* his posterior credence, whereupon the synchronic form applies.
- 13 See my “Calibration: A Frequentist Justification of Personal Probability,” in L. Laudan and R. Cohen, eds., *Philosophy, Physics, Psychoanalysis* (Boston: Reidel, 1983). Please note well that calibration by itself is not a good scoring rule, and the criterion explained below does not entail that better calibration is always better *tout court*.
- 14 It would not help to say that $P(A|B)$ is the probability that A would have for me if B were to become my total new evidence, just because that would tell us nothing about what $P(A|B)$ is when B is not the sort of proposition that could be one’s total new evidence. Instead I interpret conditional probability in a way that has no logical connection with learning. To say that $P(A) = 2/3$ is to say that, to me, A is twice as likely to be the case as not – this re-expresses the opinion in terms of personal odds for A as against $\sim A$. Similarly, $P(A|B) = 2/3$ expresses my personal odds for $(A \& B)$ as against $(\sim A \& B)$.
- 15 See my “A Temporal Framework for Conditionals and Chance,” *Philosophical Review*, LXXXIX, 1 (January 1980), 91–108, and reprinted in W. L. Harper, *Ifs* (Boston: Reidel, 1981); and David Lewis, “A Subjectivist’s Guide to Objective Chance,” *ibid.*, pp. 267–298.
- 16 See Richard Jeffrey’s review of articles by David Miller et al., *Journal of Symbolic Logic*, xxxv, 1 (March 1970): 124–127.
- 17 If we generalize (Miller) to $P_t(A | \text{ch}_{t+x}(A) = r) = r$, then we can derive the stronger result that if the truth value of A becomes settled at time $t + x$ [this truth value then equals $\text{ch}_{t+x}(A)$, and must be 0 or 1], the agent cannot at t believe with certainty that the present chance of A is something different from 0 or 1 if he also believes that A will be true (respectively false) at its settling time (“there are no crystal balls”).
- 18 This is not meant as an argument against conditionalization as a rational procedure; more sophisticated machinery than single one-place probability functions can be explored. This problem of how to represent certainty without dogmatism, which I shall not go into further here, is broached in Isaac Levi, *The Enterprise of Knowledge* (Cambridge, Mass.: MIT Press, 1980). It is not a problem if full certainty is not rational.
- 19 This emphasis on vagueness, and this sort of way to represent it, is especially to be found in Isaac Levi’s and Richard Jeffrey’s writings. For more technical details see also my “Rational Belief and Probability Kinematics,” *Philosophy of Science*, XLVII, 2 (June 1980): 165–187.

20 It is never easy to gauge one's agreement with other writers, but I think that in this I side with de Finetti – see p. 189 of his *Probability, Induction and Statistics* (New York: Wiley, 1972) – against Ramsey – see “Truth and Probability” in his *Foundations of Mathematics and Other Essays* (New York: Humanities Press, 1950). I would also like to refer to Stuart Hampshire's discus-

sions of the connections between intention and knowledge or belief, in his *Freedom of the Individual* (Princeton, N.J.: University Press, 1975). Let me emphasize, however, with reference to the examples used here, that I regard acceptance of scientific theories as involving both more and less than belief; see my *The Scientific Image* (New York: Oxford, 1980), pp. 12/3, 80–83, 198–200.

Chapter 3: Internal and External Reasons

BERNARD WILLIAMS

Sentences of the forms 'A has a reason to ϕ ' or 'There is a reason for A to ϕ ' (where ' ϕ ' stands in for some verb of action) seem on the face of it to have two different sorts of interpretation. On the first, the truth of the sentence implies, very roughly, that A has some motive which will be served or furthered by his ϕ -ing, and if this turns out not to be so the sentence is false: there is a condition relating to the agent's aims, and if this is not satisfied it is not true to say, on this interpretation, that he has a reason to ϕ . On the second interpretation, there is no such condition, and the reason-sentence will not be falsified by the absence of an appropriate motive. I shall call the first the 'internal', the second the 'external', interpretation. (Given two such interpretations, and the two forms of sentence quoted, it is reasonable to suppose that the first sentence more naturally collects the internal interpretation, and the second the external, but it would be wrong to suggest that either form of words admits only one of the interpretations.)

I shall also for convenience refer sometimes to 'internal reasons' and 'external reasons', as I do in the title, but this is to be taken only as a convenience. It is a matter for investigation whether there are two sorts of reasons for action, as opposed to two sorts of statements about people's reasons for action. Indeed, as we shall eventually see, even the interpretation in one of the cases is problematical.

I shall consider first the internal interpretation, and how far it can be taken. I shall then consider, more sceptically, what might be involved in an external interpretation. I shall end with some very brief remarks connecting all this with the issue of public goods and free-riders.

The simplest model for the internal interpretation would be this: A has a reason to ϕ iff A has some desire the satisfaction of which will be served by his ϕ -ing. Alternatively, we might say... some desire, the satisfaction of which A believes will be served by his ϕ -ing; this difference will concern us later. Such a model is sometimes ascribed to Hume, but since in fact Hume's own views are more complex than this, we might call it *the sub-Humean model*. The sub-Humean model is certainly too simple. My aim will be, by addition and revision, to work it up into something more adequate. In the course of trying to do this, I shall assemble four propositions which seem to me to be true of internal reason statements.

Basically, and by definition, any model for the internal interpretation must display a relativity of the reason statement to the agent's *subjective motivational set*, which I shall call the agent's S. The contents of S we shall come to, but we can say:

- (i) An internal reason statement is falsified by the absence of some appropriate element from S.

The simplest sub-Humean model claims that any element in S gives rise to an internal reason. But there are grounds for denying this, not because of regrettable, imprudent, or deviant elements in S – they raise different sorts of issues – but because of elements in S based on false belief.

The agent believes that this stuff is gin, when it is in fact petrol. He wants a gin and tonic. Has he reason, or a reason, to mix this stuff with tonic and drink it? There are two ways here (as suggested already by the two alternatives for

formulating the sub-Humean model). On the one hand, it is just very odd to say that he has a reason to drink this stuff, and natural to say that he has no reason to drink it, although he thinks that he has. On the other hand, if he does drink it, we not only have an explanation of his doing so (a reason why he did it), but we have such an explanation which is of the reason-for-action form. This explanatory dimension is very important, and we shall come back to it more than once. If there are reasons for action, it must be that people sometimes act for those reasons, and if they do, their reasons must figure in some correct explanation of their action (it does not follow that they must figure in all correct explanations of their action). The difference between false and true beliefs on the agent's part cannot alter the *form* of the explanation which will be appropriate to his action. This consideration might move us to ignore the intuition which we noticed before, and lead us just to legislate that in the case of the agent who wants gin, he has a reason to drink this stuff which is petrol.

I do not think, however, that we should do this. It looks in the wrong direction, by implying in effect that the internal reason conception is concerned only with explanation, and not at all with the agent's rationality, and this may help to motivate a search for other sorts of reason which are connected with his rationality. But the internal reasons conception is concerned with the agent's rationality. What we can correctly ascribe to him in a third-personal internal reason statement is also what he can ascribe to himself as a result of deliberation, as we shall see. So I think that we should rather say:

- (ii) A member of S, D , will not give A a reason for ϕ -ing if either the existence of D is dependent on false belief, or A 's belief in the relevance of ϕ -ing to the satisfaction of D is false.

(This double formulation can be illustrated from the gin/petrol case: D can be taken in the first way as the desire to drink what is in this bottle, and in the second way as the desire to drink gin.) It will, all the same, be true that if he does ϕ in these circumstances, there was not only a reason why he ϕ -ed, but also that that displays him as, relative to his false belief, acting rationally.

We can note the epistemic consequence:

- (iii) a. A may falsely believe an internal reason statement about himself, and (we can add)

- b. A may not know some true internal reason statement about himself.

(b) comes from two different sources. One is that A may be ignorant of some fact such that if he did know it he would, in virtue of some element in S , be disposed to ϕ : we can say that he has a reason to ϕ , though he does not know it. For it to be the case that he actually has such a reason, however, it seems that the relevance of the unknown fact to his actions has to be fairly close and immediate; otherwise one merely says that A would have a reason to ϕ if he knew the fact. I shall not pursue the question of the conditions for saying the one thing or the other, but it must be closely connected with the question of when the ignorance forms part of the explanation of what A actually does.

The second source of (iii) is that A may be ignorant of some element in S . But we should notice that an unknown element in S, D , will provide a reason for A to ϕ only if ϕ -ing is rationally related to D ; that is to say, roughly, a project to ϕ could be the answer to a deliberative question formed in part by D . If D is unknown to A because it is in the unconscious, it may well not satisfy this condition, although of course it may provide the reason why he ϕ 's, that is, may explain or help to explain his ϕ -ing. In such cases, the ϕ -ing may be related to D only symbolically.

I have already said that

- (iv) internal reason statements can be discovered in deliberative reasoning.

It is worth remarking the point, already implicit, that an internal reason statement does not apply only to that action which is the uniquely preferred result of the deliberation. ' A has reason to ϕ ' does not mean 'the action which A has overall, all-in, reason to do is ϕ -ing'. He can have reason to do a lot of things which he has other and stronger reasons not to do.

The sub-Humean model supposes that ϕ -ing has to be related to some element in S as causal means to end (unless, perhaps, it is straightforwardly the carrying out of a desire which is itself that element in S). But this is only one case: indeed, the mere discovery that some course of action is the causal means to an end is not in itself a piece of practical reasoning.¹ A clear example of practical reasoning is that leading to the conclusion that one has reason to ϕ because ϕ -ing would be the most convenient, economical, pleasant, and so on way of satisfying some element in S , and this of course is controlled by other elements in S , if not necessarily in a

very clear or determinate way. But there are much wider possibilities for deliberation, such as: thinking how the satisfaction of elements in *S* can be combined, e.g. by time-ordering; where there is some irresolvable conflict among the elements of *S*, considering which one attaches most weight to (which, importantly, does not imply that there is some one commodity of which they provide varying amounts); or, again, finding constitutive solutions, such as deciding what would make for an entertaining evening, granted that one wants entertainment.

As a result of such processes an agent can come to see that he has reason to do something which he did not see he had reason to do at all. In this way, the deliberative process can add new actions for which there are internal reasons, just as it can also add new internal reasons for given actions. The deliberative process can also subtract elements from *S*. Reflection may lead the agent to see that some belief is false, and hence to realise that he has in fact no reason to do something he thought he had reason to do. More subtly, he may think he has reason to promote some development because he has not exercised his imagination enough about what it would be like if it came about. In his unaided deliberative reason, or encouraged by the persuasions of others, he may come to have some more concrete sense of what would be involved, and lose his desire for it, just as, positively, the imagination can create new possibilities and new desires. (These are important possibilities for politics as well as for individual action.)

We should not, then, think of *S* as statically given. The processes of deliberation can have all sorts of effect on *S*, and this is a fact which a theory of internal reasons should be very happy to accommodate. So also it should be more liberal than some theorists have been about the possible elements in *S*. I have discussed *S* primarily in terms of desires, and this term can be used, formally, for all elements in *S*. But this terminology may make one forget that *S* can contain such things as dispositions of evaluation, patterns of emotional reaction, personal loyalties, and various projects, as they may be abstractly called, embodying commitments of the agent. Above all, there is of course no supposition that the desires or projects of an agent have to be egoistic; he will, one hopes, have non-egoistic projects of various kinds, and these equally can provide internal reasons for action.

There is a further question, however, about the contents of *S*: whether it should be taken, consistently with the general idea of internal rea-

sons, as containing *needs*. It is certainly quite natural to say that *A* has a reason to pursue *X*, just on the ground that he needs *X*, but will this naturally follow in a theory of internal reasons? There is a special problem about this only if it is possible for the agent to be unmotivated to pursue what he needs; I shall not try to discuss here the nature of needs, but I take it that insofar as there are determinately recognisable needs, there can be an agent who lacks any interest in getting what he indeed needs. I take it, further, that that lack of interest can remain after deliberation, and, also that it would be wrong to say that such a lack of interest must always rest on false belief. (Insofar as it does rest on false belief, then we can accommodate it under (ii), in the way already discussed.)

If an agent really is uninterested in pursuing what he needs; and this is not the product of false belief; and he could not reach any such motive from motives he has by the kind of deliberative processes we have discussed; then I think we do have to say that in the internal sense he indeed has no reason to pursue these things. In saying this, however, we have to bear in mind how strong these assumptions are, and how seldom we are likely to think that we know them to be true. When we say that a person has reason to take medicine which he needs, although he consistently and persuasively denies any interest in preserving his health, we may well still be speaking in the internal sense, with the thought that really at some level he *must* want to be well.

However, if we become clear that we have no such thought, and persist in saying that the person has this reason, then we must be speaking in another sense, and this is the external sense. People do say things that ask to be taken in the external interpretation. In James' story of Owen Wingrave, from which Britten made an opera, Owen's family urge on him the necessity and importance of his joining the army, since all his male ancestors were soldiers, and family pride requires him to do the same. Owen Wingrave has no motivation to join the army at all, and all his desires lead in another direction: he hates everything about military life and what it means. His family might have expressed themselves by saying that *there was a reason for Owen to join the army*. Knowing that there was nothing in Owen's *S* which would lead, through deliberative reasoning, to his doing this would not make them withdraw the claim or admit that they made it under a misapprehension. They mean it in an external sense. What is that sense?

A preliminary point is that this is not the same question as that of the status of a supposed categorical imperative, in the Kantian sense of an 'ought' which applies to an agent independently of what the agent happens to want: or rather, it is not undoubtedly the same question. First, a categorical imperative has often been taken, as by Kant, to be necessarily an imperative of morality, but external reason statements do not necessarily relate to morality. Second, it remains an obscure issue what the relation is between 'there is a reason for *A* to . . .' and '*A* ought to . . .' Some philosophers take them to be equivalent, and under that view the question of external reasons of course comes much closer to the question of a categorical imperative. However, I shall not make any assumption about such an equivalence, and shall not further discuss 'ought'.²

In considering what an external reason statement might mean, we have to remember again the dimension of possible explanation, a consideration which applies to any reason for action. If something can be a reason for action, then it could be someone's reason for acting on a particular occasion, and it would then figure in an explanation of that action. Now no external reason statement could *by itself* offer an explanation of anyone's action. Even if it were true (whatever that might turn out to mean) that there was a reason for Owen to join the army, that fact by itself would never explain anything that Owen did, not even his joining the army. For if it was true at all, it was true when Owen was not motivated to join the army. The whole point of external reason statements is that they can be true independently of the agent's motivations. But nothing can explain an agent's (intentional) actions except something that motivates him so to act. So something else is needed besides the truth of the external reason statement to explain action, some psychological link; and that psychological link would seem to be belief. *A*'s believing an external reason statement about himself may help to explain his action.

External reason statements have been introduced merely in the general form 'there is a reason for *A* to . . .', but we now need to go beyond that form, to specific statements of reasons. No doubt there are some cases of an agent's ϕ -ing because he believes that there is a reason for him to ϕ , while he does not have any belief about what that reason is. They would be cases of his relying on some authority whom he trusts, or, again, of his recalling that he did know of some reason for his ϕ -ing, but his not being able to remember what it was. In these respects, reasons

for action are like reasons for belief. But, as with reasons for belief, they are evidently secondary cases. The basic case must be that in which *A* ϕ 's, not because he believes only that there is some reason or other for him to ϕ , but because he believes of some determinate consideration that it constitutes a reason for him to ϕ . Thus, Owen Wingrave might come to join the army because (now) he believes that it is a reason for him to do so that his family has a tradition of military honour.

Does believing that a particular consideration is a reason to act in a particular way provide, or indeed constitute, a motivation to act? If it does not, then we are no further on. Let us grant that it does – this claim indeed seems plausible, so long at least as the connexion between such beliefs and the disposition to act is not tightened to that unnecessary degree which excludes *akrasia*. The claim is in fact *so* plausible, that this agent, with this belief, appears to be one about whom, now, an *internal* reason statement could truly be made: he is one with an appropriate motivation in his *S*. A man who does believe that considerations of family honour constitute reasons for action is a man with a certain disposition to action, and also dispositions of approval, sentiment, emotional reaction, and so forth.

Now it does not follow from this that there is nothing in external reason statements. What does follow is that their content is not going to be revealed by considering merely the state of one who believes such a statement, nor how that state explains action, for that state is merely the state with regard to which an internal reason statement could truly be made. Rather, the content of the external type of statement will have to be revealed by considering what it is to *come to believe* such a statement – it is there, if at all, that their peculiarity will have to emerge.

We will take the case (we have implicitly been doing so already) in which an external reason statement is made about someone who, like Owen Wingrave, is not already motivated in the required way, and so is someone about whom an internal statement could not also be truly made. (Since the difference between external and internal statements turns on the implications accepted by the speaker, external statements can of course be made about agents who are already motivated; but that is not the interesting case.) The agent does not presently believe the external statement. If he comes to believe it, he will be motivated to act; so coming to believe it must, essentially, involve acquiring a new motivation. How can that be?

This is closely related to an old question, of how 'reason can give rise to a motivation', a question which has famously received from Hume a negative answer. But in that form, the question is itself unclear, and is unclearly related to the argument – for of course reason, that is to say, rational processes, can give rise to new motivations, as we have seen in the account of deliberation. Moreover, the traditional way of putting the issue also (I shall suggest) picks up an onus of proof about what is to count as a 'purely rational process' which not only should it not pick up, but which properly belongs with the critic who wants to oppose Hume's general conclusion and to make a lot out of external reason statements – someone I shall call 'the external reasons theorist'.

The basic point lies in recognising that the external reasons theorist must conceive *in a special way* the connexion between acquiring a motivation and coming to believe the reason statement. For of course there are various means by which the agent could come to have the motivation and also to believe the reason statement, but which are the wrong kind of means to interest the external reasons theorist. Owen might be so persuaded by his family's moving rhetoric that he acquired both the motivation and the belief. But this excludes an element which the external reasons theorist essentially wants, that the agent should acquire the motivation *because* he comes to believe the reason statement, and that he should do the latter, moreover, because, in some way, he is considering the matter aright. If the theorist is to hold on to these conditions, he will, I think, have to make the condition under which the agent appropriately comes to have the motivation something like this, that he should deliberate correctly; and the external reasons statement itself will have to be taken as roughly equivalent to, or at least as entailing, the claim that if the agent rationally deliberated, then, whatever motivations he originally had, he would come to be motivated to ϕ .

But if this is correct, there does indeed seem great force in Hume's basic point, and it is very plausible to suppose that all external reason statements are false. For, *ex hypothesi*, there is no motivation for the agent to deliberate *from*, to reach this new motivation. Given the agent's earlier existing motivations, and this new motivation, what has to hold for external reason statements to be true, on this line of interpretation, is that the new motivation could be in some way rationally arrived at, granted the earlier motiva-

tions. Yet at the same time it must not bear to the earlier motivations the kind of rational relation which we considered in the earlier discussion of deliberation – for in that case an internal reason statement would have been true in the first place. I see no reason to suppose that these conditions could possibly be met.

It might be said that the force of an external reason statement can be explained in the following way. Such a statement implies that a rational agent would be motivated to act appropriately, and it can carry this implication, because a rational agent is precisely one who has a general disposition in his *S* to do what (he believes) there is reason for him to do. So when he comes to believe that there is reason for him to ϕ , he is motivated to ϕ , even though, before, he neither had a motive to ϕ , nor any motive related to ϕ -ing in one of the ways considered in the account of deliberation.

But this reply merely puts off the problem. It reapplies the desire and belief model (roughly speaking) of explanation to the actions in question, but using a desire and a belief the content of which are in question. *What* is it that one comes to believe when he comes to believe that there is reason for him to ϕ , if it is not the proposition, or something that entails the proposition, that if he deliberated rationally, he would be motivated to act appropriately? We were asking how any true proposition could have that content; it cannot help, in answering that, to appeal to a supposed desire which is activated by a belief which has that very content.

These arguments about what it is to accept an external reason statement involve some idea of what is possible under the account of deliberation already given, and what is excluded by that account. But here it may be objected that the account of deliberation is very vague, and has for instance allowed the use of the imagination to extend or restrict the contents of the agent's *S*. But if that is so, then it is unclear what the limits are to what an agent might arrive at by rational deliberation from his existing *S*.

It is unclear, and I regard it as a basically desirable feature of a theory of practical reasoning that it should preserve and account for that unclarity. There is an essential indeterminacy in what can be counted a rational deliberative process. Practical reasoning is a heuristic process, and an imaginative one, and there are no fixed boundaries on the continuum from rational thought to inspiration and conversion. To someone who thinks that reasons for action

are basically to be understood in terms of the internal reasons model, this is not a difficulty. There is indeed a vagueness about 'A has reason to ϕ ', in the internal sense, insofar as the deliberative processes which could lead from A's present S to his being motivated to ϕ may be more or less ambitiously conceived. But this is no embarrassment to those who take as basic the internal conception of reasons for action. It merely shows that there is a wider range of states, and a less determinate one, than one might have supposed, which can be counted as A's having a reason to ϕ .

It is the external reasons theorist who faces a problem at this point. There are of course many things that a speaker may say to one who is not disposed to ϕ when the speaker thinks that he should be, as that he is inconsiderate, or cruel, or selfish, or imprudent; or that things, and he, would be a lot nicer if he were so motivated. Any of these can be sensible things to say. But one who makes a great deal out of putting the criticism in the form of an external reason statement seems concerned to say that what is particularly wrong with the agent is that he is *irrational*. It is this theorist who particularly needs to make this charge precise: in particular, because he wants any rational agent, as such, to acknowledge the requirement to do the thing in question.

Owen Wingrave's family may not have expressed themselves in terms of 'reasons', but, as we imagined, they could have used the external reasons formulation. This fact itself provides some difficulty for the external reasons theorist. This theorist, who sees the truth of an external reason statement as potentially grounding a charge of irrationality against the agent who ignores it, might well want to say that if the Wingraves put their complaints against Owen in this form, they would very probably be claiming something which, in this particular case, was false. What the theorist would have a harder time showing would be that the words used by the Wingraves *meant* something different from what they mean when they are, as he supposes, truly uttered. But what they mean when uttered by the Wingraves is almost certainly *not* that rational deliberation would get Owen to be motivated to join the army – which is (very roughly) the meaning or implication we have found for them, if they are to bear the kind of weight such theorists wish to give them.

The sort of considerations offered here strongly suggest to me that external reason statements, when definitely isolated as such, are false,

or incoherent, or really something else misleadingly expressed. It is in fact harder to isolate them in people's speech than the introduction of them at the beginning of this chapter suggested. Those who use these words often seem, rather, to be entertaining an optimistic internal reason claim, but sometimes the statement is indeed offered as standing definitely outside the agent's S and what he might derive from it in rational deliberation, and then there is, I suggest, a great unclarity about what is meant. Sometimes it is little more than that things would be better if the agent so acted. But the formulation in terms of reasons does have an effect, particularly in its suggestion that the agent is being irrational, and this suggestion, once the basis of an internal reason claim has been clearly laid aside, is bluff. If this is so, the only real claims about reasons for action will be internal claims.

A problem which has been thought to lie very close to the present subject is that of public goods and free riders, which concerns the situation (very roughly) in which each person has egoistic reason to want a certain good provided, but at the same time each has egoistic reason not to take part in providing it. I shall not attempt any discussion of this problem, but it may be helpful, simply in order to make clear my own view of reasons for action and to bring out contrasts with some other views, if I end by setting out a list of questions which bear on the problem, together with the answers that would be given to them by one who thinks (to put it cursorily) that the only rationality of action is the rationality of internal reasons.

1. Can we define notions of rationality which are not purely egoistic?
Yes.
2. Can we define notions of rationality which are not purely means–end?
Yes.
3. Can we define a notion of rationality where the action rational for A is in no way relative to A's existing motivations?
No.
4. Can we show that a person who only has egoistic motivations is irrational in not pursuing non-egoistic ends?

Not necessarily, though we may be able to in special cases. (The trouble with the egoistic person is not characteristically irrationality.)

Let there be some good, G , and a set of persons, P , such that each member of P has egoistic reason to want G provided, but delivering G requires action C , which involves costs, by each of some proper subset of P ; and let A be a member of P : then

5. Has A egoistic reason to do C if he is reasonably sure either that too few members of P will do C for G to be provided, or that enough other members of P will do C , so that G will be provided?

No.

6. Are there any circumstances of this kind in which A can have egoistic reason to do C ?

Yes, in those cases in which reaching the critical number of those doing C is sensitive to his doing C , or he has reason to think this.

7. Are there any motivations which would make it rational for A to do C , even though not in the situation just referred to?

Yes, if he is not purely egoistic: many. For instance, there are expressive motivations – appropriate e.g. in the celebrated voting case.³ There are also motivations which derive from the sense of fairness. This can precisely transcend the dilemma of ‘either useless or unnecessary’, by the form of argument ‘somebody, but no reason to omit any particular body, so everybody’.

8. Is it irrational for an agent to have such motivations?

In any sense in which the question is intelligible, no.

9. Is it rational for society to bring people up with these sorts of motivations?

Insofar as the question is intelligible, yes. And certainly we have reason to encourage people to have these dispositions – e.g. in virtue of possessing them ourselves.

I confess that I cannot see any other major questions which, at this level of generality, bear on these issues. All these questions have clear answers which are entirely compatible with a conception of practical rationality in terms of internal reasons for action, and are also, it seems to me, entirely reasonable answers.

Notes

- 1 A point made by Aurel Kolnai: see his ‘Deliberation is of Ends’, in *Ethics, Value and Reality* (London and Indianapolis, 1978). See also David Wiggins, ‘Deliberation and Practical Reason’, *PAS*, LXXVI (1975–6); reprinted in part in *Practical Reasoning*, ed. J. Raz (Oxford, 1978).
- 2 It is discussed in chapter 9 of *Moral Luck*.
- 3 A well-known treatment is by M. Olson Jr. *The Logic of Collective Action* (Cambridge, Mass., 1965). On expressive motivations in this connexion, see S. I. Benn, ‘Rationality and Political Behaviour’, in S. I. Benn and G. W. Mortimore, eds., *Rationality and the Social Sciences* (London, 1976). On the point about fairness, which follows in the text, there is of course a very great deal more to be said: for instance, about how members of a group can, compatibly with fairness, converge on strategies more efficient than everyone’s doing C (such as people taking turns).

Chapter 4: Paradoxes

R. M. SAINSBURY

ACTING RATIONALLY

I. Newcomb's Paradox

You are confronted with a choice. There are two boxes before you, *A* and *B*. You may either open both boxes, or else just open *B*. You may keep what is inside any box you open, but you may not keep what is inside any box you do not open. The background is this.

A very powerful being, who has been invariably accurate in his predictions about your behavior in the past, has already acted in the following way:

He has put \$1,000 in box *A*.

If he has predicted that you will open just box *B*, he has in addition put \$1,000,000 in box *B*.

If he has predicted that you will open both boxes, he has put nothing in box *B*.

The paradox consists in the fact that there appears to be a decisive argument for the view that the most rational thing to do is to open both boxes; and also a decisive argument for the view that the most rational thing to do is to open just box *B*. The arguments commend incompatible courses of action: If you take both boxes, you cannot also take just box *B*. Putting the arguments together entails the overall conclusion that taking both boxes is the most rational thing and also not the most rational thing. This is unacceptable, yet the arguments from which it derives are apparently acceptable.

The argument for opening both boxes goes like this. The powerful being – let us call him

the Predictor – has already acted. Either he has put money in both boxes or he has put money in just box *A*. In the first case, by opening both boxes you will win \$1,001,000. In the second case, by opening both boxes you will at least win \$1,000, which is better than nothing. By contrast, if you were to open just box *B*, you would win just \$1,000,000 on the first assumption (i.e., that the Predictor has put money in both boxes) and nothing on the second assumption (i.e., that the Predictor has put money just in box *A*). In either case, you would be \$1,000 worse off than had you opened both boxes. So opening both boxes is the best thing to do.

The argument for opening just box *B* goes as follows. Since the Predictor has always been right in his previous predictions, you have every reason for thinking that he will be right in this one. So you have every reason to think that if you were to open both boxes, the Predictor would have predicted this and so would have left box *B* empty. So you have every reason to think that it would not be best to open both boxes. Likewise, you have every reason to think that if you choose to open just box *B*, the Predictor will have predicted this, and so will have put \$1,000,000 inside. Imagine a third party, who knows all the facts. He will bet heavily that if you open just box *B* you will win \$1,000,000. He will bet heavily that if you open both boxes you will get only \$1,000. You have to agree that his bets are rational. So it must be rational for you to open just box *B*.

This paradox has been used to compare two different principles for determining how it is rational to act. One principle is this: You should act so as to maximize the benefit you can expect

from your action. In stating this principle, “benefit” is usually replaced by the technical term “utility.” Part of the point of the technical term is to break any supposed connection between rationality and selfishness or lack of moral fiber. A benefit or “utility” consists in any situation that you want to obtain. If you are altruistic, you may desire someone else’s welfare, and then an improvement in his welfare will count as a utility to you. If you want to do what is morally right, an action will attract utility simply by being in conformity with what, in your eyes, morality requires, even if from other points of view, say the purely material one, the consequences of the action are not beneficial to you.

There is obviously something appealing in the principle that it is rational to act so as to *maximize expected utility* – MEU for short. Consider gambling: The bigger the prize in the lottery, the more money it is rational to pay for a ticket, everything else being equal; the larger the number of tickets, the less money it is rational to pay. The MEU principle tells you to weigh both these factors. If there are 100 tickets and there is just one prize of \$1,000, then you will think that you are doing well if you can buy a ticket for less than \$10. (For consider: If you could buy them *all* for less than \$10 each, then you could be certain of gaining \$1,000 for an expenditure of less than \$1,000.) If the tickets cost more than \$10, you may have to think of the lottery as a way of raising money for a charity that you wish to support, if you are to buy a ticket.

Such an example contains a number of quite unrealistic assumptions. Some of these are inessential, but at least one is essential if the MEU principle is to compare any possible pair of actions for their degree of rationality. This is the supposition that utilities and probabilities can be measured.^{1,2,3} If they can, then we can simply compute which of the actions open to us have greatest expected utility: We multiply the measure of utility by the measure of the probability of that utility accruing. Suppose that there are two lotteries, one as described above, with 1,000 tickets at \$1 and a single \$1,000 prize, and another with 99 tickets at \$10 and a single \$999 prize. The MEU principle tells you to prefer buying tickets in the second lottery rather than the first. For the first, the expected utility is the chance you think you have of winning, $\frac{1}{1000}$, multiplied by the utility of the win, which can be represented as 1,000; so the expected utility is 10. For the second, it is $\frac{1}{99} \times 999 = 10.09$ (approximately).

	<i>the Predictor has not put money in B</i>	<i>the Predictor has put money in B</i>
you open $A + B$	\$1,000	\$1,001,000
you open just B	\$ 0	\$1,000,000

Figure 1. Newcomb’s Paradox.

The MEU principle does not commend you to buy a ticket in either lottery. There may well be (and one would hope that there in fact were) many alternative ways of spending your money with expected utilities higher than those associated with either lottery. The principle only tells you that *if* you are going to buy a ticket for either, it should be for the second.⁴

The notion of utility was introduced in terms of what upshot an agent wants. What someone wants sometimes means what he or she wants all things considered. If I decide to go to the dentist, then typically I want to go – that is, want to go all things considered. However, what a person wants can also mean anything to which he attaches some positive value. In this sense, it is true of me, when I freely and willingly go to the dentist, that I want not to go: Not going has the positive value of sparing time and present discomfort. If I go, it is because this want is trumped by another: I want to avoid decay, and for the sake of that benefit I am prepared to put up with the loss of time and the discomfort. The appropriate connection between utility and wanting should exploit not what an agent wants overall, but rather that to which he attaches any positive value.

The situation that gives rise to Newcomb’s Paradox can be represented as shown in Figure 1. The expected utility of opening both boxes is calculated as follows. By the background of the problem, you regard it as very likely that the Predictor will have correctly predicted your choice. Hence if you open both boxes you must think that it is very likely that the Predictor will have predicted this and so will have put no money in box B . So the expected utility is some high ratio, call it h , measuring the likelihood of this outcome, multiplied by 1,000, measuring the utility. Analogously, the expected utility for you of opening just box B is the same high ratio, measuring the likelihood of the Predictor having correctly predicted that this is what you would do, and so having put \$1,000,000 in box B , multiplied by 1,000,000, measuring the utility of that outcome. Since, whatever exactly h may

be, $1,000 \times h$ is much less than $1,000,000 \times h$, MEU commends opening just box B .⁵

The MEU principle underwrites the argument for opening just box B . To resolve the paradox, however, one would need to show what was wrong with the other argument, the argument for opening both boxes. Those who are persuaded that it is rational to open both boxes will regard the fact that the MEU principle delivers the contrary recommendation as a refutation of the principle.

One attractive feature of MEU is that it is a quite general, and independently attractive, principle. Are there any other principles of rational action that are also attractive, yet that deliver a different recommendation? There are. One example is the so-called *dominance principle* – DP for short.

According to DP, it is rational to perform in action α if it satisfies the following two conditions:

- (a) Whatever else may happen, doing α will result in your being no worse off than doing any of the other things open to you.
- (b) There is at least one possible outcome in which your having done α makes you better off than you would have been had you done any of the other things open to you.

DP has commonsensical appeal. If you follow it you will act in such a way that nothing else you could do would have resulted in your faring better, except by running the risk of your faring worse.

Figure 1 shows that opening both boxes satisfies DP, and that opening only box B does not. Whatever the Predictor has done, you are better off opening both boxes than opening just one. In either case, you stand to gain an extra \$1,000 as compared with the other course of action open to you. Hence DP and MEU conflict: They commend opposite courses of action.

One way to diagnose Newcomb's Paradox is precisely as the manifestation of this conflict of principle. The constructive task is then to explain how the principles are to be restricted in such a way that they cease to conflict, while retaining whatever element of truth they contain.

How is the Predictor so good at predicting? Suppose it worked like this. Your choice would cause the Predictor to have made the correct prediction of it. To take this alleged possibility seriously, we have to take seriously the possibility of

"backward causation": that is, a later event (here your choice) causing an earlier one (here the Predictor's prediction). Let us for the moment take this in our stride. If one knew that this was how things worked, surely there could not be two views about what it would be rational to do. One should open just box B , for this would cause the Predictor to predict that this is what one would do, which would lead to his putting \$1,000,000 in box B . Not making this choice, by contrast, would lead to his not putting the \$1,000,000 in box B . Clearly it would be crazy not to choose to open just box B .

The original case was, perhaps, underdescribed. Perhaps it did allow for the possibility (if there is such a possibility) of backward causation. To prevent confusion, let us stipulate that the *original case* is one that excludes backward causation. It is instructive, however, to consider this *other case*, where there is supposed to be backward causation. Perhaps the attraction of opening just box B in the original case sprang from thinking of it as the backward causation case. More generally, perhaps the paradox strikes us as paradoxical only to the extent that we confuse the original case with the backward causation case. To the extent that we think of the case as involving backward causation, we are tempted by MEU. To the extent that we think of it as excluding backward causation we are tempted by DP. What strikes us as conflicting views of the same case are really views of different cases.

In the original case, one might suppose that the Predictor bases his decision on general laws, together with particular past facts. These might all be physical, or they might be psychological: For example, the laws might be laws of psychology, and the particular facts might concern your personality. There is no question of backward causation. Then the basis for the prediction consists in facts that lie in the past. Rejecting backward causation, this means that nothing you can now do can affect the basis for the prediction. Hence nothing you now do can make any difference to whether there is or is not money in box B . So you should open both boxes.

There is a complicating factor: Suppose that determinism is true. Suppose, in particular, that the psychological laws, together with data about your character up to the time at which the Predictor made his prediction, determine how you will now act, in the sense of making it impossible for you to do anything other than what, in fact, you will do. This may totally undermine the idea of rational decision, and so make the whole

question of what is best to do one that cannot arise. In short, there is a case for saying that if there were such a Predictor, then there could be no question about which choice is rational. I shall ignore this case, and argue that it is rational to open both boxes. Those who are moved by it could read my conclusion as hypothetical: If we can make sense of rationality at all in the Newcomb situation, then the rational thing is to open both boxes.⁶

In defending this conclusion, I need to consider whether, as claimed earlier, it is rational for the onlookers to bet heavily on the following two conditionals:

- (a) if you select both boxes, box *B* will be empty.
- (b) if you select just box *B*, it will contain \$1,000,000.

If they are rational, the onlookers will bet in accordance with their expectations. Their expectations are the same as yours. They have very strong reason to believe the two conditionals, given the Predictor's past successes. How can this be reconciled with my claim that if the Predictor bases his prediction on past evidence, then it is rational to open both boxes? If it is rational for the onlookers to expect the conditionals to be true, it must be rational for you to expect the same. However, it seems, you have a *choice* about which conditional will count. It is rational, surely, to make the second conditional count, and you can do this by opening just box *B*. How can one reconcile the rationality of belief in the conditionals with the rationality of opening both boxes?

Let us look more closely at the basis of the rationality of belief in the conditionals. We can do this by looking at it from the point of view of the onlookers. They reason as follows. The Predictor has always been right in the past. Since he has already filled the boxes, his prediction is based on knowing some past facts about you and your circumstances, and applying some generalizations. Our best evidence for what he has predicted is what you choose to do. This is why we believe the conditionals. Your opening just box *B* is evidence that the Predictor has predicted this and, hence, by the way the problem is set up, is evidence that he has filled box *B* with \$1,000,000. Likewise for the other possibility.

The rationality of these beliefs does not entail the rationality of opening just box *B*. This is most easily seen if we switch to the subject's point of view: to *your* point of view, as we are pretending.

The Predictor makes his choice on the basis of past facts about you, together with some generalizations. To simplify, let us say that there are two relevant possible facts about what sort of person you were at the time the Predictor made his prediction: Either you were a one-boxer – that is, a person disposed to open just box *B* – or you were a two-boxer – that is, a person disposed to open both boxes. Now if you find a tendency to open both boxes well up in you, that is bad news.⁷ It is evidence that you are now a two-boxer and, all other things being equal, is thereby evidence that you were a two-boxer at the time when the Predictor made his decision. Hence it is evidence that he will have predicted that you will open both boxes, and so it is evidence that there will be no money in the *B* box. However, there is no point in trying to extirpate this disposition, and it would be a confusion to think that you could make any difference to the situation by resisting it. There is no point trying to extirpate it *now*, since either the Predictor has made his prediction on the basis of perceiving such a disposition in you or he has not; and getting rid of it now, supposing it has been perceived, is closing the stable door after the horse has bolted. It would be a confusion to think that anything you can now do can make any difference as to whether or not you were a two-boxer at the time the Predictor made his prediction. If you found in yourself an inclination to open just box *B*, that would be good news, for analogous reasons; but it is an inclination that it would be more prudent to resist. By resisting it and opening both boxes, you cannot make the money that you can reasonably presume is already in the *B* box go away, and you will gain the extra \$1,000 in the *A* box.

Here is an objection. If this is where the reasoning were to end, would not a really good Predictor have predicted this, and therefore have ensured that there is nothing in box *B*? Furthermore, had you taken the reasoning through a further twist, using the fact just mentioned as a reason for in the end taking just box *B*, the Predictor would have predicted this too, and so would have filled box *B*. So is not this what you should do?

However, the original difficulty remains and cannot be overcome. No matter what twists and turns of reasoning you go in for now, you cannot affect what the Predictor has already done. Even if you could make yourself now into a one-boxer, it would not help. What mattered was whether you were a one-boxer, or a person likely to become a one-boxer, at the time when

the Predictor made his prediction. You cannot change the past.^{8,9}

We have said that the Predictor has *always* been right in the past.¹⁰ Let us imagine, in particular, that he has always been right about Newcomb problems. We shall suppose that each person is confronted with the problem only once in his life (there is no second chance), and that the Predictor has never been wrong: That is, never has a two-boxer found anything in box *B*, and never has a one-boxer found box *B* empty. Most of your friends have already had the chance. The one-boxers among them are now millionaires. You wish above all things that you were a millionaire like them, and now your chance has come: You are faced with the Newcomb problem. Is it not true that all you have to do is choose just box *B*? Is that not a sure-fire way to riches? So how could it be rational to refuse it?

So far, this raises no new considerations: The two-boxer's reply still stands. However, I have put the matter this way in order to add the following twist. Being of good two-box views, you think that the Predictor is, for some crazy reason, simply rewarding irrationality: He makes one-boxers rich, and one-boxers are irrational. Still, if you want to be rich above all things, then is not the *rational* thing to do to join the irrational people in opening just box *B*? Sir John Harington (1561–1612) wrote that

Treason doth never prosper; what's the reason?

Why, if it prosper, none dare call it treason.

Likewise, if "irrationality" pays, then it is not irrationality at all! You want to be rich like your millionaire friends, and if you think as they do you will be. It is rational to adapt means to ends, so it is rational to think the way they think.

This suggestion can be represented as involving two main points. The first is that one might reasonably want to be a different sort of person from the sort one is: here, a less rational sort. Some people committed to lucidity and truth as values find this suggestion unpalatable.¹¹ However, a second point is needed: that if it is reasonable to want to be a different sort of person, then it is reasonable, even as things are, to act as that other sort of person would have acted. The second point is what secures the passage from envying the one-boxers to the claim that it would be rational to follow their lead. Once clearly stated, this second point can be seen to be incorrect: Given that you are not a "natural" one-boxer, given that you are persuaded by the

argument for two-boxing, nothing can as things stand make it *rational* for you to one-box.¹²

A clear perception of the advantages of being a one-boxer cannot give you a *reason* for becoming one – even if that were in your power. An atheist might clearly perceive the comfort to be derived from theism, but this does not give him or her a *reason* for believing that God exists. The light of reason cannot direct one toward what one perceives as irrational. To adopt a position one regards as irrational one needs to rely on something other than reason: drugs, fasting, chanting, dancing, or whatever.

This way of dealing with the paradox takes no account of the two principles, MEU and DP. Is either to be accepted? MEU cannot be correct, since it commends taking just box *B*. DP cannot be correct since, in the other version of the paradox, in which backward causation was admitted, DP wrongly commended taking both boxes.^{13,14} However, we may be able to see why the principles let us down when they did, and this may lead to ways of suitably restricting them.

In the backward causation case, it is no accident that DP gives the wrong result. It has no means of taking into account the fact that your choice will affect what is in the boxes, by affecting the Predictor. More generally, it gives the wrong result because it makes no provision for the ways in which one's acting can affect the probabilities of outcomes. The backward causation case alone shows that DP cannot serve as it stands as a correct principle of rational action: It cannot be rational to act in such a way as to cause a diminution in the likelihood of someone else doing something that would increase one's benefits.

Equally, it is no accident that MEU gives the right result for the backward causation case. The rationale of MEU is given by the thought that it is rational to act in ways one takes to be likely to *promote* one's benefits. In the backward causation case, one has reason to believe that how one acts will affect one's benefits by affecting the Predictor's decision. In this case, the conditional probabilities reflect the probability of one's action genuinely promoting one rather than another outcome.

By contrast, in the original case, this does not hold. The conditional probabilities obtain, but in a way that fails to reflect the underlying rationale of the MEU. The probability that if you open both boxes, box *B* will be empty is indeed high; but it is not high because your opening both boxes will have any causal role in bringing it about that box *B* is empty. The right

restriction on MEU, so far as Newcomb's Paradox goes, is that one should act on the principle only when the conditional probabilities reflect what one believes one's actions will *produce*.¹⁵

We have seen that DP is not an acceptable principle of rational action, since it takes no account of conditional probabilities. This fact explains why it happens to give the right result in the original case. Here, because the probabilities are irrelevant, in that they do not reflect the likely effects of the possible actions, it is right to ignore them. So far as this case goes, the appropriate restriction on DP is that it can be used only when there is no relevant difference in the probability of the various possible outcomes.

Though these considerations explain away Newcomb's Paradox, they leave a great deal of work to be done within the wider task of understanding the nature of rational action. A first point to consider would be whether the modified versions of MEU and DP are *consistent*: whether, that is, they would deliver the same account for all cases of how it is rational to act.¹⁶ One would have to go on to ask whether they are *correct*: whether either delivers for all cases a correct account of how it is rational to act. It is unlikely that any such simple principles would be adequate to this task. Indeed, many philosophers are skeptical concerning many of the notions upon which this discussion has been based. It is not at all plausible to think that the values that are at issue in deciding what to do are measurable in the way that has been presupposed. It would be important to consider whether any substantive principles of rationality can be formulated that do not rest on this supposition. A wider issue is whether we have any right to a supposedly objective, culture-independent notion of rationality as a scale against which any action at all can be measured. Perhaps there are species of rationality, or perhaps rationality is simply one value among others. In the next section, I consider one alleged threat to the coherence of the notion of rationality.

2. The Prisoner's Dilemma

You and I have been arrested for drug running and placed in separate cells. Each of us learns, through his own attorney, that the district attorney has resolved as follows (and we have every reason to trust this information):

1. If we both remain silent, the district attorney will have to drop the drug-running charge for lack of evidence, and will

	<i>you confess</i>	<i>you don't confess</i>
I confess	<5,5>	<0,10>
I don't confess	<10,0>	<1,1>

Figure 2. The Prisoner's Dilemma.

- instead charge us with the much more minor offense of possessing dangerous weapons: We would then each get a year in jail.
2. If we both confess, we shall both get five years in jail.
3. If one remains silent and the other confesses, the one who confesses will get off scot-free (for turning State's evidence), and the other will go to jail for ten years.
4. The other prisoner is also being told all of (1)–(3).
How is it rational to act? We build into the story the following further features:
5. Each is concerned only with getting the smallest sentence for himself.
6. Neither has any information about the likely behavior of the other, except that (5) holds of him and that he is a rational agent.

There is an obvious line of reasoning in favor of confessing. It is simply that whatever you do, I shall do better to confess. For if you remain silent and I confess, I shall get what I most want, no sentence at all; whereas if you confess, then I shall do much better by confessing too (five years) than by remaining silent (ten years). We can represent the situation by Figure 2, and the reasoning in favor of confessing is the familiar dominance principle (DP).

In the figure <0,10> represents the fact that on this option I go to prison for zero years, and you go for ten years; and so on. The smaller the number on my (left) side of the pair, the better I am pleased. It is easy to see that confessing dominates silence: Confessing, as compared to silence, saves me five needless years if you confess, and one if you do not.

Since you and I are in relevantly similar positions, and [by (6)] we are both rational, presumably we shall reason in the same way, and thus perform the same action. So if it is rational for me to confess, it is rational for you to do likewise; but then we shall each go to prison for five years. If we both remain silent, we would go to prison for

only one year each. By acting supposedly rationally, we shall, it seems, secure for ourselves an outcome that is worse for both of us than what we could achieve.

On this view, rational action in some circumstances leads to worse outcomes than other courses of action. Even if this is depressing, it is not as it stands paradoxical: We all know that irrational gambles can succeed. What is arguably paradoxical is that the case is one in which the failure of rationality to produce the best results is not a matter of some chance intervention, but is a predictable and inevitable consequence of so-called rational reasoning. How, in that case, can it be rational to be "rational"?¹⁷ The allegedly unacceptable consequence of the apparently acceptable reasoning is that rational action can be seen in advance to make a worse outcome highly likely.

If this is a paradox, then the correct response, I believe, is to deny that the consequence is really unacceptable. The unacceptability is supposed to consist in the fact that if we were both to act in a certain way, we would be better off than if each were to follow the supposed dictates of rationality. Hence rationality is not the *best* guide to how to act, in that acting in the other way would lead to a better outcome for both. The trouble with this suggestion is that any guide to action has to be available to the agent's decision-making processes. To be guided by the thought that we would both be better off if both remained silent than if both confessed, I would need to know that you would remain silent. What it is rational to do must be relative to what we know. If we are ignorant, then of course acting rationally may not lead us to the best upshot. Here, the ignorance of each concerns what the other will do; and this, rather than some defect in rationality, is what yields the less than optimal upshot.

However, we are now close to a paradox of a different sort. I have said that there is a compelling argument for the rationality of confessing. However, it appears that there is also a strong case for the rationality of remaining silent. If this case is good, then two apparently acceptable arguments lead to conclusions that, taken together, are unacceptable.

The argument for silence goes like this. We both know we are rational agents, because that is built into the story. We therefore know that any reason one of us has for acting will apply to the other. Hence we know that we shall do the same thing. There are two courses of action that count as doing the same thing: both con-

fessing or both remaining silent. Of these, the latter is preferable for both of us. So of the available courses of action, it is obvious which each of us must rationally prefer: remaining silent. This, then, is the rational choice.

This argument invites a revenge. Suppose silence is the rational choice, and that I know it is. Then, in knowing that you are rational, I know that it is the choice you will make. So I know that you will remain silent. However, in that case it must be rational for me to confess, thus securing my preferred outcome: getting off scot-free. On the other hand, I know that you can reason like this too; therefore you, if rational, will not keep silent. In that case it is again – but more urgently – rational for me to confess. The way of silence is unstable. Thus the hypothesis that keeping silent is the rational choice is refuted.

This shows that the Prisoner's Dilemma does not really entail an unacceptable conclusion concerning rationality. We should not, however, be content with simply showing this: We should see how the case connects with the principles of rational action already discussed.

The MEU principle, as stated in Section 1, claimed that the rational act was whatever maximized expected utility, where this was to be understood in terms of two factors; the desirability of a certain outcome and its probability, conditional upon the performance of a given act. In connection with Newcomb's Paradox, I originally said that the relevant probabilities were

- (a) the probability of there being \$1,000,000 in box *B*, given that I choose to open both boxes, and
- (b) the probability of there being \$1,000,000 in box *B*, given that I choose to open just box *B*.

In the discussion, I claimed that these are not the right probabilities to consider in those cases in which these conditional probabilities do not reflect the tendency of my action to *produce* the outcome in question. So what are the right probabilities to consider? One suggestion is that they are

- (a') the probability of my bringing it about that there will be \$1,000,000 in box *B* by choosing both boxes, and
- (b') the probability of my bringing it about that there will be \$1,000,000 in box *B* by choosing one box.

Both of these probabilities are 0. If we stipulate that anything known to be true anyway (having a probability of 1, regardless of my action) is something that *anything* I do counts as bringing about, then opening box *A* has an expected utility equal to the utility of \$1,000, and opening only box *B* has an expected utility of 0. The version of MEU that considers the probabilities (a') and (b'), rather than (a) and (b), supports two-boxing.

Let us apply the contrast between these two versions of MEU to the Prisoner's Dilemma, starting with the original version. The probability of you confessing, given that I confess, is high and equal to the probability of you remaining silent, given that I remain silent. Moreover, the probability of you confessing, given that I remain silent, is low, and so is the probability of the converse. These conditional probabilities follow from my knowledge, built in to the example, that you and I will reason in similar ways, since we are both rational.¹⁸ With suitable utilities, there will be versions of the dilemma in which MEU, in its original form, designates silence as the rational course of action.¹⁹

In its modified form, MEU was to take into account the probability of an action *producing* the relevant outcome. Since that probability is by stipulation 0 in the present case, because each of us makes his decision before knowing what the other has decided, the modified MEU does not give us any guidance: All the expected utilities, understood in this way, are the same. However, this fact would be a telling reason for applying DP: If you have no idea what outcomes your actions will bring about, choose that action that will make things better for you whatever the other person does.

It has been suggested that Newcomb's Paradox is simply a version of the Prisoner's Dilemma. In Newcomb's Paradox, the crucial matter – whether or not there is anything in box *B* – is one of match: The money is in the box if and only if my action matches the “prediction.” It does not matter whether the “prediction” occurs before or after the act of choice; what matters is that the act of choice should have no effect on the content of the prediction. Likewise, match is of the essence in the Prisoner's Dilemma: Knowing that we are both rational, I expect my action to match yours, just as I expect the prediction to match my choice. Moreover, just as I cannot affect the prediction, so I cannot affect your choice. Figure 3 sets out the similarities.

In a nutshell, the two arguments we have considered are these:

	šent one b	conšs two b
X conšs two b	1	3
Y šent one b	2	4

Figure 3. Similarities between Newcomb's Paradox and the Prisoner's Dilemma. I have to choose whether to do *X* (confess, take both boxes) or *Y* (remain silent, take just one box). The column indicates what the other character in the story may do: The other prisoner remains silent or confesses; the Predictor predicts that I shall one-box or else that I shall two-box. My preferences among the outcomes, from best to worst, are in this order: 1,2,3,4. The “matching possibilities” are shaded: The other prisoner does what I do, the Predictor predicts correctly. I know that my choice cannot affect whether or not a match will occur. I know that a match is much more likely than a mismatch.

- A. Do *X*, since you are better off, whatever the other does, than you would be if you were to do *Y*: 1 is better than 2, and 3 is better than 4.
- B. Do *Y*, since match is the most likely kind of outcome, and of these 2 is better than 3.

If this analogy is correct, then one has *consistent* views on the problems only if one is either a two-boxer and a believer in confessing, or else a one-boxer and a believer in silence. My view is the first.

The Prisoner's Dilemma is a simplified version of a well-known conflict: If our cooperating means each of us forgoing something that he (or she) would otherwise have preferred, then cooperation appears not to be in my best interests. What serves my purposes best is to secure cooperation from you, while not being cooperative in return. In the Prisoner's Dilemma, what would be best for me is that you remain silent, perhaps under the influence of persuasion, threats, or promises from me, while I, perhaps renegeing on undertakings to you, confess. If the first view is correct, and *X*-ing is the rational thing to do, then if we both pursue our interests rationally, we shall end up serving these interests less well than we might. This is not really unacceptable, for it is true; but it may seem depressing.

In the case we have considered, there is just a single situation requiring a decision. Suppose instead that we are confronted with a “multiple Prisoner’s Dilemma”: Suppose that there are a series of choices, and that we each know this – in particular, we each know that this is not the last time we shall be playing the game with each other – and that we also know that the other will remember, and no doubt be guided by, what has happened on previous occasions. There is an argument to the effect that this new situation would push me in the direction of silence. Suppose you get the idea that I am the sort of person who generally confesses. Then I know that this will make you confess too, to protect yourself from the disastrous consequences of silence, and the overall result will be less than the best for me, time after time. So I have an interest in getting you to believe that I am the sort of person who generally remains silent. One way I can propagate this view is by in fact remaining silent. (We all know, from our knowledge of used car salesmen and politicians, that this is not the only way to try to achieve this kind of effect.) I also know that you will follow the same policy. So in this situation the cooperative policy of silence would appear to be the rational one.²⁰

There is fascinating evidence that this is not far from the truth. In some computer simulations of Prisoner’s Dilemma situations, the following strategy did better than any other: Start by remaining silent; thereafter do what the other player did during the previous round. In suitable circumstances, this will lead to a situation of stable cooperation. Since the multiple Prisoner’s Dilemma corresponds more closely to more of real life than the single case, it may be that the upshot of the discussion ought not to be so depressing: Perhaps rational self-interest is not doomed to lead to a nonoptimal outcome. However, the main point that I have been concerned to establish is that the paradoxical appearance of the Prisoner’s Dilemma, like that of Newcomb’s Paradox, can be resolved.

BELIEVING RATIONALLY

This part of this chapter concerns problems about what it is to have knowledge or rational belief. It is in two main sections: The first, called “Paradoxes of Confirmation,” is about two paradoxes that might be called “philosophers’ paradoxes.” Let me explain.

Most of the paradoxes in this book are quite straightforward to state. Seeing what is paradoxical about them does not require any special knowledge – you do not have to be a games theorist or a statistician to see what is paradoxical about Newcomb’s Paradox or the Prisoner’s Dilemma, nor do you have to be a physicist or sportsman to see what is paradoxical about Zenon’s paradoxes. By contrast, the paradoxes of confirmation arise, and can only be understood, in the context of a specifically philosophical project. Therefore these paradoxes need some background (Section 1.1) before being introduced (in Section 1.2 and 1.3). The background section sets out the nature of the project within which the paradoxes arise.

The second main section of the chapter concerns the paradox of the Unexpected Examination. Although it is hard to resolve, it is easy enough to state. This paradox has been used to cast doubt on intuitively natural principles about rational belief and knowledge.

1. Paradoxes of Confirmation

1.1. Background

We all believe that there is a firm distinction between strong, good, or reliable evidence on the one hand, and weak, bad, or unreliable evidence on the other. If a stranger at the race-track tells you that Wolf-face will win the next race, and you have no other relevant information, you would be a fool to bet heavily on Wolf-face. The evidence that he will win is extremely thin. However, had the trainer given you the same tip, that would have provided you with much stronger evidence. It would be stronger still if you knew that the trainer was a crook who believed that you were on to him, and if you also knew that he thought a good tip would buy you off.

Most of our actions are guided by scarcely conscious assessments of how good our evidence is for certain of our beliefs. When we choose what film to see or what restaurant to patronize we are often guided by past experience: by whether the director or actors have good track records, or whether the restaurant has produced good food in the past. We are also guided by what other people say: We weigh their testimony, trusting some – good reviewers, or people we know to be good judges of food – more than others. In such everyday cases, our assessment of the quality of the evidence is pretty rough and ready: We recognize good judges and bad judges,

good signs and bad signs; but we never normally ask ourselves what *constitutes* a good judge or a good sign.

The philosophical project within which the paradoxes of Section 1 arise is to state general principles determining what counts as good evidence. Such principles sometimes surface outside philosophy departments. In law courts, for example, explicit categorizations of the evidence ("circumstantial," "inadmissible") are used to grade it; and in scientific investigations, in particular those involving certain kinds of numerically structured data, there are elaborate and sophisticated statistical theories bearing on the question of the extent to which data support a hypothesis.

The branch of philosophy in which philosophers have tried to articulate general principles determining the quality of evidence is called "confirmation theory." These attempts have given rise to surprising paradoxes. Understanding them will lead to a better idea of the nature of evidence.

If a body of propositions constitutes *some* evidence (however slight) for a hypothesis, let us say that these propositions *confirm* the hypothesis. From this starting point one might hope to develop an account of what one should believe. For example, one might think that one ought to believe, of all the relevant hypotheses that one can conceive, that which is best confirmed by all of one's data. Be that as it may, there are problems enough even with the starting point, let alone what one might develop from it.

A very natural thought is that the following principle will play some fundamental role in an account of confirmation:

G1. A generalization is confirmed by any of its instances.

Here are some examples of generalizations:

1. All emeralds are green.
2. Whenever the price of cocaine falls, its consumption rises.
3. Everyone I have spoken to this morning thinks that the Democrats will win the next election.
4. All AIDS victims have such-and-such a chromosome.

G1 asserts that these propositions are confirmed by their instances – that is, respectively, by this, that, or the other emerald being green; by cases in which the price of cocaine falls and

its consumption increases; by the fact that I spoke to Mary this morning, and she thinks that the Democrats will win; and by the fact that Frank, who has AIDS, also has this chromosome. Notice that G1 does not assert, crazily, that an instance can *establish* a generalization, A single instance can *confirm*, according to G1, but obviously that does not settle the matter. A single instance does not even show that it is rational to believe the hypothesis, let alone that it is true.

I have spoken both of objects (like emeralds) and of facts (like the fact that Frank has AIDS and also this chromosome) as instances of generalizations, and I shall continue to do so. However, on state occasions I shall say that an instance of a generalization is itself a proposition. When the generalization has the form

All *A*'s are *B*'s,

an *instance* of it is any proposition of the form

This *A* is a *B*.

Thus

This emerald is green

is an instance of

All emeralds are green.

A *counterinstance* of a generalization "All *A*'s are *B*'s" is a proposition of the form

This *A* is not a *B*.

So

This emerald is not green

is a counterinstance of "All emeralds are green." Just as we may, on nonstate occasions, speak of green emeralds as instances of this latter proposition, so we can speak of nongreen emeralds as counter-instances of it.

The opposite of confirmation is *disconfirmation*. A hypothesis is disconfirmed by propositions that tend to show it to be false. An extreme case is *falsification*: A generalization is falsified by any counterinstance of it.

The principle G1 is to be understood to mean that any proposition that is an instance of a generalization confirms that generalization. It is not always clear how this is meant to link up with the notion of good evidence. Obviously, one AIDS victim with a certain chromosome does not alone constitute good evidence for the hypothesis that all AIDS victims have it; but perhaps a large number of instances, and no counterinstances, do add up to good evidence.

If so, we shall think of each instance as making a positive contribution to this good evidence, and this is what people have in mind by the notion of confirmation. G1 does not say, absurdly, that an instance of a generalization would, in and of itself, give us good reason to believe that generalization. Rather, it says that an instance makes a positive contribution, however slight, and however liable to be outweighed by other factors, toward constituting good evidence. The idea is that if we know of an instance of a generalization, we have taken one small step toward having good evidence for that generalization, even though other things we know may undermine this evidence. Indeed, our other knowledge might include a counterinstance of that same generalization.

The quality of evidence is a matter of degree: Some evidence is stronger, other evidence weaker. One way we might try to build toward this from the idea of confirmation, together with G1, is by saying that your evidence for a generalization is stronger the more instances of it your total body of knowledge contains – provided that it contains no counterinstances. However, one must beware of supposing that it is at all easy to arrive at a correct account. The following shows that what has just been suggested is indeed wrong. One could well have come across many instances, and no counterinstances, of the generalization

All places fail to contain my spectacles

(one has searched high and low without success); yet one would be quite right to be certain that this generalization is false.

The appeal of G1 comes in part from the thought that *extrapolation* is reasonable. If all the things of kind *A* that you have examined have also been of kind *B*, then you have some reason to extrapolate to the hypothesis that all things of kind *A* are of kind *B*. Of course, the evidence may be slight, and it may be outweighed by other evidence.

We are not usually interested in confirmation (in the technical sense used here) in cases of generalizations such as “Everyone I met this morning said that the Democrats would win.” If I had met a reasonably small number of people, I might say in the afternoon: “I don’t need evidence – I already *know* that it’s true.” The idea is that my own experience already determines the truth of the generalization. The contrast is with generalizations such as “Whenever the price of cocaine falls, its consumption increases.” You may know

that this has held so far, but this does not settle that the proposition is true, for it speaks to future cases as well as past ones. This is the sort of generalization for which we feel we need evidence: a generalization not all of whose instances one has encountered.²¹

Inductive reasoning, as philosophers call it, consists in arguing from evidence or data to hypotheses not entailed by these data. One traditional philosophical problem has been to justify this process: to show that it is at least sometimes legitimate to “go beyond the data.” Let us call this the problem of *justification*. Another philosophical problem is this: to give a general account of the kinds of inductive reasoning we *take* to be legitimate (without necessarily pronouncing on whether or not they are really legitimate). Let us call this the problem of *characterization*. We take it that it is legitimate to argue from the fact that the sun has risen every day so far to the conclusion that it will, probably, rise every day in the future; or, at least, to the conclusion that it will, probably, rise tomorrow. By contrast, we do not think that it is legitimate to argue from these same data to the conclusion that the sun will sometime cease to rise, or to the conclusion that it will not rise tomorrow.²² The problem of characterization is to give an illuminating general account of the features of evidence that make us count it as *good* evidence, as a legitimate basis for the hypothesis in question.

An initial answer to the problem of characterization is that inductive reasoning is generally taken to be legitimate when it is a case of extrapolation: when one reasons on the assumption that what one has not experienced will resemble what one has. G1 is connected with this initial suggestion, for it specifies a way of extrapolating.

These problems of induction are akin to problems already encountered. Earlier, we asked, “Under what conditions are data good evidence for a hypothesis?” If we can answer this question in some illuminating way (and not merely by saying, for example, “When they are”), we shall thereby be close to having solved the problem of justification – for we shall then be close to showing that it is sometimes legitimate to go beyond the data.²³ Moreover, if we could answer the question “Under what conditions are data *taken to be* good evidence for a hypothesis?” we would have answered the problem of characterization.

We shall be concerned only with the characterization problem: not the question of whether

there is any genuinely legitimate inductive reasoning, but rather the question of what sort of inductive reasoning we (rightly or wrongly) take to be legitimate. Though this seems the easier problem, attempts to answer it lead quickly to contradictions.

1.2. *The Paradox of the Ravens*

Despite the initial appeal of G1, it leads, in conjunction with other apparently innocuous principles, to a paradox discovered by Carl Hempel [1945], and now generally known as the Paradox of the Ravens.

In order to derive the paradoxical consequence, we need just one other principle:

E1. If two hypotheses can be known *a priori* to be equivalent, then any data that confirm one confirm the other.

This needs some explanation.²⁴ Something can be known *a priori* if it can be known without any appeal to experience. For example, one does not have to conduct any kind of social survey to discover that all women are women: Indeed, one could not discover this by a survey. What can be known *a priori* can be known simply on the basis of reflection and reasoning.

Two hypotheses are equivalent just on condition that if either one is true, so is the other, and if either one is false, so is the other. E1 asks us to consider cases in which two hypotheses can be known *a priori* to be equivalent. An example would be the hypotheses

R1. All ravens are black

and

There are no ravens that are not black

and also

R2. Everything nonblack is a nonraven.

Any two of these three hypotheses are equivalent, and this can be shown simply by reflection, without appeal to experience; so the equivalence can be known *a priori*. For example, suppose R1 is true: All ravens are black. Then, clearly, any nonblack thing is not a raven, or, as R2 puts it, is a nonraven. So if R1 is true, so is R2. Now suppose that R1 is false; then some ravens are not black. However, this means that some things that are not black are ravens, so R2 is false, too. Thus R1 and R2 are equivalent, and this can be known *a priori*.²⁵

We can now show how the Paradox of the Ravens is derived from G1 and E1. By G1, R2

is confirmed by its instances – for example, by a white shoe, or (using the state-occasion notion of an instance) by, for example:

P1. This nonblack (in fact, white) thing is a nonraven (in fact, a shoe).

Instance P1 confirms R2, but R2 can be known *a priori* to be equivalent to R1. So, by E1, P1 confirms R1, “All ravens are black.” This, on the face of it, is absurd. Data relevant to whether or not all ravens are black must be data about ravens. The color of shoes can have no bearing whatsoever on the matter. Thus G1 and E1 – apparently acceptable principles – lead to the apparently unacceptable conclusion that a white shoe confirms the hypothesis that all ravens are black. This, finally, is our paradox.

The principles of reasoning involved do not appear to be open to challenge, so there are three possible responses:

- (a) to say that the apparently paradoxical conclusion is, after all, acceptable;
- (b) to deny E1; or
- (c) to deny G1.

Hempel himself makes the first of these responses. One could argue for it as follows. First, we must bear in mind that “confirm” is being used in a technical way. It does not follow from the supposition that a white shoe *confirms* that all ravens are black that observing a white shoe puts you in a position reasonably to believe that all ravens are black. Second, there are cases in which it seems quite natural, or at least much less absurd, to allow that P1 confirms that all ravens are black – that is, that P1 could make a positive contribution to some good evidence for the hypothesis. Suppose that we are on an ornithological field trip. We have seen several black ravens in the trees and formulate the hypothesis that all ravens are black. We then catch sight of something white in a topmost branch. For a moment we tremble for the hypothesis, fearing a counterinstance – fearing, that is, that we have found a white raven. A closer look reveals that it is a shoe. In this situation, we are more likely to agree that a white shoe confirms the hypothesis. Hempel tells a similar story for a more realistic case. Investigating the hypothesis that all sodium salts burn yellow, we come across something that does not burn yellow. When we discover that the object is a lump of ice, we regard the experiment as having confirmed the hypothesis.

The first point appeals to the idea that some complicated story must be told in order to link

confirmation to having good reason to believe. Furthermore, in the telling, it will be apparent why observing white shoes, despite their confirmatory character with respect to the hypothesis that all ravens are black, does not normally contribute to giving one good reason to believe the hypothesis. We cannot assess the suggestion until we know the details of this story.

The second of these points emphasizes that confirmation, as we normally think of it, is not an absolute notion but is relative to what background information we possess. Making this point leaves unstated the task of specifying how the technical notion of confirmation – which, so far, has been taken as absolute – should be modified so as to take account of this relativity.

Perhaps these points can be developed so as to justify the first response, (a); but I shall now turn to the other possible responses.

Response (b) is to deny E1. For example, one might simply insist that anything that confirms a generalization must be an instance of it. This avoids the paradox and is inconsistent with E1, but it is very hard to justify. For example, suppose that we are investigating an outbreak of Legionnaires' disease. Our hypothesis is that the source of the infection was the water at St. George's school, consumed by all the children who attended last week. Will only an instance of the generalization "All pupils attending St. George's last week contracted Legionnaires' disease" confirm it? Imagine that we find some St. George's children who are free from the disease, but that it then turns out they they missed school last week. We would normally count this as evidence in favor of our hypothesis – some potential and highly relevant counterinstances have been eliminated – and yet these children are not instances of the hypothesis.

There is a more general argument against the rejection of E1. Suppose we find some data that confirm two hypotheses, H1 and H2. It is standard practice to reason as follows: H3 is a consequence of H1 and H2, so to the extent that H1 and H2 are confirmed, so is H3. For example, if we had data that confirmed both the hypothesis that all anorexics are zinc-deficient and the hypothesis that everyone who is zinc-deficient is zinc-intolerant, the data would surely confirm the hypothesis that all anorexics are zinc-intolerant. However, if we allow that data confirm the *a priori* knowable consequences of hypotheses they confirm, we have in effect allowed E1.²⁶

The third possible response to the paradox is to reject G1. This is both the most pop-

ular response, and also, I believe, the correct one. The Paradox of the Ravens already gives us some reason to reject it, if the other responses are unsatisfactory. The paradox of "grue," to be considered in the next section, gives a decisive reason for rejecting it. Moreover, there are quite straightforward counterexamples to it. Consider, for example, the hypothesis that all snakes inhabit regions other than Ireland. According to G1, a snake found outside Ireland confirms the hypothesis; but however we pile up the instances, we get no evidence for the hypothesis. Quite the contrary: The more widespread we find the distribution of snakes to be, the more unlikely it becomes that Ireland is snakefree. A non-Irish snake does not confirm the hypothesis, since it makes no positive contribution to the evidence in favor of the hypothesis, and may even count against it.

Rejecting G1 resolves the paradox, but it leaves us in a rather unsatisfactory position regarding confirmation: We have made very little progress toward uncovering the principles that underlie our discrimination between good and bad evidence. The next paradox brings to light more difficulties in the path of this project.

1.3. "Grue"

According to G1, green emeralds confirm the hypothesis that all emeralds are green. Now consider the predicate "grue," invented by Nelson Goodman [1955] with an eye to showing the inadequacy of G1. The meaning of "grue" ensures, by stipulation, that a thing *x* counts as *grue* if and only if it meets either of the following conditions:

- Gr1. *x* is green and has been examined, or
- Gr2. *x* is blue and has not been examined.²⁷

The class of grue things is thus, by definition, made up of just the examined green things together with the unexamined blue things. All examined emeralds, being all of them green, count as grue, by Gr1. It follows from G1 that the hypothesis that all emeralds are grue is confirmed by our data: Every emerald we have examined is a confirming instance because it was green. This is absurd. If the hypothesis that all emeralds are grue is true, then unexamined emeralds (supposing that there are any) are blue. This we all believe is false, and certainly not confirmed by our data. G1 must be rejected.²⁸

What is paradoxical is that a seeming truth, G1, leads, by apparently correct reasoning, to a seeming falsehood: that our data concerning

emeralds confirm the hypothesis that they are all grue.²⁹ The paradox relates to the problem of *characterization* – of saying what kinds of evidence we take to be good, or what sorts of inductive argument we take to be legitimate – because we need to say what makes us treat green and grue differently. G1 does not discriminate the cases.

Notice that the conclusion is unacceptable even if we recall that “confirms” is being used in a technical sense: It is not equivalent to “gives us good reason to believe,” but means only something like “would make a positive contribution to a good reason for believing.” It strikes us as unacceptable to suppose that an examined green emerald makes any contribution at all to giving a good reason for supposing that all emeralds are grue.³⁰

We have already seen in connection with the ravens (section 1.2) that there is a case for rejecting G1; that case is, of course, strengthened by the present Grue Paradox. If we reject G1, then the paradox is, for the moment, resolved, for we shall have said that an apparently acceptable premise is not really acceptable. However, what can we put in its place? It would seem that something like G1 must be true. Is there an appropriate modification? If not, then the Grue Paradox remains unresolved; for to say that there is no appropriate modification of G1 is to say that there are no principles governing what makes a body of data confirm a hypothesis. This seems as unacceptable as the view that green emeralds confirm the hypothesis that all emeralds are grue.

Several suggestions have been made. Most of them can be seen as falling into one of two patterns:

1. The blame is placed on the word “grue,” which is said to be of a particularly nasty kind, rather than on the structure of G1. All we need is a general principle for excluding the *gruesome* words, and G1 will be acceptable for the remainder.
2. The blame is placed not so much on “grue” as on the attempt to formulate a principle, like G1, that takes no account at all of *background information* – information that is always in play in any real-life case of evidence or confirmation.

If we try the first response, the difficulty is to say exactly what is nasty about “grue.” It is not enough to say that “grue” is an invented word, rather than one that occurs naturally in our lan-

guage. Scientists often have to invent words (like “electron”) or use old words in new ways (like “mass”), but it would be extravagant to infer that these new or newly used words cannot figure in confirmable generalizations.

It is more appealing to say that what is wrong with “grue” is that it implicitly mentions a specific time in its definition. Its definition appeals to what has *already* been examined, and this refers to the time at which the definition is made. In this respect, “grue” and “green” differ sharply, for there is no *verbal* definition of “green” at all, and so it is not the case that the definition of “green” involves reference to a particular time.

However, if we were to restrict G1 to generalizations in which there is no reference to a time, we would make it too restrictive. For example, the generalization “In Tudor times, most agricultural innovations were made in the north of the country” is one that could be confirmed or disconfirmed on the pattern of G1. In addition, G1 would not be restrictive enough. The structure of the Grue Paradox is preserved if we can find a way of picking out just the emeralds we have already examined. We might do this by giving each one a name, e_1, e_2, \dots ; or it might be that all and only the emeralds so far examined have come from a certain emerald mine (now exhausted); or something of the kind. Then we could define a predicate equivalent to “grue” without mentioning a time: In the one case we could say that it is to apply to any of e_1, e_2, \dots just on condition that that thing is green, and to anything else just in case it is blue; in the other case we could say that it is to apply to everything taken from a certain mine just on condition that it is green, and to anything else just on condition that it is blue. Therefore it is not of the essence of the paradox that the definition of “grue” mentions a time.

There are other ways of trying to say what is nasty about “grue.” Goodman’s own attempt has at least superficial similarities to one I rejected earlier. He says that what is wrong with “grue” is that it is not “well-entrenched”; that is, the class of entities to which it applies is a class that has not been alluded to much – indeed, at all – in the making of predictions. To treat being poorly entrenched as sufficient for being incapable of figuring in confirmable generalizations seems to put an intolerable block on scientific innovativeness. Though Goodman is well aware of this problem, there is room for doubt about whether he deals with it successfully.³¹

I now want to consider a response of the other kind I mentioned: not restricting G1 by

limiting it to generalizations that do not contain words sharing the supposed nasty features of “grue,” whatever these features may be; but rather restricting G1 by appeal to background information. Intuitively, what is wrong with supposing that our information about examined emeralds gives us any reason for thinking that all emeralds are grue is that we know that the examined ones are grue only in virtue of having been examined. We do not believe that our examining the emeralds had any “real” effect on them. We believe that if they had not been examined they would not have been grue. What makes it so absurd to suppose, on the basis of our data, that all emeralds are grue is that we know that the unexamined ones lack the property in virtue of which the examined ones *are* grue: namely, having been examined. An initial attempt to formulate this thought might look like this:

G2. A hypothesis “All *F*'s are *G*'s” is confirmed by its instances if and only if there is no property *H* such that the *F*'s in the data are *H*, and if they had not been *H*, they would not have been *G*.³²

We might try to support G2 by applying this to the following case, which in some respects looks similar to the grue emeralds. Suppose that we are gathering evidence about the color of lobsters, but unfortunately we have access only to boiled ones. All the lobsters in our sample are pink. Moreover, we know that the lobsters in the sample are pink only in virtue of having been boiled. Then it would be absurd for us to think that our sample confirms the hypothesis that all lobsters are pink. Here the hypothesis is “All lobsters (*F*) are pink (*G*),” and *H* is the property of having been boiled. Because the lobsters in the sample are boiled, and had they not been boiled would not have been pink, the data do not meet the condition imposed by G2 for confirming the hypothesis.

The lobster case brings to light a difficulty, or series of difficulties, connected with G2. We start to uncover them if we ask: How do we know that the lobsters in the sample would not have been pink had they not been boiled? It would seem that if we know this, then we know that some lobsters are not pink at all times, and thus we are in a position to know that the hypothesis is false.

This shows that we can explain, without appealing to G2, why the evidence for the hypothesis that all lobsters are pink was deficient. A body of evidence fails to confirm any hypothesis to which it contains a counterinstance. However, the case in addition brings to

light something more fundamental: that G2, as it stands, does not require our *body of data* to contain the proposition that there is no *H* such that the examined *F*'s would not have been *G* had they not been *H*. It requires only that this proposition be true. What would be relevant to G2 would thus be a variant of the lobster case in which all observed lobsters are pink, but we, the observers, do not realize that they are pink only because they have been boiled. G2 does *not rule* that, in this state of ignorance, our data confirm the generalization that all lobsters are pink.³³ Is this acceptable?

This raises an important issue. If it sounds wrong to say that the person who has observed only pink lobsters, and who knows nothing of the connection between boiling and color (and perhaps does not even know that the sample lobsters have been boiled), lacks data that would confirm the hypothesis that all lobsters are pink, this is because we intuitively feel that evidence should be *transparent*. By this I mean that we intuitively feel that if a body of data is evidence for a hypothesis, then we ought to be able to tell that this is so merely by examining the data and the hypothesis: One ought, in other words, to be able to tell that this is so *a priori*. This intuitive feeling might be supported by the following argument. Suppose that no evidence is, in this sense, transparent. Then, a claim to the effect that a body of data *D* confirms a hypothesis *H* will itself be a hypothesis needing confirmation. We shall need to cast around for data to confirm, or disconfirm, the hypothesis that *D* confirms *H*. It looks as if we are set on an infinite regress, and that we could never have any reason to suppose that anything confirms anything unless evidence is transparent.

Not all evidence is transparent. Spots can confirm the hypothesis that the patient has measles, but one needs medical knowledge to recognize that the data, the spots, are thus related to the hypothesis: One needs to know that only people, or most people, with spots of this kind have measles. In other words, it is clear that in many cases the evidence is not transparent. In any case, the most the argument of the preceding paragraph could show is that *some* evidence needs to be transparent, since this is all that is needed to block the alleged regress.

If we feel that some evidence should be transparent, we shall surely feel that an example is the limiting case in which everything that *can* be included among the data *has* been included. In this case, we shall feel that one ought to be able to tell *a priori*, without further investigation,

which hypotheses these data confirm. However, this is not guaranteed by G2, for two reasons.

First, for some hypotheses, "All *F*'s are *G*'s," our data may include plenty of instances and no counterinstances but fail to contain either the proposition "There is no *H* such that all examined *F*'s are *H* and would not have been *G* had they not been *H*" or its negation. In this case, if G2 is true, we could not tell *a priori* whether our data confirm the hypothesis, since we could not tell whether the condition it places on the instances of the hypothesis obtains or not.

Second, it is a debatable question whether this condition *could* properly be included among our data. One might hold that all data must, in the end, be observations, and that a condition such as "There is no *H* such that all examined *F*'s are *H* and would not have been *G* had they not been *H*" is not something immediately available to observation, and so cannot be a datum.

These objections point in controversial directions. The second objection presupposes a form of *foundationalism*, which is highly controversial. Perhaps, contrary to the presupposition, there is nothing in the intrinsic nature of a proposition that qualifies it as a datum; thus, on occasion, the counterfactual condition could count as a datum. If this is allowed, then we could envisage a variant of G2 that meets the first of the two objections.

G3. A hypothesis "All *F*'s are *G*'s" is confirmed by a body of data containing its instances if and only if the data also contain the proposition "There is no such property *H* such that the *F*'s in the data are *H*, and if they had not been *H*, they would not have been *G*."

Like G2, this does not rule that "All emeralds are grue" is confirmed by its instances, if we can allow that our data contain the proposition "There is a property, namely *being examined*, such that the emeralds in the data have been examined, and had they not been examined, they would not have been grue." It has the further merit of being consistent with transparency: Whether or not a body of data confirms a hypothesis depends only on the body and the hypothesis themselves, and not on other, perhaps inaccessible, facts. However, it has the apparently dubious feature that smaller bodies of data can confirm more than can larger bodies.

To see how this works, imagine two people, both confronted with pink boiled lobsters, and both concerned to consider the question

of whether their data confirm "All lobsters are pink." One person does not realize that all the lobsters he has seen have been boiled, or else does not realize that boiling them affects their color. If G3 is correct, that person's data do confirm the hypothesis "All lobsters are pink." The other person, by contrast, knows that the lobsters would not have been pink had they not been boiled. G3 does not entail that that person's data confirm the hypothesis that all lobsters are pink. If you know more, your data may confirm less.

This feature is one that should come as no surprise. A body of data full of instances of a generalization, and containing no counter-instances, may confirm the generalization, though the same body enriched by a counterinstance would not. Still, G3 needs refinement. For one thing, it still leads, in conjunction with E1, to the Ravens Paradox.³⁴ For another thing, we need to relax it a little, as the following example shows.

Suppose you find, year after year, that although all the other vegetables in your garden are attacked by pests, your leeks are always pest-free. Would it be reasonable to conclude that leeks are immune to pests? Let us suppose that you know no proposition to the effect that your leeks would not have been healthy had they not possessed some property *P*. According to G3, the hypothesis that all leeks are immune to pests is confirmed by your data; but I think that we should not, in fact, put much confidence in the hypothesis, given the data. Even if one knows no proposition of the relevant kind, one may strongly suspect that *there is* one, even though one does not know it. One knows in a general way that susceptibility to pests is likely to be affected by such factors as the nature of the soil, how strongly the plant grows, and what other vegetation is around. Even though your data do not include a proposition that selects a factor that explains the pest-free quality of your leeks, you might well believe that *there is* a proposition of this kind. If so, you should not put much faith in the hypothesis that all leeks, including those grown in very different conditions, are immune to pests.

If it is to deliver the results we want in such cases, the proviso in G3 must be understood in such a way that:

- (a) The data must not contain even the proposition that *there is* a proposition to the effect that the *F*'s are *G* only in virtue of being *H*; and

- (b) The background information in general, and this in particular, do not have to be *known* or be *certain*.

All other things being equal, the fact that we think it quite *likely* that there are conditions under which leeks suffer from pests is enough to diminish, or even perhaps cancel, the confirmatory impact of our pest-free leeks. I shall assume that these modifications to G3 have been made.

G3 entails that the hypothesis that all emeralds are grue is confirmed by the data consisting just of propositions of the form “This is an emerald,” “This has been examined,” and so on; but it does not entail that this hypothesis is confirmed by the body of data, including background information, that we in fact possess. That body of data includes the proposition that the examined emeralds would not have been grue had they not been examined; that is, it includes a proposition of the form “There is a property *H* (*having been examined*) such that the emeralds would not have been grue had they not had *H*.”

The Grue Paradox has been held to have more distant ramifications. To gesture toward these, let us consider a corollary that Goodman stresses:

Regularities are where you find them, and you can find them anywhere.

The old idea – found, for example, in Hume – was that the reasoning from experience that we take to be legitimate is that in which we extrapolate regularities obtaining within our experience to portions of the world that lie outside our experience. One thing that Goodman’s “grue” shows is that this is, at best, a highly incomplete account. The question is: What is to count as a regularity? The regular connection between being an emerald and being green? *And* the regular connection between being an emerald and being grue? Our original problem reemerges in this form: Either we can give no account of what a regularity is, in which case the account that uses the notion is useless; or else we give an account of regularity that includes the undesirable emerald–grue regularity as well as the desirable emerald–green one.

This relatively narrow point about confirmation suggests a deeper metaphysical one: that whether a series of events counts as a regularity depends upon how we choose to describe it. This has suggested to some a quite thoroughgoing conventionalism, according to which there is no separating how the world is in itself from the conventions we bring to bear in describing and

classifying it. To others, it has had the effect of deepening their skepticism about the legitimacy of inductive reasoning. If there are endless regularities that we could have extrapolated, what makes it rational to pick on the ones we in fact do? It is bad enough having to justify extrapolating a regularity, but it is worse when one must, in addition, justify selecting one rather than any of the countless other regularities in the data to extrapolate. To yet others, the Grue Paradox has suggested that there is something quite undetermined, at least at the individual level, about our concepts. Wittgenstein asked us to consider someone who, having added 2 to numbers all the way up to 1,000, continues this way – 1,004, 1,008, . . . – and yet protests that he is “going on in the same way.” We could define a gruelike operator “+*” as follows: $x + * 2 = x + 2$, if $x < 1,000$; otherwise $x + * 2 = x + 4$. It has been suggested that there are no facts, or at least no individual facts, that make it true of us that we use concepts like *green* and + rather than concepts like *grue* and +*.

The impact of grue thus goes well beyond the problems of finding a nonparadoxical account of our notion of confirmation.

2. The Unexpected Examination

The teacher tells the class that sometime during the next week she will give an examination. She will not say on which day for, she says, she wants it to be a surprise. On the face of it, there is no reason why the teacher, despite having made this announcement, should not be able to do exactly what she has announced: give the class an unexpected examination. It will not be totally unexpected, since the class will know, or at least have good reason to believe, that it will occur sometime during the next week. However, surely it could be unexpected in this sense: that on the morning of the day on which it is given, the class will have no good reason to believe that it will occur on *that* day, even though they knew, or had good reason to believe, the teacher’s announcement. Cannot the teacher achieve this aim by, say, giving the examination on Wednesday?

The class reasons as follows. Let us suppose that the teacher will carry out her threat, in both its parts: That is, she will give an examination, and it will be unexpected. Then the teacher cannot give the examination on Friday (assuming this to be the last possible day of the week); for, by the time Friday morning arrives, and we know that all the previous days have been

examination-free, we would have every reason to expect the examination to occur on Friday. So leaving the examination until Friday is inconsistent with giving an *unexpected* examination. For similar reasons, the examination cannot be held on Thursday. Given our previous conclusion that it cannot be delayed until Friday, we would know, when Thursday morning came, and the previous days had been examination-free, that it would have to be held on Thursday. So if it were held on Thursday, it would not be unexpected. Thus it cannot be held on Thursday. Similar reasoning supposedly shows that there is no day of the week on which it can be held, and so supposedly shows that the supposition that the teacher can carry out her threat must be rejected. This is paradoxical, for it seems plain that the teacher *can* carry out her threat.

Something must be wrong with the way in which the class reasoned; but what?

The class's argument falls into two parts: One applies to whether there can be an unexpected examination on the last day, Friday; the other takes forward the negative conclusion on this issue, and purports to extend it to the other days.

Let us begin by looking more closely at the first part. On Friday morning, the possibilities can be divided up as follows:

- (a) The examination will take place on Friday and the class will expect this.
- (b) The examination will take place on Friday and the class will not expect this.
- (c) The examination will not take place on Friday and the class will expect this.
- (d) The examination will not take place on Friday and the class will not expect this.

When we speak of the class's expectations, we mean their rational or well-grounded ones. It is not to the point that they may have expectations to which they are not entitled, or lack expectations to which they are entitled. For example, it is not to the point that the class might irrationally (without entitlement or justification) believe that the examination would take on Wednesday. Even if it then did take place on Wednesday, this would not show that the teacher's announcement was false, for she said that the class would have *no good reason* to believe it would occur when it did.

The overall structure of the class's argument is meant to be a *reductio ad absurdum*: They take as a supposition that the teacher's announce-

ment is true, then aim to show that this leads to a contradiction, and hence that the supposition must be rejected. In this first part of the argument, the supposition is used to show that the examination cannot occur on Friday. This is extended to every day of the week in the second part of the argument, so that, in the end, the supposition is rejected. Thus the teacher's announcement is disproved.

Given that the examination has not occurred on the previous days, at most possibility (b) is consistent with the truth of the teacher's announcement. The class's argument aims to show that (b) is not a real possibility.

The idea is that the class can infer that if the examination occurs on Friday, then the announcement is false, contrary to the supposition. The inference is based on the consideration that the class will know that Friday is the last possible day for the examination. So, given the supposition that the teacher's announcement is true, they would expect the examination, were it to occur on Friday; but this is inconsistent with the truth of the announcement. If we hold on to the supposition, the examination cannot take place on Friday.

That this argument is not straightforward can be brought out by the following. Imagine yourself in the class, and it is Friday morning. There is surely a real question, which you may well feel that you do not know how to answer: Has the teacher forgotten or changed her mind, or will the examination indeed take place that day? It would seem that this doubt is enough to ensure that if it does take place that day, it will be unexpected: The class was not entitled to expect it.

The class's argument is meant to circumvent this difficulty by using the truth of the teacher's announcement as a supposition – one that, in the end, is going to be rejected. Given this supposition, the class on Friday morning can rule out the nonoccurrence of the examination. On the other hand, it can also rule out its occurrence – and this is what is meant to show that, if the supposition is true, the examination cannot occur on Friday.

However, it is a mistake to think that the supposition merely of the *truth* of the teacher's announcement will do the required work. To see this, imagine ourselves once more among the class on Friday morning. Suppose that the teacher's announcement is true but that we do not know or even believe this. Then we may not believe that the examination will occur. This is

enough to make the truth of the announcement possible: If the examination does occur, we shall not have expected it. This shows a fallacy in the reasoning as so far presented. Merely supposing, for *reductio*, that the teacher's announcement is true is not enough to establish that the examination will not be held on Friday. At that point in the argument, we need as a supposition that we *know* that the teacher's announcement is true.³⁵

If we are to have a paradoxical argument worth discussing, we need to make some changes. There are various ways in which one could do this; I shall consider two. The details are quite complicated: To make the discussion manageable, we shall soon need to use some abbreviations.

One modification we could make is to leave the announcement unchanged but alter the structure of the argument. Instead of taking the announcement itself as our supposition, we shall suppose that the class *knows* the truth of the announcement. This supposition is refutable, on Friday, by the considerations outlined. If on Friday we know that the announcement is true, we know that the examination will occur on Friday. If we know that the examination will occur on Friday, the announcement is not true. If the announcement is not true, then we do not know that it is true. The supposition that we know that it is true entails its own falsehood, and so can be rejected. Applying similar reasoning to the other days of the week, the upshot would be that the class can show that it cannot *know* that the announcement is true. This may seem paradoxical: Intuitively, we want to say that we knew, from the announcement, that there would be an examination sometime, though we did not know when, and so it was unexpected.

An alternative modification involves changing the announcement to include the fact that the class will not know, on the basis of the announcement, that the examination will take place on the day that it does. In a way that can only be made clear by some abbreviations, this will give us a valid argument for the conclusion that the announcement is false. If this is paradoxical, it is because it seems intuitively obvious that such an announcement could be true.

Let us call the original version of the argument OV, the first proposed modified version MV1, and the second proposed modified version MV2. Since the number of days of the week is irrelevant, let us simplify by supposing that there are just two possible examination days, Monday

or Tuesday. For OV and MV1, I shall abbreviate the announcement as:

- A1. I shall give you an examination on either Monday or Tuesday, and you will not know – or have good reason to believe – on the morning of the examination that it will occur that day.

The other abbreviations are as follows:

M for “the examination occurs on Monday”;

T for “the examination occurs on Tuesday”;

$K_M(\dots)$ for “the class knows on Monday morning that ...”; and

$K_T(\dots)$ for “the class knows on Tuesday morning that... ”³⁶

We can express A1 symbolically as:

$([M \text{ and not-}K_M(M)] \text{ or } [T \text{ and not-}K_T(T)])$ and not both M and T.

(That is, either there will be an examination on Monday and the class does not know this on Monday morning, or there will be an examination on Tuesday and the class does not know this on Tuesday morning; and there will be an examination on at most one morning.)³⁷

OV can be represented as follows:

1. Suppose A1.
2. Suppose not-M
3. $K_T(\text{not-M})$ [from 2 + memory]
4. If not-M, T. [by the definition of A1]
5. $K_T(T)$ [from 3 + 4]
6. If $K_T(T)$ and not-M, then not-A1 [by the definition of A1]
7. not-A1 [from 2, 5, + 6]
8. So, still supposing A1, we must conclude that M (and so not-T)
9. $K_M(M)$ [from 8 + A1]
10. If $K_M(M)$ and not-T, then not-A1 [definition of A1]
11. not-A1 [from 8, 9, + 10]
12. not-A1 [from 1 + 11]

The overall shape of the argument is *reductio ad absurdum*: One makes an assumption in order to show that it leads to a contradiction and so must be rejected. In the present case, the supposition of A1 is supposed to lead eventually to the conclusion that A1 is false. (Indentation is used to show that – and how – some steps of the argument occur within the scope of a supposition.)³⁸ It seems that we intuitively hold that A1 can be true; and that clash constitutes the paradox.

OV suffers from the defect that no adequate justification is provided for step (5). The idea is meant to be this: If A1 is true, then the examination must occur on Tuesday if it does not occur on Monday; so if we knew the examination did not occur on Monday, we would know that it would occur on Tuesday. However, this is not a sound inference: We would also need to *know* that the examination must occur on Tuesday if it does not occur on Monday.³⁹

MV1 can be represented as follows:

1. Suppose $K(A1)$
2. Suppose not-M
3. $K_T(\text{not-M})$ [from 2 and memory]
4. If not-M, T [by the definition of A1]
5. $K_T(\text{If not-M, T})$ [by supposition 1]
6. $K_T(T)$ [from 3 + 5]
7. If $K_T(T)$, then not-A1 [definition of A1]
8. If not-A1, then not-K(A1) [only the truth is known]
9. If $K_T(T)$ then not-K(A1) [from 7 + 8]
10. So, given $K(A1)$, we must conclude that M (and so not-T)
11. $K_M(M)$ [from 10]⁴⁰
12. If $K_M(M)$ and M, then not-A1 [definition of A1]
13. not-A1 [from 10, 11, + 12]
14. If not-A1, then not-K(A1) [only the truth is known]
15. not-K(A1) [from 13 + 14]
16. not-K(A1) [from 1 + 15]

Even if MV1 is valid (and footnote 40 gives a reason for doubt on this point), it is questionable whether there is anything paradoxical in this conclusion. To have a paradox, we would need

also to have an argument for the conclusion that $K(A1)$. Perhaps it is just intuitively obvious that $K(A1)$, given, if you like, the class's knowledge of the teacher's unimpeachable reputation for veracity and constancy of purpose; but suppose someone failed to share this intuition?

If not- $K(A1)$, then it is very easy for A1 to be true: The class will not on the basis of A1 have any expectations, since the students can establish that they cannot know A1. This gives the teacher plenty of scope for surprising them.

However, the class can also go through the reasoning of the preceding paragraph: "Our proof that A1 cannot be known shows us how easy it is for A1 to be true. If it *can* be true, then, given the teacher's proven veracity and determination, we have every reason to believe that it is true." If the class is led by this consideration to believe the announcement, then there is a case for thinking that their belief amounts to knowledge. So it seems that *if* the argument is valid, we have a paradox.⁴¹

MV2 requires a different announcement:

- A2. Either [M and not- $K_M(\text{If A2, then M})$] or [T and not- $K_T(\text{If A2, then T})$].

(That is, the examination will take place on Monday or Tuesday, but you will not know on the basis of this announcement which day it will be.) Notice that A2 differs from A1 in a striking respect: The specification of A2 refers to A2 itself; in other words, A2 is a *self-referential* announcement.

MV2 can be represented as follows:

1. Suppose A2
2. Suppose not-M
3. $K_T(\text{not-M})$ [from (2) + memory]
4. $K_T(\text{If not-M, then if A2, then T})$ [the class understands A2]
5. $K_T(\text{If A2, then T})$ [from 3 + 4]
6. not-A2 [from 2 + 5]
7. M [from 1, 2, + 6]
8. If A2, then M [summarizing 1–7]
9. $K_M(\text{If A2, then M})$ [the proved is known]
10. If $K_M(\text{If A2, then M})$, then if A2, then not-M [from definition of A2]
11. If A2, then not-M [from 9 + 10]
12. not-A2 [from 8 + 11]

MV2 purports to prove that A2 is not true. This is paradoxical only if we have some good reason to think that it is, or could be, true. We seem to have some reason: Have we not all been exposed to such threats of unexpected examinations? The form of A2 admittedly has the self-referential feature already noticed, but it is not clear that this should make any difference. When the teacher says that the examination is to be unexpected, what is clearly intended is that it be unexpected on any basis, including on the basis of this present announcement. So the intuitions that told us that A1 could be true, and could be known, should also tell us that A2 could be true. However, intuition may be less than wholly confident when faced with the validity of MV2.

Using a self-referential type of announcement, one can construct a further announcement, call it A3, that is certainly paradoxical. It has come to be called the Knower Paradox.⁴²

A3. $K(\text{not-A3})$.

(That is, A3 is as follows: "The class knows that this very announcement is false.")

We can represent the argument that establishes both A3 and not-A3 as follows—call it MV3:

- | | |
|----------------------------|-------------------------------|
| 1. Suppose A3 | |
| 2. $K(\text{not-A3})$ | [definition of A3] |
| 3. not-A3 | [what is known is true] |
| 4. If A3, then not-A3 | [summarizing 1–3] |
| 5. not-A3 | [from 4] |
| 6. not- $K(\text{not-A3})$ | [from 5 + definition of A3] |
| 7. $K(\text{not-A3})$ | [5 + what is proved is known] |

Lines (6) and (7) are contradictory.

In view of this result, we must examine carefully (a) the nature of the announcement and (b) the epistemic principles – the principles involving the nature of knowledge – used to reach the paradoxical conclusion. If there is anything wrong with the principles, then we may have to revise our views about the earlier arguments, for they, too, rest on these principles.

(a) It is important to see that we cannot satisfy ourselves merely by saying that A3 is contradictory. A contradiction is false, whereas A3, if the argument MV3 is sound, is demonstrably true [see line (7)]. More hopeful would be to say that A3 is *unintelligible*, perhaps in part because of its self-referentiality. What, we might ask, does it

say? What is it that it claims cannot be known? If we say it claims that it itself cannot be known, we seem to be grappling in thin air rather than genuinely answering the question.

Some of this doubt might be removed by changing the example. Suppose now that we have two teachers, X and Y. X says "What Y will say next is something you can know to be false." Y then says "What X has just said is true." It looks as though we have to count both utterances as intelligible, since in other contexts they certainly would have been intelligible, and even in this context we can understand X's without knowing what Y will say, and can understand Y's without knowing what X has said. However, in the context Y's announcement appears to be equivalent to A3. We could argue informally for the contradiction like this. Suppose Y is true (let X and Y now also abbreviate the respective teachers' remarks). Then X is true, so you can know Y to be false, so it is false. So the supposition that Y is true leads to the conclusion that it is false. Hence we can conclude that it is false [cf. MV3(5)]. Hence we can conclude that *we can know Y to be false*. However, if Y is false, then X is false; i.e., *we cannot know Y to be false*. So it seems we have an argument that has the essential features of A3, but that is not open to the charge that the announcement is unintelligible.⁴³

(b) Let us isolate the epistemic principles concerning knowledge appealed to in MV3. There are three: The first – call it EK1 – is what licenses the move from (2) to (3) in MV3. In its most general form it is that what is known is true. We could write it:

EK1. If $K(\varphi)$, then φ .

The other point at which appeal to epistemic principles is made is the move at (7) from (5). It cannot be true that anything that is provable on the basis of no matter what assumptions is knowable. Given an assumption that $5 > 7$, I could perhaps prove that $5 > 6$, but obviously I could not *know* this. So the principle that we need at this point is that anything proved from known assumptions (or from no assumptions) is known.⁴⁴ We could write this as:

EK2. If C is provable from (P_1, \dots, P_n) and $K(P_1, \dots, P_n)$, then $K(C)$.

What assumptions (corresponding to P_1 , etc.) are in play in the move from (5) to (7)? Just one: EK1. So, in order to apply EK2, we need to add:

EK3. $K(\text{EK1})$.

Are these three principles plausible? Expressed informally they are the following:

EK1. What is known is true.

EK2. What is provable from things known is known.

EK3. It is known that what is known is true.

The first principle has sometimes been doubted on the grounds that, for example, people once knew that whales were fish; but this doubt is dispelled by the reflection that the correct account of the matter is that people *thought* they knew this, although they really did not. How could they have known it if it is not even true?

EK2 does not hold generally: We do not know all the infinitely many things that could be proved from what we know; we do not even believe all these things, if only because it would be beyond our powers to bring them all to mind. However, this implausible aspect of EK2 is not required for the paradox, which only needs this much narrower claim: that at least one person who has constructed a correct proof of not-A3 from a known premise knows that not-A3.

The third principle cannot be seriously questioned, once we have granted the first. So the only doubt about the premises attaches to EK2. We could circumvent this by using an even weaker and very hard to controvert principle: What is provable from something known is *capable* of being known by a fully rational subject. With appropriate modifications to A3, we shall be able to prove a contradiction from principles that appear indubitable, together with the admission of the intelligibility of the teacher's announcement.⁴⁵

It is very hard to know what to make of this paradox. One promising suggestion sees a similarity between it and the Liar Paradox (see Section 5.2 [of author's book *Paradoxes*]). Knowledge quite clearly involves the notion of truth, and the Liar Paradox shows that this notion can lead to paradox. So perhaps what is at fault in the concept of knowledge is the concept of truth it contains, as displayed in EK1; and perhaps the remedy consists in applying to knowledge whatever nonparadoxical elaboration of the notion of truth we can extract from consideration of the Liar Paradox.

The suggestion cannot be quite right for the following reason. Unlike knowledge, belief does not entail truth; yet a paradox rather like the Knower – we could call it the Believer – can be constructed in terms just of belief. Consider the following:

B₁. α does not believe what B₁ says.⁴⁶

Question: Does α believe B₁, or not? If α does believe B₁, then he can see that he is believing something false. There is no gap between seeing that something is false and not believing it, so if α believes B₁, he does not believe it. Equally, however, if α does not believe B₁, then he can see that B₁ is true. There is no gap between seeing that something is true and believing it, so if α does not believe B₁ he believes it. The paradox depends on at least two assumptions:

1. that α *can* see that, if he believes B₁, it is false, and if he does not believe it, it is true;
2. that what α can see he *will* see.

Neither assumption would be capable of true generalization. For (1) to hold of α requires, among other things, that he be able to see that he is α . One could arguably envisage this not being true, if α had an unusually low level of self-awareness. For (2) to hold of α requires a positive level of intellectual energy: One does not always take advantage of one's epistemic opportunities. However, we have a paradox if we can make the following highly plausible assumption: that there is at least one person with the self-awareness and energy required to make (1) and (2) true of him (or her).

We can represent the argument to the contradiction, and the assumptions upon which it depends, in a manner analogous to the representation of the Knower Paradox.⁴⁷ We abbreviate " α believes that ()" as "B()"; then B₁ = not-B(B₁).

1. Suppose B(B₁)
2. If B(B₁), then B[B(B₁)] [self-awareness]
3. B [B(B₁)] [from 1 + 2]
4. B [If B₁, then not-B(B₁)] [α understands B₁]
5. If B [B(B₁)], then not-B[not-B(B₁)] [rationality]
6. not-B [not-B(B₁)] [from 3 + 5]
7. not-B (B₁) [4, 6, + closure]
8. If B (B₁), then not-B(B₁) [summarizing 1–7]
9. not-B(B₁) [from 8]
10. B[not-B(B₁)]. [from 9 + self-awareness]
11. B(B₁) [from 10 + definition of B₁]

The unconditionally derived lines (9) and (11) are contradictory.

Let us examine the assumptions upon which the argument depends. The first principle to be used is what I have called “self-awareness.” In its most general form it could be represented as follows:

EB1. If $B(\varphi)$, then $B[B(\varphi)]$.

This is not very plausible. If it were true, then having one belief, say φ , would involve having infinitely many: that you believe that φ , that you believe you believe that φ , and so on. However, all that is required for the paradox are two instances of EB1: that if α believes B_1 , under circumstances that can be as favorable as you like to self-awareness, then he will believe he does so; and if α does not believe B_1 , then he will believe he does not. It seems impossible to deny that there could be a person of whom this is true.

The second assumption is that α understands B_1 and therefore realizes (and so believes), from the definition of B_1 , that if B_1 , then not- $B(B_1)$. Again, it seems impossible to deny that there could be a person who has this belief.

Next comes the principle called rationality. A generalization would be the following:

EB2. If $B(\varphi)$ then not- $B(\text{not-}\varphi)$.

Put so generally, this is not plausible, since people in fact have contradictory beliefs without realizing it; but we need only impute a fairly modest degree of rationality to α in order for the premise needed at line (5) to obtain.

A generalization of the closure principle is this:

EB3. If $B(\text{if } \varphi, \text{ then } \psi)$ and $B(\text{not-}\psi)$, then $B(\text{not-}\varphi)$.

For normal persons, this is not a plausible principle: We do not believe all the consequences of things we believe. However, it again seems easy to imagine that α verifies the particular case of the principle needed in the above argument.

Let us step back. A suggestion was that the Knower Paradox should be treated like the Liar Paradox, on the grounds that knowledge entails truth, and the Liar Paradox shows that the notion of truth requires special treatment. The point of introducing the Believer Paradox was to challenge this suggestion. Belief does not entail truth, yet belief gives rise to a paradox quite similar to the Knower.

The conclusion is that the reason given for treating the Knower and the Liar in similar ways is deficient.

Notes

- 1 Q: Suppose that on Monday you are penniless and starving, but that on Tuesday you win \$1,000,000 in a betting pool. Do you think that the number 5 can be used to measure the utility of \$5 to you on each of these days?
- 2 Q: Suppose you have four courses of action open to you, (a)–(d), associated with rewards as follows: (a) \$1, (b) \$6, (c) \$10,000, (d) \$10,005. Do you think that the number 5 can be used to measure both the difference between the utilities of (a) and (b) and the difference between the utilities of (c) and (d)?
- 3 Q: Discuss the following view:

Although people want things other than money, we can nevertheless measure how much they want things in numerical terms, by finding out how much they would be willing to pay, supposing, perhaps *per impossibile*, that what they want could be bought. If a man says he wants a happy love affair, we can measure the utility of this upshot to him by finding out how much money he would be willing to give up to get what he wants. Would he give up his car? His house? His job? All that is needed is the ability to imagine things being other than they are: to imagine that things that in fact cannot be bought can be bought.

- 4 Q: Could the MEU principle register a general dislike of gambling, as opposed to other ways of spending money? If so, how?
- 5 In more detail, the expected utility of an action is calculated as follows. First, you determine the possible outcomes O_i . Each is associated with a probability, conditional upon doing A , and a utility. The expected utility of an *outcome*, relative to an action A , is the product of its utility and its probability given A . The expected utility of an action A is the sum of the expected utilities of its outcomes relative to A :

$$EU(A) = [\text{prob}(O_1/A)U(O_1)] \\ + [\text{prob}(O_2/A)U(O_2)] + \dots$$

Here $EU(A)$ stands for the expected utility of A , $\text{prob}(O_i/A)$ for the probability of outcome O_i given A , and $U(O_i)$ for the utility of that outcome. Applied to Newcomb's paradox, using B for the action of opening only box B , and $A\&B$ for the action of opening both boxes, we have:

$$EU(B) = [\text{prob}(B \text{ is empty}/B)U(B \text{ is empty})] \\ + [\text{prob}(B \text{ is full}/B)U(B \text{ is full})] \\ = (1-h)0 + h 1,000,000.$$

$$EU(A\&B) = [\text{prob}(B \text{ is empty}/A\&B) \\ \times U(B \text{ is empty and } A \text{ is full})] \\ + [\text{prob}(B \text{ is full}/A\&B) \\ \times U(B \text{ is full and } A \text{ is full})] \\ = h1,000 + [(1-h)1,001,000].$$

Setting $h = 0.9$ makes $EU(B) = 900,000$ and $EU(A\&B) = 101,100$, giving a nearly ninefold advantage to taking just box B .

- Here I have taken for granted the notion of the probability an agent associates with an upshot. How is this probability determined, and how analyzed? My own preference is for the pioneering account in Ramsey [1926]. However, the reader should consult Jeffrey [1965]; and, for wider applications of probability, Kyburg [1961] and Levi [1967].
- 6 If you think that the arguments for one-boxing and for two-boxing are equally compelling, then you could see this as refuting the story (as in the case of the Barber). That is, you could see the unacceptable consequence as showing that there could not be a being capable of predicting free choices. For this line, see Schlesinger [1974]. See also a critical discussion by Benditt and Ross [1976], which makes some important distinctions.
- 7 Q: How would you respond to the following argument?
- It would come as wonderful news to learn that I am one-boxer, for then I will be able to infer that I will soon be rich. However, I can give myself that news simply by deciding to be a one-boxer. So this is what I should decide to do.
- 8 Q: We have envisaged the choice before you being a once-in-a-lifetime chance. However, suppose you know that you were going to be allowed to make this choice once a week for the rest of your life, and suppose the facts about the Predictor remain the same. What is the most rational policy to pursue?
- 9 Q: Consider a variant of the problem – let us call it the “sequential Newcomb.” The difference is that you are allowed to make your choice in two stages: You can elect to open box *B*, reserving your choice about box *A* until you find out what is in box *B*. Suppose you open *B* and there is nothing inside. Should you elect also to open *A*? Suppose you open *B* and there is \$1,000,000 inside. Should you elect also to open *A*? Do your answers have any implications for the original Newcomb?
- 10 Q: Consider a variant in which he has *mostly* been right in the past. Would this make any difference to the argument? Try working out what the MEU commends if we set the probability of the Predictor being right at 0.6.
- 11 Q: What are your own views on this point? Some people say that they wish they could believe in life after death. If this wish involves wishing that they could cease to be moved by the evidence *against* life after death, it is an example of the sort of desire whose reasonableness or rationality is in question.
- 12 Human frailty being what it is, no doubt social pressures would, in the envisaged circumstances, make one-boxers of all but the stoutest of us. This does not touch the question of what the *rational* course of action in such circumstances would be.

- 13 Q: Consider some familiar gambling game (e.g., roulette or poker). Can DP be used to say which bets in your selected game are rational? Assume that the only aim is to win as much money as possible.
- 14 Q: Israel is wondering whether to withdraw from territories it occupies. Egypt is wondering whether or not to go to war with Israel. From Israel’s point of view, the utilities are as follows:

	<i>Egypt declares war</i>	<i>Egypt does not declare war</i>
Israel withdraws	0	2
Israel remains	1	3

Show how this example can be used to demonstrate that DP does not always give correct results. (See Bar-Hillel and Margalit [1972]).

- 15 One could capture this by saying that the relevant probability, for a correct MEU, is not the conditional probability of an outcome upon an action, but rather the unconditional probability of a statement of the form “If I were to act thus, this would be the outcome.” This so-called counterfactual conditional requires for its truth something approaching the relation between act and upshot mentioned in the text: The act should *produce* the upshot. Compare Gibbard and Harper [1978].
- 16 Q: How would you respond to the following argument?

The dominance principle DP cannot conflict with the MEU principle, if by this is meant that there is a situation in which an action with maximum expected utility would fail to be preferred by the dominance principle. For any upshot, the probability of its occurring is the same regardless of the action, so the only relevant fact, for each upshot, is the utility. So MEU and DP cannot diverge. The table makes this plain:

	P_1	P_2
A_1	5	2
A_2	4	2

A_1 and A_2 are actions open to you. The possible outcomes are P_1 and P_2 . If you do A_1 and P_1 is the outcome, your utility is measured by the number 5. Likewise for the other cells in the table. The dominance principle commends A_1 in preference to A_2 . The MEU either does likewise or else is indifferent between A_1 and A_2 and in either case the principles do not conflict. To show this, let us call the agent’s probabilities of P_1 and P_2 respectively π_1 and π_2 . We do not know what these values are, but we can be sure that $5 \times \pi_1$ is greater than $4 \times \pi_1$, and that $2 \times \pi_2$

- is not greater than $2 \times \pi_2$. So MEU must either commend A_1 or else be neutral.
- 17 Compare: How could it be rational to be a two-boxer, if being a one-boxer would ensure that one would be a millionaire?
- 18 Q: Clarify the assumption behind the remark that if two people are rational, then for any problem both will reason about it in similar ways. Is the assumption justifiable?
- 19 Q: Using the numbers in the table in the text as the utilities of the various outcomes (prefix each with a minus sign to show that the outcomes are mostly undesirable), how could you assign conditional probabilities (using numbers between 0 and 1) in such a way as to make the expected utility of silence higher than that of confession? [For details, you may find it useful to refer to footnote 5 above.] Your assignment will justify the sentence in the text.
- 20 Q: Suppose, however, that all parties know in advance how many times they will be in this situation – fifty times, say. How would you state the case for the view that the most rational policy is always to confess?
- 21 Q: There are generalizations of which one could not be sure that one had encountered all the instances. What are some examples?
- 22 Q: Victims of the so-called Monte Carlo fallacy dispute this. They hold that the longer the run of successive reds on a fair roulette wheel the *less* likely it is that red will come up on the next spin. What, if anything, is wrong with this view? Is there anything right about it?
- 23 Q: How might answering this question fail to show that inductive reasoning is sometimes legitimate, and thus fail to be a complete answer to the problem of justification?
- 24 I should note a departure from Hempel's formulation – and his is the formulation used in almost all discussions. The equivalence relation he uses is that of *logical* equivalence, not a *priori* equivalence. Two propositions are logically equivalent just on condition that some system of formal logic has a theorem saying that either both propositions are true, or else both are false. Thus “Tom is a bachelor” and “Tom is a bachelor or the earth is round or not-round” are logically equivalent, but “Tom is a bachelor” and “Tom is an unmarried man” are not logically equivalent (though they can be known *a priori* to be equivalent). The intuitive motivation for the equivalence principle is this, in my view: If P and Q are in the appropriate sense equivalent, then if we can find evidence supporting P , we need no further empirical data to see that Q is thereby supported to the same extent. If this motivation is accepted, it seems clear that the appropriate equivalence relation is wider than logical equivalence, and is precisely, *a priori* equivalence.
- 25 The proof of equivalence may seem incomplete: The definition of equivalence also required that if R_2 is true, so is R_1 , and if R_2 is false, so is R_1 ; yet these issues were not explicitly addressed. However, classical logic has it that, for any propositions P and Q , the truth of
 If P is false, then Q is false
 ensures the truth of
 if Q is true, then P is true.
 Likewise classical logic has it that the truth of
 If P is true, then Q is true
 ensures the truth of
 If Q is false, then P is false.
 Given these implications of classical logic, what is said in the text *does* establish the equivalence of R_1 and R_2 .
- 26 Q: How does this follow?
- 27 There has been controversy about how Goodman defines “grue.” He writes that “grue” is to be introduced so that:
 it applies to all things examined before t just in case they are green but to other things just in case they are blue. (1955, p. 74)
 The time t is arbitrary, and was introduced on Goodman's previous page. In giving my account, I have imagined ourselves being at that time. For discussion of some alternative interpretations, see Jackson [1975].
- 28 Goodman [1955], p. 74:
 although we are well aware which of the two incompatible predictions [sic, “All emeralds subsequently examined will be green,” “All emeralds subsequently examined will be grue”] is genuinely confirmed, they are equally well confirmed according to our definition [of confirmation – a definition close to G1].
- 29 Q: An alternative presentation of the paradox identifies the apparently unacceptable conclusion as being that the same body of data can confirm the *inconsistent* hypotheses that all emeralds are green and that all emeralds are grue. Is it unthinkable that a body of data should confirm inconsistent hypotheses?
- 30 We could rework the paradox using “gives good reason to believe” rather than “confirms.” Our observations of emeralds, we suppose, give us good reason to believe that all emeralds are green. “Parity of reasoning” seems to require that our observations of emeralds also give us good reason to believe that they are all grue. If we tried to identify what this parity of reasoning consisted in, we would no doubt finger G1 or some very similar principle.
- 31 For his discussion of the problem, see Goodman [1955], esp. p. 97ff. Goodman's theory of entrenchment is more sophisticated than my very brief mention of it would suggest.
- 32 Cf. Jackson [1975]. It is no doubt true that Goodman's overall project would preclude him from accepting this version of G2 because it contains a subjunctive conditional (“If it had not been that . . . , it would not have been that . . .”).

- However, the current project is simply to address what I have called the problem of characterization (section 1.1), and it is unclear that any prohibition upon the use of subjunctive conditionals attends this project.
- 33 Q: How would G2 need to be modified for it to rule that, in this variant lobster case, our data do *not confirm* the generalization?
- 34 Q: How can one “prove” the Ravens Paradox using G3 rather than G1?
- 35 This point is made by Quine [1953].
- 36 I offer no view about whether believing or knowing are to be properly represented by an operator or by a predicate. Those who prefer the operator treatment will have to read “A1,” as it occurs in the formal argument, as short for “A1 is true.” Those who prefer the predicate treatment will have to read various expressions within the scope of K as names of (equiform) expressions, rather than as expressions in use. It may be worth reminding those familiar with these matters that Montague and Kaplan [1960] present the paradox using the predicate treatment to avert the suspicion that operators are to blame (see p. 272). Asher and Kamp [1986] take the Knower Paradox (discussed later in this section) to bear essentially on the question of what is the appropriate account of propositional attitude constructions.
- 37 Q: Would it be better to have A1 abbreviate the following? (M or T) and not- $K_M(M)$ and not- $K_T(T)$?
- 38 I hope that the intended structure of the argument will be self-explanatory, but some observations may be useful for those unused to seeing arguments presented in this sort of way. What is the difference between lines (7), (11), and (12)? Each has the same conclusion, but it has been reached from different suppositions. At (7), as the extra indent shows, the argument claims that we have reached *not-A1* on the basis of supposing that A1 is true and that not-M is true. This would mean that we have reached a contradiction: Since anything entails itself, the supposition of both A1 and not-M leads to the contradiction that A1 and not-A1. We must therefore reject at least one of these. Line (8) claims that if we hold on to A1, we must reject not-M (equivalently, T). At line (11), *not-A1* depends only on the supposition of A1 itself. In other words, at this point we have shown that A1 entails its own negation. This is enough to show that, on the basis of *no* suppositions at all, we can infer the falsehood of A1, since anything entailing its own negation is false, and this is what (12), by having *no* indent, expresses.
- 39 Q: Does this criticism also apply to (9)?
- 40 The argument is suspect at this point. We have supposedly proved M [at (10)] on the basis of K(A1). It is quite plausible to hold that this means that we can know the corresponding conditional, viz.:
- If $K(A1)$, then M.
- However, to obtain $K_M(M)$ from $K[\text{If } K(A1), \text{ then } M]$ would appear to require as a premise not merely $K(A1)$, but $K[K(A1)]$. We should avoid obtaining the latter by the dubious schema:
- If $K(\phi)$, then $K[K(\phi)]$.
- However, it could be argued that, in the envisaged case, $K(A1)$ would ensure $K[K(A1)]$: Nothing relevant to whether the class knows A1 would be unknown to it. Q: Why is this last principle—if $K(\phi)$, then $K[K(\phi)]$ —dubious?
- 41 Once one starts thinking about knowledge, one can rather easily convince oneself that there is less of it than one might have thought. So I would not be surprised if someone were to say, “We could not *know* that the teacher would carry out her threat, however reliable we knew her to have been in the past. The most we would be entitled to is the justified belief that she would.”
- Q: Rework MV1 in terms of justified belief rather than knowledge. (You will probably find you have to make an inference from “It was rational for the class to believe the teacher’s announcement when it was made” to “It would be rational for the class to believe the teacher’s announcement on the morning of the last day, if the exam had not yet been given.”) [Is this inference sound? Is the parallel inference in the case of knowledge sound? At what points was it assumed in the arguments displayed above?]
- 42 Cf. Montague and Kaplan [1960]. A similar paradox is in Buridan’s Sophism 13; see Hughes [1982].
- 43 Compare a similar line of argument in Burge [1978], p. 30.
- 44 Compare with the principle sometimes called “epistemic closure”:
- If $K(\text{if } \phi, \text{ then } \Psi)$ and $K(\phi)$, then $K(\Psi)$.
- Q: Is EK2 is entailed by the closure principle? Does the converse entailment hold?
- 45 Q: Provide the modified A3 (call it A4) and the appropriate argument, setting out the epistemic principles in detail.
- 46 A version of the Believer analogous to the “What I am now saying is false” version of the Liar would be as follows:
- The person now reading this sentence does not believe what it says.
- 47 For a different version of the argument, see Burge [1978], esp. p. 29.

Section 2: Fallacies and Rationality

Chapter 5: When Rationality Fails

JON ELSTER

1. Introduction

There are two ways in which theories can fail to explain: through indeterminacy and through inadequacy. A theory is indeterminate when and to the extent that it fails to yield unique predictions. It is inadequate when its predictions fail. Of these, the second is the more serious problem. A theory may be less than fully determinate and yet have explanatory power if it excludes at least one abstractly possible event or state of affairs. To yield a determinate prediction, it must then be supplemented by other considerations. The theory is weak, but not useless. It is in more serious trouble if an event or state of affairs that actually materializes is among those excluded by the theory. In saying this, I am not espousing naïve falsificationism, but simply making the common-sense observation that it is worse for a theory to predict wrongly than to predict weakly but truthfully.¹ In the former case it must be replaced or modified, not supplemented.

My concern here is not with scientific theories in general, but with failures of rational-choice theory. As argued below, rational-choice theory is first and foremost a normative theory and only secondarily an explanatory approach. It tells people how to act and predicts that they will act in the way it tells them to. To the extent that it fails to give unambiguous prescriptions, it is indeterminate. To the extent that people fail to follow its prescriptions – to the extent, that is, that they behave irrationally – the theory is inadequate. In this book as a whole, the emphasis is on the indeterminacy of rational-choice theory.² The inadequacy of the theory is also a constant theme, closely intertwined with that of indeterminacy. I argue, in fact, that failure to recognize

the indeterminacy of rational-choice theory can lead to irrational behaviour.

Let me sketch, as a foil to the later discussion, how the problems of indeterminacy and inadequacy arise in another normative domain – the theory of distributive justice. My point of departure will be John Rawls's view that theories of distributive justice are constrained by data, namely people's intuitions about particular moral problems.³ Any theory of justice can be judged, therefore, by the criteria of determinacy and adequacy. A theory of justice is determinate if it allows us to tell, at least in principle, how a given allocation problem should be resolved.⁴ It is adequate if its prescriptions about particular cases correspond to our considered intuitions about these cases. In addition, of course, the theory must be independently plausible – that is, correspond to some general moral principle that can be defended in abstraction from particular cases.

Among the major theories of justice, utilitarianism and Robert Nozick's theory are intended to be determinate. Rawls's theory is explicitly not advanced with this intention. It is concerned only with the justice of the basic structure of society,⁵ not with justice in particular contexts such as the allocation of scarce medical resources or the selection of soldiers for military service. For such problems, the theory has to be supplemented by local principles. I believe, although the argument cannot be made here,⁶ that none of the major theories is adequate. Each yields consequences that are strongly counterintuitive,⁷ even when we allow intuitions to be refined and modified *pari passu* with the construction of the theory. They stand

in need of being replaced rather than supplemented.

These remarks are also relevant to the methodology of rational choice. Like the theory of justice, the theory of rational choice is constrained at both ends. On the one hand, the notion of rationality has to be independently plausible as a normative account of human behaviour. On the other hand, it has to yield prescriptions about particular cases that fit our preanalytical notions about what is rational in such cases. As in the case of justice, these notions are somewhat elastic. As we construct a theory of what is rational, some intuitions about what is rational in particular contexts may change. In particular, theory may force determinacy on our intuitions in situations where initially they were indeterminate. The theoretical notion of an equilibrium, for instance, can serve as a guide to intuition and action when otherwise we would not know what to think or to do. Other, more recalcitrant intuitions can force us to modify the theory.⁸

In what follows, I first set out the bare bones of rational-choice theory (2), including a discussion of whether desires can be rational. I then consider failures of rationality that are due to a lack of determinacy (3) and go on to discuss failures due to a lack of adequacy (4). In the final section (5), I briefly discuss how rationality can be supplemented or replaced by other guides to action. In chapter IV of *Solomonic Judgements*, the same issues are examined with respect to political choices.

2. Rational Action

As I said, rational-choice theory is first and foremost normative.⁹ It tells us what we ought to do in order to achieve our aims as well as possible. It does not, in the standard version, tell us what our aims ought to be. (Some nonstandard comments on this problem are offered later.) From the normative account, we can derive an explanatory theory by assuming that people are rational in the normatively appropriate sense. The privileged, but not exclusive status of this assumption is discussed in 5.

The central explananda of rational-choice theory are *actions*. To explain an action, we must first verify that it stands in an optimizing relationship to the desires and beliefs of the agent. The action should be the best way of satisfying the agent's desires, given his beliefs. Moreover, we must demand that these desires and beliefs be themselves rational. At the very least, they

Figure 1.

must be internally consistent. With respect to beliefs, we must also impose a more substantive requirement of rationality: they should be optimally related to the evidence available to the agent. (The substantive rationality of desires is discussed later.) In forming their beliefs, the agents should consider all and only the relevant evidence, with no element being unduly weighted. As a logical extension of this requirement, we also demand that the collection of evidence itself be subject to the canons of rationality. The efficacy of action may be destroyed both by the gathering of too little evidence and by the gathering of too much. The optimal amount of evidence is determined partly by our desires: more important decisions make it rational to collect more evidence. It is determined partly by our prior beliefs about the likely cost, quality and relevance of various types of evidence. Schematically, these relations can be represented as in Figure 1.

Rational action, then, involves three optimizing operations: finding the best action, for given beliefs and desires; forming the best-grounded belief, for given evidence; and collecting the right amount of evidence, for given desires and prior beliefs. Here, desires are the unmoved movers, reflecting Hume's dictum that 'reason is, and ought only to be the slave of the passions'.¹⁰ Hume did not mean that reason ought to obey every whim and fancy of the passions. In particular, he would not have endorsed the direct shaping of reason by passion found in wishful thinking, illustrated by the blocked arrow in the diagram. To serve his master well, a slave must have some independence of execution; beliefs born of passion serve passion badly.¹¹

It follows from this sketch that rational-choice theory can go wrong at three levels, and that in each case the failure may be due either to indeterminacy or to irrationality. There may not exist a uniquely optimal action, belief or amount of evidence. Or people may fail to carry out the action, form the belief or collect the evidence as rationality requires them to do. Such failures of rationality are discussed in 3 and 4. Here I want

to consider whether one can impose substantive rationality conditions on the desires of the agent.¹² The first idea that comes to mind is that it is rational to have the desires and emotions having which tends to make one happy. The proposal, however, turns out to be flawed.

To have a strong desire for something that is manifestly out of reach can make one desperately unhappy. Sometimes it seems natural to say that desires such as this are irrational. A person with moderate means who is tormented by desires for expensive luxury goods might well be called irrational. But we would not usually say that a person who lives in a totalitarian regime is irrational if he does not get rid of the desires for freedom that makes him deeply miserable.¹³ Human beings are more than happiness machines:

Example 1. Psychiatric treatment of Soviet dissidents. The Serbsky Institute for Forensic Psychiatry in Moscow has become notorious for its treatment of political dissidents as mentally ill. 'Some psychiatrists have buttressed their argument about the dissenter's poor adaptation by pointing to the tenacity with which he acts out his beliefs despite the odds. . . . The dissenter does indeed operate in dangerous territory; the reaction of the regime is often harsh. But he is fully aware of the risks inherent in his non-conformist behaviour; his moral integrity compels him to take them. Some dissidents have parried the psychiatrists on this point by asking whether Lenin and his colleagues were "poorly adapted" when, in their struggle against the tsarist regime, they were constantly subject to harassment and arrest'.¹⁴

If anything, it is the conformist – the happy slave – rather than the dissident who appears to be irrational. Unconscious adaptation to the inevitable is a heteronomous mechanism, while rational desires must be autonomous.¹⁵ One cannot be rational if one is the plaything of psychic processes that, unbeknownst to oneself, shape one's desires and values. This preanalytical idea is at least as strong as the intuition that rational desires are desires having which one is happy. Sometimes the two ideas point in the same direction. People who always most want what they cannot get are neither autonomous nor happy. People who adapt to their environment by a process of conscious character planning are both autonomous and happy.¹⁶ At other times, as with the unconscious conformist and the autonomous dissident, the two ideas

diverge. Tocqueville captures this ambiguity of conformism when he asks, 'Should I call it a blessing of God, or a last malediction of His anger, this disposition of the soul that makes men insensible to extreme misery and often even gives them a sort of depraved taste for the cause of their afflictions?'¹⁷

Could one entertain a similar proposal with respect to belief rationality? Could one argue, that is, that it is rational to have the beliefs having which one tends to be happy? In general, we would expect that one's happiness is best promoted by having beliefs which are well grounded in the evidence, since these are by definition the beliefs most likely to be true. Successful action requires correct factual beliefs. Yet in special cases this connection fails. To keep away from dangerous substances it may be necessary to have an exaggerated notion about the dangers of drug abuse.¹⁸ High levels of motivation and achievement often require an unrealistically positive self-image, whereas people with more accurate self-perceptions tend to lose the motivations to go on with the business of living. They are sadder, but wiser.¹⁹

Example 2. Stability of marriage. 'Expectations about divorce are partly self-fulfilling because a higher expected probability of divorce reduces investments in specific capital and thereby raises the actual probability'.²⁰ 'It is far from clear that a bride and a groom would be well advised to believe, on their wedding day, that the probability of their divorce is as high as .40'.²¹ The low-probability expectations of divorce are only partly self-fulfilling. Our misplaced confidence in ourselves motivates us to achievements that make it somewhat less misplaced, but still less than fully justified.

A belief which is unjustified and indeed false may well be instrumentally useful, but it seems odd to call it rational. Rationality, as usually understood, is a variety of intentionality. For something to be rational, it has to be within the scope of conscious, deliberate action or reflection. Useful false beliefs obtain by fluke, not by conscious reflection upon the evidence. Although one cannot in the short run choose one's desires or one's emotional patterns, one can over time shape and bend them to some extent. Beliefs, by contrast, resist manipulation for instrumental purposes. Believing at will, for the sake of the good consequences of having the belief, is a self-defeating enterprise because one cannot – conceptually cannot – at one and

the same time believe something and believe that the belief has been adopted on noncognitive grounds.²² It is easy, therefore, to understand why exhortations to self-esteem, propagated by manuals on self-help therapy, have very limited success.²³

3. Indeterminacy

To explain and predict events or states of affairs, a theory must have determinate implications about what will happen under given initial conditions. Ideally, the implications should be not only determinate, but unique. Among all possible events or states, exactly one should be singled out by the theory. Outside quantum mechanics, this is the explanatory ideal of science. A theory which does not yield unique predictions is incomplete. It may still, of course, be vastly superior to there being no theory at all. It can be very valuable to know that certain things will *not* happen. Also, for practical purposes it may not matter much which of the events consistent with the theory is actually realized. This said, the prospect of unique prediction dominates and guides scientific work.

In economics, and increasingly in the other social sciences, the neoclassical theory of choice holds out the promise of uniqueness. By its relentless insistence that all behavior is maximizing, it can draw on a basic mathematical theorem which says that every well-behaved function has exactly one maximum in a well-behaved set.²⁴ Moreover, in economic contexts many functions and sets are well behaved in the relevant sense. For the consumer, there is usually exactly one consumption bundle that maximizes utility within the set of purchases that satisfy his budget constraint. For the producer, there is exactly one combination of the factors of production which maximizes profit per unit of output.

Here I discuss a variety of circumstances under which rational-choice theory fails to yield unique predictions. There may be *several* options which are equally and maximally good. More important, there may be *no* option with the property that it is at least as good as any other.

The problem of multiple optima is, with one notable exception, relatively trivial. It arises when the agent is indifferent between two or more alternatives, each of which is deemed superior to all others. In such cases, rational-choice theory must be supplemented by other approaches to predict which of the equi-optimal alternatives will actually be chosen or 'picked'.²⁵

If they are very similar to one another, it is not important to be able to make this prediction. Nobody cares which of two apparently identical soup cans on the supermarket shelf is chosen. If the options differ from one another in off-setting ways, as when a consumer is indifferent between two cars with different strengths and weaknesses, the choice is more consequential. The car dealers will certainly care about the choice. I believe, however, that most cases of this kind are better described by saying that the consumer is unable to rank and compare the options (as discussed later). If he really were indifferent, a reduction of one dollar in the price of one car should induce a clear preference, but I do not believe it usually would.

The exception referred to is game theory, in which multiple optima abound. In noncooperative games with solutions in mixed strategies, it can be shown that an agent will always be indifferent between the strategy prescribed to him by the solution and any other linear combination of the pure strategies that enter into the solution, always assuming that the other players stick to their solution behaviour. John Harsanyi argues that the lack of a good reason for the agent to conform to the solution in such cases is a flaw in game theory as traditionally conceived. In his substitute solution concept, only 'centroid' or equiprobabilistic mixed strategies are allowed. This proposal reflects the idea that when there are several optima, one is chosen at random by 'what amounts to an unconscious chance mechanism inside [the agent's] nervous system'.²⁶ Here rational choice is supplemented by a purely causal mechanism. I have more to say about randomized strategies in II.3 of *Solomonic Judgements*.

Nonexistence of rational choice is a more serious difficulty than nonunicity. The problem arises at all three levels distinguished earlier: when gathering evidence, when deriving beliefs from the given evidence, and when deriving an action from the given beliefs and desires. I shall consider them in the reverse order.

If the agent has an incomplete preference ordering, that is, is unable to compare and rank all the options in his feasible set, there may be no action which is optimal.²⁷ It would be misleading to say that the agent is irrational: having complete preferences is no part of what it means to be rational. On the contrary, to insist that preferences must be complete and all pairs of alternatives be comparable can be a form of hyperrationality – that is, of irrationality. Other forms of hyperrationality are considered in 4.

Example 3. Choice of career. 'Life is not long, and too much of it must not pass in idle deliberation how it shall be spent: deliberation, which those who begin it by prudence, and continue it with subtlety, must, after long expence of thought, conclude by chance. To prefer one future mode of life to another, upon just reasons, requires faculties which it has not pleased our Creator to give to us'.²⁸ Suppose that I am about to choose between going to law school or to a school of forestry – a choice not simply of career but of lifestyle. I am attracted to both professions, but I cannot rank and compare them.²⁹ If I had tried both for a lifetime, I might be able to make an informed choice between them. As it is, I know too little about them to make a rational decision. What often happens in such cases is that peripheral considerations move to the center. In my ignorance about the first decimal – whether my life will go better as a lawyer or as a forester – I look to the second decimal. Perhaps I opt for law school because that will make it easier for me to visit my parents on weekends. This way of deciding is as good as any – but it is not one that can be underwritten by rational choice as superior to, say, just tossing a coin.

The nonexistence of an optimal action can also arise because of peculiar features of the feasible set. In planning models with infinite horizons and no time discounting, one can run into the paradox that 'there is always an incentive to postpone consumption: on the other hand postponing consumption for ever is clearly not optimal'.³⁰ While a theoretical possibility, this problem is not central to actual decision making. By contrast, the difficulties stemming from incomplete preferences are real and important. In addition to the problem of intrapersonal comparisons of welfare referred to in Example 3, the difficulty of making interpersonal comparisons can prevent us from ranking the options, if the ranking takes account of the welfare others derive from them.³¹

At the next level, nonexistence of an optimal belief can arise in two ways: because of uncertainty and because of strategic interaction. 'Uncertainty' here means radical ignorance, the lack of ability to assign numerical probabilities to the possible outcomes associated with the various options. If such assignments are possible, we face a problem of decision making under risk, in which the rational decision rule – to maximize expected utility – can be counted on to yield

an optimal choice. Farmers deciding on a crop mix or doctors deciding whether to operate act under risk. They can rely on well-defined probabilities derived from past frequencies. Stock market speculators, soldiers and others who have to act in novel situations cannot rely on frequencies. If they have sufficient information and good judgement, they may be able to make good probability estimates to feed into the expected utility calculus. If they have little information or poor judgement, rationality requires them to abstain from forming and acting upon such estimates. To attempt to do so would, for them, be a form of hyperirrationality.

Example 4. Nuclear waste. 'Different geological mechanisms may be capable of generating the release of radioactive waste in the environment. Among these are groundwater flow, faulting, diapirism, erosion, fall of meteorites, magma intrusion, and modification of the drainage level of water. An approach to geological confinement is often sought by trying to quantify the probability of occurrence of any of these events and their nuisance value to man. Then, by combining these probabilities and nuisance values, one tries to assess the safety coefficient of the repository and to compare it to the accepted safety coefficient for present risks. This approach does not seem realistic to us *because basically the earth's development has not been a random phenomenon* (possibly apart from the fall of meteorites) and no geologist can seriously give reasonable figures for these probabilities'.³² Here is a case in which objective probabilities and judgemental, subjective probabilities are equally out of reach.

When the situation is recognized as one of uncertainty, rational-choice theory is limited, but not powerless. Sometimes we are able to dismiss an option in the presence of another that, regardless of which state of the world obtains, has better consequences. Having done this, however, we are often left with several options for each of which there is some state in which it has better consequences than one of the others. Decision theory tells us that in choosing among these we are allowed to take account only of the best and the worst consequences of each action.³³ This may also narrow the field a bit, but often more than one option will be left. In choosing among these, one may adopt the rule of thumb to choose the option with the best worst-consequences (maximin), but there are no grounds for saying that this is more rational than

to choose the option with best-consequences (maximax). To illustrate, consider the following matrix of outcomes as dependent on actions and states:

	S_1	S_2	S_3
A_1	3	4	5
A_2	1	2	8
A_3	2	0	7
A_4	0	0	6

Outcome A_4 can be excluded from consideration since under any state of affairs it yields worse consequences than A_2 . Among the remaining, A_3 can also be excluded since both its best consequence and its worst consequence are worse than those of A_2 . Of the remaining, maximin reasoning would make us prefer A_1 over A_2 , while maximax would lead to the opposite choice. Psychological theories may be able to explain which choice will be made, but rational-choice theory, by itself, is indeterminate.

A special case arises when we have to choose among several scientific theories. Let us assume that each theory assigns numerical probabilities to the events that can occur, but that the choice of one theory rather than another is a matter of uncertainty. Controversies about the effect of CO₂ release in the atmosphere are of this kind. As shown by Jørgen Aasness and Aanund Hylland in unpublished work, this kind of theoretical uncertainty is less devastating than total ignorance, since we can use the content of the theories even if we do not know which of them is correct. If we can assume that one of them is correct, many abstractly possible states of affairs can be excluded and the optimal decision may differ from what it would have been had there been no restrictions on what could happen.

To illustrate the point, assume that we have to choose between acts A_1 and A_2 . There are two theories T_1 and T_2 . According to T_1 , state S_1 occurs with probability $1/3$ and state S_2 with probability $2/3$. According to T_2 , state S_3 is certain to occur. The act-state matrix is the following:

	S_1	S_2	S_3
A_1	12	0	6
A_2	3	15	5

The best and worst outcomes of A_1 are, respectively, 12 and 0; those of A_2 , 15 and 3. Define now X as the set of all triples $(\frac{2}{3} \cdot b, \frac{1}{3} \cdot b, 1 - b)$, where b ranges from 0 to 1. X is a subset

of the set Y of all triples $(p_1, p_2, 1 - p_1 - p_2)$, with p_1 and p_2 ranging from 0 to 1. Y can be understood as the set of all abstractly possible probability vectors for the states S_i , whereas X is the restricted set that incorporates the information provided by the two theories. The standard theory of choice under uncertainty, defined over the full set Y , says that A_2 should be chosen, since it has a better best-consequence and a better worst-consequence than A_1 . On the restricted set, however, A_1 is the best choice. It has a utility of $2b + 6$, whereas A_2 yields only $2b + 5$.

.....

Consider next strategic interaction as an obstacle to rational-belief formation. Often, rational choice requires beliefs about choices to be made by other people. These beliefs, to be rational, must take account of the fact that these others are similarly forming beliefs about oneself and about each other. Sometimes, these beliefs are indeterminate, when the situation has multiple equilibria with different winners and losers. The games of Chicken and Battle of the Sexes are well-known examples. Each of these games has two equilibria, each of which is better for both players than the worst outcome and preferred by one party to the other equilibrium. In the absence of enforcement or commitment devices, there is no way in which a player can form a rational belief about what the other will do.³⁴

Example 5. Rational expectations. To make decisions about consumption and investment, economic agents must form expectations about the future state of the economy. According to an earlier view, these are 'adaptive expectations', or extrapolations from current and past states. This view is unsatisfactory, because it assumes that people react mechanically without using all the information available to them. For instance, following the quadrupling of oil prices in 1973, we would expect expectations to change more radically and rapidly than what would be predicted by the theory of adaptive expectations. The theory of rational expectations, which emerged as a dominant paradigm in the 1970s, assumes that people are forward looking, not backward looking, when forming their expectations and that, moreover, they make the best use of the information available to them. Essentially, people predict the future development of the economy using a correct economic model. Since expectations

are part of the model, rational expectations must be self-fulfilling. The problem³⁵ is that often there are several sets of expectations about the economy that, if held by everybody, would be self-fulfilling. In the absence of government intervention to eliminate some of the equilibria, rational agents will not be able to form mutually supporting, self-fulfilling expectations.

Uncertainty and strategic interaction, taken separately, create problems for rational belief formation. When both are present, they wreak havoc. In planning for war, generals are hindered both by uncertainty about whether their sophisticated systems will work and by strategic complexities. The old dictum – Don't base your plans on the enemy's intentions but on his capabilities – no longer applies, if it ever did, since generals are equally uncertain about the effectiveness of the weapons of the enemy (and about the degree of uncertainty among the generals on the other side).

Example 6. Explaining investment. 'The outstanding fact is the extreme precariousness of the basis of knowledge on which our estimates of prospective yield will have to be made. Our knowledge of the factors which will govern the yield of an investment some years hence is usually very slight and often negligible. If we speak frankly, we have to admit that our basis of knowledge for estimating the yield ten years hence of a railway, a copper mine, a textile factory, the goodwill of a patent medicine, an Atlantic liner, a building in the city of London amounts to little and sometimes to nothing; or even five years hence'.³⁶ For the special case of investment in research and innovation, this lack of foreknowledge decomposes into the elements of uncertainty and strategic interaction. On the one hand, the outcome of innovative activities is inherently uncertain. One may strike gold, or find nothing. As Humphrey Lyttelton is reported to have said, 'If I knew where jazz was going I'd be there already'. But suppose one could know how the chance of finding gold is related to the amount one has invested. Under the 'winner-take-all' system of modern industry, it also matters whether one finds it before others do. If other firms invest massively, the chances that a given firm will be first past the post may be too small to make the investment worth while. If other firms do not invest, the chances are much higher.

But if it is true of each firm that it should invest if and only if others do not, it has no basis for anticipating what others will do.³⁷ Entrepreneurs might as well follow Keynes's advice and be guided by their 'animal spirits'.

Finally, determinacy problems arise with respect to the optimal amount of information one should collect before forming an opinion. Information is useful, but costly to acquire. Ideally, the rational agent would strike a balance between these two considerations: he would acquire information up to the point at which the marginal cost of acquiring information equaled its expected marginal value. In some areas of decision making these calculations can be carried out with great accuracy. Thus 'To detect intestinal cancer, it has become common to perform a series of six inexpensive tests ('guaiacs') on a person's stool. The benefits of the first two tests are significant. However, when calculations are done for each of the last four tests to determine the costs of detecting a case of cancer (not even curing it), the costs are discovered to be \$49 150, \$469 534, \$4 724 695 and \$47 107 214, respectively. To some these calculations suggest that the routine should be reduced, say to a three-guaiac test'.³⁸

Sometimes it is impossible to estimate the marginal cost and benefit of information. Consider a general in the midst of battle who does not know the exact disposition of the enemy troops. The value of more information, while potentially great, cannot be ascertained. Determining the expected value would require a highly implausible ability to form numerical probability estimates concerning the possible enemy positions. (Indeterminacy of rational belief due to strategic interaction is important here.) The costs of acquiring information are equally elusive. The opportunity costs might be enormous, if the time spent gathering information offered the enemy a chance to attack or to prepare his defence, or they might be quite trivial. Under such circumstances, one might as well follow Napoleon's maxim 'On s'engage et puis on voit'.

In between these extremes – medical diagnosis and the conduct of battle – fall most everyday situations. The observations that a rational person should make 'greater investment in information when undertaking major than minor decisions',³⁹ while true, does not help him to decide *how* much to invest. That decision requires estimates about the probable costs and benefits of the search for information. Search

theories of unemployment, for instance, assume that the unemployed worker knows the distribution of job offers or at least the general shape of the distribution. Using this knowledge, he can calculate the optimal time spent searching for well-paid jobs. This argument is of dubious value. The doctor carrying out a medical diagnosis finds himself *many* times in the *same situation*. Most persons are unemployed only once or, if more than once, under widely diverging circumstances. They have no way of learning by experience what the job distribution looks like. To be sure, they know something about the job market, but there is no reason to think that they can piece together their bits of information to a reliable subjective distribution.⁴⁰ Similar arguments apply to many consumer decisions, like the purchase of a car or an apartment. People know that it makes sense to spend some time searching and that it would be pointless to search forever, but between these lower and upper limits there is usually an interval of indeterminacy.

4. Irrationality

In this section I survey some main varieties of irrationality, including, as a special case, hyperrationality. The latter notion is defined as *the failure to recognize the failure* of rational-choice theory to yield unique prescriptions or predictions. As in Kant's critique, the first task of reason is to recognize its own limitations and draw the boundaries within which it can operate. The irrational belief in the omnipotence of reason is what I call hyperrationality.

Failures to conform to well-defined prescriptions of rational-choice theory arise at all three levels distinguished in Figure 1. Consider first how actions can fail to relate optimally to given desires and beliefs. The paradigm case is weakness of will, characterized by the following features. (a) There is a *prima facie* judgement that *X* is good. (b) There is a *prima facie* judgement that *Y* is good. (c) There is an all-things-considered judgement that *X* is better than *Y*. (d) There is the fact that *Y* is chosen. Often, *X* is an act that is in the long-term interest of a person or corresponds to his moral will, whereas *Y* is a short-term impulse or a self-interested desire. There is no conceptual link, however, between weakness of will, myopia and selfishness.⁴¹

Example 7. Neo-Freudianism. Freud depicted two forms of human irrationality: being under

the sway of the pleasure-seeking id and being dominated by the rigid, compulsive superego. As bearer of the rational will, the ego is engaged in a two-front war against these two enemies. The nature of the id, ego and superego in Freud's theory is somewhat unclear. Are they separate homunculi, each with a will of its own and capable of engaging in strategic interaction with the others?⁴² Or, more soberly, are they conflicting tendencies of one and the same subject? In his recent reinterpretation of Freud's trichotomy, George Ainslie has clarified the matter.⁴³ The ego's struggle with the id is interpreted in terms of time preference functions with the peculiar feature that a larger delayed reward which is preferred to a small early reward when they are both in the distant future becomes less preferred when the time for choice approaches. (Think of a person who makes an appointment with his dentist and then cancels it the day before.) To avoid such weak-willed behaviour, the ego can ally itself with the future, for if the situation can be expected to recur, *bunching* of all the small rewards and of all the large rewards makes it easier to choose the latter. By its rigid, uncompromising character, however, bunching may be as crippling to rationality as the problem it was supposed to resolve. If the ego abdicates its will to get rid of the id, it substitutes one form of weakness of will for another. Even when the person sees that it makes sense to give himself a break, he cannot bring himself to do so.

There is another set of cases in which desires and beliefs can fail to bring about the end for which they provide reasons. They have been referred to as 'excess of will',⁴⁴ although they are not in any sense the contrary of weakness of will. Assume that if I do *X*, I shall bring about *Y*, which is what I most desire. Moreover, I am able to do *X*, in the straightforward sense in which I am able to raise my arm. The snag, however, is that *X* will bring about *Y* only if I do *X* without the intention to bring about *Y*. Doing *X* for the purpose of bringing about *Y* will not succeed. Examples of *X* and *Y* could be: drinking hot tea at bedtime and falling asleep; working hard and forgetting a humiliating experience; looking at erotic pictures and becoming sexually aroused; joining a political movement and achieving self-respect.⁴⁵ Further examples are discussed at more length below.

Figure 2.

It might appear that someone who does *X* to achieve *Y* acts rationally. He is doing what he believes is (let us assume) the best way of getting what he most desires. This would be true if the situation conformed to the standard scheme of action, depicted in Figure 2.

The scheme goes from beliefs and desires through the intention to the action and finally to the outcome of the action. There is no guarantee, of course, that the intended outcome will occur. The belief that *X* brings about *Y* could be mistaken. Extraneous factors might intervene. Actions that fail to bring about their intended outcomes for such reasons are not irrational. They fail, as it were, honourably. Matters stand differently when the failure is intrinsic to the action, as when the very intention to do *X* for the sake of *Y* interferes with the efficacy of *X* to bring about *Y*. This nonstandard scheme is shown in Figure 3.

Example 8. Don't wait for return of husband. This was the heading of a column in the *Miami Herald* (April 1987), in which Howard Halpern, a psychologist in private practice in New York City, answered the following question: 'I am a 57-year-old woman whose husband of 36 years has decided to live alone. We've sold our house and are living in separate dwellings. He speaks of "hope" and

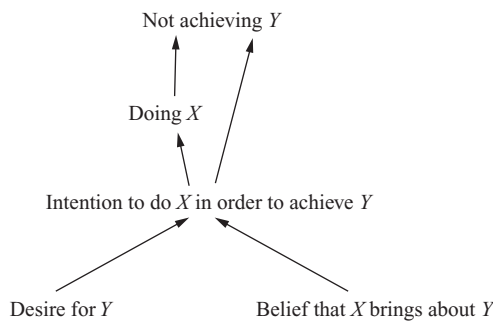

Figure 3.

"working things out", while happily living the single life. I am unable to get on with my life in such an independent manner. We've had a great deal of joint and individual therapy, but it has not restored our relationship. We've lived together for a few months in the past two years. Each time I thought we would get back together, but then he would leave again. Is there something I should be doing besides waiting?' Mr Halpern answered, 'When you use the word "waiting", I get the impression that you have put your life on hold until your husband's hoped-for return. It is time to stop waiting. By that I don't mean you should make your separation legal – I'm not suggesting any action in particular. I think you must accept your situation as real, understand that your husband may not return and refuse to let your life be dependent on his decision. You have already made efforts to get him to return. Now you must pay attention to your own life and outline your own goals. Focusing on yourself may make you more appealing to him, but that is not the reason to do it. You must do it for yourself'. It is hard to think of advice that would be more misguided. The remark that focusing on herself might make her more appealing to him, while obviously intended to motivate her efforts, is sure to ruin their effect.

Consider next the varieties of irrationality that arise at the level of beliefs and desires. These can be subverted and distorted by causal forces in two main ways: by drives and motivations or by inadequate cognitive processing. Since the end result can be a motivational state (a desire) or a cognitive one (a belief), we have four categories, which I now proceed to illustrate.

The Motivational Basis of Motivations

By this phrase, I do not have in mind conscious character planning, the shaping of preferences by metapreferences. Rather it refers to non-conscious motivational mechanisms that shape our desires 'behind our back'. The best known is what Festinger called 'cognitive dissonance reduction', the natural tendency of the mind to rearrange its desires and beliefs so as to reduce the tension created by high valuations of objects believed to be unattainable or low valuations of objects believed to be inescapable.⁴⁶ Also, being faced, like Buridan's ass, with two objects that appear equally attractive creates a form of

cognitive dissonance extensively discussed in chapter II of *Solomonic Judgements*.

Some applications of dissonance theory focus on the adjustments of beliefs, while others emphasize the motivated change in evaluations.

*Example 9. The Hungarian black market.*⁴⁷ One mechanism of dissonance reduction is 'I paid a lot for it, so it must be good'. A Hungarian coffee shop begins to offer high-quality coffee to customers who are willing to pay a bit extra. Since the shop has a limited quota of coffee beans, each customer who pays the high price creates an externality for the customers who pay the official price. The official cups of coffee being increasingly diluted, more and more customers are willing to pay the premium. Yet, as more and more do so, the quality of black-market coffee approaches the initial quality of the ordinary coffee. In the end, everybody pays the higher price for coffee of ordinary quality. It would appear, therefore, that everybody has lost, in a standard *n*-person Prisoner's Dilemma. The twist to the story is that because of cognitive dissonance nobody experiences any subjective loss. Since everyone is paying more for the coffee, it must be better than it used to be. The Prisoner's Dilemma yields a Pareto improvement: the shop keeper gains more and the customers are happy.

It is not obvious that desires shaped by dissonance reduction are, ipso facto, irrational. They do, after all, make people happier. Desires shaped by dissonance-increasing mechanisms are more obviously irrational. Many people, for instance, have a preference for novelty that gets them into trouble:

Example 10. What father does is always right. In H. C. Andersen's story of this name, a farmer goes to the market in the morning to sell or exchange his horse. First, he meets a man with a cow, which he likes so much that he exchanges it for the horse. In successive transactions, the cow is then exchanged for a sheep, the sheep for a goose, the goose for a hen and, finally, the hen for a sack, of rotten apples. The farmer's road to ruin is paved with stepwise improvements.⁴⁸ (Actually he is not ruined, because a pair of English tourists make and lose a bet that his wife will be angry with him when he comes back with the apples.) Although the story does not say so, it is likely that the farmer would have refused to exchange his horse for a sack full of rotten

apples. Curiosity and the thirst for novelty are triggered by options which are neither too similar nor too dissimilar from the current state.⁴⁹ In Johannes V. Jensen's story of the same name – a take-off on Andersen's classic tale – the farmer goes to the market with a set of rotten apples.⁵⁰ By a series of lucky accidents, he comes back with a horse. When he tells his wife about the deals, she manages to see each of them in an unfavourable light. Although the story is not fully clear on this point, it appears that she even thought a horse for a sack of apples a bad deal. Thus her perverse attitude can probably be explained by her belief that her husband cannot do anything right, not by an inherent conservatism that would be the converse of a preference for novelty. If the latter was the case, she would probably prefer the end state over the initial state, while being opposed to each of the intermediate steps.

The Motivational Basis of Cognitions

Dissonance reduction can also take the form of belief adjustment. Workers who take jobs in unsafe industries alter their estimated probabilities of accidents.⁵¹ As a result, when safety equipment becomes available, they may choose not to purchase it. Here, as in other cases, misformation of private beliefs (or preferences) creates a case for government intervention.⁵² In addition to direct motivational interference with the cognition, there can be indirect interference with the evidence on which cognition is based. People who dread having a dangerous disease put off seeing the doctor. People who fear they might be gaining weight avoid stepping on the scales.

Belief-oriented dissonance reduction is a form of wishful thinking. To the extent that it makes one feel happy, it might be thought to be a good thing. Usually, however, the pleasure of wishful thinking is of brief duration, like the warmth provided by pissing in one's pants. Acting on beliefs formed in this way can be disastrous and is likely to force a change in the beliefs. When action is not called for, the wishful beliefs can be more stable. The 'just-world' theory, for instance, suggests that people adjust their beliefs about guilt and responsibility so as to preserve their belief that the world is fundamentally just.⁵³ The best-known example is the 'blame the victim' syndrome, further discussed in II.8 *Solomonic Judgements*. While it would be perverse to say that blaming the victim is rational, it can certainly contribute to one's peace of mind.

Some forms of motivated belief formation do not even have that effect. The congenital pessimist, who systematically believes that the world is as he would *not* like it to be, creates dissonance instead of reducing it. Dissonance reduction, while a threat to autonomy and rationality, is at least intelligible in terms of the 'wirings of the pleasure machine', as Amos Tversky has put it. Dissonance production indicates that the wires have been crossed and that something is radically wrong.

The Cognitive Basis of Motivations

Under this heading fall the violations of expected utility theory that have been extensively studied over the past decade or so.⁵⁴ An important example is 'framing', that is, preference reversal induced by redescription of the choice situation.⁵⁵ People who would abstain from buying credit cards if firms impose a 3 per cent surcharge on card users may be less deterred if firms offer a 3 per cent discount on cash purchases.⁵⁶ Time preferences can be manipulated by presenting the difference between present and future consumption as a delay premium or as a speed-up cost.⁵⁷ These are examples in which the reference points or frames are imposed from the outside. A more intriguing problem arises if we ask about the principles that regulate spontaneous choice of frames.⁵⁸ It has been suggested that people choose the frame that induces the choice that makes them happy,⁵⁹ but it is far from obvious that nonconscious motivational mechanisms are capable of operating in this indirect manner.

Another set of deviations from expected utility theory arises because people do not treat known probabilities as the theory tells them to. (The problem comes on the top of their difficulties in estimating unknown probabilities.) Thus 'low probabilities are over-weighted, moderate and high probabilities are underweighted, and the latter effect is more pronounced than the former'.⁶⁰ In other words, people exaggerate the difference between impossible events and low-probability events and, especially, between near-certain and certain events. Attitudes towards nuclear accidents and other great disasters may, for this reason, include elements of irrationality. The point is *not* that it is irrational to feel anxiety at the prospect of a low-probability nuclear accident. What is irrational is that this attitude, when combined with other attitudes that may also appear unobjectionable in isolation, can be made to yield inconsistent choices. 'It is not easy

to determine whether people value the elimination of risk too much or the reduction of risk too little. The contrasting attitudes to the two [logically equivalent] forms of protective action, however, are difficult to justify on normative grounds'.⁶¹

The Cognitive Basis of Cognitions

There is by now a massive body of evidence showing how belief formation can fail because people rely on misleading heuristic principles or, more simply, ignore basic facts about statistical inference.⁶² Securities and futures markets seem excessively sensitive to current information.⁶³ Baseball trainers who notice that last season's star is not living up to his past performance are rapid to conclude that he has been spoiled by success, ignoring the statistical principle that, on the average, an outstanding performance is likely to be followed by one closer to average ('regression to the mean').⁶⁴ 'Labeling' theorists of mental illness cite as evidence for their theory the fact that the longer people have been in mental hospitals, the less likely they are to get well, ignoring the alternative explanation that the probabilities of getting well may differ across people but be constant over time.⁶⁵

Example 11. Calvinism. The previous two examples turn upon a confusion between causal and noncausal interpretation of the facts. Max Weber's interpretation of the affinity between Calvinism and economic activity invokes a similar tendency to infuse diagnostic facts with causal value. "Thus, however useless good works might be as a means of attaining salvation, for even the elect remain beings of the flesh, and everything they do falls infinitely short of divine standards, nevertheless, they are indispensable as a sign of election. They are the technical means, not of purchasing salvation, but of getting rid of the fear of damnation'.⁶⁶ It has been argued that the mechanism invoked here is motivational, a form of dissonance reduction.⁶⁷ It could, however, be a purely cognitive tendency to confuse diagnostic and causal efficacy. When people ask themselves, 'If not now, when?' and 'If not me, who?' they commit similar fallacies, albeit very useful ones.⁶⁸ People who open only one box in Newcomb's Problem do the same.⁶⁹

I conclude this section with a few remarks about hyperrationality. Since the concept is discussed extensively in later chapters of *Solomonic*

Judgements, especially in II.3 and II.8, I content myself here with a brief enumeration of some main varieties. (a) Sometimes people attempt to eliminate uncertainty of beliefs or incompleteness of preferences, although the choice situation is essentially indeterminate. It is always possible to devise questions that will force a person to reveal his preferences or subjective probabilities, but often there is no reason to believe in the robustness of the results. If the outcome depends on the procedures of elicitation, there is nothing 'out there' which is captured by the questions. (b) Sometimes people look to the second decimal when they are ignorant about the first. In some contexts, this method of problem solving is as good as any other. In others, it can be very wasteful, if people differ in their assessment of the second decimal and spend resources arguing about it. (c) Sometimes people will reframe an indeterminate decision problem so as to make it appear determinate. If one option stands out along one dimension, that dimension may take on increased importance so as to make the choice an easier one. (d) Sometimes people seek out what is rational to do in any given situation instead of looking for more general rules that cover many similar cases. Focusing on rules rather than acts can economize on costs of decision (see Chapter III of *Solomonic Judgements*) and also have superior incentive effects.⁷⁰ (e) Sometimes people ignore the costs of decision making. They search for the solution that would have been best if found instantaneously and costlessly, ignoring the fact that the search itself has costs that may detract from optimality.

5. Alternatives to Rationality

In light of earlier sections, several questions arise. How serious are these failures of rational-choice theory? Is there any reason to think that the theory has a privileged status in the study of human action? What are the alternative accounts that could supplement or replace the theory?

The failures of indeterminacy appear to me to be quite serious. One way of assessing the power of the theory is to distinguish choice situations by two criteria: the importance of the problem and the number of agents involved. 'Small' problems, that is, problems in which the options do not differ much in value from one another, do not lend themselves to the rational approach. Either the options are equally good or it is not clear that it would pay to find out which is the better, or pay to find out whether it will pay to find out. 'Large' problems,⁷¹ in which the choice

can be expected to have wide-ranging consequences, also tend to fall outside the scope of the theory. Preference rankings over big chunks of life tend to be incomplete, and subjective probabilities over events in the distant future tend to be unreliable. The theory is more powerful when applied to medium-sized problems like the purchase of a car or a house, but even here the question of optimal search is largely indeterminate.

Other things being equal, decision problems with one agent or with many agents are more likely to yield determinate solutions than problems with a small number of agents. By definition, one-agent problems have no strategic indeterminacy. With many sellers and many buyers, competition forces a unique set of equilibrium prices. With one seller and one buyer, there is often a large range of mutually acceptable outcomes and much indeterminacy concerning which outcome will be realized.⁷² A rough conclusion is that rational-choice theory is applicable mainly to one-agent and many-agent problems of intermediate size. Although precise quantification is impossible, indeterminacy is not a marginal problem that can be assimilated to 'friction' or 'noise'.

The factual importance of irrationality does not lend itself to a similarly systematic analysis. The central issue is whether people deal irrationally with important problems. The issue cannot be studied experimentally, since limitations on funding rarely allow stakes to be high enough and subjects to be numerous enough to get reliable results.⁷³ Introspection, casual observation, historical case studies and novels suggest that irrationality is quite widespread. Drug abuse is perhaps the most striking evidence. More generally, the widespread inability to be properly swayed by future consequences of present action points to a serious deficit in rationality.⁷⁴ Studies of 'group think'⁷⁵ suggest that political and military decisions are often made in disregard of the evidence. The motivated ignorance of the Holocaust is a massive example of irrational belief formation.⁷⁶ The vast sales of self-therapy manuals suggest that many people believe that they can talk themselves into self-confidence and self-respect. I could go on enumerating cases, but they would not add much to the general idea. Irrationality is neither marginal nor omnipresent.

Although indeterminacy and irrationality are widespread, they do not affect the normative privilege of rationality. First and foremost, rationality is privileged because we want to be rational.⁷⁷ We take little pride in our occasional

or frequent irrationality, although sometimes it has to be accepted as the price we pay for other things we value. In our dealings with people, we are compelled to treat them as, by and large, rational. Communication and discussion rest on the tacit premise that each interlocutor believes in the rationality of the others, since otherwise there would be no point to the exchange.⁷⁸ To understand others, we must assume that, by and large, they have rational desires and beliefs and act rationally upon them. If a person says that he wants *X* and yet deliberately refrains from using the means that he knows to be the most conducive to *X*, we usually conclude not that he is irrational but that he does not really want *X*. Sometimes, of course, we may conclude that irrationality offers the best explanation of a given kind of behaviour, but even then most of the evidence about the agent that goes into that conclusion is formed on the assumption that he is, by and large, rational.⁷⁹

The explanatory privilege of rationality rests on two grounds. As just observed, rationality is presupposed by any competing theory of motivation, whereas rationality itself does not presuppose anything else. On grounds of parsimony, therefore, we should begin by assuming nothing but rationality.⁸⁰ Also, while rationality may have its problems, the opposition is in even worse shape. The dictum that you cannot beat something with nothing applies here, with some modifications. As will be clear from what I shall say about the alternatives to rational-choice theory, they are more than nothing, but they do not quite amount to something either.

Herbert Simon's theory of satisficing is intended to supplement rational-choice theory when it is indeterminate.⁸¹ It has been applied to technical change,⁸² consumer choice,⁸³ and numerous other problems. The strength and main weakness of the theory are its realism. On the one hand, it is true and important that many people are happy once their aspiration level has been reached. They stop searching once they have found something that is good enough. On the other hand, there is to my knowledge no robust explanation of why people have the aspiration levels they do, nor of why they use the particular search rules they do. The theory describes behaviour, but does not really explain it. Now, one might say that a similar criticism applies to rational-choice theory, which does not, after all, explain why people have the preferences they do. The hypothesis that people behave rationally is nevertheless simpler, more general and more

powerful than the assumption that they are guided by their aspiration levels. In the theory of the firm, for instance, rational-choice theory needs only one assumption, namely that the firm maximizes profits. Satisficing theory needs many assumptions, stipulating one aspiration level for each of the many subroutines of the firm and, when that level is not attained, one search mechanism for each routine.

Simon's theory, and other theories in the same vein,⁸⁴ are intended to *supplement* rational-choice theory, both as a guide to and as an explanation of action. They are rarely intended to *replace* the rationality assumption. Proponents of these alternatives usually grant that rational-choice theory has substantial explanatory power in the absence of uncertainty, but add that most real-life decision making is characterized by a high degree of uncertainty that is costly or impossible to resolve. This is also the point of departure of the theory offered by Isaac Levi to guide and explain decision making under value conflicts and uncertainty.⁸⁵ Under conditions of unresolved value conflict, he recommends that we use lexicographically secondary values to decide among the options that are 'admissible' according to the primary, conflicting values, an admissible option being one that is optimal according to one of these values (or to some weighted average of them). Under conditions of uncertainty, he similarly recommends the use of *security* and *deferability* to supplement the expected-value criterion. Levi also argues that many apparent violations of rationality can be understood by assuming that the agents are acting in accordance with his prescriptions. Their choices reflect reasonable ways of coping with unresolved value conflicts and uncertainty rather than cognitive illusions of the kind discussed above.⁸⁶ Levi does not try, however, to account for all the apparent violations of expected utility theory.

Other theories, offered squarely as alternatives to rational-choice theory, aim to explain what they admit to be violations of rationality. They can be classified, very roughly, into psychological, biological and sociological alternatives to the economic approach to behaviour.

Psychological theories attempt to explain the observed violations of expected utility theory referred to earlier by providing an account that (a) is simple and intuitively plausible, (b) explains all observed deviations from expected utility theory and (c) predicts no unobserved deviations. Attempts to achieve this goal

include prospect theory,⁸⁷ generalized expected utility theory⁸⁸ and regret theory.⁸⁹ This is a field where nonexperts should tread warily, and I abstain from evaluating the various proposals, beyond making the presumably uncontroversial remark that only prospect theory appears to be capable of explaining framing phenomena. I note later, however, an apparent example of irrationality through framing that is more plausibly explained by a sociological alternative to rational-choice theory.

Biological alternatives take off from findings about animal behaviour. Animals can be constrained to choose between two responses, each of which has a particular reward schedule. In variable-ratio (VR) schedules we set up a constant probability of reward for each response. The one-armed bandit of the Las Vegas variety illustrates this reward schedule. It is a mechanism with no memory: if we hit the jackpot on one occasion, we are just as likely to hit it again the next time. In variable-interval (VI) schedules we set up a mechanism with memory, so that each unrewarded response increases the probability that the next response will be rewarded. In each period the experimenter uses a chance device, with constant probabilities, to decide whether food is to be made available. Once it has been made available, it stays available. The animal does not know, however, whether it is available. To find out, and to get the food, it must make the appropriate response.

The central question is whether animals allocate their attention optimally between the two responses, that is, whether they act to maximize their rewards. Faced with the choice between two VR schedules, animals often do the rational thing and allocate all their attention to the response with the highest probability of reward. Sometimes, however, they commit 'gambler's fallacy' of distributing the stakes in proportion to the odds. With two VI schedules, the findings are also ambiguous. In a VI-VR schedule, animals usually do not optimize. Instead of equalizing the marginal return of the two responses, as rationality would require them to do, they equalize the average return. They forget, as it were, that most of the VI rewards come from a few responses, and that it is not really profitable to pay attention to this schedule beyond visiting it from time to time to collect any reward that might have come due after its last visit.

Richard Herrnstein argues that the principle of equalizing average returns ('the matching law') is a more fundamental principle than

utility maximization.⁹⁰ In addition to explaining allocation of behaviour across schedules, it can explain the allocation over time. Specifically, the matching law predicts that time discounting will be steeper than the exponential discount functions usually stipulated by economists. Although the empirical verdict is not yet in, there is evidence that much animal and human discounting is nonexponential.⁹¹ On the other hand, the matching law explains only the most naïve forms of human behaviour. People can use conscious thought processes to analyse the structure of the choice situation. Unlike animals, they are not restricted to myopic learning. The matching law may describe 'prerational' behaviour, but it is powerless to explain more sophisticated choice processes.

A sociological alternative to the economic approach is the theory of social norms.⁹² I define social norms mainly by their non-outcome-oriented character. Whereas rationality tells people, 'If you want Y, do X', many social norms simply say, 'Do X'. Some social norms are hypothetical, but they make the action contingent on past behaviour of oneself or others, not on future goals. These norms say, 'If others do Y, do X' or 'If you have done Y, do X'. The norms are *social* if they satisfy two further conditions: they are shared with other members of the community and they are in part enforced by sanctions provided by others.

Here are some examples of social norms, chosen with a view to the contrast with rational action: (a) the norm of voting is very strong in Western democracies. It accounts for most voting in national elections.⁹³ Selfish voters have virtually nothing to gain from voting, while the costs are non-negligible. Altruistic voters might find voting rational, were it not for problems of strategic interaction. Altruistic voting is a game with multiple equilibria, in each of which most but not all voters go to the polls.⁹⁴ (b) The norm of vengeance practised in many traditional societies is triggered by an earlier offence, not motivated by future rewards. Indeed, from the future-oriented point of view vengeance is point-less at best, suicidal at worst. (c) In most Western societies there is a norm against walking up to someone in a cinema queue and asking to buy his place. The norm is puzzling, as nobody would lose and some could gain from the transaction. (d) Norms of dress and etiquette do not seem to serve any ulterior purpose, unlike for instance traffic rules that serve to prevent accidents.

Consider finally an example that could be explained both in terms of framing and in terms of social norms. Consider a suburban community where all houses have small lawns of the same size.⁹⁵ Suppose a houseowner is willing to pay his neighbour's son ten dollars to mow his lawn, but not more. He would rather spend half an hour mowing the lawn himself than pay eleven dollars to have someone else do it. Imagine now that the same person is offered twenty dollars to mow the lawn of another neighbour. It is easy to imagine that he would refuse, probably with some indignation. But this has an appearance of irrationality. By turning down the offer of having his neighbour's son mow his lawn for eleven dollars, he implies that half an hour of his time is worth at most eleven dollars. By turning down the offer to mow the other neighbour's lawn for twenty dollars, he implies that it is worth at least twenty dollars. But it cannot both be worth less than eleven and more than twenty dollars.

The explanation in terms of framing suggests⁹⁶ that people evaluate losses and gains for-gone differently. Credit card companies exploit this difference when they insist that stores advertise cash discounts rather than credit card surcharges. The credit card holder is affected less by the lost chance of getting the cash discount than by the extra cost of paying with the card. Similarly, the houseowner is affected more by the out-of-pocket expenses that he would incur by paying someone to mow his lawn than by the loss of a windfall income. But this cannot be the full story, because it does not explain why the houseowner should be indignant at the proposal. Part of the explanation must be that he does not think of himself as the kind of person who mows other people's lawns for money. It *isn't done*, to use a revealing phrase that often accompanies social norms.

Economists often argue that norms can be reduced to individual rationality. One version of the reductionist claim is that norms are 'nothing but' raw material for strategic manipulation; that people invoke norms to rationalize their self-interest while not believing in them. But this is absurd: if nobody believed in the norms, there would be nothing to manipulate.⁹⁷ A more serious reductionist argument proceeds from the fact that norms are maintained by sanctions. Suppose I face the choice between taking revenge for the murder of my cousin and not doing anything. The cost of revenge is that I might in turn be the target of countervengeance. The cost of not doing

anything is that my family and friends are certain to desert me, leaving me out on my own, defencelessly exposed to predators. A cost-benefit analysis is likely to tell me that revenge is the rational choice. More generally, norm-guided behaviour is supported by the threat of sanctions that make it rational to obey the norm.

Against this argument, each of the following objections is a sufficient refutation. First, sometimes norms are followed in the absence of any observers who could sanction violations. Many people vote even when nobody would notice if they did not. Second, we have to ask why anyone would want to impose the sanctions. Perhaps they follow a metanorm to sanction people who violate first-order norms, but then we have to ask whether it is rational to follow that norm. In the regress that now arises, there must come a point at which the cost of expressing disapproval is less than the cost of receiving disapproval for not expressing it, since the former cost is approximately constant while the second goes rapidly to zero. The chain of norms must have an unmoved mover, to which the rationalist reduction does not apply.

Among the alternatives to rational-choice theory, the (as yet undeveloped) theory of social norms holds out most promise. It is radically different from rational-choice theory, whereas the other alternatives are largely variations on the same consequentialist theme. They are different species of the same genus, whereas the theory of norms is of a different genus altogether. Other species of that genus might include the theory of neurotic behaviour, which is similarly rigid, mechanical and nonconsequentialist. Eventually, the goal of the social sciences must be to construct the family comprising both genera – to understand outcome-oriented motivations and nonconsequentialist ones as elements in a general theory of action. As long as this task is not accomplished, rational-choice theory will probably remain privileged, by virtue of the simplicity and power of the maximizing assumption. And in the event that it should one day be accomplished, rationality would still retain its privilege as a normative account of action.

Notes

- 1 The Popperian view that it is better to predict strongly than weakly, because strong predictions are more likely to be falsified and therefore more surprising if not falsified, is quite consistent with this assertion. Popper was concerned with the

- ex ante choice of research strategy, whereas I am here discussing ex post properties of predictions.
- 2 In Elster (1983a, 1984), the emphasis is mainly on cases of inadequacy.
 - 3 Rawls (1971), pp. 19–20.
 - 4 In practice, there are many obstacles to determinacy. Some theories require information about preferences and productive capacities that may be impossible to collect, if only because people may not find it in their interest to reveal them. Others require irretrievable information about events in the distant past or about hypothetical events that would have ensued if these past events had been different.
 - 5 Rawls (1971), p. 8.
 - 6 This is largely a euphemism for ‘I don’t yet have it’.
 - 7 Yaari and Bar-Hillel (1984); Frohlich, Oppenheimer and Eavey (1987).
 - 8 For an example, see Elster (1984), p. 121, n. 17. A recent debate of similar issues is Binmore (1987).
 - 9 The following draws heavily on Elster (1983a), ch. 1, and Elster (1986a).

 - 45 These examples and many others are extensively discussed in Elster (1985a), ch. 2.
 - 46 Festinger (1957, 1964); Wicklund and Brehm (1976). Economic applications include Akerlof and Dickens (1982) and Schlicht (1984).
 - 47 The example draws upon Galasi and Kertesi (1987).
 - 48 von Weizsäcker (1971) offers a formal model of this process.
 - 49 Middleton (1986).
 - 50 I am indebted to Hilde Sejersted for bringing this story to my attention.
 - 51 This example is taken from Akerlof and Dickens (1982). This otherwise excellent article is marred by the idea that people can choose their own beliefs so that, for instance, they can weigh the psychic benefits of believing that their job is safe against the cost of increased chances of accidents. Although I am sure that both the costs and the benefits of dissonance reduction influence

- the extent to which it occurs, I do not think they do so by virtue of conscious comparison since, as argued above, beliefs cannot be deliberately chosen.
- 52 Sunstein (1986) has a general discussion of such cases.
- 53 Lerner and Miller (1978).
- 54 A recent summary is Machina (1987).
- 55 Tversky and Kahneman (1981).
- 56 Thaler (1980).
- 57 Loewenstein (1987).
- 58 Fischhoff (1983).
- 59 Machina (1987), p. 146.
- 60 Tversky and Kahneman (1981), p. 454.
- 61 *Ibid.*, p. 456.
- 62 Good summaries are Nisbett and Ross (1981) and Kahneman, Slovic and Tversky, eds. (1982).
- 63 Arrow (1982).
- 64 Nisbett and Ross (1981), p. 164, referring to 'the sophomore slump'.
- 65 Gullestad and Tschudi (1982).
- 66 Weber (1985), p. 115.
- 67 Barry (1978), p. 41.
- 68 See Quattrone and Tversky (1986) for the latter fallacy and Elster (1985b) for a discussion of the former.
- 69 For exposition and discussion of this problem, see the articles collected in Campbell and Sowden, eds. (1985). A perfect illustration is a circular letter issued by English Baptists around 1770: 'Every soul that comes to Christ to be saved . . . is to be encouraged. . . . The coming soul need not fear that he is not elected, for none but such would be willing to come' (Thompson 1968, p. 38).
- 70 In addition, focusing on rules can protect one against weakness of will.
- 71 See Ullmann-Margalit (1985) for an analysis of 'big decisions' which nicely complements the analysis of 'small-decisions' in Ullmann-Margalit and Morgenbesser (1977).
- 72 Although noncooperative bargaining theory has done much to force determinacy in such problems (Rubinstein 1982), it is mainly of use in two-person contexts. Three-person bargaining problems remain largely indeterminate even in the noncooperative approach (Sutton 1986).
- 73 To get around this problem it has been suggested that in Third World countries experiments be conducted in which five- or ten-dollar rewards represent high stakes. To get around any ethical problems, all subjects could receive the maximal reward when the experiment was completed, even though told beforehand that they would get it only if they performed well. For reasons explained in Barry (1986), severe ethical problems would still remain.
- 74 Against those who say that discounting the future only shows a 'taste for the present' and that *de gustibus non est disputandum*, I would reply, first, that much time discounting is inconsistent (Elster 1985b) and, second, that even consistent time discounting beyond what is justified by mortality tables is a failure of rationality.
- 75 Janis (1972).
- 76 Laqueur (1980).
- 77 Føllesdal (1982).
- 78 Midgaard (1980); Habermas (1982).
- 79 Davidson (1980).
- 80 The situation is somewhat similar to the privileged status of the assumption of selfishness. We can consistently imagine a world in which everybody behaves selfishly all the time, but not a world in which everybody behaves altruistically all the time, because altruism presupposes some nonaltruistic pleasures that the altruist can promote.
- 81 I disregard the interpretation of satisficing as maximizing under constraints on information-processing capacities. Limited calculating ability is only one obstacle to first-best rationality. A more important obstacle, in my view, is our inherently limited knowledge about the value of information. Also, people with severely limited cognitive capacities may not be able to understand their limits and hence are not, subjectively, constrained by them.

- 83 Hey (1981, 1982).
- 84 Notably Heiner (1983, 1988).
- 85 Levi (1974, 1986).
- 86 Levi (1986), p. 33, shows that a perfectly sensible way of handling unresolved value conflicts can lead to violation of Sen's 'property alpha', which says that if a is chosen in the set (a, b) , b should never be chosen in a larger set (a, b, c) . Similarly he argues (Levi 1986, ch. 7) that the Ellsberg and Allais paradoxes of choice under risk can be handled without imputing irrationality to the agents who make these apparently inconsistent decisions.

Chapter 6: Extensional Versus Intuitive Reasoning: The Conjunction Fallacy in Probability Judgment

AMOS TVERSKY AND DANIEL KAHNEMAN

Uncertainty is an unavoidable aspect of the human condition. Many significant choices must be based on beliefs about the likelihood of such uncertain events as the guilt of a defendant, the result of an election, the future value of the dollar, the outcome of a medical operation, or the response of a friend. Because we normally do not have adequate formal models for computing the probabilities of such events, intuitive judgment is often the only practical method for assessing uncertainty.

The question of how lay people and experts evaluate the probabilities of uncertain events has attracted considerable research interest in the last decade (see, e.g., Einhorn & Hogarth, 1981; Kahneman, Slovic, & Tversky, 1982; Nisbett & Ross, 1980). Much of this research has compared intuitive inferences and probability judgments to the rules of statistics and the laws of probability. The student of judgment uses the probability calculus as a standard of comparison much as a student of perception might compare the perceived sizes of objects to their physical sizes. Unlike the correct size of objects, however, the “correct” probability of events is not easily defined. Because individuals who have different knowledge or who hold different beliefs must be allowed to assign different probabilities to the same event, no single value can be correct for all people. Furthermore, a correct probability cannot always be determined even for a single person. Outside the domain of random sampling, probability theory does not determine the probabilities of uncertain events – it merely imposes constraints on the relations among them. For

example, if A is more probable than B, then the complement of A must be less probable than the complement of B.

The laws of probability derive from extensional considerations. A probability measure is defined on a family of events and each event is construed as a set of possibilities, such as the three ways of getting a 10 on a throw of a pair of dice. The probability of an event equals the sum of the probabilities of its disjoint outcomes. Probability theory has traditionally been used to analyze repetitive chance processes, but the theory has also been applied to essentially unique events where probability is not reducible to the relative frequency of “favorable” outcomes. The probability that the man who sits next to you on the plane is unmarried equals the probability that he is a bachelor plus the probability that he is either divorced or widowed. Additivity applies even when probability does not have a frequentistic interpretation and when the elementary events are not equiprobable.

The simplest and most fundamental qualitative law of probability is the extension rule: If the extension of A includes the extension of B (i.e., $A \supset B$) then $P(A) \geq P(B)$. Because the set of possibilities associated with a conjunction A&B is included in the set of possibilities associated with B, the same principle can also be expressed by the conjunction rule $P(A\&B) \leq P(B)$: A conjunction cannot be more probable than one of its constituents. This rule holds regardless of whether A and B are independent and is valid for any probability assignment on the same sample space. Furthermore, it applies not

only to the standard probability calculus but also to nonstandard models such as upper and lower probability (Dempster, 1967; Suppes, 1975), belief function (Shafer, 1976), Baconian probability (Cohen, 1977), rational belief (Kyburg, 1983), and possibility theory (Zadeh, 1978).

In contrast to formal theories of belief, intuitive judgments of probability are generally not extensional. People do not normally analyze daily events into exhaustive lists of possibilities or evaluate compound probabilities by aggregating elementary ones. Instead, they commonly use a limited number of heuristics, such as representativeness and availability (Kahneman et al., 1982). Our conception of judgmental heuristics is based on *natural assessments* that are routinely carried out as part of the perception of events and the comprehension of messages. Such natural assessments include computations of similarity and representativeness, attributions of causality, and evaluations of the availability of associations and exemplars. These assessments, we propose, are performed even in the absence of a specific task set, although their results are used to meet task demands as they arise. For example, the mere mention of "horror movies" activates instances of horror movies and evokes an assessment of their availability. Similarly, the statement that Woody Allen's aunt had hoped that he would be a dentist elicits a comparison of the character to the stereotype and an assessment of representativeness. It is presumably the mismatch between Woody Allen's personality and our stereotype of a dentist that makes the thought mildly amusing. Although these assessments are not tied to the estimation of frequency or probability, they are likely to play a dominant role when such judgments are required. The availability of horror movies may be used to answer the question, "What proportion of the movies produced last year were horror movies?", and representativeness may control the judgment that a particular boy is more likely to be an actor than a dentist.

The term *judgmental heuristic* refers to a strategy – whether deliberate or not – that relies on a natural assessment to produce an estimation or a prediction. One of the manifestations of a heuristic is the relative neglect of other considerations. For example, the resemblance of a child to various professional stereotypes may be given too much weight in predicting future vocational choice, at the expense of other pertinent data such as the base-rate frequencies of occupations. Hence, the use of judgmental heuristics gives rise to predictable biases. Natural assess-

ments can affect judgments in other ways, for which the term *heuristic* is less apt. First, people sometimes misinterpret their task and fail to distinguish the required judgment from the natural assessment that the problem evokes. Second, the natural assessment may act as an anchor to which the required judgment is assimilated, even when the judge does not intend to use the one to estimate the other.

Previous discussions of errors of judgment have focused on deliberate strategies and on misinterpretations of tasks. The present treatment calls special attention to the processes of anchoring and assimilation, which are often neither deliberate nor conscious. An example from perception may be instructive: If two objects in a picture of a three-dimensional scene have the same picture size, the one that appears more distant is not only seen as "really" larger but also as larger in the picture. The natural computation of real size evidently influences the (less natural) judgment of picture size, although observers are unlikely to confuse the two values or to use the former to estimate the latter.

The natural assessments of representativeness and availability do not conform to the extensional logic of probability theory. In particular, a conjunction can be more representative than one of its constituents, and instances of a specific category can be easier to retrieve than instances of a more inclusive category. The following demonstration illustrates the point. When they were given 60 sec to list seven-letter words of a specified form, students at the University of British Columbia (UBC) produced many more words of the form *----ing* than of the form *-----n_*, although the latter class includes the former. The average numbers of words produced in the two conditions were 6.4 and 2.9, respectively, $t(44) = 4.70$, $p < .01$. In this test of availability, the increased efficacy of memory search suffices to offset the reduced extension of the target class.

Our treatment of the availability heuristic (Tversky & Kahneman, 1973) suggests that the differential availability of *ing* words and of *_n_* words should be reflected in judgments of frequency. The following questions test this prediction.

In four pages of a novel (about 2,000 words), how many words would you expect to find that have the form *----ing* (seven-letter words that end with "ing")? Indicate your best estimate by circling one of the values below:

0 1–2 3–4 5–7 8–10 11–15 16+.

A second version of the question requested estimates for words of the form *_____ n*. The median estimates were 13.4 for *ing* words ($n = 52$), and 4.7 for *_ n* words ($n = 53$, $p < .01$, by median test), contrary to the extension rule. Similar results were obtained for the comparison of words of the form *_____ly* with words of the form *_____l*; the median estimates were 8.8 and 4.4, respectively.

This example illustrates the structure of the studies reported in this article. We constructed problems in which a reduction of extension was associated with an increase in availability or representativeness, and we tested the conjunction rule in judgments of frequency or probability. In the next section we discuss the representativeness heuristic and contrast it with the conjunction rule in the context of person perception. The third section describes conjunction fallacies in medical prognoses, sports forecasting, and choice among bets. In the fourth section we investigate probability judgments for conjunctions of causes and effects and describe conjunction errors in scenarios of future events. Manipulations that enable respondents to resist the conjunction fallacy are explored in the fifth section, and the implications of the results are discussed in the last section.

Representative Conjunctions

Modern research on categorization of objects and events (Mervis & Rosch, 1983; Rosch, 1978; Smith & Medin, 1981) has shown that information is commonly stored and processed in relation to mental models, such as prototypes and schemata. It is therefore natural and economical for the probability of an event to be evaluated by the degree to which that event is representative of an appropriate mental model (Kahneman & Tversky, 1972, 1973; Tversky & Kahneman, 1971, 1982). Because many of the results reported here are attributed to this heuristic, we first briefly analyze the concept of representativeness and illustrate its role in probability judgment.

Representativeness is an assessment of the degree of correspondence between a sample and a population, an instance and a category, an act and an actor or, more generally, between an outcome and a model. The model may refer to a person, a coin, or the world economy, and the respective outcomes could be marital status, a sequence of heads and tails, or the current price of gold. Representativeness can be investigated empirically by asking people, for example, which

of two sequences of heads and tails is more representative of a fair coin or which of two professions is more representative of a given personality. This relation differs from other notions of proximity in that it is distinctly directional. It is natural to describe a sample as more or less representative of its parent population or a species (e.g., robin, penguin) as more or less representative of a superordinate category (e.g., bird). It is awkward to describe a population as representative of a sample or a category as representative of an instance.

When the model and the outcomes are described in the same terms, representativeness is reducible to similarity. Because a sample and a population, for example, can be described by the same attributes (e.g., central tendency and variability), the sample appears representative if its salient statistics match the corresponding parameters of the population. In the same manner, a person seems representative of a social group if his or her personality resembles the stereotypical member of that group. Representativeness, however, is not always reducible to similarity; it can also reflect causal and correlational beliefs (see, e.g., Chapman & Chapman, 1967; Jennings, Amabile, & Ross, 1982; Nisbett & Ross, 1980). A particular act (e.g., suicide) is representative of a person because we attribute to the actor a disposition to commit the act, not because the act resembles the person. Thus, an outcome is representative of a model if the salient features match or if the model has a propensity to produce the outcome.

Representativeness tends to covary with frequency: Common instances and frequent events are generally more representative than unusual instances and rare events. The representative summer day is warm and sunny, the representative American family has two children, and the representative height of an adult male is about 5 feet 10 inches. However, there are notable circumstances where representativeness is at variance with both actual and perceived frequency. First, a highly specific outcome can be representative but infrequent. Consider a numerical variable, such as weight, that has a unimodal frequency distribution in a given population. A narrow interval near the mode of the distribution is generally more representative of the population than a wider interval near the tail. For example, 68% of a group of Stanford University undergraduates ($N = 105$) stated that it is more representative for a female Stanford student "to weigh between 124 and 125 pounds" than "to weigh more than 135 pounds".

On the other hand, 78% of a different group ($N = 102$) stated that among female Stanford students there are more “women who weigh more than 135 pounds” than “women who weigh between 124 and 125 pounds.” Thus, the narrow modal interval (124–125 pounds) was judged to be more representative but less frequent than the broad tail interval (above 135 pounds).

Second, an attribute is representative of a class if it is very diagnostic, that is, if the relative frequency of this attribute is much higher in that class than in a relevant reference class. For example, 65% of the subjects ($N = 105$) stated that it is more representative for a Hollywood actress “to be divorced more than 4 times” than “to vote Democratic.” Multiple divorce is diagnostic of Hollywood actresses because it is part of the stereotype that the incidence of divorce is higher among Hollywood actresses than among other women. However, 83% of a different group ($N = 102$) stated that, among Hollywood actresses, there are more “women who vote Democratic” than “women who are divorced more than 4 times.” Thus, the more diagnostic attribute was judged to be more representative but less frequent than an attribute (voting Democratic) of lower diagnosticity. Third, an unrepresentative instance of a category can be fairly representative of a superordinate category. For example, chicken is a worse exemplar of a bird than of an animal, and rice is an unrepresentative vegetable, although it is a representative food.

The preceding observations indicate that representativeness is nonextensional: It is not determined by frequency, and it is not bound by class inclusion. Consequently, the test of the conjunction rule in probability judgments offers the sharpest contrast between the extensional logic of probability theory and the psychological principles of representativeness. Our first set of studies of the conjunction rule were conducted in 1974, using occupation and political affiliation as target attributes to be predicted singly or in conjunction from brief personality sketches (see Tversky & Kahneman, 1982, for a brief summary). The studies described in the present section replicate and extend our earlier work. We used the following personality sketches of two fictitious individuals, Bill and Linda, followed by a set of occupations and avocations associated with each of them.

Bill is 34 years old. He is intelligent, but unimaginative, compulsive, and generally lifeless. In school, he was strong in mathe-

matics but weak in social studies and humanities.

Bill is a physician who plays poker for a hobby.

Bill is an architect.

Bill is an accountant. (A)

Bill plays jazz for a hobby. (J)

Bill surfs for a hobby.

Bill is a reporter.

Bill is an accountant who plays jazz for a hobby. (A&J)

Bill climbs mountains for a hobby.

Linda is 31 years old, single, outspoken, and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations.

Linda is a teacher in elementary school.

Linda works in a bookstore and takes Yoga classes.

Linda is active in the feminist movement. (F)

Linda is a psychiatric social worker.

Linda is a member of the League of Women Voters.

Linda is a bank teller. (T)

Linda is an insurance salesperson.

Linda is a bank teller and is active in the feminist movement. (T&F)

As the reader has probably guessed, the description of Bill was constructed to be representative of an accountant (A) and unrepresentative of a person who plays jazz for a hobby (J). The description of Linda was constructed to be representative of an active feminist (F) and unrepresentative of a bank teller (T). We also expected the ratings of representativeness to be higher for the classes defined by a conjunction of attributes (A&J for Bill, T&F for Linda) than for the less representative constituent of each conjunction (J and T, respectively).

A group of 88 undergraduates at UBC ranked the eight statements associated with each description by “the degree to which Bill (Linda) resembles the typical member of that class.” The results confirmed our expectations. The percentages of respondents who displayed the predicted order ($A > A \& J > J$ for Bill; $F > T \& F > T$ for Linda) were 87% and 85%, respectively. This finding is neither surprising nor objectionable. If, like similarity and prototypicality, representativeness depends on both common and distinctive features (Tversky, 1977), it should be enhanced by the addition of shared features. Adding eyebrows to a schematic face makes it

Table 1: Tests of the Conjunction Rule in Likelihood Rankings

Subjects	Problem	Direct Test				Indirect Test		
		V	R(A & B)	R(B)	N	R(A & B)	R(B)	Total N
Naive	Bill	92	2.5	4.5	94	2.3	4.5	88
	Linda	89	3.3	4.4	88	3.3	4.4	86
Informed	Bill	86	2.6	4.5	56	2.4	4.2	56
	Linda	90	3.0	4.3	53	2.9	3.9	55
Sophisticated	Bill	83	2.6	4.7	32	2.5	4.6	32
	Linda	85	3.2	4.3	32	3.1	4.3	32

Note. V = percentage of violations of the conjunction rule; R (A & B) and R (B) = mean rank assigned to A & B and to B, respectively; N = number of subjects in the direct test; Total N = total number of subjects in the indirect test, who were about equally divided between the two groups.

more similar to another schematic face with eyebrows (Gati & Tversky, 1982). Analogously, the addition of feminism to the profession of bank teller improves the match of Linda's current activities to her personality. More surprising and less acceptable is the finding that the great majority of subjects also rank the conjunctions (A & J and T & F) as more *probable* than their less representative constituents (J and T). The following sections describe and analyze this phenomenon.

Indirect and Subtle Tests

Experimental tests of the conjunction rule can be divided into three types: *indirect tests*, *direct-subtle tests*, and *direct-transparent tests*. In the indirect tests, one group of subjects evaluates the probability of the conjunction, and another group of subjects evaluates the probability of its constituents. No subject is required to compare a conjunction (e.g., "Linda is a bank teller and a feminist") to its constituents. In the direct-subtle tests, subjects compare the conjunction to its less representative constituent, but the inclusion relation between the events is not emphasized. In the direct-transparent tests, the subjects evaluate or compare the probabilities of the conjunction and its constituent in a format that highlights the relation between them.

The three experimental procedures investigate different hypotheses. The indirect procedure tests whether probability judgments conform to the conjunction rule; the direct-subtle procedure tests whether people will take advantage of an opportunity to compare the critical events; the direct-transparent procedure tests whether people will obey the conjunction rule when they are compelled to compare the critical events. This sequence of tests also describes the

course of our investigation, which began with the observation of violations of the conjunction rule in indirect tests and proceeded – to our increasing surprise – to the finding of stubborn failures of that rule in several direct-transparent tests.

Three groups of respondents took part in the main study. The statistically *naive* group consisted of undergraduate students at Stanford University and UBC who had no background in probability or statistics. The *informed* group consisted of first-year graduate students in psychology and in education and of medical students at Stanford who were all familiar with the basic concepts of probability after one or more courses in statistics. The *sophisticated* group consisted of doctoral students in the decision science program of the Stanford Business School who had taken several advanced courses in probability, statistics, and decision theory.

Subjects in the main study received one problem (either Bill or Linda) first in the format of a direct test. They were asked to rank all eight statements associated with that problem (including the conjunction, its separate constituents, and five filler items) according to their probability, using 1 for the most probable and 8 for the least probable. The subjects then received the remaining problem in the format of an indirect test in which the list of alternatives included either the conjunction or its separate constituents. The same five filler items were used in both the direct and the indirect versions of each problem.

Table 1 presents the average ranks (R) of the conjunction R(A & B) and of its less representative constituents R(B), relative to the set of five filler items. The percentage of violations of the conjunction rule in the direct test is denoted by

V. The results can be summarized as follows: (a) the conjunction is ranked higher than its less likely constituents in all 12 comparisons, (b) there is no consistent difference between the ranks of the alternatives in the direct and indirect tests, (c) the overall incidence of violations of the conjunction rule in direct tests is 88%, which virtually coincides with the incidence of the corresponding pattern in judgments of representativeness, and (d) there is no effect of statistical sophistication in either indirect or direct tests.

The violation of the conjunction rule in a direct comparison of B to A & B is called the *conjunction fallacy*. Violations inferred from between-subjects comparisons are called *conjunction errors*. Perhaps the most surprising aspect of Table 1 is the lack of any difference between indirect and direct tests. We had expected the conjunction to be judged more probable than the less likely of its constituents in an indirect test, in accord with the pattern observed in judgments of representativeness. However, we also expected that even naive respondents would notice the repetition of some attributes, alone and in conjunction with others, and that they would then apply the conjunction rule and rank the conjunction below its constituents. This expectation was violated, not only by statistically naive undergraduates but even by highly sophisticated respondents. In both direct and indirect tests, the subjects apparently ranked the outcomes by the degree to which Bill (or Linda) matched the respective stereotypes. The correlation between the mean ranks of probability and representativeness was .96 for Bill and .98 for Linda. Does the conjunction rule hold when the relation of inclusion is made highly transparent? The studies described in the next section abandon all subtlety in an effort to compel the subjects to detect and appreciate the inclusion relation between the target events.

Transparent Tests

This section describes a series of increasingly desperate manipulations designed to induce subjects to obey the conjunction rule. We first presented the description of Linda to a group of 142 undergraduates at UBC and asked them to check which of two alternatives was more probable:

Linda is a bank teller. (T)

Linda is a bank teller and is active in the feminist movement. (T&F)

The order of alternatives was inverted for one half of the subjects, but this manipulation had no effect. Overall, 85% of respondents indicated that T&F was more probable than T, in a flagrant violation of the conjunction rule.

Surprised by the finding, we searched for alternative interpretations of the subjects' responses. Perhaps the subjects found the question too trivial to be taken literally and consequently interpreted the inclusive statement T as T & not-F; that is, "Linda is a bank teller and is *not* a feminist." In such a reading, of course, the observed judgments would not violate the conjunction rule. To test this interpretation, we asked a new group of subjects ($N = 119$) to assess the probability of T and of T & F on a 9-point scale ranging from 1 (extremely unlikely) to 9 (extremely likely). Because it is sensible to rate probabilities even when one of the events includes the other, there was no reason for respondents to interpret T as T & not-F. The pattern of responses obtained with the new version was the same as before. The mean ratings of probability were 3.5 for T and 5.6 for T & F, and 82% of subjects assigned a higher rating to T & F than they did to T.

Although subjects do not spontaneously apply the conjunction rule, perhaps they can recognize its validity. We presented another group of UBC undergraduates with the description of Linda followed by the two statements, T and T & F, and asked them to indicate which of the following two arguments they found more convincing.

Argument 1. Linda is more likely to be a bank teller than she is to be a feminist bank teller, because every feminist bank teller is a bank teller, but some women bank tellers are not feminists, and Linda could be one of them.

Argument 2. Linda is more likely to be a feminist bank teller than she is likely to be a bank teller, because she resembles an active feminist more than she resembles a bank teller.

The majority of subjects (65%, $n = 58$) chose the invalid resemblance argument (Argument 2) over the valid extensional argument (Argument 1). Thus, a deliberate attempt to induce a reflective attitude did not eliminate the appeal of the representativeness heuristic.

We made a further effort to clarify the inclusive nature of the event T by representing it as a disjunction. (Note that the conjunction rule can also be expressed as a disjunction rule $P(A \text{ or } B) \geq P(B)$.) The description of Linda was used

again, with a 9-point rating scale for judgments of probability, but the statement T was replaced by

Linda is a bank teller whether or not she is active in the feminist movement. (T*)

This formulation emphasizes the inclusion of T & F in T. Despite the transparent relation between the statements, the mean ratings of likelihood were 5.1 for T & F and 3.8 for T* ($p < .01$, by t test). Furthermore, 57% of the subjects ($n = 75$) committed the conjunction fallacy by rating T & F higher than T*, and only 16% gave a lower rating to T & F than to T*.

The violations of the conjunction rule in direct comparisons of T & F to T* are remarkable because the extension of "Linda is a bank teller whether or not she is active in the feminist movement" clearly includes the extension of "Linda is a bank teller and is active in the feminist movement." Many subjects evidently failed to draw extensional inferences from the phrase "whether or not," which may have been taken to indicate a weak disposition. This interpretation was supported by a between-subjects comparison, in which different subjects evaluated T, T*, and T & F on a 9-point scale after evaluating the common filler statement, "Linda is a psychiatric social worker." The average ratings were 3.3 for T, 3.9 for T*, and 4.5 for T & F, with each mean significantly different from both others. The statements T and T* are of course extensionally equivalent, but they are assigned different probabilities. Because feminism fits Linda, the mere mention of this attribute makes T* more likely than T, and a definite commitment to it makes the probability of T & F even higher!

Modest success in loosening the grip of the conjunction fallacy was achieved by asking subjects to choose whether to bet on T or on T & F. The subjects were given Linda's description, with the following instruction:

If you could win \$10 by betting on an event, which of the following would you choose to bet on? (Check one)

The percentage of violations of the conjunction rule in this task was "only" 56% ($n = 60$), much too high for comfort but substantially lower than the typical value for comparisons of the two events in terms of probability. We conjecture that the betting context draws attention to the conditions in which one bet pays off whereas the other does not, allowing some subjects to discover that a bet on T dominates a bet on T & F.

The respondents in the studies described in this section were statistically naive undergraduates at UBC. Does statistical education eradicate the fallacy? To answer this question, 64 graduate students of social sciences at the University of California, Berkeley and at Stanford University, all with credit for several statistics courses, were given the rating-scale version of the direct test of the conjunction rule for the Linda problem. For the first time in this series of studies, the mean rating for T & F (3.5) was lower than the rating assigned to T (3.8), and only 36% of respondents committed the fallacy. Thus, statistical sophistication produced a majority who conformed to the conjunction rule in a transparent test, although the incidence of violations was fairly high even in this group of intelligent and sophisticated respondents.

Elsewhere (Kahneman & Tversky, 1982a), we distinguished between positive and negative accounts of judgments and preferences that violate normative rules. A positive account focuses on the factors that produce a particular response; a negative account seeks to explain why the correct response was not made. The positive analysis of the Bill and Linda problems invokes the representativeness heuristic. The stubborn persistence of the conjunction fallacy in highly transparent problems, however, lends special interest to the characteristic question of a negative analysis: Why do intelligent and reasonably well-educated people fail to recognize the applicability of the conjunction rule in transparent problems? Postexperimental interviews and class discussions with many subjects shed some light on this question. Naive as well as sophisticated subjects generally noticed the nesting of the target events in the direct-transparent test, but the naive, unlike the sophisticated, did not appreciate its significance for probability assessment. On the other hand, most naive subjects did not attempt to defend their responses. As one subject said after acknowledging the validity of the conjunction rule, "I thought you only asked for my opinion."

The interviews and the results of the direct transparent tests indicate that naive subjects do not spontaneously treat the conjunction rule as decisive. Their attitude is reminiscent of children's responses in a Piagetian experiment. The child in the preconserver stage is not altogether blind to arguments based on conservation of volume and typically expects quantity to be conserved (Bruner, 1966). What the child fails to see is that the conservation argument is decisive

and should overrule the perceptual impression that the tall container holds more water than the short one. Similarly, naive subjects generally endorse the conjunction rule in the abstract, but their application of this rule to the Linda problem is blocked by the compelling impression that T & F is more representative of her than T is. In this context, the adult subjects reason as if they had not reached the stage of formal operations. A full understanding of a principle of physics, logic, or statistics requires knowledge of the conditions under which it prevails over conflicting arguments, such as the height of the liquid in a container or the representativeness of an outcome. The recognition of the decisive nature of rules distinguishes different developmental stages in studies of conservation; it also distinguishes different levels of statistical sophistication in the present series of studies.

More Representative Conjunctions

The preceding studies revealed massive violations of the conjunction rule in the domain of person perception and social stereotypes. Does the conjunction rule fare better in other areas of judgment? Does it hold when the uncertainty regarding the target events is attributed to chance rather than to partial ignorance? Does expertise in the relevant subject matter protect against the conjunction fallacy? Do financial incentives help respondents see the light? The following studies were designed to answer these questions.

Medical Judgment

In this study we asked practicing physicians to make intuitive predictions on the basis of clinical evidence.¹ We chose to study medical judgment because physicians possess expert knowledge and because intuitive judgments often play an important role in medical decision making. Two groups of physicians took part in the study. The first group consisted of 37 internists from the greater Boston area who were taking a postgraduate course at Harvard University. The second group consisted of 66 internists with admitting privileges in the New England Medical Center. They were given problems of the following type:

A 55-year-old woman had pulmonary embolism documented angiographically 10 days after a cholecystectomy.

Please rank order the following in terms of the probability that they will be among the conditions and experienced by the patient (use 1 for the most likely and 6 for the least likely). Naturally, the patient could experience more than one of these conditions.

dyspnea and hemiparesis (A & B)	syncope and tachycardia hemiparesis (B)
calf pain	hemoptysis
pleuritic chest pain	

The symptoms listed for each problem included one, denoted B, which was judged by our consulting physicians to be nonrepresentative of the patient's condition, and the conjunction of B with another highly representative symptom denoted A. In the above example of pulmonary embolism (blood clots in the lung), dyspnea (shortness of breath) is a typical symptom, whereas hemiparesis (partial paralysis) is very atypical. Each participant first received three (or two) problems in the indirect format, where the list included either B or the conjunction A & B, but not both, followed by two (or three) problems in the direct format illustrated above. The design was balanced so that each problem appeared about an equal number of times in each format. An independent group of 32 physicians from Stanford University were asked to rank each list of symptoms "by the degree to which they are representative of the clinical condition of the patient."

The design was essentially the same as in the Bill and Linda study. The results of the two experiments were also very similar. The correlation between mean ratings by probability and by representativeness exceeded .95 in all five problems. For every one of the five problems, the conjunction of an unlikely symptom with a likely one was judged more probable than the less likely constituent. The ranking of symptoms was the same in direct and indirect tests: The overall mean ranks of A & B and of B, respectively, were 2.7 and 4.6 in the direct tests and 2.8 and 4.3 in the indirect tests. The incidence of violations of the conjunction rule in direct tests ranged from 73% to 100%, with an average of 91%. Evidently, substantive expertise does not displace representativeness and does not prevent conjunction errors.

Can the results be interpreted without imputing to these experts a consistent violation of the conjunction rule? The instructions used

in the present study were especially designed to eliminate the interpretation of Symptom B as an exhaustive description of the relevant facts, which would imply the absence of Symptom A. Participants were instructed to rank symptoms in terms of the probability "that they will be among the conditions experienced by the patient." They were also reminded that "the patient could experience more than one of these conditions." To test the effect of these instructions, the following question was included at the end of the questionnaire:

In assessing the probability that the patient described has a particular symptom X, did you assume that (check one)

X is the *only* symptom experienced by the patient?

X is *among* the symptoms experienced by the patient?

Sixty of the 62 physicians who were asked this question checked the second answer, rejecting an interpretation of events that could have justified an apparent violation of the conjunction rule.

An additional group of 24 physicians, mostly residents at Stanford Hospital, participated in a group discussion in which they were confronted with their conjunction fallacies in the same questionnaire. The respondents did not defend their answers, although some references were made to "the nature of clinical experience." Most participants appeared surprised and dismayed to have made an elementary error of reasoning. Because the conjunction fallacy is easy to expose, people who committed it are left with the feeling that they should have known better.

Predicting Wimbledon

The uncertainty encountered in the previous studies regarding the prognosis of a patient or the occupation of a person is normally attributed to incomplete knowledge rather than to the operation of a chance process. Recent studies of inductive reasoning about daily events, conducted by Nisbett, Krantz, Jepson, and Kunda (1981), indicated that statistical principles (e.g., the law of large numbers) are commonly applied in domains such as sports and gambling, which include a random element. The next two studies test the conjunction rule in predictions of the outcomes of a sports event and of a game of chance, where the random aspect of the process is particularly salient.

A group of 93 subjects, recruited through an advertisement in the University of Oregon newspaper, were presented with the following problem in October 1980:

Suppose Bjorn Borg reaches the Wimbledon finals in 1981. Please rank order the following outcomes from most to least likely.

- A. Borg will win the match (1.7)
- B. Borg will lose the first set (2.7)
- C. Borg will lose the first set but win the match (2.2)
- D. Borg will win the first set but lose the match (3.5)

The average rank of each outcome (1 = most probable, 2 = second most probable, etc.) is given in parentheses. The outcomes were chosen to represent different levels of strength for the player, Borg, with A indicating the highest strength; C, a rather lower level because it indicates a weakness in the first set; B, lower still because it only mentions this weakness; and D, lowest of all.

After winning his fifth Wimbledon title in 1980, Borg seemed extremely strong. Consequently, we hypothesized that Outcome C would be judged more probable than Outcome B, contrary to the conjunction rule, because C represents a better performance for Borg than does B. The mean rankings indicate that this hypothesis was confirmed; 72% of the respondents assigned a higher rank to C than to B, violating the conjunction rule in a direct test.

Is it possible that the subjects interpreted the target events in a nonextensional manner that could justify or explain the observed ranking? It is well known that connectives (e.g., *and*, *or*, *if*) are often used in ordinary language in ways that depart from their logical definitions. Perhaps the respondents interpreted the conjunction (A and B) as a disjunction (A or B), an implication (A implies B), or a conditional statement (A if B). Alternatively, the event B could be interpreted in the presence of the conjunction as B and not A. To investigate these possibilities, we presented to another group of 56 naive subjects at Stanford University the hypothetical results of the relevant tennis match, coded as sequences of wins and losses. For example, the sequence LWWLW denotes a five-set match in which Borg lost (L) the first and the third sets but won (W) the other sets and the match. For each sequence the subjects were asked to examine the four target events of the original Borg problem and to indicate, by marking + or -, whether

the given sequence was consistent or inconsistent with each of the events.

With very few exceptions, all of the subjects marked the sequences according to the standard (extensional) interpretation of the target events. A sequence was judged consistent with the conjunction "Borg will lose the first set but win the match" when both constituents were satisfied (e.g., LWWLW) but not when either one or both constituents failed. Evidently, these subjects did not interpret the conjunction as an implication, a conditional statement, or a disjunction. Furthermore, both LWWLW and LWLWL were judged consistent with the inclusive event "Borg will lose the first set," contrary to the hypothesis that the inclusive event B is understood in the context of the other events as "Borg will lose the first set and the match." The classification of sequences therefore indicated little or no ambiguity regarding the extension of the target events. In particular, all sequences that were classified as instances of B&A were also classified as instances of B, but some sequences that were classified as instances of B were judged inconsistent with B&A, in accord with the standard interpretation in which the conjunction rule should be satisfied.

Another possible interpretation of the conjunction error maintains that instead of assessing the probability $P(B/E)$ of Hypothesis B (e.g., that Linda is a bank teller) in light of evidence E (Linda's personality), subjects assess the inverse probability $P(E/B)$ of the evidence given the hypothesis in question. Because $P(E/A \& B)$ may well exceed $P(E/B)$, the subjects' responses could be justified under this interpretation. Whatever plausibility this account may have in the case of Linda, it is surely inapplicable to the present study where it makes no sense to assess the conditional probability that Borg will reach the finals given the outcome of the final match.

Risky Choice

If the conjunction fallacy cannot be justified by a reinterpretation of the target events, can it be rationalized by a nonstandard conception of probability? On this hypothesis, representativeness is treated as a legitimate nonextensional interpretation of probability rather than as a fallible heuristic. The conjunction fallacy, then, may be viewed as a misunderstanding regarding the meaning of the word *probability*. To investigate this hypothesis we tested the conjunction rule in the following decision problem, which

provides an incentive to choose the most probable event, although the word *probability* is not mentioned.

Consider a regular six-sided die with four green faces and two red faces. The die will be rolled 20 times and the sequence of greens (G) and reds (R) will be recorded. You are asked to select one sequence, from a set of three, and you will win \$25 if the sequence you chose appears on successive rolls of the die. Please check the sequence of greens and reds on which you prefer to bet.

- (a) RGRRR
- (b) GRGRRR
- (c) GRRRRR

Note that Sequence 1 can be obtained from Sequence 2 by deleting the first G. By the conjunction rule, therefore, Sequence 1 must be more probable than Sequence 2. Note also that all three sequences are rather unrepresentative of the die because they contain more Rs than Gs. However, Sequence 2 appears to be an improvement over Sequence 1 because it contains a higher proportion of the more likely color. A group of 50 respondents were asked to rank the events by the degree to which they are representative of the die; 88% ranked Sequence 2 highest and Sequence 3 lowest. Thus, Sequence 2 is favored by representativeness, although it is dominated by Sequence 1.

A total of 260 students at UBC and Stanford University were given the choice version of the problem. There were no significant differences between the populations, and their results were pooled. The subjects were run in groups of 30 to 50 in a classroom setting. About one half of the subjects ($N = 125$) actually played the gamble with real payoffs. The choice was hypothetical for the other subjects. The percentages of subjects who chose the dominated option of Sequence 2 were 65% with real payoffs and 62% in the hypothetical format. Only 2% of the subjects in both groups chose Sequence 3.

To facilitate the discovery of the relation between the two critical sequences, we presented a new group of 59 subjects with a (hypothetical) choice problem in which Sequence 2 was replaced by RGRRRG. This new sequence was preferred over Sequence 1, RGRRR, by 63% of the respondents, although the first five elements of the two sequences were identical. These results suggest that subjects coded each sequence in terms of the proportion of Gs and Rs and ranked the sequences by the

discrepancy between the proportions in the two sequences (1/5 and 1/3) and the expected value of 2/3.

It is apparent from these results that conjunction errors are not restricted to misunderstandings of the word *probability*. Our subjects followed the representativeness heuristic even when the word was not mentioned and even in choices involving substantial payoffs. The results further show that the conjunction fallacy is not restricted to esoteric interpretations of the connective *and*, because that connective was also absent from the problem. The present test of the conjunction rule was direct, in the sense defined earlier, because the subjects were required to compare two events, one of which included the other. However, informal interviews with some of the respondents suggest that the test was subtle: The relation of inclusion between Sequences 1 and 2 was apparently noted by only a few of the subjects. Evidently, people are not attuned to the detection of nesting among events, even when these relations are clearly displayed.

Suppose that the relation of dominance between Sequences 1 and 2 is called to the subjects' attention. Do they immediately appreciate its force and treat it as a decisive argument for Sequence 1? The original choice problem (without Sequence 3) was presented to a new group of 88 subjects at Stanford University. These subjects, however, were not asked to select the sequence on which they preferred to bet but only to indicate which of the following two arguments, if any, they found correct.

Argument 1: The first sequence (RGRRR) is more probable than the second (GRGRRR) because the second sequence is the same as the first with an additional G at the beginning. Hence, every time the second sequence occurs, the first sequence must also occur. Consequently, you can win on the first and lose on the second, but you can never win on the second and lose on the first.

Argument 2: The second sequence (GRGRRR) is more probable than the first (RGRRR) because the proportions of R and G in the second sequence are closer than those of the first sequence to the expected proportions of R and G for a die with four green and two red faces.

Most of the subjects (76%) chose the valid extensional argument over an argument that formu-

lates the intuition of representativeness. Recall that a similar argument in the case of Linda was much less effective in combating the conjunction fallacy. The success of the present manipulation can be attributed to the combination of a chance setup and a gambling task, which promotes extensional reasoning by emphasizing the conditions under which the bets will pay off.

Fallacies and Misunderstandings

We have described violations of the conjunction rule in direct tests as a fallacy. The term *fallacy* is used here as a psychological hypothesis, not as an evaluative epithet. A judgment is appropriately labeled a fallacy when most of the people who make it are disposed, after suitable explanation, to accept the following propositions: (a) They made a nontrivial error, which they would probably have repeated in similar problems, (b) the error was conceptual, not merely verbal or technical, and (c) they *should* have known the correct answer or a procedure to find it. Alternatively, the same judgment could be described as a failure of communication if the subject misunderstands the question or if the experimenter misinterprets the answer. Subjects who have erred because of a misunderstanding are likely to reject the propositions listed above and to claim (as students often do after an examination) that they knew the correct answer all along, and that their error, if any, was verbal or technical rather than conceptual.

A psychological analysis should apply interpretive charity and should avoid treating genuine misunderstandings as if they were fallacies. It should also avoid the temptation to rationalize any error of judgment by ad hoc interpretations that the respondents themselves would not endorse. The dividing line between fallacies and misunderstandings, however, is not always clear. In one of our earlier studies, for example, most respondents stated that a particular description is more likely to belong to a physical education teacher than to a teacher. Strictly speaking, the latter category includes the former, but it could be argued that *teacher* was understood in this problem in a sense that excludes physical education teacher, much as *animal* is often used in a sense that excludes insects. Hence, it was unclear whether the apparent violation of the extension rule in this problem should be described as a fallacy or as a misunderstanding. A special effort was made in the present studies to avoid ambiguity by defining the critical event

Figure 1. Schematic representation of two experimental paradigms used to test the conjunction rule. (Solid and broken arrows denote strong positive and negative association, respectively, between the model *M*, the basic target *B*, and the added target *A*.)

as an intersection of well-defined classes, such as bank tellers and feminists. The comments of the respondents in postexperimental discussions supported the conclusion that the observed violations of the conjunction rule in direct tests are genuine fallacies, not just misunderstandings.

Causal Conjunctions

The problems discussed in previous sections included three elements: a causal model *M* (Linda's personality); a basic target event *B*, which is unrepresentative of *M* (she is a bank teller); and an added event *A*, which is highly representative of the model *M* (she is a feminist). In these problems, the model *M* is positively associated with *A* and is negatively associated with *B*. This structure, called the $M \rightarrow A$ paradigm, is depicted on the left-hand side of Figure 1. We found that when the sketch of Linda's personality was omitted and she was identified merely as a "31-year-old woman," almost all respondents obeyed the conjunction rule and ranked the conjunction (bank teller and active feminist) as less probable than its constituents. The conjunction error in the original problem is therefore attributable to the relation between *M* and *A*, not to the relation between *A* and *B*.

The conjunction fallacy was common in the Linda problem despite the fact that the stereotypes of bank teller and feminist are mildly incompatible. When the constituents of a conjunction are highly incompatible, the incidence of conjunction errors is greatly reduced. For example, the conjunction "Bill is bored by music and plays jazz for a hobby" was judged as less probable (and less representative) than its constituents, although "bored by music" was

perceived as a probable (and representative) attribute of Bill. Quite reasonably, the incompatibility of the two attributes reduced the judged probability of their conjunction.

The effect of compatibility on the evaluation of conjunctions is not limited to near contradictions. For instance, it is more representative (as well as more probable) for a student to be in the upper half of the class in both mathematics and physics or to be in the lower half of the class in both fields than to be in the upper half in one field and in the lower half in the other. Such observations imply that the judged probability (or representativeness) of a conjunction cannot be computed as a function (e.g., product, sum, minimum, weighted average) of the scale values of its constituents. This conclusion excludes a large class of formal models that ignore the relation between the constituents of a conjunction. The viability of such models of conjunctive concepts has generated a spirited debate (Jones, 1982; Osherson & Smith, 1981, 1982; Zadeh, 1982; Lakoff, Note 1).

The preceding discussion suggests a new formal structure, called the $A \rightarrow B$ paradigm, which is depicted on the right-hand side of Figure 1. Conjunction errors occur in the $A \rightarrow B$ paradigm because of the direct connection between *A* and *B*, although the added event, *A*, is not particularly representative of the model, *M*. In this section of the article we investigate problems in which the added event, *A*, provides a plausible cause or motive for the occurrence of *B*. Our hypothesis is that the strength of the causal link, which has been shown in previous work to bias judgments of conditional probability (Tversky & Kahneman, 1980), will also bias judgments of the probability of conjunctions (see Beyth-Marom, Note 2). Just as the thought of a personality and a social stereotype naturally evokes an assessment of their similarity, the thought of an effect and a possible cause evokes an assessment of causal impact (Ajzen, 1977). The natural assessment of propensity is expected to bias the evaluation of probability.

To illustrate this bias in the $A \rightarrow B$ paradigm consider the following problem, which was presented to 115 undergraduates at Stanford University and UBC:

A health survey was conducted in a representative sample of adult males in British Columbia of all ages and occupations.

Mr. F. was included in the sample. He was selected by chance from the list of participants.

Which of the following statements is more probable? (check one)

- Mr. F. has had one or more heart attacks.
- Mr. F. has had one or more heart attacks and he is over 55 years old.

This seemingly transparent problem elicited a substantial proportion (58%) of conjunction errors among statistically naive respondents. To test the hypothesis that these errors are produced by the causal (or correlational) link between advanced age and heart attacks, rather than by a weighted average of the component probabilities, we removed this link by uncoupling the target events without changing their marginal probabilities.

A health survey was conducted in a representative sample of adult males in British Columbia of all ages and occupations.

Mr. F. and Mr. G. were both included in the sample. They were unrelated and were selected by chance from the list of participants.

Which of the following statements is more probable? (check one)

- Mr. F. has had one or more heart attacks.
- Mr. F. has had one or more heart attacks and Mr. G. is over 55 year old.

Assigning the critical attributes to two independent individuals eliminates in effect the $A \rightarrow B$ connection by making the events (conditionally) independent. Accordingly, the incidence of conjunction errors dropped to 29% ($N = 90$).

The $A \rightarrow B$ paradigm can give rise to dual conjunction errors where $A \& B$ is perceived as more probable than each of its constituents, as illustrated in the next problem.

Peter is a junior in college who is training to run the mile in a regional meet. In his best race, earlier this season, Peter ran the mile in 4:06 min. Please rank the following outcomes from most to least probable.

- Peter will run the mile under 4:06 min.
- Peter will run the mile under 4 min.
- Peter will run the second half-mile under 1:55 min.
- Peter will run the second half-mile under 1:55 min, and will complete the mile under 4 min.
- Peter will run the first half-mile under 2:05 min.

The critical event (a sub-1:55 minute second half *and* a sub-4 minute mile) is clearly defined as a conjunction and not as a conditional. Nevertheless, 76% of a group of undergraduate students from Stanford University ($N = 96$) ranked it above one of its constituents, and 48% of the subjects ranked it above both constituents. The natural assessment of the relation between the constituents apparently contaminated the evaluation of their conjunction. In contrast, no one violated the extension rule by ranking the second outcome (a sub-4 minute mile) above the first (a sub-4:06 minute mile). The preceding results indicate that the judged probability of a conjunction cannot be explained by an averaging model because in such a model $P(A \& B)$ lies between $P(A)$ and $P(B)$. An averaging process, however, may be responsible for some conjunction errors, particularly when the constituent probabilities are given in a numerical form.

Motives and Crimes

A conjunction error in a motive-action schema is illustrated by the following problem – one of several of the same general type administered to a group of 171 students at UBC:

John P. is a meek man, 42 years old, married with two children. His neighbors describe him as mild-mannered, but somewhat secretive. He owns an import-export company based in New York City, and he travels frequently to Europe and the Far East. Mr. P. was convicted once for smuggling precious stones and metals (including uranium) and received a suspended sentence of 6 months in jail and a large fine.

Mr. P. is currently under police investigation.

Please rank the following statements by the probability that they will be among the conclusions of the investigation. Remember that other possibilities exist and that more than one statement may be true. Use 1 for the most probable statement, 2 for the second, etc.

- Mr. P. is a child molester.
- Mr. P. is involved in espionage and the sale of secret documents.
- Mr. P. is a drug addict.
- Mr. P. killed one of his employees.

One half of the subjects ($n = 86$) ranked the events above. Other subjects ($n = 85$) ranked a modified list of possibilities in which the last event was replaced by

Mr. P. killed one of his employees to prevent him from talking to the police.

Although the addition of a possible motive clearly reduces the extension of the event (Mr. P. might have killed his employee for other reasons, such as revenge or self-defense), we hypothesized that the mention of a plausible but nonobvious motive would increase the perceived likelihood of the event. The data confirmed this expectation. The mean rank of the conjunction was 2.90, whereas the mean rank of the inclusive statement was 3.17 ($p < .05$, by t test). Furthermore, 50% of the respondents ranked the conjunction as more likely than the event that Mr. P. was a drug addict, but only 23% ranked the more inclusive target event as more likely than drug addiction. We have found in other problems of the same type that the mention of a cause or motive tends to increase the judged probability of an action when the suggested motive (a) offers a reasonable explanation of the target event, (b) appears fairly likely on its own, (c) is nonobvious, in the sense that it does not immediately come to mind when the outcome is mentioned.

We have observed conjunction errors in other judgments involving criminal acts in both the $A \rightarrow B$ and the $M \rightarrow A$ paradigms. For example, the hypothesis that a policeman described as violence prone was involved in the heroin trade was ranked less likely (relative to a standard comparison set) than a conjunction of allegations – that he is involved in the heroin trade and that he recently assaulted a suspect. In that example, the assault was not causally linked to the involvement in drugs, but it made the combined allegation more representative of the suspect's disposition. The implications of the psychology of judgment to the evaluation of legal evidence deserve careful study because the outcomes of many trials depend on the ability of a judge or a jury to make intuitive judgments on the basis of partial and fallible data (see Rubinstein, 1979; Saks & Kidd, 1981).

Forecasts and Scenarios

The construction and evaluation of scenarios of future events are not only a favorite pastime of reporters, analysts, and news watchers. Scenarios are often used in the context of planning, and their plausibility influences significant decisions. Scenarios for the past are also important in many contexts, including criminal law and

the writing of history. It is of interest, then, to evaluate whether the forecasting or reconstruction of real-life events is subject to conjunction errors. Our analysis suggests that a scenario that includes a possible cause and an outcome could appear more probable than the outcome on its own. We tested this hypothesis in two populations: statistically naive students and professional forecasters.

A sample of 245 UBC undergraduates were requested in April 1982 to evaluate the probability of occurrence of several events in 1983. A 9-point scale was used, defined by the following categories: less than .01%, .1%, .5%, 1%, 2%, 5%, 10%, 25%, and 50% or more. Each problem was presented to different subjects in two versions: one that included only the basic outcome and another that included a more detailed scenario leading to the same outcome. For example, one half of the subjects evaluated the probability of

a massive flood somewhere in North America in 1983, in which more than 1000 people drown.

The other half of the subjects evaluated the probability of

an earthquake in California sometime in 1983, causing a flood in which more than 1000 people drown.

The estimates of the conjunction (earthquake and flood) were significantly higher than the estimates of the flood ($p < .01$, by a Mann-Whitney test). The respective geometric means were 3.1% and 2.2%. Thus, a reminder that a devastating flood could be caused by the anticipated California earthquake made the conjunction of an earthquake and a flood appear more probable than a flood. The same pattern was observed in other problems.

The subjects in the second part of the study were 115 participants in the Second International Congress on Forecasting held in Istanbul, Turkey, in July 1982. Most of the subjects were professional analysts, employed by industry, universities, or research institutes. They were professionally involved in forecasting and planning, and many had used scenarios in their work. The research design and the response scales were the same as before. One group of forecasters evaluated the probability of

a complete suspension of diplomatic relations between the USA and the Soviet Union, sometime in 1983.

The other respondents evaluated the probability of the same outcome embedded in the following scenario:

a Russian invasion of Poland, and a complete suspension of diplomatic relations between the USA and the Soviet Union, sometime in 1983.

Although *suspension* is necessarily more probable than *invasion and suspension*, a Russian invasion of Poland offered a plausible scenario leading to the breakdown of diplomatic relations between the superpowers. As expected, the estimates of probability were low for both problems but significantly higher for the conjunction *invasion and suspension* than for *suspension* ($p < .01$, by a Mann-Whitney test). The geometric means of estimates were .47% and .14%, respectively. A similar effect was observed in the comparison of the following outcomes:

a 30% drop in the consumption of oil in the US in 1983.

a dramatic increase in oil prices and a 30% drop in the consumption of oil in the US in 1983.

The geometric means of the estimated probability of the first and the second outcomes, respectively, were .22% and .36%. We speculate that the effect is smaller in this problem (although still statistically significant) because the basic target event (a large drop in oil consumption) makes the added event (a dramatic increase in oil prices) highly available, even when the latter is not mentioned.

Conjunctions involving hypothetical causes are particularly prone to error because it is more natural to assess the probability of the effect given the cause than the joint probability of the effect and the cause. We do not suggest that subjects deliberately adopt this interpretation; rather we propose that the higher conditional estimate serves as an anchor that makes the conjunction appear more probable.

Attempts to forecast events such as a major nuclear accident in the United States or an Islamic revolution in Saudi Arabia typically involve the construction and evaluation of scenarios. Similarly, a plausible story of how the victim might have been killed by someone other than the defendant may convince a jury of the existence of reasonable doubt. Scenarios can usefully serve to stimulate the imagination, to establish the feasibility of outcomes, or to set bounds on judged probabilities (Kirkwood &

Pollock, 1982; Zentner, 1982). However, the use of scenarios as a prime instrument for the assessment of probabilities can be highly misleading. First, this procedure favors a conjunctive outcome produced by a sequence of likely steps (e.g., the successful execution of a plan) over an equally probable disjunctive outcome (e.g., the failure of a careful plan), which can occur in many unlikely ways (Bar-Hillel, 1973; Tversky & Kahneman, 1973). Second, the use of scenarios to assess probability is especially vulnerable to conjunction errors. A detailed scenario consisting of causally linked and representative events may appear more probable than a subset of these events (Slovic, Fischhoff, & Lichtenstein, 1976). This effect contributes to the appeal of scenarios and to the illusory insight that they often provide. The attorney who fills in guesses regarding unknown facts, such as motive or mode of operation, may strengthen a case by improving its coherence, although such additions can only lower probability. Similarly, a political analyst can improve scenarios by adding plausible causes and representative consequences. As Pooh-Bah in the *Mikado* explains, such additions provide "corroborative details intended to give artistic verisimilitude to an otherwise bald and unconvincing narrative."

Extensional Cues

The numerous conjunction errors reported in this article illustrate people's affinity for non-extensional reasoning. It is nonetheless obvious that people can understand and apply the extension rule. What cues elicit extensional considerations and what factors promote conformity to the conjunction rule? In this section we focus on a single estimation problem and report several manipulations that induce extensional reasoning and reduce the incidence of the conjunction fallacy. The participants in the studies described in this section were statistically naive students at UBC. Mean estimates are given in parentheses.

A health survey was conducted in a sample of adult males in British Columbia, of all ages and occupations. Please give your best estimate of the following values:

What percentage of the men surveyed have had one or more heart attacks? (18%)

What percentage of the men surveyed both are over 55 years old and have had one or more heart attacks? (30%)

This version of the health-survey problem produced a substantial number of conjunction errors among statistically naive respondents: 65% of the respondents ($N = 147$) assigned a strictly higher estimate to the second question than to the first.² Reversing the order of the constituents did not significantly affect the results.

The observed violations of the conjunction rule in estimates of relative frequency are attributed to the $A \rightarrow B$ paradigm. We propose that the probability of the conjunction is biased toward the natural assessment of the strength of the causal or statistical link between age and heart attacks. Although the statement of the question appears unambiguous, we considered the hypothesis that the respondents who committed the fallacy had actually interpreted the second question as a request to assess a conditional probability. A new group of UBC undergraduates received the same problem, with the second question amended as follows:

Among the men surveyed who are over 55 years old, what percentage have had one or more heart attacks?

The mean estimate was 59% ($N = 55$). This value is significantly higher than the mean of the estimates of the conjunction (45%) given by those subjects who had committed the fallacy in the original problem. Subjects who violate the conjunction rule therefore do not simply substitute the conditional $P(B/A)$ for the conjunction $P(A \& B)$.

A seemingly inconsequential change in the problem helps many respondents avoid the conjunction fallacy. A new group of subjects ($N = 159$) were given the original questions but were also asked to assess the "percentage of the men surveyed who are over 55 years old" prior to assessing the conjunction. This manipulation reduced the incidence of conjunction error from 65% to 31%. It appears that many subjects were appropriately cued by the requirement to assess the relative frequency of both classes before assessing the relative frequency of their intersection.

The following formulation also facilitates extensional reasoning:

A health survey was conducted in a sample of 100 adult males in British Columbia, of all ages and occupations. Please give your best estimate of the following values:

How many of the 100 participants have had one or more heart attacks?

How many of the 100 participants both are over 55 years old and have had one or more heart attacks?

The incidence of the conjunction fallacy was only 25% in this version ($N = 117$). Evidently, an explicit reference to the number of individual cases encourages subjects to set up a representation of the problems in which class inclusion is readily perceived and appreciated. We have replicated this effect in several other problems of the same general type. The rate of errors was further reduced to a record 11% for a group ($N = 360$) who also estimated the number of participants over 55 years of age prior to the estimation of the conjunctive category. The present findings agree with the results of Beyth-Marom (Note 2), who observed higher estimates for conjunctions in judgments of probability than in assessments of frequency.

The results of this section show that nonextensional reasoning sometimes prevails even in simple estimates of relative frequency in which the extension of the target event and the meaning of the scale are completely unambiguous. On the other hand, we found that the replacement of percentages by frequencies and the request to assess both constituent categories markedly reduced the incidence of the conjunction fallacy. It appears that extensional considerations are readily brought to mind by seemingly inconsequential cues. A contrast worthy of note exists between the effectiveness of extensional cues in the health-survey problem and the relative inefficacy of the methods used to combat the conjunction fallacy in the Linda problem (argument, betting, "whether or not"). The force of the conjunction rule is more readily appreciated when the conjunctions are defined by the intersection of concrete classes than by a combination of properties. Although classes and properties are equivalent from a logical standpoint, they give rise to different mental representations in which different relations and rules are transparent. The formal equivalence of properties to classes is apparently not programmed into the lay mind.

Discussion

In the course of this project we studied the extension rule in a variety of domains; we tested more than 3,000 subjects on dozens of problems, and we examined numerous variations of these problems. The results reported in this article constitute a representative though not exhaustive summary of this work.

The data revealed widespread violations of the extension rule by naive and sophisticated subjects in both indirect and direct tests. These results were interpreted within the framework of judgmental heuristics. We proposed that a judgment of probability or frequency is commonly biased toward the natural assessment that the problem evokes. Thus, the request to estimate the frequency of a class elicits a search for exemplars, the task of predicting vocational choice from a personality sketch evokes a comparison of features, and a question about the co-occurrence of events induces an assessment of their causal connection. These assessments are not constrained by the extension rule. Although an arbitrary reduction in the extension of an event typically reduces its availability, representativeness, or causal coherence, there are numerous occasions in which these assessments are higher for the restricted than for the inclusive event. Natural assessments can bias probability judgment in three ways: The respondents (a) may use a natural assessment deliberately as a strategy of estimation, (b) may be primed or anchored by it, or (c) may fail to appreciate the difference between the natural and the required assessments.

Logic Versus Intuition

The conjunction error demonstrates with exceptional clarity the contrast between the extensional logic that underlies most formal conceptions of probability and the natural assessments that govern many judgments and beliefs. However, probability judgments are not always dominated by nonextensional heuristics. Rudiments of probability theory have become part of the culture, and even statistically naive adults can enumerate possibilities and calculate odds in simple games of chance (Edwards, 1975). Furthermore, some real-life contexts encourage the decomposition of events. The chances of a team to reach the playoffs, for example, may be evaluated as follows: "Our team will make it if we beat team B, which we should be able to do since we have a better defense, or if team B loses to both C and D, which is unlikely since neither one has a strong offense." In this example, the target event (reaching the playoffs) is decomposed into more elementary possibilities that are evaluated in an intuitive manner.

Judgments of probability vary in the degree to which they follow a decompositional or a holistic approach and in the degree to which the assessment and the aggregation of probabilities

are analytic or intuitive (see, e.g., Hammond & Brehmer, 1973). At one extreme there are questions (e.g., What are the chances of beating a given hand in poker?) that can be answered by calculating the relative frequency of "favorable" outcomes. Such an analysis possesses all the features associated with an extensional approach: It is decompositional, frequentistic, and algorithmic. At the other extreme, there are questions (e.g., What is the probability that the witness is telling the truth?) that are normally evaluated in a holistic, singular, and intuitive manner (Kahneman & Tversky, 1982b). Decomposition and calculation provide some protection against conjunction errors and other biases, but the intuitive element cannot be entirely eliminated from probability judgments outside the domain of random sampling.

A direct test of the conjunction rule pits an intuitive impression against a basic law of probability. The outcome of the conflict is determined by the nature of the evidence, the formulation of the question, the transparency of the event structure, the appeal of the heuristic, and the sophistication of the respondents. Whether people obey the conjunction rule in any particular direct test depends on the balance of these factors. For example, we found it difficult to induce naive subjects to apply the conjunction rule in the Linda problem, but minor variations in the health-survey question had a marked effect on conjunction errors. This conclusion is consistent with the results of Nisbett et al. (1981), who showed that lay people can apply certain statistical principles (e.g., the law of large numbers) to everyday problems and that the accessibility of these principles varied with the content of the problem and increased significantly with the sophistication of the respondents. We found, however, that sophisticated and naive respondents answered the Linda problem similarly in indirect tests and only parted company in the most transparent versions of the problem. These observations suggest that statistical sophistication did not alter intuitions of representativeness, although it enabled the respondents to recognize in direct tests the decisive force of the extension rule.

Judgment problems in real life do not usually present themselves in the format of a within-subjects design or of a direct test of the laws of probability. Consequently, subjects' performance in a between-subjects test may offer a more realistic view of everyday reasoning. In the indirect test it is very difficult even for a sophisticated judge to ensure that an event has no subset

that would appear more probable than it does and no superset that would appear less probable. The satisfaction of the extension rule could be ensured, without direct comparisons of A & B to B, if all events in the relevant ensemble were expressed as disjoint unions of elementary possibilities. In many practical contexts, however, such analysis is not feasible. The physician, judge, political analyst, or entrepreneur typically focuses on a critical target event and is rarely prompted to discover potential violations of the extension rule.

Studies of reasoning and problem solving have shown that people often fail to understand or apply an abstract logical principle even when they can use it properly in concrete familiar contexts. Johnson-Laird and Wason (1977), for example, showed that people who err in the verification of *if then* statements in an abstract format often succeed when the problem evokes a familiar schema. The present results exhibit the opposite pattern: People generally accept the conjunction rule in its abstract form (B is more probable than A & B) but defy it in concrete examples, such as the Linda and Bill problems, where the rule conflicts with an intuitive impression.

The violations of the conjunction rule were not only prevalent in our research, they were also sizable. For example, subjects' estimates of the frequency of seven-letter words ending with *ing* were three times as high as their estimates of the frequency of seven letter words ending with *_n_*. A correction by a factor of three is the smallest change that would eliminate the inconsistency between the two estimates. However, the subjects surely know that there are many *_n_* words that are not *ing* words (e.g., *present*, *content*). If they believe, for example, that only one half of the *_n_* words end with *ing*, then a 6:1 adjustment would be required to make the entire system coherent. The ordinal nature of most of our experiments did not permit an estimate of the adjustment factor required for coherence. Nevertheless, the size of the effect was often considerable. In the rating-scale version of the Linda problem, for example, there was little overlap between the distributions of ratings for T & F and for T. Our problems, of course, were constructed to elicit conjunction errors, and they do not provide an unbiased estimate of the prevalence of these errors. Note, however, that the conjunction error is only a symptom of a more general phenomenon: People tend to overestimate the probabilities of representative (or available) events and/or underestimate the probabili-

ties of less representative events. The violation of the conjunction rule demonstrates this tendency even when the "true" probabilities are unknown or unknowable. The basic phenomenon may be considerably more common than the extreme symptom by which it was illustrated.

Previous studies of the subjective probability of conjunctions (e.g., Bar-Hillel, 1973; Cohen & Hansel, 1957; Goldsmith, 1978; Wyer, 1976; Beyth-Marom, Note 2) focused primarily on testing the multiplicative rule $P(A \& B) = P(B)P(A/B)$. This rule is strictly stronger than the conjunction rule; it also requires cardinal rather than ordinal assessments of probability. The results showed that people generally overestimate the probability of conjunctions in the sense that $P(A \& B) > P(B)P(A/B)$. Some investigators, notably Wyer and Beyth-Marom, also reported data that are inconsistent with the conjunction rule.

Conversing Under Uncertainty

The representativeness heuristic generally favors outcomes that make good stories or good hypotheses. The conjunction *feminist bank teller* is a better hypothesis about Linda than *bank teller*, and the scenario of a Russian invasion of Poland followed by a diplomatic crisis makes a better story than simply *diplomatic crisis*. The notion of a good story can be illuminated by extending the Gricean concept of cooperativeness (Grice, 1975) to conversations under uncertainty. The standard analysis of conversation rules assumes that the speaker knows the truth. The maxim of quality enjoins him or her to say only the truth. The maxim of quantity enjoins the speaker to say all of it, subject to the maxim of relevance, which restricts the message to what the listener needs to know. What rules of cooperativeness apply to an uncertain speaker, that is, one who is uncertain of the truth? Such a speaker can guarantee absolute quality only for tautological statements (e.g., "Inflation will continue so long as prices rise"), which are unlikely to earn high marks as contributions to the conversation. A useful contribution must convey the speaker's relevant beliefs even if they are not certain. The rules of cooperativeness for an uncertain speaker must therefore allow for a trade-off of quality and quantity in the evaluation of messages. The expected value of a message can be defined by its information value if it is true, weighted by the probability that it is true. An uncertain speaker may wish to follow the maxim of value: Select the message that has the highest expected value.

The expected value of a message can sometimes be improved by increasing its content, although its probability is thereby reduced. The statement "Inflation will be in the range of 6% to 9% by the end of the year" may be a more valuable forecast than "Inflation will be in the range of 3% to 12%," although the latter is more likely to be confirmed. A good forecast is a compromise between a point estimate, which is sure to be wrong, and a 99.9% credible interval, which is often too broad. The selection of hypotheses in science is subject to the same trade-off: A hypothesis must risk refutation to be valuable, but its value declines if refutation is nearly certain. Good hypotheses balance informativeness against probable truth (Good, 1971). A similar compromise obtains in the structure of natural categories. The basic level category *dog* is much more informative than the more inclusive category *animal* and only slightly less informative than the narrower category *beagle*. Basic level categories have a privileged position in language and thought, presumably because they offer an optimal combination of scope and content (Rosch, 1978). Categorization under uncertainty is a case in point. A moving object dimly seen in the dark may be appropriately labeled *dog*, where the subordinate *beagle* would be rash and the superordinate *animal* far too conservative.

Consider the task of ranking possible answers to the question, "What do you think Linda is up to these days?" The maxim of value could justify a preference for T & F over T in this task, because the added attribute *feminist* considerably enriches the description of Linda's current activities, at an acceptable cost in probable truth. Thus, the analysis of conversation under uncertainty identifies a pertinent question that is legitimately answered by ranking the conjunction above its constituent. We do not believe, however, that the maxim of value provides a fully satisfactory account of the conjunction fallacy. First, it is unlikely that our respondents interpret the request to rank statements by their probability as a request to rank them by their expected (informational) value. Second, conjunction fallacies have been observed in numerical estimates and in choices of bets, to which the conversational analysis simply does not apply. Nevertheless, the preference for statements of high expected (informational) value could hinder the appreciation of the extension rule. As we suggested in the discussion of the interaction of picture size and real size, the answer to a question can be biased by the availability of an answer

to a cognate question – even when the respondent is well aware of the distinction between them.

The same analysis applies to other conceptual neighbors of probability. The concept of surprise is a case in point. Although surprise is closely tied to expectations, it does not follow the laws of probability (Kahneman & Tversky, 1982b). For example, the message that a tennis champion lost the first set of a match is more surprising than the message that she lost the first set but won the match, and a sequence of four consecutive heads in a coin toss is more surprising than four heads followed by two tails. It would be patently absurd, however, to bet on the less surprising event in each of these pairs. Our discussions with subjects provided no indication that they interpreted the instruction to judge probability as an instruction to evaluate surprise. Furthermore, the surprise interpretation does not apply to the conjunction fallacy observed in judgments of frequency. We conclude that surprise and informational value do not properly explain the conjunction fallacy, although they may well contribute to the ease with which it is induced and to the difficulty of eliminating it.

Cognitive Illusions

Our studies of inductive reasoning have focused on systematic errors because they are diagnostic of the heuristics that generally govern judgment and inference. In the words of Helmholtz (1881/1903), "It is just those cases that are not in accordance with reality which are particularly instructive for discovering the laws of the processes by which normal perception originates." The focus on bias and illusion is a research strategy that exploits human error, although it neither assumes nor entails that people are perceptually or cognitively inept. Helmholtz's position implies that perception is not usefully analyzed into a normal process that produces accurate percepts and a distorting process that produces errors and illusions. In cognition, as in perception, the same mechanisms produce both valid and invalid judgments. Indeed, the evidence does not seem to support a "truth plus error" model, which assumes a coherent system of beliefs that is perturbed by various sources of distortion and error. Hence, we do not share Dennis Lindley's optimistic opinion that "inside every incoherent person there is a coherent one trying to get out" (Lindley, Note 3), and we suspect that incoherence is more than skin deep (Tversky & Kahneman, 1981).

It is instructive to compare a structure of beliefs about a domain (e.g., the political future of Central America) to the perception of a scene (e.g., the view of Yosemite Valley from Glacier Point). We have argued that intuitive judgments of all relevant marginal, conjunctive, and conditional probabilities are not likely to be coherent, that is, to satisfy the constraints of probability theory. Similarly, estimates of distances and angles in the scene are unlikely to satisfy the laws of geometry. For example, there may be pairs of political events for which $P(A)$ is judged greater than $P(B)$ but $P(A/B)$ is judged less than $P(B/A)$ – see Tversky and Kahneman (1980). Analogously, the scene may contain a triangle ABC for which the A angle appears greater than the B angle, although the BC distance appears to be smaller than the AC distance.

The violations of the qualitative laws of geometry and probability in judgments of distance and likelihood have significant implications for the interpretation and use of these judgments. Incoherence sharply restricts the inferences that can be drawn from subjective estimates. The judged ordering of the sides of a triangle cannot be inferred from the judged ordering of its angles, and the ordering of marginal probabilities cannot be deduced from the ordering of the respective conditionals. The results of the present study show that it is even unsafe to assume that $P(B)$ is bounded by $P(A \& B)$. Furthermore, a system of judgments that does not obey the conjunction rule cannot be expected to obey more complicated principles that presuppose this rule, such as Bayesian updating, external calibration, and the maximization of expected utility. The presence of bias and incoherence does not diminish the normative force of these principles, but it reduces their usefulness as descriptions of behavior and hinders their prescriptive applications. Indeed, the elicitation of unbiased judgments and the reconciliation of incoherent assessments pose serious problems that presently have no satisfactory solution (Lindley, Tversky, & Brown, 1979; Shafer & Tversky, Note 4).

The issue of coherence has loomed larger in the study of preference and belief than in the study of perception. Judgments of distance and angle can readily be compared to objective reality and can be replaced by objective measurements when accuracy matters. In contrast, objective measurements of probability are often unavailable, and most significant choices under risk require an intuitive evaluation of probability. In the absence of an objective criterion of

validity, the normative theory of judgment under uncertainty has treated the coherence of belief as the touchstone of human rationality. Coherence has also been assumed in many descriptive analyses in psychology, economics, and other social sciences. This assumption is attractive because the strong normative appeal of the laws of probability makes violations appear implausible. Our studies of the conjunction rule show that normatively inspired theories that assume coherence are descriptively inadequate, whereas psychological analyses that ignore the appeal of normative rules are, at best, incomplete. A comprehensive account of human judgment must reflect the tension between compelling logical rules and seductive nonextensional intuitions.

Notes

- 1 We are grateful to Barbara J. McNeil, Harvard Medical School, Stephen G. Pauker, Tufts University School of Medicine, and Edward Baer, Stanford Medical School, for their help in the construction of the clinical problems and in the collection of the data.
- 2 The incidence of the conjunction fallacy was considerably lower (28%) for a group of advanced undergraduates at Stanford University ($N = 62$) who had completed one or more courses in statistics.

Chapter 7: Can Human Irrationality Be Experimentally Demonstrated?

L. JONATHAN COHEN

Introduction

The experimental study of human rationality – that is, of validity in deductive or probabilistic reasoning – has become entangled during the past decade or so in a web of paradox. On the one hand, reputable investigators tell us that “certain psychological discoveries have bleak implications for human rationality” (Nisbett & Borgida 1975), or that “for anyone who would wish to view man as a reasonable intuitive statistician, such results are discouraging” (Kahneman & Tversky 1972b) or that “people systematically violate principles of decision-making when judging probabilities, making predictions, or otherwise attempting to cope with probabilistic tasks” and they “lack the correct programs for many important judgmental tasks” (Slovic, Fischhoff & Lichtenstein 1976). On the other hand, those investigators are reminded that people could not even drive automobiles unless they could assess uncertainties fairly accurately (Edwards 1975). The ordinary person is claimed to be prone to serious and systematic error in deductive reasoning, in judging probabilities, in correcting his biases, and in many other activities. Yet, from this apparently unpromising material – indeed, from the very same students who are the typical subjects of cognitive psychologists’ experiments – sufficient cadres are recruited to maintain the sophisticated institutions of modern civilisation. Earlier decades, in an era of greater optimism, may well have overestimated the natural reasoning powers of human beings. But

there seems now to be a risk of underestimating them.

What is needed here is a conceptual framework within which to think coherently about problems of cognitive rationality and the relevant experimental data, and the object of the present paper is to sketch such a framework. For this purpose it is necessary first of all to examine the credentials of those normative theories by reference to which investigators may legitimately evaluate the rationality or irrationality of a native subject’s inference or probability judgment. Such a normative theory, I shall argue, is itself acceptable for the purpose only so far as it accords, at crucial points, with the evidence of untutored intuition. This thesis was also argued long ago by Goodman (1954, pp. 66–67). But the argument needs to be expanded and fortified against more recent opposition. What then follows from the thesis is that ordinary human reasoning – by which I mean the reasoning of adults who have not been systematically educated in any branch of logic or probability theory – cannot be held to be faultily programmed: it sets its own standards. Of course, various kinds of mistakes are frequently made in human reasoning, both by laboratory subjects and in ordinary life. But in all such cases some malfunction of an information-processing mechanism has to be inferred, and its explanation sought. In other words, the nature of the problem constrains us to a competence-performance distinction. Our fellow humans have to be attributed a competence for reasoning validly, and this provides the

backcloth against which we can study defects in their actual performance. That is the theme to be argued in the first part of the paper.

At the same time, allegations of defects in performance need to be carefully scrutinised. Some of these allegations are correct and important. But others seem to arise from a misapplication or misconception of the relevant standards of rationality by which the experimentally revealed phenomena should be judged, even when those phenomena themselves are quite robust and incontestable. The second part of the paper will therefore suggest four categories to which a critical assessment of existing allegations of performance defects might appropriately assign them.

In sum, those who once tended to exaggerate human reasoning powers may be construed as having concentrated their attention too much on the facts of competence, while those who have more recently tended to underestimate these powers have concentrated their attention too much on the facts of performance, and in some cases have judged these facts too harshly.

I. The Argument for Rational Competence

1. Intuitions as the Basis of Normative Criteria for the Evaluation of Deductions

Investigators who wish to evaluate the validity of their subjects' deductions would turn naturally to some educationally well regarded textbook of formal logic, such as Quine (1952), Copi (1954), or Lemmon (1965). The assumption would be that all and only the rules of inference that are given or derivable in those systems of so-called natural deduction are valid principles of deducibility, so far as deducibility hinges on the interplay of the logical particles "not," "and," "or," "if," "some," and "every" (or their equivalents in French, German, or any other language). But how can an assumption of this kind be defended? I shall argue that at a crucial point it has to rely on ordinary people's intuitions of deducibility.

Note, however, that the term "intuition" here is not being used in the sense of Spinoza (1914), Bergson (1903), or Husserl (1911). It does not describe a cognitive act that is somehow superior to sensory perception. Nor, on the other hand, does it refer merely to hunches that are subsequently checkable by sensory perception or by calculation. Nor does this kind of intuition entail introspection,¹ since it may just be implicit in a

spoken judgment. Its closest analogue is an intuition of grammatical well-formedness. In short, an intuition that p is here just an immediate and untutored inclination, without evidence or inference, to judge that p .

To avoid any reliance on intuition in that sense, it would be necessary to show that the assumption in question (about the nature of deducibility) is defensible within some well-recognised system of scientific procedure. Transcendental (that is, Kantian) arguments are obviously too controversial for the purpose. So either this procedure has to be empirically based and inductive, or it has to depend on some appropriate metamathematical theorem. But, as it turns out, neither of these strategies can wholly succeed: at crucial nodes an appeal to ordinary people's intuition is indispensable.

The empirical-inductive strategy offers us an account of logic (as in Stich 1975) in which it is viewed as an adjunct to science in general rather than, like geometry, an adjunct to physics in particular: Such an applied logic is understood as the combination of a formal system with appropriate interpretative rules; and it is to be tested, we are told, by assessing the explanatory and predictive power of the total theory that results from meshing it with the theories of the several sciences. In this way, it seems, what are accepted as logical truths turn out just to constitute one type of component in the total holistic system of what is accepted as scientific truth. They seem as much beholden to experiment and observation for the warranty as are any other scientific discoveries.

However, this kind of hard-line positivism comes up against some serious difficulties, which preclude it from supplying an intuition-free validation of deductive logic. First, certain regulative principles for theory construction, such as ideals of comprehensiveness, consistency, and simplicity, have in any case to be granted a priori status, so that in the defence of this status at least some principles of reasoning may be conceded an intuitive warranty. Second, much of the reasoning for which we need a logically articulate reconstruction does not take place in science at all but in law or administration, and is concerned not with what is in fact the case but with what ought to be. Third, the same logical principles have to be applied within each piece of scientific reasoning about the relative merits of two or more hypotheses, so that if ever any hypothesis has to be given up in the face of adverse experience it is always a factual, rather than a logical, one. For example, we cannot claim, as does

Reichenbach (1944), that quantum physics constitutes a restriction on the range of application of classical two-valued logic as well as of classical mechanics because it is only in accordance with shared logical principles that it would be fair to elicit and compare the differing experimental consequences of classical mechanics and quantum theory.² Hence, so far as we treat the totality of acceptable scientific hypotheses as constituting a single holistic system, we also need a single set of logical principles. Fourth, logically true statements are statements that are true in all logically possible worlds, and the evidence of happenings in the actual world must thus fall far short of establishing them.

Moreover, so far as the epistemology of a particular discipline is obligated to endorse the criteria of evaluation that are generally accepted in practice by reputable investigators in the field, it is certainly the appeal to intuitions that deserves endorsement for applied logic rather than the empirical-inductive strategy. Applied logicians make no attempt at all to test out the theories empirically within the context of a project to the holistic systematisation of all knowledge. On all the issues that are much discussed – issues about modality (for example, Quine 1960), subjunctive conditionals (Lewis 1973), indirect discourse (Carnap 1947), relative identity (Griffin 1977), proper names (Kripke 1972), adverbs (Davidson 1966), and so on – an implied or explicit appeal to intuition provides some of the vital premises for the applied logician's argument.

Nor are the prospects for a metamathematical justification of applied logic any better than those for an empirical-inductive one. Any system in which rules of derivation are specified in formal terms is said to be "sound" if under some interpretation for the formalism of the system it can be proved that from true premises these rules lead only to true conclusions. So it might seem as though, by thus using a semantic definition of logical consequence to check on a syntactic one, the rationality of a set of inferential rules could be established by experts in a metamathematical proof, without any recourse to intuitions other than those involved in the perception of the proof (Dummett 1978). But, though such a strategy has an agreeably professional appeal, it does not come to grips with the whole of the underlying epistemological problem. No reason is provided for supposing that the deductive liaisons of the logical particles of natural language can be mapped onto those of the connectives and quantifiers in the normal system that is proved to be sound.

For example, in any natural deduction system for the classical calculus of propositions the formula

$$((A \rightarrow B) \& (C \rightarrow D))$$

(or a notational variant) can constitute a premise from which

$$((A \rightarrow D) \vee (C \rightarrow B))$$

(or a notational variant) is derivable. And under the interpretation that Russell (1919) proposed for this calculus, a derivation could turn into an inference from

If John's automobile is a Mini, John is poor,
and if John's automobile is a Rolls, John is rich

to

Either, if John's automobile is a Mini, John is rich,
or, if John's automobile is a Rolls, John is poor

which would obviously be invalid. But what makes this invalidity obvious? The fact is that our own intuitions about the legitimate deductive liaisons of the logical particles (for example, the intuition that from the conditional "If John's automobile is a Mini, John is rich," we should be able to deduce the existence of a connection between antecedent and consequent that is independent of truth values) combine with our empirical knowledge of automobile costs to make it easy to imagine situations in which (3) is true and (4) is false. So though the propositional calculus is demonstrably sound, it resists Russell's interpretation as a logic of everyday reasoning in which conditional sentences may have a role, because it cannot capture intuitions like those on the basis of which we judge an inference from (3) to (4) to be invalid.³ Admittedly, those intuitions might be said just to concern the *meanings* of the logical particles "if," "and," and "or," and there is nothing particularly remarkable, it might be objected, about the fact that one has to understand the meaning of an utterance to be able to appraise its validity. But the relevant point is that knowing the meanings of "if," "and," and "or" is indistinguishable from knowing, in principle, their legitimate deductive liaisons. So we cannot avoid appealing to intuitions of inferential validity in order to determine the claim of an interpreted formal system to constitute a theory of deducibility for everyday reasoning.

In other words, the problem of justification takes two rather different forms in regard to

theories of deducibility. On the one hand, there is the issue of the theory's soundness, on the other, the issue of its application. Intuitions of inferential validity supply data in relation to the latter issue, not the former. But these intuitions are nevertheless an indispensable type of evidence for any theory of deducibility in everyday reasoning. Unless we assume appropriate intuitions to be correct, we cannot take the normative theory of everyday reasoning that they support to be correct. No doubt two different people, or the same people on two different occasions, may sometimes have apparently conflicting intuitions. But such an apparent conflict always demands resolution. The people involved might come to recognise some tacit misunderstanding about the terms of the problem, so that there is no real conflict; or they might repudiate a previously robust intuition, perhaps as a result of becoming aware that an otherwise preferred solution has unacceptable implications; or they might conclude that different idiolects or conceptions of deducibility are at issue.⁴

2. Intuitions as the Basis of Normative Criteria for the Evaluation of Probability Judgments

The position in regard to normative theories of probabilistic reasoning is rather analogous. We can take the mathematical calculus of chance, as axiomatised by Kolmogorov (1950), Reichenbach (1949), or Popper (1959a), to be a formal system that is open to semantical interpretation as a theory of the constraints that probability judgments of certain kinds *ought* to place on one another. But to just what kinds of probability judgment does the theory apply? This question has been much discussed. For example, proofs or arguments are available (Ramsey 1931; de Finetti 1931) to show that where probabilities are measured by betting quotients within a suitably coherent system of wagers their system conforms to the calculus of chance. A similar conformity has been demonstrated by Reichenbach (1949) and von Mises (1957) for the conception of probability as a relative frequency; by Carnap (1950) for the conception of probability as a type of logical relation that varies in strength along a spectrum that extends from contradiction at one extreme to entailment at the other; by Popper (1959b, 1968) and Mellor (1971) for the conception of probability as a causal propensity – a causally rooted tendency – and so on.

But none of those proofs or arguments establishes which conceptions of probability are oper-

ative – and under what conditions – in the everyday reasoning of lay adults, such as are the typical subjects of experiments carried out by cognitive psychologists. That is to say, it is one thing to establish one or more probabilistic interpretations for the calculus of chance, and quite another to show that the resultant theory applies to some or all of the probability judgments that are made in everyday reasoning. In order to discover what criteria of probability are appropriate for the evaluation of lay reasoning we have to investigate what judgments of probability are intuitively acceptable to lay adults and what rational constraints these judgments are supposed to place on one another. We have to select the conception or conceptions of probability in terms of which the most coherent account of lay judgments can be given, rather than evaluate those judgments by some single independently established standard.

The importance of this selection should not be underestimated. There are at least four ways in which it can make a lot of difference.

First, where probabilities are measured by betting quotients or construed as logical relations, we have to say – properly speaking – that they are functions of propositions; where they are relative frequencies they are functions of sets; and where they are causal propensities, they are functions of properties (Cohen 1977b). Such categories of functions differ considerably in regard to their appropriateness for the evaluation of definite singular instances, as has often been pointed out (see Reichenbach 1949, pp. 376–77; Carnap 1950, pp. 226–28; Nagel 1939, pp. 60–75). They differ also in regard to their appropriateness for counterfactual inference (Cohen 1977b, pp. 306–9).

Second, where a probability is measured by a betting quotient, its statement is normally treated as an assertion about the strength of the speaker's belief in the outcome. Such a subjective fact is logically quite consistent with another speaker's having a different strength of belief in relation to the same issue. So when two people measure the probability of the same outcome subjectively by different betting quotients, they are not contradicting one another, whereas assertions of different relative frequencies, different logical relations, or different causal propensities would be logically inconsistent if they concerned the same issue.

Third, different probability functions may legitimately be assigned different values in relation to the same situation of uncertainty. Carnap, for example, demonstrated the existence of

a nondenumerably infinite number of different measures for his logical relation type of probability; the odds that are taken as appropriate to betting on a particular outcome on a given occasion need not correspond with the actual frequency of such outcomes in the relevant population; and the high frequency of *B*'s among *A*'s may be due to a series of coincidences, so that as a measure of causal propensity $p(B|A)$ [i.e., $p(B \text{ given } A)$] = $p(B)$ even though as a measure of relative frequency $p(B|A) > p(B)$. There is no mathematically demonstrable reason, therefore, why people should not in fact use different measures of probability for different situations or purposes, just as traders sometimes find it worthwhile to measure quantities of apples by weight and sometimes by number.

Fourth, if one or more semantic characterisations of probability are possible (as distinct from an implicit definition in terms of a set of mathematical axioms), then one might even need other formal systems than the calculus of chance to represent the syntax of some semantically defined categories of probability judgments other than the four already mentioned. The mathematics of probability may have no more reached its apogee in the work of Kolmogorov, than the mathematics of space did in that of Euclid. Nonclassical theories of probability may turn out to have an interest analogous to that of non-Euclidean geometries.

3. *The Systematisation of Normative Intuitions*

It has been argued so far that any normative analysis of everyday reasoning – any statement that such and such lay judgments of deducibility or probability are correct, or incorrect, as the case may be – must in the end rely for its defence on the evidence of relevant intuitions. You cannot dodge this by an appeal to textbooks of logic or statistics. Of course, on any issue that can be settled empirically we naturally treat intuitions only as hunches that either will be confirmed by favourable observation or will give way to counter-observations. And in some area, such as the grammar of natural language, the question whether ultimate data are observational or intuitive or both is currently controversial: compare Chomsky (1965) and Sampson (1975). But on indisputably normative issues – on issues about how people *may* or *ought* to think or behave as distinct from how they *do* – we cannot expect a major point at stake to be settled by observation. Here, if our aim is

to build up a comprehensive system of theory, it is prudent to check our general hypotheses against intuitions in concrete individual cases – though in order to avoid an obvious risk of bias, these must always be the intuitions of those who are not theorists themselves. For example, the practice of the courts provides much evidence for a theory of lay intuitions about probability in forensic reasoning (Cohen 1977b), but writers on this subject should not invoke their own intuitions.

Normative theories are subject to the usual inductive criteria. They are better supported if they apply to a wider rather than a narrower range of significantly different kinds of intuitive inference or judgment, just as the more comprehensively explanatory theories have greater merit in natural science. But there would obviously be a point at which even the mere process of putting problems to a person in varied contexts, in order to extract his intuitions, could reasonably be taken to cross over into a procedure for changing his normative outlook instead of just recording it. Thus recent writers on ethics (for example, Rawls 1972; Daniels 1979, 1980) have distinguished between the narrow reflective equilibrium that is constituted by coherent reconstruction of a person's existing moral principles, where only an occasional intuition is repudiated (for the sake of consistency), and the wide reflective equilibrium that is obtained when a person chooses between his existing moral principles and proposed alternatives, on the basis of sociological, historical, economic, psychological, or other considerations that may weigh with him. In matters of deducibility or probability the analogue of this philosophical choice would occur in the process of education research, or philosophising whereby hitherto uncommitted students are sometimes transformed into the thoroughgoing Quineians, say, or Bayesians, or Popperians so that they come to adopt substantially different conceptions of deducibility or probability from those once operating in their untutored judgments. But the normative theories that are at issue in the present context require a narrow, not a wide, reflective equilibrium. The judgments of everyday reasoning must be evaluated in their own terms and by their own standards.

4. *The Derivation of an Account of Human Competence in Deductive or Probabilistic Reasoning*

If a physicist observes the position of the needle on a certain dial under chosen experimental

conditions, then the datum to be explained is the position of the needle, not the fact that someone observes it. The event observed, not the act of observing it, is what is relevant. Otherwise optics (and perhaps acoustics) would be all the science that there is. Analogously, the datum that the moralist has to take into account is the rightness or wrongness of a particular action, not the deliverance of conscience that pronounces it right or wrong; and the logician's datum is the validity or invalidity of a particular inference, not the intuition that assures us of it. So enquiry into the norms of everyday reasoning no more aims at a theory *about* intuitions than physics or chemistry aims at a theory *about* observations. Epistemology does not dominate ontology here. And fortunately it is not necessary for present purposes to determine what exactly the study of moral value, probability, or deducibility has as its proper subject matter. For example, an applied logician's proper aim may be to limn the formal consequences of linguistic definitions (Ayer 1946), the most general features of reality (Quine 1960), or the structure of ideally rational belief systems (Ellis 1979). But, whatever the ontological concern of applied logicians, they have to draw their evidential data from intuitions in concrete, individual cases; and the same is true for investigations into the norms of everyday probabilistic reasoning.

It follows that for every such normative theory, which determines how it is proper to act or reason, there is room to construct a factual theory that does take intuitions as its subject matter. This factual theory will describe or predict the intuitive judgments that formulate the data for the corresponding normative theory. It will be a psychological theory, not a logical or ethical one. It will describe a competence that normal human beings have – an ability, uniformly operative under ideal conditions and often under others, to form intuitive judgments about particular instances of right or wrong, deducibility or nondeducibility, probability or improbability. This factual theory of competence will be just as idealised as the normative theory from which it derives. And though it is a contribution to the psychology of cognition it is a by-product of the logical or philosophical analysis of norms rather than something that experimentally oriented psychologists need to devote effort to constructing. It is not only all the theory of competence that is needed in its area. It is also all that is possible, since a different competence, if it actually existed, would just generate evidence that called for a revision of the corresponding normative theory.

In other words, where you accept that a normative theory has to be based ultimately on the data of human intuition, you are committed to the acceptance of human rationality as a matter of fact in that area, in the sense that it must be correct to ascribe to normal humans beings a cognitive competence – however often faulted in performance – that corresponds point by point with the normative theory. Of course, it would be different if you believed in some other source of normative authority. If, for instance, you believe in a divinely revealed ethics, you are entitled to think that some people's competence for moral judgment may fall short of correct moral ideals: you could consistently invoke some doctrine of original sin to account for the systematic failure of untaught intuition to accord with the correct norms of moral judgment. But, if you claim no special revelation in ethics, you will have to take intuitive judgments as your basis, and then people's competence for moral judgment – as distinct, of course, from their actual performance in this – cannot be faulted. Analogously, if you claim no special revelation in matters of logic or probability, you will have to be content there too to accept the inherent rationality of your fellow adults.

To ascribe a cognitive competence, in this sense, within a given community is to characterise the content of a culturally or genetically inherited ability which, under ideal conditions, every member of the community would exercise in appropriate circumstances. It states what people can do, rather than what they will do, much as the characterisation of a linguistic competence can be taken to describe what it is that native speakers must be assumed capable of recognising about the structure of morphophonemic strings (Chomsky 1965) rather than what they do actually recognise. The fact is that conditions are rarely, if ever, ideal for the exercise of such a competence. Just as passion or self-interest may warp our moral discernment, or memory limitations may restrict the length of the sentences we utter, so too a variety of factors may interfere with the exercise of a competence for deductive or probabilistic reasoning. A local unsuitability of childhood environment may inhibit the maturation of innate ability, education (that is, education in subjects other than logic and probability theory) may fail to make the most of it, individual disabilities or normal memory limitations may set limits to what even the best environment and education can achieve, and various motivational and other factors may operate to induce malfunctions of the relevant information processing mechanisms. To suppose that all

normal adults are able to reason deductively is certainly not to suppose that they will never err in their judgments of logical validity, and still less that they will in practice execute any particular finite chain of reasoning that is called for, however complex it may be, just so long as it is licensed by intuitively evident rules of natural deduction. In practice, our rationality is "bounded" (Simon 1957, pp. 198–202). We are all able to walk, if in normal health, but it does not follow that we can all walk on a tight rope, or for a thousand miles without stopping, or that none of us ever stumbles. It is here that the issues arise that will be discussed in the second part of this paper.

In short, accounts of human competence can be read off from the appropriate normative theories, so far as they are based on the evidence of intuitions; accounts of actual performance under different conditions are to be obtained by experiment and observation; and hypotheses about the structure and operation of human information-processing mechanisms must then be tested against the facts of competence and performance that it is their task to explain. The structure of design of such a mechanism must account for the relevant competence, but its operation must be subject to various causes of malfunction that will account for the flaws found in actual performance.

One may be tempted to ask: "How do we know that any intuition of the relevant kind is veridical?" But to ask for knowledge here is to ask for what is in principle impossible, at least in the sense in which knowledge is something like justified true belief, and where there is no alternative to invoking intuition, since an intuitive judgment that p essentially lacks any external ground to justify accepting that p . The best that normative theorists can hope for in this field (and also what they need to achieve), if they do not claim any special revelation, is that the contents of all relevant intuitions – suitably sifted or qualified, if necessary – can be made to corroborate one another by being exhibited as the consequences of a consistent and relatively simple set of rules or axioms that also sanctions other intuitively acceptable, but previously unremarked, patterns of reasoning. The inductive principle of mutual corroboration here is analogous to that operative in natural science, as Bacon long ago pointed out in regard to normative theories of ethics or jurisprudence (Kocher 1957; cf. Cohen 1970).

It would be different if we were evaluating the cognitive competence of some other species,

or even of human children. We should be free to find their intuitive efforts at probabilistic reasoning, for example, or their moral sensitivity, to be rather inferior by the standard of our own norms. But we cannot attribute inferior rationality to those who are themselves among the canonical arbiters of rationality. Nothing can count as an error of reasoning among our fellow adults unless even the author of the error would, under ideal conditions, agree that it is an error.

Other arguments about rationality do not concern us here: It is true that, even where animals, children, or Martians are concerned, there are limits to the extent to which we can impute irrationality. As has been well remarked (Dennett 1979, p. 11), if the ascription of a belief or desire to a mouse is to have any predictive power, the mouse must be supposed to follow the rules of logic insofar as it acts in accordance with its beliefs and desires. But this is not to suppose that the mouse has any great powers of ratiocination. Equally (Quine 1960) we have to impute a familiar logicity to others if we are to suppose that we understand when they say: different logics for my idiolect and yours are not coherently supposable. But there is always the possibility that we understand less than we think we do and that some imputations of logicity are therefore not defensible on this score. Again, evolutionary pressure in the long run eliminates any species that is not sufficiently well equipped to surmount threats to its biological needs. But evolutionary considerations are better fitted to put an explanatory gloss on the extinction of a species after this event has already occurred than to predict the precise level of rationality that is required for this or that species' continued survival within its present environment.

What I have been arguing is that normative criteria for ordinary human reasoning rely for their substantiation on a procedure analogous to what is called "boot strapping" in artificial intelligence (see Dawes & Corrigan 1974). The intuitions of ordinary people are the basis for constructing a coherent system of rules and principles by which those same people can, if they so choose, reason much more extensively and accurately than they would otherwise do.⁵ Consequently these ordinary people cannot be regarded as intrinsically irrational in regard to any such cognitive activity. An investigator who wanted to make out a serious case for deep-level human irrationality in this area might be tempted to operate with normative criteria that were the product of philosophical argument for some appropriately wide reflective

equilibrium and consequently differed from the narrow, bootstrapping, reflective equilibrium which merely reconciles intuitions. But any kind of scientific or mathematical reasoning to which such criteria directly apply has a specialised and technically regimented quality that makes it difficult or impracticable for those who have not been trained appropriately. For example, it may involve deduction within an artificial language system, or employ relatively sophisticated concepts of statistical theory. Hence the investigator's experiments would founder in characteristic indeterminacy. They would constitute an accurate test of their subjects' competence for reasoning only to the extent that these subjects were not ordinary people but specially trained experts. So the results of the test might reveal how good was the training or how effective were the procedures for selecting people to be trained; they would tell us nothing about the rationality or irrationality of untrained people. Though a person may well acquire a wide reflective equilibrium with regard to ethical issues that is inconsistent with a previously existing narrow reflective equilibrium, there is no possibility of an analogous inconsistency with regard to deducibility or probability. In the case of deducibility, narrow reflective equilibrium remains the ultimate framework of argument about the merits of other deductive systems, and in the case of probability, we are merely replacing some modes of measuring uncertainty by others.

II. Four Categories of Research into Defects of Cognitive Rationality

The past decade or so has seen the growth of a vast literature of psychological research into replicable defects of human reasoning. Often investigators are content just to argue for the existence of such defects and to suggest explanations. But sometimes they also claim justification for extensive criticisms of human rationality. Several convenient reviews of this literature are already available (for example, Slovic, Fischhoff & Lichtenstein 1977; Nisbett & Ross 1980; Einhorn & Hogarth 1981), and I do not aim to produce another here. Rather, the purpose of the second part of the paper is to establish four categories, into one or the other of which, on close assessment, any item in this literature may be seen capable of being assigned without "bleak implications for human rationality," once an account of the normative criteria for ordinary human

reasoning is agreed to entail an ascription of the corresponding competence to ordinary human adults (as argued in part I). For reasons that will emerge in the sequel, these four categories of research activity are appropriately entitled "Studies of cognitive illusions," "Tests of intelligence or education," "Misapplications of appropriate normative theory," and "Applications of inappropriate normative theory." Examples will be furnished for each category. It will be assumed in every case that the phenomena reported are replicable, and that no technical faults occur in the presentation of the data, such as miscalculations of statistical significance: if the examples furnished here are in fact faulty, others are easily found. The issues raised here do not concern the robustness of the phenomena, solely their interpretation.

The categorisation is intended to be an exhaustive one, not in the sense that every item in the literature is actually assigned to one of the four categories but that in principle it could be. Claims that human reasoning tends to be invalid in certain circumstances are either correct or incorrect. The correct claims relate either to fallacies that, on reflection, everyone would admit to be such, as in studies of cognitive illusions, or to fallacies that require some more elaborate mode of demonstration as in tests of intelligence or education; the incorrect claims result either from misapplications of appropriate normative theory or from applications of inappropriate normative theory.

1. *Studies of Cognitive Illusions*

In view of what has been argued above about ordinary people's competence for deductive and probabilistic reasoning, there is a *prima facie* presumption, in regard to any experimental data in this area, that they can be explained as a manifestation of some such competence, even though the details of the explanation may not be easy to fill in. Where no explanation of this kind is available, one possibility is that experimenters have created a cognitive illusion. They have manipulated the circumstances of a situation in such a way that subjects are induced to indulge in a form of reasoning that on a few moments' prompted reflection they would be willing to admit is invalid.

A very good example of this is the familiar four-card problem (Wason 1966). The subjects are presented with four laboratory cards showing, respectively, 'A,' 'D,' '4,' and '7,' and

know from previous experience that every card, of which these are a subset, has a letter on one side and a number on the other. They are then given this rule about the four cards in front of them: "If a card has a vowel on one side, then it has an even number on the other side." Next they are told: "Your task is to say which of the cards you need to turn over in order to find out whether the rule is true or false." The most frequent answers are "A and 4" and "only A," which are both wrong, while the right answer "A and 7" is given spontaneously by very few subjects.

Wason and his colleagues, in attempting to account for these data (see Johnson-Laird & Wason 1970), interpret the error as a bias towards seeking verification rather than falsification in testing the rule. But if that were the nature of the error one would expect "D" to show up in the answer like "4" does, since the contrapositive equivalent of the rule is, "If a card does not have an even number on one side, it does not have a vowel on the other." Perhaps it will be said that this is simply owing to a failure to grasp the equivalence of contrapositives here. But such a failure would account also for the absence of "7" from most answers, without the need to suppose that in testing a conditional rule subjects do anything other than check, in each case in which the antecedent holds true, whether the consequent does also: this is because the presence of "4" in many answers may then be put down to the prevalence of inference from an utterance that is of the form "if p then q " to an utterance that is of the form "if q then p " – a prevalence for which there is independent evidence (see II.3 in regard to the fallacy of illicit conversion). I shall assume, therefore, that the subjects' specific error here is best interpreted as a failure to apply the law of contraposition. What then causes that failure?

It would be wrong to conclude that the deductive competence of most logically untutored subjects does not embrace the law of contraposition. A subsequent experiment (Wason & Shapiro 1971) has been claimed to show that if the four cards are those related to a more concrete rule, namely, "Every time I go to Manchester, I go by train," then substantially more subjects are successful. Even better results were obtained (Johnson-Laird, Legrenzi & Sonino Legrenzi 1972) when the rule was, "If a letter is sealed, then it has a fivepenny stamp on it" and the laboratory cards were replaced by (sealed or unsealed, stamped or unstamped) envelopes.

Further experimentation (Van Duyne 1974, 1976) has also been claimed to show that degrees of realism in fact affect performance in a continuous, linear way. However, it looks as though we need to distinguish here between two different ways in which realism may be increased. One is by writing descriptive words or sentences on the cards, instead of just letters and numerals, and altering the rule accordingly: the other is by using real objects (envelopes) instead of cards. The results of Manktelow and Evans (1979) suggest that when realism is increased in the former manner the fallacy still occurs. But those results do not weaken the finding that when real objects replace cards the fallacy hardly ever occurs. It seems, therefore, that experimenters' power to generate an illusion here depends on the relative unfamiliarity and artificiality of their apparatus. In their familiar concrete concerns human beings show themselves well able to apply the law of contraposition to appropriate problems. Faced instead with a situation in which the items against which a conditional rule is to be checked are things (cards bearing letters, numerals, words, sentences, geometrical diagrams, and the like) that echo the symbolism in which the conditional rule itself is formulated, subjects' reasoning tends to be led astray in the "matching bias" to which Manktelow and Evans have traced the fallacy.

The point of describing experimental effects like Wason's as cognitive illusions is to invoke the analogy with visual illusions: it is in no way intended to derogate from their importance, nor to suggest that if the circumstances that cause the illusion occur naturally (as distinct from being the result of an experimenter's contrivance) then the illusion will not occur.⁶ The discovery of any such effect in human performance generates a significant piece of evidence about the way in which the underlying information-processing mechanism operates. The findings about the four-card problem may legitimately be said (Johnson-Laird & Wason 1977) to support the view (Piaget 1972) that most people manage to apply their logical competence without ever formulating it expressly at a level of generality sufficient for it to be readily applicable to wholly unfamiliar tasks. People will distinguish form from content in their reasoning, or extrapolate accurately from one content to another, only to the extent that similarity of form is accompanied by some rough equality of vital interest. So subjects who reason fallaciously about the four-card problem need not

be supposed to lack the correct deductive “program.” Indeed, none of the experimenters in the area suggests this. The subjects merely fail to recognize the similarity of their task to those familiar issues in which they have profited by using the deductive procedure of contraposition. As a result, either that procedure receives no input or its output is deleted, and the behaviour of the subjects manifests a matching bias.

Analogously, other experimental data show, it has been argued (Wason 1960, 1968), that in an abstract task, like hypothesising about the rule that generates a given series of numbers, most people are unable to use the procedure of proving a hypothesis by eliminating alternatives to it.⁷ They tend to seek confirmatory evidence for their favoured hypothesis rather than disconfirmatory evidence for alternatives to it. In addition, they often do not relinquish hypotheses that have been shown to be false. Nor is people’s eliminative performance substantially better when confronted with a computer-screen simulation of a simple mechanical problem (Mynatt, Doherty & Tweney 1977). Yet it hardly needs an experiment to show that most people are quite capable of using eliminative procedures correctly when dealing with real objects – not simulated ones – in familiar everyday situations: if the soap is not in the basin, we reason, it must be in the bath; if one’s caller has not come by automobile, he must have walked; and so on. So it is not that ordinary people lack competence for the kind of deductive inference that moves from “ p or q ” and “not- p ” to “ q ,” which is essential to all such eliminative reasoning. It seems rather that in normal investigative situations the disjunctive premise for this pattern of reasoning is supplied by previous experience, and in an artificial or unfamiliar situation we lack the relevant kind of previous experience to supply the input. To build up that experience some pursuit of confirmatory (as distinct from disconfirmatory or eliminative) strategies would not be unreasonable, as is recognised by Mynatt, Doherty, and Tweney (1978, p. 405); and retention of a falsified hypothesis would even be desirable if it explained quite a lot of the evidence and no unfalsified hypothesis were available that had as good explanatory value. So too the sharply falsificationist model of scientific progress that was originally offered by Popper (1959a) has rightly met with substantial criticism from other historians and philosophers of science (for example, Swinburne 1964; Lakatos 1970).

Again, it may seem puzzling that subjects seem unable to judge correctly in the laboratory that some event is controlled by another, or is independent of it, as the case may be, and yet the very same subjects gets along all right most of the time in their everyday life (Jenkins & Ward 1965). But the puzzle may be lessened by considering some of the ways in which their expert mental tasks are not representative of the normal conditions for such judgments: check-ups are excluded, temporal variations are absent, the output considered unnaturally discrete, the response has to be a relatively hurried one, and so on.

Experimenters need to devise a great variety of experiments involving such cognitive illusions in order to test out theories about how human beings in fact perform, or fail to perform, the various acts of reasoning for which they apparently possess a competence. But one should recognise these experiments for what they are, and not conceive of the illusions that they generate as some kind of positive, though fallacious, heuristic that is employed by the subjects. Consider for example, the supposed heuristic of availability (Tversky & Kahneman 1973). A person is said to employ this heuristic whenever he estimates frequency or probability by the ease with which instances or associations are brought to mind. For example, if student subjects, when asked in the laboratory, erroneously judge English words beginning with *re* to be more frequent than words ending with *re*, they are diagnosed to have employed the heuristic of availability because the former words are more easily brought to mind than the latter. But a heuristic is a way of finding something out that one does not already have at the front of one’s mind. The availability illusion consists instead in relying on data that one already has at the front of one’s mind. There is a lot of evidence most people are too slow to change certain kinds of beliefs (Ross & Lepper, 1980). But no one thinks that this evidence establishes a “conservatism heuristic,” rather than that it just manifests the influence of factors which make for belief inertia. Analogously, if the argument for rational competence (in part I) is accepted, the “availability” results must be interpreted to have shown, not that the subjects are estimating the frequency or probability of an x by reference to the availability of an x , but that they are doing this by reference to those x ’s that happen to be available. The subjects are not to be construed as operating on the evidently wild assumption that

frequency can safely be taken to equal availability. Rather, where A is the available population, they are to be construed as operating on the not so evidently wild assumption that frequency can safely be taken to equal frequency in A , which is a very different matter.

In other words, to be entitled to recognise an error in subjects' reasoning here, we have to attribute to them a conception of the frequency or probability of an x , $p(x)$, such that it is incorrect to infer $p(x) = n$, where x 's are y 's, from $p(x|y)$ [$p(x$ given $y)$] = n , unless the y 's are a suitably representative sample of the total population. So we thereby (see part I) also attribute to them competence to avoid those incorrect inferences. It follows that their probability-estimating mechanism must be supposed to include some such procedure as: check whether available evidence constitutes a fair sample in relevant respects, and, if not, seek evidence that is of the missing kind or kinds. What happens is just that the operation of this procedure tends to be obstructed by factors like the recency or emotional salience of the existing evidential input, by the existence of competing claims for computing time, or by a preference for least effort. Cognitive illusions, in the laboratory or in real life, depend on the power of such factors to hold subjects back, under the pressure of interrogation, from obtaining an appropriate additional input to their information-processing operation, just as when a visual conjurer relies at a crucial moment on his own speed of action, and on the visual inattentiveness of those who are watching, to hold the latter back from obtaining an appropriate additional input to their visual information-processing operation.

Another procedure referred to in the literature as a "heuristic" is the method of anchoring and adjustment, whereby a natural starting point or anchor is used as a first approximation to the required judgment of frequency, probability, expected value, and so on, and is then adjusted to accommodate the implications of additional information. Tversky and Kahneman (1974) have shown the existence of a tendency for adjustments to be insufficient: subjects with high starting points end up with higher estimates than those with lower ones. This tendency has also been noted (Lichtenstein & Slovic 1973) in an experiment with people who were gambling in a Las Vegas casino. Even there, an element of conjuring was present, in that the game that was played was specially designed for the purpose. But it would obviously be implausible to

suppose that any kind of cognitive illusion occurs only when the circumstances that cause it are deliberately contrived: conjuring is not the only source of visual illusions either.

A somewhat similar phenomenon has been demonstrated in relation to hindsight (Fischhoff 1975): judges with knowledge of the outcome tend to overestimate the probability that they would have declared prior to the event. This is like starting with an anchor at 100% probability and adjusting to allow, not for more information, but for less, that is, for ignorance of the actual outcome.

However, unlike in the case of the supposed heuristic of availability, there is nothing intrinsically fallacious in the procedure of anchoring and adjustment. It is a perfectly legitimate heuristic if correctly operated. What goes wrong is just that the effects of recency or salience are generally too strong to permit correct operation. Thus, Slovic et al. (1976) are right to point out that bias from anchoring, like that from availability, is congruent with the hypothesis that human reasoners resemble computers that have the right programs and just cannot execute them properly. But Slovic et al. also claim that there are certain other errors prevalent in probabilistic reasoning, concerned with sampling and prior probabilities that are not congruent with this hypothesis, and we shall see shortly that the latter claim cannot be sustained.

2. *Tests of Intelligence or Education*

A second category of research activity found in the literature concerns ignorance, not illusion. It demonstrates a lack of mathematical or scientific expertise.

A lack of mathematical expertise here amounts to an ignorance of principles that not everyone can be expected to acknowledge readily, still less to elicit spontaneously from their relevant competence. Possession of a competence for deductive or probabilistic reasoning entails the possession of a mechanism that must include not only certain basic procedures, corresponding to a set of axioms or primitive rules for the normative system concerned, but also a method of generating additional procedures, corresponding to the proof of theorems or derived rules in that normative system. But the actual operation of this method, beyond its simplest forms, may require skills that are relatively rare, just as a particular talent is required for the discovery of proofs in logic or mathematics whenever no mechanical decision procedure is known. In

the latter case what are needed in an outstanding degree are such capacities as those for discerning shared structure in superficially different materials, for memorising complex relationships, and the like – in other words, whatever promotes the proposal of worthwhile hypotheses in the trial-and-error search for appropriate connexions. Correspondingly, only people with those skills in an outstanding degree can be expected to generate interesting new procedures for eliciting deductive consequences or estimating probabilities. Only they will be able to supply spontaneously the input, in terms of perceived similarities and the like that will enable the method of generating additional procedures to operate fruitfully. Others will have to learn these proofs or derivations, or acquire the additional procedures, at second hand. Education must supplement innate intelligence, where intelligence is understood not as the competence that everyone has but as the level of those skills that are required to supply the novel input essential for the discovery of proofs. So experiment in this area may be able to show us the limits of ordinary people's intelligence, in the appropriate sense, or the extent to which subjects have profited from logical or mathematical education. But it cannot demonstrate an erroneous competence.

For example, it required the genius of a great mathematician (Bernoulli 1713) to discover and prove that, if you estimate the probability of a certain characteristic's incidence in a population from its frequency in a sample, then the probability of your estimate's being correct, within a specifiable interval of approximation, will vary with the size of the sample. So it is easily understandable that psychological experiment finds a tendency among ordinary people, untutored in statistical theory, to be ignorant of this principle and its applications (Tversky & Kahneman 1971). No doubt equally cogent experiments could be designed to establish the fact that those untutored in Euclidean geometry are still ignorant of the fact that the square on the longest side of a right-angled triangle is equal in area to the sum of the squares on the other two sides, since it required another outstanding mathematician, Pythagoras, to discover a proof of this fact. Again, it is said (Tversky & Kahneman 1971, p. 109) that at a meeting of mathematical psychologists and at a general session of the American Psychological Association the typical respondent attached excessive significance to inferences from relatively small samples. But what this adds to the previous finding is just a

reason for reassessing the extent or success of the education that the respondents had in fact undergone. And the same holds true in relation to those who are supposed to have some statistical training but still fail to recognise new examples of regression to the mean for what they are (Kahneman & Tversky 1973).

Not all errors of estimation that are due to ignorance arise from subjects' deficiencies in mathematical expertise. Some arise instead from subjects' deficiencies in scientific (for example, psychological) expertise. For example, there is a good deal of evidence (reviewed in Slovic et al. 1977, pp. 5–6) that people are often overconfident in their second-order estimates of the accuracy of their own primary estimates. What happens here is that they are unaware of the various ways in which the information-processing mechanism that generates the primary estimates may be affected by performance error. However, this is scarcely surprising, since the facts about those patterns of error are being discovered only gradually and only by difficult (and sometimes controversial) research. No doubt it would be salutary if all nonpsychologists were taught every such fact that has been properly established. But all that is discovered, when their ignorance of such a fact is discovered, is a gap in their education.

3. Misapplications of Appropriate Normative Theory

We have been concerned so far with genuine fallacies, to which experiments reveal that people are prone because of either illusion or ignorance. However the literature also contains several examples of more questionable claims that a common fallacy exists. These are situations in which the experimental data may be explained as a direct manifestation of the relevant competence without any need to suppose an error in performance. Such claims arise either through a misapplication of the appropriate normative theory or through an application of an inappropriate one.

One particularly instructive example of the former kind relates to the alleged prevalence of the fallacy of illicit conversion, and, in particular, of inference from a proposition of the form "if p then q " to one of the form "if q then p ." Intellectuals have remarked for over two millennia (Hamblin 1970) on the tendency of their inferiors to commit this fallacy, and in recent years it too has been a topic for psychological investigation (Wason & Johnson-Laird 1972). The investigators conclude that, in situations in which

subjects are apparently prone to illicit conversion of conditionals, “this is not because the subjects possess faulty rules of inference but because they sometimes make unwarranted interpretations of conditional statements” (p. 65). The subjects are claimed to treat these conditionals as if they were statements of causal connexion which allow one to infer from effect to cause as well as from cause to effect.

But it is not clear that the subjects must in fact be supposed even to be making an unwarranted interpretation. We have to bear in mind here that the principles of a normative theory, such as one that systematises criteria for deducibility, inevitably involve abstraction and idealisation (see Part I, Section 3). So what are to be taken as the actual, concrete premises that are represented by the initial formulas in a primitive or derived rule for natural deduction, when such rules are taken to be the norms relevant to some actual sequence of human reasoning? The mere sentences uttered do not normally constitute all of the premises conveyed by the total act of communication, since we are presumptively entitled to take the latter as including also any judgments that are implied by the act of uttering those sentences in the contextual circumstances. For example, as far as human conversation is governed by rules of relevance, brevity, informativeness, and so on, as required by the purpose in hand (Grice 1975),⁸ the information provided by the utterance of a solitary conditional sentence – if p then q – may be presumed, unless there are specific indications to the contrary, to be all that is required in the circumstances to satisfy the interest either of someone who wants to know what is also true if the antecedent of the conditional is true, or of someone who wants to know the conditions under which the consequent of the conditional sentence is true. In the former case (“If you interrupt him now, he’ll be cross”) the conditional is convertible because its utterance would normally be pointless unless “if not- p then not- q ” were also true and “if not p then not- q ” is formally equivalent to the converse of “if p , then q .” In the other case (“If you give him a tip, he’ll let you in”) the conditional is convertible because its solitary utterance may be presumed to state the only condition under which the consequent is true.

Hence if we consider the total content of the message communicated, rather than just the conditional sentence that is uttered, it would not be fallacious or unwarranted for subjects to presume, unless there are specific indications to the contrary, that the converse of the condi-

tional is implicit in the message, and the convertibility of causal conditionals is just a special form of this. A psychological experimenter who wishes to exclude the legitimacy of presuming the converse in such a case must contrive suitable instructions to his subjects and teach them how to distinguish between the implications of a sentence uttered and the implications of its utterance. But how could we judge the suitability of such instructions without taking into account the extent of their success in averting inferences to the converse? In other words, a tendency to commit the fallacy of illicit conversion in everyday life is demonstrable only on the basis of an unrealistic assumption – namely, that when a normative theory is invoked for the evaluation of commonsense reasoning its criteria should be applied to nothing but the linguistic forms that are actually uttered.

Another line of research activity (see, for example, Wagenaar 1972) in which appropriate norms seem to be sometimes misapplied is in studies of judgments of randomness. Results over quite a variety of tests seem to confirm the hypothesis that subjects who are attempting to behave randomly will produce series that have too many alternations and too few repetitions. But as has been well pointed out (Lopes 1980), a series may have randomness with respect to its atomic or elementary events, while still possessing molecular units, such as groups of ten consecutive atomic events, that do not exhibit randomness. Or randomness may be achieved for a certain category of molecular events, at the cost of sacrificing randomness with respect to elementary events. Unless this distinction between different kinds of randomness is clearly presented to the subjects, they are not in a position to know what kind is being sought by the experimenters. And again it is not easy to see how the subjects’ apparent failure to produce correct judgments of randomness should not be regarded as simply a measure of the aptness of their instructions.

A different way in which an appropriate normative theory may be misapplied was instantiated in the course of an attempt to show that, as compared with their treatment of predictive evidence, people are prone to “a major underestimation of the impact” of diagnostic evidence “which could have severe consequences in the intuitive assessment of legal, medical, or scientific evidence” (Tversky & Kahneman 1977, p. 186). Subjects were given two sets of questions that were regarded by the experimenters as similar in relevant structure. But in fact the

predictive set concerned conditional probabilities, as in – for one instance – “The chance of death from heart failure is 45% among males with congenital high blood pressure,” while the diagnostic set concerned unconditional ones, as in “The radiologist who examined Bill’s X-ray estimated the chance of a malignancy to be 45%,” and this difference sufficed to account quite rationally for differences in the numerical answers to the two sets of questions (see Cohen 1979, pp. 403–5). Moreover, when the dissimilarity of structure was remedied, the alleged phenomenon of diagnostic underestimation failed to emerge. Other results that appear to evince this phenomenon have to be discounted for different reasons (Cohen 1979, pp. 401–3). But the failure to distinguish appropriately here between conditional and unconditional probabilities is a good example of how the appearance of a fallacy in subjects’ reasoning may be generated by a slip in the application of the appropriate probabilistic analysis,⁹ since within normative probability theory the distinction between conditional and unconditional probabilities is well established.

Even the so-called gambler’s fallacy, or “fallacy of the maturity of chances,” which is sometimes referred to in the literature on cognitive irrationality (Tversky & Kahneman 1974; Hogarth 1975), comes under some suspicion. More empirical work seems necessary here, but there are at least three possible approaches to the phenomenon that call into question its interpretation as a fallacy of probabilistic reasoning.

If some people believe that after a long run of heads the probability of tails on the next toss will be greater than $\frac{1}{2}$, then one possibility is that they should be interpreted as believing thereby in a spirit of distributive justice that regulates the whole cosmos with a policy that ensures ever-increasing probabilities of a trend-reversing intervention whenever identical outcomes begin to succeed one another within an otherwise chance set-up. On this construal, a gambler’s metaphysical belief may be at fault, but not the rationality of his reasoning from it. However, such an interpretation needs independent evidence to support the attribution of belief in the particular case. Otherwise it is open to the charge of being culpably ad hoc, if not of merely repeating what is to be explained within the explanation.

Second, we may need to distinguish here between two rather different probabilities, either of which might be a matter for estimation. Is the gambler supposed to be estimating, in relation to the next toss of a fair coin, the

probability of a tails outcome within a space that consists of the two alternative outcomes: heads and tails? Or is the probability in mind, at the n th toss of a fair coin, that of having at least one tails outcome within any space that consists of n outcomes? Whereas the correct figure for the former would be $\frac{1}{2}$, the correct figure for the latter would get greater and greater than $\frac{1}{2}$ as n itself increases beyond 1, in accordance with Bernoulli’s theorem. To ascertain clearly and unmistakably which of the two probabilities is being estimated it would be necessary to question the gambler in a way that would tend to discourage any incorrect estimate, since in order to convey the exact meaning of a particular type of probability assignment (or, indeed, of any other type of statement), one needs to state the conditions under which such a judgment is true. So we are left with a characteristic indeterminacy here. Any attempt to extract an exact answer from the gambler would transform the situation in a way that would tend to disconfirm the occurrence of fallacious reasoning, and to the extent that the situation was not so transformed, the exact nature of the situation would remain in doubt. But it remains an open question, in view of what was said earlier about ordinary people’s ignorance of Bernoulli’s theorem, whether ordinary gamblers may legitimately be expected to be aware of its implications.

Finally, it may be that the matter at issue needs to be regarded more as a pragmatic than as a cognitive phenomenon. In the long run a gambler could integrate the so-called fallacy into a winning strategy against any opponent who always insists on even odds but is willing to play as long as the gambler wants: the gambler has only to continue increasing the stakes sufficiently at each toss until tails actually comes up. But, of course, such a strategy could be executed only within the limits of any restriction that is imposed on the stakes either by the opponent or by the gambler’s resources, just as any intellectual competence is subject to limitations in actual performance.

4. Applications of Inappropriate Normative Theory

There is a tendency for some investigators of irrationality to proceed as if all questions about appropriate norms have already been settled and the questions that remain open concern only the extent of actual conformity to these norms. It is as if existing textbooks of logic or statistics had some kind of canonical authority. But in fact

many important normative issues are still controversial. For example, it seemed at one time that at least the Frege-Russell logic of quantification had become a universally received doctrine. But its closeness of fit for the appraisal of natural-language reasoning is now under a powerful challenge (Sommers 1981) from work that exploits hitherto undiscovered ways of developing the Aristotelian tradition. Again, it seemed at one time to be generally agreed – and accepted by psychological investigators of decision making (see Slovic et al. 1977) – that the rational way to base action on estimates of chance was to follow the rule: “Rank possible courses of action according to their conditional subjective estimations of utility.” But this rule has been seriously challenged in recent years because it seems not to take proper account of the difference between actions as symptoms, and actions as causes, of states of affairs that we act to promote or avert (Jeffrey 1980).

Great care has certainly to be taken also in selecting the normative criteria by which the correctness of subjects’ probability judgments is assessed. In one experiment, for example, subjects were told that in a certain town blue and green cabs operate in a ratio of 85 to 15, respectively. A witness identifies a cab in a crash as green, and the court is told that in the relevant light conditions he can distinguish blue cabs from green ones in 80% of cases. The subjects were then asked: what is the probability (expressed as a percentage) that the cab involved in the accident was blue? The median estimated probability was .2, and investigators (Kahneman & Tversky 1972a) claim that this shows the prevalence of serious error, because it implies a failure to take base rates (that is, prior probabilities) into account. Kahneman and Tversky commented: “Much as we would like to, we have no reason to believe that the typical juror does not evaluate evidence in this fashion.” Lyon and Slovic (1976) have confirmed the robustness of the phenomenon, which is impervious to variations in the topic, numerical details, and sequential formulation of the story told to the subjects (with the proviso that blue and green cabs were present in equal numbers during the tests on the witness). And they complain that “since the world operates according to Bayes’s theorem, experience should confirm the importance of base rates” despite the apparent failure of subjects to recognize that it does so.

At best, these experiments would constitute a test of their subjects’ intelligence or education, since the ordinary person might no more

be expected to generate Bayes’s theorem spontaneously than Bernoulli’s. But in fact it is doubtful whether the subjects have made any kind of mathematical error at all. The experimenters seem to be reasoning as follows. In the long run, they say to themselves, the witness may be expected to make 68% correct identifications of a cab as blue ($\frac{4}{5} \times 85\%$), 3% incorrect identifications of a cab as blue ($\frac{1}{5} \times 15\%$), 12% correct identifications of a cab as green ($\frac{4}{5} \times 15\%$), and 17% incorrect identifications as green ($\frac{1}{5} \times 85\%$). Therefore he will altogether make 29% identifications as green, and the fraction of them that will be incorrect is $\frac{17}{29}$. Consequently, according to the way in which the experimenters seem to be reasoning, the probability that the cab involved in the accident was blue is $\frac{17}{29}$, not $\frac{1}{5}$.

But this last step is a questionable one. The ratio $\frac{17}{29}$ is the value of the conditional probability that a cab colour identification by the witness is incorrect, on the condition that it is an identification as green. Jurors, however, or people thinking of themselves as jurors, ought not to rely on that probability if they can avoid doing so, since reliance on it assumes the issue before the court to concern a long run of cab-colour identification problems – whereas in fact it concerns just one problem of this type. Jurors here are occupied, strictly speaking, just with the probability that the cab actually involved in the accident was blue, on the condition that the witness said it was green. And the latter probability is equivalent in the circumstances to the probability that a statement to the effect that the cab actually involved in the accident was green, is false, on the condition that the statement is made by the witness. If the jurors know that only 20% of the witness’s statements about cab colours are false, they rightly estimate the probability at issue as $\frac{1}{5}$, without any transgression of Bayes’s law. The fact that cab colours actually vary according to an $\frac{85}{15}$ ratio is strictly irrelevant to this estimate, because it neither raises nor lowers the probability of a specific cab-colour identification being correct on the condition that it is an identification by the witness. A probability that holds uniformly for each of a class of events because it is based on causal properties, such as the physiology of vision, cannot be altered by facts, such as chance distributions, that have no causal efficacy in the individual events. For example, if the green cab company suddenly increased the size of its fleet relative to that of the blue company, the accuracy of the witness’s vision would not be affected, and

the credibility of his testimony would therefore remain precisely the same in any particular case of the relevant kind.

The same point can be put another way by emphasizing the difference between probability functions that measure relative frequencies and probability functions that measure causal propensities (see Part I, Section 2 of this chapter). Propensity-type probabilities may be *estimated from* frequencies in appropriate samples (as with the witness's reliability), but what is actually evaluated is something different: a propensity, not a frequency. And propensity-type probabilities can be derived for individual events because they are predictable distributively. So it is natural to suppose that this is the kind of probability with which a jury is properly concerned, whereas the mere relative frequency of blue and green cabs is an accidentally accumulated characteristic of the town's cab population, considered collectively, and does not generate any causal propensity for the particular cab in the accident. Of course, if no testimony is mentioned and subjects know nothing except the relative frequency of the differently coloured cabs, then no causal propensity is at issue and the only basis for estimating the required probability is indeed the relative frequency. And this is in fact the kind of estimate that the investigators have then found to occur under experimental conditions (Lyon & Slovic 1976, p. 294).

The issue here is an important one since it has many ramifications. If the investigators had been right to impugn the rationality of common-sense judgments in the above example, it would have certainly been difficult to defend the continued use of lay juries. Consider too what you yourself would decide in the following circumstances. You are suffering from a disease that, according to your manifest symptoms, is either A or B. For a variety of demographic reasons disease A happens to be nineteen times as common as B. The two diseases are equally fatal if untreated, but it is dangerous to combine the respectively appropriate treatments. Your physician orders a certain test which, through the operation of a fairly well understood causal process, always gives a unique diagnosis in such cases, and this diagnosis has been tried out on equal numbers of A- and B-patients and is known to be correct on 80% of those occasions. The tests report that you are suffering from disease B. Should you nevertheless opt for the treatment appropriate to A, on the supposition (reached by calculating as the experimenters did) that the probability of your suffering from A is $19/23$? Or should you opt for

the treatment appropriate to B, on the supposition (reached by calculating as the subjects did) that the probability of your suffering from B is $4/5$? It is the former option that would be the irrational one for you, qua patient, not the latter; and in a rather comparable experimental situation (Hammerton 1973) subjects tended in fact to judge the matter along just those lines. Indeed, on the other view, which is the one espoused in the literature, it would be a waste of time and money even to carry out the tests, since whatever *their* results, the base rates would still compel a more than $4/5$ probability in favour of disease A. So the literature under criticism is propagating an analysis that could increase the number of deaths from a rare disease of this kind.

Admittedly, the standard statistical method would be to take the prior frequency into account here, and this would be absolutely right if what was wanted was a probability for any patient considered not as a concrete particular person, not even as a randomly selected particular person, but simply as an instance of a long run of patients. The administrator who wants to secure a high rate of diagnostic success for his hospital at minimal cost would be right to seek to maximise just that probability, and therefore to dispense altogether with the tests. But a patient is concerned with success in his own particular case, not with stochastic success for the system. So he needs to evaluate a propensity-type probability, not a frequency-type one, and the standard statistical method would then be inappropriate. Note, however, that the causal propensity analysis does not involve any repudiation of Bayes's theorem. It is just that the prior probabilities have to be appropriate ones, and there is no information about you personally that establishes a greater predisposition in your case to disease A than to disease B. We have to suppose equal predispositions here, unless told that the probability of A is greater (or less) than that of B among people who share all your relevant characteristics, such as age, medical history, blood group, and so on. An analogous supposition has to be made about the cab colours, unless we are told that because of faulty maintenance, say, the probability of a blue cab's being involved in accidents that share all the relevant characteristics of the present one, such as poor braking, worn tires, and the like, is greater (or less) than that of a green cab's being involved. Similarly, in a criminal law court the object is to do justice in each individual case, without taking a defendant's past criminal record, if he has one, into account. But it is easy enough to imagine analogous cases in which a

shoplifter, say, would escape conviction on the basis of probabilistic testimony about identification, if the relative frequency of honest shoppers could be cited in his defence! Or consider an example very like that cited by Todhunter (1949/1865, p. 400) in connection with the danger of applying the standard statistical method – which he traces to Condorcet – indiscriminately. A witness of 99.9% reliability asserts that the number of the single ticket drawn in a lottery of 10,000 tickets was, say, 297: ought we really to reject that proposition just because of the size of the lottery?

The difference between frequency probability and propensity probability is a difference between two functions that both satisfy the formal axioms of the classical calculus of chance. The two functions differ in their semantics, that is, with regard to the nature x and y must have, and the relation they must bear to one another, when, for a particular n , it is true that $p(x|y) = n$. But both functions have the same logical syntax; that is, each satisfies a multiplicative law for conjunction, a complementational law for negation, and so on. Nevertheless (as remarked above) it should by no means be taken for granted that all valid types of probability judgment in everyday reasoning can be modeled by functions that share this syntax.

For example, it has been held (Kahneman & Tversky 1972b, 1973, 1974; Tversky & Kahneman 1974) that intuitive judgments of probability are biased towards predicting that outcomes will be similar to the evidence afforded by typical cases. It is claimed that people use a representativeness heuristic as a rough-and-ready, though often misleading, guide in their probabilistic reasoning. But the validity of this claim depends on the assumption that such a judgment about degree of representativeness has to be interpreted as a means towards drawing some conclusion about probability in a sense of that term that conforms to the classical calculus of chance. If instead we abandon that assumption, we can avoid imputing any fallacies here. We can suppose that the judgment of representativeness leads to a conclusion about probability in a sense in which an inference from representativeness to probability is always quite legitimate – albeit a sense that conforms to principles different from those derivable within the calculus of chance. In fact, these principles can be shown to be implicit in the logic of controlled experiment, which was first developed by Francis Bacon (Cohen 1979). Bacon, in the preface to his *Novum Organum*, described the

central concern of his own enquiry in just the same terms as Bernoulli (1713, p. 211) described his, namely, the determination of “degrees of certainty.” But Bacon’s method defines a different concept of probability from Bernoulli’s (Cohen 1980b). Hume (1739) called it “probability arising from analogy,” and he wrote:

Without some degree of resemblance, as well as union, 'tis impossible there can be any reasoning; but as this resemblance admits of many different degrees, the reasoning becomes proportionally more or less firm and certain. An experiment loses of its force, when transfer'd to instances, which are not exactly resembling; tho' 'tis evident it may still retain as much as may be the foundation of probability, as long as there is any resemblance remaining.

When all this is made precise and its implications are developed systematically, one can show that, in appropriate contexts, concern with representativeness is not a potentially fallacious heuristic but rather a quite reliable, albeit somewhat crude, mode of commonsense reasoning under conditions of uncertainty (Cohen 1979, 1980d). It appears otherwise only if evaluated against a type of normative theory that is inappropriate in the circumstances (though admirably appropriate in many other circumstances).

Conclusion

The upshot of all this may be summarised as follows. No doubt ordinary people often err in their reasoning, and such a mistake begins to be of scientific interest when it can be shown to instantiate some regular pattern of performance error. However, nothing in the existing literature on cognitive reasoning, or in any possible future results of human experimental enquiry could have bleak implications for human rationality, in the sense of implications that establish a faulty competence. At best, experimenters in this area may hope to discover revealing patterns of illusion. Often they will only be testing subjects' intelligence or education. At worst they risk imputing fallacies where none exist.

Notes

- 1 The same is true for intuitions of grammaticality, pace Sampson (1975).
- 2 This issue is too complex to be treated adequately here; for a useful review; see Haack (1974).

- 3 I leave open here the much discussed question whether (Lewis and Langford 1959), Anderson and Belnap, 1974, or some other system provides a better fitting logic of everyday reasoning.
- 4 For example, the intuition that *B* is deducible from *A* whenever *A*-and-not-*B* is inconsistent (Lewis & Langford 1959) clashes with the intuition that one may not deduce every proposition from an inconsistent one (Anderson & Belnap 1974). So, though consistency is normally an overriding ideal for theory construction, one cannot treat the demand for it as the only foundation needed for a theory of deducibility: other intuitions, too, have to be taken into account.
- 5 Cf. how, in a maximally specific case, the systematic model of a clinician's judgmental strategies may be a better predictor than the clinician's own judgment (Goldberg 1970).
- 6 The analogy with perceptual illusion (such as the Muller & Lyer) was also drawn by Chapman and Chapman (1967, p. 194) in their interpretation of the partly experimental and partly real-life data about erroneous use of Draw-a-Person tests in psychiatric diagnosis. Both here and in their work on the psychodiagnostic use of Rorschach cards (1969) they traced the source of illusory correlations to a powerful bias by verbal association, since subjects with no clinical experience all tended to make the same erroneous correlations as many clinicians.
- 7 Apparently none of Wason's subjects objected, as would have been justified, that no finite number of questions and answers, whether falsificatory or verifactory, could prove such a hypothesis correct.
- 8 I take Grice to have established the mental or social reality of some such rules. In the logical context, however he does not use them, as I do, to explain the alleged prevalence of the fallacy of illicit conversion. Instead he tries to use them to explain away the apparent inappropriateness of a truth functional logic for the analysis of deductive reasoning a natural language, and in this he attempts an impossible task (see Cohen 1971; 1977a).
- 9 This has now been acknowledged by its authors (Kahneman & Tversky 1979).

Chapter 8: Breakdown of Will

GEORGE AINSLIE

1. Introduction

There have been plenty of books and articles that describe how irrational we are – in consuming drugs and alcohol and cigarettes, in gambling, in forming destructive relationships, in failing to carry out our own plans, even in boring ourselves and procrastinating. The paradoxes of how people knowingly choose things they'll regret don't need rehashing. Examples of self-defeating behaviors abound. Theories about how this could be are almost as plentiful, with every discipline that studies the problem represented by several. However, the proliferation of theories in psychology, philosophy, economics, and the other behavioral sciences is best understood as a sign that no one has gotten to the heart of the matter.

These theories almost never mention failures of will.¹ This is just not a concept that behavioral scientists used much in the twentieth century. Some writers have even proposed that there's no such thing as a "will," that the word refers only to someone's disposition to choose. Still, the word crops up a lot in everyday speech, especially as part of "willpower," something that people still buy books to increase.

It's widely perceived that some factor transforms motivation from a simple reflection of the incentives we face to a process that is somehow *ours*, that perhaps even becomes *us* – some factor that lies at the very core of choice-making. We often refer to it as our will, the faculty by which we impose some overriding value of ours on the array of pressures and temptations that seem extrinsic. People usually ascribe control of temptation to the power of will and the unpredictability of this control to the freedom of will.

Unfortunately, there has been no way to talk about such a faculty in the language of science, that is, in a way that relates it to simpler or better-understood elements. Without addressing this factor, science paints a stilted picture of human experience in general. However, quantitative motivational research has produced a distinctly new finding that promises to account for the phenomenon of will – with elements that are already familiar to behavioral science. That, in a sentence, is the topic of this book.

1.1. A Brief History of Self-Defeating Behavior

A lot has been said about the will since the classical Greeks wrote about why people don't – or shouldn't – follow their spontaneous inclinations. Plato quoted Socrates describing what can go wrong when people weigh their future options:

Do not the same magnitudes appear larger to your sight when near, and smaller when at a distance? . . . Is not [the power of appearance] that deceiving art which makes us wander up and down and take the things at one time of which we repent at another? . . . Men err in their choice of pleasures and pains, that is, in their choice of good and evil, from defect of . . . that particular knowledge that is called measuring.

Aristotle gave this disorder a name, *akrasia*, "weakness of will."² Thus a human faculty, not called will until later, was defined by the situation in which it failed.

Normally, a person was said to follow “reason,” to weigh her options in proportion to their real importance; but sometimes an option seemed to loom too large, a process called “passion.” Passion was the enemy of reason. As this dichotomy evolved, it began to define a functional anatomy of the self. Reason was the major part of your real identity; passion was something that *came over you* – the term was often contrasted with “action,” something you *do*.³

The self used reason to defend itself from passions and, if successful, developed a “disposition” to behave temperately. Reason and a temperate disposition were the good guys; passion and *akrasia* were the bad guys, perhaps the *other* guys. The Roman physician Galen said that their relationship was that of a man to an animal: “Irascible” passions could be tamed, but “concupiscible” passions (appetites, like sex and gluttony) were too wild and could be controlled only by starving them.⁴

The Judeo-Christian theological view of “weakness of the flesh” developed in parallel with the Greek rationalist one. A noteworthy difference was that the theological view made reason somewhat external to the self, and passion more internal. Reason was the word of God, and a function called will was, to a large extent, supplied by God’s grace. Passion was sin, a relentless part of man’s identity since Adam’s fall; but passion was sometimes augmented by external possession in the form of demons. The self swayed between reason and passion, hoping, in its reflective moments at least, that God would win:

I do not even acknowledge my own actions as mine, for what I do is not what I want to do, but what I detest. But if what I do is against my will, it means that I agree with the law and hold it to be admirable. But as things are, it is no longer I who perform the action, but sin that lodges in me . . . the good which I want to do, I fail to do; but what I do is the wrong which is against my will; and if what I do is against my will, clearly it is no longer I who am the agent, but sin that has its lodging in me. I discover this principle, then: that when I want to do the right, only the wrong is within my reach. In my inmost self I delight in the law of God, but perceive that there is in my bodily members a different law, fighting against the law that my reason approves and making me a prisoner under the law that is in my members, the law of sin.⁵

The assertion that the individual will had somewhat more power than this, and thus might not

depend on the grace of God, was rejected as one of the great heresies, Pelagianism.⁶

Other philosophies and religions have all included major analyses of the passions. They also discuss how to avoid them. Buddhism, for instance, concerns itself with emancipation from “the bond of worldly passions” and describes five strategies of purification, essentially: having clear ideas, avoiding sensual desires by mind control, restricting objects to their natural uses, “endurance,” and watching out for temptations in advance. However, the ways that non-Western religions enumerate causes of and solutions to self-defeating behaviors seem a jumble from any operational viewpoint of trying to maximize a good.

Despite all the attention paid, not many really new ideas about self-control have appeared over the years, even in the great cultural exchanges that brought the whole world into communication. One significant advance was Francis Bacon’s realization that reason didn’t have its own force, but had to get its way by playing one passion against another: It had to

set affection against affection and to master one by another: even as we use to hunt beast with beast. . . . For as in the government of states it is sometimes necessary to bridle one faction with another, so it is in the government within.⁷

The implication was that passion and reason might be just different patterns in the same system. Furthermore, they might be connected not by cognition but by some internal economic process, in which reason had to find the wherewithal to motivate its plans.

Another new idea was the Victorian discovery that the will could be analyzed into specific properties that might respond to strengthening exercises. We’ll look at these in detail later (Section 3.1.4 of this chapter).

Even as some nineteenth-century authors were dissecting the will, others began to get suspicious of it. Observers had long known that the will could get bogged down in minutiae, a problem that medieval scholastics called a “scrupulous conscience.”⁸ In early Victorian times Soren Kierkegaard warned of a more general but insidious affliction that seemed to come from the very success of willpower in controlling passion – a loss of what the existential school of philosophy, Kierkegaard’s heirs, came to call “authenticity.” The existentialists said that authenticity comes from a responsiveness to the immediacy of experience, a responsiveness that is lost when

people govern themselves according to preconceived “cognitive maps.”⁹

At the turn of the twentieth century, Freud described a division of motivational processes into those that serve long-range goals (the “reality principle”) and those that serve short-range ones (the “pleasure principle”). But the long-term processes are always distorted by an alien influence, “introjected” from parents, making them rigid. Freud rarely used the word “will,” and used it trivially when he did; but his farsighted processes and the “superego” that made them rigid would have been recognizable to his audience as components of will and willpower.¹⁰

Interest in the will grew steadily until about the time of World War I. After that the concept of will suddenly became highly unfashionable, even distasteful – as if people blamed it for their countries’ steadfastness in commanding millions of soldiers to face murderous fire and perhaps for the fortitude that led the soldiers to obey. Whatever the reason, the twentieth century saw our concepts of impulsiveness and self-control become diffuse. We continued to analyze reason in the form of utility theory, which defined that perfect rationalist, Economic Man. Passion and *akrasia*, however, are another story entirely, as are any devices that might be needed to overcome them. Explanations of them are ad hoc and higgledy-piggledy.

Willpower had become a popular Victorian virtue without any examination of where it came from. When it became tainted there was no agreed-upon way to analyze what was wrong, or what alternatives there might be, or even precisely what function it was supposed to perform.

1.2. *How to Study Self-Defeating Behavior*

Something is obviously wrong or at least incomplete about the way we’ve understood *akrasia* and self-control. I believe that new findings make it possible to say a lot about the will and the reasons why it succeeds and fails where it does; but first, we have to look at what’s already been said. Behavioral scientists still study weakness and strength of will, although usually without those specific concepts in their minds – sometimes without even the concept of motivation. But these scientists don’t talk to most of their colleagues. Like so many fields where people are probing a mystery, decision science has split into schools whose members agree within their groups on certain assumptions and ways of doing research. Reading other schools’ writings means forging the shorthand you’ve become adept at

in your own school, not to mention the confidence that what you write yourself will have a willing audience. Mostly, we don’t bother.

But these schools have separately discovered many different tools to work on the will problem. Before we start work, we need to look at the available methods. Here’s an informal list of the schools that have studied will-related decisions:

Behaviorism is the school that has designed most of the systematic experiments on utility theory. The behaviorists have made especially good use of animal models. Lower animals are different from people, of course, but their subcortical brain structures are similar, including the systems that govern motivation, and this similarity is reflected in a similar response to most (but not all) schedules of reward. For instance, animals can become addicted to all the substances that affect people. Based on their ability to judge how rich different sources of reward are, animals often seem to be more rational than people.¹¹

The neurologist Paul MacLean once observed that the human cortex rides on lower brain functions like a man riding a horse. Although we can’t use animals to study some higher functions – wit, irony, or self-consciousness, for instance – we can use them to study the horse we all ride. And when a mental process can be demonstrated in animals – like a conflict between motives at successive times – it spares us speculation about subtle causes like quirks of culture.

However, the careful experiments that the behaviorists do have been overshadowed by their righteousness about method. To the average educated person, a behaviorist is somebody who believes that the mind doesn’t exist, and that people’s behavior can be accounted for entirely by the observable stimuli that impinge on them. Even the academic community tired of this brand of logical positivism and stripped the behavioral school of most of its glory. As a source of carefully controlled data, however, it remains unsurpassed, and its data are the starting place of this book.

Cognitive psychology, often as applied to social psychology, is currently the most widespread approach to both research and theory dealing with irrational behavior. It generally has high standards of experimental proof and has described many examples of maladaptive behavior. However, its theorists seem to have gone out of their way to avoid dealing with the process of motivation, seeing it as at most some kind of internal communication that a higher judge – the irreducible person – can and often should disregard. Thus its theories of irrationality have

been restricted to finding errors of perception or logic.

Economics is the field that deals with rational decision-making in the real world. In modern times it has embraced the assumptions of utility theory, as characterized by Paul Samuelson: "The view that consumers maximize utility is not merely a law of economics, it is a law of logic itself." Gary Becker showed that economic concepts could handle even nonmonetary incentives like drug highs and the risk of jail.¹²

However, economists have made some unrealistic assumptions about decisions: that they're all deliberate, that they're based only on external goods (as opposed to rewards that you might generate in your own head), and that they're naturally stable in the absence of new information. Since this stability should make decisions consistent, economic theories have attributed irrationality only to inadequate information or steep discounting of the future, explanations that are both inadequate, as we'll see.

Philosophy of mind looks at model-making itself, and has pioneered thought experiments whereby every reader can test a particular theory.¹³ However, it has stayed within the conventional assumptions of a unitary self – unitary in the sense of not housing contradictory or unconscious elements. If anything should allow exploration of a more molecular model of the self, it should be thought experiments; but the seeming paradoxes that some have demonstrated have not led analysis beyond standard utility theory. They remain paradoxical.

Psychoanalysis was the first major attempt to confront self-contradictory behaviors with utility analysis. As an explorer of scientifically virgin territory, Freud sketched out several different models – one based on motivation ("libido"), one based on consciousness, one based on organization ("id," "ego," "superego"), and so on. But he didn't work out how the various models got along with each other. Without the discipline of either controlled observation or conceptual parsimony, psychoanalysis grew overinclusive, until it resembled the polytheisms from which it drew some of its observations.

Oversold in the middle third of the twentieth century, psychoanalysis has lately been the target of vigorous attacks aimed at its standards of observation and proof. The essayist Frederick Crews concluded that

the designer of psychoanalysis was at bottom a visionary but endlessly calculating artist, engaged in casting himself as the hero of a

multivolume fictional opus that is part epic, part detective story, and part satire on human self-interestedness and animality.¹⁴

It hasn't been fashionable to ask whether even a fictional opus that once had such immense popularity among intelligent people may offer insights worth keeping.

Actually, Freud brought together a lot of previous work that describes disunity of the self, and this has gone into limbo with him.¹⁵ Worse, people who have found his answers wrong or incomplete have stopped asking his questions, and these questions have to be in the forefront of any attempt to explain impulsiveness and impulse control: Is all behavior motivated? How can someone obey internally contradictory motives? How can you hide information from yourself? How can self-control sometimes make you worse off? On many questions I'll start with Freud's ideas – because, in my view, after modern criticism tacked the ball carrier, no one ever picked up the ball.

Bargaining research, a new discipline, has used elementary games to see how small groups of competing agents can reach stable relationships. It is especially suggestive when it shows how such a group can reach stable decisions that are not in all or any member's best interest. However, until now, bargaining research has not seemed applicable to conflict within the individual because of the supposed unity of the person. Given a rationale for disunity, we'll find it useful.

Chaos theory, an even newer theory of analysis, has been applied to other subjects – the weather, for instance – to explore how outcomes may depend on a recursive feedback system. It has also shown how such a system may lead to similar patterns at different levels of magnification and even to the growth of the different levels themselves. So far chaos theory has lacked any important motivational example. However, the fundamental unpredictability of the human will, which has defied attempts to explain it by antecedent causes, makes it look like some of the natural phenomena where the chaos approach has proven useful. As we find recursive processes in the will, chaos theory will become relevant.

Sociobiology has studied competition among populations of reward-seeking organisms, so it has developed concepts that might be useful for populations of behaviors – the range of behaviors that an organism tries out – as well. Behaviorists have proposed that reinforcement acts on behaviors the way natural selective factors act on organisms.¹⁶ This suggests some way that

sociobiological theory might apply to conflicting motives.

Neurophysiology has produced increasingly precise findings on brain mechanisms, including those that create motivation. It's possible to see, for instance, exactly where and by what neurotransmitters cocaine rewards the behaviors that obtain it;¹⁷ but pinpointing the transmitters doesn't explain how a conflict between alternative rewards gets resolved or why it fails to get resolved in some cases. It may be, for instance, that some alcoholics have inherited settings in their reward mechanisms that make alcohol more rewarding for them than for most people; but this doesn't tell us why many alcoholics are conflicted about their drinking – why they often decide not to drink despite the intensity of this reward and, having decided this, why they sometimes fail to carry out their own decision. Neurobiology will be useful here mainly as a check on reality, as a body of findings with which any motivational theory must at least be consistent.

Theology shouldn't be disregarded. It has studied a part of our decision-making experience that seems to lie outside the will and has been least influenced by the lure of utility theory. Despite its own theory that its insights come mystically, by faith, revelation, or some such nonempirical route, theology actually demands that its tenets ring true to experience. Sin, for instance, seems synonymous with the self-defeating behaviors that the more scientific disciplines have talked about; the debates that have occurred over the power of the individual will to overcome sin have appealed to what is, in effect, clinical experience. But what this inspirational approach has gained in sensitivity it has lost in testability, and it becomes arbitrary when it tries to nail down its insights in a systematic way. Like psychoanalysis, it will be a source more of questions than of answers. But the questions are important ones.

Finally, any explanation of *akrasia* has to be at least compatible with *subjective experience* and might well find evidence there. Some behavioral scientists sniff at experiential evidence as “folk psychology” and warn of the days when psychologists tried to gather data using trained introspectors. While common sense is suggestible at best and, as theory, almost always inconsistent and ad hoc, it is by far the largest body of human observations. Useful samples of common experience appear in the writings of the pre-experimental (Victorian) psychologists and of later clinicians who have interviewed patients, as well as in those works of fiction that have rung

true with generations of readers. Jon Elster has been especially insightful in sorting the pieces of our written heritage by their motivational implications.¹⁸

1.2.1. MY APPROACH TO THE PROBLEM

So how should we assemble a working tool kit from all of these methods? I'll suggest one way, obviously not the only one possible. But as far as I can tell, it's the only proposal so far that reconciles the familiar paradoxes of motivation with basic research.

I warn the reader in advance that this approach is *reductionistic*. That is, I assume that every change in thinking, feeling, wanting, planning, and so on, has a physical basis in the nerve cells of the brain, which in turn depend on chemical changes within the cells, and so on. I'm not saying that thinking and feeling are best studied by studying the chemistry of cells – only that all explanations of behavior should at least be consistent with what's known in the physical and biological sciences.

Nonreductionistic (and antireductionistic) theories have been created for a reason, of course. In the past, reductionistic theories ignored causes that were hard to observe or to imagine – that is, too hidden or complex or internally fed back – like cognitions, or intuitions, or will. “Scientific” explanations therefore made people seem like robots.¹⁹

By the same token, my proposals are *deterministic*. Aside from some irrelevant arguments about whether the movements of subatomic particles are strictly determined, the physical sciences assume that all things that happen are shaped completely by prior causes, which have causes in turn. I do, too. I don't mean that these causes can be found. Some are probably too hidden or complex or internally fed back ever to be useful for practical prediction; but again, explanations of behavior should never depend on some uncaused or otherwise imponderable factor.

Students of human behavior often rebel against reductionism and determinism in favor of holistic, humanistic approaches so that science can still examine feelings, not to mention the many other private subtleties that can be introspected but not tested. However, I'll argue that these subtleties – among them self-deception, self-control and its loss, self-esteem and its loss, and freedom of will itself – are completely consistent with a reductionistic theory of choice.

So please don't be put off by my warning. The humanist reader will find protection, even

ammunition, in the model of choice I'm going to propose.

1.3. Summary

The human bent for defeating our own plans has puzzled writers since antiquity. From Plato's idea that the better part of the self – reason – could be overwhelmed by passion, there evolved the concept of a faculty, will, that lent reason the kind of force that could confront passion and defeat it. The construct of the will and its power became unfashionable in twentieth-century science, but the puzzle of self-defeating behavior – what Aristotle called *akrasia* – and its sometime control has not been solved. With the help of new experimental findings and conceptual tools from several different disciplines, it will be possible to form a hypothesis about the nature of will that does not violate the conventions of science as we know it.

2. The Warp in How We Evaluate the Future

If the headache would only precede the intoxication, alcoholism would be a virtue.

Samuel Butler

Lore abounds not only about how people mistrust their own future preferences, but how they sometimes engage in strategic planning to outsmart the future selves that will have these preferences. Here is Ulysses facing the Sirens or Coleridge moving in with his doctor to be protected from his opium habit. We know that the stakes in this intertemporal game sometimes reach tragic proportions. Yet we can't reconcile this game with utility theory's basic meat-and-potatoes notion that people try to maximize their prospects. The irony of smart people doing stupid things – or having to outsmart themselves in order not to – appears in literature again and again, but without an explanation.

This quandary may have been one reason for the popularity of cognitive explanations, which at least stay close to intuition. The problem hasn't undermined utility theorists, but it has cramped their style. They go from success to success in areas like finance and sociobiology, where tough competition selects strongly for individuals who function like calculating machines. However, their attempts to explain self-defeating choice on a rational basis have been unconvincing; the most notable has been the effort by economists Gary Becker and Kevin

Murphy to show how a person who sharply devalues the future might maximize her prospective pleasure by addictive behavior. Their proposal is basically that devaluation of the future leads to addictive behaviors, which further increase this devaluation. They suggest no rationale for fearing future choices, much less for trying to restrain them.²⁰ Utility theorists have mostly stayed away from the subject. Some writers have thrown up their hands altogether by concluding that there are options that, although substitutable for one another, can't be weighed against each other.²¹ While science stands by, mystified, people keep wrecking their own lives.

2.1. The Hyperbolic Curve that Discounts Future Events

Another solution to the self-harm puzzle has always been logically possible, but utility theorists and cognitivists alike keep ruling it out, perhaps because its implications would require the rethinking of basic assumptions about rationality: People indeed maximize their prospective rewards, but they discount their prospects using a different formula from the one that's obviously rational. It will take a little arithmetic to illustrate this possibility clearly.

Few utility theorists question the assumption that people discount future utility the way banks do: by subtracting a constant proportion of the utility there would be at any given delay for every additional unit of delay. If a new car delivered today would be worth \$10,000 to me and my discount "rate" is 20% a year, then the prospect of guaranteed delivery today of the same car would have been worth \$8,000 to me a year ago, \$6,400 two years ago, and so on (disregarding inflation, which merely subtracts another fixed percentage per unit of time).

Utility theory operates the same way for reward itself, although it has to use a fanciful unit of measure like the "utile." If drinking a bottle of whisky is worth 100 utiles to me right now and my discount rate for drinking is 20% per day, the prospect of today's drinking would have been worth 80 utiles to me yesterday, 64 utiles the day before, and so on. Furthermore, if the drinking has a cost of 120 utiles that has to be paid the day after in the form of a hangover, reproaches from my family, and so on, and I discount these at the same rate, the net utility of drinking today will be $100 - (120 \times 80\%, \text{ or } 96)$, or 4 utiles. So I should decide to drink. If I foresaw this episode from a day away, the net value would

have been $(100 \times 80\%) - (120 \times 80\% \times 80\%)$, viz., $80 - 76.8$, or 3.2 utiles. At that point I would still have decided to drink.

The arithmetic is simple. You just multiply each discounted value on any day by 80% for each anticipated day of further delay and find the difference: 3.2 utiles for one day in advance, 2.56 utiles for two days in advance, and so on. The discounting method can be summarized for delays of any length by the formula

$$\text{Value} = \text{"Objective" value} \\ \times (1 - \text{Discount rate})^{\text{Delay}}$$

This discount function is called "exponential" because it calculates value by an exponential, or power, function of the discount rate.²²

With exponential discounting, the difference in the utility of drinking in our example gradually gets smaller, but the important thing is that it never goes negative or even gets to zero. If I'd choose to drink when the opportunity was right at hand, I'd also choose to drink when it was a week or a year away. If I'd choose not to drink from the vantage point of some delay – if, say, my discount rate were just 10% – then I'd still choose not to drink when the opportunity was immediately at hand, as well as at all other distances. (The net value of drinking would be -8 utiles at no delay, -7.2 utiles one day in advance, -6.48 at two days, and so on.)

This arithmetic seems to describe the consistency many people show toward large purchases – bankers, at least, and others who decide "rationally"; but it misses the mark for drinkers, or at least for people whose drinking is serious enough to involve hangovers and reproaches from their families. People who are strongly drawn to drinking – or taking drugs, or gambling, or kleptomania, or any other thrills of the kind that people later regret – typically experience swings of preference between indulging their habit and giving it up. And the swings are often influenced by how close an opportunity for indulgence is. People trying to control a bad habit tend to keep a distance between themselves and opportunity – avoid the streets where their favorite bars are located and similar strategies.²³

Faced with this instability of choice – economists have taken to calling it "dynamic inconsistency," but it amounts just to a temporary preference for the poorer alternative – writers have come up with various fudge factors to make it fit the principle that people strictly maximize their exponentially discounted prospects for reward

(see the introduction to this chapter). The most obvious suggestion is that people discount different kinds of reward at different rates. If I discount drinking by 40% per day but discount not having a hangover the day after (worth 120 utiles) by 20%, then the net utility of an immediate drinking bout would be $100 - (120 \times 80\%)$, or 4 utiles; but its net utility a day in advance would be $(100 \times 60\%) - (120 \times 80\% \times 80\%)$, $60 - 76.8$ or -16.8 utiles. I would drink if the chance were at hand but not if it were delayed.

The trouble with this solution is that many cases of temporary preference involve the same kind of reward on both sides of the choice; a difference in discount rate for different kinds of reward can't be a factor. The punishment for gambling to win money is to lose money. Likewise, people in experiments do things like choosing a shorter period of relief from noxious noise over a longer but later period of relief from the same noise if and only if the shorter, earlier period is imminent. It makes no sense to hypothesize that the earlier relief is discounted at 40% but the later relief of the same kind is discounted at 20%.

Long ago philosophers noted that avarice was a bad habit partly because it was self-defeating – that impatience for riches usually made people poorer in the long run.²⁴ If the basic reward-weighting mechanism is the same among all the higher animals – the same assumption that lets us study addictive drugs in rats, for instance – we can see this self-defeating phenomenon clearly in quantitative experiments. For instance, pigeons will choose a shorter, earlier access to grain over a later, larger one when the shorter one is immediate and not when it's delayed; and some of them will actually peck a colored key in advance to prevent themselves from later getting offered a differently colored key that produces the smaller reward – showing that in some way the pigeons themselves are responding to their own tendency to choose the smaller, earlier reward as a problem.²⁵

In light of such findings, it's not enough to say that the kinds of things that reward impulses are discounted more steeply than the kinds of things that reward rational choices. Exponential discounting can't account for temporary preferences in knowing subjects. On the other hand, any kind of nonexponential discounting should lead to maladaptive behavior.

The main theoretical rival to the exponential curve is *hyperbolic* – more bowed than an exponential curve; when goods at both very short and very long delays would be valued the same as

Figure 1. An exponential discount curve and a hyperbolic (more bowed) curve from the same reward. As time passes (rightward along the horizontal axis), the motivational impact – the *value* – of her goals gets closer to its undiscounted size, which is depicted by the vertical line.

with exponential discounting, goods in between would be valued less²⁶ (Figure 1). If people devalue future goods proportionately to their delay, their discount curve will be hyperbolic.

The greater bowing means that if a hyperbolic discounter engaged in trade with someone who used an exponential curve, she'd soon be relieved of her money. Ms. Exponential could buy Ms. Hyperbolic's winter coat cheaply every spring, for instance, because the distance to the next winter would depress Ms. H's valuation of it more than Ms. E's. Ms. E could then sell the coat back to Ms. H every fall when the approach of winter sent Ms. H's valuation of it into a high spike. Because of this mathematical pattern, only an exponential discount curve will protect a person against exploitation by somebody else who uses an exponential curve.²⁷ Thus exponential curves seem not only rational, in the sense that they're consistent, but also adaptive. At first glance, it looks as if natural selection should have weeded out any organism that didn't discount the future exponentially.

Nevertheless, there's more and more evidence that people's natural discount curve is not only nonexponential, but specifically hyperbolic. The simplest sign is that such curves cross if they're from alternative rewards available at different times.

The experiment used to test whether a subject's discount curves cross is simple: You offer subjects a choice between a small reward at delay D versus a larger reward of the same kind that will be available at that delay plus a constant lag, L . A subject gets the small reward at delay D from the moment she chooses or the larger reward at delay $D + L$. If she discounts the choices according to conventional theory, her curves will stay proportional to each other (Figure 2A). If she chooses the larger reward when D is long but switches to the smaller reward as D

Figure 2A. Conventional (exponential) discount curves from two rewards of different sizes available at different times. In the experimental design described in the text, the delay D is the distance between when the subject chooses and when the earlier and later rewards will be available, and the lag L is the distance between when the earlier and later rewards will be available, shown by the vertical lines. At every point at which the subject might evaluate them, their values stay proportional to their objective sizes.

gets shorter, she's showing the temporary preference effect that implies a discount curve more bowed than an exponential one (Figure 2B).

This research strategy has one potential problem: If people really discount the future with highly bowed curves that cross, then when D is long they'll be motivated not only to choose the later, larger reward but somehow to forestall the change of choice that occurs as D gets shorter. Like the pigeons that learned to peck the colored key to forestall the tempting, other-colored key, subjects might have learned ways to make up for this tendency. Otherwise, they'll have been at risk of exploitation by other people who have learned these ways – as in the overcoat example. An experiment like this might not uncover their natural, spontaneous preferences, but only those that they had been educated

Figure 2B. Hyperbolic discount curves from two rewards of different sizes available at different times. The smaller reward is temporarily preferred for a period before it is available, as shown by the portion of its curve that projects above that from the later, larger reward.

to express. This kind of learned compensation might be a serious obstacle to observation.

The best way around this obstacle should be to use the kind of reward that the subject experiences ("consumes") on delivery and also the kinds that don't lend themselves to mental arithmetic. When experimenters have used this kind of reward, people have shown a persistent tendency to reverse their preferences as D changes, evidence that their basic discount curves cross and are thus more hyperbolic than exponential: People exposed to noxious noise and given a choice between shorter, earlier periods of relief and longer, more delayed periods choose the shorter periods when D is small and the longer periods when D is long. College students show the same pattern when choosing between periods of access to video games. Retarded adolescents show it in choosing between amounts of food. Certainly at the gut level, people's discount curves cross.²⁸

Furthermore, it turns out that whatever method people may have learned in order to compensate for hyperbolic discounting, it doesn't spoil temporary preference experiments. Even money, the archetypical token reward – "token" in the sense that it has its effect only by letting subjects buy other rewards later, and invites the counting and comparing of alternatives – turns out sometimes to be chosen differently, depending on D . If I ask a roomful of people to imagine that they've won a contest and can choose between a certified check for \$100 that they can cash immediately and a postdated certified check for \$200 that they can't cash for three years, more than half of the people usually say they would rather have the \$100 now. If I then ask what about \$100 in six years versus \$200 in nine years, virtually everyone picks the \$200. But this is the same choice seen at six years' greater distance.

This is an experiment you can perform for yourself. I recommend it as a way of getting direct experience with this unexpected warp in people's outlook. You might want to confront the people you ask with the fact that they've changed their preference on the basis of their vantage point, and ask how they explain it. Answers involving inflation or uncertainty about getting the later amount obviously make no sense, since the lag between the alternatives is the same in both examples. Some subjects have suggested that the promise of immediate money has a sensory (sensuous?) quality that money at any delay doesn't have, and other subjects say that the three-year lag doesn't seem as

long when postponed; neither of these explanations is inconsistent with the notion of a high spike of value at short delays. The one explanation that might preserve exponential discounting is that a student expects to graduate within the next three years, and thus thinks she needs the money significantly more right now than she will at three, six, or nine years. However, getting the temporary preference effect doesn't depend on having young and perhaps temporarily poor subjects or, for that matter, on making the smaller value of D zero. Various groups of subjects have shown the change of preference over a range of D values. Some excellent recent work has made it possible to describe the exact shape of subjects' discount curve in similar amount-versus-delay experiments.²⁹ It's clearly hyperbolic for all age groups, although older subjects discount the future less steeply than younger ones, introverts less steeply than extroverts, and ordinary adults less steeply than heroin addicts or even smokers.³⁰

Subjects working for actual cash don't always show the temporary preference effect. The factors that determine whether they'll show it or not have just begun to be explored, but the early findings are revealing: For instance, when subjects had to choose between amounts of money such that choice A produced a conspicuously larger reward than choice B, but choice A led to poorer subsequent payoffs for both choices, the outcome depended on an important detail of the design: Where choice of a larger amount reduced the *amounts* to choose between on subsequent turns, most subjects soon discovered the strategy of picking the smaller amount in the current choice so as to have better choices later. However, where choosing the larger amount led to greater *delay* before subsequent choices, thus reducing total income in trials of fixed duration, subjects tended to keep picking the larger amounts and getting smaller subsequent returns. They were lured into what the experimenters called "melioration," taking what by itself seems the best choice without considering the bigger picture. Amounts are well defined and obvious, lending themselves to conscious scrutiny; delays are vague unless you specifically count the seconds. As we might expect, when the experimenters pointed out to their subjects the greater delay that came from choosing the larger reward, these subjects, too, started choosing the smaller one.³¹

Hyperbolic discounting is even more evident in lower animals, which shows that it isn't some quirk of human culture. In scores

of experiments, animals have always chosen rewards in inverse proportion to their delays – and, similarly, punishments in direct proportion. Animals also do what crossing discount curves predict: In amount-versus-delay experiments they choose the smaller, earlier reward when D is short and the larger, later reward when D is long. It was the consistency of animal findings that led Herrnstein nearly forty years ago to propose a universal law of choice, which he called the “matching law”: that rewards tend to be chosen in direct proportion to their size and frequency of occurrence and in inverse proportion to their delay. Many researchers have since offered variations to fine-tune the matching law to describe individual differences in impatience, but the best seems to be one of the simplest:³²

$$\text{Value} = \text{Amount}/(\text{Constant}_1 + (\text{Constant}_2 \times \text{Delay}))$$

In practice the constants seem to stay close to 1.0 which simplifies the equation still further. When I discuss the likely consequences of hyperbolic discounting, I’ll be using this formula.

2.2. *Implications of Hyperbolic Discounting*

Does this apparent universality of hyperbolic discounting mean that utility theorists through the ages have been wrong – that philosophers and bankers and welfare economists should have been calculating the worth of goods using the deeply bowed curves of Figure 2B? This can’t be true either. We saw in the overcoat example that exponential discounting is better than hyperbolic discounting, in the sense that exponential discounters win out in competition with hyperbolic discounters.

The conventional answer would almost certainly be that since only exponential curves produce consistent preferences, they’re the ones that are objectively rational, and that people should learn to correct their spontaneous valuations to fit them. After all, science has long known that the intensity of many other subjective experiences is described by hyperbolic curves and that people can learn to correct such impressions. It soon becomes second nature to a child that the telephone pole down the street is as tall as the one nearby, even though it forms a smaller image on her retina. Even where spontaneous impressions are misleading, you learn to trust instruments for measuring objective size – light by your camera’s light meter, distance to

travel by an odometer or map, and so on – without feeling that you’re wrestling with some inner resistance. You develop “object constancy.” Can’t people learn to value reward in proportion to its objective amount, just as we learn to gauge objective brightness and distance?

That’s what conventional utility theory calls for; but despite data from your clocks and calendars, such an adjustment seems to occur irregularly, sometimes not at all. It usually takes some kind of effort (willpower again) to evaluate a smaller present satisfaction as less desirable than a greater one in the future. This is where the analogy of delay to other sensory impressions like length breaks down: You may move through time toward a goal just as you move through space toward a building, and the matching law formula describing your spontaneous valuation of a goal is indeed close to the formula for the retinal height of the building.³³ But the building doesn’t seem to get larger as it gets closer, whereas the goal often seems to get more valuable. Insofar as you fail to make the correction in value that corresponds to your correction of retinal height, poorer goals that are close can loom larger than better distant goals. Although people develop some faculty for utility constancy, it takes effort and remains tenuous.

These observations provide additional help with the question we discussed earlier: Which is more basic, cognitive or motivational evaluation? If cognitive judgments ultimately control choice, it should make no difference whether you’re estimating the size of a building or a reward; either way, an evaluation with full knowledge should parallel the objective size of the objects in question, and any choices that depend on this evaluation should follow without further effort. If hedonistic effects are primary, however, the two cases will differ: A larger image on the retina doesn’t of itself pull a person one way or another and thus doesn’t resist cognitive transformation. But if reward is the fundamental selective force of choice, then however you perceive or categorize it, you’re still acted upon by its direct influence. You should often prefer lesser alternatives during the period when they’re imminent; and this is just what the foregoing research describes. Thus experience suggests that there’s a raw process of reward that constitutes the active determinant of value. While it can be perceived abstractly, it doesn’t occur differently because of this abstraction.

In the following comparison of lines, the second one continues to look longer, even after

we've measured them and found that they are the same length:

In the same way, knowing that, all things considered, eating another dessert or putting off going to the dentist will make me less happy in the long run doesn't of itself reduce my urge to do these things. Still, any sensible person would argue that we learn not to do them – most of the time, anyway. Doesn't this mean that we've learned to change our discount curves?

Yes and no. If we infer someone's curve from her expressed preferences, then as she gets older and wiser, we'll see her apparent curve get shallower and less bowed; often we'll see her act exactly as if she discounted future goods exponentially at the rate of inflation plus 3% or so a year. But as we've seen, there will be situations where she'll be both more impatient and more inconsistent than that. These are signs of the persistence of another curve – one that is both steeper and has a tendency to cause reversals of preference. The banker-like curve seems to represent an added accomplishment, not a fundamental change.

This is what we should expect. If a person could learn to change the discount curve she was born with, there would always be a strong incentive to do so as much as possible: If some distant prospect – a Christmas present, say – was worth only 3 utiles to you now, but by some trick you could make it worth 5 utiles, you could make yourself 2 utiles richer just by doing this trick. If you could act directly on your discount curves, you could coin reward for yourself, so to speak. We'd expect everyone to exploit this trick all the time, as much as they could. If it was the kind of trick you had to keep doing, it would be like candy or a tranquilizer, something you did *instead* of getting impatient. If it was the kind of trick you could do once and for all, then your impulsive urges to drink or smoke or spend should just disappear. The point is that we study people – and animals, for that matter – after whatever curve-flattening they're capable of should have already happened. The hyperbola we detect is what has survived this learning. The trick of behaving as if your curve were exponential has to be an effortful, sometime thing, not a modification your basic curve.

Of course, nature doesn't always put things together in the simplest way. The widespread appearance of hyperbolic discounting may not mean that it's a universal form, the underlying pattern from which all other valuation patterns are derived. The appearance of hyperbolic discounting in some situations and exponential discounting in others may turn out to have an explanation now hidden from us. But theories should always start in the simplest way. Let's assume that the ubiquitous hyperbola is the basic discount curve – that our basic instinct is to evaluate future events by dividing their amount by their delay – and see where its implications lead us.

2.2.1. HOW UTILITY THEORY CAN PREDICT INCONSISTENCY

The most basic implication is that you'll tend to prefer smaller, earlier rewards to larger, later ones temporarily, during the time that they're imminent. Then the obvious task is to find out what kind of effort could sometimes make your expressed preferences look exponential. Hyperbolic discounting is a shock for utility theory. Suddenly the pavement moves beneath our feet, and we have to take the simple concept of maximizing expected reward not as a description of basic human nature but just as a norm that we try to implement. Only if a person is lucky or skillful can she achieve such consistency in the face of this screwball valuation system.

The good news is that hyperbolic discounting, and its consequent temporary preferences, will let utility theory move beyond its stalemate with cognitivism. Let's return to the problems that the two approaches have had in explaining *akrasia*. In cognitive models the person ultimately stands outside of her emotions – emotions being the closest cognitivist equivalent of motivation – and says, "This experience is misleading. I'll select my behavior instead on the basis of accurate calculations of its value." The trouble is that there's a lot of leeway in the calculation process, as cognitive research itself has shown; when someone has a choice among different ways of calculating value, how does she choose the one she'll use? To be sure, everyone has had the experience of mistrusting an emotion, or even disowning it. We inhibit an emotion sometimes or "nurse" one. To some extent we can indeed mold the influence that in turn molds us. But when I stand outside of my emotions, what am I standing on? In other words, what determines my choice of cognitions?

The argument between the cognitive and utilitarian schools has been about whether

choice is fundamentally determined by some kind of internal marketplace, or else by a planned economy, in effect an internal bureaucracy of principles and logic. The conventional view of a person's self-command structure is definitely bureaucratic, on the model of a corporation or an army, where superior agents simply pass commands down to inferior ones. However, closer examination of corporations and armies has shown that despite the establishment of hierarchical command structures, they remain marketplaces where officers must motivate rather than simply ordering behaviors.³⁴ Sheer instructions aren't enough to control someone's behavior, as bureaucrats have discovered again and again; any system that tries to govern behavior by regulations develops an underground economy of motives – of favors and obstructions, and hiding places from supervisory procedures – that ultimately determines what gets done.³⁵

Utility theory says that the experience of reward is the fundamental selective factor for behaviors, so that you can't stand outside of that experience and choose dispassionately among rewards. You might as well say, "The thermometer tells me not to feel cold, so I won't." The utilitarians' problem has been that they've assumed a person's evaluation of rewards (or emotions) to be exponentially discounted, and hence consistent over time; as a result, utility theory hasn't been able to account for self-defeating choices, or for the various kinds of uniquely human effort that we call forth to avoid them. If we simply maximize our prospective reward, what use do we have for self-control? What role is there for a will, either strong or free?

My argument is that exchanging hyperbolic discounting for the exponential kind in the reward-maximizing process supplies utility theory with its missing element. Utility theory can now explain the seductiveness of self-defeating choices; and the assumption that a person has to strictly maximize her expected, discounted reward explains why she doesn't automatically learn to be objective, the way she does with sizes and distances. Reward has its effect directly, and intellectual adjustment takes place only tangentially. With hyperbolic instead of exponential discounting, utility theory now says that people will naturally go for smaller, earlier over larger, later rewards. We're unable *not* to choose the reward that looms largest when discounted to the moment of choice. *Akrasia* is just maximizing expected reward, discounted in highly bowed curves.

2.2.2. THE SELF AS A POPULATION

Hyperbolic discounting shifts the main problem for utility theory. We're no longer at a loss to explain shortsighted choices. Now we have to account for how people learn the adaptive controls that let them behave like bankers. How does an internal marketplace that disproportionately values immediate rewards grow into what can be mistaken for either the reasoning self of the cognitivists or the long-range reward maximizer of conventional utilitarians?

We can no longer regard people as having unitary preferences. Rather, people may have a variety of contradictory preferences that become dominant at different points because of their timing. The orderly internal marketplace pictured by conventional utility theory³⁶ becomes a complicated free-for-all, where to prevail an option not only has to promise more than its competitors, but also act strategically to keep the competitors from turning the tables later on. The behaviors that are shaped by the competing rewards must deal not only with obstacles to getting their reward if chosen, but also with the danger of being un-chosen in favor of imminent alternatives.

How does a marketplace of hyperbolically discounted choices ever come to look like a single individual? If I discount future reward hyperbolically, and make whatever choices maximize my discounted prospective reward at the moment I make them, then my choices won't consistently follow the same set of goals over time, the way they would if I were ruled either by reason or by exponentially discounted passion. If I'm a susceptible person and I'm close to a bottle of whisky or a box of chocolates, or perhaps a provocation to rage or panic, I'll value these options differently than when I'm far away from them. Often I'll choose in the opposite direction when I'm close and when I'm distant, which means I'll regularly do things at one time and undo them at another. Obviously if what I do in a particular situation regularly gets undone later, I'll learn to stop doing it in the first place – but not out of agreement with the later self that undoes it, only out of realism. I'll keep trying to find ways to get what I want from this particular vantage point, things that won't get undone, and take precautions against a future self that will try to undo them. In this way I'll be like a group of people rather than a single individual; often these people will be as different as Jekyll and Hyde.

An agent who discounts reward hyperbolically is not the straightforward value estimator

that an exponential discounter is supposed to be. Rather, it is a succession of estimators whose conclusions differ; as time elapses, these estimators shift their relationship with one another between cooperation on a common goal and competition for mutually exclusive goals. Ulysses planning for the Sirens must treat Ulysses hearing them as a separate person, to be influenced if possible and forestalled if not.

To take an everyday example: You may hate to go to bed at a prudent hour, even though you hate even worse getting up in the morning without enough sleep. Your mind this morning curses your mind of last night and tries to forestall your expected mind of tonight, but runs up against the effect of hyperbolic discount curves: Your mind holds a population of reward-seeking processes that have grown to survive in contradiction to each other, and that endure despite each other. You keep on staying up late when the chance is at hand and the morning is far away – unless you can do something to bring the incentives to sleep, which are larger in the long run, to bear on your evening self.

What can you do? If a person is a population of processes that have grown in the same mind through the selective action of reward, what factors, if any, impose unity on this population? For single moments we can model unity easily. The process by which diverse needs interact to produce a single decision doesn't have to be different from the process that motivates a social group to reach agreement.

Separate individuals can have widely diverse interests that conflict with the interests of others, because they have separate organs for reward that can act differently at the same time. One person can be tearful while her neighbor is rapturously happy, or seek out parties while her neighbor avoids them, without there being any necessary confrontation between these opposite choices. What coordinates diverse interests in separate people is limitation of resources. If there's only one room to sit in, the sad person and the happy one will have to see each other, and each will have to deal with the other's effect on her own mood. If they're roommates, they'll have to decide whether or not to use the room for a party that evening. It seems reasonable to suppose that analogous constraints impose at least some unity on the competing processes within the individual person, but that this unity is incomplete insofar as contradictory goals can coexist.

There may or may not be separate neural centers for different kinds of reward. As we've

discussed, there's evidence that the reward process is at least concentrated in specific location(s) rather than diffused throughout the brain.³⁷ The question doesn't matter much when you have only one set of limbs – or, more to the point, a finite channel of attention that has to direct those limbs. There may be a lot of people or part-people in your mind, but they're all constrained to coordinate what they do by the fact of being permanent roommates. If a given behavior can be influenced by more than one center, these centers must compete for the exercise of this influence, and whatever process governs this competition will act in effect like a single comprehensive reward center.³⁸ Insofar as one behavior can be replaced by another, it has to compete with the other for expression, and this competition operates as a single reward clearinghouse for all substitutable behaviors – all behaviors among which a person can choose. This is the constraint that unifies a person's behavior at any given moment.

Integration over time is more difficult. Any explanation has to account for our observations not only of unity but also of varying degrees of disunity, ranging from preference reversals in "normal" people to Jeckylls and Hydes. The key factor is doubtless the highly concave shape of the discount curves in Figure 2B, which limits what the market of choice can do to unify a person's purposes over time. Ulysses' wish to sail home and his wish to hear the Sirens will be integrated only for individual moments; this piecemeal integration will make different options dominant, depending on when the choice occurs. There will be a regular conflict between the mental operations that win out when the lure of the Sirens' song is dominant and those that win out when the prospect of finishing the journey is dominant.

You could call the mental operations selected for by a particular kind of reward the person's "interest" in that reward. Interests within the person should be very similar to interests within a social group, those factions that are rewarded by ("have an interest in") the goal that names them (e.g., "the petroleum interest," "the arts interest"). Since a person's purposes should be coherent except where conflicting rewards dominate at successive times, it makes sense to name an interest only in cases of conflict. I wouldn't be said to have separate chocolate and vanilla ice cream interests, even though they're often alternatives, because at the time when I prefer chocolate I don't increase my prospective reward by forestalling a possible switch to vanilla. But I may

have an ice cream interest and a diet interest, such that each increases the prospective reward in its own time range by reducing the likelihood of the other's dominance. Put another way, I don't increase my prospective reward in either the long or short range by defending my choice of chocolate against the possibility that I may change to vanilla; but I increase my prospective long-range reward by defending my diet against ice cream, and I increase my prospective short-range reward by finding evasions of my diet for the sake of ice cream. Whichever faction promises the greatest discounted reward at a given moment gets to decide my move at that moment; the sequence of moves over time determines which faction ultimately gets its way.

Where alternative rewards are available at different times, each will build its own interest, and one interest will be able to forestall the other only if it can leave some enduring commitment that will prevent the other reward from becoming dominant: If my diet interest can arrange for me not to get too close to ice cream, the discounted prospect of ice cream may never rise above the discounted prospect of the rewards for dieting, and the diet interest will effectively have won. However, whenever the value of ice cream spikes above that of dieting, the ice cream interest may undo the effect of many days of restraint. The ultimate determinant of a person's choice is not her simple preference, any more than the determinant of whether a closely contested piece of legislation becomes law is simple voting strength in the legislature; in both processes, strategy is all.

This process – power bargaining made necessary by finite means of expression – may be all that unifies a person. Philosophers and psychologists are used to speaking about an organ of unification called the “self” that can variously “be” autonomous, divided, individuated, fragile, well-bounded, and so on,³⁹ but this organ doesn't have to exist as such. The factor that impels toward unity the various behavioral tendencies that grow from a person's rewards may be the realization that they are, in effect, locked up in a room together.

If this room is divided, so that only some of the person's learned processes ever have access to particular resources for expression, she starts to behave like two people. This actually happened when neurosurgeons developed an operation for epilepsy that cut the main connection between the cerebral hemispheres, the corpus callosum. The right half of the brain controlled the left hand and the left half, the right hand; if

the two halves were fed information separately, they sometimes fought over a decision to the extent that one hand restrained the other by the wrist. Conversely, when convention or necessity makes two people act in concert over long periods – for example, in some identical twinships and some marriages – the site of the marketplace seems to shift somewhat from the individual to the pair. But where in the pair? Here the choice-maker is clearly not an organ but a process, something in the empathic engagement between the two twins; and if that is true for the pair, why not for the individual or the neurosurgeon's half-individual? The constraint of limited resources for expression may be all that impels a person toward selfhood; and the success of her currently dominant interests in bargaining with interests that will be dominant in the future may be what determines the kind of unity her self will have.⁴⁰

Are ordinary people really populations of interests rather than something more solid? It's disturbing to think of yourself as so fluid, so potentially unstable, held together only by the shifting influence of available rewards. It's like being told that atoms are mostly empty and wondering how they can bear weight. Yet the bargaining of interests in a society can produce highly stable institutions; perhaps that's also true of the internal interests created by a person's rewards. Shortly we'll look at the patterns of choice that hyperbolic discounters would be likely to follow, and see if these patterns look like familiar properties of personality.

Of the basic discounting phenomenon there can no longer be much doubt. Remarkably, hyperbolic discounting seems to occur over all observable time ranges. Subjects choosing between hypothetical amounts of money at delays of years show it as much as those choosing between differences in food, or comfort, or direct brain stimulation, over periods of seconds. Economist Charles Harvey has pointed out that the most long-range planning that ever occurs – choices to preserve the environment or leave money to grandchildren – follows a hyperbolic discount pattern rather than the exponential one that the planners themselves sometimes claim to be using. He points out that exponential discounting of goals decades away at even moderate rates would make them relatively worthless in a competitive economy; it's only the comparatively high tails of hyperbolic curves that could make us concern ourselves with the distant future at all. Accordingly, respondents to a random household survey on the hypothetical

value of saving lives 25, 50, and 100 years from the present demonstrated that “if [exponential] discount rates are computed under the assumption that they vary with time, the mean annual discount rate is 7% today and 0% in 100 years.”⁴¹ That is, the more delayed an option is, the less discounted it is, just the pattern that hyperbolic discounting predicts.

Economists David Laibson and Christopher Harris have recently modeled people’s lifetime saving/spending patterns with hyperbolic curves, and have found that they predict many observed behaviors that exponential curves don’t. For instance, hyperbolic curves make a preference for illiquid savings rational – such savings serve as commitments – and thus can explain why people borrow on credit cards at 18% to avoid dipping into savings that are earning far less (see Section 6.2).⁴²

2.3. *The Adaptiveness of Hyperbolic Discounting*

If our basic discount curve has been hyperbolic, then the biggest job of civilization must have been to change people’s spontaneous choice into something that produces fewer internal conflicts and reversals of preference. Before assuming that this has been the case, we should ask an obvious question: How could such a curve, with such potential to put an individual at a competitive disadvantage, survive the process of natural selection?

Sociobiologists, who used to believe that animals maximize their expected intake of resources over time, have now also done experiments demonstrating the hyperbolic shape of the basic discount curve.⁴³ However, despite their interest in evolution, these authors haven’t tried to reconcile this finding with survival of the fittest. I’ll suggest two ways that highly bowed discount curves could have survived natural selection. They could have preserved genes at the expense of the individual, or they could have been a harmless by-product until too recently to have affected evolution. Arguments about evolutionary fitness can aim only for plausibility, not proof. Take your pick.

1. The evolution of species occurs through the survival of genes, not of individuals. There are many familiar cases where an individual organism must sacrifice itself to maximize survival of its genes. Maybe hyperbolic discounting is a way to get an animal to do that: The anger that makes an animal fight to defend its young probably isn’t much different from the anger

that recruiting sergeants exploit in wartime, and neither is in the individual’s own long-range interest. If cool reason prevailed, the animal would survive more often and the gene-bearing offspring less often. Similarly, bearing young is probably never in an animal’s selfish interest. Of course, it may be that many human mothers in previous centuries accepted the roughly 15% risk of eventual death in childbirth out of altruism, or from cultural pressures that made the alternatives worse, but impulsive romances must have made a big contribution too. Even in modern times,

[C]ourtship leads to romantic love, a temporary suspension of reason, in which the couple is conveyed by the most compelling of short-term rewards, into marriage, a commitment with a lifetime horizon.⁴⁴

The mechanism by which individuals come to reduce their rational utility for the sake of a larger group has been controversial even since Erasmus first praised the seeming folly of having children or going into politics.⁴⁵ Hyperbolic discounting is one candidate.

2. It’s also possible that hyperbolic discounting has been carried along as a hitherto harmless by-product of vertebrates’ basic perceptual tooling. All higher animals get sensory impressions in proportion to the *change* in level of stimulation, rather than perceiving its absolute level. The same perceptual processes that make you sense a change in light or temperature proportionately to its previous intensity may prepare you to evaluate delays the same way. This wouldn’t have been a great problem for animals that couldn’t change the environments in which they evolved. Where survival has demanded foresighted behavior – sleep at a certain time, or hoarding of food or mating in a certain season – instinctual mechanisms have evolved to convert such long-range interests into short-range rewards. The animal experiences an immediate appetite to sleep or hoard or mate, and there’s no intertemporal conflict unless a devious experimenter creates one.

By contrast, people have learned to manipulate both their environment and their instinctual appetites. We learn to divorce sleep from darkness, to cultivate appetites for hoarding what we don’t need, to mate without reproducing, indeed to obtain many of the rewards of mating vicariously, through fiction or fantasy, and in general to cultivate motives that overwhelm the incentives of nature. We’ve also changed our environments radically from the ones in which

we evolved. We've increasingly taken our long-range plans into our own hands, and are threatened to the same extent by the operation of our hyperbolic discount functions. As we overcome the historical limitations imposed by poverty and primitive technology, the scope of the decisions governed directly by these discount functions becomes broader. Evolution hasn't had time to respond to these, if indeed it has mechanisms available. It's unlikely that modern humans will ever grow wheels instead of feet, for instance, adaptive as that might be.⁴⁶

Thus there's good reason to believe – and nothing to keep us from believing – that the human race evolved with a very regular but deeply bowed discount curve for evaluating the future. That hypothesis can explain a lot about why people defeat their own plans so relentlessly. However, it raises more questions than it answers. How do people become consistent choice makers? How do painful options interact with pleasurable ones? Why do we often choose according to logical categories? How do “higher” mental functions fit in?

The answers will come by deducing how a bent for temporary preference can be expected to create a marketplace of choice within the individual, the behavior of which depends on strategy rather than the simple value comparisons depicted by exponential curves. For that reason, I've suggested that this approach represents the most microscopic application of economic thinking – micromicroeconomics, perhaps, or piceoeconomics.⁴⁷

2.4. Summary

There is extensive evidence that both people and lower animals spontaneously value future events in inverse proportion to their expected delays. The resulting hyperbolic discount curve is seen over all time ranges, from seconds to decades. Because a hyperbolic curve is more bowed than the exponential curve that most utility theories go by, it describes a preference pattern that these theories would call irrational: It predicts temporary preferences for the poorer but earlier of two alternative goals during the time right before the poorer goal becomes available. Regular temporary preferences, in turn, predict that a population of conflicting interests will grow and survive within the individual, sometimes leading to choices that are self-defeating in the long run. A self that is a marketplace for such interests differs radically from the conventional image, and needs exploring in detail.

3. The Elementary Interaction of Interests

I have described a model of learned interests that compete freely on the basis of the time frames over which their rewards are preferred. The most important implication of such a model is an incentive within each interest to learn strategic behaviors that forestall competing interests.

If a person is a population of these kinds of roommates, each clamoring to control the use of the room, how does she make decisions? An interest can't eliminate a competitor simply by providing more reward than the other does, either at one time or on the average, since the competitor might undo the first choice when it became dominant at a particular time in the future. On the other hand, to continue to exist, each interest has to be the highest bidder at some time or it will extinguish; to achieve this, each may have to constrain others and can't be too constrained by them. Just because an interest is dominant at one moment in time doesn't mean it will get its intended reward; while an interest is dominant it has to forestall conflicting interests long enough to realize the reward on which it's based.

3.1. How One Interest Binds Another

For long-range interests, this usually means committing the person not to give in to short-range interests that might become dominant in the future. Long-range interests don't usually conflict with each other, except in the trivial sense of being close choices, because the effect of distant rewards tends to be proportional to their “objective” size; the less well rewarded of two equally long-range interests tends not to survive, but there is no time when this interest includes an incentive to resist this fate, that is, no time when such resistance would increase your prospective discounted reward. I won't be examining this kind of choice-making.

For short-range interests, survival usually means evading commitments. However, short-range interests are also served by committing you not to act on other, incompatible short-range interests; and sometimes they can even commit you to disobey long-range interests. While on an eating binge, you avoid information about calories that might remind you of a diet, for instance, and you're incidentally forestalled from giving in to temptations that aren't compatible with absorption in eating, like having a sexual adventure.

There seem to be four kinds of tactics an interest can employ to commit future choice.

3.1.1. EXTRAPSYCHIC COMMITMENT

You can make it physically impossible to choose a future alternative or arrange for additional outside incentives that will influence a future self. Most examples involve a long-range interest controlling a shorter-range one.

Both the problem and the solution are basic. They're not the results of sophisticated human cognition. They can be shown to exist in birds: As I described earlier, pigeons can learn to peck a key, the only effect of which is to commit them to wait for a later, larger food reward.⁴⁸

Examples of this elementary tactic persist in modern times. Many authors return to Ulysses' problem. The economist Robert Strotz, for instance, pointed out that apparently rational consumers pay to have their future range of choice narrowed. Movie stars pay financial managers to keep them from spending their own money, and many people used to put money in Christmas Club accounts that didn't pay interest in order to give themselves an extra incentive to save money. Jon Elster named a book after Ulysses' problem.⁴⁹

Addiction therapists have been especially interested in disulfiram, a drug that changes the metabolism of alcohol so that drinking leads to nausea or even violent sickness. Disulfiram seemed to be a perfect solution to the temporary preference problem, but its results have been disappointing, probably because addictions can have some strategic value for long-range interests; we discuss these in Chapter 9 [of *Breakdown of Will*].⁵⁰

Some self-control devices make sense even in a world of purely exponential discounting – for instance, diet pills that act by reducing a person's appetite. If a rational planner decides that she ought to eat less, it's certainly easier if she can arrange not to be hungry. But devices that tie you to the figurative mast don't act by spoiling your appetite – for drinking or spending money, for instance. They keep you from acting when your appetite is strong. Such a plan makes no sense for conventional utility theory, which has people maximizing their prospects consistently over time. Hyperbolic discounting predicts a market for exactly this kind of commitment; and, as we saw, even pigeons will sometimes work to get it.

The availability and usefulness of physical committing devices are obviously limited. Even if you can get someone to hold your money until a certain time arrives, you may find that you

really need it in the meantime. For that reason – or just because of the change of preference you originally foresaw – you may find yourself spending a lot of energy undoing the same plan you set up – for instance, by finding a way to borrow against your expectations of getting your money when your commitment has expired.

More often people find other people to influence them. We join groups that seem to be doing what we want to do – Weight Watchers or Alcoholics Anonymous, or a fitness club or even a discussion group. We may just let a friend know that changing a certain behavior is important for us, so that the friend will be disappointed if we don't actually change it. The tactic is to put your reputation in a community at stake. It was described by the sociologist Howard Becker as cultivating other people's respect or love so that this forms a "side bet," an additional incentive to avoid the impulses that these people would disapprove of.⁵¹

Social side bets are much more flexible than physical commitments, but they, too, are limited. For instance, they're useless against concealable impulses and against any impulse of which other people don't happen to disapprove; they would actually be counterproductive against an impulse to buy popularity. Furthermore, vulnerability to social influence has costs, especially in a cosmopolitan society, which multiplies a person's chances of meeting predators who would exploit this vulnerability. Despite these problems, it's a major strategy for people with strong social motivations. Carol Gilligan suggests that it may be more important in women than in men, a possibility I'll talk more about later.⁵²

Short-range interests may use extrapsychic committing tactics against longer-range interests, too, but most examples are trivial. Getting drunk means that you can't be sober for a while, but there isn't much to say about this kind of commitment.

3.1.2. MANIPULATION OF ATTENTION

You can try to avoid information that would change your mind. If you already know that a seductive reward is available, you can try to avoid thinking about it: "If you speak of the Devil, he'll appear." This is the advice that was most respected in our culture before Freud pointed out the bad side effects of repression. A typical example appears in an early-twentieth-century book called *Right and Wrong Thinking and Their Results*, which advised the reader to "avoid discordant thoughts," by distraction if possible and

if necessary by “the rule at Donnybrook Fair: ‘whenever you see a head, hit it.’ The least is not too small to be terminated if it is wrong.” Behavioral writers even today advocate “stimulus control” as a useful way of avoiding impulses. It’s a large part of what psychologists Janet Metcalfe and Walter Mischel suggest that people use to control passion. Even economists have begun to consider the “value of ignorance (in the form of not acquiring [even] free information)” for this purpose.⁵³

Attentional tactics seem to be especially effective against very-short-range urges that require only a moment of attention to become dominant. In a previous chapter [of *Breakdown of Will*], I mentioned examples of structuring people’s attention as a way of controlling dental or obstetrical pain. Similarly, I’ve known patients who have told of “fighting off” panic attacks, dissociative episodes, and even epileptic seizures by vigorously directing their minds away from the feeling that these events were about to occur.

There are obviously occasions when a blind eye at the right time keeps you from giving in to an urge. The trouble is that short-range interests may actually make more effective use of attention control than long-range interests can. When it’s in your long-range interest not to realize that a temptation is available, it’s also in your short-range interest not to get information on the long-range consequences of giving in. In the competition between long- and short-range interests, attention control is a two-edged sword. In fact, much of the psychotherapy developed by Freud and his followers involved teaching patients to catch themselves using suppression (deliberate avoidance of a thought), repression (unconscious but still goal-directed avoidance of a thought), and denial (avoidance of the implications of a thought). If a person could just avoid fooling herself, Freud thought, she would be simply rational.

Many writers besides the psychoanalysts have described how wishful thinking undermines people’s long-range plans. Examples date back to Aristotle, who said that desire had the same effect on belief as being drunk, an observation often reported by people who have suffered lapses while trying to give up bad habits.⁵⁴ Motivated changes of perception are yet another phenomenon that makes no sense in a scheme where people discount the future exponentially.

Given temporary preference for present comfort, it isn’t hard to picture a mechanism for repression. Many ways have been described

whereby selective attention can systematically distort the information you collect. Experiments have shown that we tend to label our memories with their emotional meanings and retrieve them by these labels. What comes to mind first when I see someone walking toward me isn’t her name or where I saw her last, but a sense of whether I’d like to see more of her or avoid her. The same is true of a book on the shelf or a place I have a chance to visit. If that first sense spells trouble, it’s easy enough to steer in another direction without ever going into why I want to or whether I have an obligation not to do so. Economist Matthew Rabin has described how self-serving moral reasoning can occur in just such an unconscious way.⁵⁵

3.1.3. PREPARATION OF EMOTION

You can cultivate or inhibit the motivational processes that have intrinsic momentum – generally the emotions. These processes can change how the expectation of reward influences your choice, at least in the near future. Once your appetite for a particular satisfaction is aroused, it has a committing effect that lasts for a while. It increases the rewarding power of its objects and may arouse distaste for things that interfere with it. The dessert cart comes, and suddenly the appeal of desserts is greater than it was. Or your anger is provoked, and suddenly it looms larger than the motives that had been present, possibly even including personal safety. Or you start to caress on a date, and sexuality looms in the same way, just as dating manuals for teenagers have always warned.⁵⁶

In a previous chapter [of *Breakdown of Will*], I described examples where people learned not to have appetites when the rewards on which they were based were certain not to occur or when punishment for them would occur. If this behavior were based on a fear of temptation, it would be an example of preparation of emotion. In fact, when someone is worried that her emotionality makes her vulnerable to other people’s influence, she may learn to almost never entertain emotion, thus developing the alexithymia that I mentioned earlier. In a laboratory setting, children as young as five who are given the choice between a better, later food and a less preferred, earlier one can learn to guide their thoughts so as to avoid appetite and thus wait for the better, later food.⁵⁷

These are forms of the impulse-controlling technique that the psychoanalysts call “isolation of affect.” It requires single-minded consistency to work. Emotionality and other appetites have

a relentless tendency to arise when there's even the slightest chance that they'll be rewarded, though some more so than others – remember Galen's observation that anger could be tamed like a horse, but that the "concupiscible" power (sexual desire) was like a wild boar or goat that had to be controlled by starvation (Section 1.1).

The psychoanalysts also describe cultivation of an emotion to forestall the development of a contrary one – "reaction formation" or "reversal of affect." If I were afraid I'd hate my mother, I might look for things to love about her; or if I thought my soft heart got me into trouble, I might look for ways to see people as my enemies. Again, the analysts only publicized what earlier writers had noticed. I've already quoted Francis Bacon, who wrote with approval about setting "affection against affection and to master one by another: even as we use to hunt beast with beast" (Section 1.1). In the eighteenth century this tactic was sometimes held out as the only practical committing device: The philosopher David Hume said, "Nothing can oppose or retard the impulse of passion but a contrary impulse."⁵⁸

The short-range committing effect of emotion can serve both short- and long-range interests, just as external commitments and attention controls can. A long-range interest may cultivate emotions in order to achieve bravery or virtue, but it's at least as common that someone seeks refuge in a passion so as not to listen to reason.

3.1.4. PERSONAL RULES

You can make a resolution. This may be the most common way that people deal with temporary preferences but also the most mysterious. What is there about "making a resolution" that adds anything to your power to resist changing motivation? This is just the will, the concept that Gilbert Ryle analyzed and found superfluous, and that conventional utility theorists like Gary Becker leave no place for.

Conventional utility theory doesn't suggest any role for a will – but of course, it doesn't recognize a temporary preference problem to begin with. Because of its assumption that people discount the future exponentially, it confounds two distinct meanings of will: a hypothetical element needed in dualistic philosophies to connect mind and body, as in "I willed my arm to move," and the faculty for resisting temptation that's commonly called willpower. If discounting is exponential, resisting temptation is a function just as superfluous as connecting mind and body; we'd be right to dispense with both.

By contrast, hyperbolic discounting can be expected to produce temporary preferences, which will in turn motivate the three committing tactics I've just talked about. The question now is whether these three tactics can account for the experience of willing things.

Most people I've talked with don't report using any of these devices while resisting temptation. When they've given up smoking or climbed out of debt, they mostly say they "just did it." Words like "willpower," "character," "intention," and "resolve" are often applied, but they don't suggest how people actually resist a temporary preference.⁵⁹ Some writers have described specific properties, however.

The most robust idea is that will comes from turning individual choices into a matter of principle. As early as the fourth century B.C., Aristotle proposed this idea (referring to dispositions to choose as "opinions"): "We may also look to the cause of incontinence [*akrasia*] scientifically in this way: One opinion is universal, the other concerns particulars. . . ." Galen said that passion was best controlled not by looking at individual opportunities but by following the general principles of reason; he noticed that impulse control was a skill that suffered disproportionately from failure to use it, and that habitual disuse made it especially hard for a person "to remove the defilement of the passions from his soul."

By Victorian times, the list of the properties of willpower had grown. The will was said to:

- come into play as "a new force distinct from the impulses primarily engaged";
- "throw in its strength on the weaker side . . . to neutralize the preponderance of certain agreeable sensations";
- "unite . . . particular actions . . . under a common rule," so that "they are viewed as members of a class of actions subserving one comprehensive end";
- be strengthened by repetition;
- be exquisitely vulnerable to nonrepetition, so that "every gain on the wrong side undoes the effect of many conquests on the right"; and
- involve no repression or diversion of attention, so that "both alternatives are steadily held in view."⁶⁰

The property that stands out in this list is still Aristotle's universality: to unite particular actions under a common rule. Similarly, two researchers from the behavioral school have explored the idea that self-control requires a

subject to think in terms of broad categories of choice rather than just seeing the particular choices at hand. Gene Heyman has found that pigeons can learn to make choices in an “overall” context instead of a “local” one if they are rewarded for following a cue telling them when they are doing this; they do not learn without this extra reward, however.⁶¹ Howard Rachlin has said that self-control comes from choosing “patterns” of behavior over time rather than individual “acts.” The latter is “molecular” and myopic, the former “molar,” that is, global, an overview, based on a series of elements taken as a whole. In an experiment he did with Eric Siegel, pigeons made an impulsive choice significantly less often when 30 previous nonimpulsive choices were required than when the choice stood by itself.⁶² These experiments don’t model will specifically; but they do suggest that choosing categorically can partially undo the effects of hyperbolic discounting, even where the complexities of human culture aren’t a factor.

Even cognitively oriented writers have noted the value of choosing in categories. Baumeister and Heatherton, for instance, speak of the need for “transcendence,” which is “a matter of focusing awareness beyond the immediate stimuli,” so that these stimuli are seen “in the context of more distal concerns.” Similarly, some philosophers of mind have recognized the importance of making “a present choice in favor of a valued sequence of future actions or a valued policy to act in certain ways on certain occasions” in order to achieve “intention stability.”⁶³

There remains the question of how these categories of choice arise and what makes them recruit extra motivation. Baumeister and Heatherton imagine an ability characterized only as “one’s strength to override the unwanted thought, feeling, or impulse.” The philosopher Edward McClennen attributes “resolute choice” to “a sense of commitment to a plan initiated by [a prior] self.” Using a more complex model, philosopher Michael Bratman argues that it is “rational to follow through with [a prior] plan in those circumstances for which one specifically planned” despite a current change of preference, not because of a commitment, but because of “a planning agent’s concern with how she will see her present decision at plan’s end.” Both philosophers are describing a conflict of impulse and plan, but neither addresses the motivational dimension of the conflict.

Even Rachlin, a “radical” behaviorist, assumes that the necessary categories are intrinsically

stable – that patterns of choice naturally hold together like the notes of a symphony, so that, once you’re aware of the pattern, you’ll be motivated not to break it up. For instance, if you see the pattern of “a healthy breakfast” as consisting of juice, cereal, a bran muffin, and skim milk, the reason you don’t substitute apple pie for the bran muffin is that it would break up the pattern, just as not hearing the last notes of a symphony would spoil the experience of hearing the symphony. Likewise, a controlled drinker doesn’t drink too much because it would spoil a pattern of temperance.⁶⁴

There’s something appealing about this viewpoint, and yet it doesn’t ring entirely true. How do patterns like healthy breakfasts and temperance get decided on in the first place? And is it really true that we forgo the apple pie for the sake of consistency *per se*? Especially in potential addictions like overeating and drinking alcohol, people report that their urge is to break the patterns, not preserve them. Sticking to them feels effortful – quite the opposite of the case of listening to a symphony, where breaking away in the middle is what takes effort. What enforces a diet or a resolution?

Basic utility theory can provide an answer, but only if the form of the discount curve is hyperbolic. Assuming only that the discounted rewarding impacts of successive events add together, we can see that series of rewards will be chosen more in proportion to their objective sizes than will single rewards. The property of additivity hasn’t been studied much, but a few experiments suggest that the hyperbolically discounted effects of each reward in a series simply add, at least in pigeons and rats.⁶⁵ Since this is also the simplest assumption, I’ll adopt it from here on.

Consider a series of larger, later rewards and their smaller, earlier alternatives – for instance, philosopher Bratman’s example of a pianist who throws his nightly performance off by drinking wine beforehand.⁶⁶ At a distance the pianist prefers to abstain and perform well, but every night at dinnertime he changes his preference to drinking the wine. However, as Figure 3A suggests, even at dinnertime he may prefer the prospect of abstaining every night to the prospect of drinking every night for the foreseeable future: The incentives for choosing between these categories of reward will be the summed expected values of the series of rewards. The incentives for choosing just for one night will be the curves from a lone pair, as we saw in Figure 2B.

Figure 3A. Summed hyperbolic curves form a series of larger-later rewards and a series of smaller-earlier alternatives. At the beginning of the series, the period of temporary preference for the series of smaller rewards is about zero. The curves from just the final pair of rewards are the same as in Figure 2B.

In the schoonerlike picture of the summed discount curves from series of rewards, the “sails” get gradually lower as the choice point moves later in the series, for they comprise a decreasing number of curves added together. The last pair of sails are the same as a lone pair. If the series has no foreseeable end, which is the case for most real-life categories, the sails may be added forward to some kind of time horizon that stays a constant distance ahead, so that the height of the summed rewards stays roughly constant. In any case, summation of a series of rewards makes the first few sails higher than the sail drawn on a lone pair of rewards would be.

More importantly, the delayed rewards add roughly in proportion to their objective sizes, so that when their aggregate height is added in, the first sail in the series of smaller rewards doesn’t protrude as high above the first sail in the series of larger rewards as it does in a solitary pair; with series of some amounts at some delays, the earliest sail doesn’t protrude above its larger, later alternative at all. That would mean that when the pianist chooses categorically, he would always prefer to abstain, even at dinner-time. The choice of a whole series of rewards will be influenced by the rewards expected after the most immediate pair, and for all the subsequent pairs the discounted value of the larger, later alternatives is greater than that of the smaller, earlier ones. Only the nearest choice in a series is dominated by the smaller, immediate reward – although the nearest choice will obviously carry more weight than any single one of the later choices.

Two recent experiments confirm that choosing between whole series of small, early versus large, late pairs increases the preference for the large, late alternatives. Psychologists Kris Kirby

and Barbarose Guastello found that undergraduates who preferred the small, early amount of money when choosing between one pair at a time regularly switched to preferring the large, late amount when choosing between series of five payoffs to be delivered at weekly intervals. The same switch occurred when amounts of pizza were offered rather than money. Similarly, psychologist John Monterosso and I have observed that rats choosing between squirts of sucrose prefer the shorter, earlier of a single pair of squirts but a series of three longer, later squirts over a series of three shorter, earlier alternatives.⁶⁷ The finding in rats suggests that the bundling effect comes from a basic property of the discount curves rather than from some cultural norm.

This property has to be a highly concave shape, such as that of hyperbolas. Exponential discount curves from a single pair stay proportional, and adding the whole series together doesn’t change their relative heights (Figure 3B). Thus, bundling choices together wouldn’t affect the direction of preference if discount curves were exponential rather than hyperbolic. The fact that hyperbolic discounting predicts the often-described – and now experimentally observed – increase in patience for bundled rewards seems to confirm that we’re on the right track: The strategic implications of these curves may be central to whatever rationality human choice-making can achieve.⁶⁸

3.1.4.1. Bundling Rewards that Extend Over Time. Most choices in real life aren’t between brief moments of different intensity, but

Figure 3B. Summed exponential curves from the two series of rewards shown in Figure 3A. Summing doesn’t change their relative heights. (This would also be true if the curves were so steep that the smaller, earlier rewards were preferred; but in that case, summing would add little to their total height anyway, because the tails of exponential curves are so low.)

Figure 4A. Curves that are the aggregate of hyperbolic discount curves from each moment of time during continuing rewards – staying up from midnight to 2 A.M. versus feeling rested from 7 A.M. to 5 P.M.

between extended experiences – the pleasure of a binge versus feeling fit and having intact prospects the next Monday, a venting of rage versus keeping a job and friends. Often the difference isn't between intensities of satisfaction-per-minute, but between different durations of comparable satisfactions. The pleasure of staying up for a couple of hours after midnight may be the same as the differential pleasure of not being tired the next day, but the latter pleasure lasts all day. However, if successive rewards are additive, it's easy to convert durations to total amounts. For instance, if you value the fun of staying up at one unit per minute and expect to lose one unit per minute of comfort from when you get up at seven the next morning until you leave work at 5 P.M., your discount curves from a day's aggregation of these rewards will look like those in Figure 4A.⁶⁹

If you face a similar choice nightly and can make your choice for a long series of future nights at once (say 10), your incentives will be

described by the curves in Figure 4B.⁷⁰ As with more discrete moments of reward, bundling these experiences into series moves your incentives toward the larger, later rewards.

So choosing behaviors in whole categories will lead to less impulsiveness, just as the philosophers have said. Here, then, is a fourth strategy to defend your long-range interest: the *personal rule* to behave alike toward all the members of a category. It's the equivalent of the philosopher Immanuel Kant's "categorical imperative": to make all choices as if they were to define universal rules. Similarly, it echoes the psychologist Lawrence Kohlberg's sixth and highest principle of moral reasoning: deciding according to principle.⁷¹

3.2. The Will's Achilles Heel

The trouble is that this insight about choosing categorically doesn't eliminate the attraction of small, immediate rewards; it offers only a

Figure 4B. Summed curves from ten pairs of the rewards depicted in Figure 4A. The effect of summation is the same as from the point rewards in Figure 3B.

discipline that a long-range interest would benefit from at the expense of short-range interests *if only the person were consistently motivated to follow it*. So far I've described no reason why, when an inferior reward is immediately available, a pigeon or person shouldn't take it. When Rachlin and Siegel (Section 3.1.4) introduced a signal to remind their pigeons of the immediate availability of single rewards, the birds' apparent discounting shifted back from the exponential toward the hyperbolic.

People have more brainpower than pigeons and can probably perceive greater series of rewards, but short-range interests as well as long-range ones can use their enhanced reasoning skills. The bad news is that knowing the power of categorical decision making isn't enough. There's persistent pressure to backslide even after you've learned about molar or overall book-keeping.

Ganging up on a short-range interest isn't the same thing as killing it. While acting in this interest, you're still motivated to learn anything that can evade the "universal principle" that dominates it. A quick mind can put together rules in any number of ways, so finding evasions is also easy. The trick is to differentiate between the choice at hand and the set of choices that are bound together by a rule. Just as the will is well described in history, so is our readiness to evade it. When William James wrote his pioneering analysis of "effort of will," he pointed out how a person's "anti-impulsive conceptions" – that is, her molar conceptions à la Rachlin – are vulnerable to exceptions:

How many excuses does the drunkard find when each new temptation comes! It is a new brand of liquor which the interests of intellectual culture in such matters oblige him to test; moreover it is poured out and it is a sin to waste it; or others are drinking and it would be churlishness to refuse; or it is but to enable him to sleep, or just to get through this job of work; or it isn't drinking, it is because he feels so cold; or it is Christmas day; or it is a means of stimulating him to make a more powerful resolution in favor of abstinence than any he has hitherto made; or it is just this once, and once doesn't count, etc., etc., *ad libitum* – it is, in fact, anything you like except *being a drunkard*.⁷²

Even Aristotle went on in his description of "universal" and "particular" interpretations

of choice to describe an ongoing competition between them.⁷³

Thus people who have learned a "higher" or "richer" principle of choice aren't thereby freed from temptation. We aren't very old before our razor-sharp wits discover a perverse truth: If behaving according to categorical principles promises more discounted, expected reward than making an isolated choice does, then making an isolated choice now and acting by rule in the future promises still more.

The problem is that there are many possible ways to define global categories. The ice cream at hand may violate one diet but not another; and even if it's so outrageously rich as to violate all conceivable diets, there's apt to be a circumstance that makes the present moment an exception, just as with James's drunkard: It's Thanksgiving dinner or my birthday, or a host has taken special trouble to get it, or I have cause to celebrate or to console myself just today, and so on. The molar principle that offers an exception *just this once* will be rewarded more than the one that doesn't, for it produces an aggregation of rewards, as shown in Figures 3 and 4, for all but the first larger, later rewards *and* the spike of reward at hand.

The tough question is not how molar book-keeping recruits motivational support for long-range interests, but how this process defends itself from short-range interests, sometimes unsuccessfully. Acting in my long-range interest, how do I keep a short-range interest from repeatedly proposing an exception to my rule "just this once?"

Simple intuition offers the answer: Excuses that are too blatant lower my expectation of following the amended principle. I may be able to go off my diet on Thanksgiving without reducing my belief that I'll stick to it at other times; but if I try proposing other holidays, I'll probably notice that I'm starting down a slippery slope. The ability to take a drink at New Years or go off the diet on Thanksgiving provides flexibility to a potentially rigid commitment to a concrete rule; but the same principle that keeps Thanksgiving from setting a precedent might also work for my birthday and, with decreasing credibility, for the Fourth of July, St. Patrick's Day, Labor Day, Arbor Day, St. Swithin's Day, and Just This Once. This kind of logic can degrade a personal rule without my ever breaking it. Once I expect myself to find an exception whenever the urge is strong, I no longer have the credible prospect of the whole series of later, larger rewards – the

cumulative benefits of my diet – available to choose.

In this way, hyperbolic discount curves make self-control a matter of self-prediction. This effect will be especially noticeable where self-control is tenuous. The hyperbolic discounter can't simply estimate whether she's better off dieting or eating spontaneously and then following the best course, the way an exponential discounter could. Even if she plans to eat less from a perspective of distance, she won't know whether or not she'll regularly prefer to eat ad lib when she's hungry. If she expects to eat ad lib, her long-range perspective will be useless to her unless she can use one of the first three kinds of commitments I described earlier – not a rich selection.

But what if she makes a new resolution to “decide according to principle” – to go on a diet – and starts off expecting to stick to it in the future if she sticks to it now? This condition may be enough to motivate sticking to it, but only insofar as she thinks it will be both necessary and enough. If she then violates the diet and loses faith in it, her principle will magically stop being enough. Personal rules are a *recursive* mechanism; they continually take their own pulse, and if they feel it falter, that very fact will cause further faltering.

Thus deciding according to molar principles is not a matter of making dispassionate judgments, but of defending one way of counting your prospects against alternative ways that are also strongly motivated. Your motivation to stick to a principle is not pure a priori reason – reason is not motivation – but the saving of your expectation of continuing to stick to it. It's the internal equivalent of the “self-enforcing contracts” made by traders who'll be dealing with each other for a long time, contracts that let them do business on the strength of handshakes.⁷⁴ This recursive process of staking the credibility of a resolution on each occasion when it's tested gives your resolve momentum over successive times. The ongoing temptation to commit a wrong act that will set a damaging precedent – and the ever-present anxiety that this may happen – is probably what makes this strategy of self-control feel effortful. It separates *intentions* from plain *expectations* and force of will from force of habit.

This model proceeds from hyperbolic discounting with almost no extra assumptions – only rough additiveness – and predicts credible weapons for either side in the closely fought contests that seem to occur as people make decisions

about self-control: Long-range interests define principles, and short-range interests find exceptions.

3.3. Summary

An interest that has survived in someone's internal marketplace must have included ways to forestall incompatible interests, at least well enough to sometimes get the reward it's based on. This need accounts for the examples of self-committing tactics that have long puzzled utility theorists. Three kinds are straightforward: finding constraints or influences outside of your psyche, sometimes physical devices like pills, but more often the opinion of other people; manipulating your attention, as in the Freudian defense mechanisms of suppression, repression, and denial; and preparing your emotions, as in the defense mechanisms of isolation and reversal of affect. A fourth tactic, willpower, seems to be at once the strongest and most versatile, but has hitherto been mysterious.

Hyperbolic discount curves from series of choices increase the preference for larger but later rewards when they're added together, which suggests a solution to the mystery: The device of choosing according to principle, which has been advocated since Aristotle's day, groups your choices into just such series. Principles of choice, or “personal rules,” represent self-enforcing contracts with your future motivational states; such contracts depend on your seeing each current choice as a precedent that predicts how you're apt to choose among similar options in the future. Short-range interests evade personal rules by proposing exceptions that might keep the present case from setting a precedent. The will is a recursive process that bets the expected value of your future self-control against each of your successive temptations.

Notes

- 1 For instance, Baumeister & Heatherton (1996), Becker & Murphy (1988), Polivy (1998), Rachlin (1995a).
- 2 Plato's *Protagoras* (sections 356–357) in Jowett's translation (1892/1937). His theories and Aristotle's are thoroughly discussed in Charlton (1988, pp. 13–59).
- 3 Averill (1988).
- 4 Galen (1963, p. 47); This man-vs.-animal figure has also had a long life.
- 5 Romans 7:15–23.

- 7 Quoted by Hirschman (1977, p. 22).
- 8 Vanderveldt & Odenwald (1952); Ricoeur (1971).
- 9 Kobasa & Maddi (1983); Perls et al. (1958).
- 10 Freud's two principles (1911, p. 223); superego (1923).
- 11 Comparative response to schedules of reward: Madden et al. (1998). Animal models of addiction are reviewed in Altman et al. (1996). Behaviorally, pigeons detect and respond to tiny changes in frequencies of electric shock even when these are not signaled by cues (Herrnstein, 1969). Human obtuseness to reward is especially conspicuous in children from ages 6 to 12, perhaps because this is when they first begin to override their feelings with preconceptions of the world (Sonuga-Barke et al., 1989).
- 12 Samuelson (1976); Becker (1976).
- 13 Sorensen (1992).
- 14 Crews (1995 p. 12).
- 15 See the many sources reviewed in Ellenberger (1970).
- 16 Vaughan & Herrnstein (1987).
- 17 Gardner (1997).
- 18 In this book I'll refer most often to his work on emotion (1999b).
- 19 For example, just 10 years ago a prominent behaviorist, Howard Rachlin, proposed that pain shouldn't be regarded as a subjective experience, but just as a behavior to get external rewards. These rewards might be anything from avoiding injury to getting sympathy, but they could never be something that occurred entirely within the person's mind (1985).
- 20 Becker & Murphy (1988).
- 21 "Some sets of commodities are simply incomparable or incommensurable" (Schwartz, 1986); see also Allison (1981), Taylor (1982).
- 22 An outcome that loses 20% of its value for every unit of time it is delayed is worth $(1.00 - .20)^1$, or .80 of its value, at 1 unit of delay, $(1.00 - .20)^2$, or .64 of its value, at 2 units of delay, $(1.00 - .20)^{10}$, or .107 at 10 units, .0000000002 at 100 units, and so on.
- 23 For most people, the availability of a good excuse is even more important; but we'll have to figure out why anybody would need to give an excuse to *herself* before talking about that.
- 24 Hume quoted in Hirschman (1977, p. 25); Senault (1649, p. C1).
- 25 Ainslie & Herrnstein (1981); Ainslie (1974).
- 26 The simplest hyperbola is:
 Value = Objective value / Delay
 However, this formula could probably never describe a natural process, since it would make value infinite at zero delay. A hyperbolic formula that makes "objective" value equal to discounted value at zero delay is:
 Value = Objective value / (1 + Delay)
- A value would fall to $1.00/(1 + 1)$, or .50 of what it would be if immediate at 1 unit of delay, $1.00/(1 + 2)$, or .33, at 2 units, and $1.00/(1 + 10)$, or .09, at 10 units of delay, but would still be worth $1.00/(1 + 100)$, or .01 at 100 units, compared to the .000030 predicted by the exponential formula at 10%. This formula still allows for no differences in discount "rate," or impatience, among different people, a rigidity that will need correcting.
- 27 And among exponential discounters, those who discount at a lower rate will accumulate money faster than those who discount at a higher rate. In that case, however, the high discounter wouldn't mind this prospect, since she devalues the future, just as Becker and Murphy's rational addict doesn't regret her addiction.
- 28 Noise: Solnick et al. (1980); Navarick (1982). Video games: Millar & Navarick, 1984. Food: Ragotzy et al. (1988).
- 29 Green et al. (1981); Kirby & Herrnstein (1995); Ostaszewski (1996); Kirby (1997); Madden et al. (1997); Richards et al. (1999); Vuchinich & Simpson (1998).
- 30 That is, older subjects have a smaller $Constant_2$ in the general discount equation ([see below]; Ainslie & Haendel, 1983; Green et al., 1981; Kirby & Herrnstein, 1995), as do introverts (Ostaszewski, 1996), nonaddicts (Kirby et al., 1999), and nonsmokers (Bickel et al., 1999).
- 31 Herrnstein et al. (1993). These findings are consistent with an earlier description of the factors that make human subjects respond differently than animals in some experimental designs (Mawhinney, 1982).
- 32 Generalized from Mazur (1987). I compare the possible formulas in Ainslie (1992, pp. 63–76). $Constant_1$ keeps the value from going to infinity when a reward is immediate; $Constant_2$ describes how steeply a subject discounts the future.
- 33 $Y = 1/X$, where Y is the magnitude in question and X is the distance to the building or goal.
- 34 Brunsson (1985), Chapters 1 and 2; Brennan & Tullock (1982, p. 226).
- 35 The classical work is by Max Weber (1925/1964).
- 36 Navon and Gopher (1979).
- 37 Olds (1992). Because of neurophysiological findings, it has been suggested that "hot" and "cool" (= passionate and reasonable) choice-making systems may be based on information processed in the amygdala and hippocampus, respectively, with the implication that the resulting motives are also in separate systems (Metcalf & Jacobs, 1998; Metcalf & Mischel, 1990).
- 38 Conversely, however concentrated the reward process is within one location, it must still have

- separate components, ultimately neurons, that compete for control of whatever output pathway it has. Localization will always be relative.
- 39 E.g., Klein (1989).
- 40 Cognitive psychologist Julius Kuhl and his colleagues have suggested what is in effect a population model of the person, in which one part sometimes controls others like a dictator but does better exercising “democratic leadership” (Kuhl, 1994). In this model a function called “autonomy” (“the holistic integrated functioning through which action is centrally regulated”) “stabilizes and boosts autonomy and action, for example, by facilitating the identification and efficient expression of goals . . . and shielding such goals from competing impulses” (Ryan et al., 1997). However, they don’t say why this stabilization, or shielding, should be needed, and imply that one faction’s attempt to control others is a cause rather than a response to conflict between them.
- 41 Cropper et al. (1991); Harvey (1994). Among other consequences, this uniformity over scale makes preference reversal a candidate for being analyzed as a fractal in chaos theory (see Gleick, 1987).
- 42 Laibson (1997); Harris & Laibson (1999). Their “quasi-hyperbolic function captures the qualitative property that discount rates decline (weakly) with horizon length” (1999, p. 2), and is adapted from the formula that Phelps and Pollack originally developed to describe the value of property transferred between generations (1968).
- 43 Foraging theory has always assumed that natural selection has shaped animals’ choices to maximize aggregate net energy gain (Krebs, 1978; Maynard Smith, 1978); its proponents haven’t examined the discounting process until recently. When they’ve done so, they’ve found that animals will regularly choose poorer, imminently available prey over better, delayed alternatives to the detriment of overall foraging efficiency (Kagel et al., 1986; Lea, 1979; Snyderman, 1983).
- 44 Offer (in 2006) *The Challenge of Affluence: Prosperity and Well-Being in the United States and Britain since 1945*, p. 11.
- 45 Erasmus (1509/1983).
- 46 See Simon (1983).
- 47 First in 1986; see also Ainslie (1992).
- 48 Ainslie (1974); see Section 2.1.
- 49 Strotz (1956) acknowledged that the problem implied a nonexponential discount curve but didn’t suggest a hyperbola; Elster (1979).
- 50 Azrin et al. (1982); Fuller & Roth (1979).
- 51 Becker (1960).
- 52 Gilligan (1977).
- 53 Right thinking: Crane (1905, p. 115); stimulus control: Kanfer (1975, pp. 309–355); Goldiamond (1965); Metcalfe & Mischel (1999); value of ignorance: Carillo (1999).
- 54 Freud (1926/1956); Aristotle’s *Nicomachean Ethics* 1147b9–15; lapses in smokers: Sjöberg & Johnson (1978).
- 55 Labeling by emotional salience: Zajonc (1980); calling up memories by category: Shiffrin & Schneider (1977); self-serving ethics: Rabin (1995).
- 56 The momentum of an appetite – a positive feedback effect that leads to potentiation rather than satiation – is what has made conditioning theories of temporary preference so attractive. These include the latest incarnation of the passion/reason model, Metcalfe and Mischel’s “hot/cool system analysis” (1999). I discuss this phenomenon at length in Ainslie (1999b).
- 57 Alexithymia: Nemiah (1977). This is the opposite of cultivating your vulnerability to influence, one of the extrapsychic committing devices. The fact that a person may see either one as serving her long-range interest doubtless comes from the fact that vulnerability to influence is a two-edged sword. Children: Mischel & Mischel (1983).
- 58 Bacon quoted in Hirschman (1977, p. 22); David Hume quoted in Hirschman (1977, pp. 24–25). Economist Robert Frank gives several examples of emotions that seem to serve as self-control devices (1988, pp. 81–84).
- 59 Psychologist Julius Kuhl (1996) proposes a similar list of “self-regulatory . . . mechanisms and strategies,” but without extrapsychic examples: “attention control,” “emotion and activation control,” and what sound like aspects of will – “motivation control,” “goal maintenance,” and “impulse control.”
- Each of Jon Elster’s “devices for precommitment” is also an example or a subset of one of these tactics. He divides extrapsychic devices into “eliminating options,” “imposing costs,” “setting up rewards,” “creating delays,” and “changing preferences [i.e., early avoidance].” Attention control is “inducing ignorance,” and preparation of emotion is “inducing passion.” As I’m about to argue, “investing in bargaining power [i.e., maintaining your credibility]” is part of the mechanism of will, but Elster separates it from my core mechanism for will, bundling of choices, which he calls “bunching” and lists as an “alternative to precommitment” (2000, pp. 6, 84–86). Similarly, I believe that all of his reasons for precommitment (“overcome passion,” “overcome self-interest,” “overcome hyperbolic discounting,” “overcome strategic time inconsistency,” and “neutralize or prevent preference change”) are ultimately motivated by one reason: the problem of hyperbolic discounting; however, he believes that passion, at least, is not

an example of that problem (see Ainslie, 1999b; Elster, 1999).

- 60 Aristotle, *Nicomachean Ethics*, 1147a24–28; Galen (1963, p. 44); new force, throw strength on weaker side, unite actions, strengthened by repetition: Sully (1884, pp. 631, 663, 669); vulnerable to nonrepetition: Bain (1859/1886, p. 440); held steadily in view: James (1890, p. 534).
- 61 Heyman (1996); Heyman & Tanz (1995).
- 62 Rachlin (1995a); Siegel & Rachlin (1996).
- 63 Baumeister & Heatherton (1996); philosophers: Bratman (quoted) (1999, pp. 50–56); McClennen (1990, pp. 157–161); others discussed in Bratman (1999, pp. 69–73).
- 64 Rachlin (1995a, 1995b).
- 65 Mazur (1986) reported that pigeons choosing between a single food reward and a series of more delayed rewards decide as if they simply added each amount divided by its delay, thus confirming less precise findings by McDiarmid and Rilling (1965).
- 66 Bratman (1999, pp. 35–57).
- 67 Making choices in the context of similar future choices can increase self-control: Kirby & Guastello (2000); bundling choices into series makes rats switch their preference from smaller, earlier to larger, later sucrose rewards: Ainslie & Monterosso (2000). In the latter experiment, rats given the choice between .4 second access to sugar water immediately and .6 second access at a 3.0 second delay regularly chose the immediate reward; they regularly chose a series of three .6 second rewards over a series of .4 second alternatives 3.0 seconds earlier, even though the first .4 second reward was immediate.
- 68 The bundling and other phenomena that follow from hyperbolic discounting are also consistent with the hyperboloid curves that some economists have adopted for their tractability (see note 42). Roland Benabou and Jean Tirole have derived most of the properties of personal rules from such curves (2000).

- 69 At midnight the value of staying up will be

$$V_{up} = \sum_{i=0.5 \rightarrow 1.5} 60/(1+i) = 64$$

and the differential value of feeling rested at work will be

$$V_{bed} = \sum_{i=7.5 \rightarrow 16.5} 60/(1+i) = 49$$

Given only this choice, you'll probably stay up and suffer the next day.

- 70 The values of your alternatives are:

$$\begin{aligned} V_{up} = & \left(\sum_{i=.5 \rightarrow 1.5} 60/(1+i) \right) + \left(\sum_{i=24.5 \rightarrow 25.5} 60/(1+i) \right) \\ & + \left(\sum_{i=48.5 \rightarrow 49.5} 60/(1+i) \right) + \dots \\ & + \left(\sum_{i=216.5 \rightarrow 217.5} 60/(1+i) \right) = 78 \end{aligned}$$

for staying up on the next 10 nights vs.

$$\begin{aligned} V_{bed} = & \left(\sum_{i=7.5 \rightarrow 16.5} 60/(1+i) \right) \\ & + \left(\sum_{i=31.5 \rightarrow 40.5} 60/(1+i) \right) + \dots \\ & + \left(\sum_{i=223.5 \rightarrow 232.5} 60/(1+i) \right) = 105 \end{aligned}$$

for going to bed.

- 71 Kant (1793/1960, pp. 15–49); Kohlberg (1963).
- 72 James (1890, p. 565).
- 73 He also illustrated the difficulty of making sense of this competition without a rationale for temporary preference. When he tried to specify the details, he got hopelessly tangled:

One opinion is universal, the other concerns particulars, things about which perception has the deciding say. When one [opinion] arises from them the soul must, in the one case, affirm the conclusion, in cases to do with doing, act at once... When, therefore, on the one hand there is the universal [opinion] forbidding to taste, and on the other, [the opinion] that everything sweet is pleasant, and this is pleasant (and it is this opinion which operates), and desire happens to be present, the one says to avoid this but desire drives; for it has the power to move each of the parts [of the body]. So it turns out that the man who acts akratically does so under the influence in a way of reason and of opinion, opinion, however, which is not opposed in itself to the right principle – it is the desire, not the opinion, which is opposed to that – but opposed incidentally. (*Nicomachean Ethics*, 1147a24–b17).

- 74 Self-enforcing contracts are described by Macaulay (1963), and by Klein and Leffler (1981), and analyzed in terms of game theory by Stähler (1998). Howard Rachlin (1995b) incorrectly ascribes the active ingredient in the piceoeconomic theory of will to “the law of exercise,” an old behaviorist term for force of habit.

PART II: MODES OF REASONING

Section 3: Deductive Reasoning

Chapter 9: Logical Approaches to Human Deductive Reasoning¹

LANCE J. RIPS

The idea that formal logic bears a close relationship to human reasoning is extremely controversial within cognitive science. For example, Wason and Johnson-Laird (1972: 245) concluded their influential study of reasoning by stating that “only gradually did we realize first that there was no existing formal calculus which correctly modeled our subjects’ inferences, and second that no purely formal system would succeed.” This kind of opposition is based on evidence that subjects’ judgments about an argument sometimes depart from the answer that the experimenter derived by translating the argument into some system of logic and assessing its correctness within that system. The strength of this evidence, however, clearly depends on the system the investigator uses. If the investigator’s conception is too narrow, what is classified as nonlogical behavior may turn out logical after all. To evaluate the evidence, we need some clear idea of what logic has to offer.

Most cognitive theories that contain a logic-like component (e.g., Braine 1978; Johnson-Laird 1975; Osherson 1974, 1975, 1976; Rips 1983) are based on the notion of proof, particularly the “natural deduction” proofs originally devised by Gentzen (1935/1969) and Jaskowski (1934). The basic notion is familiar to anyone who has taken a high school mathematics course: If you want to know whether a particular argument is deductively correct, you can find out by

taking its premises as given and then trying to derive its conclusion by applying a specified set of rules. If a proof or a derivation is possible, then the argument is deductively correct; the conclusion is *deducible* from the premises. We also can say, by extension, that the argument as a whole is deducible. The left column of Table 1 summarizes this terminology.

Contemporary logical theory supplements the notions of formal proof and deducibility with a twin “semantic” system whose central concepts are the truth of a sentence and the validity of an argument (Tarski 1936/1956). In the semantic system the deductive correctness of an argument is a matter of the relationship between the truth of the premises and the truth of the conclusion. In particular, an argument is deductively correct if and only if the conclusion is true in all states of affairs in which the premises are true. In this case, the conclusion is (*semantically*) *entailed* by the premises, and the entire argument is *valid*, as shown in the right column in Table 1. (We also can speak of a single sentence as valid if it is true in all states of affairs. This is, of course, a stronger notion of semantic correctness for a sentence than the simple truth of a sentence in the *actual* state of affairs; it is the difference between *Insects have six legs*, which is true in our present state but false in a logically possible state in which they have eight, and *Six is less than eight*, which is true in all possible states.)

Table 1: Summary of Logical Terminology

	<i>Proof Theory</i>	<i>Semantics</i>
Correctness of the relation of the conclusion to the premises	deducibility (= conclusion provable from the premises)	semantic entailment (= conclusion true in all states of affairs in which the premises are true)
Correctness of an argument	deducibility	validity

In this dual setup, then, we have two criteria of deductive correctness: deducibility and validity. We might hope that these two criteria coincide in confirming exactly the same set of arguments. For simple logical systems – for example, classical sentential and predicate logic – they do coincide; such systems are said to be *complete*. In these systems, it doesn't matter which criterion we use, as long as all we are interested in is determining which arguments are the correct ones. However, there are three reasons for keeping both criteria in mind. First, the proof-theoretic description is computationally relevant: The description contains rules that yield a finite proof of a deducible argument. By contrast, the semantic description is computationally independent, since the criterion it gives for validity does not depend on there being any finite procedure for assessing it. Second, there are more complex logical systems in which the criteria *don't* coincide – incomplete systems in which some entailments are not deducible. Third, according to an intriguing theory put forth by Johnson-Laird (e.g., 1983; Johnson-Laird and Byrne 1991), it is the semantic rather than the proof-theoretic criterion that is important in human reasoning (contrary to the other cognitive theories cited earlier).

Of course, changing the deduction rules of a logical system (or changing the way in which truth is assigned to propositions) can alter which arguments are deemed deductively correct. Logicians and philosophers of logic have in fact proposed a variety of plausible systems that differ in the elements of natural language that come in for formal treatment, and in the analysis that they give these elements. Current logics are available for concepts such as knowledge and belief, temporal precedence and succession, causality, obligation and permission, and logical necessity and possibility. For each of these concepts, there are alternative logics differing in exactly which arguments are deductively correct. Psychologists have almost completely overlooked this variety, tacitly assuming a single standard of deductive correctness. This means that,

when subjects' judgments have failed to conform to the standard, psychologists have been too ready to label them illogical, or, at least, to assume that logic is of no help in understanding them.

Formal Proof

At the most general level, a formal proof is a finite sequence of sentences (s_1, s_2, \dots, s_k) in which each sentence is either a premise, an axiom of the logical system, or a sentence that follows from preceding sentences by one of the system's rules. An argument is deducible in the system if there is a proof whose final sentence, s_k , is the conclusion of the argument. For example, consider a system that includes modus ponens among its inference rules. Modus ponens stipulates that the sentence Q follows from sentences of the form *IF P THEN Q* and P . Thus, (1) is deducible in this system.

- (1) IF Calvin deposits 50 cents THEN Calvin will get a coke.

Calvin deposits 50 cents.

Calvin will get a coke.

The proof consists simply of the sequence of three sentences in the order listed above, since (a) each sentence in the sequence either is a premise or follows from preceding sentences by modus ponens and (b) the final sentence is the conclusion of the argument. (Capital letters are used for *IF* and *THEN* to mark the fact that these words are parts of the proof system and are not necessarily equivalent in meaning or force to English *if... then...*).

In this stripped-down system, we also could prove the deducibility of (2).

- (2) IF Calvin deposits 50 cents THEN Calvin gets a coke.

IF Calvin gets a coke THEN Calvin will buy a burger.

Calvin deposits 50 cents.

Calvin will buy a burger.

In this case, a proof involves two applications of modus ponens, as (3) shows.

- (3) a. IF Calvin deposits 50 cents THEN Calvin gets a coke. Premise
- b. Calvin deposits 50 cents. Premise
- c. Calvin gets a coke. Modus ponens
- d. IF Calvin gets a coke THEN Calvin will buy a burger. Premise
- e. Calvin will buy a burger. Modus ponens

Sentences (3a), (3b), and (3d) are premises of argument (2), and sentences (3c) and (3e) are derived by modus ponens from preceding ones.

To prove a more diverse set of arguments, we will clearly need greater deductive power. We can get it, within this framework, by introducing axioms or additional inference rules. An *axiomatic* (or *logistic*) proof system contains a set of axioms and usually has modus ponens as its only rule. *Natural-deduction* systems contain several distinct inference rules and eliminate axioms. The two kinds of system can be equivalent in proving exactly the same set of theorems, but they possess rival advantages and disadvantages in other respects. On the one hand, axiomatic systems sometimes have an advantage over natural-deduction systems when we must derive characteristics *about* the proof system itself (though natural-deduction systems have interesting metatheoretic properties of their own – see Fine 1985a, 1985b; Gentzen 1935/1969; Prawitz 1965; Ungar 1992). On the other hand, it is usually easier to prove theorems *within* a natural-deduction system, and consequently most elementary textbooks on logic make use of natural deduction as a main proof method (e.g., Copi 1954; Thomason 1970). For the same reason, natural deduction has been the method of choice in psychological models, and I’ll concentrate on versions of natural deduction systems here.

Natural-deduction methods simplify proofs by permitting us to make other temporary assumptions or suppositions. As an example of how suppositions can simplify a proof, consider the argument in (4):

- (4) IF Calvin deposits 50 cents THEN Calvin gets a coke.
- Calvin does not get a coke.
-
- Calvin does not deposit 50 cents.

An informal justification of (4) might look like this:

- (5) a. According to the first premise, if Calvin deposits 50 cents then Calvin gets a coke.
- b. Suppose, contrary to the conclusion, that Calvin *does* deposit 50 cents.
- c. Then (by modus ponens), Calvin would get a coke.
- d. But the second premise tells us that Calvin does not get a coke.
- e. Hence, Calvin must not have deposited 50 cents.

This justification embodies a typical *reductio ad absurdum* (or NOT Introduction) pattern: In (5b) we assume temporarily the opposite of the conclusion we wish to prove and then show that this leads to contradictory information. Because the supposition could not hold, the conclusion itself must follow from the premises. In other words, (5) tacitly appeals to an inference rule stating that if a supposition leads to a pair of contradictory sentences then the negation of that supposition must follow. This *reductio* rule, together with modus ponens, is sufficient to show that (4) is deducible.

Natural-deduction systems formalize this method of making suppositions in the service of a proof. Within these systems, we can introduce suppositions freely as lines of a proof in order to draw further inferences from them. Before the proof is complete, however, we must apply a rule that resolves or “discharges” the supposition, because the conclusion of the proof must depend on the premises alone and not on any of the arbitrary assumptions we have made along the way. In (5), for example, the supposition made in line b is resolved when we conclude that the supposition could not in fact hold (because of the contradiction).

To state this a bit more systematically, we can use the term *domain* to refer to a designated set of lines of the proof that are associated with a supposition. Then no supposition (apart from the premises) can include the conclusion of the proof in its domain. In (5) the domain of the premises comprises lines a, d, and e, and the domain of the supposition in line b is just lines b and c. Figure 1 illustrates these domains. In the figure, solid lines indicate which sentences are used in deducing others (e.g., line c is deduced by modus ponens from lines a and b), and dashed lines indicate the scope of the domains. The premises in lines a and d are connected by dashed

Figure 1. A proof diagram for the argument:
 IF Calvin deposits 50 cents THEN Calvin gets a coke.
Calvin does not get a coke.
 Calvin does not deposit 50 cents.

lines to the conclusion e, and the supposition in line b is connected by a dashed line to c. One domain can be subordinated to another: The domain of b and c is a subdomain of the premises' domain. A sentence can be said to *hold* in the domain in which it appears, and this means that deduction rules that apply to the domain can use it freely. In the systems for classical sentential and predicate logic, sentences also hold in all subdomains of their domain. According to this system, for example, line a holds throughout the proof, including the subdomain. (Of course, line c holds only in the subdomain.) Other logical systems, however, place special restrictions on which sentences hold in subdomains.

Search

Blindly applying logical rules is a poor strategy for even simple deduction problems. As long as the rules are stated in the unconstrained form of most elementary logic textbooks, they will not automatically lead to a proof in an acceptable amount of time. Because some rules produce infinite sets of irrelevant sentences, finding a short proof by randomly applying rules would be a matter of sheer luck. If deductive reasoning is anything like a practical process, then there must be better ways to direct the search for a proof. The constraints on proofs that investigators in computer science have found differ in how encompassing they are. At one extreme, there are general methods that are applicable to all proof-finding situations; at the other, there are special-purpose heuristics that take advantage of particular types of rules or lines in the

proof. It turns out that the heuristics are more important for psychological purposes.

One innovation due to Newell, Shaw, and Simon (1957) was to apply the system's proof rules in a backward direction. The idea was to keep the rules aimed in the right direction by applying them only when needed to prove the conclusion. Applied in this way, modus ponens takes a conclusion Q as input and checks for a corresponding assertion $IF P THEN Q$; if such an assertion is available, the rule then tries to prove P . If it succeeds, then Q must follow. In this case, P serves as a *subgoal* for Q . I will call these goal-to-subgoal procedures *backward rules*. We can contrast these with *forward rules* that operate in the more typical premise-to-conclusion direction. As a forward rule, modus ponens takes as input the sentences P and $IF P THEN Q$, and it adds the sentence Q to the proof.

It is easy to see that certain deduction rules will work in a reasonable way only in the backward direction. For example, the natural deduction rule called AND Introduction enables the conclusion $P AND Q$ to be added to a proof whenever the proof already contains P and Q separately. There is no doubt about the validity of this inference, but applying it in the forward direction yields infinitely many new sentences, most of which will be irrelevant to the proof at hand. From P and Q , we can derive $P AND Q$; from P and $P AND Q$, we can then derive $P AND (P AND Q)$; from P and $P AND (P AND (P AND Q))$, we can derive $P AND (P AND (P AND (P AND Q)))$; and so on, mindlessly. Limiting AND Introduction to use as a backward rule reigns in this unlimited productivity.

Other rules, however, can apply in the forward direction without the same runaway consequences. Modus ponens, for example, applies just once to sentences of the form P and $IF P THEN Q$ to yield the result Q . Because modus ponens does not apply to its own output, it will yield just a single new sentence for each pair of input sentences (provided that we have a way to ensure that it doesn't repeatedly apply to the same pair). Thus, we can use modus ponens in a forward direction as soon as its input conditions are met. Having a forward rule like this, however, doesn't preclude having a backward version, too. In the context of certain proof systems, it is sensible to include backward modus ponens, in addition to the forward version just described. There may be situations, for instance, where the system needs to prove Q , has $IF P THEN Q$ as an assertion, but does not yet have P . In this case, it may be necessary to propose P as a subgoal in order to finish the proof.

A Theory for Sentential Reasoning

The rest of this chapter outlines a theory for sentential reasoning along natural-deduction lines and demonstrates that the theory can explain data from a reasoning experiment in which subjects evaluated the deducibility of arguments.

The central notion in the theory will be that of a mental proof. I assume that when people confront a problem that calls for deduction they attempt to solve it by generating in working memory a set of sentences linking the premises or givens of the problem to the conclusion or solution. Each link in this network embodies an inference rule that the individual recognizes as intuitively sound and that provides some control on search. Taken together, this network of sentences then provides a bridge between the premises and the conclusion that explains why the conclusion follows. Of course, people are not always successful in producing a mental proof of this sort. They may not possess or may not be able to apply an inference rule that is crucial for a particular proof. Resource limitations – for example, capacity restrictions in working memory – may keep them from completing a proof. They may even possess nonstandard rules of inference that lead them to conclusions not sanctioned in classical predicate logic. Nevertheless, the claim is that people will at least *attempt* a mental proof during their problem-solving process.

In this chapter I explore the idea of mental proof by asking how *sentential* proofs are produced. But of course this is only one of the challenges that a theory of deduction faces. We don't want to stop with sentential reasoning, because much of deduction's power depends on its ability to bind variables. Although developing a full theory of quantificational reasoning is beyond the scope of this chapter, interested readers can find such an extension in Rips (1994, 1999, 2000).

Overview of the Core Theory

The basic inference system consists of a set of deduction rules that construct mental proofs in the system's working memory. If we present the system with an argument to evaluate, the system will use those rules in an attempt to construct an internal proof of the conclusion from the premises. If we present the system with a group of premises and ask for entailments of those premises, the system will use the rules to generate proofs of possible conclusions. The model comes up with a proof by first storing the input premises (and conclusion, if any) in working memory. The rules then scan these memory contents to determine whether any inferences are possible. If so, the model adds the newly deduced sentences to memory, scans the updated configuration, makes further deductions, and so on, until a proof has been found or no more rules apply. Thus, the inference routines carry out much of the work in the basic system, deciding when deductions are possible, adding propositions to working memory, and keeping the procedure moving toward a solution. In what follows, I will refer to the system as PSYCOP (short for Psychology of Proof). The system was implemented as a PROLOG program for personal computers.

PSYCOP's strategy in evaluating arguments is to work from the outside in, using forward rules to draw implications from the premises and using backward rules to create subgoals based on the conclusion. The forward rules operate in a breadth-first way, and create a web of new assertions. The backward rules operate depth-first: PSYCOP pursues a given chain of backward reasoning until it finds assertions that satisfy the required subgoals or until it runs out of backward rules to apply. In the first case, the proof is complete, because there is a logical pathway that connects the premises to the conclusion. In the second case, PSYCOP must backtrack to an

earlier choice point where some alternative subgoal presented itself and try to satisfy it instead. If all the subgoals fail, PSYCOP gives up. In situations in which PSYCOP is expected to produce conclusions rather than to evaluate them, it can use only its forward rules to complete the task, because there is no conclusion-goal to trigger the backward rules.

Assumptions about Memory

The PSYCOP model possesses a standard memory architecture that is divided into long-term and working-memory components. The two systems are similar in structure, the main difference between them being working memory's smaller capacity. Both memory systems contain internal sentences connected by labeled links, as in earlier memory models proposed by Anderson (1983), Collins and Loftus (1975), and others. We can examine the main features of both memory systems by returning to the proof in Figure 1.

The links connecting memory sentences are probably of a large variety of types, but there are two that are especially relevant to the deduction process. Let us call them *deduction links* and *dependency links*. The deduction links – represented as solid arrows in the figure – run from memory sentences to any other sentences that they immediately entail. In Figure 1, for example, there are deduction links that connect the sentences *IF Calvin deposits 50 cents THEN Calvin gets a coke* and *Calvin deposits 50 cents* to the sentence *Calvin gets a coke*, indicating that PSYCOP deduced the latter sentence from the two former sentences in a single inference step. Each deduction link is the product of a particular rule (modus ponens, in this example). In cases like this, two sentences combine to produce a third. To indicate that sentences like these are jointly responsible for an inference, I use an arc to connect the deduction links emanating from them, as in Figure 1. Thus, deduction links give us a record of the individual steps in a derivation, each link (or set of arc-connected links) corresponding to the application of a single deduction rule.

The dependency links in memory (dashed lines) represent the way the sentences depend on premises or suppositions in the mental proof. As we've already noted, the dependency link from sentence b to c in Figure 1 represents the fact that c belongs to supposition b's domain. This is important because subdomain sentences like c usually do not hold in their superdomains, and

confusion about a sentence's domain can lead to logical inconsistencies.

We assume, of course, that working memory has a limited capacity. If mental proofs exceed this capacity, a person will usually have to recompute and recode information in order to avoid making mistakes. This is in line with demonstrations by Hitch and Baddeley (1976) and by Gilhooly, Logie, Wetherick, and Wynn (1993) that a working-memory load from an unrelated task can produce errors on deduction problems.

Assumptions about Inference Rules

Exactly which inferences are immediate or primitive is an empirical matter, and so it is not possible to enumerate them before the evidence is in. Nevertheless, theoretical considerations and previous experiments suggest some plausible candidates for rules to add to PSYCOP's repertoire. Table 2 lists some of the ones that are needed to prove the arguments from an experiment on reasoning, to be reported in the next section. The rules appear in Table 2 in their conventional argument form (on the left side of the table) and then in the form of inference routines (on the right). These rules come from the theories of Braine, Reiser, and Rumain (1984), Johnson-Laird (1975), Osherson (1975), Rips (1983), Sperber and Wilson (1986), and others. (Not all rules from these sources necessarily appear in the table. The names given these rules are not standard ones in all cases, but they may help in keeping the rules in mind.)

Many of the inference patterns embodied in the rules of Table 2 could be derived in alternative ways. For example, we can capture Disjunctive Modus Ponens – the inference from *IF P OR Q THEN R* and *P* to *R* – by means of the regular modus ponens rule (IF Elimination) together with OR Introduction. Psychologically, however, Disjunctive Modus Ponens appears simpler than OR Introduction. In research to be discussed later, I estimated the probability that subjects correctly applied each of these rules when it was appropriate for them to do so in evaluating a sample of sentential arguments. According to this measure, subjects applied the Disjunctive Modus Ponens rule on 100 percent of relevant trials, but applied OR Introduction on only 20 percent. If these estimates are correct, the subjects could not have been using OR Introduction to achieve the effect of Disjunctive Modus Ponens. Thus, it seems reasonable to

Table 2: Examples of PSYCOP's Inference Routines

Forward Rules:

Forward IF Elimination

IF P THEN Q	(a) If a sentence of the form IF P THEN Q holds in some domain D,
P	(b) and P holds in D.
Q	(c) and Q does not yet hold in D,
	(d) then add Q to D.

Forward DeMorgan (NOT over AND)

NOT(P AND Q)	(a) If a sentence of the form NOT (P AND Q) holds in some domain D,
(NOT P) OR (NOT Q)	(b) and (NOT P) OR (NOT Q) does not yet hold in D,
	(c) then add (NOT P) OR (NOT Q) to D.

Forward Disjunctive Syllogism

P OR Q	(a) If a sentence of the form P OR Q holds in some domain D,
NOT Q	(b) then if NOT P holds in D and Q does not yet hold in D,
P	(c) then add Q to D.
	(d) Else, if NOT Q holds in D and P does not yet hold in D,
	(e) then add P to D.

Forward Disjunctive Modus Ponens

IF P OR Q THEN R	(a) If a sentence of the form IF P OR Q THEN R holds in some domain D,
P	(b) and P or Q also holds in D,
R	(c) and R does not yet hold in D,
	(d) then add R to D.

Forward AND Elimination

P AND Q	(a) If a sentence of the form P AND Q holds in some domain D,
P	(b) then if P does not yet hold in D,
	(c) then add P to D,
	(d) and if Q does not yet hold in D,
	(e) then add Q to D.

Backward Rules:

Backward IF Elimination

IF P THEN Q	(a) Set D to domain of current goal.
P	(b) Set Q to current goal.
Q	(c) If the sentence IF P THEN Q holds in D,
	(d) and D does not yet contain subgoal P,
	(e) then add P to the list of subgoals.

Backward DeMorgan (NOT over AND)

NOT(P AND Q)	(a) Set D to domain of current goal.
(NOT P) OR (NOT Q)	(b) If current goal is of the form (NOT P) OR (NOT Q),
	(c) and NOT (P AND Q) is a subformula of a sentence that holds in D,
	(d) then add NOT(P AND Q) to the list of subgoals.

Backward Disjunctive Syllogism

P OR Q	(a) Set D to domain of current goal.
NOT Q	(b) Set Q to current goal.
P	(c) If a sentence of the form P OR Q or Q OR P holds in D,
	(d) and NOT P is a subformula of a sentence that holds in D,
	(e) and D does not yet contain the subgoal NOT P,
	(f) then add NOT P to the list of subgoals.

(continued)

Table 2 (*continued*)*Backward Rules:***Backward Disjunctive Modus****Ponens**

IF P OR Q THEN R

P

R

- (a) Set D to domain of current goal.
- (b) Set R to current goal.
- (c) If the sentence IF P OR Q THEN R holds in D,
- (d) and D does not yet contain the subgoal P,
- (e) then add P to the list of subgoals.
- (f) If the subgoal in (e) fails,

- (d) and IF P THEN Q is a subformula of the premises or conclusion,
- (e) then set up a domain of D, D', with supposition P,
- (f) and add the subgoal of proving Q in D' to the list of subgoals.

suppose that Disjunctive Modus Ponens functions as a primitive inference rule on its own, despite its logical redundancy. Braine et al. (1984) and Sperber and Wilson (1986) present further reasons for favoring Disjunctive Modus Ponens as a primitive.

Psychological models of deduction differ in which rules they consider to be the primitive ones. These differences are not merely notational, since some arguments are provable in one system but not in others. But the choice of rules is not the most important point of comparison between models. This is because most investigators have been cautious about claiming that the particular rules incorporated in their models exhaust the primitive ones. (The work by Braine 1978 and Braine et al. 1984 is an exception.) The usual claim (Osherson 1975; Rips 1983) is that the incorporated rules are a subset of the primitive ones. It is also worth noting that the evidence on the status of a rule is sometimes ambiguous, particularly if primitive rules can vary in how easy they are to deploy. It is not always clear, for example, whether subjects are proving a given argument by means of two very efficient primitives or by means of one more global but not-so-efficient primitive. The problem becomes even more complex if we allow for individual differences and for the learning or the compiling of new primitive rules. For these reasons, it seems wise to concentrate on other criteria in compar-

ing and evaluating deduction systems. In developing PSYCOP, I have tried to include most of the rules that earlier models have taken as primitive, so the model's current repertoire is fairly large. (See Rips 1994 for the full set of rules.)

Notice that the backward rules in Table 2 are stated in a way that appears much less general than their usual formulation in logic texts. One reason for this is that many of these rules can lead to infinite backward searches unless they are constrained. Take the case of the rule called AND Elimination, which allows us to deduce P (or Q) from the sentence P AND Q. If we use AND Elimination backward on goal P to produce subgoal P AND Q, then we should be able to use it again on P AND Q to obtain the subgoal (P AND Q) AND R, and so on. Perhaps the most reasonable solution, under these circumstances, is to restrict the rules so that no subgoal can be produced that isn't already a "part" of the current set of assertions. To pin down this notion of part more precisely, let us use the term *subformula* to denote any consecutive string of symbols in a sentence (including the entire sentence) that would also qualify as a grammatical sentence on its own. Thus, *Calvin gets a coke AND Calvin buys a burger* is a subformula of *IF Calvin deposits 50 cents THEN (Calvin gets a coke AND Calvin buys a burger)*, but *(Calvin gets a coke AND Calvin buys a burger) AND Calvin*

deposits 50 cents is not. The restriction in question prohibits a rule from pursuing a subgoal that is more complex than the premises or conclusion of the problem it is working on.

Assumptions about Control

The rules in Table 2 leave room for some further decisions about the order in which PSYCOP should deploy them. We need to specify, for example, when PSYCOP should apply forward rules and when backward rules, as well as which rules in each class it should try first. In making these choices, we need to consider the internal characteristics of the rules. Clearly, PSYCOP can apply its forward rules in a nearly automatic way, because their self-constraining nature requires little external monitoring and will never lead to infinite forward searches. It therefore seems reasonable to activate them as soon as possible whenever a triggering assertion appears in the database. Backward rules, however, present more of a control problem. Although the constraints we have placed on the backward rules keep them from producing infinite loops, they nevertheless have the potential to produce extremely inefficient searches. This means that we might want to adopt a flexible approach to using these rules, allowing the system to profit from heuristic advice about which subgoals to follow up.

Currently, when PSYCOP has to evaluate an argument it begins by applying its forward rules to the premises until no new inferences are forthcoming. It then considers the conclusion of the argument, checking to see whether the conclusion is already among the assertions. If so, the proof is complete; if not, it will treat the conclusion as a goal and attempt to apply one of the backward rules. PSYCOP tests each of the backward rules to see if it is appropriate in this situation, and it does this in an order that is initially determined by the complexity of the backward rules. The idea is that simple rules should be tried first, since less work will have been lost if these rules turn out to lead to dead ends. PSYCOP prefers backward rules that can be satisfied by a single subgoal and that do not require new subdomains; thus, it tries Backward IF Elimination and similar rules first. If none of these rules is applicable, it next tries Backward AND Introduction, which requires two subgoals to be satisfied but which does not use subdomains. Finally, it will resort to the subdomain-creating rules IF Introduction, OR Elimination, and NOT Introduction.

Once a backward rule has been activated and has produced a subgoal, PSYCOP checks whether the new subgoal matches an assertion. If not, PSYCOP places the subgoal on an agenda, reruns the forward rules in case some assertions were added, and repeats its cycle. In principle, PSYCOP could try the subgoals on the agenda in any order – for instance, according to a heuristic measure of how “easy” these subgoals seem. In the absence of other instructions, however, it will follow a depth-first search; that is, it first tries to fulfill the conclusion-goal, then a subgoal to the conclusion that a backward rule has proposed, then a sub-subgoal to the first subgoal, and so on. If it reaches a subgoal to which no backward rules apply, it backtracks to the preceding subgoal and tries to fulfill it another way via a different backward rule. There is also a provision in PSYCOP for a bound on the depth of its search, limiting the length of a chain of subgoals to some fixed number. Finally, PSYCOP halts with a proof if it has found assertions to fulfill all the subgoals along some path to the conclusion. It halts with no proof if it can complete none of the subgoal paths.

An Example

As an example of how the system operates, consider (6) – a simple argument that it can evaluate using the rules in Table 2.

- (6) IF Betty is in Little Rock THEN Ellen is in Hammond.
 Phoebe is in Tucson AND Sandra is in Memphis.

IF Betty is in Little Rock THEN (Ellen is in Hammond AND Sandra is in Memphis).

At the start of this problem, working memory will contain just these three sentences, as shown in Figure 2a. The conclusion appears with a question mark to indicate its status as a goal, and the premises end with periods to show that they are assertions. To begin, PSYCOP notices that the second premise is a conjunction and is therefore subject to Forward AND Elimination. Applying this rule creates two new sentences, *Phoebe is in Tucson* and *Sandra is in Memphis*, which it stores in working memory (Figure 2b).

At this stage of the proof no other forward rules apply, but it is possible to begin some work in the backward direction. Since the conclusion (and goal) of the argument is a conditional, Backward IF Introduction is appropriate here. According to this rule (Table 2), we

a.

b

c.

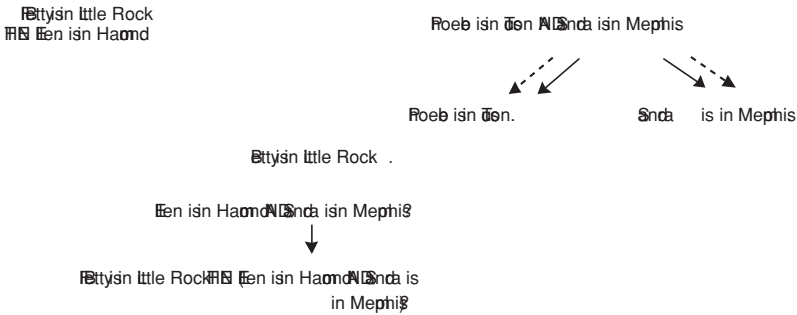

Figure 2. PSYCOP's proof of the argument:

IF Betty is in Little Rock THEN Ellen is in Hammond.

Phoebe is in Tucson AND Sandra is in Memphis.

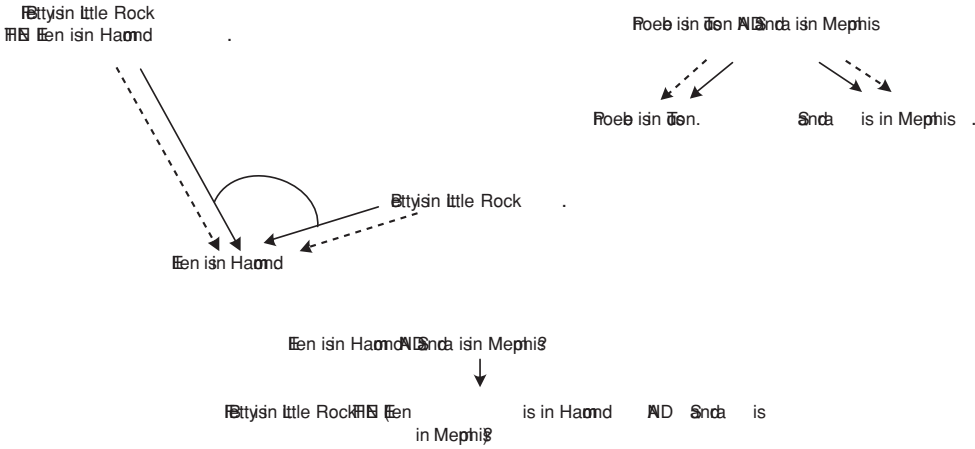

IF Betty is in Little Rock THEN (Ellen is in Hammond AND Sandra is in Memphis).

should try to deduce the conclusion by setting up a new subdomain whose supposition is *Betty is in Little Rock* (the antecedent of the conditional conclusion) and attempting to prove *Ellen is in Hammond AND Sandra is in Memphis* in that subdomain. Figure 2c shows this supposition and the resulting subgoal in the developing memory structure. (The structure represents subdomains by means of the pattern of dashed arrows, as mentioned earlier.) Because we are now assuming both *Betty is in Little Rock* and *IF Betty is in Little Rock THEN Ellen is in Hammond*, the forward IF Elimination (i.e., modus ponens) rule will automatically deduce *Ellen is in Hammond* (Figure 2d). However, we must still satisfy the subgoal of proving *Ellen is in Hammond AND Sandra is in Memphis*. The relevant rule is, of course, Backward AND Introduction, which advises us to set up subgoals corresponding to the two halves of this conjunction. The first of

these, *Ellen is in Hammond*, is easy to fulfill, since it matches the assertion that we have just produced. (Double lines are used in the figure to represent the match between assertion and subgoal.) The second subgoal can also be fulfilled by an earlier assertion. Satisfying these two subgoals satisfies the conjunction, and this in turn satisfies the main goal of the problem. Thus, Figure 2e is a complete proof of argument (6).

PSYCOP's core system fulfills some of the criteria for an adequate deduction theory in psychology. Even with the limited rule set in Table 2, PSYCOP can prove an infinite set of theorems in sentential logic. Of course, we also need to be careful that the model isn't too productive, generating irrelevant inferences when it should be focusing more narrowly on the task at hand. The combination of forward and backward rules, however, helps eliminate irrelevancies while ensuring that the model will be able

d

e.

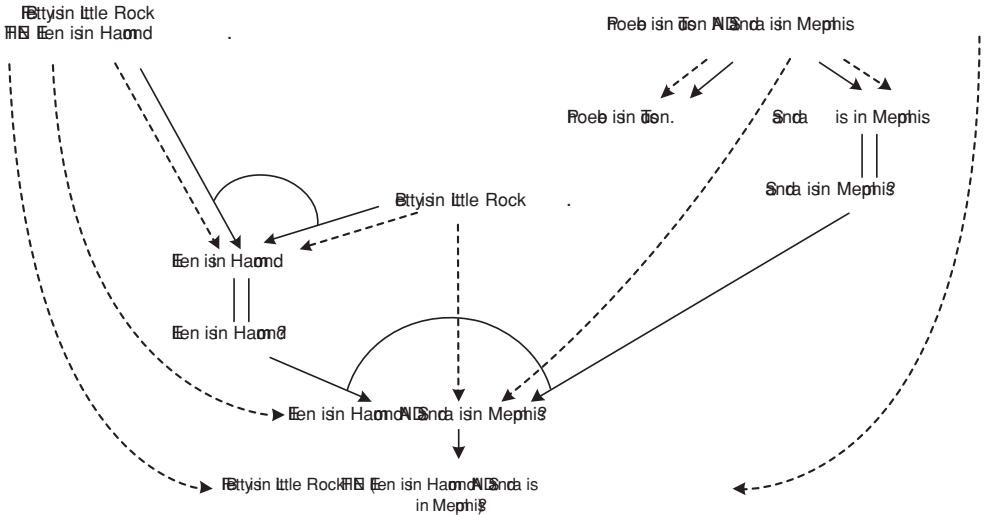

Figure 2 (continued)

to derive needed sentences. Rules such as IF Introduction also allow PSYCOP to manipulate suppositions in order to advance its proof of complex arguments. This characteristic matches subjects' use of suppositions. In Figure 2, for instance, the system used the supposition *Betty is in Little Rock* as a crucial element in the proof. The memory links shown in the figure provide a way of keeping track of these suppositions and the sentences that depend on them.

Empirical Findings

The traditional experiment in the psychology of reasoning is one in which subjects study a set of arguments and decide which of them are

valid. This paradigm dates at least as far back as Storing's (1908) experiments. In view of this long history, it might be useful to show that the model can predict these results. In order to conduct such a test, I assembled the 32 problems listed in Table 3. (The table uses "&" for AND, "v" for OR, "-" for NOT, and "→" for IF . . . THEN.) These problems are all deducible in classical sentential logic. The critical rules for these problems are IF Elimination, IF Introduction, DeMorgan (NOT over AND), Disjunctive Syllogism, Disjunctive Modus Ponens, AND Elimination, AND Introduction, OR Introduction, NOT Introduction, and OR Elimination. Although the experiment does not test the full range of PSYCOP's inference skills, it does test

Table 3: Percentage of Correct “Valid” Responses from Experiment (Observed) and Predictions from the PSYCOP Model

an important subset. The arguments were constructed so that each could be proved by means of three rules selected from the above list. In addition to these deducible arguments, there were also thirty-two nondeducible ones, created by recombining the premises and conclusions of the first set. Finally, forty filler arguments were added to the ensemble; most of these were simple deducible problems.

The subjects in this study saw the arguments in a single randomized list. For each argument, they were to circle the phrase “necessarily true” beneath the problem if the conclusion had to be true whenever the premises were true, and the phrase “not necessarily true” otherwise. Subjects responded to each problem in this way even if they had to guess. For half of the subjects, the arguments appeared in instantiations having to do with the location of people in cities. For example, argument E in Table 3 would have looked like (7).

(7) If Judy is in Albany or Barbara is in Detroit,
then Janice is in Los Angeles.

If Judy is in Albany or Janice is in Los Angeles, then Janice is in Los Angeles.

The remaining subjects saw the same problems rephrased in terms of the actions of hypothetical machines. Thus, for these subjects, the sample argument appeared in the following guise:

(8) If the light goes on or the piston expands,
then the wheel turns.

If the light goes on or the wheel turns, then the wheel turns.

The subjects in both groups were students or nonstudents of approximately the same age. None of them had taken a formal course in logic.

According to our theory, subjects should correctly respond that the conclusion of such an argument is necessarily true if they can construct a mental proof of that conclusion, and success in doing so will obviously depend on whether they can muster all the inference rules needed to complete the proof. As a working assumption, we will suppose that errors on these problems are due to a failure to apply the rules. The failure may be due to retrieval difficulties, slips in carrying out the steps of the rule, failure to recognize the rule as applicable in the current context, or other factors. In general, we can think of each rule R_i as associated with a probability

p_i that the rule will be available on a given trial. This means that there will be some occasions on which R_i would be useful in completing a proof but is not available to the subject. On these occasions, the subject will have to search for an alternative proof that uses rules other than R_i . (Such alternatives are sometimes possible because of the redundancy of the system.) If no such alternative exists, we will assume that the subject either guesses at the answer (with probability p_g) or simply responds incorrectly that the conclusion does not necessarily follow (with probability $1 - p_g$). For example, when all the rules listed above are available, the model will prove (7) or (8) using a combination of IF Introduction, OR Elimination, and Disjunctive Modus Ponens. If these rules are available with probabilities p_1 , p_2 , and p_3 , respectively, then (assuming independence) the probability of a correct “necessarily true” response might be (9), where the first term is the probability of a correct mental proof and the second term reflects a correct guess after failure to find the proof.

$$(9) \quad P(\text{“necessarily”}) = p_1 p_2 p_3 + 0.5 p_g (1 - p_1 p_2 p_3),$$

This equation is not quite right, however, because the model can still find a proof of these arguments even if Disjunctive Modus Ponens is missing. OR Introduction and IF Elimination can combine to fill the same role played by the unavailable rule. (All the remaining rules are necessary for the problem, since omitting them keeps the model from producing any proof at all.) To correct for this alternative derivation, we must add some new terms to the equation. If p_4 is the probability that IF Elimination is available and p_5 is the probability that OR Introduction is available, then the proper expression is (10).

$$(10) \quad P(\text{“necessarily”}) = p_1 p_2 p_3 + (1 - p_3) p_1 p_2 p_4 p_5 + 0.5 p_g [1 - p_1 p_2 p_3 - (1 - p_3) p_1 p_2 p_4 p_5]$$

The first term is again the probability of finding a proof by the original method, the second term is the probability of finding the alternative proof, and the third is the probability of a correct guess.

To derive predictions from the model, then, we need two pieces of information about each of the arguments in Table 3: the rules that are used in a proof of that argument, and the probability that each of these rules will be available. We can obtain the first type of information by simulation, giving the model the argument

and inspecting the proof to find which rules it employs. These rules can then be omitted (singly and in combination) to determine whether there are alternative proofs. The process is then repeated until no new proofs are forthcoming. This simulation allows us to formulate an equation like (10) for each of the arguments. The rule availabilities can be estimated by treating them as parameters when fitting the resulting equations to the data.

Table 3 gives the obtained and predicted percentages of correct “necessarily true” responses for the critical deducible problems. An analysis of variance of the data turned up no effect of the problem content (people in locations vs. machine actions) and no interaction of this factor with scores on the individual problems. Hence, the data from the two groups of subjects are combined in the table. The overall rate of correct responses is fairly low (50.6%), although there is obviously a very wide range across individual problems – from 16.7 percent correct on the hardest problem to 91.7 percent correct on the easiest. The percentage of incorrect “necessarily true” responses to the nondeducible problems (i.e., false alarms) was 22.9 percent. Thus, despite the low hit rate, subjects were distinguishing the deducible from the nondeducible items. In experiments like this one involving choice of alternative responses, the absolute response rate depends not only on subjects’ accuracy but also on the criterion they adopt for a “necessarily true” response. Cautious subjects, for example, are likely to give somewhat low rates of positive responses, even though they are able to discriminate correct from incorrect arguments with reasonable accuracy. In accounting for these results, we therefore need to concentrate on the relative scores across the set of problems.²

The predicted scores in the table are the result of fitting equations similar to (10) to the data. The full model requires a large number of availability parameters, since we need a distinct parameter for each inference rule. To reduce this number somewhat, we have collapsed forward and backward versions of a given rule, using the same parameter for both members of a pair. For example, the same parameter represented the availability of backward and forward IF Elimination. We also set the guessing parameter, p_g , using the data from the nondeducible problems: If subjects respond “necessarily true” to these nondeducible items only because of bad guesses, then the guessing rate (after fail-

Table 4: Parameter Estimates for the Model as Applied to the Argument-Evaluation Experiment

<i>Rule</i>	<i>Estimate</i>
Disjunctive Modus Ponens	1.000
AND Introduction	1.000
AND Elimination	0.963
IF Introduction	0.861
OR Elimination	0.858
IF Elimination	0.723
DeMorgan (NOT over AND)	0.715
Disjunctive Syllogism	0.713
NOT Introduction	0.238
OR Introduction	0.197

ure to find a proof) should be twice this value, or 45.8 percent. (This is not the overall probability of guessing; it is the conditional probability of guessing rather than saying “not necessarily true” given that no proof was forthcoming.) These economy moves still leave ten parameters, but there are twenty-one remaining degrees of freedom for a test of the model.³

Although the fit of the model is difficult to summarize because of the varied nature of the problems, Table 3 shows that the predictions are reasonably accurate. The correlation between predicted and observed scores, 0.93, yields a significant proportion of variance accounted for when tested against the Problem \times Subject interaction from an analysis of variance: $F(10,1054) = 26.43$, $p < 0.01$. The residual variance is fairly small, but it is also significant because of the large number of residual degrees of freedom: $F(21, 1054) = 1.88$, $p < 0.05$. The parameter estimates are those in Table 4. For the most part, these parameters are what we might expect on the basis of the intuitive nature of the rules. The easiest rules are those that seem obviously correct, including AND Introduction, AND Elimination, and Disjunctive Modus Ponens. The most difficult rule is OR Introduction, which allows us to deduce sentences of the form $P \text{ OR } Q$ from P . Many subjects apparently fail to apply this rule, probably for pragmatic reasons (Grice 1989; Gazdar 1979; McCawley 1981; Pelletier 1977): The conclusion of such an inference contains information that may seem to be irrelevant to the premise on which it is based and thus to violate conversational conventions.⁴ (For more empirical evidence on the difficulty of OR Introduction, see Rips and Conrad 1983.)

One puzzling aspect of these estimates is the very low availability for NOT Introduction versus the relatively high availabilities for OR Elimination and IF Introduction. The routines for these rules in Table 2 make them seem about equally complex: All three are backward rules that involve subdomains. So why should NOT Introduction be so much harder to apply? The difficulty might be explained as an artifact of the particular sample of problems, but in fact we can also find evidence for such difficulty in other paradigms (see Rips 1994: Ch. 5). Evidently, the *reductio* strategy of assuming the opposite of what one wants to prove is not an obvious move for subjects who haven't had extensive mathematics training. A plausible guess is that this difficulty is related to the conceptual distance between the main goal of proving *NOT P* and the subgoal of proving a contradiction *Q* and *NOT Q* on the basis of *P*. By contrast, OR Elimination and IF Introduction seem more direct, more intimately tied to the goals and assertions that trigger them.

One way to see what the model buys us is to compare the fits just mentioned against what we can obtain using other possible measures of problem difficulty. We might expect, for example, that the greater the number of premises in an argument, the more difficult that argument would be to evaluate. Similarly, the greater the number of atomic sentences in the argument, the harder it should be. For instance, argument *F'* in Table 3 contains four types of atomic sentences (*r*, *s*, *t*, and *u*), and seven atomic sentence tokens or occurrences. It should therefore be more difficult than *B'*, which contains only two atomic sentence types and five tokens. In general, however, these measures of surface complexity fail to provide a good account of the data. The correlation between the percentage of correct responses and the number of premises is -0.23 , and the correlations with number of types and tokens of atoms are -0.04 and 0.10 , respectively. This suggests that the true difficulty of the arguments is associated with the inference patterns they display, where these patterns are close to those specified in PSYCOP.

Summary

One way to think about the theory developed here is as a merger of two main ideas about the human nature of deductive reasoning. One of these ideas is that reasoning involves the ability to make suppositions or assumptions – that is, to entertain propositions temporarily in order to

trace their consequences. This idea comes from formal natural-deduction systems in logic, but it is clearly psychological at root. Nothing about deduction *per se* forces suppositions on us, since there are perfectly good deduction systems that do without them; we could start with a set of axioms and derive all the same theorems. But human styles of reasoning aren't like that, as both Gentzen and Jaskowski observed. We tend to assume propositions for the sake of the argument in order to focus our efforts in exploring what follows.

The second of the key ideas is that reasoning includes subgoals. People are able to adopt on a temporary basis the desire to prove some proposition in order to achieve a further conclusion. This idea seems more mundane than the one about suppositions, because we are accustomed to the use of subgoals in cognitive and computer science. Even the simplest AI programs use subgoaling to reduce the amount of search. But, again, deduction itself doesn't require subgoals. Even natural-deduction systems, as logic textbooks formulate them, don't have subgoals. Instead instructors in elementary logic have to provide informal hints about strategies for applying the rules, generally in the form of advice about working backward from the conclusion to more easily achievable lemmas. If these subordinate conclusions don't pan out, we can abandon them for others that may prove more successful. Our theory gives this purposefulness a status equal to that of suppositions.

Although I have borrowed suppositions from logic and subgoals from computer science, these concepts are closely interrelated. Suppositions are roughly like provisional beliefs, and subgoals roughly like provisional desires. In something like the way beliefs and desires about external states guide external actions, provisional beliefs and desires guide internal action in reasoning. According to the current theory, what gives human reasoning its characteristic tempo is the way these suppositions and subgoals coordinate: Can we show that some sentence *C* follows from another sentence *P*? Well, *C* would follow if we can show that *C'* follows from *P'*; so let's assume *P'* for now and try to find out whether *C'* holds; and so on. From one perspective, this sequence helps to simplify the problem at hand by lemma-izing it into manageable parts. But reasoning of this type also presupposes some fairly sophisticated cognitive apparatus for keeping track of the nesting of suppositions within suppositions and sub-subgoals en route to subgoals.

In the present theory, most of the responsibility for handling suppositions and subgoals devolves on the deduction rules. The rules in the model are a conservative choice of principles that seem psychologically (although not always logically) primitive. Research in this area should consider expanding this set of principles, and perhaps amending the current set, to achieve better coverage of the logical resources of natural language (see, e.g., Dowty 1993). But the present rules seem to provide a good starting point.

Notes

- 1 This chapter is a slightly modified excerpt from Rips (1994: Chs. 2–5).
- 2 For this reason, it is unwarranted to conclude from a low score on a given problem that subjects weren't engaged in reasoning about the problem. In this vein, Braine et al. (1984: 360) point to problem B in Table 3 as one in which "the conclusion seems to follow transparently from the premises," and state that the subjects' score on this item (66.7 percent "necessarily true" responses) "suggests that the experiment often failed to engage the reasoning procedure of subjects." It is unclear what rationale Braine et al. are applying in judging that this argument "transparently follows." The basic point, however, is that it is impossible to determine the extent to which subjects were engaged in reasoning from an absolute score without also knowing the response criterion the subjects were adopting. Fred Conrad and I (Rips and Conrad 1983) have replicated the experiment described here and found higher absolute scores (62% vs. 51% of subjects judged the classically valid arguments "necessarily true") but a very similar pattern of scores across problems.
- 3 Another method for estimating parameters is to include in the stimulus set an argument that turns on a single rule. The percentage of correct answers for that argument is then the estimate for that rule's availability (Braine et al. 1984; Osherson 1974, 1975, 1976). One difficulty with this procedure, for our theory, is that some of the rules, such as IF Introduction and NOT Introduction, can't be the sole rule used in the proof of an argument. Thus, the alternative method gives us no estimates for these items. Second, use of simple arguments to estimate parameters may sometimes spuriously inflate the fit of the theory. This is because the premise or the conclusion of a single-rule argument will often share the syntactic structure of the premise or conclusion of the argument that the investigator is trying to predict, especially when the proof is short. Hence, any difficulties associated with comprehending the syntax

will increase the correlation with the arguments' scores.

- 4 This pattern of parameter values explains some observations about this experiment that Johnson-Laird, Byrne, and Schaeken (1992) have made. The low availabilities for OR Introduction and NOT Introduction mean that the model predicts a fairly low proportion of "necessarily true" responses on arguments that involve these rules and a fairly high proportion on arguments that don't. Johnson-Laird et al. also claim that the scores for the problems in Table 3 depend on whether or not the arguments "maintain the semantic information of the premises." By the amount of "semantic information," Johnson-Laird et al. mean the percentage of possible states of affairs that the premises eliminate. A possible state of affairs is, in turn, determined by an assignment of truth or falsity to each of the atomic sentences that appear in the argument (Johnson-Laird 1983: 36; Johnson-Laird et al. 1992: 423). For example, consider the simple argument:

$$\frac{p \text{ AND } q}{q}$$

Because this argument contains just two atomic sentence types, the four possible states of affairs are one in which p is true and q is true, one in which p is true and q is false, one in which p is false and q is true, and one in which p is false and q is false. (Thus, the states of affairs are equivalent to the horizontal lines of a standard truth table for the argument.) In the sample argument, the premise rules out all but one of these states of affairs (the one in which p is true and q is true). However, the conclusion rules out only two states of affairs (the ones in which p is false). Of course, in any valid argument the conclusion must be true in all states of affairs in which the premises are true, and this means that the amount of semantic information conveyed by the premise must be greater than or equal to the amount conveyed by the conclusion. Johnson-Laird (1983) talks of an argument "maintaining semantic information" if the premises and conclusion have the same amount of semantic information, and "throwing away semantic information" if the conclusion contains less semantic information than the premises. Thus, the argument above throws away semantic information.

According to Johnson-Laird et al. (1992: 428), "to throw away semantic information is to violate one of the fundamental principles of human deductive competence, and so we can predict that performance with these problems should be poorer." They then report a test comparing sixteen arguments in Table 3 that purportedly maintain semantic information with sixteen arguments that don't. However,

Johnson-Laird et al. apparently miscalculated the amount of semantic information in these arguments; according to the criterion of Johnson-Laird (1983), only three of the thirty-two arguments (C, O, and X) maintain semantic information. The percentage of “necessarily true” responses for these problems was 48.2 percent, nearly the same as the percentage for the entire problem set (50.6%). Instead, Johnson-Laird et al. seem to have decided which arguments maintained semantic information according to whether the conclusion contains an atomic sentence token that does not appear in the premises. (E.g., the conclusion of Argument A contains an *r* that does not appear in the premises.) Adding atomic sentences to the conclusion, however, is not the only way of reducing semantic information, as we have already seen with respect to the sample argument above.

In short, contrary to Johnson-Laird et al., there is no evidence from these data that “throwing away semantic information” hurts subjects’ performance. What does seem to cause difficulty is the presence of atomic sentences in the conclusion that did not appear in the premises and may therefore seem irrelevant to those premises. This may be traced in turn to rules like OR Introduction (*P*; Therefore, *P* OR *Q*) that add sentences in this way.

Chapter 10: Mental Models and Deductive Reasoning

PHILIP N. JOHNSON-LAIRD

How do people reason? The view that I learned at my mother's knee was that they rely on logic. During the 1960s and 1970s when the study of thinking had become respectable again after the Dark Ages of Behaviorism, psychologists – including the present author – took this view for granted. The idea that logic provided the norms of reasoning can be traced back to the rise of modern logic, and was defended in the nineteenth century by both Boole (1854) and Mill (1874). In the twentieth century, the Swiss psychologist, Jean Piaget, and his colleagues argued that the construction of a formal logic in the mind was the last great step in children's intellectual development, and that it occurred at about the age of twelve (see, e.g., Inhelder and Piaget, 1958). And so thirty years ago the task for psychologists appeared to be to determine which particular formal logic was laid down in the mind and which particular rules of inference were used in its mental formulation. That, at least, was how several like-minded authors conceived their research (see, e.g., Osherson 1974–1976; Johnson-Laird 1975; Braine 1978; Rips 1983). In the parallel “universe” of artificial intelligence, researchers were similarly developing computer programs that proved theorems relying on formal rules of inference (e.g., Bledsoe 1977). The main skeptics were those engaged in trying to analyze everyday arguments. They discovered that it was extraordinarily difficult to translate such arguments into formal logic. As a result, many of them abandoned logic as a method of analysis (see, e.g., Toulmin 1958; Scriven 1976), and later they went on to found a pedagogical society, AILACT (Association for Informal Logic and Critical Thinking), in which they advocated a variety of other methods of analysis.

The event that woke me from my dogmatic slumbers was the late Peter Wason's discovery of the effects of content on his “selection” task. In

the abstract version of the task (Wason 1966), the experimenter lays down four cards in front of you, such as: A, B, 2, 3. You know that each card has a number on one side and a letter on the other side. Your task is to select just those cards to turn over that are relevant to determining whether a general claim is true or false. The general claim in one version of the task is:

If a card has an “A” on one side then it has a “2” on the other side.

Like all the studies described in the present article, the experiment tested “naïve” individuals – I use the term, not to impugn their intelligence, but merely to mean that they had received no training in logic. In the selection task, they tended to choose the A card, and sometimes the 2 card. But, they rarely chose the 3 card. You can grasp the need to do so if you think about the consequences of turning over the A card. If a 3 is on its other side, the general claim is false. By parity of argument, if you turn over the 3 card and find an A on its other side, the general claim is also false. Hence, you do need to select the 3 card. If you select the 2 card, then nothing on its other side can show that the general claim is false, unless you take the claim to mean: if and *only if* a card has an “A” on one side then it has a “2” on its other side. In this case, however, you ought to select all four cards.

The selection task was inspired by Popper's philosophy of science. He had argued that what divides science from nonscience is “falsifiability”: a scientific hypothesis is one that in principle observations could show to be false (Popper 1959). Any hypothesis that could not be refuted in this way is outside the borders of science. What Wason discovered is that individuals unfamiliar with logic or with Popper's idea have a perverse propensity *not* to try to falsify general claims. The failure was embarrassing to

Piagetians, because Piaget had argued that once children attain the level of “formal operations” – the level corresponding to the acquisition of logic – they would check the truth of conditionals of the form, *If A then B*, by searching for counterexamples of the form: *A and not-B*. But, the participants signally failed to reason in this way: the 3 card corresponds to not-B, and they did not select it. For anyone who had studied logic, this error of omission was puzzling. And so Wason and I embarked on a three-year research program, helped by a graduate, Diana Shapiro, to try to understand what was going on.

Why don't individuals select that 3 card? There were many possibilities. The experimental procedure might somehow mislead them. Psychological experiments are social interactions in a microcosm, and sensitive to all sorts of unforeseen factors. The participants may construe the task in ways quite different from what the experimenter has in mind. The psychologist may use inappropriate materials or procedures, or fail to control the experiment properly. The instructions explain the task, but the participants also think for themselves. This point became vivid to me when I read a participant the instructions, and he then said, “Yes, but what do you *really* want me to do?” We tried all sorts of experimental manipulations in order to elicit a correct performance. We changed the form of the rule; we put all the information on one side of a card; we gave participants brief “intellectual psychotherapy.” None of these manipulations did much good (see Wason and Johnson-Laird 1972).

Wason then suggested changing the *content* of the cards and the claim. Perhaps because my head was still stuffed with formal logic, I thought that this manipulation was crazy (although I didn't say so). Wason and Shapiro went ahead with the experiment. They used a general claim with an underlying conditional meaning:

Every time I go to Manchester I travel by train and four cards about journeys, with a destination on one side and a mode of transport on the other side: Manchester, Leeds, train, car. The participants were now much more likely to realize that a journey by *car* (the *not-B* case) was pertinent to the truth or falsity of the claim, and to select this card. If the destination on the other side was Manchester, then the claim was false (Wason and Shapiro 1971). It is hard to convey the stunning nature of this result at the time. A change in content alone had a striking effect on reasoning, even though the two sorts of contents were identical in formal structure. Paolo and Maria

Legrenzi and I carried out a similar experiment using a regulation about the postage required on sealed envelopes. The same robust change in performance occurred, and it did not transfer to the abstract version of the task (Johnson-Laird, Legrenzi, and Sonino Legrenzi 1972).

The true reason for the difference in performance between abstract and concrete selection tasks remains a matter of controversy, and several hypotheses purport to explain it (e.g., Cheng and Holyoak 1985; Cosmides 1989; Johnson-Laird and Byrne 1991; Oaksford and Chater 1998; see also the chapters in this volume by Fodor and by Sperber). But, at the time, the phenomenon convinced several psychologists that formal logic could not explain human reasoning. Formal logic, by definition, is concerned solely with the logical form of assertions, not their content. Yet, the selection task showed that content mattered just as much as form in reasoning (Wason and Johnson-Laird 1972).

The search for an alternative theory took some time, but it led to the topic of the present chapter, the theory of mental models or the “model theory” for short. The chapter begins with an outline of this theory. It examines in some detail the theory's account of negation, and of how one model is conjoined with another. Unlike logic, the interpretation of sentences in daily life is often modulated by knowledge, both a knowledge of what is being referred to and general knowledge. The chapter explains these phenomena, and their consequences on reasoning. It considers how individuals develop strategies for reasoning with particular sorts of problem. And, finally, it draws some general morals about reasoning.

The Mental Model Theory

The mental model theory has various antecedents of which the most important is the use of models in logic to provide a systematic method for the interpretation of assertions in logical calculi. However, this article is concerned, not with the history of the theory (for that, see Johnson-Laird 2004), but with its current formulation. This section accordingly outlines its main principles. Its fundamental assumption is that reasoning is about possibilities. When we read a description of a situation, we try to envisage the alternative possibilities with which the description is compatible. If someone tell us:

My house is in the middle of the street,

we construct a mental model of a single possibility. The proposition could be true in infinitely many ways (as model theory in logic recognizes), but we cannot hold in mind such an infinitude. So, strictly speaking, our mental model of the situation captures what is common to this swarm of possibilities, namely, that the speaker's house is (roughly) in the middle of the street rather than toward one end or the other. The sort of diagram that we might draw to convey this proposition is along the following lines:

House House Speaker's house House House

It has an interesting property, which the great nineteenth-century philosopher and logician Charles Sanders Peirce called "iconicity" (see, e.g., Peirce, 1931–1958, Vol. 4, paragraph 433). He meant that the structure of such a diagram is the same as the structure of what it represents, and so the parts of the diagram map onto the parts of the scene, and the relations among the parts of the diagram are the same as the relations among the parts of the scene. Mental models are similarly as iconic as possible. An iconic representation, as Peirce (Vol. 2, para. 279, and Vol. 4, para. 530) pointed out, has the advantage that it can yield a conclusion that was not asserted by any of the premises used in its construction. As a simple example, consider the following premises:

The cup is on the right of the saucer.

The spoon is on the left of the saucer.

An iconic diagram of the possibility compatible with these premises is as follows:

spoon saucer cup

where the left-to-right axis in the diagram corresponds to the left-to-right axis of the scene. The diagram shows that the cup is on the right of the spoon, and this conclusion follows from the premises, but it was not asserted in them. The inferential system must work according to the principle that in such cases the axes have a spatial interpretation. Various ways exist to keep track of this information, but no one knows which way the human system uses. In contrast, the use of formal logic calls for a single noniconic notation for all inferences, additional premises about the logical properties of the spatial terms, and the use of formal rules of inference.

We have difficulty in thinking about more than one possibility at a time. Working memory, which holds models in mind while we cogitate, is limited in its capacity (see, e.g., Baddeley 1986).

Hence, we much prefer to consider just a single possibility at a time, and a sure way to get us to make mistakes is to overload us with alternative possibilities. The word "or" in English is an excellent device for causing us problems, as several experiments have shown (Bauer and Johnson-Laird 1993). The logical meaning of "or" in an assertion, such as:

The broadcast is on network TV or it's on the radio, or both

conveys three different possibilities, and individuals can readily list them, as I have done here in abbreviated form on separate horizontal lines:

network TV
radio
network TV radio

Reasoning becomes very difficult if we have to juggle such possibilities in our minds. Hence, if, in addition, we receive a second premise:

The broadcast isn't on the radio or it's on cable TV, or both.

we have to consider the different possibilities compatible with both the first premise and this new one. That's difficult, and few of us can cope with the task.

One way to carry out the task of multiplying possibilities – a method used in a program that I wrote – is, first, to flesh out the possibilities to make them fully explicit. The two premises are:

1. The broadcast is on network TV or it's on the radio, or both.
2. The broadcast isn't on the radio or it's on cable TV, or both.

These premises are compatible with the following two sets of possibilities respectively:

1. network TV not radio
not network TV radio
network TV radio

and:

2. not radio not cable TV
radio cable TV
not radio cable TV

Two simple procedures multiply the two sets of possibilities in order to yield those that are compatible with both premises. The first procedure is used when one possibility, such as: *not on radio*,

is incompatible with another, such as: *on radio* (see procedure 2 in Table 1). Their conjunction yields the null model, which is a special model, akin to the empty set, that represents impossibilities. The second procedure is that if one possibility is consistent with another, their conjunction combines the information in both of them without redundancy (see procedure 3 in Table 1).

The two procedures can be applied to the two sets of models above. The three possibilities for the first premise have to be multiplied by three possibilities for the second premise, that is, a total of nine conjunctions. The conjunction of the first possibility for the first premise with the first possibility for the second premise:

network TV not radio

and:

not radio not cable TV

is consistent, and yields the following possibility:

network TV not radio not cable TV

The conjunction of the first possibility for the first premise with the second possibility for the second premise is inconsistent – one asserts that the broadcast wasn't on radio and the other asserts that it was – and so the conjunction yields the null model. The nine conjunctions yield the following possibilities, where I have omitted the null models because they represent impossibilities:

network TV	not radio	not cable TV
network TV	not radio	cable TV
not network TV	radio	cable TV
network TV	radio	cable TV

These possibilities support various conclusions, notably:

The broadcast is on network TV or it's on cable TV, or both.

This conclusion holds for all the possibilities compatible with the premises, and so, as logicians say, it is *valid*, that is, it must be true given that the premises are true.

Naïve individuals are most unlikely to make inferences in this way. The method is a good one, but it is too demanding on working memory. One assumption of the model theory is accordingly the principle of *truth*: mental models repre-

sent clauses in the premises, affirmative or negative, only when they are true, and not when they are false (Johnson-Laird and Savary 1999). As an example, consider again the disjunction:

The broadcast isn't on the radio or it's on cable TV.

Its three fully explicit models are shown earlier. But, its mental models depend on the principle of truth, and so each of its two clauses (the broadcast isn't on radio, it's on cable TV) is represented in a possibility only when it is true. Hence, the disjunction has the mental models:

not radio	cable TV
not radio	cable TV

In the model of the first possibility, for example, the second clause of the disjunction is false, and so it isn't represented in the model.

Readers sometimes assume that mental models merely represent whatever clauses occur in assertions, and do not represent what is not explicitly mentioned in assertions. But, if that were so, then assertions containing the two clauses here would have the same mental models regardless of whether the sentential connective interrelating them was "if," "and," or "or." The right way to think of the principle of truth is therefore that mental models represent only those states of affairs that are possible given an assertion, and that within each of these possibilities they represent a clause in the assertion, whether it is affirmative or negative, only if it is true in that possibility. (Table 1 spells out explicitly just how such a system can work.) Individuals may make a mental footnote about what is false in a possibility, and, if they retain it, then they can try to flesh out mental models into fully explicit models. Mental models lighten the load on working memory, because they represent less information. But, as we'll see, they have some unexpected and unfortunate consequences.

Even with mental models, we may not try to multiply out the possibilities. The model theory allows that we can develop a variety of strategies for reasoning, which I describe presently. One strategy is to make a supposition – for the sake of inference, we assume that a particular proposition holds. The previous premises are:

The broadcast is on network TV or it's on the radio, or both.

The broadcast isn't on the radio or it's on cable TV, or both.

Hence, we might think to ourselves: suppose that the broadcast isn't on network TV. We can try to combine a model of this possibility with the first mental model of the first premise, but there's an inconsistency. We can combine it with the second model, which yields the possibility that the broadcast is on the radio. So, if the broadcast isn't on network TV, then it's on the radio. We can combine the model of this possibility with the models of the second premise, and it is compatible with only one of them: the broadcast is on cable TV. It follows that if the broadcast isn't on network TV, then it's on cable TV. A moment's thought should convince you that this claim is equivalent to the disjunctive conclusion, which I proved earlier: The broadcast is on network TV or it's on cable TV.

One problematical connective is the conditional: "if." An assertion such as:

If the broadcast isn't on network TV, then it's on cable TV

is compatible with the possibility:

not network TV cable TV

But, suppose that the broadcast *is* on network TV, what does the conditional assert then? The answer, which is borne out by psychology evidence, is that it allows that the broadcast may, or may not, be on cable TV (see, e.g., Barrouillet, Grosset, and Leças 2000). The conditional is accordingly compatible with three possibilities:

not network TV	cable TV
network TV	not cable TV
network TV	cable TV

These possibilities are the same as those for the disjunction:

The broadcast is on network TV or it's on cable TV, or both.

This fact explains the ability of individuals to paraphrase conditionals as disjunctions and vice versa (Ormerod and Richardson 2003).

When individuals reason from conditionals, they normally rely on mental models, and the theory postulates that the mental models of conditionals represent the initial possibility but use a wholly implicit model (shown as an ellipsis here) to represent the possibilities in which the antecedent clause (the if-clause) is false:

not network TV cable TV.

...

One consequence of these models is that inferences of the sort known as "modus ponens" are easy:

If the broadcast isn't on network TV, then it's on cable TV.

The broadcast isn't on network TV.

Therefore, it's on cable TV.

In contrast, inferences of the sort known as "modus tollens" are difficult:

If the broadcast isn't on network TV, then it's on cable TV.

The broadcast isn't on cable TV.

Therefore, it's on network TV.

To make this inference, reasoners have either to flesh out their mental models into fully explicit models, or to use some other strategy such as the suppositional one.

An inference can fail to be valid in two different ways. One way is for its conclusion to be inconsistent with the premises. Consider this putative inference:

The broadcast is on network TV or it's on the radio, or both.

The broadcast isn't on the radio or it's on cable TV, or both.

Therefore, the broadcast is neither on network TV nor on cable TV.

This conclusion corresponds to the possibility:

not network TV not cable TV

And this possibility is inconsistent with each of the four possibilities compatible with the two premises (shown earlier). Hence, the conclusion, far from following from the premises, contradicts them.

Another way in which an inference can be invalid is if its conclusion fails to follow from the premises, though it is consistent with them. Consider this putative conclusion from the previous premises:

The broadcast is on network TV and it is on cable TV.

This conclusion is compatible with the premises: it corresponds to the second and fourth possibilities listed above. So, how can we discover that it is invalid? If we use formal rules of inference, one method is to show that no proof yields the conclusion from the premises. Such a method

would be exhausting, and would predict that the task of establishing invalidity would be interminable. Reasoning with mental models, in contrast, allows us a much simpler method. We merely find a *counterexample* to the conclusion, where a counterexample is a possibility consistent with the premises but inconsistent with the conclusion (Johnson-Laird and Hasson 2003). Such a counterexample to the previous conclusion is, for example:

network TV not cable TV

So much for the general principles of the model theory. In order to explain a crucial prediction, the next section details the procedures for constructing mental models.

The Procedures for Negation and Conjunction

When individuals draw conclusions from a set of premises, they envisage possibilities compatible with the premises. They can cope with this task for two or three possibilities (García-Madruga, Moreno, Carriedo, Gutiérrez, and Johnson-Laird 2001), but the task gets progressively harder when the number of possibilities increases beyond this point (Bauer and Johnson-Laird 1993). But, what are the procedures for combining possibilities? The answer is that they depend on negation and conjunction.

A problem that is harder than it seems at first is to list the possibilities given the following assertion:

It is not the case that both Pat is here and Viv is here.

The task isn't trivial, because we don't have the answer in memory: we have to work it out. And how do we do that? First, we have to work out what the unnegated proposition means:

Both Pat is here and Viv is here.

It allows just one possibility, which I'll abbreviate as:

Pat Viv

The negative proposition rules out this possibility to leave its complement, that is, all the other possibilities. The first one that we're likely to think of is the mirror image of the possibility above in which neither Pat nor Viv is here:

not Pat not Viv

Some individuals go no further, but others are likely to realize that there are two other possibilities, in which one or other of the two individuals isn't here. Hence, the proposition as a whole is compatible with three possibilities:

not Pat not Viv
 not Pat Viv
 Pat not Viv

In general, the way to interpret a negative proposition is to take the propositions that occur within the negation, and to work out all the possible combinations of them and their negations. One removes from these combinations those that are compatible with the unnegated proposition, and the remaining possibilities are those for the negative proposition. No wonder that people do not cope very well with the task of listing the possibilities compatible with negative assertions (Barres and Johnson-Laird 2003). They tend to be better at negating a disjunction than a conjunction, perhaps because the former yields fewer models than the latter. They often assume that the negation of a complex proposition consists solely of a conjunction of the negations of each of its constituent propositions.

A disjunction of alternative possibilities can be represented as a list of alternative models. To combine two such sets of models according to any logical relation between them calls only for negation, which I've described, and logical conjunction. When individuals interpret a set of premises, their task is to construct a model of an initial clause or premise, and then to update this model from the remaining information in the premises. Table 1 summarizes the procedures for conjoining one model with another, and it illustrates them for the conjunction of the premises:

If Pat is here then Viv is here.

Mo is here or else Pat is here, but not both.

Before you read Table 1, you might like to think for a moment what possibilities are compatible with the two premises. Most people think that there are two: Pat and Viv are here, or else Mo is here.

The procedures in Table 1 apply to both mental models and fully explicit models. In both cases, the core of the interpretative process is the conjunction of one model with another. Although the mental models of the preceding premises yield a valid conclusion (see Table 1), they omit a possibility compatible with the

Table 1: The Procedures for Conjoining Sets of Models Illustrated with an Example

The premises:

If Pat is here then Viv is here.
Mo is here or else Pat is here, but not both.

The first premise has the mental models:

Pat Viv
 . . .

The second premise has the mental models:

Mo
 Pat

The procedures:

Procedure 1 (which applies only to mental models): The conjunction of two mental models, such as *A B*, and *B*, depends on the set of models from which the second model of *B* alone is drawn. If *A* occurs in one of these models, then its absence in the current model is treated as its negation. The conjunction is in effect a contradiction: *A B*, and *not-A B*. If *A* does not occur in the set of models from which *B* is drawn, then its absence does not yield a contradiction. Hence, the four conjunctions from the models yield the following equivalences:

Pat Viv *and* Mo is equivalent to: Pat Viv *and* Mo *not*-Pat
... *and* Pat is equivalent to: *not*-Pat ... *and* Pat
Pat Viv *and* Pat is equivalent to: Pat Viv *and* Pat Viv
... *and* Mo is equivalent to: Mo ... *and* Mo

Procedure 2. The conjunction of a pair of models containing respectively a proposition and its negation yield the *null* model, which represents contradictions:

Pat Viv *and* Mo *not*-Pat *yield nil.*
not-Pat ... *and* Pat *yield nil.*

Procedure 3. The conjunction of a pair of models that do not contain a contradiction yields a model containing all the elements of both models (except that explicit content replaces implicit content):

Pat Viv *and* Pat Viv *yield Pat Viv*
Mo ... *and* Mo *yield Mo*

Procedure 4. The conjunction of a pair of models in which at least one of them is the *null* model yields the *null* model, for example:

Pat Viv *and nil* *yield nil.*

The results:

The conjunction of the two sets of mental models above yields:

Pat Viv
 Mo

These models support the valid conclusion:

Pat and Viv are here, or else Mo is here.

premises. The conjunction of fully explicit models shows that a third possibility is:

not Pat Viv Mo

The same conclusion as the one in Table 1 still follows, but reasoners who rely on mental models will fail to envisage this possibility. They should think that it is impossible for both Viv and Mo to be here. This prediction is typical of the model theory.

Mental models are based on the principle of truth, and, as I mentioned, they yield a crucial prediction, which I illustrate in two contrasting inferences. The first is:

Either Jane is kneeling by the fire and she is looking at the TV or else Mark is standing at the window and he is peering into the garden.

Jane is kneeling by the fire.

Does it follow that she is looking at the TV?

Most people say: "yes." The second inference has the same initial premise, but it is followed instead by the categorical assertion:

Jane is not kneeling by the fire.

and the question is:

Does it follow that Mark is standing by the window?

Again, most individuals say: "yes." Let's see what the theory predicts.

The first premise in both inferences is an exclusive disjunction of two conjunctions. The theory predicts that individuals should rely on mental models, and use the procedures in Table 1. Hence, they should use the meaning of the first conjunction, Jane is kneeling by the fire and she is looking at TV, to build a mental model representing this possibility, which I abbreviate as follows:

Jane: kneeling looking

They should build an analogous model of the second conjunction:

Mark: standing peering

These two models must now be combined according to the exclusive disjunction in the premises. An exclusive disjunction of the form, *either A or else B*, has two mental models, which represent its clauses only in the possibilities in which they are true. Hence, the exclusive disjunction as a whole has the mental models:

Jane: kneeling looking

Mark: standing peering

In the first inference, the categorical premise is:

Jane is kneeling by the fire

According to Table 1, its conjunction with the preceding models of the disjunction yields:

Jane: kneeling looking

And so individuals should respond: yes, Jane is looking at the TV. This analysis may strike you as glaringly obvious.

In fact, the inference is a fallacy. The principle of truth postulates that individuals normally represent what is true in possibilities, but not what is false. When I first wrote a computer program to simulate the theory, and inspected its output, I thought that there was an error in the program. I searched for this "bug" for half a day, before

I discovered that the program was correct, and the error was in my thinking. What the program revealed is that for some inferences a discrepancy occurs between mental models and fully explicit models. The theory accordingly predicts that individuals should reason in a systematically fallacious way for these inferences. In some cases, the fallacies are so compelling that they resemble cognitive illusions, and so my colleagues and I refer to them as "illusory" inferences.

If you succumbed to the illusion, then you are in the company of Clare Walsh and myself. We worked with the inferences above for two days, in designing an experiment on another topic, before we realized that we were making an illusory inference, and that was *after* the discovery of other sorts of illusion. The fully explicit models of the disjunctive premise reveal the correct conclusion. The disjunction has six fully explicit models, because when one conjunction is true, the other conjunction is false, and you will remember that there are three possibilities compatible with the falsity of a conjunction. So, suppose that Mark is standing at the window and peering into the garden, then Jane can be kneeling provided that she isn't looking at the TV. This possibility is a counterexample to the illusory inference.

The second problem had the categorical premise that Jane is not kneeling by the fire, and posed the question of whether it followed that Mark is standing by the window. Most people respond "yes," which is a conclusion supported by the mental models shown above. This inference is valid. Walsh and I carried out an experiment examining a series of illusory inferences and control problems of this sort. The participants were much more likely to respond correctly to the control problems (78% correct) than to the illusory problems (10% correct), and all but one of participants showed this difference (Walsh and Johnson-Laird 2004). Analogous illusions occur in many other domains – from reasoning about probabilities to reasoning about whether a set of assertions is consistent (for a review, see Johnson-Laird 2006). Certain logical systems can be formulated so that they yield the same valid deductions whether they are based on models or on formal rules (Jeffrey 1981). The same principle holds for psychological theories based on mental models or on formal rules (Stenning and Yule 1997). But, because the theories differ in the procedures they use, a way to distinguish between them empirically is, for example, in the systematic errors that they predict. Illusory inferences are accordingly a

crucial test for mental models, because no other current theory including those based on formal rules predicts them.

Semantic and Pragmatic Modulations and Their Effects on Inference

The picture of reasoning that you are likely to have developed from the theory so far is a logical one. We use premises to construct mental models, which are sometimes fleshed out into fully explicit models. If we reason with fully explicit models and make no mistakes, then our reasoning is logical. Unfortunately, our capacity to hold information in working memory is limited, and so we tend to reason with mental models, which represent only what is true, and which can accordingly lead us to make illusory inferences. Nevertheless, it may seem that our method of reasoning is logical, and so you might suppose that the logic and psychology of reasoning are quite similar. In fact, another gap exists between them. What causes this divergence is that when human beings reason, they take their knowledge into account. As a result, they often go beyond the explicit information given to them, and take a step into inductive reasoning (as knowledge is fallible).

Suppose that the following claim is true:

Ed played soccer or he played some game.

If you learn that Ed didn't play soccer, you can infer that at least he played some game. The procedures that I have described yield this inference. Its formal pattern is valid in logic, and at first sight it seems to be valid in life – to the point that when theorists postulate formal rules (see, e.g., Johnson-Laird 1975; Rips 1994), they include a rule of the form:

A or B.

Not A.

Therefore, B.

Consider the premise again:

Ed played soccer or he played some game.

And suppose that you learn:

Ed didn't play any game.

This fact denies the second clause of the premise, and so you should infer:

He played soccer.

This inference also follows from a formal rule for disjunction. Yet, the inference is absurd. No one in her right mind (apart from a logician) would draw it. The reason is obvious. You know that soccer is a game. That's part of the *meaning* of the word "soccer." So, if Ed didn't play any game, he can't have played soccer.

Your knowledge of the meaning of the word, "soccer," blocks the construction of a possibility in the interpretation of the assertion. And so the assertion is compatible with just two possibilities. In one of them, Ed played soccer; and in the other, he played a game. So, either way, he played a game, and the possibility that knowledge blocks is the one in which Ed played soccer but didn't play a game. The second premise asserts that Ed didn't play a game, and so it eliminates both possibilities. The second premise contradicts the first, and individuals tend to infer:

Ed didn't play soccer

This analysis shows that the meaning of a word can modulate the interpretation of a sentential connective.

General knowledge and knowledge of the context can produce yield similar pragmatic modulations. Consider this inference, for example:

If Pat entered the elevator then Viv got out one floor up.

Pat entered on the second floor.

Therefore, Viv got out on the third floor.

You envisage a possibility in which Pat entered the elevator on the second floor, Viv was already in it, the two of them traveled up together to the next floor up, the third floor, and then Viv got out. You infer this sequence of events from your knowledge of how elevators work. In such cases, pragmatic modulation adds information about temporal and spatial relations between the events referred to in a conditional (Johnson-Laird and Byrne 2002).

Another effect of knowledge is to lead individuals to flesh out mental models into fully explicit models. Given the assertion:

Either the roulette wheel comes up red or else Viv is bankrupt

you are likely to envisage two possibilities. In one, the wheel does come up red and Viv isn't bankrupt; in the other, the wheel doesn't come

up red, and as a result Viv loses all her money and goes bankrupt:

Wheel: red Viv: not bankrupt
 not red bankrupt

You are likely to represent both possibilities in a fully explicit way, unlike your interpretation of disjunctions that do not engage your knowledge, such as: “Either there is a triangle or else there is a circle, but not both.” Your knowledge overrides the principle of truth, and you think about both possibilities in full.

Modulation can help or hinder reasoning. These effects have been demonstrated in studies in which the participants make the same form of inference with different contents (e.g., Johnson-Laird and Byrne 2002). Assertions such as: *Pat is in Rio or she is in Norway*, elicit knowledge that one person cannot be in two places at the same time, and so the truth of the first clause implies the falsity of the second clause. In an unpublished experiment carried out in collaboration with Tom Ormerod, participants were accordingly faster and more accurate in drawing conditional conclusions from such disjunctions than from those with neutral contents, such as *Pat is in Rio or Viv is in Norway*. Neutral contents in turn led to faster and to a greater number of valid inferences than contents, such as: *Pat is in Rio or she is in Brazil*, for which, contrary to the disjunctive form of the assertion, the truth of the first clause implies the truth of the second clause.

Experiments with conditionals have also corroborated the same effects on reasoning from conditional premises (Johnson-Laird and Byrne 2002). Conditionals describing spatial inclusions enhanced modus tollens. For example, the premises:

If Bill is in Rio de Janeiro then he is in Brazil.
 Bill is not in Brazil.

readily yielded the conclusion:

Bill is not in Rio de Janeiro

Reasoners knew that Rio de Janeiro is in Brazil, and so if Bill is not in Brazil then he cannot be in Rio. In contrast, spatial exclusions inhibited modus tollens. For example, given the premises:

If Bill is in Brazil then he is not in Rio de Janeiro.
 Bill is in Rio de Janeiro.

reasoners tended to balk at the conclusion:
 Bill is not in Brazil.

They knew that if Bill is in Rio then he must be in Brazil. The participants in the experiment drew twice as many modus tollens inferences from the spatial inclusions than from the spatial exclusions.

Most theories of reasoning allow for pragmatic effects, and the semantic and pragmatic modulation of mental models explains how these effects occur according to the model theory. It may be possible to explain them without recourse to models in, say, a framework based on formal rules of inference. However, as Byrne and I argued, the potential for meaning and knowledge to modulate the interpretation of connectives means that the system for interpreting sentences must always be on the lookout for such effects. It must always examine the meaning and reference of clauses to check whether they and the knowledge that they elicit modulate interpretation. This step must occur even for examples that turn out to receive a logical interpretation. The system for interpreting sentential connectives cannot work in the “truth functional” way that logic works, taking into account only the truth values of clauses (see, e.g., Jeffrey 1981). It must take meaning, reference, and knowledge into account. That is why the process of interpretation is never purely logical. The fact that modulation can add spatial and temporal relations between the events described in a sentence means that sentences of a given form, such as conditionals or disjunctions, have an indefinite number of different interpretations and cannot be interpreted as truth functions – an implication that has eluded some commentators on the model theory (pace Evans, Over, and Handley 2005).

The Development of Strategies for Reasoning

You might suppose that individuals are equipped with a single deterministic strategy for reasoning, which unwinds like clockwork. But, over the years, psychologists have discovered various embarrassments for this view. The order of the premises, for instance, has robust effects on inferences from conditional premises. It is easier to make a modus tollens inference when the categorical premise is presented before the conditional than vice versa – presumably the categorical can immediately block the representation

of the otherwise salient case in which the antecedent is true (Giroto, Mazzocco, and Tasso 1997). Such effects seem inconsistent with a single inferential strategy. Perhaps the principal reason for postulating a single strategy, however, is that studies were often insensitive to strategy. They used no more than two premises; they recorded only the conclusions that the participants drew and perhaps how long it took them to draw them. Such data cannot reveal how the participants reached their conclusions. In contrast, studies with three or four premises, even though the inferences were easy to make, revealed that individuals spontaneously developed a variety of strategies.

Consider, for instance, the following problem from a study of strategies (Van der Henst, Yang, and Johnson-Laird 2002):

There is a red marble in the box if and only if there is a brown marble in the box.

Either there is a brown marble in the box or else there is a gray marble in the box, but not both.

There is a gray marble in the box if and only if there is a black marble in the box.

Does it follow that: If there is not a red marble in the box then there is a black marble in the box?

When most individuals encounter such a problem for the first time, they are nonplussed for a moment. Gradually, however, they work out its solution. The problem is, in fact, so easy that they almost always get it right. Over the course of a few problems of a similar sort, they develop a strategy, and different individuals develop different strategies. An obvious corollary is equally important. Individuals do not come to the psychological laboratory already armed with strategies for these sorts of inferences.

The correct answer to the preceding problem is: yes, if there isn't a red marble in the box then there is a black marble. As you think about the problem, you will see what is meant by a strategy, which my colleagues and I define as follows:

A *strategy* in reasoning is a systematic sequence of elementary steps that an individual follows in making an inference.

When you learn long multiplication, you learn a strategy, but it is a deterministic one. Each juncture leads to just one next step. When you develop a strategy for reasoning, however, it doesn't fix the sequence of steps in such a rigid

way. Each step in a strategy is a *tactic*. The procedures underlying a tactic are seldom, if ever, available to consciousness. You can't introspect on what enables you to combine two premises to draw a conclusion (see Table 1). But, individuals do report the particular tactical steps that they make when they carry out inferences such as the one above.

In the study from which the preceding example was taken (Van der Henst et al. 2002), the premises of each problem were compatible with just two possibilities, and half of them were presented with a valid conclusion and half of them were presented with an invalid conclusion. The participants had to think aloud as they reasoned, and they were allowed to use paper and pencil. A video camera was above them and focused down on the desk at which they sat. The participants occasionally made uninterpretable remarks, and they also made false starts that petered out. But, everyone correctly evaluated every problem, and it was clear what strategies they had used for nearly every problem. Sometimes they changed from one strategy to another in the middle of a problem. Overall in this experiment and subsequent ones, the participants developed five distinct strategies, which I will outline.

1. Integrated diagrams. This strategy relies on the construction of a single diagram that integrates all the information from the premises, very much along the lines of a set of mental models of the premises. With the problem above, a participant read the first premise aloud: "There's a red marble if and only if there's a brown marble," and made an immediate inference, "If brown then red." He then drew a simple diagram of this conclusion, where the arrow presumably denoted the conditional relation:

brown \rightarrow red

He read the second premise aloud, "Brown or else gray," and added an element to his diagram to represent an alternative possibility:

gray

brown \rightarrow red

His performance on earlier problems showed that he represented separate possibilities on separate lines. He read the third premise: "There's a gray marble if and only if there's a black marble," inferred: "If gray then black," and added a new referent to his diagram:

gray \rightarrow black

brown \rightarrow red

The diagram supports the conclusion: if not red then black, which he accepted. He then checked the inference, working through the premises again, and comparing them with his diagram of the two possibilities. His protocol allowed us to identify his strategy and its component tactics. But, he said nothing along the following lines, "my aim is to build a single diagram based on all the premises from which I can check whether the conclusion follows." And, as one would expect, he said nothing about the procedures underlying the tactical steps. Some participants who used this strategy drew a vertical line down the page and wrote down the colors of the marbles in the two possibilities on either side of it. Others, as in the preceding protocol, arranged the possibilities horizontally. One participant merely drew circles around the terms in the premises themselves to pick out one of the two possibilities. A telltale sign of the integrated diagram strategy is that the participants work through the premises in the order in which they are stated, and they include in their diagrams information from premises that are irrelevant to evaluating the conclusion.

2. The step strategy. The participants follow up step by step the consequences of a single possibility. If a problem includes a premise that makes a categorical assertion, then they may follow up its consequences. Otherwise, they make a supposition, that is, an assumption, to start the strategy rolling. Here's an example. The premises were as follows in abbreviation:

A pink if and only if a black.

Either a black or else a gray.

A gray if and only if a blue.

Does it follow that: If not a pink then a blue?

The participant began by reading each premise aloud, and then said: "Assuming we have no pink," which is a supposition corresponding to the "if" clause of the conclusion. The participant repeated: "There is no pink," and crossed out the word "pink" in the first premise. The participant inferred: "So there is no black," thereby drawing the first of a series of conclusions concerning a single possibility. The participant crossed out the word "black" in the first and second premises, and drew another conclusion: "There is gray," circling the word "gray" in the third premise. The participant drew another conclusion: "There is blue." Finally, the participant said, "Yes," to accept the conclusion, adding, "not pink and blue," and reiterated the imprimatur, "yes."

The participants did not always use suppositions correctly. Given, say, a conclusion to evaluate, such as:

If not a red then a black

they sometimes made the supposition:

Suppose there's a black.

and were able to infer that there is not a red. They then responded that the conditional followed from the premises. They may have made the correct response, but they haven't truly shown that the conditional follows from the premises. A conditional allows that the "then" clause can be true even when the "if" clause is false, and so the right way to proceed is to make a supposition of the "if" clause and to show that it leads to the truth of the "then" clause.

One variant of the step strategy was sophisticated. A few participants made a supposition of a *counterexample* to a conclusion, and then used the step strategy to pursue its consequences. For instance, given the problem:

Either a red or else a blue.

Either a blue or else a gray.

A gray if and only if a white.

Does it follow that: A red if and only if a white?

one participant reasoned as follows:

Assuming red and not white. [a counterexample to the conclusion]

Then not gray. [from the supposition and the third premise]

Then not red. [from the previous step and the second and first premises]

No, it is impossible to get from red to not red.

The main diagnostic signs of the step strategy are that reasoners start by stating a supposition or a categorical premise, and then infer a series of simple categorical conclusions, each concerning a single possibility. In cases where an inference yields more than one model, the conclusion often has a modal qualification, for example, "possibly, there isn't a black marble," and any subsequent conclusions are themselves modal in the same way.

3. The compound strategy. Reasoners drew a compound conclusion from a pair of compound premises, where "compound" means that a sentence contains a connective. They sometimes made the inferences from diagrams of the premises. They expressed the conclusion either

verbally or by drawing a new diagram, or both. By combining the conclusion with a new compound, they drew another compound conclusion, and so on, until they finally reached the answer to the question. Here's an example based on the premises:

A white if and only if a blue.

If a blue then a pink.

Either a pink or else a brown.

Does it follow that: a white or a brown?

The participant read aloud all the premises, and then drew a diagram to represent the first premise:

blue \rightarrow white

The participant read the second premise again, wrote it down, and drew a conclusion (which was invalid) from these two premises:

If there's a pink then there's a white

The participant drew a diagram to represent this conclusion:

pink \rightarrow white

From this conclusion and the third premise, the participant inferred:

If there's a brown then there isn't a white

Finally, from this conclusion, the participant inferred the answer to the question:

Either there's a brown or else a white.

In the compound strategy, one premise is used to construct models, and the other premise is used to update them. The combination of two compound premises can put a heavy load on working memory, especially when both premises have multiple models, and so it is not surprising that individuals sometimes draw a modal conclusion about only one possibility.

4. The chain strategy. This strategy was totally unexpected, and no mention of it appears to be in either the psychological or logical literature. The reasoner constructs a chain of conditionals leading from one clause in a conditional conclusion to the other clause. This "chain" strategy resembles the step strategy, but has two crucial differences. First, reasoners do not announce that they are making a supposition. Indeed, they are not making a supposition, because they do not draw any intermediate conclusions. Second, they convert any premise that is not a conditional into

a conditional, either verbally or in a diagram. These conversions include cases where a biconditional, such as:

There's a gray if and only if there's a red

is transformed into a conditional, such as:

If there isn't gray then there isn't a red.

The reasoner's aim is to ensure that the "then" clause in one conditional matches the "if" clause of the next conditional. A participant using this strategy began by drawing a separate diagram for each premise in the problem. The premises were depicted as I have shown in this statement of the problem:

A gray if and only if a red.	$r \leftrightarrow g$
Either a red or else a white.	$r \vee w$
A white if and only if a blue.	$w \leftrightarrow b$

Does it follow that: If not a gray then a blue?

The participant, pointing at each diagram in turn, then said:

If not gray then not red.

If not red then white.

White comes from blue.

Yes.

The final "yes" was to acknowledge that the conclusion followed from the premises. This "chain" strategy is correct provided that reasoners construct a chain leading from the "if" clause of the conclusion to its "then" clause. However, reasoners often worked incorrectly in the opposite direction. It is easier to make inferences from conditionals than from disjunctions, because conditionals have only one explicit mental model whereas disjunctions have at least two explicit mental models. Hence, the model theory predicts that chains of conditionals are much more likely than chains of disjunctions. Indeed, my colleagues and I have never observed anyone who developed a strategy in which the premises are converted into a chain of disjunctions.

5. The concatenation strategy. This strategy occurred only occasionally. The participants concatenated two or more premises in order to form an intermediate conclusion. They usually went on to use some other strategy, but sometimes they formulated their own conclusion by concatenating all the premises, and this conclusion was then used as the premise for an immediate inference yielding the required conclusion.

For example, one participant argued from the premises:

A white and a blue.

A blue if and only if a black.

A black if and only if a red.

to the concatenation:

A white and a blue if and only if a black

and thence to the further concatenation:

A white and a blue if and only if a black if and only if a red.

At this point, the participant made an immediate inference to the required conclusion:

A white and a red.

The strategy accordingly depends on concatenating at least two premises into a single conclusion, and then either drawing such a conclusion, or else evaluating a given conclusion, if necessary by an immediate inference. The telltale sign of the strategy is that the participants join together premises and their connectives to form a single conclusion.

You might suppose the strategy depends on a formal procedure. On the contrary, it depends critically on mental models of possibilities. To see why, consider premises of the form:

A if and only if B.

Either B or else C.

C if and only if D.

where A, B, C, D, refer to the presence of different colored marbles in the box. Five different concatenated conclusions are possible, depending on the placing of the parentheses, for example:

A if and only if (B or else (C if and only if D))

((A if and only if B) or else C) if and only if D.

You might wonder which of them follows validly from the premises. In fact, none of them does. Four participants in one of our experiments used the concatenation strategy with these premises (see Van der Henst et al. 2002), and each of them spontaneously constructed this conclusion:

(A if and only if B) or else (C if and only if D).

It is the only concatenation out of the five possibilities that has the same mental models as those of the premises:

A B
C D

But, the conclusion is invalid, because its fully explicit models do not correspond to the mental models of the premises. Ten participants out of the twenty in this experiment used the concatenation strategy. On 82 percent of occasions, the resulting conclusions were compatible with the mental models of the premises, and nine of the ten participants concatenated more conclusions of this sort than not. Van der Henst and his colleagues accordingly concluded that concatenation depends on mental models.

Depending on the particulars of the experimental procedure, variation occurs in the frequencies with which the participants develop the different strategies. For example, when they have to formulate their own conclusions, they tend not to use the chain strategy. Conversely, the concatenation strategy is more frequent when they do have to formulate their own conclusions. The most frequent strategy in both cases, however, was the integrated diagram strategy. Participants mix strategies, and switch from one to another. Sometimes a switch occurs in the middle of a problem; sometimes from one problem to the next. There are no fixed sequences of steps that anyone invariably followed. Likewise, although the problems are all within the scope of sentential reasoning, the participants quite often went beyond its scope to draw intermediate conclusions about possibilities. Regardless of strategy, as a further experiment showed, problems that yield only one mental model are easier than those that yield two mental models, which in turn are easier than those that yield three mental models (Van der Henst et al. 2002).

The variety of strategies is not unique to reasoning on the basis of sentential connectives. It occurs when individuals reason about the relations between relations (Goodwin and Johnson-Laird 2005a, 2005b), and when they reason with quantifiers such as “all” and “some” (Bucciarelli and Johnson-Laird 1999). It also occurs when they have to refute invalid conclusions based on sentential connectives. Given a conclusion that is consistent with the premises but that does not follow from them of necessity, their most frequent strategy is to try to construct a counterexample (Johnson-Laird and Hasson 2003). With a conclusion that is not even consistent with the premises, the same studies showed that individuals tend to detect the inconsistency, that is, they

grasp that the conclusion is impossible given the premises.

Conclusions

This article has outlined the model theory's account of deductive reasoning. Its main principles are:

1. Reasoning is based on models of possibilities, and each mental model represents what is common to a possibility.
2. As far as possible, a mental model is iconic: its structure represents the structure of the possibility that it represents.
3. Human reasoners tend to think about possibilities one model at a time.
4. Reasoning can proceed by conjoining the possibilities compatible with the different premises, but conjunctions of inconsistent models yield the null model.
5. Mental models are based on the principle of truth: they represent clauses in the premises only when they are true in possibilities. If individuals retain mental footnotes about what is false then they can flesh out mental models into fully explicit models representing both what is true and what is false.
6. Semantic and pragmatic modulation affect the interpretation of connectives so they cannot be treated as strictly truth-functional.
7. Individuals develop different strategies for reasoning, for example, they may use integrated diagrams to represent multiple possibilities, make steps from a single possibility, or think of a possibility that serves as a counterexample to a putative conclusion.

The theory has been applied to most domains of reasoning. They include reasoning with temporal relations (e.g., Schaeken, Johnson-Laird, and d'Ydewalle 1996), spatial relations (e.g., Vandierendonck, Dierckx, and De Vooght 2004), and other relations (e.g., Carreiras and Santamaria 1997). It also has been applied to counterfactual reasoning (Byrne 2005), causal reasoning (Goldvarg and Johnson-Laird 2001), deontic reasoning (Bucciarelli and Johnson-Laird 2005), reasoning from suppositions (Byrne and Handley 1997), and reasoning about probabilities (e.g., Johnson-Laird, Legrenzi, Girotto, Legrenzi, and Caverni 1999). Recently, it has

begun to be extended to inductive reasoning, especially the sorts that occur in problem solving (Lee and Johnson-Laird 2005a), in the revision of beliefs in the face of inconsistency (Johnson-Laird, Legrenzi, Girotto, and Legrenzi 2000), in diagnoses (Goodwin and Johnson-Laird 2005c), and in the reverse engineering of simple systems (Lee and Johnson-Laird 2005b).

The chapter began with the effects of content on the selection task. Their discovery motivated the development of the model theory, and so you may be curious about what the theory has to say about the selection task. It postulates that individuals rely on mental models of abstract claims, such as, "If a card has an 'A' on one side then it has a '2' on the other side." They think of the salient possibility represented in the one explicit mental model:

A 2

and they choose the "A" card, and sometimes the innocuous "2" card, too. To make the correct selections, they need to overrule the principle of truth in order to envisage a *counterexample* to the conditional:

A not 2

and then to choose the corresponding cards: A and 3. Most people fail. Any manipulation that makes counterexamples more salient, including the use of sensible contents or claims about what is permissible, yields an improvement in performance (see Johnson-Laird 2001).

At the heart of the model theory is the assumption that individuals who have had no training in logic are able to make deductions. The theory does not abandon logic entirely (pace, e.g., Toulmin 1958). Mental models relate to the model theory of logic, and to the logical principle that an inference is valid if there are no counterexamples to its conclusion. Individuals accordingly reason by constructing mental models of possibilities. These models are parsimonious in that they represent what is true, not what is false. The advantage is that individuals are able to make inferences that depend on more than one possibility. The disadvantage is that mental models can mislead individuals into thinking that they have grasped possibilities that in fact are beyond them.

Acknowledgments

The theory of mental models has developed as a result of the work of many researchers; see

the Webpage maintained by Ruth Byrne and her colleagues: http://www.tcd.ie/Psychology/Ruth_Byrne/mental_models/.

I am grateful to these researchers for their help over the years. I am also grateful to the editors of this volume for their invitation to contribute this chapter, and for their helpful comments on an initial draft. The research was made possible in part by a grant from the National Science Foundation (Number 0076287) to study strategies in reasoning.

Chapter 11: Interpretation, Representation, and Deductive Reasoning

KEITH STENNING AND MICHIEL VAN LAMBALGEN

A View with no Room

Is the psychology of deduction about the few well-known laboratory tasks in which subjects are presented with logical puzzles and asked to solve them: the selection task, syllogisms, the suppression task, conditional reasoning, . . . ? And if our capacity of deduction is not just for performing these tasks, what is it for? What everyday functions does it serve? How are theoretical analyses of deductive performance in these laboratory tasks related to analyses of other cognitive functions?

From the position of being absolutely central in the cognitive revolution, which was founded on conceptions of reasoning, computation and the analysis of language, the psychology of deduction has gone to being the deadbeat of cognitive psychology, pursued in a ghetto, surrounded by widespread scepticism as to whether human reasoning really happens outside the academy. “Isn’t what we *really* do decision?” we increasingly often hear. Many eminent psychology departments do not teach courses on reasoning. Imagine such a psychology department (or indeed any psychology department) not teaching any courses on perception. Even where they do teach reasoning they are more likely to be focused on analogical reasoning, thought of as a kind of reasoning at the opposite end of some dimension of certainty from deduction.

We believe that the reason for this ghettoisation can be traced to a series of assumptions which we will consider shortly. We will argue that the way out of the ghetto is to drop these assumptions, none of which bears scrutiny anyway. It is then possible to give an account of the relation between the abstracted laboratory tasks and the real life reasoning which was

the original goal. Dropping these assumptions not only reconnects the laboratory to the wild, but also reconnects formal to empirical contributions.

Within the ghetto, the issue with the highest visibility has been about the nature of the mental representations underlying deduction – is it “rules” or is it “models.” There has been almost universal acceptance that the goal of the field is the characterisation of “the fundamental human (deductive) reasoning mechanism,” and that it must work on one or the other of these two kinds of representation. Yet there are good formal reasons for doubting whether these kinds of representations can be discriminated on the basis of data of the kind offered – data simply about input premises and output conclusions. And if this really is the most important issue, why aren’t data about representations sought – data about working memory for “models” or “cases,” for example? The empirical investigations seem ill-fitted to the purported theoretical goal.

Along with confidence that there is a single fundamental human reasoning mechanism, goes confidence that classical logic is the unchallenged arbiter of correct reasoning, although classical logic is often simultaneously rejected as a useful guide to mental representation or process. It is assumed that the classical logical form of the materials used in the experiments lies very near to their surface without any substantial interpretative process. This idea of interpretation as the superficial translation of natural language into logical form, carries over into neglect of the processes whereby artificial logical languages are interpreted – assigned a mapping onto the world. Natural languages do not come with this mapping in anything like the detail

required for discourse interpretation – artificial languages still less so – witness the flourishing industry of trying to explain how it is done.

Even if classical logic were the only logic involved in peoples' reasoning in these tasks (and it clearly isn't), why do we not hear about its interpretative apparatus, but only its proof-theoretical machinery of derivation-rule applications in proof? This field sees itself as studying *representations*. We believe it is chiefly studying the outcomes and processes of *interpretation*. Of course, these are both rich and slippery concepts, which will require some introduction.

Representational systems can be studied at the level of specifying *what* information is represented, and what is abstracted away from – the functional “input-output” level of analysis Marr called the “computational” level. This is the level that logical analysis generally addresses. At this level many of the studies in the field do contribute to the study of representations. But at this level there are simple theorems showing that for the range of materials concerned, these studies cannot discriminate between rules and models treatments. This level is crucial for the foundations of cognitive analyses – get the wrong analysis and all more detailed work is doomed to bark up the wrong tree. But what psychologists generally intend when they make representational claims is not at this level – it is at the level of the *implementation* of systems. In fact, this word is often a useful way of distinguishing this level of representational concern. This level is concerned with how the abstract structures of informational analysis – discourses, sentences, models, proofs – are implemented, both in the world and in the mind. Is there something like a diagram, or like a text implemented in the mind? Or on the paper the subject is using? Here one is concerned with memory, both long-term and working memory, with modalities (visuo-spatial, phonetic, orthographic, . . .), with the environment (as it functions representationally), and eventually with the brain – all the paraphernalia of psychological analysis. Here differences may certainly be expected between how the information specified in sentences and the information specified in models gets implemented. But remarkably little study has been aimed at this level until very recently, and much of what has been aimed at it has been based on dubious informational-level analyses.

Interpretation also gets used at several levels. The interpretation of a representational system is an abstract analysis of a mapping from abstract representations (a language, a diagrammatic sys-

tem, . . .) to things in the world – shoes, ships, sealing wax.¹

From a logical perspective, the most active and interesting part of this mapping is not the very general concerns about how natural language lexical items such as “shoe” map on to shoes past, present, and future, but the much more local issues about just exactly which shoes are “in play” in the current fragment of discourse – perhaps just the ones in the hall cupboard, or the ones Shoe Co. plans to make in the United Kingdom next year. At this level an interpretation of a language is a purely informational structure. But, of course, just like representations, interpretations also have more concrete implementations. Especially when we pay this very local attention to how interpretations become constructed during discourses, interpretation is also a process. Processes of interpretation may be thought of at the abstract informational level at which one characterises *what* choices of mapping are possible and what choices are actually made, or at the concrete implementational level where one gives cognitive accounts of particular mental processes that implement these choices.

This might all seem very academic and irrelevant to psychological analysis, but it is exactly such processes which we believe are the dominant processes observed in the experiments in the psychology of deductive reasoning. These processes come very near to the surface when we engage subjects in “socratic dialogues” about their reasoning in these tasks (for extended quoted examples, see Stenning and van Lambalgen [2004]). Interpretations, even at this abstract informational level, also become much more obviously “psychological” when logical analysis shows that interpretations have to include the *goals* of reasoning as well as the propositions involved. Earlier, we used the contrast between interpretation and reasoning to complain that interpretation had been rather neglected in this field, but this terminology can be confusing. Taken as a process, interpretation involves a kind of reasoning, and at least some examples of that kind of reasoning can be given an abstract informational analysis in terms of logics. These are the logics that we will chiefly be concerned with here. Defeasible reasoning *to* interpretations can be given models based on nonmonotonic logics.

Bringing interpretation center-stage, and modeling particular examples in logical (informational) systems, invites the accusation of regress. The new nonmonotonic logic is a

language (a representational system) and so it has a semantics – a mapping of sentences onto worlds – and can be given proof theoretical apparatus such as inference rules. Reasoning to an interpretation of the original object-language being interpreted, will have to be implemented in the mind somehow, but there will now have to be a process of interpretation of this new nonmonotonic logic – and so on. We believe that this regress in fact grounds out – it is a virtuous regress – and that one of the great insights offered is that the nonmonotonic logic is a crucial part of an implementational account of how languages are grounded and given content. This must remain a promissary note, though we believe the neural implementation of a particular nonmonotonic logic in Section 3.2.1 goes some way to suggesting how this grounding might go.

Perhaps it is possible to forestall at least one misunderstanding about this regress. The implementation of reasoning about what interpretation to adopt for a discourse, does not itself have to be a cogitative process. All the psychological indications are that subjects who have not studied logic to some depth have very little access to the interpretative decisions they make, and that they are often triggered by superficial analyses of problems based on habits of understanding developed over very extensive practise with our mother tongue. In Subsection 4.1, we suggest that these implemented logics of interpretation may correspond to an important part of “System 1” processes as invoked by Evans (2003). Neither the fact there is a logic of interpretation, nor the assumption that it is really implemented in our minds, need necessarily lead to a regress of cogitation. This warning we hope at least makes it clear that we take the process of interpretation very seriously, both at an informational level (reasoning *to* as opposed to reasoning *from*) and at a concrete implementational level (as a real-time process in the mind).

In summary, interpretation sometimes contrasts with reasoning and sometimes with representation. Interpretation and representation are both susceptible to informational-level and implementational-level analyses. Our complaint about the field of the psychology of reasoning can be summarised by saying that it has pretty much ignored interpretation (save for some small details within classical logic), and that it has confused informational and implementational issues about representation.

Rehearsing these relations between interpretation, reasoning and representation should not

lead us to forget that there are those with much more radical rejections of this entire machinery. Recently, there have been rejections of the appropriateness of logical deductive models of reasoning in favour of inductive information gain models, which turn reasoning into decision. But even those who have departed from accepting classical logic as the relevant competence model (Oaksford and Chater 1994), have continued to accept that it makes sense to treat all subjects as “trying to do the same thing” and so the goal might be described as changing to that of characterising the “fundamental human information gain mechanism.” But as Stenning and van Lambalgen (2005) argue even this apparently radical move to a completely different competence model, still smuggles classical logic in at the back door.

The dissatisfactions of the ghetto have led even some prominent community members to depart entirely, claiming that once the ecological context of real life is considered seriously, what we find are decision processes, not reasoning processes, and that fast and frugal heuristics without any reference to competence models can replace logic, probability and all other cumbersome systems of reasoning. Reasoning is the idle pastime of the academy, but not the bread-and-butter of the real world.

We believe that the route out of this ghetto lies in taking interpretation seriously. In fact we believe that the mental processes mainly evoked by the laboratory tasks mentioned are interpretative processes – the processes of reasoning *to* interpretations. Modern logic provides a rich landscape of possibilities and we believe the empirical evidence is that subjects are engaged in setting a series of parameters in this space in order to formalise their understanding of what it is they are being asked to do. The evidence is that in these abstracted and unnatural settings student subjects are error-prone – so rich interpretation does not mean infallible reasoning. However, recasting the phenomena as interpretative provides a bridge between the laboratory and the wild. Laboratory tasks force interpretation in a vacuum, and the scattering that results can tell us much about what happens at more normal pressures. Furthermore, the wild, at least in “developed” societies with extended formal schooling, is full of tasks that are abstracted in ways rather closely related to the laboratory tasks, which were, after all, originally collected or adapted from various teaching sources. The nature of this bridge is then a good guide to the tasks in the wild, which most bring reasoning into play.

An immediate corollary of the formal stance of taking the multiplicity of interpretations seriously is the empirical consequence of needing to take individual differences seriously. Subjects do different things in the experiments, and this has so far been treated as simply stringing them out along a dimension of intelligence. They are all deemed to be trying to do the same thing, but succeeding or failing in different degrees. If there are many interpretations and each poses a qualitatively different task, then subjects are not even trying to do the same thing (at least at any finer grain than “understand what the hell they are being asked to do”), and suddenly the data and the theoretical demands become far richer. And most important of all, the working relation between formalisation and experiment changes entirely. Taking interpretation seriously and separating semantic from representational issues offers a room with a view quite panoramic enough to serve as foundations for human cognition.

The plan of the paper is as follows. We begin by illustrating the improvements in empirical understanding which can be purchased in the analysis of the laboratory tasks by taking them as being dominantly about reasoning *to* interpretations. We then present a sketch of the reconceptualisation of logical form which is involved in taking interpretation seriously – that is, of the landscape of many logical systems related by different kinds of parameter settings that characterise discourses’ syntactic and semantic properties and their concepts of validity (or reasoning goals). This sets the scene for recasting the debate about the nature of the representations underlying reasoning. We will argue that the rules/models debate is conceptually ill-posed, and this has led to a mismatch between theoretical presentation and empirical investigation, and to the failures of empirical analysis illustrated in Section 2.1.

The following section introduces closed world reasoning, a variety of nonmonotonic logic. These logics can, for example, be used to analyze the suppression task and to show how the reasoning to an interpretation can be implemented in neural networks. The implementability is crucially dependent on the defeasibility of the semantics. Choosing these logics over classical logic as a basis for cognitive modeling hugely narrows the gap between formal competence model and psychological process account. So nonmonotonic logics offer a variety of precise and general accounts of interpretation. Although we will not expand on this

issue here, these logics provide another illustration of how existing psychological data mainly fails to bear on issues of representation. Stenning and van Lambalgen (2006) describe how nonmonotonic systems show the same representational indeterminacy between rules and models accounts. Just as with the classical cases considered in the rules/models debate, it is possible to conceive of these nonmonotonic systems as being represented and processed in several different modes. So by giving a nonmonotonic logical account of the interpretation of materials in these reasoning tasks we are *not* taking the “mental logic” side of the debate, nor the other. Specifying the logic does not settle how it is to be represented, and even when we give a particular neural implementation in Section 3.2.1 all that it shows is how implementations of sentences work together with implementations of models in computing consequence of discourses. To resolve representational issues one has to study how representations are implemented. The psychological study of these representations has hardly begun.

The paper ends with consideration of the resulting reconnection of the study of interpretation and reasoning to other cognitive fields. Where might reasoning to and from interpretations be most evident in the wild? What can logical and psychological theories of interpretation and reasoning contribute to these fields? What can it gain from them? And how are formal and empirical researchers to work together to study them?

2. Taking Interpretation Seriously

2.1. *Empirical Illustrations*

2.1.1. SELECTION TASK

Wason’s 1968 selection task presents subjects with a rule. They have to select cases (cards) in order to make judgements, either about the cases’ compliance or about the truth of the rule itself. This task provides a fascinating study of the problem of interpreting material into one of several logics, and the problems encountered in doing this in a context which obscures or removes the normal cues on which this choice of interpretation depends. Versions of the task compare the rules “If a card has a vowel on one side, it has an even number on the other” (the so-called abstract task) with “If a drinker’s drink is alcoholic, then they must be over 18 years of age” (the so-called thematic task). The content of the latter rule is sufficient to cue subjects from the

populations tested to adopt a deontic interpretation. The semantic consequence of this interpretation is that the task cannot be to test the truth of the rule since deontic rules don't have truth values. Indeed, the instructions in this latter task are to test the compliance of drinkers, given their drinks and ages. Such an interpretation leads to very simple reasoning in the selection task because this semantic relation between rule and case (unlike truth) is one-to-one. There are therefore no contingencies between choices of cards (whether one drinker violates the rule has no bearing on whether any other drinker does). Stenning and van Lambalgen (2004) use these semantic observations to make predictions about problems which will show up in the content of socratic dialogues about the task. The abstract task of judging truth of a descriptive rule is essentially in conflict with most subjects' initial interpretations of the rule. Stenning and van Lambalgen (2004) use their semantic observations to design several novel versions of the task and make and test predictions about them.

The interpretation of the abstract task is far more complex, even though the task is, of course, as concrete as it is possible to be. The root of the problem is that subjects' habitual interpretation of descriptive natural language conditionals, especially ones described as "rules," is as law-like conditionals robust to exceptions. Armed with this interpretation, subjects face an immediate impasse – they have no basis for telling exceptions (which still allow the rule to be true) from counterexamples (which reveal its falsehood). Notoriously, no test of a finite sample of cases will establish truth of such conditionals. It is true that Wason's instructions are that the conditional applies to only these four cards, but this merely conflicts with subjects' notions of what a rule is. One might object that if robust interpretation is subjects' problem, then they should object to the experimenter that the task is impossible. We would not expect this kind of response on the grounds of subjects' tendency to compliance (and, it must be said, lack of opportunity), and because they are neither conceptually well aware of the structure of their interpretations, nor in possession of a vocabulary for expressing their problems. The 'conjunctive rule' condition of Stenning and van Lambalgen (2004) provides vivid illustration of the tendency to comply by choosing some cards, even when the rule is blatantly false on the evidence before turning any cards.

Besides the problem of robustness to exceptions, once the task is about the truth of rules,

rather than the compliance of single cases, this creates extra difficulties. The semantic relation is not one-to-one any more – several cases may need to be examined, and a judgement is only possible on the basis of the configuration of results (as Wason argues). So, in general, *sets* of cards are required to test truth, and this raises the problem of contingency of choice. If I choose this card and find it does not fit the rule, then that may affect whether I need to turn other cards. The vernacular relation of truth is, unlike the deontic relation which can be assessed a case-at-a-time, better seen as a whole family of relations: a card complying with a descriptive rule is a very different relation from the relation of a card making a rule true, and this ambiguity is predicted, and observed, to cause problems both in dialogues and in experiments.

For example, a two-rule version of the task was designed. This task presented two conditionals, one of which subjects are instructed is true and the other false, and their task is to choose cards to decide which rule is which. The rules were of the form: (1) if P then Q, and (2) If not P then Q. Here turning the false-consequent card alone is sufficient to guarantee a resolution. However, in socratic dialogues in this task, several subjects turned the true consequent card (Q), which turned out to comply with both rules, and then complained that this *showed that both rules are true* and the experiment was therefore flawed. Here is a confusion between the card complying with a rule, and a card showing that the rule is true. Our interpretation of the dialogues is supported by the fact that this impasse often precipitated insight into the contrast between these two meanings of "true," and into the task in general.

How does this approach explain the patterns of card choice in the task? Our most general claim is that none of the combinations of cards chosen is sufficient to fix the subjects' reasons for choice. In particular, the modal P, Q choice can be arrived at for several reasons, and only dialogue evidence is rich enough to start to isolate specific reasons. Table 3 in Stenning and van Lambalgen (2008) attempts to give some impression of the complexities involved.

This semantic analysis integrates accounts of a wide range of observations from the large number of versions of this task which have been run over the last thirty-five years. Many of the observed phenomena were known in the literature (many to Wason himself in the earliest days of his experiment) but remained unconnected. For example, Wason (1987) himself observed

that subjects struggled with the contingencies of response involved in having to make all one's choices without any feedback. Wason and Green (1984) showed that a "reduced array" version of the task in which only the true-consequent and false-consequent cards were offered induced subjects to choose the false consequent over the true consequent they typically chose in the full array task. Of course, this reduction of array eliminates the contingency problem arising from this descriptive interpretation. Wason and Johnson-Laird's (1970) own investigations revealed subjects who realised that a 7 card with an A on the back *would* fail to fit the rule, but still refused to choose to turn it, as one might expect if the subjects problem is that nonfitting cases could be exceptions or counterexamples and it is not possible to tell which. Gigerenzer and Hug (1992) showed that when a rule which would standardly be interpreted as deontic was combined with task instructions to test whether it or an alternative were "in force" (i.e., to test the truth of a *description* of the rule in force), the task reverted to performance similar to that in descriptive tasks. Although others (Manktelow and Over 1990; Oaksford and Chater 1994; Fodor 2000) had pointed out that the drinking age task was deontic, and Cheng and Holyoak (1985) had proposed what was essentially an informal fragment of deontic logic in their account of "pragmatic reasoning schemas," no one had previously drawn out the semantic consequences of this interpretation in the context of a case selection task.

As mentioned earlier, the semantically based account makes new predictions such as those tested in the new two-rule task. This task is of considerably greater complexity than the single rule versions but it backgrounds the problem of robust interpretation. This deflection of the problems of robustness produced six times as many classically correct solutions as the corresponding single rule task, despite its added complexity, and even though subjects had to suppress the temptation to turn the ever attractive true consequent, and turn only the false-consequent card. A second prediction of problems induced by the contingency between the feedback from turn and the necessity for further turns was tested by simple instructions to "make your choices before any feedback." This quadrupled the classically correct responding in the single rule task by eliminating the contingency problems. Even more basically, the semantic analysis predicted that many of subjects' problems should not be limited to conditional

rules but should apply equally well to conjunctive ones, and indeed it was shown that a conjunctive rule "The cards have vowels on one side and even numbers on the other" produces almost exactly the same performance as the conditional rule. One factor which arises here from novel conflicts with the instructions (classically correct choice is to refuse to turn any cards) is the possibility of interpreting the conjunctive rule deontically. But it had also been known at least since Fillenbaum (1978) that conjunctive interpretations of natural language conditionals are common.

Revisiting the old experiments which were supposed to have revealed content effects on identical logical forms reveals that these effects are mediated through contents' influence on the choice of deontic vs. descriptive interpretations. For example, Johnson-Laird et al. (1972) showed that a rule based on a U.K. postal regulation familiar to their subjects facilitated classical performance, but the same materials failed to influence U.S. subjects unfamiliar with the regulation (Griggs and Cox 1982). This was interpreted as a familiarity effect. Reexamination of the materials shows that the rule was stated indicatively: "If a letter has a second class stamp, it is left unsealed." So U.K. subjects familiar with the rule interpret it deontically; U.S. subjects with no cue that the rule is a deontic regulation suffer all the problems just listed with the interpretation of descriptive conditionals.

The two rules: "If a card has a vowel on one side, it has an even number on the other" and "If a drinker's drink is alcoholic, then they must be over 18 years of age," as interpreted in the experimental settings, are of quite different logical forms and the subjects' judgments can be largely predicted by which logical form is adopted. A single generalization captures almost all the variance in the very large number of experiments in the literature: if interpretation is deontic, the task will yield Wason's "competence response"; if the task is interpreted descriptively, it will yield the scattering of interpretations outlined earlier and the card choices Wason originally observed. This generalization was missed by all the theoretical accounts: mental models, matching theory, evolutionary psychology, relevance theory, and information gain. The phenomena observed are driven by interpretational processes. None of the theories took the phenomena to be primarily interpretative phenomena. All assume classical logic as providing the only possible interpretation and seek to explain what are, on this interpretation, baffling observations.

2.1.2. SUPPRESSION TASK

Byrne's 1989 task develops syllogism about content and form, inherited from the study of the selection task, into an argument about mental representations – rules versus models. When subjects are presented with the modus ponens premises "If she has an essay she studies late in the library. She has an essay," they almost universally draw the conclusion that she studies late. When instead they are presented with the same premises *plus* the premise: "If the library is open she studies late in the library," about half of them withdraw the inference. Analogously, many subjects presented with "If she has an essay to write, she studies late in the library. She doesn't have an essay to write" draw the (classically invalid) conclusion "She doesn't study late in the library." When instead they are presented with these premises plus "If she has a textbook to read, she studies late in the library," then again many who did draw the inference withdraw it. Byrne concludes that inference rules cannot be used to explain the initial performances since they evidently cannot explain the subsequent withdrawal of inferences. Rules, if they are to be invoked, must be invoked universally and uniformly. So much the worse for mental logics – so mental models are the underlying representations, concludes Byrne.

While the selection task is, we have argued, a disguised interpretation task, here the task is much more obviously interpretative. Subjects are presented with mini-discourses, and a large proportion of them experience enough tension in the materials to make some accommodation, which is evidenced in their withdrawal of inferences, as they seek to find the intended model, using whatever knowledge or guesswork comes to hand. Once one enters into dialogue with subjects engaged in this task, it is even more evident that tensions are experienced even when inferences are not withdrawn. Stenning and van Lambalgen (2005) show that in the nonmonotonic logic appropriate to this interpretative process, on at least one plausible interpretation, modus ponens does not apply to the triple-premise discourses. This then explains the withdrawal of the inferences by substantial numbers of subjects. The experiment does not bear on a choice between rules and models. Funnily enough, this nonmonotonic logic is in fact the logic one requires to capture the subjects' likely initial interpretation of the lawlike robust conditional rules in the selection task. We will see more of this logic later when we discuss discourse semantics and representational issues.

In taking her experiment to be about representation by models or rules, Byrne misses several important issues: First, the difference between reasoning *to* an interpretation and reasoning *from* an interpretation. Classical logic, which she assumes is the only relevant logic, is clearly only relevant to reasoning from interpretations. One possibility is that mental models theory is being extended to encompass a theory of this defeasible interpretational process. But mental models theory was developed as a theory of classical reasoning *from* interpretations (in the syllogism). If it is now to be taken to be a model of defeasible reasoning it had better be compared to logics of defeasible reasoning, not classical logic. And if it is being extended, then we need to be told when it is doing the one thing and when the other. Unfortunately what we find is simultaneous claims for both within the compass of the same paper:

According to the model theory of deduction, people make inferences according to the semantic principle that a conclusion is valid if there are no counterexamples to it. (Byrne et al. 1999: 350)²

The explanation attempts to stay with a classical concept of validity and, in a roundabout way, to retain classical logic's interpretation of the conditional as material implication as the "basic" meaning of conditionals. It therefore comes as something of a surprise to see that the penultimate section of Byrne et al. (1999) is entitled "*Suppression and the nonmonotonicity or defeasibility of inferences*," where it is claimed that "the model theory attempts to provide an account of one sort of nonmonotonic reasoning, undoing default assumptions..." (Byrne et al. 1999: 370; see Stenning and van Lambalgen 2005: 930 for fuller analysis of this equivocation).

But perhaps more seriously still for a psychological theory, Byrne's account of the suppression task ignores most of the data. What, for example, are the other half of the subjects doing who don't "suppress" the modus ponens inference after the second conditional is presented? A moment's thought suggests that there are several interpretations of the materials which are quite consistent with continuing to draw the inference. For example, the "suppression" interpretation interprets the second conditional as a kind of "repair" on the part of the speaker – a weakening of the originally strong claim, perhaps after remembering, say, that it's a bank holiday. There is an equally good interpretation which

treats the speaker as *strengthening* the original claim – “In fact she’s such a diligent student, she’ll be in the library whether she has an essay or not.” Lechler (2004) conducts an exploration of the range of interpretations that subjects do in fact develop, and indeed this strengthening class is common. Yet another possibility is a presuppositional interpretation (i.e., presupposing that the library is open) which is clear evidence that non-suppression is consistent with a nonmonotonic nonclassical reading. Later we present a formal analysis which relates some of these different interpretations.

Individual differences as diagnosed by interpretation have received some attention in the psychological literature. For example, Stanovich (1999) presents evidence that the 5 percent of student subjects in the selection task who choose the cards Wason claims are “correct,” show significantly higher SAT scores than the rest of the subjects. Our theory proposes many possible interpretations in both the selection and suppression tasks, and so if one assumed these are all equally good fits to the information the subject is presented with, Stanovich’s results would be hard to explain. We do not make this assumption. The small minority of students getting Wason’s answer are clearly more adept at finding the interpretation intended amongst all the conflicting information Wason supplied. Because this task of understanding the strange instructions of professors is very close to many of the problems set in school, we would expect correlation with SAT scores. Stenning (2002) presents evidence that one mechanism by which real logic courses can improve general reasoning skills is through increasing flexibility of interpretation.

If mental models theory is really about the process of interpretation, why so little empirical curiosity about the range of interpretations people actually adopt? Empirical curiosity is the victim of the focus on the representational issue of models versus rules which the data cannot decide. Because there is obviously interpretative variety, the data of individual differences should become primary. It is not that all subjects are trying to do the same thing, and merely succeeding or failing to different degrees. If subjects have different interpretations, then we need to be able to characterise them. We might want a principled theory of why some interpretations are more sustainable than others, but we can’t get such a theory until we acknowledge interpretational variety. Muddling together the pro-

cesses of reasoning to and reasoning from interpretations has the consequence of obscuring the needed empirical insights.

2.1.3. IMMEDIATE INFERENCE AND THE SYLLOGISM

The syllogism, for the logic teacher, and perhaps for the psychological experimenter, is a fragment of classical monadic predicate logic, usually with some existence assumptions thrown in. This interpretation does not extend to the majority of experimental subjects. Newstead (1989–1995) was among the first to systematically study subjects’ interpretations of syllogistic quantifiers using what he called the “immediate inference” task. His goal was to reconcile interpretation with reasoning, which was known to be extremely prone to error by the standards of classical interpretation.

In the immediate inference task, subjects were asked to assume that, say, “All A are B” and then asked whether it followed that, say, “All B are A” must be true, false, or could be either.³ This pattern of presenting a single premise and asking about a targeted conclusion was then repeated for all combinations of quantifiers and subject/predicate inversions. Newstead showed that a healthy majority of subjects did not even approximate a classical logical interpretation of the quantifiers, many drawing patterns of Gricean implicature feature such as, for example, concluding “Some A are not B” from the assumption that “Some A are B” (Grice 1975). Many other nonclassical patterns of inference appear in his data and were known from earlier data, notably “illicit conversion” (responding “true” to the example with “all” above). In this literature, illicit conversion is simply defined as a syntactic pattern observed in the data, and no semantic rationale for this behaviour is supplied.

Despite extended analysis, Newstead failed to find any systematic relation between subjects’ patterns of interpretation in this task, and their subsequent syllogistic reasoning – drawing conclusions from pairs of the same premises. Roberts et al. (2001) extended this approach and claimed to rule out Gricean models of interpretation in syllogistic reasoning. Their best fitting models involved “illicit conversion.”

But taking a broader perspective, “illicit conversion” and Gricean implicature are closely related patterns of credulous reasoning. Illicit conversion is what is called in AI “closed-world reasoning.” For example, given only the information that “if it’s an A then it’s a B,”

closed-world reasoning on this single rule permits the conclusion that the only way something can get to be a B is if it is an A – the illicit conversion pattern. This inference is closely related to Grice's Maxim of Quantity which generates the implicatures illustrated earlier. The Maxim enjoins speakers to "say enough and not too much." Closed-world reasoning results from the assumption that the specification of the world we have been given is all that we are reasoning about. One might observe that relations between the Gricean account and closed world reasoning are already complicated. One might argue that the speaker's decision to say "All As are Bs" instead of "As and Bs are the same" enough to generate the implicature that not all Bs are As? However, if this were so it is too strong, and indeed Grice's theory has much room for wriggle. "As and Bs are the same" has interpretations which such a speaker might not want to suggest, and there is also the issue of economy of expression. Grice's theory is notoriously hard to turn into a processing model and was not intended as such. The important point here is that Grice's theory and closed-world-reasoning are overlapping accounts of credulous interpretation, and this connection has either not been made or explicitly denied in this literature.

So we can define a more general approach to discourse interpretation as *credulous* discourse processing. A hearer attempts to construct the speaker's "intended model" of the discourse, using whatever general and contextual knowledge can be brought to bear and assuming that the speaker is cooperative (the suppression task discourses quoted above are good examples). Credulous processing goes "beyond the information given" in that, for example, it draws implicatures based on surmises about the speaker's intentions, and retrieves relevant general knowledge from databases of conditionals in long-term memory (Stenning and van Lambalgen (2005).

Once a broader view of the semantic/pragmatic theories is adopted, the data takes on a different cast. Stenning and Cox (2006) show that Newstead's operationalisation of Gricean implicature is too narrow. It operationalises Gricean implicature in terms of a couple of implicatures and neglects the reasons why these implicatures might sometimes be suppressed. It also misses the close affinity to illicit conversion, seeing conversion as an unrelated arbitrary pattern of reasoning. Finally, Roberts *et al.* misin-

terpret Grice's pragmatics as licensing fixed patterns of reasoning regardless of the pragmatic circumstance. The latter point can be illustrated with an example.

Roberts *et al.*'s (p. 174) considers the syllogism *All B are A. Some C are B*, and observes that with Gricean interpretations it may either get encoded with set A identical to set C, or with the two sets partially overlapping. They then argue that "with the outcome sets made explicit, a problem for anyone adopting these interpretations becomes apparent. Gricean interpretations affect not only the *encoding* of a problem, but also its *decoding* of the final outcomes so that conclusions can be generated... The [Gricean] assumption of the mutual exclusivity of *some* and *all* during encoding will result in a contradiction on decoding."

But this argument supposes that the hearer treats the "output models" of the interpretation process like models of classical logical conclusions, true in all models of the premises, and that now, from the point of view all speaker concluding from this construction. *Some A are B* is inconsistent with *All A are B* – not merely that it would be misleadingly uninformative to say the former when the latter is true in the intended model. In Grice's theory, the aim of processing determines the semantics of the representations and in giving a competence model, one should not forget this and return to a classical interpretation in midstream. The credulous process which Grice described is defeasible and therefore non-monotonic. Inferences that might be made at the end of premise one may not be made after premise two. The construal of the task and the interpretation mechanism are perfectly homogeneous across tasks, though they have the effect that implicatures arising at one point may get canceled at another.

These theoretical insights suggest empirical questions. By adopting a more exploratory approach to immediate inference data, Stenning and Cox show that there are broad patterns interpretable along two dimensions – whether the subject's interpretation is credulous or sceptical (classical), and whether subject/predicate conversion is involved in the inference. Conversion, it turns out, is not merely of interest when it is "illicit." A hitherto unnoticed subgroup of subjects refuse to draw subject/predicate inverted conclusions, even when they are classically valid (e.g., given "Some A are B" they refuse to infer that "Some B are A"). Interestingly, the subgroup who show this pattern are disjoint

from the subgroup who illicitly convert the “all” example.

Superficially, this observation that drawing implicatures is at least somewhat independent from drawing illicit conversions is at odds with the observation that both are credulous patterns of reasoning. If a subject is credulous in one pattern, why not the other? Well, they may both be credulous patterns but there are psychologically important differences. The relevant kind of closed-world reasoning is a kind of “backward” reasoning from result to initial conditions. From the truth of a consequent, and the absence of other conditionals with that consequent, an inference is made to the truth of its antecedent. Gricean quantifier implicatures of the kind illustrated here are forward reasoning guided by the grammatical organisation of the discourse. As we shall now see, the empirical evidence is that these two aspects of credulous reasoning are differentially adopted by different subjects and in different tasks. Here we will not dwell on the subclassification of credulous reasoning but rather note the empirical evidence is that further logical work remains to be done to understand why this should be.

And at a surface level, subject/predicate inversion in the simple existentially quantified sentences such as “Some A are B” operates as a form of information packaging – structural variation which leaves truth conditions unchanged. Information packaging is a vital part of credulous discourse processing, guiding the hearer’s focus of attention toward identification of the “intended” model. Much of the difficulties students have learning elementary classical logic is with learning to put aside thesis focusing of credulous discourse. So, although “Some A are B” is true just whenever “Some B are A,” the conditions under which a cooperative speaker would choose to utter the one are different from the conditions that would lead to the other choice.

Stenning and Cox (2006), armed with their two-dimensional analysis of immediate inference data, show that it is then possible to predict aspects of several subgroups of subjects’ reasoning in the syllogistic task. Indeed, so large are the differences between these subgroups’ performances that it is possible to find subgroups of syllogisms for which subgroups of subjects defy most of the powerful generalisations in the literature derived from analysing group data without regard to individual differences. The search of the ‘fundamental human reasoning mechanism’ has produced models that may not fit any of the subjects’ actual mental processes.

Stenning and Cox (2006) incorporate their newly characterised individual difference dimensions into Stenning and Yule’s 1997 “source-premise identification model” of conclusion term order through the different heuristics which subjects employ to identify the source-premises on which they construct their discourse representations. The model reveals several novel phenomena in this much studied domain. For example, the subgroup of subjects who refuse the “some” inference quoted above are saved from making many classically illegitimate inferences by the information packaging of the premises. In contrast, there is a subgroup of subjects who not only draw the “forward” Gricean implicatures from “Some A are B” to “Some A are not B,” but are equally happy to draw the inverted implicature “Some B are not A.” Stenning and Yule’s 1997 original development of the source-founding model had already disposed of mental model theory’s claims to be able to predict conclusion term-order in syllogistic reasoning on the basis of the FIFO (first-in-first-out) properties of working memory. They showed that far from having to arrange the three terms with the middle-term (B) in between A and C so that it could be “canceled,” in fact subjects’ commonest arrangement of terms in their working memory is with B initial (see Cooper 2002: 170 ff. for computational modeling of the source-founding model). Besides the observations, it is odd that a model-based theory should plump for such a syntactically dependent “cancellation” mechanism.

The search for the fundamental human reasoning mechanism through these three tasks – selection, suppression, and syllogism – has employed narrow hypothesis testing methodology rather than an exploratory convergent-evidence approach. It has ignored the support available from modern logical, semantic and pragmatic methods, and instead targeted its criticism of logic on inappropriate classical logic which it has still not eradicated from its normative pronouncements. Rejecting logic has led only to attempts to reinvent it and produced some strange hard-to-interpret systems. Wanting to focus on grand representational issues has led to missing the most important empirical generalisations which are about the semantics of alternative interpretations. Later we will show that mistaking representation for interpretation has also mangled the study of representations. With this much empirical motivation, in the next section we turn to a sketch of the concept of logic which has

lain not far submerged beneath these empirical analyses.

2.2. Formal Consequences of an Interpretative Stance

2.2.1. THE MANY LANGUAGES OF THOUGHT

In the psychology of reasoning literature one commonly finds a picture of reasoning as proceeding according to preestablished logical laws, which can be applied by anybody in any circumstances whatsoever.

It would not do to blame the psychologists alone for this, because it is a picture frequently promulgated in the philosophical literature. To take just one example, we see Ryle (*Dilemmas*, 1954) characterising logical constants (for example *all*, *some*, *not*, *and*, *or*, *if*) as being indifferent to subject matter, or *topic neutral*. Characterisations such as this are related to a superficial reading of the classical definition of validity, say for a syllogism such as

All *A* are *B*.

All *B* are *C*.

Therefore, all *A* are *C*.

The validity of this schema is taken to mean something like “whatever you substitute for *A*, *B* and *C*, if the premises are true for the substitution, then so is the conclusion.” Analyzing an argument thus consists of finding the topic-neutral expressions (the logical constants), replacing the topic-dependent expressions by variables, and checking whether a substitution that verifies the premises also verifies the conclusion. If so, one knows that the argument is correct for the particular substitution one is interested in.

This *schematic* character of inference patterns is identified with the “domain-independence” or “topic-neutrality” of logic generally, and many take it to be the principal interest of logic that its laws seem independent of subject matter. In fact, however, logic is very much domain-dependent in the sense that the relevant schemata (i.e., logical forms) depend on the domain in which one reasons, *with what purpose*. We therefore view reasoning as consisting of two stages: first one has to establish the domain about which one reasons and its formal properties (what we will call “reasoning to an interpretation”) and only after this initial step has been taken can one’s reasoning be guided by formal laws (what we will call “reasoning *from* an interpretation”).

2.2.2. REASONING TO AN INTERPRETATION AS PARAMETER SETTING

Let us first be slightly more specific about what is involved in formalising a domain. It is very hard to pin down the notion of domain itself; for now, we restrict ourselves to listing some examples that will be treated in this chapter: actions, plans and causality; contracts; norms; other people’s beliefs; mathematical objects; natural laws. Formally, a domain is described by a set of mathematical representations, called structures, of the main ingredients of the domain, together with a formal language to talk and reason about these structures; the latter require a definition of how the formal language is interpreted on the relevant set of structures. This notion of structure is extremely general, and instead of being more precise at this point, we refer the reader to the different examples that will be given below.

The reader may wonder why language should be relative to a domain: isn’t there a single language – our natural language – which we use to talk and reason about everything? A moment’s reflection shows however that it is not useful to have a single language (*with a single semantics*) for talking about everything. Even though we use natural language to reason about both legal laws and scientific laws, the semantic structures of these domains are radically different. Hence it is best to keep these languages distinct: there are many “languages of thought” instead of Fodor’s monolith. This reflects a different (and, as we believe, more useful) conception of language, as consisting not only of symbolic expressions, but as a set of symbolic expressions together with a semantics.

Thus far, what is proposed here is analogous to the approach to logic known as “model theoretic logics” (see Barwise and Feferman 1985). However, we also want to formally incorporate the *purpose* for which we reason, and this often involves taking into account the definition of logical consequence. A good illustration of this is furnished by legal reasoning in the courtroom, of which the following is a concrete example (simplified from a case which recently gained notoriety in The Netherlands). A nurse is indicted for murdering several terminally ill patients, who all died during her shifts. No forensic evidence for foul play is found, but the public prosecutor argues that the nurse must have caused the deaths, because she was the only one present at the time of all the deaths. This is an example of “plausible” or “credulous” reasoning: an inference is drawn on the basis of data gathered

and plausible causal relationships. This can be viewed as an inference where the premises are interpreted on a very restricted class of models, namely models in which no “mysterious” events happen, neither divine intervention nor unknown intruders.

The defence countered the prosecutor’s argument with an instance of “skeptical” reasoning, by arguing that the cause of death might as well have been malfunctioning of the morphine pumps, and contacted the manufacturer to see whether morphine pumps had had to be recalled because of malfunctioning – which indeed turned out to be the case. The move of the defense can be viewed as enlarging the class of models considered, thus getting closer to the standard notion of logical consequence where one considers all models of the premises instead of a restricted class.

The approach to logic which we would like to advocate views logics from the point of view of possible syntactic and semantic choices, or what we will call parameter settings. This metaphor should not be taken too literally: we do not claim that a logic can be seen as a point in a well-behaved many-dimensional space. The use of the term “parameter” here is analogous to that in generative linguistics, where “Universal Grammar” is thought to give rise to concrete grammars by fixing parameters such as word order. The set of parameters characterizing a logic can be divided in three subsets

1. choice of a formal language
2. choice of a semantics for the formal language
3. choice of a definition of valid arguments in the language

Different choices may be appropriate in different domains – a domain gives rise to a semantics (that is, a notion of structure), and in principle each domain comes with its own language.

We claim that subjects in reasoning tasks such as the ones discussed above are mostly engaged in a process of interpretation, of the verbal material *and* of the task, and that this process can be viewed as the imposition of logical form, in the sense just defined. The reader may balk at this: Surely a reasoner does not literally choose a formal language? Although it certainly true that reasoners do not have the terminology of the logical theories, and their choice of interpretation is made in context and without much awareness of the reasons applied or the decisions taken, there is nevertheless good evidence that

they do make these decisions. For example, some subjects in the selection task allow true conditionals to have exceptions, others do not. The latter operate with a representation of the conditional as of the form⁴ $p \rightarrow q$ (i.e., featuring the atoms p, q only); the former operate with a more elaborate syntactic representation, something of the form $p \wedge \neg e \rightarrow q$, where e is an atom denoting an exceptional situation. Analogously for the other parameters: the claim is that a theory of the phenomena observed must have recourse to these notions. Educationally, and psychologically, the process of gaining more explicit control over adoption of interpretations is an important one which we address below.

It is, in particular, subjects’ interpretation of the task that has an important influence on the assignment of logical form. This can be seen very clearly in the suppression task, repeated here for convenience: “If she has an essay she studies late in the library. If the library is open she studies late in the library. She has an essay.” Here the subject may view the task as trying to make the implied speaker’s utterances consistent (the “credulous stance”), or she may adopt the “skeptical stance” by interpreting the second conditional as refuting the first. The skeptical stance leads to the adoption of classical logic as the logical form: the subject considers the first conditional to be a proposal for a universal generalization which is falsified by a situation in which the protagonist has an essay while the library is closed. In the credulous stance, the first conditional is not abandoned but modified. However, even within the credulous stance there are several possibilities; the subject may view the second conditional as a weakening or on the contrary as a strengthening of the original claim. In the first case, the subject chooses a representation for the conditional which allows exceptions, such as $p \wedge \neg e \rightarrow q$ (as in the selection task), together with a clause saying that closure of the library (c) constitutes an exception e . Nonmonotonic logic then allows one to infer the weaker rule $p \wedge \neg c \rightarrow q$, from which nothing follows given p only. Here we have a case of a parameter-setting which differs from classical logic in all parameters. If the subject views the second conditional as a strengthening, this can be represented by the same form of nonmonotonic reasoning, this time applied to the second conditional, given formally by $r \wedge \neg \acute{e} \rightarrow q$, where \acute{e} again denotes an exceptional circumstance, this time relevant to the second conditional. It might be thought for instance that not having an essay counts as such an exception \acute{e} , but the “strengthening interpretation” says that

there are in effect no exceptions: that's how diligent the student is. This is again a difference in logical form: strengthening affects the formal representation of the second conditional, while weakening influences that of the first.

A final remark for those who are still sceptical about the use of a logical form featuring a non-monotonic consequence relation. Such a logical form comes naturally to subjects because they are used to it as speakers of natural language. If one views language understanding as the construction of discourse models (Kamp and Reyle [1993]), then one must allow that these models may have to be revised completely as new information is coming in. This can be illustrated by means of the two sentences (1a) and (1b) (adapted from Asher and Lascarides 2003; for related examples, see van Lambalgen and Hamm 2004).

- (1) a. Max fell. John pushed him.
 b. Max fell. John pushed him over the edge of the abyss to dispose of the corpse.

World knowledge applied to (1a) leads to the computation of an event structure in which the pushing precedes the falling. However, (1b) conjures up a scenario in which John shoots Max causing the latter to fall, after which he is shoved over the edge. We perform such recomputations of the event order effortlessly⁵ all the time, and it is not particularly bold to suggest that subjects applies these skills to reasoning tasks.

3. Representational Issues

In Section 2.1, we argued that both models- and rules-based theories missed empirical generalizations in interpreting the experimental data in three central paradigms used in the psychology of deductive reasoning. What is it about the theories that led to this outcome? In Section 2, we argued that one problem was mistaking reasoning *to* interpretations for reasoning *from* them. But it was also caused by a general tendency to conflate logical/semantic issues with representational/implementational ones, and it is to this problem we turn now. We begin by clarifying the levels distinction and its bearing on the inadequacy of the kind of data which has dominated the field, for resolving representational issues. We propose nonmonotonic logics give a better fit to informational analyses of subjects' actual understandings of these tasks, but choosing these

logics over classical logics does not resolve representational/implementational issues.

In fact, one might suppose that nothing changed with respect to the representational issues with this shift in logic. That would be a mistake. Although the early forms of nonmonotonic logic (Reiter 1980; McCarthy 1980) developed bad reputations for intractability of reasoning, the newer systems derived from logic programming proposed here are radically more tractable than classical logic. This has immediate consequences for representation. Sets of premises have single preferred models which can be identified with "intended" models in credulous discourse processing. The gap between semantics and psychology closes up. At the end of the section, we show how this means that these logics can be interpreted in neural networks, or alternatively as rules in production system architectures such as ACT-R (Anderson and Lebiere 1998: Ch. 12). Thus, the shift in logical framework shows how real representational questions can be approached, at least in computational analysis if not yet in experimental analysis. We end the section with some speculations about how these computational treatments offer possibilities of bridging the gap to more psychologically conventional studies of memory.

3.1. Models and Rules – Some Formal Concepts

A semantic (model-theoretic) level and a syntactic (proof-theoretic) level are easily distinguished in logical systems. At the more fundamental semantic level, logics employ an apparatus of interpretation (a mapping of nonlinguistic elements of the world onto a vocabulary of the language studied). The interpretations (models) that figure are *not* implementations (or representations), and this semantic level of logic is *not* a mode of implementation (representation). Models are abstract specifications of mappings – the information would need to be implemented in some mode before any computations could be performed. At this level, specifying models specifies *what* information is to be implemented, but not *how* any implementations or computations on them are to be performed.

One source of confusion is that the logical use of "model" often inverts the everyday sense. Whereas we generally think of representational elements (such as the cardboard model of the house we are building) as being a model of the real-world nonrepresentational thing (the house), in logic this relation gets inverted.

Because logic is focused on representing languages, the nonrepresentational world that the language is about becomes the “model” for the language. A still further source of confusion is that much of the technical logical apparatus of modern logic was developed for dealing with worlds which really are abstract – mathematical worlds. Our only access to these worlds is via representation systems and calculations in them. Here the grounding onto the world all too easily becomes backgrounded to the point of disappearance.

Needless to say, models in this logical sense can be represented by (sets of) sentences in a language, by diagrams (at least in some cases where the models are sufficiently simple), and by other means as well. Psychologically what is important about these abstract mappings is that there is evidence that some sorts of natural language discourse processing are strongly organized around them (e.g., for some early observations: Bransford et al. 1972; Craik 1967; Stenning 1978). Just as Chomsky showed that sentences had to be regarded as abstract hierarchical structures without which theories of language knowledge and processing were impossible, so a number of authors in the early 1970s showed that the abstract objects logicians call models are also essential players in theories of discourse semantics (Kamp 1981). Just as psycholinguistics has studied how the abstract objects which are sentences are implemented in the mind, so the business of psychological studies of reasoning is to explain the implementation of abstract models in the mind, and, of course, the interplay between implementations of sentences and implementations of models. Just as with implementing sentences (e.g., working memory implementations are different from long term memory implementations), so multiple kinds of implementation are to be expected for models.

Moving to the syntactic level, what is known as a proof theory provides a set of rules (or axioms) which are designed to capture the semantically valid inferences embodied in the chosen notion of logical consequence. If the rules can be shown to not produce any non-consequences, then they are sound. If they can generate all the semantic consequences, then the rule system is complete. Although many systems of interest to mathematicians are provably incomplete (there are semantic consequences not computable within the rule system), for the systems studied by psychologists of reasoning, incompleteness is not an operative issue. Rules

are a way of capturing the underlying semantic consequences. To make a computational process out of such a rule system one still requires a theorem prover which chooses which rule to apply at any given point in a derivation, either heuristically or algorithmically. So, from a logical point of view, it is very natural to think of the syntactic level as the level at which computational processes of reasoning go on, and if modeling mental processes is the goal, this object-language level is a natural place to begin, though it is as well to remember that “proof theories” can be given for nonsentential reasoning as well as sentential (for some diagrammatic examples, see Stenning 2002).

There is, however, another possibility – and that is to compute consequences “directly” at a model-theoretic level. An example would be reasoning by model generation and model checking. At first sight, this might appear to be what mental models theory proposes for mental processes. For example, the syllogism is treated by giving model-construction and model-checking algorithms. But the directness is a bit of an illusion. Reasoning meta-linguistically over models, without object-language sentential rules of inference, still has to go on in some meta-language and with regard to some representation of the models involved. Such meta-logical reasoning is generally presented in English as the meta-language, but for a computational account, the meta-language is generally set-theory – the need is to talk of sets of models involved in consequence relations.

If the processes of reasoning about models in this meta-language is to be proposed as an analogue for the mental processes of subjects, then the meta-language comes center-stage. What are the inference rules of this language which constitute reasoning? How are the models reasoned over represented? What is *the meta-language's* proof-theory? What is the theorem prover for this language? How are all these abstractions implemented? When pressed along these lines, Johnson-Laird falls back on his implementation of the theory in a computer program written in LISP. Perhaps we should construe LISP as the meta-language? But this won't help. LISP is sufficiently powerful to express any kind of reasoning procedure over syllogistic models. The program is only substantive if the program uses a constrained set of model-generating and model-checking procedures. We have argued elsewhere that mental models theory is not consistent in its specification of constraints (Stenning and van Lambalgen 2008).

The various expositions of mental models theory are both incomplete (in the nontechnical sense) and inconsistent the one with the other. If we attempt to understand the notations offered as embodying mental models theory we should be clear that what we are doing is giving an account of the proof-theory of the mental-models “language,” although we should also be clear that we are given to start from is a formalism with no better than an intuitive treatment of its own semantics. Far from studying “directly semantic” reasoning over models we are at two steps removed from any grounded semantic study.

In this connection it is worth observing that one of the central motivations of mental models theory was always to explain the “content dependence” of reasoning which it claimed to be observed in the selection task. We have seen in Section 2.1 that the effects of content in that task are best understood as the effects of content on the selection of differently formalised interpretations. However, a further problem with mental models theory is that it is formulated in terms of formal manipulations of token letters in some implicit meta-language and this does not address content effects. This reasoning by manipulating model-representations is formal, even if not fully formalized. So mental models theory’s appeals to “direct semantic processing” fail to engage with content. In contrast, the implementation of a default logic given in Subsection 3.2.1 provides an account of the grounding of interpretation in the content encoded in a database of conditionals in long-term memory.

So we have argued that models as abstractions are essential to psychological theory (at an informational level) because model theory (in the logical sense) is essential to giving accounts of discourse meanings, and psychology needs the concepts of logic for foundations for its theories as much as logic does. What about representations of models implementing mental structures and computational processes: Either external representations such as maybe diagrams or internal (mental) representations of models? Is there some useful employment for implementations of models at this computational level? Well, the first thing to be said is that we should expect in general that there will be lots of different implementations of models – in languages, in diagrams, . . . Looking at external representation examples which are easier to lay hands on, there are obviously linguistic and diagrammatic representations of models, and other kinds besides. But is there some kind of implementation of

models which is particularly closely related to abstract-level models?

Stenning (2002) develops a theory of a subclass of “directly” interpreted diagrammatic representations which are, (in their primitive form) rather close to representing single logical models. The technical definition of directness involved here is “lacking an abstract syntax interpolated between representation and represented.” Direct representations are contrasted with “indirectly interpreted representations” which require an interpolated “abstract syntax” – natural and artificial sentential languages being the obvious examples.

For example, Euler diagrams, suitably interpreted, are shown to provide a well-specified, directly interpreted, analogue of mental models notation for syllogisms. This direct mode of representation has interesting consequences for processing. Once dealing with explicit external direct representations such as diagrams it is possible to contrast their behavior with external linguistic representations – written language. Empirical studies show that subjects are differentially affected by learning from explicit external representations. Here is palpably representational evidence suggestive that nonsentential representations of models are psychologically active in at least some subjects some of the time.

What are we to make of the large body of “mental models” experiments which study subjects’ solutions to linguistically presented deductive puzzles and claim thereby to show that the fundamental human deductive reasoning mechanism uses model-like rather than sentence-like representations (Johnson-Laird and Byrne 1991)? At the most general level, we know from completeness proofs, that any inference in expressed in models-style will correspond to an inference in a sentential-rule system. But this is a weak kind of correspondence – there might in principle be little correspondence in complexity of these inferences (supposing we had an arguably appropriate measure of complexity). However, there are much stronger correspondences between the mental models representational apparatus and natural deduction sentential rules systems (Stenning and Yule 1997). Mental models derivations correspond to a style of proof known as “proof by cases” in natural deduction systems. There is not just weak input-output correspondence, but operation by operation correspondence. The psychological literature has assumed that in comparing complexity of derivations, number of inference rule applications is the relevant metric. But

the correspondence between proof-by-cases and mental models shows that if the metric chosen is number of cases, then the data offered cannot discriminate. There is no principled reason why the mental implementation of proof-by-cases should not implement the representation of cases in such a way as to yield this result (for a proposal along these lines, see Stenning and Oberlander 1994).

One might argue that even so, mental models experiments provide richer data through error-patterns, reaction times, and so on. But exploiting this richness requires a specification of the kinds of corruption of memory representations that occur, and this kind of representational detail is just what is missing from mental models theory. To make claims about representation one has to study representations, and input-output functions from sentences to sentences are not enough. We shall see presently that where serious study of representations has been undertaken, the evidence is that both model-like and sentence-like representations appear to be involved and that differences between subjects are cognitively important – there is no evidence for a single fundamental human deductive reasoning mechanism. This empirical evidence is supported by the computational account given below of neurally implemented default logics. In those implementations there are simultaneously representations of (sets of) sentences (as network structures) and representations of models (as activated subsets of nodes in the networks). And the database of conditionals in default systems really does connect episodes of reasoning to content.

In summary, we agree with mental models theory that the logician's concept of model provides a specification of information which is clearly important for accounts of psychological processing. A psychology based on the abstract object of the sentence alone is not going to be able to give useful accounts of the meaning of natural languages, and meaning dominates human processing. But the kinds of evidence required to show how models are represented has not been forthcoming from mental models theorists. In the next section, we turn to more formal studies of discourse meaning which implicate abstract models in human processing.

3.2. *Really Representational Questions*

The tasks discussed in Section 2.1 have been used to make representational claims. In particular to argue against mental rules and for mental

models. We have seen that the arguments proffered are not convincing, but it is of course an extremely interesting question whether reasoning experiments together with sound logical theorising can yield information about representations. Here we put forward a proposal for one set of mental representations which could underly performance in the suppression task – a neural network implementation.

To position this proposal with regard to the rest of the chapter, what we will specify is a network which has been constructed as a result of interpreting an example discourse from the suppression task. So we assume that the subject has decided that the appropriate task is credulous interpretation of this discourse and has set the requisite logical parameters according to the prescriptions of our particular default logic. We do not provide a model of the process of construction of the network, some of which will be taken from structures already existing in long-term memory, and some of which will be new, perhaps in working memory, although for more discussion of that problem, see Stenning and van Lambalgen (2008: Ch. 8). The resulting network fragment will, given as its inputs any set of valuations (in the three-valued semantics) of the relevant atomic propositions from the discourse, compute the "intended model." So the network represents a mapping from a set of valuations onto particular discourse models. Needless to say, all the usual questions about how the propositions represented in the network are grounded to their real-world content remain unanswered, as they do in mental models and mental logic theories. There are also of course interesting questions about how the novel episodic features of the discourse (perhaps that the student in the library is called Ermintrude) is related to the representation of the long-term general knowledge about libraries, essays, students, and closing, and so on. These questions will not be pursued here.

3.2.1. NETWORK IMPLEMENTATIONS

We have seen that reasoning performance on the suppression task can be explained logically in a defeasible logic operating on conditionals of the form $p \wedge \neg ab \rightarrow q$, in words: "if p and nothing exceptional occurs, then also q ." The various answers can be explained as different manipulations on e . For example, if a subject "suppresses" the modus ponens inference this can be viewed as the addition of a rule $c \rightarrow ab$, where c denotes closure of the library, and applying closed world reasoning to get $c \leftrightarrow ab$, whence $p \wedge \neg c \rightarrow q$ – from which q does not follow given only p .

Now let us look more carefully at the computations that are taking place here, starting from the task materials. There are two steps to be distinguished:

1. coding the materials into rules, and
2. the computation showing that q does not follow.

For both steps, the particular logical form of the task materials turns out to be essential. Suppose that indeed the materials are represented as rules $p \wedge \neg ab \rightarrow q$ and $c \rightarrow ab$. Logic has much to say about rules of this form, characterised by the fact that the consequent is atomic, in particular about their semantics. In general, that is, starting from an arbitrary set of propositional formulas, it is impossible to compute models of this set efficiently, as a consequence of the $P = NP$ problem. The situation is different for rules of this special form. These rules form part of so-called *logic programs*, whose models can be computed in a time linear in the size of the input.

Of especial relevance is the observation that there is a strong connection between logic programs and recurrent neural networks (see Hölldobler and Kalinke 1994, and for an extension to closed world reasoning, see Stenning and van Lambalgen 2005). To each logic program one can associate a recurrent neural network in such a way that models of the program (which are abstract entities) are represented by stable states of the network (which in principle can be realised physically). This takes care of (2): the stable state of the neural network associated to the suppression task (via a suitable logic program) is such that q is not activated.

The network implementation makes a representational choice – the models-mode. But unlike mental models theory it comes with a very specific account of how the language is incorporated into the network. The main issue to be discussed here is the representation of conditionals as links in a network, that is, (1). We will indicate briefly how such links may be set up in working memory, following the highly suggestive treatment in a series of papers by von der Malsburg starting with 1981 (see von der Malsburg 2003 for a recent summary), some of which were written in collaboration with Bienenstock. Bienenstock and von der Malsburg (1987), von der Malsburg and Bienenstock (1987), von der Malsburg (1988) and with Willshaw von der Malsburg and Willshaw (1977), Willshaw and von der Malsburg (1976, 1979), von der Malsburg and Willshaw (1981). These authors

observed that, apart from the “permanent” connection strengths between nodes created during storage in declarative memory, one also needs variable connection strengths, which vary on the psychological time scale of large fractions of a second. More formally, let the synaptic connection between brain cells i and j be characterised by a strength w_{ij} . It is postulated that the weight w_{ij} of an excitatory synapse depends on two variables with different time scale of behaviour, a_{ij} and s_{ij} . The set $\{s_{ij}\}$ constitutes the permanent network structure. Its modification (synaptic plasticity) is slow and is the basis for long-term memory. The new dynamic variable a_{ij} termed the *state of activation* of the synapse ij (as distinct from the activation of the cell), changes on a fast time scale (fractions of a second) in response to the correlation between the signals of cells i and j . These changes may be viewed as subserving working memory. The overall weight of a connection w_{ij} is then a function of the s_{ij} and the a_{ij} , for instance via the simple rule $w_{ij} = a_{ij}s_{ij}$.

If we apply the ideas just outlined to our representation of the suppression task, we get something like the following. Declarative memory, usually modeled by some kind of spreading activation network, contains units representing the “concept library,” with links to units representing concepts such as “open,” “study,” “essay,” and “book.” These concepts may combine into propositions. Neurally, one may view an atomic proposition (“the library is open”) as a single unit (say U_p) which is activated when the units for the constitutive concepts (“library,” “open”) are activated; for example, because mutual reinforcement of the units for “library” and “open” makes their combined weighted output exceed the threshold of U_p . Two propositional units p, q (“the library is open,” “she will study late in the library”) can be combined into a conditional by the activation of a further link from p to q .

All these links can be viewed at two time scales. At large time scales the links are connections laid down in declarative memory; these links have positive (although small) weights and correspond to the $\{s_{ij}\}$ in the above description. At small time scales, links may become temporarily reinforced by sensory input, through an increase of the $\{a_{ij}\}$. For example, upon being presented with the conditional “if she has an essay, she will study late in the library” ($p \wedge \neg ab \rightarrow q$), the link from p to q via ab in Figure 1 becomes temporarily reinforced by synaptic modulation, and thus forms a fast functional link. As a result, the system of units and links

Figure 1. A hidden layer of abnormalities.

thereby becomes part of working memory, forming a network like the ones studied above, where the $\{w_{ij}\}$ are a function of the $\{a_{ij}\}$ and the $\{a_{ij}\}$. Working memory then computes the stable state of the network, and the state of the output node is passed on to the language production system.

As a further refinement we may incorporate abnormalities in the neural representations of rules, as illustrated in Figure 1. As we have seen, abnormalities play a special role as inhibitors in rules. They may inhibit an inference, and they also may inhibit actions. Abnormalities in rules are furthermore special in that they need not occur in the overt linguistic representation of a rule. They may, however, be activated, or suppressed, by material which is overtly represented. We therefore prefer to represent abnormalities as a hidden layer in the network and hypothesize that normally this layer is present in all networks representing condition – action rules. We hypothesize that this hidden layer is responsible for the possibility of flexible planning.

Consider a conditional like $p \wedge \neg ab \rightarrow q$ together with a further determination of the abnormality as $\neg\tau \rightarrow ab$. The effect of the abnormality is captured by an ANDNOT unit, which has two incoming links, one excitatory (for the left argument of ANDNOT) and one inhibitory (for the right argument), and threshold 1. The p unit is connected to the excitatory channel, and the $\neg\tau$ unit to the inhibitory channel (see Figure 1). If ab is not connected to an atom (i.e., if there is no condition of the form $C \rightarrow ab$), the inhibitory channel never fires.

It should be noted once again that this result very much depends on the logic adopted here – logic programs governed by closed-world reason-

ing – and would not hold for classical logic. The computational properties of this logic are highly suggestive as candidates for “System 1 processes” much discussed in dual process theories of reasoning (Evans 2003):

System 1 is . . . a form of universal cognition shared between animals and humans. It is actually not a single system but a set of subsystems that operate with some autonomy. System 1 includes instinctive behaviours that are innately programmed and would include any innate input modules of the kind proposed by Fodor. . . . The System 1 processes that are most often described, however, are those that are formed by associate learning of the kind produced by neural networks. . . . System 1 processes are rapid, parallel and automatic in nature; only their final product is posted in consciousness (Evans 2003: 454).

In these theories, logical reasoning is considered to belong to “System 2” which is “slow and sequential in nature and makes use of the central working memory system” (Evans 2003: 454).

Our proposals certainly challenge the idea that fast and automatic processes are thereby not logical processes, thus drawing a different boundary between System 1 and System 2 processes. It depends on the logic whether it allows fast automatic processing or not. Classical logic can be viewed as a conscious repair process: the subject observes the output of the automatic reasoning process, reflects on it and decides to incorporate more models, thereby perhaps invalidating a conclusion.

4. Peering over the Ghetto Walls

This last section will conclude the paper by surveying the view from the edifice so far constructed. What connections to the rest of cognitive science are prominent from this viewpoint? What in the wild brings out interpretation and reasoning? We have argued that much of the psychology of reasoning is about interpretation, and that we should reinterpret an important subset of System 1 processes as defeasible reasoning to interpretations.

The nonmonotonic logics advocated here for modeling defeasible credulous interpretation processes are also known as “planning logics.” This association by label to planning is important but possibly obscure. We perhaps tend to think first of conscious deliberate planning – a form of problem solving – rather than the

sort of effortless automatic planning involved in say planning motor actions. The connection between planning and System 1 is through the latter kind of planning, though relations to the former deliberate kind are important in considering relations between System 1 and System 2.

The fundamental logical connection of interpretation to planning is its defeasibility. When we plan (deliberately or automatically) we plan in virtue of our best guess about the world in which we will have to execute our plan. We may plan for what to do if we miss the bus, but we don't plan for what to do if the bus doesn't come because the gravitational constant changes, even though that is a logical possibility. If we used classical logic throughout our planning we would have to consider all logically possible worlds, or at least make explicit exactly what range of worlds we consider. This necessity is what gives rise to the notorious frame problem in AI.

With this association of planning in mind, we will begin by discussing what our account of System 1 processes reveals about the connections of the psychology of reasoning to other areas of cognition, then ask how System 2 processes manifest themselves, and finally how the two kinds of processes are related.

4.1. System 1 Processes

As we saw in implementing a particular version of planning logic in Subsection 3.2.1, a single model of the discourse was maintained at every point of its development. Maintaining a single model of our best guess about the current situation and its relevance to current goals is a very much more plausible biological function than reasoning about all logically possible models of our current assumptions. As we also saw, along with biological plausibility of function came efficiency of computation – the model is derived from the representation of the assumptions in linear time. Focusing on biologically plausible automatic planning is helpful in connecting this approach to other cognitive processes.⁶

On the account of the nature of System 1 processes as defeasible reasoning to an interpretation, they have of course already received considerable attention in a range of psychological literatures. Closest to reasoning is the psycholinguistics literature (Gernsbacher 1994). Here the whole enterprise is to ask how subjects defeasibly derive interpretations for discourses, and the story ends with successful interpretation. Because the problem is of such practical concern, there is very considerable study how how this

process of interpretation can be implemented in computers.

Psycholinguistics has recently branched out beyond the interpretation of purely linguistic input to treat situations in which visual perception of the nonlinguistic world goes on in parallel with linguistic interpretation of relevant utterances (Tanenhaus et al. 1995). Indications are that linguistic and nonlinguistic interpretation is about as integrated as it is possible to be. Visual evidence can be used “immediately” to resolve linguistic choices in interpretation. This should serve to remind us that defeasible processes modeled by planning logics are not particularly linguistic. Perception is a process of interpretation, and a good part of psycholinguistics is just about the perception of language. The production side of psycholinguistics is about action and the planning of action. Perception produces interpretations and action acts upon them.

When thinking of what planning logic might reconnect us to, one should not, of course, neglect work more explicitly about planning itself. Conscious deliberate planning has been studied in normal subjects in the context of problem solving, and indeed it is strange that this literature is regarded as so separate from the psychology of reasoning literature. When Newell and Simon's 1972 subjects have to solve a tower of Hanoi problem, reasoning seems to be what is called for. This, at first experience, evokes System 2 planning. But the surprising outcome of Simon and Newell's empirical studies and theoretical conclusions was that expertise resulted in System 2 processes “going underground” and being compiled into System 1 skills. The expert chess player or doctor has, to a large extent automated the planning process and indeed may have done so to the extent that the skill is no longer accessible to reflective analysis – a hallmark of System 1 processes. This change was indeed conceptualized by Simon and Newell as the acquisition of very large databases of “productions” – conditional default rules.

This same turn toward the study of learning and acquisition of reasoning skills has not happened in the psychology of reasoning. As long as the goal is characterisation of the fundamental human reasoning mechanism, learning, acquisition, and even skill are deemed irrelevant, and as processes which are “educational,” rather than part of the nature of human cognition in the wild. Stenning (2002) shows how differences between subjects' reasoning and learning can be explained in terms of their representational

strategies, developed by slow deliberate System 2 learning. Representational differences are just as relevant to the study of System 1 processes as to System 2. Indeed, representational variety can be studied as a real empirical issue here. It is a fine irony that professors should come to the view that conceptual learning is not a part of human nature, but merely a cultural oddity.

The other considerable literature growing out of planning is the neuropsychological literature on executive function. Lots of categories of patient have planning problems, often to do with inhibiting prepotent responses, managing goals and subgoals, and so forth. This literature straddles automatic and deliberative planning and control. Perhaps the moral of this literature of most current relevance here is that although human System 1 processes include our biological heritage from nonhuman cognition, System 1 is also distinctively changed in humans. Our System 1 not only keeps a model of our best interpretation of our current real-world circumstances but also can maintain a model of our best interpretation of, at the other extreme, a completely fictional discourse where relation to the real worlds is totally unspecified. It is understanding such fictional discourses in the laboratory that provides the data that we began by discussing. Studies of the evolution of human language and cognitive skills also exploit this relation between planning and language skills (Arbib and Rizzolatti 1997; Greenfield 1991; Steedman 2002).

One thing that is special about interpreting discourse (as opposed to present perceptual circumstances) is that it requires reasoning about others' intentions and meanings. One sees this made concrete in pragmatic frameworks such as Grice's where credulous interpretation of discourse involves assumptions of cooperativeness, knowledge, and ignorance, for example. The "theory of mind" reasoning that has been studied in the developmental literature provides further examples. Stenning and van Lambalgen (2006) sketch a treatment of the reasoning about beliefs in "false belief" tasks in default logic. The key idea here is to analyze communications, perceptions, and beliefs, as causes and consequences of a specific kind, and the reasoning as a variety of causal reasoning.

Mention of Grice raises questions about how the proposed approach is related to pragmatic theories such as Grice's and Sperber and Wilson's Relevance Theory, and what general

effects it has on the boundary between pragmatics and semantics. To take the second question first, it is clear that the boundary does shift. Default logic makes at least some pragmatic implicatures in Grice's theory into logical inferences in its new semantics. Whether all of pragmatics would become incorporated in a more extensive development of the approach remains to be seen, but we have our doubts. However, this preference for giving precise fully formalized accounts of limited phenomena, over giving extremely generalized accounts such as Grice's or Relevance Theory is an important methodological preference. An good example of our reason for this preference can be seen in the analysis of the selection task. Sperber has written at some length on how pragmatic phenomena explain observations in the selection task, but without ever observing that the contrast between deontic and descriptive semantics is sufficient to derive the vast majority of the differences in his own examples. So while we agree with the general thrust of his conclusion that subjects are able interpreters rather than logical dunces, it appears that Relevance Theory is couched at such an abstract level that it misses the crucial detail here.

Finally, in this survey of System 1 cognition from the perspective of planning, we should note that planning also brings motivation and emotion into the cognitive picture. We plan with respect to goals, and those goals induce subgoals and sub-subgoals as we negotiate the obstacles to achieving our desires. Even if motivation and emotion don't always seem the most obvious destinations of a logic-based cognition, Damasio (1994) made a forceful argument that without motivation to reason, precious little rationality is likely, and he has made a plausible case for a class of patients with intact reasoning capacities but malfunctioning motivation. Gambling paradigms reveal their deficits as aberrant utility functions which unreasonably discount the future in their planning.

In summary, we need an account of how human System 1 processes evolved and develop, so that nonmonotonic logics appear in human cognition implemented in such a way they can deliver interpretations of situations other than the here-and-now. It is hard to see how a creature could evolve human abilities for entertaining System 1 interpretations of circumstances at some remove from its present circumstances, without also evolving some System 2 processes for managing and repairing interpretations. And

without the former capacities, human language would not be possible – languages of fixed interpretation would not be natural languages. This account also needs to be augmented by an account of how System 2 processes are related to System 1, and where they happen outside the lab. The key proposal here is that the former grow out of repair processes called into action when System 1 breaks down and no intended model is therefore available.

The reader might be puzzled at this association between breakdown in defeasible interpretations and resort to different kinds of reasoning. Were not defeasible systems designed precisely for tackling the problems of apparent contradictions arising in interpretation? To take the classic example, when we infer that Tweety can fly from the premise that Tweety is a bird, and later we find out that Tweety is a penguin, we are faced with a conflict. The defeasibility of the logic was designed to model precisely this kind of accommodation by withdrawal of the inference. The default logic proposed here is similar in that it will resolve such conflicts automatically – when the library turns out to be closed, it drops the inference that our heroine will be inside. But this does not mean that *all* conflicts are resolvable, and so we assume that whatever default system is considered makes a demarcation between conflicts that can be automatically resolved, and those which will require a change of machinery. While trying to forstall misunderstandings, it's important to note that the particular defeasible logics proposed here as models of System I reasoning contrast with the early defeasible logics in being highly tractable, and this is what makes them interesting candidates for System 1 processes.

4.2. System 2 Processes

Breakdown of mutual interpretation in credulous processing interrupts a discourse if the hearer's interpretation yields an interpretational impasse. Here, however much the hearer is willing in general to accept the speaker's assertions, a contradiction or other divergence of new utterances from the hearer's model of the speaker's intentions to this point, means that no model can be found, and no model means no "intended model." The hearer now has to engage in repair, and may interrupt the speaker to find out how to repair understanding. Such repair of contradiction may be based on interludes of skeptical reasoning *from* interpretations (or broken attempts

at interpretation), embedded in credulous reasoning *to* interpretations.

On this story, classical logic is a good account of some reasoning that does occur in the wild under particular circumstances – the circumstances of "adversarial" communication. The credulous interpretation of discourse assumes a certain asymmetry of authority between speaker and hearer. The hearer accepts that speaker's authority for the truth of the discourse, at least for the purposes of the current episode of communication. The purest case is where a speaker tells a novel fictional story to the hearer who patently accepts he has no grounds for disagreement. But as we have just seen, this acceptance of asymmetry of authority breaks down when contradiction is encountered and can only be restored by repair. The discourses of adversarial communication are cases where breakdown of mutual interpretation is much wider spread. In the discourse of argument, participants consider themselves to have equal authority for assertions, and a disagreement about what is true.

In full-fledged argument, the parties may be unwilling to accept offered repairs. They may explore for reinterpretations of the assumptions on which they can agree, or they may resort to less communicative tactics. Here it is plausible that the logic governing the derivations from assumptions is classical – demanding that conclusions be true in all logically possible interpretations of the assumptions. Here is what lies behind Ryle's 1954 statement:

There arises, I suppose, a special pressure upon language to provide idioms of the [logical] kind, when a society reaches the stage where many matters of interest and importance to everyone have to be settled or decided by special kinds of talk. I mean, for example, when offenders have to be tried and convicted or acquitted; when treaties and contracts have to be entered into and observed or enforced; when witnesses have to be cross-examined; when legislators have to draft practicable measures and defend them against critics; when private rights and public duties have to be precisely fixed; when complicated commercial arrangements have to be made; when teachers have to set tests to their pupils; and [...] when theorists have to consider in detail the strengths and weaknesses of their own and one another's theories.

One of the hallmarks of formal adversarial communication is that reasoning is intended to proceed from the explicit assumptions negotiated to obtain – the “admissible evidence” as written down. Introduction of extraneous assumptions not formally entered in the record is strictly impermissible. This making explicit of what is assumed for reasoning classically from interpretations contrasts with the vagueness of what long-term knowledge is in play in defeasible reasoning *to* interpretations. This difference in demarcation is reflected in the relations between long-term and working memory in the network implementation of our nonmonotonic logic.

In adversarial communication, reasoning is not defeasible, at least when the rules are followed literally, and finding some interpretation which makes the premises true and the opponent’s desired conclusion false is sufficient to defeat it. What combination of classical or defeasible logics provides the best model of how real legal and parliamentary practise works is a complex question, but an albeit highly idealized core of adversarial legal reasoning arguably provides one model for classical logical reasoning in the wild. The study of adversarial reasoning played an important part in the emergence of logical theory in classical Athens. A purer example of adversarial communication involving sceptical classical reasoning is the discourse of mathematical proof – another Athenian preoccupation. Yet another example of adversarial communication is argument about the correct interpretation of religious texts – the context which seems to have been particularly important in the emergence of Indian logical theory. Of course, we assume that capacities for sceptical reasoning preceded these developments of theories about the conduct of sceptical reasoning.

One might ask whether breakdown of automatic System I interpretation processes always leads to a resort to sceptical reasoning and classical logic. There are two other possibilities and we believe these are open empirical questions worth exploration. The first is that the stalled interpreter might resort to more powerful, and perhaps more effortful, but nevertheless defeasible systems. The second is that she might resort to sceptical reasoning in some monotonic system other than classical logic. The reader familiar with the analysis of real argument will be aware that it is often proposed that defeasible logics are the right framework for this (Chesnevar et al. 2000). On our view this would be because most real arguments (e.g., legal argument) involve a

considerable component of mutual interpretation to identify what premises are shared and which at variance. These processes would be best modeled defeasibly. So our claimed association between sceptical reasoning and monotonic logic is intended only to apply to the portions of argument in which reasoning is *from* an interpretation.

The relation between adversarial communication and logic was traditionally very much the focus of late secondary and tertiary education, at least of the élites who were trained for performance in lawcourt and parliament (and later scientific laboratory). We have already made reference to legal reasoning in Subsection 2.2.2. The tasks of the psychology of reasoning are directly taken from, or derived by small extensions from, the curriculum of this tradition of education (Stenning 2002).

It would be a great mistake to assume that such discourse is limited to court and parliament, or to professional practise. Conceptual learning in educational dialogue has many of the same features. Teacher and student start out, by definition, conceptually misaligned – teacher knows some concepts that student doesn’t. The abstract concepts of secondary and tertiary education are not teachable by ostension, and require teaching indirectly through rehearsal of their axioms and applications of those axioms in argument. For example, to teach a student to differentiate the physical concepts of amount, weight, density, volume and mass it is no good pointing at an instance of one, because any instance of one is an instance of all the others. Instead, one has to rehearse the transformations which leave them invariant and the ones that change them. For example, compression changes density and volume but not weight or mass. Going to the moon changes weight but not mass. (Stenning 1998 discusses the close analogy between learning abstract physical concepts and learning logical concepts such as truth, validity, consequence, inference rule, . . .). The part that multiple representations play in teaching these abstract subjects points from a different perspective to the same centrality of interpretation in mental life. Multiple representational systems (languages, diagrammatic systems, multimedia animations, . . .) mean multiple interpretations and that there is an ever present task of selecting between interpretations/representations or constructing new ones. The empirical literature which has studied the effects of multiple representations (reviewed in this reference) attests

to the cognitive costs as well as the benefits of learning new interpretations.

Although such teaching dialogue is superficially highly asymmetrical in authority (teacher is boss), teacher's aim should be to hand over authority for inference to student. By the end of successful teaching, the student commands the authority which is provided by the inference patterns from the newly learned concepts, and appreciates *why* these inferences are true, without recourse to the argument from authority that "teacher said so." The successful student can now convict the teacher of mistakes in reasoning. Of course, there may be ways of acquiring these adversarial discourse skills outside of formal educational circumstances. For example, Bernstein's 1971 theory of different familial discourse styles ("extended" and "restricted" codes) could be construed as a proposal along such lines.

This literature is focused on the effects of different "representational surfaces" (various diagrams, new terminology, alternative descriptions, ...) on conceptual learning. As such it emphasizes the other 'face' of interpretation than the one that we have been mainly concerned with here. For example, all these different surfaces may be all mapped onto, say, a classical logical interpretation. Even our brief earlier discussion showed that formally these "faces" of interpretation are not entirely separable. For example, choosing a nonmonotonic logic over a classical logic (a semantic choice) changed the syntactic characterization (the surface) of the conditional from the syntax of material implication to a noniterable syntax for defaults. Changes in representational surface are just as important as changes in underlying semantics. Both are needed to give a rounded account of conceptualization and its part in learning, and both can have profound effects on the tractability of reasoning. Again, assuming a single fundamental human deductive reasoning mechanism has ensured that this aspect of reasoning has not been studied under the heading of reasoning.

On this account, classical deductive reasoning is important not because an implementation of it is the "universal deductive reasoning mechanism," but, rather, because classical reasoning is important for aligning and repairing mutual interpretation across some gulf of understanding or agreement, and that learning more explicit control over System 2 processes, and their relation to System 1 processes, can have a large impact on many students' interpretation, learn-

ing and reasoning processes. The skills of skeptical reasoning are then one extremely important set of concepts and skills for learning to learn.

The Relation Between System 1 and System 2

If the skills required for reasoning in something approaching classical logic are acquired or honed in this kind of education, are the mental processes acquired, implementations of patterns of reasoning explicitly taught – implementation of a novel formalism of "Ps and Qs," or mnemonics for valid syllogisms, say – or are they somehow implementations founded on new strategic uses of existing defeasible machinery? For example, one might think of the grasp of classical logical discourse as growing out of more and more extended episodes of repair of credulous discourse. Certainly the traditional teaching of logic focused on teaching students the skill of detecting equivocations in arguments – cases in which the same word is used in different interpretations. There are several well-known empirical studies of logic teaching which show little transfer to general reasoning ability (Cheng et al. 1986; Lehman et al. 1988). However, Stenning (2002) reviews these studies as seeking transfer at inappropriate levels, and presents empirical evidence from real classroom logic learning that it can transfer if the teaching objective is transfer at plausible levels. It isn't new inference rules (MP, MT, etc.) that transfer (perhaps because these rules aren't new, being shared with defeasible logics), but the much more general semantic skills of insulating the "admissible evidence" (current assumptions) from "general knowledge" and exploring all interpretations rather than just the most plausible ones, along with a much more explicit grasp of (and terminology for) discussing the contrasts between credulous and sceptical stances. Not to speak of the need to unlearn the influences of the information packaging of natural languages designed to focus the credulous interpreter's understanding on the intended model.

There is an issue whether adversarial discourse can best be modelled as alternations between nonmonotonic logics and classical logic, or whether they are better modeled entirely within a nonmonotonic framework as an enlargement of the set of models considered, is one that will not be resolved here. Much of this issue hangs on the degree to which assumptions are made explicit in the process (thus cutting down

on the number of models a classical approach needs to consider), or remain implicit although now mutual.

Stenning's study of logic learning arose out of comparisons between diagrammatic and linguistic presentations of classical logic in teaching reasoning skills. Like Amarel's work cited earlier, it focuses on the importance of representation and rerepresentation in human problem solving and learning. Its slogan is "Human reasoning proceeds by finding an interpretation in which the problem at hand is trivial to solve – if it can't find one, then it gives up." This does not cover *all* human reasoning, but outside of professional practises it covers a surprisingly large proportion. Rerepresentation is a form of reinterpretation which has not been studied in the psychology of reasoning. If the goal is to characterize the "fundamental human reasoning mechanism," and that is to be done by plumping for rules or models, then rerepresentation is not an issue that can be studied.

The educational process of *learning* to reason classically correctly in their laboratory tasks has not been seen as within the psychology of reasoning's remit. This can only be because the field does not believe that learning logic is something that goes on in the wild, or has much impact on what goes on in the wild. In turn, this relies on the idea that classical logic is just an empty formalism unrelated to "natural behavior." On our view, the skills of the sceptical stance which can be enhanced by logic learning are central to conceptual learning (a central preoccupation of the academic bit of the wild which we happen to inhabit) and are in the curriculum precisely for the help they offer those destined for some of the wildest parts of the wild where disagreement is the main business.

System 1 and System 2 processes work together from early on in human development. System 1 processes are rather direct implementations of a range of nonmonotonic logics. System 2 processes start as repair processes when System 1 meets an impasse. The great variety of logics available for interpreting tasks has been our focus here. This variety comes with variety in linguistic conceptualizations and in diagrammatic systems. Another aspect of interpretation is choosing between these alternative surfaces which we have said little about here. System 1 and System 2 interact to create this wealth of alternative systems. Cognitive development and learning stocks this representational supermarket, and teaches intelligent consumption. This is a rather different picture of reasoning than the

Fodorian one in which sentences in the already (presumably classically) interpreted language of thought are spat out of the encapsulated perception modules into the reasoning mill to grind out the inferences of mental life.

Notes

- 1 There are, of course deep issues about what worlds are for this purpose. Shoes and ships may be less fraught than sets, numbers, possibilities . . . This is especially so when our discourse turns to discussion of representations themselves, as ours so often must. But these problems are not the ones that most afflict cognitive analyses of reasoning, and it is important to keep in mind that semantics is a mapping onto things – not just some new language.
- 2 In principle, a counterexample is different from an exception: the former falsifies a rule, the latter does not. It seems however that Byrne et al. reinterpret counterexamples as exceptions, as the next quotations indicate.
- 3 These inferences are "immediate" only in the sense that they involve single premises – not necessarily in the logical sense of being derived by single rule-applications.
- 4 We use \rightarrow for implication, \wedge for conjunction, and \neg for negation.
- 5 ERP studies indicate that this inference is not quite literally effortless (Baggio et al. Submitted).
- 6 In this connection, it should be noted, planning logics are also used in robotics for planning motor actions (Shanahan 2000).

Chapter 12: Reasoning with Quantifiers

BART GEURTS

1. Introduction

In logic, inference and interpretation are always closely tied together. Consider, for example, the standard inference rules associated with conjunctive sentences:

$$\frac{\varphi \ \& \ \psi}{\varphi} \quad \frac{\varphi \ \& \ \psi}{\psi} \quad \&-exploitation$$
$$\frac{\varphi}{\varphi \ \& \ \psi} \quad \frac{\psi}{\varphi \ \& \ \psi} \quad \&-introduction$$

&-introduction allows a sentence of the form “ $\varphi \ \& \ \psi$ ” to be derived whenever φ and ψ are given, and &-exploitation licenses the derivation of either conjunct of “ $\varphi \ \& \ \psi$ ”. Of course, this is what one should expect in view of the meaning of “&”, which is that “ $\varphi \ \& \ \psi$ ” is false unless φ is true and ψ is true. In logic, the search for a system of inference is usually guided by a (possibly informal) construal of a set of logical constants, and inference rules are judged by the constraints they impose on the interpretation of such logical vocabulary as they involve. Not that such customs are particularly remarkable, for there clearly must be an intimate connection between the meaning of an expression and valid arguments which make essential use of that expression. What is remarkable is that such connections have not played an equally central part in the psychological study of deductive reasoning, and especially of syllogistic reasoning.

In the past two or three decades, the semantics of natural language has come into its own, and quantification may have received more attention than any other semantic topic. During

the same period, the psychological study of deduction made great advances, too, and one of its central topics is syllogistic inference, which is just a restricted form of reasoning with quantifiers. Strangely enough, these two enterprises have remained disconnected so far. All current approaches to syllogistic reasoning are based on first-order mental representations, which encode quantified statements in terms of individuals. Such representations are unsuitable for dealing with many quantified statements (e.g., “Most A are B”, “At least three A are B”, etc.), but semanticists have developed a general framework which overcomes these problems, and it will be argued that this framework should be adopted in the psychology of reasoning, too.

The plan for this paper is as follows. I start out with a survey of the central facts concerning syllogistic reasoning, and then go on to discuss the main approaches to deductive inference, arguing that each is flawed in the same way: they all employ representational schemes that are inadequate in principle for dealing with natural-language quantification, and in this sense they are all *ad hoc*. I then turn to the interpretation of quantified expressions, and sketch the outlines of a general framework for dealing with quantification that is widely accepted in the field of natural-language semantics. Research within this framework has shown that certain logical properties are especially important to natural systems of quantification, and I contend that the very same properties go a long way to explain the peculiarities of syllogistic reasoning.

It bears emphasizing, perhaps, that the general view on syllogistic reasoning adopted here is not original with me. Indeed, the key ideas

have a venerable ancestry and can be traced back in part to medieval times and partly to the founder of syllogistic logic, Aristotle. More recent developments in semantic theory have systematized these ideas and incorporated them in a much broader framework. Therefore, my objective is a modest one: to show that this view on quantification is relevant to the *psychology* of syllogistic inference, too.

2. Syllogistic Reasoning

The syllogistic language is confined to four sentence types, or “moods”:

- All A are B : universal affirmative (A)
 Some A are B : particular affirmative (I)
 No A are B : universal negative (E)
 Some A are not B : particular negative (O)

Although the scholastic labels A, I, E, O, (from Latin “Affirmo” and “nEgO”) have all but ceased to be mnemonic, they are still widely used, and I will use them here, too. Most psychological studies on syllogistic reasoning have adopted the traditional definition according to which there are four classes of syllogisms, called “figures”, which are determined by the arrangement of terms in the arguments’ premisses; the order of the terms in the conclusion is always the same:¹

Figure 1	Figure 2	Figure 3	Figure 4
B C	C B	B C	C B
<u>A B</u>	<u>A B</u>	<u>B A</u>	<u>B A</u>
A C	A C	A C	A C

Following standard practice, I will sometimes identify syllogisms by their moods and figures. Thus, “AE4O” stands for the syllogism of the fourth figure whose premisses are of type A and E, in that order, and whose conclusion is of type O; that is:

	All C are B
AE4O:	<u>No B are A</u>
	Some A are not C

There are 256 syllogistic arguments altogether, 24 of which are valid according to the canons of traditional syllogistic logic. Of these 24, only 15 are valid in modern predicate logic. The difference lies in the interpretation of the universal quantifiers “all” and “no”. In predicate logic, sentences of the form “All A are B” or “No

A are B” are vacuously true if the set of As is empty, and therefore the following inferences are not valid in predicate logic:

<u>All A are B</u>	<u>No A are B</u>
Some A are B	Some A are not B

Intuitively, these inferences appear to be valid, however, and they are accepted as such by traditional logicians; therefore, for example, syllogism AE4O (displayed above) is valid in traditional logic but not in predicate logic. It is the traditional notion of validity that is adopted in the psychological literature, and I will do so, too.² Hence, by default I will use the term “validity” to denote traditional validity.

Experimental investigations in syllogistic reasoning have explored a number of paradigms. In most cases, subjects were given two premisses and then asked either to choose from a list of possible conclusions (e.g., Dickstein, 1978, 1981) or simply to say what, if anything, followed from the premisses; the latter format has always been used by Johnson-Laird and his associates. Relatively few researchers (including Rips, 1994) have used evaluation tasks, asking subjects to decide whether a given argument was valid or not. By and large, these various paradigms yield the same results, but there are some differences, too, as we will presently see.

Chater and Oaksford (1999) compared five experimental studies that used the full set of 256 syllogisms: two by Dickstein (1978), two by Johnson-Laird and Steedman (1978), and one by Johnson-Laird and Bara (1984). Chater and Oaksford found that the results of these experiments are very similar, and that differences in design appear to have had little effect. In fact, the weakest correlation they observed was not between Dickstein’s multiple-choice studies and Johnson-Laird’s production studies, but between the two experiments by Johnson-Laird and Steedman (1978), which adopted the same paradigm. Chater and Oaksford computed the average number of times (weighted by sample size) each conclusion was drawn in the five studies just listed; their data are reproduced in Table 1.³ None of the studies collated by Chater and Oaksford used an evaluation paradigm, but their figures are very much in agreement with those of Rips (1994), who did. There are just two salient exceptions: for the valid AAI syllogisms Rips obtained much higher scores than one should expect on the basis of Chater and Oaksford’s meta-analysis, and the same holds for the valid AEO and EAO syllogisms. Almost

Table 1: Percentage of Times Each Syllogistic Conclusion was Endorsed According to the Meta-Analysis by Chater and Oaksford (1999)^a

Premises & Figure	Conclusion				Premises & Figure	Conclusion				Premises & Figure	Conclusion			
	A	I	E	O		A	I	E	O		A	I	E	O
AA1	90	5	0	0	AO1	1	6	1	57	IO1	3	4	1	30
AA2	58	8	1	1	AO2	0	6	3	67	IO2	1	5	4	37

EA3	0	0	64	22	EI3	0	6	15	48	OE3	0	5	12	18
EA4	1	3	61	8	EI4	0	2	32	27	OE4	0	19	9	14
										OO1	1	8	1	22
										OO2	0	16	5	10
										OO3	1	6	0	15
										OO4	1	4	1	25

A = all E = no
 I = some O = some...not

^a All figures have been rounded to the nearest integer; valid conclusions are shaded. Whenever two conclusions in the same row are valid, only the first one is valid in predicate logic.

certainly, these discrepancies are due to the fact that in an evaluation task alternative inferences never have to compete with each other: the paradigm allows subjects to endorse several conclusions for the same pair of premisses. By contrast, in the multiple-choice and production paradigms, a subject who judges AA4A to be valid (which it isn't) is thereby prevented from endorsing AA4I (which is valid). Furthermore, production and multiple-choice tasks may be more susceptible to interference from response factors (see below). So all things considered, the evaluation paradigm may be more suitable for gauging reasoning capabilities. In practice, however, this consideration is of minor importance, since all paradigms paint the same general picture.

Turning to the main trends in the data of Table 1, it is evident that logical validity is a major factor in determining performance on syllogistic tasks. To begin with, the most widely endorsed syllogisms tend to be valid. According to Chater and Oaksford's data, valid syllo-

gisms are endorsed 51% of the time on average; invalid syllogisms, 11% of the time. Seventeen valid syllogisms score above the upper quartile point ($P_{0.75} = 16.5$), and the remaining seven are presumably undervalued because they are in competition with more popular syllogisms. In Rips' data the effect of validity is even clearer, for his first 22 syllogisms are all valid. Furthermore, high-frequency errors tend to occur in the vicinity of valid argument forms. For example, of the four AAA syllogisms, only one is valid (i.e., AA1A), and it is typically recognized as such; in fact, it is one of the easiest syllogisms. But the invalid AAA arguments appear to share in this popularity, and are endorsed well above average. Other clusters of arguments for which this holds are AII, IAI, AEE, EAE, AOO, and OAO. The upshot of these observations is that people are rather good at syllogistic reasoning: not only are valid arguments very often recognized as such, but when invalid arguments are considered to be valid, they are often identical, *modulo* figure, to valid arguments.

Of the four syllogistic sentence types, two license *conversion* whilst the other two do not; whereas it follows from “Some A are B” and “No A are B” that “Some B are A” and “No B are A”, respectively, conversion is illegitimate in the case of “All A are B” and “Some A are not B”. There are 256 pairs of syllogisms that are identical up to conversion which is to say that they can be made to coincide by applying conversion to one of the premisses. For example, EA1E and EA2E are a conversion pair, because conversion applied to the first premiss of one yields the other:

No B are C	No C are B
EA1E: <u>All A are B</u>	EA2E: <u>All A are B</u>
No A are C	No A are C

From a logical point of view, one would expect people to perform the same on the members of a conversion pair, and this expectation is not disappointed: for the set of pairs $\langle \varphi, \psi \rangle$ which are intertranslatable by means of conversion alone, the correlation between the φ s and the ψ s is quite good ($r = 0.93$).⁴ This observation lends additional credit to the notion that many of the errors in syllogistic reasoning are caused by *illicit* conversion. This idea, which goes back to Wilkins (1928) and has since been supported by many researchers, comes in a variety of incarnations, the most promising of which is that people have a certain tendency to infer “All B are A” from “All A are B”, and likewise (though less importantly) “Some B are not A” from “Some A are not B”. Illicit conversion accounts in large part for the errors made in syllogistic reasoning. In Chater and Oaksford’s data, the 16 most frequently occurring erroneous inferences (endorsed 49–75% of the time) are all attributable to illicit conversion.

There is also independent evidence that people make conversion errors. In an experimental task with single-premiss arguments, about one-third of the participants will incorrectly convert “all” propositions, and for “some not” propositions about two-thirds will endorse conversion (Newstead & Griggs, 1983); performance on this task correlates with errors predicted by illicit conversion in syllogistic tasks (Newstead & Griggs, 1983). Further evidence for illicit conversion is the finding by Dickstein (1981) that more elaborate clarification of a syllogistic task substantially improves performance, but in a selective way: clarification is significantly less effective with conversion errors. Dickstein suggests that illicit conversion can be accounted for

by a general preference for symmetric relations, as demonstrated, for example, by Tsai (1977), and this explanation accords with the observation made above about the importance of *licit* conversion in syllogistic reasoning.

It has often been suggested that figure is a major factor affecting the difficulty of syllogistic arguments. Proponents of this view typically hold that syllogisms in figure 1 are the easiest, those in figure 4 are the hardest, while figures 1 and 3 lie in between (e.g. Evans, Newstead, & Byrne, 1993). Such claims are not entirely without foundation, but it is doubtful that they bear much weight. To begin with, we don’t find straightforward empirical support for the proposition that easier syllogisms tend to be in the lower figures. Amongst the ten easiest syllogisms in Table 1, figures 2 and 4 are represented twice each, while figures 1 and 3 are represented three times each, which indicates already that the figural effect, such as it is, is not a particularly strong one. Furthermore, it is unlikely that a figural effect could be particularly forceful in view of the fact that syllogisms which are conversion pairs tend to evoke similar responses; as we have just seen any two syllogisms that are identical up to conversion tend to be equally difficult, though conversion always entails a change in figure.

Dickstein (1978) observed that quite a few of the early reports on figural effects were flawed for various methodological reasons, but chiefly because they confounded potential figural effects with the effects of other variables, such as validity and illicit conversion (cf. also Rips, 1994). Dickstein argued that when all these factors are taken into account, only 12 argument forms remain that are suitable for testing the effects of figure. From an experiment with this restricted sample, he inferred that “figure is a significant determinant of performance *within a specific subset of syllogisms*” (p. 80, emphasis added). The tacit implication is that, when all proper precautions have been taken, it cannot be established that figure is a major factor in syllogistic reasoning.

Rather more impressive results have been reported by Johnson-Laird and his associates who showed that premisses of the form AB-BC encouraged subjects to produce AC conclusions, while premisses of the form BA-CB inclined them more towards CA conclusions; the other two ways of arranging terms in the premisses caused no clear preferences (Johnson-Laird & Bara, 1984; Johnson-Laird & Steedman, 1978). Johnson-Laird et al. attribute these results to two

factors: the fact that they adopt a production paradigm, which forces subjects to formulate their own conclusions, and, relatedly, the fact that subjects are allowed to draw AC as well CA conclusions, which effectively doubles the standard set of syllogisms from 256 to 512.⁵ However, a study by Wetherick and Gilhooly (1990), which had the same enlarged set of syllogisms but used a multiple-choice test instead of a production design, failed to replicate Johnson-Laird et al.'s findings, so it seems rather likely that it is the change of paradigm alone that is crucial.

It has often been suggested that figural effects are linguistic in origin (e.g., Rips, 1994; Wetherick & Gilhooly, 1990). The pattern found by Johnson-Laird et al. is that there is a preference for co-opting the subject of one of the premisses to fill the same grammatical slot in the conclusion. Given that the middle term (i.e., B) cannot figure in the conclusion, this simple rule predicts a preference for AC conclusions for figure 1 syllogisms, a preference for CA conclusions for figure 4 syllogisms, and no distinct preferences otherwise: in figure 2, the A and C terms both act as subject in one of the premisses, and in figure 3 neither of them do. The rationale behind the subject rule is obviously pragmatic. An argument is just a special kind of discourse, and one of the main structural principles underlying natural discourse is topic continuity: you keep talking about Fred, say, until other topics become more urgent, and whatever is the topic of conversation will tend to act as grammatical subject; that is what subjects are for, pragmatically speaking. This line of thinking explains why figural effects are so much stronger in production experiments than in other designs: a subject who has to formulate his own conclusion perforce relies more on his linguistic competence than one who just has to say yes or no, or choose from a list of alternatives. However, this account also implies that figural effects tell us little about deductive reasoning *per se*.

To sum up the main findings of our brief empirical survey, we have seen that validity is one of the main factors shaping performance in syllogistic tasks, and that a good deal of the errors in syllogistic reasoning are due to illicit conversion of A ("all") and O ("some...not") propositions. Conversion is central in a more general way, too, since syllogisms that are conversion pairs strongly tend to elicit equivalent responses. Finally, I considered so-called "figural effects", arguing that they are less substantial than they have been claimed to be, and suggest-

ing that such directionality effects as have been demonstrated are plausibly viewed as being linguistic not inferential in nature.

Although in its long history psychological research on syllogistic reasoning has accumulated a rich supply of experimental results, it must be noted that in a way its empirical base is rather narrow. Syllogistic logic covers only a fragment of predicate logic, and even predicate logic falls short of the plethora of deductive arguments expressible in natural language. Hence, there are ample opportunities for varying experimental materials, yet these opportunities have barely been explored. As far as I am aware, there have been no studies on cardinal quantifiers like "five", "at least six", "at most seven", etc., no studies on the role of negation in syllogistic reasoning, almost no studies on arguments with multiple quantifiers or relational predicates, and so on. Inevitably, this preoccupation with a handful of argument schemas demands its toll; for, as will be shown in the next section, *no* current theory can deal with certain extensions of the syllogistic language, some of which are downright trivial.

3. Psychological Theories of Syllogistic Reasoning

Over the years, many theories about syllogistic reasoning have been proposed, the large majority of which fall into one of three families: logic-based approaches, mental-model theories, and heuristic theories. The theory to be presented below belongs to the first family. Existing accounts in the logic-based tradition are mostly based on natural deduction, which is a species of proof theory developed by Jakowski and Gentzen in the 1930s.⁶ The inference rules for "&" cited in Section 1 are natural-deduction rules. The inference rules for the quantifiers are in the same format, as the following definitions for the universal quantifier illustrate; here " $\varphi[a/x]$ " denotes the result of replacing all free occurrences of x in φ with the individual constant a :

$$\frac{\forall x \varphi}{\varphi[a/x]} \quad \forall\text{-exploitation} \qquad \frac{\varphi[a/x]}{\forall x \varphi} \quad \forall\text{-introduction}$$

The basic idea is straightforward: if $\forall x \varphi$ is given one may derive $\varphi[a/x]$, for any individual constant a . Conversely, if we have $\varphi[a/x]$, and a was chosen arbitrarily, then we may conclude $\forall x \varphi$.⁷

Here is an example of a proof that involves both \forall -rules and both $\&$ -rules:

- [1] $\forall x [Px \& Qx]$ *premiss*
- [2] $Pa \& Qa$ \forall -*exploitation applied to* [1]
- [3] Pa $\&$ -*exploitation applied to* [2]
- [4] Qa $\&$ -*exploitation applied to* [2]
- [5] $Qa \& Pa$ $\&$ -*introduction applied to* [3]
and [4]
- [6] $\forall x [Qx \& Px]$ \forall -*introduction applied to* [5]

In words: since “ $Px \& Qx$ ” holds for all individuals x , the same must be true for an arbitrary individual a , and as “ $Pa \& Qa$ ” is true, Pa and Qa are true, as well; therefore, “ $Qa \& Pa$ ” is true, and since a was chosen arbitrarily, this holds for all individuals, and therefore “ $\forall x [Qx \& Px]$ ” cannot fail to be true. This proof illustrates how, in order to arrive at a quantified conclusion, we have to reason about arbitrary *individuals*. This setup leads to implausible consequences. Intuitively, one is inclined to say that “ $\forall x [Qx \& Px]$ ” follows directly from “ $\forall x [Px \& Qx]$ ” by transposition of the conjuncts. But in standard systems of natural deduction, this cannot be proved directly, since the proof has to go via arbitrary individuals. The problem is quite general, and affects syllogistic arguments, too. Consider, for example, the archetypical syllogism known since medieval times as “Barbara”:

All B are C
AA1A: All A are B
All A are C

As this is one of the easiest syllogisms, one should expect the conclusion to follow more or less immediately, but a standard proof will take no less than seven steps. In an attempt to remedy this type of problem, psychologists working with natural deduction have introduced further rules of inference, which enable the reasoner to make inferential shortcuts. For example, Rips (1994) postulates, in effect, that Barbara is a rule of inference, which means, of course, that the argument above becomes provable in one step.

From a logical point of view, such shortcut rules are simply pointless, since they don’t enhance the system’s logical power; they merely help to shorten some of the proofs. From a psychological viewpoint, however, this strategy is more objectionable. On the one hand, it is blatantly stipulative. Rips’ system, for example, predicts purely by fiat that AA1A and EA1E are easy, which of course diminishes the theory’s

explanatory potential. On the other hand, the introduction of shortcut rules raises the question of how deduction skills could ever develop. Consider the quantified version of “mental logic” by Braine (1998), which has no less than a dozen rules for reasoning with “all”. The system is highly redundant, and its redundancy has to be of just the right sort: practically any other collection of shortcut rules would yield different predictions about the relative difficulty of deductive arguments. How might such a system be acquired? On what grounds does a child “decide” that AA1A is easier than most other syllogisms, and therefore merits a special shortcut rule? Or, if mental logic is innate, why did Mother Nature fit us with *this* particular set of rules? Such questions are never easy, to be sure, but theories such as Braine’s and Rips’ add a whole new dimension to what is already a hairy issue, simply because it is unclear why any cognitive system should be redundant in one particular way, as opposed to (literally) infinitely many others.

Logic-based approaches to deduction tend to be more powerful than others in that they generalize more easily beyond syllogistic argument forms. Since natural deduction was designed as a method of proof for full predicate logic, systems based on this method have the logical resources for dealing with propositions containing multiple quantifiers and many-place predicates. Yet, such systems have their limitations, too, especially if we want to use them as psychological models. To begin with, some quantifiers, such as “most” and “at least half of” aren’t expressible in standard predicate logic at all. The reason for this, informally speaking, is that they refer to *sets*, not individuals. For example, “At least half of the foresters are vegetarians” states that the set of foresters who are vegetarians is not smaller than the set of foresters who aren’t. Since predicate logic only allows for talk about individuals, it is not expressive enough for representing such sentences. By the same token, any system of inference that deals with quantifiers in terms of arbitrary individuals cannot handle arguments like the following, if Q is replaced with “most”, say:

All Vegetarians are teetotallers
Q foresters are vegetarians
Q foresters are teetotallers

Intuitively, it doesn’t make much of a difference if Q stands for “all” or “most”, and experimental evidence confirms this impression (Oaksford &

Chater, 2001). However, even if it is granted that they are adequate for “all” and other universal quantifiers, current logic-based theories cannot be extended in a straightforward way to deal with “most” and its kin.

Even if a quantifier is expressible in predicate logic, the representations involved may be ill-suited for psychological purposes. Consider, for example, how “At least two foresters are teetotallers” goes over into predicate logic:

$$\exists x \exists y [x \neq y \ \& \ \text{forester}(x) \ \& \ \text{teetotaller}(x) \ \& \ \text{forester}(y) \ \& \ \text{teetotaller}(y)]$$

Since predicate logic doesn’t offer the means for talking about sets, a rather cumbersome representation is called for: we have to introduce two individual variables and ensure that their values are distinct and that both stand for a forester as well as a teetotaller. The complexity of this representation is proportional to the rank of the cardinal that needs to be represented: “At least n A are B” requires n variables and $0 + \dots + n - 1$ clauses of the form $x \neq y$. This peculiarity makes predicate logic an unlikely vehicle for reasoning with cardinal numbers. It entails, for example, that if we replace the Q in the argument above with “some” or “at least twenty”, the former argument should be much easier than the latter. This is intuitively false, and the intuition is corroborated by experimental evidence (see Section 5 below).

I have argued that the mental representations used by logic-based theories of reasoning are unsatisfactory. They are incapable of capturing even the simplest non-standard quantifiers, the hurdle being that in predicate logic we cannot speak and reason about sets. This is what renders it flatly impossible to represent proportional quantifiers, such as “most” and “at least half of”, and it is for the same reason that the predicate-logical way of dealing with cardinals yields representations that, though logically impeccable, are inadequate from a psychological point of view. And it is not only logic-based approaches that suffer from these problems: all extant theories of reasoning run into the same sort of trouble. To illustrate this, I will briefly discuss Johnson-Laird’s mental-model framework and the probabilistic treatment of quantification proposed by Chater and Oaksford.

In the theory of mental models developed by Johnson-Laird et al. over the past two decades, quantified propositions are represented directly in terms of arbitrary individuals. For example,

Table 2: Representation and Integration According to the Theory of Mental Models

	<i>Mental Model</i>		
<i>1st premiss: “All A are B”</i>	[a]	b	
	[a]	b	
<i>2nd premiss: “All B are C”</i>		[b]	c
		[b]	c
<i>Integrated model of the two premisses</i>	[a]	[b]	c
	[a]	[b]	c
<i>Extended model, i.e. counterexample against “All C are A”</i>	[a]	[b]	c
	[a]	[b]	c
			c

in the Bucciarelli and Johnson-Laird (1999) version of the theory, processing the premisses of AA1A (in non-canonical order) results in the suite of mental models shown in Table 2. Every line in a mental model represents an individual, so for the first premiss we have two individuals, which have the same properties, A and B. The second premiss gives rise to a similar model, which merges with the first so as to produce an integrated representation of the two premisses. This representation is a partial one; further information may be added, though not all possible extensions are allowed, with square brackets signalling that the property in question is “exhaustively represented”. Once the argument’s premisses have been encoded, preliminary conclusions can be formulated. In the case at hand, the integrated model verifies “All A are C” as well as “All C are A”, but as these conclusions are based on a partial model they are not necessarily valid, and have to be tested. This is done by trying to refute each of the preliminary conclusions by a counterexample: an extended model in which the premisses are still true but the conclusion is false. Such a counterexample can be found for “All C are A” (as shown in the last row of Table 2) but not for “All A are C”, so only the latter survives and is spelled out as the final conclusion.

One of the things critics of mental-model theory have complained about is that it is not quite clear what it is, not only because the theory has gone through so many revisions, but because its key tenets remain somewhat under-specified. Usually, a version of the mental-model theory comes with one or more computer implementations and a description of what these programs do, but in general this does not suffice to

pin down exactly what mental models are. To illustrate, while the first model in Table 2 is said to represent the proposition “All A are B”, we are also told that the model in the third row verifies the proposition “All C are A”. The former claim suggests that individuals representing the subject term must be enclosed in square brackets, to encode that its representation is exhaustive; the latter suggests that this is not necessary. It is only because mental models lack an explicit semantics that such inconsistencies tend to go unnoticed.

Or consider the sentence “Two A are B”. How can we represent this in a mental model? One might think that the first model of Table 2 is a plausible candidate, but this cannot be right, for two reasons at least. First, this model already represents the interpretation of “All A are B”, which is patently not synonymous with “Two A are B”. Secondly, if it takes two individuals to represent “two”, then presumably it takes sixty individuals to represent “sixty”, which gets us back to the same problem we discussed in connection with predicate-logical representations of cardinalities. This is not a coincidence, of course, since predicate logic and mental-model theory are both individual-based systems, which forswear reference to entities other than individuals. It is for this reason that the two accounts get into the same trouble with non-standard quantifiers.⁸

A rather different way of dealing with quantification is Chater and Oaksford’s probabilistic semantics, which underlies their “probability heuristics model” of syllogistic reasoning (Chater & Oaksford, 1999; Oaksford & Chater, 2001). According to Chater and Oaksford, humans are geared towards reasoning with uncertainty; we were designed by evolution to reason not logically but probabilistically, hence it is quite reasonable to ask for a probabilistic interpretation of quantified expressions. And for some quantifiers at least such an interpretation is easy enough to provide. Thus, “All A are B” means, probabilistically speaking, that $P(B|A) = 1$, i.e., the conditional probability of B given A equals 1. Similarly, “No A are B” conveys that $P(B|A) = 0$, and “Some A are B” that $P(B|A) > 0$. As a matter of elementary probability theory, the conditional probabilities of the premisses of a syllogism will occasionally restrict the conditional probability of the conclusion, and whenever this happens, “logical” inferences can be drawn (shudder quotes are called for here, because the probabilistic account implies that there is nothing logical about such inferences). For example,

if the conditional probability of the conclusion is 1, a proposition with “all” can be inferred.

One virtue of the probabilistic approach is that it affords a representation of proportional quantifiers, such as “most”: according to Chater and Oaksford’s definition, “Most A are B” means that $P(B|A)$ is high though less than 1. In this respect, a probabilistic semantics is more expressive than the approaches we have considered before, but it is still not expressive enough. In general, propositions involving cardinal quantifiers cannot be translated into a probabilistic format. For example, if it is given that “Two A are B”, we do not know what $P(B|A)$ is unless it is also known how many As there are. It might be proposed, therefore, that “Two A are B” means that $P(B|A) = 2/\text{card}(A)$ (where “card(A)” stands for the cardinality of the set of As). Thus, if there are five vegetarians altogether, “Two vegetarians are liberals” means that there is a 0.4 probability that a given vegetarian is a liberal. This proposal is up to a number of problems, the most obvious one being that it suffices for “Two vegetarians are liberals” to be true that there are two liberal vegetarians; the grand total of vegetarians is irrelevant. In brief, going probabilistic is tantamount to claiming that *all* quantifiers are proportional, which is unintuitive for some (like “some”) and demonstrably false for others (like the cardinals).

In the foregoing we have looked at each of the main approaches to deductive reasoning, and found that they all lack the expressive power for dealing with some quantifiers that would appear to be quite innocuous. I have focused my attention on cardinal expressions because they are common, simple, and yet manage to create problems of principle for all current theories. However, the trouble is not restricted to one or two types of quantifier; it is symptomatic of a much deeper problem, which is that all approaches to syllogistic reasoning are *ad hoc* from the vantage point of language understanding. It is a truism that solving a syllogistic task begins with an exercise in interpretation: how are the premisses (and, in some paradigms, the conclusion) to be construed? The range of possible answers to this question is restricted by what is known about the interpretation of quantified sentences, obviously, and as quantification happens to be one of the central topics in the field of natural-language semantics, one might expect semantic theorizing to have had at least some impact on psychological accounts of syllogistic reasoning. As it turns out, however, any such expectations will

be disappointed: thus far the impact has been practically nil.

And it is not as if the semantic theory hadn't made any progress on the subject of quantification. On the contrary, it is widely agreed that the past two decades have taught us a great deal about this topic, and there is even a broad consensus on what is the best general framework for dealing with quantified expressions. In the following I will argue that this framework goes a long way to explain how people reason with quantifiers.

The plan for the remainder of this paper is as follows. Since my central claim is that a psychological account of syllogistic reasoning presupposes an adequate theory of interpretation, I start out by discussing the general framework for treating quantification that semanticists have settled on. Research within this framework has shown that there are certain logical properties that are especially relevant to natural-language quantifiers, and I present an inference system that capitalizes on these properties. The resulting model of syllogistic reasoning is motivated almost entirely by semantical considerations. It is therefore not *ad hoc* in the way current theories of syllogistic reasoning are nor does it share their representational shortcomings.

4. Interpreting Quantifier Expressions

In the field of natural-language semantics, expressions like “all”, “most”, “some”, etc. are analyzed as denoting relations between sets, or generalized quantifiers.⁹ Thus, “All A are B” is taken to mean that the set of As is a subset of the set of Bs, while “No A are B” asserts that the intersection between the As and the Bs is empty. Formally, if we render “Q A are B” as “Q(A, B)”, and use $\|X\|$ to refer to the extension of a term (i.e., the set of all Xs), “all” and “no” are interpreted as follows:¹⁰

all (A, B) is true iff $\|A\| \subseteq \|B\|$

no (A, B) is true iff $\|A\| \cap \|B\| = \emptyset$

This style of interpretation extends in a natural way to other quantifying expressions. For example, “Some A are B” means that the intersection between the As and the Bs is nonempty:

some (A, B) is true iff $\|A\| \cap \|B\| \neq \emptyset$

“Three A are B” means that the cardinality of the intersection between the As and the Bs equals three:

three (A, B) is true iff $\text{card}(\|A\| \cap \|B\|) = 3$

Quantifiers like “most”, “many”, and “few” are more challenging, because they are vague and perhaps ambiguous, to boot. This is just to say, however, that they spell trouble for *any* semantic analysis. But the general kind of meaning they convey can be captured in the present framework without further ado. For example, to a first approximation at least “Most A are B” means that the majority of the As are B, i.e., that there are more As that are B than As that aren't:

most (A, B) is true iff $\text{card}(\|A\| \cap \|B\|) > \text{card}(\|A\| - \|B\|)$

One of the reasons why predicate logic is inadequate as a semantics for natural language is that it cannot express this kind of meaning, which *essentially* involves reference to sets.

Viewing quantifiers as relations between sets means that we can try and capture semantic distinctions and similarities amongst quantifying expressions in terms of properties of relations. There are various such properties that have proved to be especially relevant to natural-language quantification, two of which I want to single out here, viz. symmetry and monotonicity. According to the definitions just given, some quantifiers are symmetric while others are not. For example, “some”, “no”, and “three” are symmetric; “all” and “most” are not. Hence, it follows from the definitions above that the following propositions must be valid:

If some lawyers are crooks then some crooks are lawyers.

If no lawyers are crooks then no crooks are lawyers.

If three lawyers are crooks then three crooks are lawyers.

This prediction is confirmed by speakers' intuitions. The following, on the other hand, should not be valid:

If all lawyers are crooks then all crooks are lawyers.

If most lawyers are crooks then most crooks are lawyers.

This prediction, too, appears to be correct. Non-symmetric quantifiers are universal (English “all”, “every”, and “each”) or proportional, like “most” and “half of the”. The distinction between symmetric and non-symmetric quantifiers has been shown to manifest itself in several ways, the best-known of which is that in many

Table 3: Monotonicity Profiles of Some Quantifiers, with Diagnostic Tests

	Validity Test for A-Position	Validity Test for B-Position
$\text{all}(A^-, B^+)$	If all pachyderms are pink, then all elephants are pink.	If all elephants are navy blue, then all elephants are blue.
$\text{some}(A^+, B^+)$	If some elephants are pink, then some pachyderms are pink.	If some elephants are navy blue, then some elephants are blue.
$\text{some}(A^+, B^-)$	If some elephants are not pink, then some pachyderms are not pink.	If some elephants are not blue, then some elephants are not navy blue.
$\text{no}(A^-, B^-)$	If no pachyderms are pink, then no elephants are pink.	If no elephants are blue, then no elephants are navy blue.
$\text{at-least-three}(A^+, B^+)$	If at least three elephants are pink, then at least three pachyderms are pink.	If at least three elephants are navy blue, then at least three elephants are blue.
$\text{at-most-three}(A^-, B^-)$	If at most three pachyderms are pink, then at most three elephants are pink.	If at most three elephants are blue, then at most three elephants are navy blue.

languages, including English, existential *there*-sentences only admit symmetric quantifiers:

There are $\left\{ \begin{array}{l} \text{some} \\ \text{no} \\ \text{three} \\ \text{*all} \\ \text{*most} \end{array} \right\}$ lawyers on the beach.

The distinction between symmetric and non-symmetric quantifiers is also implicated in the interpretation of donkey sentences,¹¹ for example, and it plays an important role in the acquisition of quantifying expressions. It is well-known that young children tend to have difficulties interpreting propositions like “All the boys are kissing a girl”, as uttered of a scene with, say, three boys kissing one girl each plus one further girl who isn’t kissed by anyone. Children are prone to believe that the sentence is false in such a situation, but they never make analogous mistakes with symmetric quantifiers. Furthermore, it has been shown that previous exposure to sentences with symmetric quantifiers has an adverse effect on children’s performance with non-symmetric quantifiers, though not vice versa.¹² It appears, therefore, that symmetry is a key element in the acquisition of quantification, too.

Another property (or rather, family of properties) that looms large in the semantic literature is monotonicity. Like symmetry, this notion is not restricted to quantifiers, and I will introduce it with the help of a non-quantified example:

Fred’s tie is navy blue.

Fred’s tie is blue.

Since “navy blue” entails “blue” (the latter predicate applies to everything of which the former holds), the first sentence entails the second. The position occupied by “navy blue” in the first sentence is *upward entailing* (or monotone increasing), which is to say that truth will be preserved if “navy blue” is replaced with a term it entails. Similarly, it follows from “Fred’s tie isn’t blue” that “Fred’s tie isn’t navy blue”. The position occupied by “blue” in the first sentence is *downward entailing* (or monotone decreasing), which is to say that truth will be preserved if “blue” is replaced with a term it is entailed by (negation reverses monotonicity). Monotonicity is a very broad concept: in principle, any linguistic position may be upward or downward entailing, or neither (non-monotone). In particular, each quantifier has its own monotonicity profile. Consider, for example, the following proposition:

If all pachyderms are navy blue, then:

- (a) all pachyderms are blue, and
- (b) all elephants are navy blue.

Since everything that is navy blue is blue, (a) implies that the second argument position of “all” is upward entailing; and as “elephant” entails “pachyderm”, (b) implies that the first argument position is downward entailing. Using a plus sign for upward entailing and a minus sign for downward entailing positions, we can summarize the monotonicity profile of “all” thus: $\text{all}(A^-, B^+)$. Table 3 gives the monotonicity profiles of the syllogistic moods and two sentence schemas with cardinal quantifiers.

Note that “exactly three” is non-monotone in both of its argument positions. The following propositions, neither of which is valid, illustrate this for the first argument position:

If exactly three pachyderms are blue, then exactly three elephants are blue.

If exactly three elephants are blue, then exactly three pachyderms are blue.

The following proposition, on the other hand, is valid:

If three elephants are blue, then some elephants are blue.

This is because the position occupied by the quantifier “three” *itself* is upward entailing, and “three” entails “some”; it follows from the definitions given above that, for any pair of predicates A, B, if “three(A, B)” is true, then “some(A, B)” is true, as well. More generally, if we have a sentence of the form “Q(A, B)”, then the position occupied by Q is upward entailing; that is to say, this property holds irrespective of the quantified expression replacing Q.

It was already mentioned in passing that negative expressions reverse monotonicity: upward becomes downward, and vice versa. For example, if “all(A⁻, B⁺)” occurs within the scope of a negation operator, we get “not all(A⁺, B⁻)”, as witness the following, which are both valid:

If not all elephants are blue, then not all pachyderms are blue.

If not all elephants are blue, then not all elephants are navy blue.

There is one syllogistic mood which involves explicit negation, namely “some(A, not B)”, whose monotonicity profile is: “some(A⁺, not(B⁻)⁺)”. Note that the position within the scope of the negation operator is downward entailing, while the argument position as such, now occupied by a negated predicate, remains upward entailing.

Monotonicity has been shown to be involved in various semantic phenomena, including donkey sentences, the semantics of temporal connectives, co-ordination, and polarity; here I will briefly illustrate the latter two. Compare the following propositions, both of which are valid:

If at least five lawyers sang *and* danced, then at least five lawyers sang and at least five lawyers danced.

If at most five lawyers sang *or* danced, then at most five lawyers sang and at most five lawyers danced.

More generally, for some Qs, we may infer from Q(A, B and C) that Q(A, B) and Q(A, C), while for other Qs, the same conclusion may be drawn from Q(A, B or C). The former pattern holds for quantifiers that are upward entailing in their second argument position, and the latter holds for quantifiers that are downward entailing in that position. Since the predicate “sing and dance” entails “sing” as well as “dance”, each of which entails “sing or dance”, and “at least five” and “at most five” are, respectively, upward and downward entailing in their second argument, the facts observed above follow from the monotonicity properties of the quantifiers “at least five” and “at most five”.

All languages have negative polarity items, which are so-called because they typically occur within the scope of a negative expression, and are banned from positive environments. English negative polarity items are “any” and “ever”, for example:

Wilma { ^{*has}
doesn't have } any luck.

{ ^{*Someone}
No one } has any luck.

On closer inspection, it turns out that negative polarity items do not necessarily require a negative environment, though there certainly are constraints on where they may occur, as witness:

If Wilma has any luck, she will pass the exam.

*If Wilma passes the exam, she must have any luck.

Everyone who has any luck will pass the exam.

*Everyone who passes the exam must have any luck.

The generalization is that negative polarity items may only occur in downward entailing positions. In effect, a negative polarity item serves to *signal* that the environment in which it occurs is downward entailing, which goes to show that monotonicity is of some importance to languages and their speakers (Ladusaw, 1979, 1996).

The purpose of the foregoing survey was to explain why semanticists count symmetry and monotonicity among the most important properties of natural-language quantifiers. Assuming that they are right about this, it is not unreasonable to hypothesize that these properties play a

role in reasoning with quantifiers, as well. I will now try to show that this hypothesis is a fertile one.

5. A Monotonicity-Based Model of Reasoning with Quantifiers

In this section I present a very simple logic which builds on the observations made in the foregoing. In this logic all valid classical syllogisms are provable, but it goes far beyond traditional syllogistic logic in that it renders many other arguments valid, as well. The logic has three rules of inference, which follow directly from the interpretation of the quantifiers and negation. The logic's workhorse is monotonicity, which turns out to be implicated in every valid syllogistic argument. Once this logic is in place, it is not very difficult to produce a processing model that accounts for the data reviewed in Section 2.^{13,14}

To begin with, we need a formal syntax for our representation language, which is not too hard to provide, because the syntax of syllogistic logic is so simple. Matters are complicated slightly because we need a representation in which upward and downward entailing positions are made explicit, but this, too, is fairly straightforward.¹⁵

Vocabulary:

- basic terms: A, B, C, . . .
- quantifiers: all, some, no
- a special two-place predicate: \Rightarrow
- diacritical signs and brackets: $^+$, $^-$,

Syntax:

- If α is a basic term, then α^+ and $(\text{not } \alpha^-)^+$ are positive terms and α^- and $(\text{not } \alpha^+)^-$ are negative terms.
- If α is a negative term and β is a positive term, then $\text{all}^+(\alpha, \beta)$ is a sentence.
- If α and β are positive terms, then $\text{some}^+(\alpha, \beta)$ is a sentence.
- If α and β are negative terms, then $\text{no}^+(\alpha, \beta)$ is a sentence.
- If α and β are both either terms or quantifiers, then $\alpha \Rightarrow \beta$ is a sentence.

These rules generate the kind of strings we have been using already, like “ $\text{all}^+(\text{A}^-, \text{B}^+)$ ”, “ $\text{some}^+(\text{A}^+, (\text{not } \text{B}^-)^+)$ ”, and so forth. Since the position of negation is not restricted to the second term, this syntax also produces strings like “ $\text{all}^+((\text{not } \text{A}^+)^-, \text{B}^+)$ ”, for which there is no use in a syllogistic logic, but which will not be in the way, either. Other strings that aren't part of tra-

ditional logic, but are essential to ours, are of the form “ $\alpha \Rightarrow \beta$ ”, where α and β are either terms or quantifiers; this proposition may be read as “ α implies β ”. If A and B are terms, then “ $\text{A} \Rightarrow \text{B}$ ” means that all As are Bs. Hence, “ $\text{A} \Rightarrow \text{B}$ ” and “ $\text{all}(\text{A}, \text{B})$ ” are synonymous, and will accordingly be treated as notational variants. Implication is not restricted to terms; quantifiers may imply each other, too. For example, in traditional syllogistic logic (though not in predicate logic) “all” implies “some”, which is rendered in the present notation as “ $\text{all} \Rightarrow \text{some}$ ”.

These syntactic rules define the official language of our logic. In practice, however, we will drop the brackets enclosing negated terms, as well as all diacritics save for the ones required by the occasion. Thus, whenever a diacritical plus or minus appears it flags a position that is actually used in a proof.

Our chief rule of inference is the following:

$$\begin{array}{r} \alpha \Rightarrow \beta \qquad \beta \Rightarrow \alpha \\ \dots \alpha^+ \dots \qquad \dots \alpha^- \dots \\ \hline \dots \beta^+ \dots \qquad \dots \beta^- \dots \text{ MON} \end{array}$$

In words: any expression α occurring in an upward entailing position may be replaced with any expression β that is implied by α , and any expression α occurring in a downward entailing position may be replaced with any expression β that implies α .

Our second rule of inference is based on symmetry, and its application is therefore restricted to symmetric quantifiers; it is the conversion rule used already by Aristotle:

$$\frac{Q(\text{A}, \text{B})}{Q(\text{B}, \text{A})} \quad \text{CONV} \quad (Q = \text{“some” or “no”})$$

Without further provisions, MON and CONV suffice to prove 11 syllogistic arguments valid in predicate logic. In all cases the conclusion is derivable in one or two steps, using either MON alone or MON and CONV. The following proof of AE4E is as complex as it gets:

- [1] $\text{all}(\text{C}, \text{B})$ *premiss*
- [2] $\text{no}(\text{B}^-, \text{A})$ *premiss*
- [3] $\text{no}(\text{C}, \text{A})$ *MON applied to [1] and [2]*
- [4] $\text{no}(\text{A}, \text{C})$ *CONV applied to [3]*

Here MON applies to an argument, but the rule is not restricted to any particular category of

expression, and may affect negated terms, too, as in the following proof of AO2O:

- [1] all(C, B) *premiss*
- [2] some(A, not B⁻) *premiss*
- [3] some(A, not C) *MON applied to [1] and [2]*

The remaining valid syllogisms cannot be obtained with MON and CONV alone. This is partly due to the fact that MON is as yet restricted in its application to terms, but we also need one further rule:

no(A, B)
all(A, not B) *NO/ALL-NOT*

Like the conversion rule, this one follows directly from the meanings of the quantifiers involved. As it turns out, the effect of the NO/ALL-NOT rule will always be to feed into the MON rule. With our new rule, we can prove all 15 syllogisms that are valid in standard predicate logic. The following proof, of syllogism EI3O, uses all rules introduced thus far:

- [1] no(B, C) *premiss*
- [2] some(B, A) *premiss*
- [3] some(A, B⁺) *CONV applied to [2]*
- [4] all(B, not C) *NO/ALL-NOT applied to [1]*
- [5] some(A, not C) *MON applied to [3] and [4]*

This is a relatively long proof, but then the syllogism is not an easy one.

The remaining syllogisms are not valid in standard predicate logic, because they require the presupposition that “all” and “no” range over non-empty domains of quantification. Slightly more accurately: traditional logic has it that “all(A, B)” and “no(A, B)” entail that there are As. In terms of generalized quantifier theory, this is to say that these quantifiers are construed as follows:

all(A, B) is true iff $\|A\| \neq \emptyset$ and $\|A\| \subseteq \|B\|$
no(A, B) is true iff $\|A\| \neq \emptyset$ and $\|A\| \cap \|B\| = \emptyset$

There is a simple way of capturing this presupposition in our system, namely by adding the following axiom, which just says that “all” implies “some”:

all \Rightarrow some *ALL/SOME*

Again, this addition is licensed directly by the interpretation of the quantifiers involved (as construed in traditional logic), and as with the

NO/ALL-NOT rule, the main function of ALL/SOME will be to feed into the MON rule. With this new axiom, “some(A, B)” can be derived from “all(A, B)”, courtesy of the MON rule, and “some(A, not B)” becomes derivable from “no(A, B)”, because NO/ALL-NOT gives us “all(A, not B)”, from which “some(A, not B)” follows through MON. The following proof of syllogism EA2O illustrates the use of ALL/SOME:

- [1] no(C, B⁻) *premiss*
- [2] all(A, B) *premiss*
- [3] no(C, A) *MON applied to [1] and [2]*
- [4] no(A, C) *CONV applied to [3]*
- [5] all⁺(A, not C) *NO/ALL-NOT applied to [4]*
- [6] some(A, not C) *MON applied to [5] and ALL/SOME*

Thus, all valid arguments can be accounted for with a handful of inference rules that follow directly from the semantics of the logical vocabulary of syllogistic logic: “all”, “some”, “no”, and “not”.

What remains to be shown is how this logic can be embedded in a processing model. In principle, there are many ways of doing this, but for current purposes it will suffice to show that even a crude processing model can produce reasonable predictions. Let us assume, therefore, that inference rules are applied in a breadth-first fashion until the right sort of conclusion is found or no new inferences can be made. What the “right sort of conclusion” is depends on the task. In an evaluation paradigm, it is the conclusion specified by the experimenter, or its negation; in a multiple-choice paradigm, any one of the given conclusions is of the right sort; and in a production paradigm, any sentence of the syllogistic language is of the right sort.¹⁶ Since inference rules are applied breadth-first, the system is guaranteed to find a minimal proof that isn’t longer than any other proof (if a proof exists, that is). In many cases, there will be more than one minimal proof of a valid syllogism, but these will only differ in the order in which inference steps are made: the rules will be the same, and so will the number of inferences.¹⁷

As is common in logic-based accounts, I take it that the complexity of a syllogism is determined chiefly by the number of inference steps needed to get from the premisses to the conclusion. In the present case, this is to say that the length of any minimal proof is the main predictor. But there is another factor, as well, viz. grammatical structure. It is a well-established fact

Table 4: Predicted Difficulty of Valid Syllogisms According to the Model Described in the Text, Compared with Chater and Oaksford's Scores (in Parentheses)

AA1A	80	(90)	OA3O	70	(69)	EA1O	40	(3)
EA1E	80	(87)	AO2O	70	(67)	EA2O	40	(3)
EA2E	80	(89)	EI1O	60	(66)	EA3O	40	(22)
AE2E	80	(88)	EI2O	60	(52)	EA4O	40	(8)
AE4E	80	(87)	EI3O	60	(48)	AE2O	40	(1)
IA3I	80	(85)	EI4O	60	(27)	AE4O	40	(2)
IA4I	80	(91)	AA1I	60	(5)			
AI1I	80	(92)	AA3I	60	(29)			
AI3I	80	(89)	AA4I	60	(16)			

that more syntactic structure makes a sentence harder to process, and as deduction tasks always involve sentence processing, it doesn't come as a surprise that grammatical complexity plays a role in reasoning, too. Grammatically speaking, three quarters of all syllogistic propositions have the same structure: "Q A are B". However, O-propositions have the form "Some A are not B", and should therefore be harder to process than propositions in the other moods.

Putting these considerations together, I propose the following model. Our abstract reasoner starts out with a budget of 100 units, which are used to pay for inferences and grammatical complexity, according to the following rules:¹⁸

- For every use of MON, subtract 20 units.
- For every use of NO/ALL-NOT, subtract 10 units.
- If a proof contains an O-proposition, subtract 10 units.

For reasons discussed in Section 2, I assume that CONV is for free. That the NO/ALL-NOT rule is cheaper than MON is plausible, too, because the latter rule combines information from two propositions, whilst the former merely maps one proposition onto another. Table 4 shows the predicted difficulty of all valid syllogisms alongside the scores of Chater and Oaksford's meta-study (cf. Table 1). The correlation between the two is good ($r = 0.93$).

We now have a monotonicity-based model which accounts quite well for people's performance on valid syllogisms, which was one of our main objectives, because validity is the major factor in syllogistic reasoning, as I argued in Section 2. In the same section, we saw that many errors in syllogistic reasoning can be put down to illicit conversion of propositions with "all" and "some . . . not". This is something that is easily incorporated in our model. We only need to

extend CONV so that it applies not only to propositions with "some" and "no" but also to propositions with "all" or "some . . . not". However, we still want to differentiate between licit and illicit conversion, because the latter is less common than the former. Therefore, we assume that, unlike its legal counterpart, illicit conversion is not for free: it costs 20 units. Even with illicit conversion, most syllogisms remain unprovable, and we simply assume that an unprovable syllogism sets the reasoner back by 80 units, which is the price of the most difficult argument that does have a proof (with illicit conversion).¹⁹ This model makes quite reasonable predictions for the complete set of syllogisms, with $r = 0.83$, and if we set aside the syllogisms which are probably under-valued by Chater and Oaksford's figures because, in the experiments analyzed by Chater and Oaksford, they had to compete with other syllogisms, then $r = 0.88$.

The main virtue that I claim for my account is that it extends in a natural way beyond the confines of traditional syllogistic logic. For example, it is a trivial exercise to incorporate cardinal quantifiers, like "at least n ". From a semantical point of view, "at least n " is of the same type as "some": both are symmetric quantifiers that are upward entailing in both of their argument positions. The proposed account predicts, therefore, that arguments with "at least n " will be equally complex as corresponding arguments with "some", regardless the size of n .

Ceteris paribus, I would predict that "at most n " affects the complexity of an argument in the same measure as "at least n " does, for the following reason. The main difference between "some" and "no" is that whereas the former is upward entailing the latter is downward entailing in both of its argument positions. Therefore, whenever we have commensurable arguments with "some" and "no", they should be equally

complex. This prediction is borne out by the data (see the Chater and Oaksford (1999) figures for AEE/EAE and AII/IAI arguments). Moreover, “at most n ” is of the same semantic type as “no”: they are both symmetric quantifiers that are downward entailing in both argument positions. Hence, by transitivity, “at least n ”, and “at most n ” should be equally difficult.

However, all things are not equal: considerations extraneous to the proposed model suggest that “at most n ” may be more difficult than “at least n ”. There is a wealth of linguistic and psychological evidence which shows that in pairs like “tall–short”, “many–few”, “happy–unhappy”, etc., the first member, which is in a sense the positive one, enjoys a privileged status (see Horn, 1989, for a survey). Linguistically, the negative form is marked, which means that it does not figure in all environments that admit its positive counterpart. For example, one normally would ask, “How tall is Fred?”, not “How short is he?”. Psychologically, negative expressions take longer to process, cause more errors, and are harder to retain than positive ones. Now, it seems likely that “at least n –at most n ” will follow the pattern of “tall–short”, “many–few”, and “happy–unhappy”, and if it does, arguments with “at most n ” will be more difficult than arguments with “at least n ”, presumably because the representation of “at most n ” contains a negative element: “At most n A are B” is represented as “Not more than n A are B”. In terms of our semantical framework, this means that we must not interpret “at most n ” directly:

at-most- n (A, B) is true iff $\text{card}(\|A \cap B\|) \leq n$

Instead, “at most n ” is interpreted as the negation of “more than n ”:

more-than- n (A, B) is true iff $\text{card}(\|A \cap B\|) > n$

From a logical point of view, these interpretations are equivalent (“at-most- n (A, B)” and “not more-than- n (A, B)” always have the same truth value), but linguistically as well as psychologically they are different.

To summarize: I predict that “at least n ” is of the same complexity level as “some”, for any n , whereas “at most n ” is more difficult. In order to test these predictions, I conducted an experiment in which subjects were presented with syllogistic arguments involving (the Dutch equivalents of) “some”, “at least n ”, and “at most n ”, where n was an integer between 20 and 30 (the variation was used as a precaution against inter-

ference between tasks). The terms of each syllogism were randomly selected from a small collection of nouns like “forester”, “communist”, “poet”, and so on. For each quantifier Q , there were four arguments to be assessed:

Figure 1	Figure 2	Figure 3	Figure 4
All B are C	All C are B	All B are C	All C are B
Q A are B	Q A are B	Q B are A	Q B are A
Q A are C	Q A are C	Q A are C	Q A are C

Note that the arguments in figures 1 and 3 are valid if the B-positions in “Q A are B” and “Q B are A” are upward entailing, and invalid otherwise; similarly, the arguments in figures 2 and 4 are valid if the B-positions in “Q A are B” and “Q B are A” are downward entailing, and invalid otherwise. With three quantifiers and four argument schemata, there were 12 syllogistic arguments altogether, which were alternated with one-premiss arguments like the following:

At least 24 communists own a blue bicycle.

At least 24 communists own a bicycle.

Note that this is a monotonicity argument, too, though it should be easier than the corresponding figure 1 syllogism, because it is shorter.

Since I had to make do without the usual experimental facilities, I cajoled 23 friends and relations into taking the test. All participants were native speakers of Dutch with an academic degree in psychology or linguistics, but no previous exposure to logic.

The results of the experiment are presented in Table 5.²⁰ To analyze these data, a repeated measures ANOVA was conducted with three within-subject factors: quantifier (“at least”, “at most”, “some”), argument length (one or two premisses), and validity (valid or invalid). This yielded main effects for quantifier ($F(2, 44) = 14.533, P < 0.001$) and argument length ($F(1, 22) = 12.517, P < 0.002$), but not for validity. There were interactions between quantifier and argument length ($F(2, 44) = 6.466, P < 0.009$) and quantifier and validity ($F(2, 44) = 4.926, P < 0.018$). Further analysis of these two interactive effects tied them to arguments featuring “at most”; in both cases there were significant differences between arguments with “at most” and “some” (quantifier/argument length: $P < 0.010$; quantifier/validity: $P < 0.033$) and between arguments with “at most” and “at least” (quantifier/argument length: $P < 0.017$; quantifier/

Table 5: Percentage of Correct Responses in the Experiment Described in the Text, with Standard Deviations in Parentheses

	<i>1 Premiss</i>	<i>2 Premisses</i>	<i>Valid</i>	<i>Invalid</i>	<i>All</i>
At least	97 (9)	92 (14)	96 (10)	93 (14)	95 (8)
Some	95 (11)	90 (12)	93 (14)	91 (14)	92 (8)
At most	89 (15)	67 (24)	70 (21)	87 (22)	78 (15)

validity: $P < 0.016$). There were no significant differences between “at least” and “some”. In order to determine if any of the differences between arguments with the same quantifier were significant, t -tests were conducted with quantifier and argument length and quantifier and validity as factors. These tests, too, attained significance only for arguments with “at most”: $t = 3.792$ ($P < 0.001$, two-tailed) and $t = -2.577$ ($P < 0.017$, two-tailed), respectively.

These results are consistent with our main predictions: that there is no relevant difference between “some” and “at least”, and that arguments with “at most” are more difficult. But at the same time they cloud the picture somewhat, because it turns out that the strictly additive measure of complexity that underlies our model is not quite adequate. It is not as if *any* argument with “at most” is harder than parallel arguments with “some” or “at least”; rather, it is valid and/or two-premiss arguments with “at most” that are more difficult than others. This, however, is a concern not only for the present proposal but for all current theories of deductive reasoning.

Of the two interactions found in this study, the one between quantifier type and validity is the most troubling, in my view. Earlier on in this chapter I argued that valid arguments tend to be easier than invalid ones (see Section 2), and now we find that some valid arguments are harder than their invalid counterparts. This need not be a contradiction, of course, but I do believe that there is a serious problem lurking here. It is that thus far we lack a good understanding of why people reject some arguments as “not valid” or maintain that “nothing follows” from a given set of premisses. If someone says that a conclusion φ does not follow, it may be either because he has a proof of “not φ ” or because he doesn’t know how to prove φ . These are quite different things, obviously, but the evaluation task used in our experiment doesn’t distinguish between the two. Other experimental techniques are more discriminating in this respect, but even the paradigms which allow

subjects to say that “nothing follows” are relatively crude instruments because there is likely to be more than one possible reason why someone should think that “nothing follows”; for example, he may judge that a given conclusion, though correct, is pointless or odd.²¹ In brief, this is a topic that calls for more, and better, experimentation.

6. Concluding Remarks

One popular way of characterizing logical inference is that a conclusion φ follows logically from a set of premisses $\psi_1 \dots \psi_n$ if the *meanings* of φ and $\psi_1 \dots \psi_n$ alone guarantee that φ is true if $\psi_1 \dots \psi_n$ are. It is not the facts but the meanings of its component propositions that render an argument valid or invalid. Hence, in order to understand logical inference we must understand how arguments are interpreted: no inference without interpretation. I have endeavoured to demonstrate that this slogan applies with a vengeance to syllogistic reasoning.

The main virtues of the model I have presented are the following. First and most importantly, my account is based on a system of inference that is independently motivated by the meaning of its logical vocabulary: “all”, “no”, “some”, and “not”. Second and relatedly, this system can be extended in a straightforward and principled way not only to the non-classical quantifiers but across the board. Third, the model predicts a complexity ranking that fits well with the experimental data. Fourthly, the current proposal is simpler than any other theory that covers the same ground, including “fast and frugal” heuristic models of syllogistic reasoning like Chater and Oaksford’s.

Methodological considerations aside, the key element in my proposal, which distinguishes it from all previous accounts in the psychological literature, is that it drops the assumption that syllogistic reasoning is always in terms of *individuals*. Generalized-quantifier theory leads us to expect that reasoning with quantifiers is done

in terms of *sets* instead, and I have tried to show that a processing model based on this assumption can be quite successful.

Logic-based approaches to deduction have been criticized on a number of counts. There is a popular view that ordinary folk are bad at logical reasoning, and that, consequently, it is a priori unlikely that they employ anything like a mental logic. A related argument, advanced by Chater and Oaksford (Chater & Oaksford, 1999; Oaksford & Chater, 2001), among others, is that everyday reasoning is not logical, so that whatever it is people do when they solve deduction tasks cannot be logic. Arguments along these lines invariably rely on carefully selected evidence. To a large extent, the rumour that people aren't good at logic is based on experimental data on conditional reasoning. In particular, it has been demonstrated again and again that subjects fail in large numbers on certain versions of the Wason task. But then conditionals rank high among the more controversial topics in semantics and the philosophy of language; at present, it is simply unclear what their logic *is*, and therefore we lack a sound normative theory against which subjects' performance can be assessed. Moreover, even if it had been established that performance on *some* conditional-reasoning tasks is poor from a logical point of view, there are scores of logical inferences that people are quite good at, like the following, for example:

The butler and the chauffeur have an alibi.

The chauffeur has an alibi.

I take it to be self-evident that very few people will have problems with this, and the experimental work of Braine, Reiser, and Romain (1984) proves, if proof is required, that there are lots of arguments like this. Such bread-and-butter inferences tend to pass unnoticed, but we are making them all the time, and it would be far-fetched to deny that they are logical inferences, pure and simple.

Another objection against logic-based accounts of reasoning has been made by evolutionary psychologists (e.g., Cosmides, 1989; Cosmides & Tooby, 1992; Gigerenzer & Hug, 1992). Logic-based theories, so the criticism goes, assume that we have a mental logic which is a domain-independent instrument for reasoning about anything that happens to arouse our interest. But how did we acquire this general-

purpose tool? There is precious little evidence that our parents teach us how to reason, nor is it clear how evolution could have hit upon such a device. It seems rather likely that Mother Nature equipped us with specialized modules for reasoning about physical objects, social relationships, snakes and spiders, and so forth, but it is utterly mysterious how a full-blown logical faculty could be the outcome of natural selection. I sympathize with this line of argument, and have used it myself to criticize previous logic-based theories of reasoning (Section 3). However, this criticism takes for granted a view on mental logic that I believe is wrong. Though it may be that some elementary notions of logic are innate, mental logic must not be conceived of as an autonomous module of the mind. As I have said a number of times already, and as I have illustrated in the foregoing with syllogistic reasoning, there has to be an intimate connection between the meaning of an expression and valid arguments which make essential use of that expression. Mental logic is largely a concomitant of our linguistic prowess, and though it is still a matter of controversy where *that* came from, nobody will doubt that we *have* it.

Notes

- 1 Sometimes, in the psychological literature, the premisses trade places, and conclusions of the form "C A" are admitted, as well; such variations can affect the outcome of an experiment, as we will see below.
- 2 However, this is not to say that I endorse the traditional notion of validity wholesale. Researchers in semantics and pragmatics generally agree that a universal quantifier *presupposes* that its domain is non-empty, and presupposition is not the same as logical consequence (see, for example, Geurts, 1999; Horn, 1989). Strictly speaking, therefore, the nine syllogisms that separate the two notions of validity have a different status, because they are contingent upon the presuppositions of "all" and "no". And this distinction is relevant from a psychological point of view, too, since the 15 syllogisms valid in predicate logic are easier than the ones that are valid in traditional logic only.
- 3 Not shown in Table 1 is the percentage of times subjects concluded that "nothing follows" from a given pair of premisses. Such non-propositional conclusions (as they have been called) raise some highly problematic issues, but as far as I can tell none of these has any bearing on the principal tenets of this paper.

- 4 As is customary in set theory, I count φ , ψ and ψ , φ as two pairs. If they are counted as one, the number of conversion pairs is halved, and we are faced with the question of what is supposed to correlate with what. This question is a delicate one, because the members of a conversion pair are connected by a symmetry relation, and there is no principled criterion for separating between the factors of the correlation. However, I expect that in practice this would not matter very much, because some random separations I tried out yielded scores that didn't deviate too much from the one quoted in the text.
- 5 Note that allowing AC as well as CA conclusions yields the same collection of syllogisms as allowing the order of the premisses to vary.
- 6 Sundholm (1983) gives a nice introduction, to natural deduction, and compares it to older Frege-Hilbert style systems.
- 7 To say that a was chosen arbitrarily means that a may neither occur in φ nor in the premisses (if any) from which φ was derived.
- 8 Johnson-Laird, Byrne, and Tabossi (1989: 672) remark in passing that “[t]he model-based theory is readily extendible to deal with non-standard quantification” (cf. also Johnson-Laird, 1983: 443). In view of the considerations adduced in the foregoing, however, such claims must be wrong.
- 9 The concept of generalized quantifier was introduced by Mostowski in 1957, and imported into natural-language semantics by Barwise and Cooper (1981), whose article remains one of the best introductions to the subject. Generalized quantifiers may be viewed not only as relations between sets, as I do here, but also as functions from sets to families of sets. From a logical point of view, one perspective is as good as the other, but the former is more natural and more adequate from a processing perspective.
- 10 In these definitions I adopt the truth-conditional stance on meaning, and explicate the meaning of a sentence by specifying the circumstances under which it is true (“iff” is an abbreviation of “if and only if”). Readers not familiar with truth-conditional semantics can take “is true iff” as synonymous with “means that”.
- 11 Donkey sentences are so-called after the classic example of Geach (1962), “Every farmer who owns a donkey beats it.” See Kanazawa (1994) and Geurts (2002) for more recent discussion.
- 12 Smith (1979, 1980). See Drozd (2001) and Geurts (2001) for discussion of symmetry in the context of language acquisition.
- 13 I am by no means the first to observe the importance of monotonicity to syllogistic reasoning. Indeed, it may be argued that the concept is implicit in the traditional *dictum de omni* and the notion of so-called distributed occurrence of terms. The most thorough discussion of the role monotonicity plays in syllogistic inference is by Sánchez Valencia (1991).
- 14 A caveat: my main concern in this paper is with the representations used in reasoning with quantifiers. The processing model presented below is my official proposal, to be sure, but whatever interest it has lies chiefly in the rules and representations it employs. I have nothing new to say about reasoning errors, and nothing at all about reasoning strategies. Concerning the latter point, I consider it quite likely that people employ different types of reasoning strategies, which may involve different types of representation (as, for example, Ford, 1995, has argued), but in this paper I confine my attention to one particular type.
- 15 For monotonicity marking in less trivial languages, see Sánchez Valencia (1991) and Dowty (1994).
- 16 More sophisticated models can be obtained by refining the notion of “right sort of conclusion”, which is somewhat simplistic as it stands. Such refinements should account for the fact that we prefer to draw conclusions that are non-trivial and relevant to our current purposes – which may be rather a tall order.
- 17 As the number of valid syllogisms is quite small, this can easily be proved by enumeration of alternatives.
- 18 Of course, this talk of “reasoning budgets” is merely a picturesque alternative to the common procedure of assigning numerical weights to inference rules. It must be admitted that it is not entirely clear what such weights stand for. The basic idea surely is that weights represent processing effort, but this notion is inappropriate if we allow for illicit inference rules. I will not attempt to sort out this matter here.
- 19 This is admittedly stipulative, but it is not entirely arbitrary because it means, in the present model, that the reasoning system begins to falter after four or five inference steps – which seems quite reasonable to me. Still, this is a matter that calls for a more refined treatment.
- 20 I am indebted to Frans van der Slik for carrying out the analyses reported in the following and helping me interpret the results.
- 21 A case in point is the well-known fact that the seemingly trivial step from “It is raining” to “It is raining or snowing” is actually quite hard to take, though it doesn't seem right to say that the inference is especially complex; it is just *odd* that someone should want to draw this conclusion. Some researchers have, implicitly or explicitly, rejected this diagnosis. Thus, Braine, Reiser, and Romain (1984) set up their “mental logic” in such a way that it is very hard to derive “ φ or ψ ” from φ alone. However, this also makes

the following argument virtually impossible to prove:

$$\begin{array}{l} \varphi \\ \text{If } \varphi \text{ or } \psi, \text{ then } \chi \\ \chi \end{array}$$

Subjects typically find it very easy to see that this is valid, and therefore Braine et al. have no choice but to stipulate that this is a valid pattern of inference. I have criticized such manoeuvres in Section 3, and argued that they should be avoided at all costs. There is quite a bit more to say about this matter, but I will not say it here.

Chapter 13: The Problem of Deduction

ROBERT C. STALNAKER

Our main concern is not with the explanation of rational action generally but with the particular cluster of rational activities which are directed toward answering the questions about the way the world is. Engaging in inquiry is of course itself a form of rational behavior and the pragmatic picture implies that such behavior should be explained according to the same belief-desire pattern as the naive, unreflective behavior of dogs and children. But in order to treat the special problems that arise in explaining those actions which explicitly concern the evaluation and modification of the agent's beliefs, we need a more specialized apparatus designed to describe that specific kind of activity. We need to be able to talk about an agent's beliefs about his beliefs, about the form in which his beliefs are expressed, and about the ways in which his beliefs may change in response to his experience.

The concept of *acceptance* will be a central concept in the account of inquiry developed here. Acceptance, as I shall use this term, is a broader concept than belief; it is a generic propositional attitude concept with such notions as presupposing, presuming, postulating, positing, assuming and supposing as well as believing falling under it. Acceptance is a technical term: claims I make about acceptance are not intended as part of an analysis of a term from common usage. But I do want to claim that this technical term picks out a natural class of propositional attitudes about which one can usefully generalize. Belief is obviously the most fundamental acceptance concept, but various methodological postures that one may take toward a proposition in the course of an inquiry or conversation are sufficiently like belief in some respects to justify treating them together with it.

To accept a proposition is to treat it as a true proposition in one way or another – to ignore, for the moment at least, the possibility that it is false. One may do this for different reasons, more or less tentatively, more or less self-consciously, with more or less justification, and with more or less feeling of commitment. As a rough criterion, one may say that a propositional attitude concept is an acceptance concept if the attitude is said to be *correct* whenever the proposition is true. Belief is an acceptance concept because a correct belief is a true belief. Correct here contrasts with justified. To say that a belief was correct is not to say it was adequately supported; to say that an assumption was correct is to say nothing about whether the assumption should have been made. Correct beliefs, assumptions, suppositions and presumptions are beliefs, assumptions, suppositions and presumptions the contents of which are true. A correct desire or hope, however, is not one that will in fact be satisfied, nor is a judgment that *P* is highly probable said to be correct because *P* turns out to be true. Thus this criterion distinguishes acceptance concepts from so-called pro attitudes like wishes and wants, from mixed emotive-cognitive attitudes like hope and fear, and from attitudes of partial belief or acceptance as represented by subjective probabilities.

Within this class of propositional attitudes there is considerable diversity. To accept a proposition is to act, in certain respects, as if one believed it, but there are several ways in which acceptance, in the intended sense, may differ from belief, and in which acceptance concepts may differ from each other. First, acceptance may have a social dimension. In a cooperative inquiry, a dialogue or a debate, what *we* accept

may be more important than what *I* accept. It is our common beliefs and assumptions, or what we take to be our common beliefs and assumptions, that will set the boundaries of our discussion and determine its direction. No matter how convinced you are that something is true, if it is what I am disputing, then you beg the question by accepting it in the context of our argument.¹

Second, acceptance may be more passive or more active. As noted in [chapter 4 of *Inquiry*], some propositions may be taken for granted or presupposed by a person only because the possibility of their being false has never occurred to him, while others are explicitly accepted after reflection or investigation. Some people may be reluctant to apply the term “belief” to tacit presuppositions, but they are among the propositions accepted.

Third, a person may accept a proposition for the moment without the expectation that he will continue to accept it for very long. If a person expects a particular one of his *beliefs* to be overturned, he has already begun to lose it, but an assumption he makes may be quite explicitly temporary, and he may presume that something is true even when expecting to be contradicted.

Fourth, what a person accepts can be compartmentalized in a way in which what he believes cannot be. A person may accept something in one context, while rejecting it or suspending judgment in another. There need be no conflict that must be resolved when the difference is noticed, and he need not change his mind when he moves from one context to the other. But something is wrong if I have separate incompatible sets of beliefs for different circumstances. I cannot reasonably believe what I disbelieved yesterday without thinking that yesterday’s belief was mistaken.

Finally, acceptance may be the product of methodological decision rather than subjective commitment. One may accept something for the sake of the argument, although one cannot believe things for this reason. The judge may direct the members of the jury to accept something, although he cannot reasonably direct them to believe it. In these ways, acceptance may diverge from belief, although belief is a kind of acceptance.

Ignoring for the moment the important differences between different kinds of acceptance, think of an inquirer as a person in an initial *acceptance state* preparing to perform some actions which are intended to lead to a change in that state. Following the strategy discussed in [chapter 4 of *Inquiry*], I will define an acceptance

state not as a set of propositions accepted, but as a nonempty set of possible situations – the possibilities that remain open for an agent in the acceptance state. The set of propositions accepted contain just those propositions that are true in all of these possible situations. This way of defining belief and acceptance states has the advantages previously discussed: it imposes on the set of propositions accepted a structure that is motivated by the pragmatic-causal picture; it allows for a natural account of unconscious beliefs, tacit presuppositions and enthymematic reasoning. But it has the disagreeable consequence that the set of propositions accepted relative to an acceptance state is always consistent and deductively closed, which seems to imply that an inquirer never has inconsistent beliefs and always accepts all the consequences of any set of propositions every member of which he accepts. And this consequence is not just a rationality condition imposed on a set of propositions accepted, but a condition that follows from the definition of an acceptance state. So one cannot soften the disagreeable consequence by calling it an ideal which ordinary acceptance states strive for. If acceptance is to be defined in this way then acceptance states, however far from the ideal, must meet the consistency and closure conditions. Thus the model of acceptance that I will develop faces the problem of deduction in a particularly acute form.

To discuss the problem of deduction, I will distinguish three deductive conditions on the set of propositions determined by an acceptance state, all of which must hold if acceptance states are to be defined in terms of possible situations in the way I have suggested. Then I will argue that each of the conditions, applied to belief, is motivated by the pragmatic picture. Finally, I will try to show how they can be reconciled with the phenomena. The three conditions are as follows:

1. If *P* is a member of a set of accepted propositions, and *P* entails *Q*, then *Q* is a member of that set.
2. If *P* and *Q* are each members of a set of accepted propositions, then *P*&*Q* is a member of that set.
3. If *P* is a member of a set of accepted propositions, then not-*P* is not a member of that set.

Beliefs, according to the pragmatic picture, are conditional dispositions to act. A rational agent

is, in general and by definition, disposed to act appropriately, where what is appropriate is defined relative to his beliefs and desires. To say that an agent believes that *P* is to say something like this: the actions that are appropriate for that agent – those he is disposed to perform – are those that will tend to serve his interests and desires in situations in which *P* is true. But this is not quite right for the following reason: it would be too strong to require that appropriate actions tend to serve the agent's ends in *any* possible situation in which one of his individual beliefs is true. Suppose I believe, as I do, that someone will be elected President of the United States in 1988. One way in which that proposition could be realized is for *me* to be the one elected, but I know that that is not the way my belief will come true. For my actions to be appropriate, given that I have this belief, it is surely not required that I take account of that possibility, since it is excluded by other of my beliefs. The actions that are appropriate for an agent who believes that *P* depend not only on what he wants but also on what else he believes. So it is necessary to define appropriateness relative to a total set of beliefs, or a belief state. And all that matters about such a belief state, as far as the appropriateness of actions or the agent's dispositions to act are concerned, are the entailments of the belief state. So there is no basis, on the dispositional account, for excluding from the set of an agent's beliefs any propositions that are entailed by his beliefs. That is, there is no basis, given the pragmatic account of belief, for defining the set of propositions believed, relative to a belief state, in a way that conflicts with the first deductive condition.

If one accepts this, then the argument for the second deductive condition is straightforward. If a person is in a belief state that entails both *P* and *Q*, then he is in a belief state that entails the conjunction of *P* and *Q*. If a person is, in general, disposed to act in ways that would tend to be successful if *P* (together with his other beliefs) were true and is also disposed to act in ways that would be successful if *Q* (together with his other beliefs) were true, then he is disposed to act in ways that would be successful if *P*&*Q* (together with his other beliefs) were true. But while the second deductive condition is a reasonable one, given the pragmatic account, to impose on the propositions determined by a belief state, it is not a reasonable condition to impose on the totality of an agent's beliefs. It is compatible with the pragmatic account that the rational dispositions that a person has at one time should arise from

several different belief states. A person may be disposed, in one kind of context, or with respect to one kind of action, to behave in ways that are correctly explained by one belief state, and at the same time be disposed in another kind of context or with respect to another kind of action to behave in ways that would be explained by a different belief state. This need not be a matter of shifting from one state to another or vacillating between states; the agent might, at the same time, be in two stable belief states, be in two different dispositional states which are displayed in different kinds of situations. If what it means to say that an agent believes that *P* at a certain time is that some one of the belief states the agent is in at that time entails that *P*, then even if every set of propositions defined by a belief state conforms to the second deductive condition, the total set of propositions believed by an agent might not conform to that condition.²

The same distinction can be made with respect to the third deductive condition – the consistency condition. Applied to the set of propositions determined by a single belief state, it must hold. This is clear since the only set of propositions conforming to the first two conditions but violating the third is the set of all propositions, and no belief state in which all propositions were believed could distinguish any actions as appropriate or inappropriate. But if an agent can be in distinct belief states at the same time in the way suggested above, then there is no reason why these belief states cannot be incompatible. In such a case an agent would believe both a proposition and its contradictory, but would not therefore believe everything. It would still be possible in such a situation to explain the agent's actions as rational actions according to the usual pattern.

I noted above, in distinguishing belief from acceptance in general, that acceptance may be compartmentalized in a way that belief cannot. Now I am suggesting that an agent may at one time be in separate, even incompatible belief states. But there is no conflict here. The earlier point was not that an agent's beliefs *are* always integrated into a single state, but rather that they ought to be. A person's beliefs are defective if they do not fit together into a single coherent system. An agent who recognizes the consequences of the conjunction of separate beliefs must either accept the consequences or abandon one of the original beliefs. An agent who discovers a conflict between his separate beliefs must modify them in some way. One cannot agree to disagree with oneself.

There are, then, two ways in which the second and third deductive conditions apply to belief. First, they are *defining* conditions of the concept of a belief state. Second, they are *rationality* conditions on the set of all beliefs that an agent has at one time. They are rationality conditions on an agent's beliefs because, ideally, an agent's beliefs should be integrated into a single system.

In calling the closure and consistency conditions rationality conditions, I do not mean to imply that an agent whose beliefs fail to conform to them is irrational but only that his beliefs diverge from an ideal of perfect rationality. The ideal is perhaps one that is never met, but that is an imperfection in rational agents, not in the model of rationality. The fact that the ideal is unrealistic does not threaten the adequacy of the theory because one can still use the theory to describe coherently the dispositions of agents whose beliefs diverge from the ideal, and to explain their actions as rational actions.

I also want to emphasize that it is not implied that conforming to the rationality conditions is an easy or a mechanical task. If the contents of beliefs were like sentences and belief were something like assent, then it would be a simple matter of noting and remembering what one is doing to put a belief that *P* and a belief that *Q* together into a belief that *P*&*Q*. But on our account, beliefs are behavioral dispositions. Separate belief states are dispositions which are displayed in different kinds of situations. To integrate such belief states is to change one's dispositions so that the actions one is disposed to perform in the two kinds of situations are appropriate relative to the same belief state – the same conception of the way the world is. To change one's rational dispositions in this way may require only a routine calculation, or it may be a challenging and creative intellectual task. It is this kind of task, I want to suggest, that deductive inquiry is designed to accomplish.

There are two complementary parts to the strategy I am suggesting for treating the problem of deduction. The first, discussed at the end of [chapter 4 of *Inquiry*], begins with the observation that it may be a nontrivial problem to see what proposition is expressed by a given sentence. The apparent failure to see that a proposition is necessarily true, or that propositions are necessarily equivalent, is to be explained as the failure to see what propositions are expressed by the expressions in question. Relative to any propositional expression one can determine two propositions: there is the proposition that is

expressed, according to the standard rules, and there is the proposition that relates the expression to what it expresses. If sentence *s* expresses (according to the standard rules) proposition *P*, then the second proposition in question is the proposition that *s* expresses *P*. In cases of ignorance of necessity and equivalence, I am suggesting, it is the second proposition that is the object of doubt and investigation.

The second part of the strategy begins with the observation that it may be a nontrivial problem to put separate beliefs together into a single coherent system of belief. All of my actions may be rational in that they are directed toward desired ends and guided by coherent conceptions of the way things are even if there is no single conception of the way things are that guides them all. There may be propositions which I would believe if I put together my separate systems of belief, but which, as things stand, hold in none of them. These are the propositions whose truth might be discovered by a purely deductive inquiry.

Is this a plausible strategy for explaining deduction? Given the very general conception of content and information that we are using, I think it can be seen as a natural, even inevitable, strategy. There are two questions posed by the problem of deduction: first, what is the nature of the information conveyed in a statement about deductive relationships? Second, how do we acquire this information? The first part of the strategy responds to the first question; the second part responds to the second question.

According to the conception of content that lies behind the possible worlds analysis of propositions and propositional attitudes, content requires contingency. To learn something, to acquire information, is to rule out possibilities. To understand the information conveyed in a communication is to know what possibilities would be excluded by its truth. Now if one asks, what real possibilities are excluded when one learns that a necessary truth is true, the answer is clear: they will not normally be situations in which extralinguistic facts are different than they actually are, but they will be possible situations where the rules for determining the truth value of the statement yield a different result from the result they actually yield.

For some examples of necessary truths, pointing this out would be sufficient to reconcile necessity with the possibility of ignorance. If someone is ignorant of the fact that all ophthalmologists are eye doctors, this is probably because he is ignorant of the meaning of one

of the words in that statement. The relevant possible situations which his knowledge fails to exclude are ones in which the *sentence* "all ophthalmologists are eye doctors" means something different from what it actually means. If a person is ignorant of the fact that Hesperus is Phosphorus, it is because his knowledge fails to exclude a possible situation in which, because causal connections between names and objects are different, one of those names refers to a different planet, and so the statement, "Hesperus is Phosphorus" says something different than it actually says. In both of these cases, there is clearly a piece of factual information which the person ignorant of the truth of a necessary truth is missing. Empirical inquiry, about language or about astronomy, is what is needed to straighten the situation out. But in the case of ignorance of mathematical truths and deductive relationships, there are no such pieces of missing factual information in terms of which the ignorance can be explained, and that is why, even given the answer to the first question, there remains a puzzle about the second. Deductive inquiry is concerned neither with lexicography nor with causal connections between names and things in the world. The information which one receives when one learns about deductive relationships does not seem to come from outside of oneself at all. It seems to be information which, in some sense, one has had all along. What one does is to transform it into a usable form, and that, it seems plausible to suppose, is a matter of putting it together with the rest of one's information.

If this conception of deductive inquiry is to fit the facts, then even to account for straightforward mechanical deductive problems one will have to postulate a large number of concurrent but separate belief states. According to the pragmatic picture, many separate belief states means many separate dispositions, each with its own domain of display. This can be plausible only where there is a natural way to match up separate beliefs with actions – where there is some basis independent of what the agent happens to do for saying which of his many belief states is relevant to explaining which of his actions. If the belief that *P* is to be kept distinct from the belief that *Q*, there must be some actions appropriate to the belief that *P* and some actions appropriate to the belief that *Q* which are different from the actions that are appropriate to the belief that *P*&*Q*. This is, I think, exactly the situation in mathematics. The answer to the first question about deductive knowledge suggested that the subject matter of mathematical proposi-

tions is notation or structures exhibited in notation. The actions that are made appropriate by belief in distinctively mathematical propositions are actions of manipulating notation: calculating in particular ways and making moves in the construction of proofs. Because mathematical beliefs concern expressions, it is easy to find actions that manifest belief in particular propositions without manifesting belief in other stronger propositions which have them as consequences. To take a simple case of calculation, a person may display his belief that four plus three equals seven by performing certain operations on numerals that contain four and three as digits – for example by writing down "7" as the first step in adding sixty-four to twenty-three. A person who is competent at doing sums but not particularly quick or intuitive could manifest his separate beliefs that four plus three equals seven and that six plus two equals eight in calculating the sum of sixty-four and twenty-three, but he would show that before doing the calculation, he did not have the belief that sixty-four plus twenty-three is eighty-seven. That last belief results only after the two simpler arithmetic beliefs were put together against a background of more general beliefs and presuppositions about arithmetic operations.³

The thesis that acquiring deductive knowledge is putting one's separate belief states together will not, by itself, throw much light on the process of deductive inquiry. It says nothing about how one goes about answering questions about deductive relationships; the focus is not on the means of deductive inquiry, but on its end, and even the end is described only in very abstract terms. But our concern is not with the special features of deductive inquiry. The problem this thesis is intended to solve is the problem of finding a way to describe deductive inquiry as a special case of inquiry in general, a way which brings out the common features which the search for mathematical knowledge shares with the search for knowledge about the world. We need a framework in which one can give analyses of such concepts as knowledge, explanation, inference, and justification which allows for their application to both mathematics and empirical investigation.

The goal of inquiry, in both cases, is the acquisition of knowledge, and this is most naturally thought of as the receiving of information from outside. The simple conception of the inquirer adjusting his beliefs in response to new data, or filling in further details in his picture of the world as a result of interaction with it obviously

fits empirical contexts more comfortably than mathematical ones. But the account of deduction as the integration of the separate belief states of a single agent provides a way to apply this conception to deductive inquiry as well. Inquiry in general is a matter of adjusting one's beliefs in response to new information, but in the case of deductive inquiry, the information that initiates the change is new, not to the agent, but only to one of his belief states. By dividing the agent into separate centers of rationality, we make it possible to see the processing of the information an agent already has as a phenomenon with the same structure as the reception of new information.

Whether this kind of account of deduction will work remains to be seen. One needs to look carefully at more detailed and challenging examples of mathematical questions, and at particular problems in the epistemology of mathematics. But I will assume that it gives us a way around the problem of deductive ignorance and inquiry – that it at least shows that the existence of deductive ignorance and inquiry is not an immediate refutation of the assumptions I am making about propositions, propositional attitudes, and inquiry.

Even if the deductive constraints on acceptance can be reconciled with the existence of deductive inquiry in the way I have suggested, there are other objections to them which must be answered. First, there are apparent counterexamples to the first deductive condition – that a person accepts any proposition that is entailed by any single proposition that he accepts. It is not obvious how the suggestion that a person's beliefs can be divided among separate belief states is relevant to explaining counterexamples to this principle. Second, there are examples and arguments that purport to show that the deductive principles are not acceptable even as rationality conditions. Sometimes, it has been suggested, one may reasonably accept each member of a set of propositions while not accepting their conjunction, even when one sees all the relevant deductive connections. I will discuss several such examples, some of them familiar in the literature, and try to show how the deductive constraints on acceptance can be defended against them.

I will begin with two counterexamples to the first deductive condition, as applied to belief. (1) William III of England believed, in 1700, that England could avoid a war with France. But avoiding a war with France entails avoiding a nuclear war with France. Did William III believe

England could avoid a nuclear war? It would surely be strange to say that he did. (2) The absentminded detective believes that the butler did it. There is no direct evidence of his guilt, but the detective has made what he thought was an exhaustive list of the possible suspects, investigated them one by one, and eliminated everyone except the butler. The problem is that he completely forgot about the chauffeur, who had both motive and opportunity. Would it be correct to say that the detective believes that the chauffeur did not do it? He does believe that no one other than the butler did it – that was essential to his reasoning – and this entails that the chauffeur did not do it. But it would be misleading to say that the detective had this belief, since that seems to suggest that the chauffeur was one of the suspects eliminated from his list.

Even if it is strange or misleading, I am not sure whether it would be literally incorrect to say that William III and the absentminded detective had these beliefs. It is not that the king was in doubt about nuclear war or that the detective suspended judgment on the chauffeur's guilt. If these propositions were not believed, they were at least tacitly presupposed, and so they were propositions which were accepted in some sense. One way or another, the king and the detective ignored the possibility that the propositions in question were false. So the examples do not threaten the principle that one must *accept* the deductive consequences of any proposition one accepts, even if they do refute the principle as applied to a more specific kind of acceptance such as belief. The examples do not suggest that acceptance states should be defined in a different way, but at most that different acceptance concepts may be used to categorize the propositions entailed by a single acceptance state.

Perhaps for it to be true that x believes that P , it is necessary that x understand the proposition that P , or that x have entertained the proposition that P . If so, then it is too simple to identify the propositions believed with the entailments of a belief state. One would have to say that the beliefs were the entailments of a belief state which met certain further conditions. One might, for example, define the *active* beliefs of an agent as those propositions which are entailed by a belief state, but not entailed by the weaker acceptance state which determines the tacit presuppositions. This would ensure that an agent's beliefs would include only propositions which distinguish between possibilities that he recognizes.

Compare some other propositional attitudes where it is clearer that this kind of move is necessary. The first analogy is with wanting. If a rational man *wants* it to be the case that *P*, and recognizes that *P* entails *Q*, must he want it to be the case that *Q*? If wanting it to be the case that *P* is wanting one of the possible worlds in which *P* is true to be the actual world, then it would seem that the consequence condition should hold for wanting. One cannot rationally want *P* to be true without *Q*, since that is a logical impossibility, and there are no possible worlds, desirable or undesirable, in which logical impossibilities are realized. But there are persuasive counterexamples to the consequence condition on rational wants. Suppose I am sick. I want to get well. But getting well entails having been sick, and I do not want to have been sick. Suppose there was a murder. I want to know who committed the murder. But my knowing who committed the murder entails that the murder was committed, and I never wanted the murder to have been committed. One can reconcile these examples with a qualified consequence condition by noting that wanting something is preferring it to certain relevant alternatives, the relevant alternatives being those possibilities that the agent believes will be realized if he does not get what he wants. Some propositions which are entailed by propositions that one wants to be true in this sense are also entailed by the relevant alternatives. It is not that I want these propositions to be true – it is just that I accept that they will be true whether I get what I want or not. Given that there was a murder, I would rather know who committed it than not know. The question of whether or not I look with favor on the fact that there was a murder – whether I am glad that it happened or wish that it had not – does not arise in that context. To raise *that* question, one needs to expand the set of relevant alternatives, to compare the actual situation with possible situations in which the murder never took place.

The qualified consequence condition for rational wants motivated by these considerations is this: the propositions one wants to be true (relative to a set of relevant alternative possibilities) includes all the consequences of any proposition one wants to be true *which distinguish between the relevant alternatives*.

The second analogy is with epistemic concepts such as knowledge and justified belief. Suppose all justification is local in the sense that it takes place against a background of beliefs and presuppositions which themselves need not be justified, at least in that context. Then justi-

fied belief, and perhaps knowledge, will conform only to a qualified consequence condition such as the one discussed above for rational wants. Here is an example, taken from an article by Fred Dretske, which tends to support such a conclusion. You are at the zoo next to the zebra cage with your son. The zebras are in plain view and the sign on the cage says “zebra.” Your son asks you what they are, and you tell him. Do you *know* that they are zebras? Of course. But that they are zebras entails that they are not mules cleverly disguised by the zoo authorities to look like zebras. Do you know that they are not mules cleverly disguised in this way? Dretske suggests that you do not. The hypothesis that they are mules may not be very plausible; it is surely reasonable to ignore the possibility that they are. But you must admit that if they were disguised mules, things would look exactly as they in fact look. The kinds of reasons you have for ignoring this hypothesis – general considerations of plausibility – do not seem sufficient to give you knowledge.⁴

The example is, of course, a typical Cartesian skeptic’s example. Given the assumption that a person knows all the known consequences of anything known, the example supports the conclusion that you do not *really* know that the animals you see are zebras. But Dretske suggests abandoning the consequence condition instead of the knowledge claim. This is not the place to discuss the adequacy of this response to the skeptic. The point I want to make here is just that this kind of context-dependent conception of justification and knowledge which rejects the consequence condition for propositions known or justifiably believed is compatible with the possible worlds analysis of states of knowledge and belief. In fact, the possible worlds framework allows for a natural formulation of such a conception.

Let me now consider some examples and arguments, drawn from the work of Henry Kyburg, which go against the second deductive condition, the conjunction principle. First, the notorious lottery paradox. I have ticket number seven in a fair lottery with a million tickets. “Consider the hypothesis ‘ticket number seven will not win. . . .’ There is only one chance in a million that the hypothesis is false. Surely . . . this is reason enough to accept the hypothesis.” The same reasoning applies to each of the other tickets, and so I should accept every hypothesis of the form “ticket *i* will not win.” But I cannot consistently accept the conjunction of all these hypotheses since I know that some ticket will win.⁵

The weak point in this argument, I think, is the assumption that a probability of .999999 is sufficient for acceptance. Why should a probability of .999999 be a reason for doing anything more than believing the hypothesis to degree .999999? The practical difference between accepting a hypothesis and believing it to degree $1 - \epsilon$ may, in some cases, become negligible as ϵ diminishes, but there does seem to be a significant difference in this case. If the price of the ticket is low enough, and the value of the prize is great enough, it is rational for me to buy a ticket even if I will benefit from the purchase only if I win. But my purchase is rational, on this assumption, only if I leave open the possibility that I might win. The day that the winning ticket is announced, I learn that ticket number seven did not win. My attitude toward the hypothesis that ticket seven would not win changes. I do not come to accept that a proposition I already accepted was true – that would be no change at all. Rather, I learn that a hypothesis I was almost sure of is indeed true.

One could easily enough define a concept of acceptance which identified it with a high subjective or epistemic probability (probability greater than some specified number between one-half and one), but it is not clear what the point of doing so would be. Once a subjective or epistemic probability value is assigned to a proposition, there is nothing more to be said about its epistemic status. Bayesian decision theory gives a complete account of how probability values, including high ones, ought to guide behavior, in both the context of inquiry and the application of belief outside of this context. So what could be the point of selecting an interval near the top of the probability scale and conferring on the propositions whose probability falls in that interval the honorific title “accepted”? Unless acceptance has some consequences, unless the way one classifies the propositions as accepted, rejected, or judgment suspended makes a difference to how the agent behaves, or ought to behave, it is difficult to see how the concept of acceptance can have the interest and importance for inquiry that it seems to have.

If the conjunction principle governs the concept of acceptance, then it is clear that one can say something, at least, about the consequences of acceptance: to accept a proposition is to permit oneself to put that proposition together with any others that one accepts, and draw any consequences that may follow. Reasoning in this way

from accepted premises to their deductive consequences (P , also Q , therefore R) does seem perfectly straightforward. Someone may object to one of the premises, or to the validity of the argument, but one could not intelligibly agree that the premises are each acceptable and the argument valid, while objecting to the acceptability of the conclusion. But given a probabilistic rule of acceptance (accept P if and only if the probability of P is at least as great as some fixed number between one-half and one), just knowing that P has the status *accepted* would give you no license to put it together with anything else. One would have to know; among other things, the probability on which the proposition achieved that status.

Another paradox, closely related to the lottery paradox, is the paradox of the preface. In the preface to his historical narrative, the author admits that he has undoubtedly made some mistakes – that some of the statements he made in his narrative are false. He is not confessing to insincerity – he continues to *believe* everything he wrote – he is just confessing to fallibility. It does not take excessive modesty to believe that *some* of one’s many beliefs or sincere assertions are false. This is only reasonable. Yet to believe this is to believe each member of a set of propositions that are recognized to be inconsistent. If these propositions were conjoined and their consequences accepted, the result would be to accept the truth of every proposition.

The paradox of the preface and the lottery paradox are alike in that both may be used to support the conclusion that a person may sometimes be justified in accepting all the members of a recognizably inconsistent set of propositions. But the two paradoxes are different in at least one important respect. The assumption that high probability is sufficient for acceptance is essential to the argument of the lottery paradox. One response to that paradox – the one I endorsed – is to reject that assumption. But the paradox of the preface does not depend on that assumption and cannot be answered in the same way. It cannot plausibly be denied that the author *accepts* the truth of each of the statements made in his narrative, nor can it be denied that he accepts that at least one of those statements is false. But it also seems plausible to say that the author accepts, or at least commits himself to, any conjunction of the statements in the narrative. In presenting his narrative, the author is aiming at a coherent total story. It is, in fact, a methodological constraint on a historian’s

construction of his narrative (as on a scientist's interpretation of his results) that the propositions he accepts fit together into a coherent story. Unless one can freely conjoin propositions, it is difficult to see how considerations of coherence can play the methodological role which they obviously play in inductive procedure.

So the historian does not intend his confession of fallibility to prevent the reader from putting together the different statements made in telling his story. He intends only that the reader recognize that the story as a whole is undoubtedly wrong in some of its details. But the fact remains that the author denies in his preface something that is entailed by what he asserts in his narrative, and the reader is obviously not supposed to conjoin these contradictory accepted propositions. So I agree with Kyburg in rejecting a global conjunction rule for accepted propositions, even as a rationality condition. This is not because high probability is sufficient for acceptance; it is rather because sometimes it is reasonable to *accept* something that one knows or believes is false.

When is it reasonable to accept something one believes is false? When one believes that it is *essentially* true, or close to the truth – as close as one can get, or as close as one needs to get for the purposes at hand. It is not obvious how one judges a false proposition, or a whole story, to be roughly or essentially correct, or even what one is judging when one does, but it is obvious that people do make such judgments and that they play a role in their decisions about what to accept. Sometimes these decisions are based on practical considerations. Accepting a certain false proposition may greatly simplify an inquiry, or even make possible an inquiry not otherwise possible, while at the same time it is known that the difference between what is accepted and the truth will have no significant effect on the answer to the particular question being asked. When a scientist makes idealizing assumptions, he is accepting something for this kind of reason. Particles or planets may be treated as point masses, the atmosphere may be assumed to be a vacuum, consumers or governments may be thought of as rational. Of course in other inquiries these same assumptions might greatly distort the results, but the scientist might be in a position to know that in his inquiry they would not. The scientist does not, of course, *believe* the propositions he accepts, but he acts, in a limited context, as if he believed them in order to further his inquiry.

Even if an inquiry has no practical motivation – even if one's aim is just to tell a story right – a divergence between acceptance and belief may be reasonable. The historian in the example believes that his narrative is *mostly* right, and the doubts he does have about it are based on general considerations of fallibility. What more effective way does he have to say just what he is *sure* of than to tell the story as best he can, and then add, in the preface, that it is probably only roughly true. Here his motive for accepting what he does not believe is that doing so is an efficient means of telling what he does believe.

I am suggesting that one may accept, for various reasons, what one does not believe, but one may not, of course, believe what one does not believe or reasonably believe what one believes is false. The explanation of the preface phenomenon that I am suggesting requires that we say that the historian does not, without qualification, *believe* that the story he accepts is correct; nor does he believe, without qualification, all of the individual statements he makes in telling the story. We must say this to reconcile the phenomenon with a conjunction condition as a rationality condition for belief. But isn't this what we do want to say? The historian, when he wrote his preface, was not just making some additional statements for the reader to believe along with those in his narrative; he was taking something back. It is a conjunction condition for belief, together with a consistency condition, which explains why the reader takes the preface as a hedge or a qualification to the text.

Kyburg has a more general reason for rejecting the conjunction principle as a rationality condition on belief: he believes that it leads to a distorted picture of the process of inductive inquiry. He points out that any system of acceptance rules that includes the strong deductive conditions will require that there be "essentially only *one* hypothesis that we may induce from given evidence. Anything else we are allowed to induce will turn out to be merely an implicate of the evidence and that one strongest hypothesis."⁶ "This approach . . . suggests that as scientists or even as people we do not induce hypothesis by hypothesis, but that induction consists in principle of inducing at each stage of inquiry . . . a single monumentally complex conjunctive statement."⁷ "It is preposterous to suppose that all our inductive knowledge has to be embodyable in a single fat statement."⁸

Kyburg is of course right that if rational belief conforms to the strong deductive conditions,

then an ideal state of rational belief could be represented by a single proposition – a proposition that is itself believed and which entails all propositions believed by someone in that ideal state. It is because of this fact that it is possible to represent any belief state meeting the strong deductive conditions by a single set of possible worlds. But is this so preposterous? Some of the things Kyburg says make this consequence seem more implausible than it is.

First, Kyburg's remarks suggest that he has a linguistic picture of the objects of propositional attitudes in mind. The strongest accepted proposition is described as a "monumentally complex conjunctive statement." But on the possible worlds conception of proposition, the complexity of a statement is in the means of representing a proposition and not in the proposition itself. And the fatter the statement, the thinner the proposition, since a proposition is defined by the possible worlds in which it is true. Some of Kyburg's reservations about the consequences of the conjunction principle may derive from questionable assumptions about the structure of propositions.

Second, it must be kept in mind that a global conjunction rule is a rationality condition for belief, which means that conjunction or integration of separate beliefs is an ideal that believers aim at rather than a feature essential to the set of a person's beliefs. It may be preposterous to suppose that anyone's inductive knowledge or beliefs actually do get embodied in a single very fat (or very thin) proposition, but that by itself does not threaten the normative force of the ideal.

Third, while it is true that any state of belief which conforms to the conjunction principle *can* be represented by a single strongest proposition, it does not follow from this that that representation has any special methodological status. Despite Kyburg's claims to the contrary, the conjunction principle does not prevent people from inducing hypothesis by hypothesis, or require them to reevaluate all of their beliefs every time they receive a new piece of evidence. The description of a rational change of belief as the replacement of one fat conjunctive hypothesis with a different one may seem to suggest that every belief change must be a scientific revolution, but if it does so, then it is a misleading description. Nothing implied by the conjunction principle says that one can't replace one fat conjunctive hypothesis with another one simply by tinkering with one of the conjuncts. Nothing

implied by the conjunction principle requires one to ignore the fact that some propositions have nothing to do with one another. Where the evidence for or against one proposition is irrelevant to another and where the actions to which the truth or falsity of the one proposition is relevant are distinct from the actions to which the truth or falsity of the other are relevant, then believing the conjunction of the two propositions is no different from believing them separately. To recognize their independence is to conjoin or integrate them in the only way that is required.

Still, I think there is a real problem which Kyburg is pointing to, not a problem with the conjunction principle but a limitation of the possible worlds representation of a belief or acceptance state. The problem can be most clearly seen by considering how one might represent a change in what one accepts – a change brought about by a discovery of information that conflicts with something that one initially accepts. If a belief state is represented by a set of possible situations, then in the case of this kind of change the initial belief state and the new one must be represented by disjoint sets of possibilities. The two sets will have no possibilities in common, even if the change of belief is, intuitively, a very small one. At this level of abstraction, there is no difference between a discovery that one was mistaken about some small isolated factual detail and a scientific revolution or global conversion. In both cases, *all* of the possibilities compatible with one's initial belief state are incompatible with the new one. But surely an adequate account of inquiry must account for such extreme differences.

It might seem that a representation of a belief state as a list of sentence-like propositions would more easily and naturally account for what is preserved in a belief change, and for the difference between minor and major belief changes. And so in terms of such a representation, it might be easier to state and defend rules for revising belief in response to discoveries that conflict with one's initial beliefs, or at least to put constraints on such rules. The following kind of rule of revision, for example, might seem initially plausible: add the new information to the list of propositions believed that constitutes one's initial belief state, and then delete from the list the items which are incompatible with the new information. But there are well-known problems here. There will not, in general, be a unique consistent revision of the list, since the new information may require

the deletion of one of a set of items without requiring the deletion of any particular one of them. And one cannot adequately compare the magnitude of a belief change simply by counting the propositions changed, since there will be logical and conceptual relations between them. A list of propositions believed will not be a list of independent pieces of information.

A simple abstract example will illustrate the problem. Suppose two agents, George and Harry, both begin by believing both P and Q , and then discover that P is false. George rejects Q along with P , while Harry retains his belief in Q . Isn't it obvious that George's beliefs change more than Harry's? Not necessarily, for P and Q won't be George and Harry's only initial beliefs. If they recognize the obvious consequences of their beliefs, then both of them will also believe, for example, $P \vee \sim Q$. Harry, to remain consistent, must give up this belief when he learns that P is false, while George need not. Each must choose between his belief that Q and his belief that $P \vee \sim Q$, and it is not obvious that one change is more minimal than the other.

This may seem artificial. One might argue that Q is more basic than $P \vee \sim Q$. The latter is believed only because P is believed, while the former is believed independently. But this may or may not be true. One cannot infer from the logical complexity of $P \vee \sim Q$ that belief in it is epistemically dependent on its parts. If George has some independent reason to believe $P \vee \sim Q$ then it will seem perfectly reasonable to take it, together with the new information that P is false as a reason for rejecting Q .

A belief change in response to conflicting information will always force one to choose between alternative revisions, none of which can be seen, on logical grounds alone, to be preferable to the others. The choice will depend on assumptions about epistemic and causal dependence and independence, on the reasons one has for one's beliefs as well as on the beliefs themselves. Whether we represent belief states by lists of sentences or by sets of possible worlds, we will need to impose additional structure on our notion of a belief state before we can say very much about the way beliefs change or ought to change in response to new information.

The abstract example we used above is reminiscent of the examples used by Nelson Goodman to refute various proposed analyses of counterfactual conditionals.⁹ The problem of belief change in response to conflicting information is closely related to Goodman's problem; a solu-

tion to one is likely to come together with a solution to the other. It was the main negative lesson of Goodman's early paper on counterfactuals that one cannot analyze this kind of statement using only logical relations such as logical independence, compatibility and entailment, together with unproblematic factual assumptions. Some additional, more substantive relations between propositions were needed. The possible worlds analysis of propositions – an analysis Goodman would have no use for – is obviously not the source of Goodman's problem, or of the related problem about belief change. What this analysis does is to make the problems manifest by representing propositions in terms of their minimal logical structure, thereby removing the illusion that we have some account of the structure of possibilities and of the intuitive notions of dependence and independence, similarity and difference between possibilities, which a solution to the problems will require.

The abstract possible worlds framework treats possible worlds as unstructured points. This is not, of course, because the theory makes a claim that possible worlds are some kind of simple unstructured object, but because the theory seeks to capture what is essential and common to a diverse range of applications. The structure of possibilities may be very different from one context to another, but in any interesting context possible situations will be quite complex, and the way we represent and express propositions as well as the way we respond to new information will depend on the structure of the possible worlds in terms of which the propositions and propositional attitudes states are defined. Possible worlds will normally have spatiotemporal structure, domains of individuals instantiating properties and standing in relations to each other. The facts and states of affairs that constitute a possible world may be more or less independent of each other. In terms of the structure of a possible world, one might characterize various relations of similarity and difference between possible worlds, and in terms of such relations one might say more about rational belief change and more generally about the process of inquiry.

Let me conclude by describing the picture of inquiry that has emerged from our discussion so far. A state of belief is most perspicuously represented, not by a set of sentences or propositions believed, but by the set of possibilities recognized as ways the world may be. Propositions believed, relative to such a belief state,

are propositions true in all possible situations in the set. There is nothing essentially linguistic about belief, according to this picture, although the subject matter of belief may be linguistic expressions, or conceptual structures that essentially involve language, and this may be true even when it is not evident from the surface forms of belief attributions.

The beliefs of a perfectly rational intelligence could be represented by a single belief state of this kind – one coherent conception of the way the world is represented by one set of alternative possibilities. But the beliefs of mere mortals will require a more complicated representation. Mortals may be in many belief states at once, represented by separate spaces of possibilities. The integration of such separate belief states may in some cases be a simple matter of putting two and two together, but it may also be a task that requires nontrivial computation or creative activity. Deductive inquiry, I suggested, is inquiry which is designed to accomplish such tasks.

Belief is not the only attitude that is relevant to the cognitive situation of inquirers. Inquirers make posits, presumptions, assumptions and presuppositions as well. These methodological attitudes may diverge from belief in various ways, giving rise to additional complexity in a representation of an epistemic situation. But, I suggested, the cluster of propositional attitudes which were grouped together under the label *acceptance* share a common structure with belief.

Inquiry is the process of changing such acceptance states, either by interaction with the world or by interaction between different acceptance states. Methodological policies are policies constraining such changes. To have a framework for describing methodological policy, we might assume that acceptance states have two components: a set of alternative possibilities representing the inquirer's current conception of the way the world is, and a change function representing his disposition to change what he accepts in response to new information. This function will take propositions (the potential new information) into new acceptance states. It seems plausible to assume that when the new information is compatible with everything initially accepted, then the new acceptance state will be the intersection of the new information with the initial state. But where the new information conflicts with something initially believed, the new acceptance state will be a dis-

joint set of possible situations. No constraints can be put on such changes without adding further structure to our representation of an inquirer's epistemic situation, or to our representation of the possible situations.

One should expect the two components of an acceptance state to interact: our current conception of the way the world is constrains our dispositions to change our beliefs in response to new evidence, and those dispositions may contribute to the formation of concepts in terms of which we describe the world.

Notes

- 1 I discuss a notion of presupposition which is a social acceptance concept of this kind in Stalnaker (1974). For discussions of closely related notions of mutual knowledge and common knowledge, see D. Lewis (1969) and Schiffer (1972).
- 2 David Lewis discusses a theory for representing fragmented states of belief, as he calls them, in D. Lewis (1982).
- 3 There will inevitably be a certain arbitrariness in drawing the line between the propositions an agent believes "straightaway" and those he is disposed to come to believe after perfunctory calculation. Where one draws this line will depend in part on what one is interested in explaining.
- 4 The example comes from Drestke (1970), 1015–1016. See also Dretske (1981), 123–134. For an interesting discussion of Dretske's example and argument, see Stine (1976).
- 5 Kyburg (1970), 56.
- 6 *Ibid.*, 74.
- 7 *Ibid.*, 76. This remark was made about two particular systems, one developed by Jaakko Hintikka and Risto Hilpinen and the other by Keith Lehrer, but Kyburg says that "any global system in which the conjunction principle is satisfied will suffer from these shortcomings" (*ibid.*, 76).
- 8 *Ibid.*, 77.
- 9 Goodman (1947), which is also chapter 1 of Goodman (1955).

Section 4: Induction

Chapter 14: Patterns, Rules, and Inferences

ACHILLE C. VARZI

Introduction

Some of our reasoning is strictly *deductive*; we conclude that the available evidence supports a certain claim as a matter of logical necessity. For example, the following reasoning is deductive, since it is not possible for the conclusion to be false if both premises are true.

- (1) Every F is G , and x is F . Therefore, x is G .

Often, however, we are not in a position to produce a deductive argument; often we can only establish that the evidence supports the conclusion to a high degree of probability. Such *inductive* reasoning, as it is normally called, is in turn divisible into two types, according to whether or not it presupposes that the universe or some relevant aspect of it is law-like, or rule-governed. Reasoning that does not require this presupposition may be classified as *statistical*, since the evidence described by the premises supports the conclusion for purely mathematical reasons. For example, the following inductive reasoning is statistical:

- (2) Almost every F is G , and x is F . Therefore, x is G .

Here it is rational to reach the conclusion even though it does not follow as a matter of logical necessity, for the probability of x 's being G is, given the facts, much higher than the probability of x 's not being G (other things being equal). The second type of inductive reasoning is generally classified as *Humean*, after the philosopher who first studied it thoroughly, and corresponds to those arguments that do require the presupposition of law-likeness. The following is an example:

- (3) Every F previously observed was G , and x is F . Therefore, x is G .

Again, the conclusion does not follow as a matter of logical necessity, so the argument is not deductive. Yet the available evidence gives excellent reasons to believe in the conclusion rather than in its negation. Unless the relationship between being F and being G is random, the evidence strongly suggests the existence of a law to the effect that *every* F is G .

Humean arguments are of great practical utility, since we often need to reach conclusions and make decisions on the basis of evidence that is neither conclusive (thus preventing us from reasoning deductively) nor complete (preventing us from reasoning statistically). The presupposition of law-likeness, however, plays a crucial and controversial role, and figuring out exactly what role it plays is no straightforward business.

The Game of the Rule

Consider the following familiar game. X thinks of a certain sequence (say, a sequence of numbers) and Y must figure out what the sequence is. To get started, X gives an initial fragment of the sequence. Y must look at it carefully and, on the basis of what she sees, she must try and figure out how the sequence continues. Which is to say: she must figure out the underlying pattern, uncover the rule by means of which the sequence is generated. For example, let us focus on (infinite) number sequences. If X 's initial segment looks like this:

- (A) 1, 3, 5, 7, 9, 11, ...

then Y is likely to come up with a quick and reasonable guess: The sequence must consist of the positive odd integers, in their natural order. If the initial segment looks like this:

- (B) 1, 2, 3, 5, 7, 11, ...

then, again, Y may easily figure out how to continue – hence the rule by means of which the sequence is generated: This is the ordered sequence of the prime numbers, that is, the positive integers that do not have any other integer factors except for 1 and themselves. If Y guesses the rule within the allotted time, she wins the game. Otherwise X wins.

Now, some cases are more challenging than others, of course, and this is where the game gets interesting. For instance, consider the segment

(C) 1, 3, 6, 10, 15, 21, 28, . . .

This is the beginning of the sequence of the so-called triangular numbers, namely, those numbers that equal the sum of consecutive integers beginning with 1. More precisely, the rule underlying this sequence is that the n th element, S_n , is the sum of the first n positive integers:

(C*) $S_n = 1 + 2 + 3 + \dots + n$.

(For example, the fourth triangular number is $10 = 1 + 2 + 3 + 4$.) One may want to run a test and see how people actually perform, but a good guess would be that in this case it takes more thinking to figure out the solution. Y might even object that she has never heard of the triangular numbers – whereas she had heard of even and prime integers – so how could she figure out the rule? Still, X may just answer that one need not *know* what a triangular number is in order to see the pattern. With some patience, Y could still figure out that the sequence obeys the rule defined in (C*). Or she could figure out the rule under a different, more intuitive description. For example, Y might realize that the numbers in the sequence correspond to the different ways in which we can form a triangular array of dots, or bowling pins, or billiard balls, as in the following diagram:

So Y could describe the sequence in terms of this intuition:

(C**) S_{n+1} = the smallest number of dots (pins, balls) that are needed to form a triangular array of size greater than S_n , starting from $S_1 = 1$.

(This is actually why these numbers are called *triangular*, in analogy with the *square* numbers,

which correspond to the different ways in which we can form a square array of dots.) How one comes up with the rule and how one describes it – X may insist – is not important in order to win the game. It is only important in a derivative sense, namely insofar as it makes the game playable by people with different backgrounds. The game is interesting precisely because the mental process whereby the rule is uncovered may involve different sorts of cognitive insight.

In fact, it is worth noting that although in these examples the rule by means of which the sequence is generated is essentially determined by its number-theoretic properties, it need not be so in general, even if the sequence consists of numbers. For instance, suppose X offers the following segment:

(D) 1, 22, 333, 4444, 55555, . . .

This is the beginning of an obvious sequence and, as it turns out, there is a mathematical key to this sequence, corresponding to the equation

(D*) $S_n = n \cdot \frac{(10^n - 1)}{9}$

But of course Y is more likely to describe the sequence on the basis of a different criterion, which reads the rule directly off the visual pattern exhibited by its elements:

1	One 1
22	Two 2s
333	Three 3s
4444	Four 4s
55555	Five 5s
:	:

In that case, Y’s rule would not be (D*) but, rather, something like this:

(D**) S_n = the string consisting of the number n repeated n times.

X himself, in giving the initial segment, may have thought of the sequence in terms of (D**), not (D*), so the fact that there is a number-theoretic description of this sequence is entirely irrelevant. And in some cases there is no number-theoretic description at all, as in

(E) 1, 3, 4, 5, 7, 8, 9, 12, 14, 17, 18, . . .

Here X may be thinking of a rule that can be defined with reference to a linguistic property

and that concerns the numerals, not the numbers:

(E*) S_n = the n th integer whose name in English has an even number of vowels.

A favorite example of this sort is actually one that does not depend on purely linguistic considerations, just as it does not depend on purely arithmetical considerations, and is due to the American mathematician John Conway:¹

(F) 1, 11, 21, 1211, 111221, 312211, 13112221, ...

Is there a rule behind this sequence? If we look for a purely arithmetical or linguistic key, we won't find any. We must look at the sequence from a different perspective. Exactly what perspectives one may consider is of course hard to tell. But if we start reading the sequence aloud we might get a clue. Let's not read it like this:

1	One
11	Eleven
21	Twenty-one
1211	One thousand, two hundred, eleven
111221	One hundred eleven thousand, two hundred, twenty-one
312211	Three hundred twelve thousand, two hundred, eleven
13112221	Thirteen million, one hundred twelve thousand, ...
⋮	⋮

Let us read it like this:

1	1
11	One 1
21	Two 1s
1211	One 2 and one 1
111221	One 1, one 2, and two 1s
312211	Three 1s, two 2s, and one 1
13112221	One 3, one 1, two 2s, and two 1s
⋮	⋮

Then we suddenly realize what is going on: this is a "self-describing" sequence. It begins with 1 and then goes on to describe itself, in the sense that each subsequent term gives an "audioactive" description of its predecessor. The rule can be put thus, where ' $d_i|r_i$ ' designates the string obtained by repeating r_i times the digit d_i :

(F*) If S_n is the string $d_1|r_1 \dots d_k|r_k$ ($d_i \neq d_{i+1}$ for all $i < k$), then S_{n+1} is the string $r_1 d_1 \dots r_k d_k$, starting with $S_1 = 1$.

The Rules of the Game

So much for this familiar game. It takes a moment now to realize that the game is a good model of what goes on when we engage in Humean inductive reasoning. For the game of the rule is a familiar one, not only insofar as it is often played for fun, or for pedagogical purposes (elementary school teachers often rely on it to explain – for instance – certain basic arithmetical concepts and operations); it is also familiar precisely because we find ourselves playing it all the time in our daily interactions with the world around us. We are constantly trying to figure out the rules or laws that govern the natural world, or the social world, or the stock market. We look at the facts and we try to figure out the underlying pattern, so as to predict what will happen next, exactly as we try to figure out the pattern of a sequence of numbers on the basis of an initial segment. We look at our history so far – that's the initial segment – and we try to figure out the underlying rationale, so as to know what to expect next. It may sound metaphorical, but it wouldn't be so far-fetched to claim that science as a whole is engaged in a game of this sort. Every F observed thus far is G (every number in the visible portion of the sequence is prime, for instance), so we think that there is a lawlike connection between being F and being G : we think that being F goes hand in hand with being G and we conclude that the next F in the sequence must be G , too. That is precisely the idea behind Humean inductive reasoning. And there are researchers who would claim that being able to reason that way – to play such a game – is a distinctive trait of rational behavior. Douglas Hofstadter and his research group, for instance, believe that this trait is close to the core – if not *the* core – of human intelligence, and that designing computer programs capable of playing the game of the rule is the deepest and most fascinating challenge that so-called artificial intelligence must face.²

To fully appreciate the import of these claims, however, it is important that we now be explicit about a few things that we have so far been taking for granted. There are, in fact, two crucial implicit assumptions that must be satisfied in order for the game to be played correctly – two tacit Rules (with the capital "R") that the players must observe.

The first tacit Rule is that the initial segment by means of which the sequence is introduced should provide enough information for Y to figure out the solution. For instance, with

(G) 1, 11, ...

rather than (F) as the sole piece of evidence, Y would hardly come up with the Conway sequence, simply because this initial segment is compatible with many other, more plausible solutions. The sequence could in fact continue in several ways, each of which corresponds to a different solution that “fits the data” equally well insofar as the data are fixed by (G). For example, it could continue in any of the following three ways:

(G_a) 1, 11, 121, 1331, 14641, 161051, ...

(G_b) 1, 11, 111, 1111, 11111, 111111, ...

(G_c) 1, 11, 1, 11, 1, 11, 1, 11, 1, 11, ...

and each way would correspond to a completely different rule:

(G*_a) $S_n = 11^{(n-1)}$

(G*_b) $S_n = 1|n$

(G*_b) $S_n = 1$ if n is odd, and $S_n = 11$ if n is even.

There are obviously lots of possibilities, and for this reason Y would be entitled to complain if all X gave her as a starter was just the small bit in (G). For the problem is not merely that one can come up with different answers; we have already seen that sometimes the same sequence can be generated or described in accordance with more than one rule, as with (D*) and (D**). The problem is that in the present case the different answers would not be equivalent: They would describe different sequences, not the same sequence in different ways.

So this is the first tacit Rule of the game, which we can approximately formulate as follows:

R1 *The initial segment must uniquely identify the sequence.*

The interesting question, of course, is whether this Rule can be successfully implemented, or even whether it can be implemented at all. We shall come back to this question shortly. First let us mention the second tacit Rule of the game, which is equally important. This second Rule says that the sequence in question cannot be a *random* sequence. For example, it would be strange if X said that the sequence in (G) continued thus:

(G_d) 1, 11, 3, 4, 5, 10, 7, 8, 9, 9, 10, 12, 12, ...

It would be strange because, on the face of it, this sequence appears to continue in a totally arbitrary fashion and there seems to be no way of subsuming it under a rule, hence no way for Y – or for anybody – to describe the sequence other than by laying out each term that compose it, one after the other. For the same reason, of course, it would be strange if Y insisted that (G_d) is on equal footing with (G_a)–(G_c). For (G_a)–(G_c) do exhibit a pattern, or so it seems, whether (G_d) does not. So, as a first approximation, the second Rule of the game can be put as follows:

R2 *The sequence must not be random, i.e., it must be rule-governed.*

In a way, R2 follows from R1. For if a sequence were random, then certainly *no* proper initial segment could uniquely identify it. Hence, by contraposition, if there is a proper initial segment that uniquely identifies the sequence, as per R1, the sequence cannot be random. In fact, this is how randomness is often defined, at least since the pioneering work of Ray Solomonoff, Andrei Kolmogorov, and Gregory Chaitin in the mid-1960s: a sequence is random if it cannot be described more efficiently than by laying out the whole sequence itself.³ However, as we said, R1 may not be entirely in order as it stands, so it is convenient to formulate R2 independently. And again, we shall come back shortly to the important question – whether this second Rule can be properly implemented, or taken for granted. Right now the point is just that R1 and R2 are standardly assumed to hold whenever two players engage in a game of this sort, for otherwise there is no way one can succeed in guessing the sequence.

Too Good to Be True

So, are R1 and R2 in order? Not quite, unfortunately. Let us begin with R1. On closer look, this rule turns out to be just as crucial as it is unsatisfiable – upsetting as this might sound to the players of the game. Let us first illustrate this negative fact with reference to the sort of cases that we have considered so far; then we may turn to generalizations.

Consider again the example with which we began – the sequence corresponding to the segment

(A) 1, 3, 5, 7, 9, 11, ...

Surely we can all see a pattern here: the odd numbers. But how do we know that this is

the pattern? How does Y know that this is the sequence X had in mind? Y doesn't know it. She sees that every number in (A) is odd, and she sees that no odd number is missing, and since she is assuming that this initial segment uniquely characterizes the whole sequence, she concludes that the dots must be filled in by the odd numbers. That is, she concludes that the underlying rule must be this:

$$(A^*) S_n = 2n - 1$$

Strictly speaking, however, she doesn't *know* that this is the rule any more than she knows the truth of any generalization based on a limited amount of data. The generalization is justified precisely because she is assuming that R1 is being observed. But how can that be right? How can the initial segment by means of which the sequence is introduced provide *enough information* for anybody to figure out the solution and continue the sequence by filling in the dots accordingly? As Wittgenstein famously put it: "Whence comes the idea that the beginning of a series is a visible section of rails invisibly laid to infinity?"⁴

Suppose Y says that the sequence in question consists of the odd numbers and X says: "No, it doesn't. It consists of the odd digits repeated once, then repeated twice, then repeated three times, and so on. Here is what it would look like if I continued a little longer:

$$(A') 1, 3, 5, 7, 9, 11, 33, 55, 77, 99, 111, \dots$$

If you want me to be more precise, I can even spell out the rule in mathematic terms:

$$(A^{**}) S_n = 2_n - 1 \text{ mod } 10, \text{ repeated } (2n \text{ div } 10) + 1 \text{ times,}$$

where mod is the function that returns the remainder of the division (of the first argument by the second) and div the function that returns the division without the remainder." Is Y entitled to complain?

In a way she is: If *that* is the rule X had in mind, then X did not comply to R1 because (A) does not amount to a uniquely identifying segment. In particular, it does not uniquely identify the sequence described in (A**), for the dots can be filled in in conformity to that rule as also in conformity to the rule that Y originally suggested, (A'). Of course, this means that (A) does not uniquely identify the sequence of the odd numbers, either, so Y's complaint is self-defeating. But never mind that. It is a fact that relative to (A**) – the rule that X had in mind

and that B was supposed to figure out – the segment in (A) is not informative enough, just as the short segment in (G) would not have been informative enough to identify the rule of the Conway sequence, (F*). So Y's complaint is right on the mark.

By contrast, what is X to make of this complaint? *What* would count as an appropriate, uniquely identifying segment for the rule he had in mind? Suppose X gives the longer segment in (A') rather than (A). Would that be enough? It would not. It would be enough to rule out the hypothesis that his sequence consists of the odd integers. But many other sequences would still be compatible with that initial segment. The sequence might continue in conformity to the pattern X actually has in mind, but it might also continue according to a different pattern. For example, the sequence could consist of the perfect palindromic odds, that is, those numbers that consist exclusively of odd digits and that are the same when written forward or backward. All the numbers in (A') are perfect palindromic odds. But whereas X's sequence would continue thus:

$$(A'_a) \dots, 333, 555, 777, 999, 1111, \dots$$

the rest of the sequence of the palindromic odds would contain several additional, intermediate elements:

$$(A'_b) \dots, 131, 151, 171, 191, 313, 333, \dots$$

Needless to say, even (A'_a) would be ambiguous as an input for guessing X's rule, for one may still think of different ways of continuing the series. The more we go on – the longer the initial segment is – the more the alternatives look convoluted and, in some way, "unnatural." But this is precisely the point. It is not R1 by itself that imposes a plausible constraint on the game, for R1 can *never* be satisfied: any finite segment can be continued in an infinite number of ways, just as any line-segment drawn on a sheet of paper can be extended in an infinite number of ways. Rather, the constraint comes from R1 together with the additional implicit assumption that the sequence in question must be a "natural" sequence. And sad as it might sound, it is a fact that what looks "natural" to Y may very well not coincide with what looks "natural" to X – and vice versa.

It takes a moment now to realize how important this is when it comes to playing the game for real – when the player to issue the initial segment is not just someone like us but the world itself.

A sequence of observed events may suggest that a certain pattern is in place and we – playing the role of player Y – eventually come to think of that pattern as revealing a corresponding law of nature. But this is not to say that the observed events uniquely identify that law. And if the next observed event is not what we expected, we can hardly voice a complaint on the grounds that the resulting sequence looks “unnatural.” We must simply admit that we were wrong, and learn to live with the possibility that our next guess will be off the mark, too. Such is the limit of our inductive practices, when they are not merely statistical but strictly Humean.⁵

Let us now look at our second meta-Rule, R2. Indeed, it might be thought that this is precisely the point where R2 enters the picture. This second Rule says that the sequence to be guessed must not be random, that is, it must be rule-governed. And for all that has been said so far, the fact that any initial segment can be continued in many different ways does not mean that it can be continued in many *rule-governed* ways. The segment in (A) can, as also the longer segment in (A'). But perhaps a sufficiently longer segment could be provided that will admit *only one* rule-governed extension. If so, then the impasse that we have just reached in connection with R1 would dissolve as soon as we plug in R2: it would be possible to uniquely identify a sequence by means of an initial segment (a sufficiently long one) on account of the fact that all the alternative ways of continuing the sequence would qualify as random and would therefore be unacceptable by R2. In fact that is precisely the intended role of this second Rule: earlier we said that R2 follows from R1, but now we see that R1 is empty unless some further constraint is added – and R2 provides such a constraint.

Unfortunately, R2 turns out to be just as useless as R1. There are two ways of making the point. The first way goes back at least as far as Leibniz, who in the *Discourse of Metaphysics* addressed the question of whether and how one could discriminate a world in which science applies from one in which it does not.⁶ Imagine – he said – that someone jots down a quantity of ink spots upon a sheet of paper helter skelter (“as do those who exercise the ridiculous art of Geomancy”). Regardless of the particular configuration that we get, Leibniz claimed that there will always be a continuous function whose graph passes through this finite set of points, a “geometrical line whose concept shall be uniform and constant that is, in accordance with a certain formula.” As far as we can tell, the

existence of such a function was purely conjectured by Leibniz, but today we know that he was absolutely right. Many good ways to construct a function that does the job are now known. For example, so-called Lagrangian polynomial interpolation will do.⁷ This is the sort of function that is implemented in most computer graphics programs: We click the mouse on each spot as we go over them, and the function returns a normalized curve that connects them all – like this:

Now, if we take it that the existence of a suitable function is an indication of the fact that the pattern is not random, then it follows that no such pattern is random. And since it is plausible to suppose that every finite sequence can be represented by a corresponding pattern of ink spots, it follows that *no* finite sequence whatsoever is random. So here is the problem: when playing the game of the rule, there is no way X can provide an initial segment that is “sufficiently long” to admit of only one rule-governed extension. *Any* finite extension of any initial segment, no matter how long, will be nonrandom. Which is to say that R2 does not impose any restriction of the desired sort, leaving R1 in the trashcan.

The second way of making the point is this. Suppose we rely on a more austere definition of randomness. Indeed, suppose we stick to the definition of randomness mentioned earlier, which today is widely accepted: a sequence is random if (and only if) it cannot be described more efficiently than by giving the whole sequence itself. In other words, although every sequence can be described by *some* function – as Leibniz pointed out – in some cases the function in question is too complex to do the job efficiently, and we can take that to be a sign of randomness. If we stick to this definition, then we can be assured that *there are* random sequences, so the above problem does not arise. This is obvious for infinite sequences, since the total number of such sequences is uncountable, whereas there are only countably many efficient, finite descriptions. But it is easy to prove that there are also infinitely many random sequences of finite length, at least if the language in which the sequences are coded is the same as the language available to describe them. (Regardless of the alphabet, the number of sequences consisting of n symbols is always

greater than the number of all sequences consisting of fewer symbols, hence greater than the number of all descriptions of length less than n .⁸) Does this help?

Unfortunately, it doesn't. The problem is not that this more austere definition of randomness depends on a notion of "efficient" description that appears to be vague. We could make that more precise. Rather, the problem is that this more austere notion of randomness turns out to be *undecidable*. That is, it can be proved that there exists no effective decision procedure (intuitively: no procedure that can be implemented as a computer program) that will always deliver a definite answer to every question of the form: Is this a random sequence?⁹ Sometimes we can deliver a negative answer. The sequence of the odd numbers, for example, or even a reasonably long finite initial segment thereof, is not random because we can efficiently describe it by means of a rule such as (A'). Ditto for the sequence of the repeated odds, the sequence of the palindromic odds, and many other sequences considered earlier. However, *in general* we may not be in a position to determine whether a given sequence (finite or infinite) is random. All we can say, if we cannot come up with a corresponding rule, is that the sequence is random *to the best of our knowledge* – and that is not enough. For example, at first sight the initial segment of the Conway sequence given in

(F) 1, 11, 21, 1211, 111221, 312211, 13112221, ...

looks pretty random. Y might have tried to come up with an algorithm to describe it and she might have failed. So Y might have been inclined to conclude that the segment is the beginning of a random sequence, when in fact it isn't. Likewise for (G_d): we have said that the series

(G_d) 1, 11, 3, 4, 5, 10, 7, 8, 9, 9, 10, 12, 12, ...

looks random, but who knows – maybe one can come up with a way of describing it that does the job. This is particularly pressing in view of the fact that there are many ways of describing a sequence: as we have seen, the description need not be number-theoretic, and it need not be in the format that comes to us most naturally. That is the lesson of the Conway sequence. (In fact, coming to think of it, even (G_d) may very well be the beginning of a nonrandom sequence. The rule

(G*_d) $S_n = n$ if the English name for this integer has an even number of vowels, otherwise $S_n = (n \bmod 5) + 9$

fits the data perfectly well. . .)

Now, why is this a problem? After all, Y knows that X is *not* thinking of a random sequence, at least if X is playing in accordance with R2, so Y knows that the sequence she has to guess *does* admit of a suitable description. Well, the problem is that Y cannot do much of this piece of knowledge. She knows that X is not thinking of a random sequence, but she doesn't know what this amounts to. Y doesn't know what sequences are ruled out because she doesn't have any effective procedure for telling what are the good candidates. She might believe that a certain way of continuing the initial segment is out because she might not be able to bring it under a rule – but she might just be wrong. Y might just be incapable of seeing the underlying pattern, so she might treat that as a random sequence when in fact it isn't. It might be precisely the sequence X is thinking about.

So here is the picture in a nutshell. If we stick to a generic notion of randomness as lawlessness, no sequence is random and R2 is perfectly useless. If, by contrast, we stick to the more austere definition of randomness as incompressibility, then there are random sequences and R2 is fine as a matter of principle. Yet it is still useless when it comes to matters of practice. We may fully convince ourselves *that* a given sequence complies with the no-randomness requirement. But we may not be in a position to determine with certainty *whether* a given sequence complies with it.

Playing the Game for Real

So what are we left with? The "game of the rule" – it turns out – cannot be safely played. But why should that be a worry? After all, there are many other games that we can play, so why bother?

Well, there are indeed many other games we can safely play, but, as we have already pointed out, this one is a game that we cannot dismiss so easily. The game of the rule is a game that *we play all the time*, whenever we engage in Humean inductive reasoning. We play it whenever we try to figure out the mechanisms of the world we live in, the laws of nature and the laws of society. We don't play it with number sequences but with the sequences of events that make up our

history, when we try to make sense of them and see where they are leading to. And to say that this game cannot be played safely is not to say that we can stop playing it altogether.

At this point we have come to full circle and our story becomes a familiar one in the philosophy of science. Some think that the sort of skepticism that we have illustrated must be taken very seriously. For all we know, the world might not even be *trying* to play the game in accordance with R1 and R2, in which case our Humean inductive practices would just rest on a false presupposition. But even if the world were trying to play by the rules – even if the events with which we have to deal were fully in agreement with the presupposition of lawlikeness – the fact that randomness phenomena cannot be effectively identified would be enough to justify a merely pragmatic attitude toward the endeavors of science. There is no way we can hope to “break the code.” We can only hope to play the game in such a way that *we* find satisfaction in the laws that we envision, just as we find satisfaction in the social and political laws with which we try to regiment our daily interactions with our peers. Others feel differently. Not only do they think that we should play the game on the assumption that the world is issuing its challenges in compliance with R1 and R2; they also believe that we should not give up our hopes to get things right. After all, when we play the game for fun, we often win. We often succeed in uncovering the hidden pattern in spite of the difficulties that have been mentioned. Even if the initial segment that we are given does not uniquely identify the intended sequence, and even if we are not in a position to keep randomness under control, we often hit the correct rule because the other options are just too far-fetched to deserve serious consideration. So why not suppose that the same can happen when we play the game with the world of nature? All we have to do is to make sure that the world and we are on the same wavelengths, so to say – that what looks natural or far-fetched to us is indeed natural or far-fetched *simpliciter*. The history of science shows that sometimes we make mistakes, but that has never blocked scientists from pursuing their research with increased determination. On the contrary, the general thought has been that we can learn from such mistakes, and that we are getting closer and closer to winning the game at the next try.

This is no place to dwell upon this controversial dialectics. We may choose our party as we

see fit. But the underlying predicament is something that can be best appreciated once we begin to see this familiar dialectics from the standpoint we have been suggesting here. For, on the one hand, we should not overlook one important sense in which playing the game with the world of nature may be easier than playing it *inter nos*. When both X and Y are people like us, each will try to win the game; in particular, X will try to issue his challenge in such a way as to make it difficult for Y to come up with the right guess – he will make every effort to design a rule that would be very hard, if not impossible, to discover in real time. By contrast, there is no reason to suppose that this is how the world out there issues its challenges. The world is not an intentional agent and does not care about “beating” us in the game, or so we may assume. In this sense, the practice of scientific induction need not be as hard as playing the game of the rule against a clever opponent trying to be smarter than we are, and the thought that we should try to be on the same wavelengths as the world is all but unreasonable. (That was indeed the main rationale behind Keynes’s principle of “limited variety,” a principle whose roots can be traced back to the philosophy of Francis Bacon:¹⁰ An object of inductive inference should not be infinitely complex, nor determined by an infinite number of generators, and if we are assuming that the world is playing by the rules, we may well suppose that it is playing according to this additional principle, too.) On the other hand, there is also an important sense in which playing the game with the world of nature is not as easy as playing it *inter nos*. When we play, one player gives the beginning of the sequence and the other must figure out the rest. That may be tough, for the reasons that we have seen, but at least the input is clear – the first player is giving it explicitly. When we play with the world, by contrast, we must be careful. Not any series of events is on equal footing. We may witness the rising of the sun every morning and take that as an input for a law that we may reasonably formulate as a Humean inductive generalization. We might even think that it’s worth looking at the series of events that we get by tossing a coin, for it might not be a random sequence after all. But when we zap channels during a commercial break, for example, the series of events that follow one another on our TV screen is not worth looking at. When we check the sky every time we hiccup, the series of events that we thereby collect is not worth any serious study. This is not

to say that such series are random; there might even be a pattern, surprising as that might be. ("Every time I watch the Yankees, they lose.") It's just that such series are not interesting. They don't count, so to speak. And they don't count because they would be there *even if it turned out that we live in a totally deterministic world*, a world where nothing is random and everything happens for a reason. To put it briefly, when we play with the world we have got to figure out *which* sequences to consider before we can start figuring out *what* they are, for the world does not tell us that. The world does not issue its challenges as explicitly as people do when they play with one another.

Now, precisely this is the main difficulty with Humean inductive reasoning. We can live with randomness and we can live with the fact that randomness is undecidable. Science has learned to cope with that, one way or the other. We can even assume that the world – unlike clever human players – has no interest in *beating* us. But we must be careful because our cognitive makeup is such that we constantly look for patterns and trends even where there may be none. And there may be none, not because we may be dealing with random sequences, but because maybe there is no sequence to deal with. Maybe we are just exercising "the ridiculous art of Geomancy," as Leibniz put it, and that's not a way to play the game. For in the end, when it comes to playing the game for real, the one tacit Rule that we can *never* rely on is also the most obvious and important of all:

R3 *The initial segment of the sequence must be given explicitly.*

Chapter 15: Inductive Logic and Inductive Reasoning

HENRY E. KYBURG, JR.[†]

In days of yore, logic was neatly divided into two parts, *Deductive Logic* and *Inductive Logic* (Mill 1949/1843). The two parts were often taught as parts of a single course. Inductive logic has faded away, and now the very term has acquired a slightly antiquated patina. It has also acquired a number of quite specific modern meanings.

One very narrow and very specific meaning is that inductive inference is the inference from a set of observations or observation sentences (crow #1 is black; crow #2 is black; . . . ; crow #n is black) to their universal generalization (all crows are black). There is not much *logic* here, but there is a big problem: to determine when, if ever, such an inference is “justified.”

A somewhat less ambitious construal of “induction” is as the inference from a statistical sample to a statistical generalization, or an approximate statistical generalization: from “51% of the first 10,000 tosses of this coin yielded heads,” to “Roughly half of the tosses of the coin will, in the long run, yield heads.” So construed (as by Baird 1992), the line between the logic of induction and the mathematics of statistics is a bit vague. This has been of little help to inductive logic, since the *logic* of statistical inference has itself been controversial.

Another way of looking at induction is as a part of logic proper. This approach takes as its guiding insight that while in the case of valid deductive inference *every* model of the premises is a model of the conclusion, in the case of valid inductive inference we should ask that *most* of the models of the premises (the statements expressing the evidence) are models of

the conclusion. The problem, of course, is how to count models in any reasonably complex language (Carnap 1950, 1991). There are an infinite number of ways of constructing models of even quite simple languages.

What most writers have focused on, at least as a long term ideal goal, is the development of standards for scientific inference. As observed by C. D. Broad (1930) (among others), much of actual scientific inference is straightforwardly deductive in character. We know that if one sample of a compound melts at t degrees centigrade under standard conditions, *all* samples of that compound will. We may agree that if one sample of compound X melts at 34°C , then *all* samples of compound X melt at 34°C , and thus obtain the universal statement concerning all samples from the observation concerning one sample. Generalizing, even on the basis of one instance, may be valid, given the right premises.

Of course, this does not mean that no uncertainty is involved. The form of the *argument* is deductive, to be sure, but there is uncertainty involved in the specific claim that *this* sample melts at t degrees centigrade (all measurement admits of error) and there may be uncertainty about the universal generalization that if one sample melts at t then all do.

In the past, many writers, recognizing that the conclusion of an inductive inference is generally not certain, have focused on the idea that the conclusion of an inductive inference may yet be *probable*. This is helpful only if we understand probability, and probability itself has been controversial; several different interpretations of probability have been offered, not all of which are of relevance to induction.

As a branch of mathematics, there is nothing mysterious about probability. Probability is defined on an algebra of *sets*; it is *nonnegative* with a maximum value of 1; and it is *additive*,

[†] We regret that Henry E. Kyburg, Jr., died during the publication of this book. The editors are grateful for his contribution to this volume and, more generally, to the study of inductive inference and non-monotonic reasoning.

which just means that if A and B are disjoint sets, the probability of their union is the sum of their probabilities.

But this is not what we want to know. We want to know what those sets *are* for which probability is defined. We want to know where the *values* of those probabilities *come from*. We want to know how these matters are related to knowledge or rational belief. In short, we want to how probability fits into logic, and to explore that question we need to reflect on the foundations of logic itself.

1. Logic

The first paragraph of George Boole's *Laws of Thought* [Boole 1854, p.1.] focuses on this general question; it reads:

The design of the following treatise is to investigate the fundamental laws of those operations of the mind by which reasoning is performed; to give expression to them in the symbolical language of a Calculus, and upon this foundation to establish the science of Logic and construct its method; to make that method itself the basis of a general method for the application of the mathematical doctrine of Probabilities; and, finally, to collect from the various elements of truth brought to view in the course of these inquiries some probable intimations concerning the nature and constitution of the human mind.

This certainly seems to have powerful psychological overtones, to say the least. Frege took it so, writing (1950/1893: p xv):

The ambiguity of the word "law" is fatal here. In one sense it states what is, in the other it prescribes what should be. Only in the latter sense can the laws of logic be called the laws of thought. . . . But the expression "law of thought" tempts us into viewing these laws as governing thinking in the same way as the laws of nature govern events in the external world. They can then be nothing other than psychological laws, since thinking is a mental process. And if logic were concerned with these psychological laws then it would be part of psychology. . . . I understand by logical laws not psychological laws of *holding true* but laws of *being true*.

In a recent article, Gil Harman argues that logic is a theory of "what follows from what" and not a theory of reasoning. On this ground, he writes (Harman and Kulkarni 2006):

. . . to call deductive rules "rules of inference" is a real fallacy, not just a terminological matter. It lies behind attempts to develop relevance logics or inductive logics that are thought better at capturing ordinary reasoning than classical deductive logic does, as if deductive logic offers a partial theory of ordinary logic.

The first thing to observe is that things are not, of course, this simple. Boole distinguishes between the "general laws of Nature," which are "never wholly divested" of "the character of probability," and the "laws of mind" in which the general truth is seen with certainty in the single instance.

Whence comes the power of that single clearly understood instance? Boole does not explain, and to my mind commits here an epistemological blunder. But although that reflects his conviction that logic is not an empirical science, not even an empirical science of the mind, it does not mean that logic is not about the mind in some sense. If it is not "descriptive" in the sense of empirical science, it bears some other relation to the mind.

What springs to mind, of course, is exactly the normative relation that Frege sought. Logic is not the theory of how we *do* reason, but the theory of how we *ought* to reason. But this seems almost as silly as the descriptive claim would be: surely it is not intended that we should *reason* in accord with some particular system of logic! We are not being exhorted to construct *proofs* in our minds, that is sequences of formulas each of which is either a premise or is inferred from earlier formulas by a permissible rule of inference. (And if that were the case, which formal system would we be supposed to follow?)

No, logic is not a prescription for psychological health. Is it that what must be intended is that our reasonings should admit of translation into proofs in a system of logic? But the notion of translation is a loose one, as Quine has pointed out (1960). Since most of our reasonings are enthymemes, it would seem that by choosing appropriate premises any reasoning could be warranted.

Here's another idea. Some of our reasoning, especially in mathematics, does seem to have the structure of a proof outline. This is particularly the case when we are doodling around with pen and paper trying to figure out how a proof could go. We think of, or perhaps even write down, a few of the significant high points of the proof. We may write down some of the premises of

the proof. At some point, if we are lucky, we *see* how the proof goes. We *see* how the conclusion follows from the premises. For many of us this is sufficient to establish the entailment from premises to conclusion. (There are also the intellectually insecure, like me, who often want to see a detailed proof!)

One thing that logic can do is to help us fill in the valleys between the peaks of such a proof sketch. What is the point of that? Well, if the idea of a logical argument is to be fully persuasive, a formal proof surely suffices. But generally a formal proof is overkill. If we are facing an interlocutor of good will, something between a very brief proof sketch and a formal proof will suffice. All this takes the *point* of logic to be to show that conclusion C follows from premises P_1, P_2, \dots, P_n , when it does. To this extent, Harman's idea seems to be vindicated: logic concerns what follows from what.

Of course there are other things that first order logic is good for. Sometimes I am my own interlocutor: I am concerned to really persuade myself that the conclusion follows from the premises. Sometimes I am constructing a proof for fun. It is often said that studying logic and constructing proofs is good training for the mind. (I have no very firm opinion one way or the other on this!)

There is nothing much about *thinking* or *reasoning* in any of this, with the possible exception of training in thinking. Yet there is the relativization to human abilities in the actual use of logic: We do not invent logic, unmotivated, out of whole cloth. We begin with an idea, presumably parasitic on ordinary language, of what follows from what. With the idea of formal proof, the role of human abilities is minimized; but we must still recognize that the antecedent of line four is the same as line three.

2. Variations on Classical Logic

Let us refer to classical first order logic as the system H . There are, of course, many variations. First, there are weaker systems: intuitionistic logic, constructive logic. These do not concern us in the present context, but stronger systems do. For example, the logic of strict implication, modal logic, and relevance logic were proposed to capture certain aspects of human reasoning and argument (concerning, for example, counterfactuals) that escaped the constraints of system H . These systems include new connectives (for example, $>$ and \diamond) and new axioms. They

are nevertheless classical in the sense that they include classical logic.

In relatively recent years (the last twenty or twenty-five) we have seen the introduction of nonmonotonic logics and probabilistic logics. These are often intended to play the role of inductive logic. These, too, are essentially classical. For example, in Reiter's default logic, *default rules* are added to the system (Reiter 1980). A default rule has the form: $\alpha : \beta_1, \dots, \beta_n / \theta$. The intent is that if none of the formulas β_1, \dots, β_n hold in the set of accepted formulas, then the formula θ may be accepted "by default." Thus we start with a set W of statements, and take the corresponding *extension* to be the deductively closed fixed point yielded by W and the set of default rules. There may be no extension, and there may be more than one. The classical example is to take W to be the single sentence "Tweety is a bird," and D to be the single rule "Tweety is a bird": "Tweety can fly." / "Tweety can fly." We can believe "Tweety can fly." But we may consistently add "Tweety is a penguin" and "No penguins can fly" to W , and we will no longer be able to apply the default rule, and so no longer justified in believing that Tweety can fly.

Autoepistemic logic (Moore 1985) is another nonmonotonic formalism. It is quite easily represented as a modal logic, and provides a natural link between default logic and the various modal logics (Lewis 1918), with " \square " interpreted as "knows that".

The idea behind this, and other AI formalisms for nonmonotonic logic, is to capture "common sense" reasoning. "If I know that Tweety is a bird, other things being equal, I know that Tweety can fly" (Reiter 1980). "If I had an older brother, I would know it" (Moore 1985). It is common sense that if all the crows I have seen are black, then it is reasonable for me to believe that crows are black. Of course, there are various ways of interpreting the vague phrase "common sense" and, in consequence, various formalisms for nonmonotonic logic. In many cases, the result of the application of the rules of inductive logic is a deductively closed set of statements – that is, a set of statements deductively closed in the sense of classical first order logic.

What is of interest from a foundational point of view is that the goal of these formalisms is the *representation* of nonmonotonic or inductive or commonsense reasoning. "Representation" is an ambiguous expression in this context. We could represent the psychological process that commonsense reasoners go through with varying degrees of accuracy and varying degrees of

normativity. By this I mean that the subject, the model, of the activity we are seeking to represent is the reasoning of an educated, intelligent, native speaker of our language – probably male, probably trained (or overtrained) in classical logic. Such reasoning, of course, is precisely the reasoning that we – you and I – take intuitively to be rational. Guess why! On the other hand (is it really other?) the system we come up with (whatever it is) we will defend as *normative*: the inductive conclusions supported by our systems are the ones that an agent, having the evidence he has, *ought* to accept.

We encounter another difficulty. What is “the evidence” that the agent has? It is all very well to symbolize the evidence with the single letter “*E*,” but if the point is to rationalize, or even represent the relation between evidence and hypothesis this is not much help. Furthermore, the single letter is ordinarily taken to represent the *conjunction* of all the evidence the agent has. But it is at least open to argument whether or not the set of sentences accepted, or accepted as evidence, if these are not the same thing, should be closed under conjunction. I have argued (Kyburg 1997) that if there is a small chance of error in each of the two acceptable statements, then there may be a greater chance of error in their conjunction. We will return to this issue in the final section of this essay.

In short, even if we could settle on one of these formalisms as the right way to approach nonmonotonic logic, there seem to be insuperable difficulties lying in the way of applying it to anything more than the simplest toy Tweety model. There is the problem of representing the evidence in such a way that it can be agreed to (or argued over); and, even more serious in the light of the difficulty with the evidence, there is the question of how the system can both be interpreted in terms of representation and normativity. How do we resolve the tension between what people actually do, what people think it is intuitively correct to do, and what people really ought to do?

3. Probabilism

Another approach to uncertain inference that has been getting a lot of press in recent years is Probabilism. I wouldn’t presume to define probabilism – I’m not even sure it should be capitalized – but the basic idea is that we replace qualitative all-or-none belief by *degrees* of belief, and we are to modify our degrees of belief in the light of new evidence by conditioning on

that evidence. This approach is called “Probabilism” because *degrees of belief* are to satisfy the probability axioms, and conditioning is to satisfy the relation imposed by the condition that the degree of belief in a conjunction is to be the product of the degree of belief in one conjunct multiplied by the conditional degree of belief in the other conjunct, *given* the first conjunct.

(There has been some misguided discussion of how you “define” conditional probability in such a way that the probability of the condition may be zero. The simple answer is that you don’t. Conditional probability has never legitimately been defined in this way. Furthermore, all sensible formalizations of probability, including Kolmogorov’s, have taken conditional probability as primitive. The idea of “defining” conditional probability as a quotient is a red herring.)

It is sometimes said that probability is nonmonotonic. This seems wrong, since, as was pointed out even by Keynes (1952), conditioning does not give you a new probability, but makes a different probability relevant. If $P(S|B) = 0.5$, where *B* is our background knowledge, and we learn *T*, then what is relevant is $P(S|B \wedge T) = 0.8$; but that does not make $P(S|B) = 0.5$ *wrong*. New information does not undermine an old probability nonmonotonically; it makes a new probability more interesting.

Naturally, the idea of connecting the logic of conditionals with conditional probability has occurred to more than one person (Adams 1975; Pearl 2000; McGee 1989). There are difficulties (Lewis 1981; Suppes 1962), but they can be seen as challenges. The upshot is that this is an extremely rich general area of logical research. There seem to be no bounds on the systems that people can come up with. At the very least, this is evidence of the unbounded ingenuity and creativeness of human beings.

How does all this ingenuity bear on inductive logic? It depends, of course, on what we want inductive logic to do. If we want it to represent inductive reasoning, or rational inductive reasoning, we must somehow settle the interplay between the normative and descriptive aspects of “representation” we have in mind. It is surely not the case that any formalism that has been proposed has been proposed as a serious description of the actual workings of the human mind. The most ardent probabilist would not suggest that any actual human being had degrees of belief satisfying the axioms of the probability calculus, much less that they were updated by conditioning. By contrast, patent failures of

coherence – for example, that an agent takes it to be more probable that Linda is a liberal banker than that she is a banker – are to be “corrected.” Note that the direction of correction is open: the agent may increase his belief that Linda is a banker, or decrease his belief that Linda is a liberal banker. If I don’t like the result of conditioning S on E , I can change the prior probability either of $S \wedge E$ or of E .

Representation is anyway only part of the story. If logic is to be a theory of what follows from what, or of what is evidence for what, then we must develop a standard, a criterion, and we must also develop a means of applying it. In the first order deductive realm, we must adopt a classical, or an intuitionistic, or a minimalist standard; and we must also develop a way of knowing when that standard is met. There are two things that this can mean: We might ask for a decision procedure: given a set of formulas and a formula, this would be a procedure that would tell us if the formula followed from the set of formulas. Or we could (as we must in first-order logic) settle for the the idea of *proof* – that is, a sequence of formulas each of which is one of the premises (the set of formulas) or is derivable from earlier formulas in the sequence by a rule of the logic. The existence of a proof of S from premises P_1, \dots, P_n *guarantees* that S follows from P_1, \dots, P_n in first-order logic, and S follows from (is entailed by) P_1, \dots, P_n guarantees that a proof exists, though it does not tell us how to construct it.

One difficulty we face in the case of inductive argument is that the set of sentences that yields our conclusion must be very large – it must comprise everything we know. This is a burden for nonmonotonic logic as well as for inductive logic. In both cases, we must allow that a conclusion S is supported by a set of evidence statements \mathcal{E} , but is not supported by a more inclusive set of evidence statements \mathcal{E}' . Both probabilists and logicians fudge this problem: the former write B for “background knowledge,” the latter write “ F ” for the set of accepted facts. It is easy to write B or F to stand for the evidence, but if we are either to represent realistic idealizations or apply the theory normatively, we need some way of unpacking the contents of \mathcal{E} .

As we remarked earlier, nobody ever thought that humans should, or could, reason in the form of proofs. The idea of a proof is that it definitively establishes that the conclusion follows from the premises. The role of ordinary “deductive” argument is to provide enough hints to show that a proof exists. Similarly “reasoning” could be

construed as a psychological process of casting about for potential arguments. To the extent that reasoning is successful in coming up with arguments to which there correspond actual proofs, it accomplishes its task. Therein lies the normative dimension of deductive logic.

Something similar could be said about uncertain reasoning, but there are important differences. The most important difference is that while a deductive argument depends on an explicit (usually short) list of premises, an inductive argument depends on “all” our background knowledge. This is a consequence of the non-monotonicity of inductive argument; new information can always undermine an inductive conclusion. As a consequence, the background knowledge B or the facts F do not easily admit of explicit listing, as do the premises of a deductive argument. But we must be able to say something about what is there.

Another significant difference is that there is nothing corresponding to “proof” for inductive arguments. We shall have more to say about this later.

A third difference (hardly unexpected) is that if S is provable from P_1, \dots, P_n then S is true in every model of P_1, \dots, P_n , while if S is inferrible from the set of evidence statements \mathcal{E} , we can at best argue that S is true in *almost all* the models of every maximal consistent subset of \mathcal{E} . We shall say then that S is supported by \mathcal{E} with maximum error ϵ , where “almost all” corresponds to $1 - \epsilon$.

Is it possible to develop an inductive logic that respects these differences, and that serves the same function as deductive logic in providing a framework in which people can come to agreement about whether S is supported by \mathcal{E} with maximum error ϵ ?

4. Probability

Like many other writers, we will take probability to be central to induction. More specifically, we shall interpret “ S is supported by \mathcal{E} with maximum error ϵ ” as “The lower bound of the evidential probability of S relative to \mathcal{E} is at least $1 - \epsilon$.” Because there are many “interpretations” of probability floating around, we shall say *evidential probability* (Kyburg and Teng 2001) to signal our interpretation.

Just as modus ponens may be taken as the sole form of deductive inference (Quine 1951), so direct inference may be taken as the sole form of inductive inference. Direct inference is the form of inference that proceeds from knowledge

of relative frequency, and of membership in a reference class, to probability (Broad 1968). For example, if you know that about a third of the freshman women are anorexic, and that Jane is a freshman woman, then there is an argument that the probability that Jane is anorexic is about a third. Of course there are other considerations. Jane is a college woman, and maybe you know that only between 10 percent and 14 percent of college women are anorexic. For that matter, you may know Jane personally, and know that she is fat and jolly.

It has been argued by some that conditioning is the basic form of inductive inference. But the inference from $P(H)$ and $P(H \wedge E)$ to $P(H|E)$ is not inductive at all, since $P(H|E)$ is just the quotient of the first two probabilities. Furthermore, conditional probabilities – $P(H|E)$ – can like any other probabilities be based on our knowledge of frequencies.

Direct inference is unlike *modus ponens*, however, since the probability to which it leads is only a *possible* conclusion. As in the example, many of these conclusions may conflict. We face the problem of sorting out and combining the various possible inferences.

To put the matter explicitly, to compute the probability of a statement S , relative to a body of evidence \mathcal{E} , we look at a set of triples of sentences. (In what follows, we use Greek τ and ρ for predicates, Greek α for a term; we enclose formulas, say $\lceil \rho(\alpha) \rceil$, in corners to indicate that we are referring to unspecified sentences of our object language.) The triples that concern us are the triples $\lceil \tau(\alpha) \rceil$, $\lceil \rho(\alpha) \rceil$, and $\lceil \%x(\tau(x), \rho(x), p, q) \rceil$ such that $\lceil S \leftrightarrow \tau(\alpha) \rceil$ is in \mathcal{E} , $\lceil \rho(\alpha) \rceil$ is in \mathcal{E} , and the statistical statement $\lceil \%x(\tau(x), \rho(x), p, q) \rceil$ (read “The proportion of items satisfying the reference formula ρ that also satisfy the target formula τ lies between the explicitly given rationals p and q ”) is in \mathcal{E} where τ is a suitable target formula and ρ is a suitable reference formula.¹ Note that α may represent a tuple of terms, and x a tuple of variables.

The point of the rules is to allow us to focus on the *relevant* parts of our statistical knowledge. To this end, we want to disregard some of the triples of sentences. We say that two statistical statements $\%x(\tau(x), \rho(x), p, q)$ and $\%x(\tau'(x), \rho'(x), p', q')$ *conflict* just in case neither $[p, q] \subseteq [p', q']$ nor $[p', q'] \subseteq [p, q]$ holds. Thus $[0.3, 0.5]$ and $[0.4, 0.7]$ conflict, as do $[0.1, 0.5]$ and $[0.8, 1.0]$, but $[0.5, 0.6]$ and $[0.4, 0.6]$ do not, nor do $[0.0, 1.0]$ and $[0.5, 0.5]$ conflict.

We apply the following rules sequentially:

1. If two statistical statements differ and the first is based on a marginal distribution, while the second is based on the full joint distribution, bracket the first. This gives conditional probabilities pride of place *when they conflict with the equivalent unconditional probabilities*.

Example: Suppose we have thirty black and thirty white balls in a collection C. The relative frequency of black balls among balls in C is 0.5, and this could serve as a probability that a specific ball a in C is black. But if the members of C are divided into three urns, one of which contains twelve black balls and twenty-eight white balls, and two of which each contain nine black balls, and one white ball, then if a is selected by a procedure that consists of (1) selecting an urn, and (2) selecting a ball from that urn, the relative frequency of black balls is $1/3(12/40) + 1/3(9/10) + 1/3(9/10) = 0.70$, and this is the appropriate probability that a , known to be selected in this way, is black. Note that it is based on relative frequencies. The marginal distribution is given by 30 black balls out of sixty; the full distribution reflects the division of the balls into the urns, and the distribution of colors in each urn.

	urn 1	urn 2	urn 3	
black	12	9	9	30
white	28	1	1	30
	40	10	10	60

2. If two statistical statements differ and the second employs a reference formula that logically entails the reference formula employed by the first, bracket the first. This embodies the well-known principle of *specificity*.

Example: Suppose you want the probability that Jane, the college freshman of our previous example, is anorexic. You know that she is a college woman, and that between 10 percent and 14 percent of college women are anorexic; but you also know that she is a freshman, and that about a third of freshman women are anorexic. These two potential direct inferences conflict. Specificity directs us to ignore the broad class in favor of the more specific class.

Those statistical statements we are not licensed to bracket we will call *relevant*. A smallest set of statistical statements that contains every relevant statistical statement that *differs* from a statement in it will be said to be *closed under difference*.

3. The probability of S is the shortest cover of any non-empty set of relevant statistical statements closed under difference; alternatively it is the intersection of all such covers.

Example: Suppose the intervals mentioned in the set of relevant statements are $[0.20,0.30]$, $[0.25,0.35]$, $[0.22,0.37]$, $[0.40,0.45]$, $[0.20,0.80]$, $[0.10,0.90]$, $[0.10,0.70]$. There are three sets that are closed under difference: $\{[0.20,0.30], [0.25,0.35], [0.22,0.37], [0.40,0.45]\}$, $\{[0.20,0.80], [0.10,0.70]\}$, and $\{[0.10, 0.90]\}$. The first set contains an interval that is included in another interval, and the third set is a singleton. The probability is $[0.20,0.45]$.

We note that probability is interval valued; it is a function from sentences S and sets of sets of evidential statements \mathcal{E} , to subintervals of $[0,1]$. If S is a finite set of statements and \mathcal{E} a set of evidence statements, then there exists a classical probability function P whose domain includes S such that for every $S \in S$, $P(S) \in \text{Prob}(S, \mathcal{E})$. Note that it need *not* be the case that for every S and T in S there is a classical probability function P such that $P(S|T) \in \text{Prob}(S, \mathcal{E} \cup \{T\})$. Bayesian conditioning need not be reflected in evidential probability.

We can show that probability is sound, in the sense that if $\text{Prob}(S, \mathcal{E}) = [p, q]$, then the proportion of models in which S is true, among models of maximal consistent subsets of \mathcal{E} lies between p and q . Note also that \mathcal{E} is not assumed to be deductively closed, or even consistent. We do assume that \mathcal{E} is closed under singular consequence – that is, that if S is in \mathcal{E} and $S \vdash T$, then T is in \mathcal{E} . This is a consequence of probabilistic induction, as we shall see.

5. Induction

The idea we take as basic for inductive logic is that we can inductively infer S from \mathcal{E} just in case the chance of our being in error is less than ϵ . We seek truth, else we would not infer at all; but we also seek to control error. We cannot ensure the truth of our inferences; we can ensure that

errors are rare. High probability does so. If the probability of S is high (its lower bound is greater than $1 - \epsilon$), then the proportion of models of our data in which S fails to hold is less than ϵ .

But can this be made to work? Can we show that in a state of empirical ignorance, empirical data can render statistical generalizations highly probable? The answer is “yes.”

First, we note that some statistical generalizations are true a priori. Consider the set of satisfiers of the formula “ $A(x)$.” We suppose that there is a large number of these things. Some of them, say an unknown proportion r , also satisfy the formula “ $B(x)$ ”. Chebycheff’s inequality – an elementary theorem of probability theory – says that the frequency with which a quantity (such as F , the relative frequency of B ’s in a sample of n A ’s) will differ from its expectation by more than k times its standard deviation, is less than $1/k^2$. We do not know the value of r , but we know that the standard deviation of F , which is $\sqrt{r(1-r)/n}$, cannot be greater than $1/2\sqrt{n}$, whatever r may be. We also know that the expectation of F is r . In English: it is a priori that the relative frequency of n membered samples in which F differs by more than $k/2\sqrt{n}$ from the relative frequency r in the original population is less than $1/k^2$. Let $nA(x)$ denote the set of n -membered samples of A ’s, and $F(x) \pm k/2\sqrt{n}$ denote the set of samples that contain a proportion of B ’s differing from r by less than $k/2\sqrt{n}$. Then we have as an a priori truth in our body of knowledge \mathcal{E} the statistical statement, $\%x(F(x) \pm k/2\sqrt{n}, nA(x), 1 - 1/k^2, 1.0)$ Indeed, we have such a statement for any n and any k . Our body of a priori knowledge is full of a priori statistical statements!

Now we must show that this statistical knowledge can confer a high probability on a statement of the form $\%x(B(x), A(x), p, q)$. Let us suppose that \mathcal{E} , in addition to the a priori information just indicated, contains the report of a sample of 10,000 A ’s, of which 3,812 were B ’s. We will show that the probability of “ $\%x(B(x), A(x), 0.3312, 0.4312)$ ” is at least $[0.99, 1.0]$. (By “at least $[0.99, 1.0]$ ”, I mean a subinterval of $[0.99, 1.0]$.) Note first that the standard deviation of the frequency F of B ’s among A ’s in a sample, though it depends on the value of r (the overall relative frequency of B ’s among A ’s), must be less than $1/2\sqrt{1/n} = .005$. By Chebycheff’s inequality the fraction of samples of 10,000 that fail to exhibit a value of F within 10 standard deviations of r (the mean of F is r), is less than $1/(10^2)$. Thus we have in \mathcal{E} (since it is true a priori) $\%x(|F(x) - r| > 0.05,$

$A^{10,000}$, .00, .01). We are supposing that the only sample we have is the sample s of 10,000 A 's. Since we know, in \mathcal{E} , that 3,812 members of the sample are B 's, we know $F(s) = 0.3812$ and therefore we know the biconditional $|0.3812 - r| \leq 0.05 \leftrightarrow \%x(B(x), A(x), 0.3312, 0.4312)$.

Thus, we have the three ingredients for the probability statement we are after:

1. $|F(s) - r| \leq 0.05 \leftrightarrow \%x(B(x), A(x), 0.3312, 0.4312)$
2. $\%x(|F(x) - r| \leq 0.05, A^{10,000}, 0.99, 1.0)$
3. $s \in A^{10,000}$

We still need to consider the three rules.

Do we know of a reference formula, target formula, and statistical statement that would lead us to bracket $\%x(|F(x) - r| > 0.05, A^{10,000}, 0.99, 1.0)$ on the basis of conditioning? Here is one difference between inductive logic and deductive logic. To know that there is no such triple of formulas entailed by \mathcal{E} is to survey the entailments of \mathcal{E} exhaustively. But there are certain natural questions that can be raised.

One possible reference formula would be that generated by background knowledge concerning the source of A . For example if the set of A 's were selected from a *set of sets* in each of which we know the distribution of B 's, this could trigger rule 1. (For example, A might be the set of balls in a bag, and the bag might be selected from a *set of bags*, containing a known distribution of the proportion of B 's in each bag.) That is to say, we might know a prior distribution over r , the relative frequency in A . This is the classical Bayesian case. We could condition on the *distribution* of values of r . But we have supposed ourselves to have only the sampling knowledge in \mathcal{E} ; were we to have knowledge of a prior distribution for r we could infer a posterior distribution on the basis of the sample by conditioning. (Note that this boils down to direct inference concerning the selection of a population and then of a sample from that population.)

Here is another alternative: if our knowledge is as described, then we also know of a sample of 6,000 A 's, *none* of which are B 's. Let this sample be s' . $F(s') = 1$, so we have, by a parallel argument:

1. $(F(s') - 0.6688 \leq r \leq F(s') - 0.5688) \leftrightarrow \%x(B(x), A(x), 0.3312, 0.4312)$
2. $\%x((F(x) - 0.6688 \leq r \leq F(x) - 0.5688), A^{6,000}, 0.0, 0.0)$, or

$$\%x(r + 0.5688) \leq F(x) \leq r + 0.6688, A^{6,000}, 0.0, 0.0)$$

3. $s' \in A^{6,000}$

The proportion of 6,000-member subsets of A that have the property in question is not *exactly* 0, of course, but as close as makes no difference. In any event, we clearly have conflict. What allows us to retain an inference based on s and to reject an inference based on s' ?

Answer: Rule 1 and our initial triple of sentences. The set $A^{6,000} \times A^{4,000}$ is the same as, or has the same statistics as the set $A^{10,000}$. That generates a triple that conflicts with the statistics of 6,000-member samples and leads to the bracketing of the corresponding statistical statement, which corresponds to a marginal distribution in the product space $A^{6,000} \times A^{4,000}$.

Of course, if we also had knowledge of a larger sample than s – a supersample of s – things would be different, just as they would be different if we had knowledge of a prior distribution for r . But, by assumption, we don't.

Do we know of a reference class that would lead us to bracket $\%x(|F(x) - r| \leq 0.05, A^{10,000}, 0.99, 1.0)$ on the basis of Rule 2, specificity? That would require our knowing of a *subset* of $A^{10,000}$ within which $|F(x) - r| \leq 0.05$ would be true with a *differing* relative frequency. In real life we might well know of such a subset to which we know that s belongs. We might know that s was obtained by a procedure that was biased against the selection of B 's, and thus that s was a member of a subset of $R^{10,000}$ in which the relative frequency of samples satisfying $|F(x) - r| \leq 0.05$ is much lower than it is in $A^{10,000}$ in general. But to know this is already to have general empirical knowledge. We have supposed that this is not the case in our example.

Finally, do we know of a set of reference classes closed under difference whose cover is properly contained in $[0.99, 1.0]$? I suspect we do, since Chebycheff's inequality is a very rough one: We can probably find a higher lower bound on the frequency of representative samples. Or, equivalently, we could tighten the notion of representativeness and achieve the same lower bound of 0.99. But this is not to the point here. Our object here was simply to show that induction in the most simple-minded sense can be justified probabilistically.

6. Inductive Logic

It is important to note that on our view, the conclusion of an inductive argument is, just

like the conclusion of a deductive argument, *accepted*: It is a sentence that “follows from” a set of sentences \mathcal{E} that we accept as evidence, in the sense that it is almost always true when sentences of \mathcal{E} are true. That is why the inference is nonmonotonic or inductive. The conclusion is not, as Carnap (1950) proposed, a sentence asserting a probability. We inductively conclude “ S ,” not “probably S ,” and certainly not the Carnapian, “The probability of S , relative to total evidence \mathcal{E} is p .” This latter form of conclusion, as Keynes (1952) observed, is not *corrected* by additional evidence \mathcal{E}' ; it is simply replaced by “The probability of S , relative to $\mathcal{E} \cup \mathcal{E}'$ is q .” The Carnapian inference is monotonic.

If inductive conclusions are to be accepted, as we suggest, however, we must immediately face the question of how a rejection level ϵ is to be chosen. But this is a question that is faced by researchers all the time, and is answered, somewhat arbitrarily, by the conventions of the trade. Psychologists are often willing to reject null hypotheses at the 0.05 or 0.02 level; in the physical sciences one supposes that measurements are not more than two and a half standard deviations in error. Engineers deal with factors of safety of two to ten, which can also be translated into probabilities of error. Some very tentative systematic ideas relating the acceptable level of error to what might be generally at stake were advanced in Kyburg (1988), but a lot more thought could be devoted to this question. The question is answered in practice but not in theory.

Furthermore, if statements are accepted on the basis of their low likelihood of error, the set of accepted conclusions will not be closed under conjunction, and thus not deductively closed (Kyburg 1997). The chance that S is in error may be less than ϵ and the chance that T is in error may be less than ϵ , while the chance that $S \wedge T$ is in error may be greater than ϵ so that the conjunction may not be accepted. Of course, this is a marginal phenomenon – there are many cases in which conjunctions are acceptable. Thus (to use the time-worn lottery once again) if our level of rejection is 0.001, in a million ticket lottery we will be able to accept the conjunction of up to a thousand “ticket i will not win” statements, and therefore also the logical consequences of such sets of statements.

Now of course that holds for the conjunction of *any* thousand such statements, so we have the lottery problem all over again: the set of acceptable statements is inconsistent. This should not

be surprising for inductive conclusions. In those disciplines in which the null hypothesis of “no effect” is tested at the 0.05 level, we reject each hypothesis rejected at this level, and simultaneously accept that in the long run one out of twenty of such hypotheses are true. Similarly, in physical measurement we may decide that one chance in a hundred of being in error is tolerable risk, and so accept that the true measure of a quantity is in an interval of 2.5 standard deviations about the observed value. But we also know, within the same margin of error, that at least one of five hundred measurements will be in error by *more* than 2.5 standard deviations. Put explicitly: the agent should believe that *each* of the next five hundred measurements is correct within 2.5 standard deviations, and the agent should believe that at least one of these measurements is not correct within 2.5 standard deviations.

There is no explosive problem here. It is true that the set of accepted statements *entails* all statements, because it is inconsistent. But “ $1 = 0$ ”, though it is entailed by the set of accepted statements is not itself one: Its probability is 0 and does not exceed $1 - \epsilon$. We would only face a deductive explosion if we took the set of accepted statements to be deductively closed, or, what is the same thing, closed under conjunction (Kyburg 1970).

This raises the question of what logical structure there is in the set of accepted statements. We can show that if $S \vdash T$, $\text{Prob}(S, \mathcal{E}) \subset [1 - \epsilon, 1]$, then $\text{Prob}(T, \mathcal{E}) \subset [1 - \epsilon, 1]$. Thus if S is acceptable and S entails T , then T is acceptable. Anything entailed by any statement accepted at a certain level is acceptable at that level. If a conjunction a thousand conjuncts long is acceptable, anything entailed by that conjunction is acceptable.

Let us turn our attention to \mathcal{E} , the set of statements relative to which we perform our inductive inferences. We note that since probabilities are based on statements of long run frequency (though not to be identified with them!), \mathcal{E} will have to include such statements. Some such statements, as we have seen, are true a priori: Any (approximately) normally distributed quantity will deviate from its mean by more than 2.5 standard deviations no more than 1 percent of the time; the proportion of hundred member samples of A 's that differ in their fraction of B 's from the set of all A 's by as much as 0.30 (\geq six standard deviations) is less than 1/36 (using Chebycheff's inequality and the fact that the standard deviation of the relative frequency

is less than $1/20$). But of course most of the probabilities that interest us are based on *empirical* frequencies that are known in \mathcal{E} – that is, they are based on induction!

That means that \mathcal{E} itself should include statements only supported with high probability (or bearing low risk of error) relative to some *other* body of evidence \mathcal{E}' , which in turn includes only statements with an even lower risk of error. Note that \mathcal{E} may contain observation statements that, according to \mathcal{E}' have low probability of error, as well as empirical statistical generalizations based on \mathcal{E}' ; there need be no foundation of incorrigible observation statements.

This is not a problem for *induction*, which concerns the rational acceptance of statements that run low risk of error, relative to a set of statements accepted as evidence, although it may be a problem for general epistemology. What concerns us here is not general epistemology, but the structure of \mathcal{E} and the fact that it has the same open structure as the set of inductive conclusions we infer from it on the basis of their high probability or low chance of error relative to \mathcal{E} . Although \mathcal{E} clearly contains an infinite number of statements (in virtue of the fact that it contains all the entailments of any statement in it), it seems reasonable to suppose that it admits of a finite basis, that is, a finite set of statements from which all and only statements in \mathcal{E} follow. So as a basis for inductive conclusions having a probability of error of less than ϵ we take as evidence a set of statements \mathcal{E} that

1. Are more reliable than $1 - \delta$, where $\delta < \epsilon$;
2. Has a finite basis;
3. May be inconsistent;
4. Are expressed in our first order language \mathcal{L} .

How does the logic of induction we have outlined stack up against first-order logic? As we observed, first-order logic does not represent how people should think deductively, or even how they should argue deductively, but, rather, through its formal notion of proof, first-order logic serves as a gold standard for the resolution of disagreements or doubts about what entails what, about what follows from what. Although there is more than one first-order logic, in most contexts the variants come to the same thing. Similarly, inductive logic is not “inductive” because it reflects how people think, but because

it concerns what is *evidence* for what, just as deductive logic concerns what *follows* from what.

But there is one big difference between deductive logic and inductive logic. If there is a proof that C follows from P_1, \dots, P_n it can ordinarily be rendered short and perspicuous. Such a proof depends only on the sentences P_1, \dots, P_n . In contrast, when we say that P_1, \dots, P_n provides *evidence* for C, citing P_1, \dots, P_n explicitly, we mean that it does so *in the context of everything else we know, \mathcal{E}* . Since an addition to our total evidence \mathcal{E} can undermine the relation of evidence, the evidential relation depends on what we don't know as well as on what we know, or, put otherwise, in depends on *all* we know. That is why the inductive evidential relation is nonmonotonic, while the entailment relation is not.

Note that there is no algorithm for producing a proof (when one exists) in deductive logic. Inductive logic is no worse off in this regard. The difficulty in inductive logic is caused by the fact that the “premises” of an inductive argument consist of everything we know, and, more seriously, on the fact that an inductive argument depends on entailments of what we know.

The biggest problem is managing \mathcal{E} . Earlier I pointed out that writing “B” for background knowledge doesn't help us in resolving disagreements about what is evidence for what. Writing “ \mathcal{E} ” is no more help. What we need to do is to represent \mathcal{E} explicitly. Of course you can't “write down everything you know.” But in a scientific context, by and large, most of what differentiates your body of knowledge from mine is irrelevant to the support provided C by P_1, \dots, P_n . It does not seem unreasonable to ask that a basis for \mathcal{E} be provided.

Furthermore, inductive support is measured by evidential probability, and all probabilities come from constructions of direct inference. Thus within this formalization, to establish the probability of S, we are looking for triples of formulas:

$$\lceil S \leftrightarrow T(a) \rceil, \lceil \% (T(x), R(x), p, q) \rceil, \text{ and } \lceil R(a) \rceil$$

implied by the \mathcal{E} . This requires first, as we have said, that the body of knowledge \mathcal{E} have a basis, and second, that we have some way of telling when a triple of sentences is entailed by sentences of \mathcal{E} . In the case of deductive logic we can manage without a procedure for finding proofs: When a proof of S from A_1, \dots, A_2 is needed, we can depend on ingenuity to come up with

one. Once we have one it is checkable, and it remains valid whatever we add to the premises A_1, \dots, A_2 . In principle, it becomes part of our social store of data.

In contrast, even checking an inductive argument from \mathcal{E} to S requires a complete survey of the consequences of \mathcal{E} ; and given a valid inductive argument yielding $\text{Prob}(S, \mathcal{E}) = [p, q]$, that argument may be undermined by additions to \mathcal{E} . This is unavoidable. It is just what it *means* for an argument to be inductive.

Note

- 1 The requirement of "suitability" has been with us since Kyburg (1961), in one form or another. In a number of places, random quantities, functions from objects in the domain to real numbers, are also taken account of explicitly. Both classes of formulas were intended to be given, recursively, as part of the specification of the language.

Chapter 16: Reasoning in Conceptual Spaces

PETER GÄRDENFORS

1. Three Levels of Modeling Reasoning

Processes of reasoning have been at the heart of analysis in analytic philosophy, artificial intelligence (AI) and in the early development of cognitive science. In these traditions, reasoning has been modeled as operations on propositions that are expressed by symbolic structures. I will call this approach the *symbolic paradigm*.

The central tenet of the symbolic paradigm is that representing and processing information essentially consists of *symbol manipulation* according to explicit *rules*. For example, Pylyshyn (1984: 29) writes: “[T]o be in a certain representational state is to have a certain symbolic expression in some part of memory.” The symbols can be concatenated to form expressions in a *language of thought* (Fodor 1975), which is sometimes called *Mentalese*. The content of a sentence in *Mentalese* is a belief or a thought of an agent. The different beliefs in the cognitive states of a person are connected via their *logical* or *inferential relations*. Thus, the manipulations of symbols are performed without considering the semantic content of the symbols. In applications within AI, first-order logic has been the dominating inferential system (or some related programming version of it, such as Prolog). But in other areas more general forms of inference, like those provided by inductive logic or decision theory, have been utilized.

The symbols are used for modeling logical inferences and the expressions represent *propositions*, which stand in various *logical relations* to each other. Information processing involves above all *computations* of logical consequences. Here I am referring to the traditional sequential kind of computer programs with “explicit” symbol representations and not to connectionist systems (see later), which may use “intrinsic” representations (compare Palmer 1978).

In brief, a cognitive agent is seen as a kind of logic machine that operates on sentences from some formal language. The following quotation from Fodor (1981: 230) is a typical formulation of the symbolic paradigm:

Insofar as we think of mental processes as computational (hence as formal operations defined on representations), it will be natural to take the mind to be, *inter alia*, a kind of computer. That is, we will think of the mind as carrying out whatever symbol manipulations are constitutive of the hypothesized computational processes. To a first approximation, we may thus construe mental operations as pretty directly analogous to those of a Turing machine.

The main methodological point of this chapter is to argue that, despite the dominance of the symbolic paradigm, *reasoning can be described on different cognitive levels* and that these levels bring out other aspects of the reasoning process (Gärdenfors 1994). Reasoning is not done by symbols alone. For instance, consider how to analyze animal reasoning. Because it is likely that human is the only species that can productively use symbols, it would follow that other forms of animal reasoning fall outside the symbolic paradigm.

There are areas where the symbolic approach to reasoning has led to problems. Maybe the most pressing concerns the attempts to explain inductive inferences. The most ambitious project of analyzing induction during the previous century has been that of the logical positivists. Inductive inferences were important for them, since such inferences were necessary for their verificationist aims. The basic objects of study for them were sentences in some more or

less regimented language. However, it became apparent that the methodology of the positivists led to serious problems in relation to induction. The most famous ones are Hempel's (1965) "paradox of confirmation" and Goodman's (1955) "riddle of induction." These problems will be presented and discussed in Section 6.

I shall describe two other levels of cognitive modeling: the *conceptual* and the *subconceptual*. The subconceptual level corresponds to what has often been called the subsymbolic (Smolensky 1988). During the last decades this level has been implemented in *connectionist* systems, also known as parallel distributed processes (Rumelhart and McClelland 1986). Connectionist systems, often called *artificial neuron networks*, consist of large numbers of simple but highly interconnected units ("neurons"). The units process information in *parallel* (in contrast to most symbolic models where the processing is *serial*). There is no central control unit for the network, but all neurons "act" as individual processors. Processes of "reasoning" in such a system are modeled by the dynamics of the activities of the artificial neurons. In many cases, it can be said that a "conclusion" is reached when the network stabilizes in some equilibrium state (see Balkenius and Gärdenfors 1991 for an analysis of nonmonotonic reasoning by artificial neuron networks in these terms).

In addition to the symbolic and the subconceptual levels, I shall present a middle level of describing reasoning – the conceptual level, based on geometric structures in conceptual spaces. My focus will be on how models on this level can be used to understand *reasoning about concepts*, in particular inductive and nonmonotonic reasoning.¹ I shall argue that these processes are described more accurately on the conceptual level.

Apart from the implications for philosophical and psychological research, models of inductive and nonmonotonic reasoning have applications within several practical areas involving computerized management of concepts. In particular, the recent attempts to create a "Semantic Web" would benefit from such models (Gärdenfors 2004). I shall return to this topic in the concluding section.

The crucial question for my task is how concepts should be modeled. On the symbolic level, basic concepts are not modeled, but just *named* by the elementary symbols. Then names of more complex concepts are constructed by compositions, logical or syntactical, of the simple names. And when it comes to connectionist systems,

concepts are often represented *implicitly* in such systems. The primary motivation for introducing a conceptual level is to provide tools for *explicit* representations of basic concepts and their roles in reasoning. It is natural to view the conceptual level as being between the symbolic and the subconceptual levels in its cognitive granularity.

My main modeling tool will be *conceptual spaces* that employ geometric structures rather than symbols or associations. Information is represented by points, vectors and regions in dimensional spaces. On the basis of these structures, reasoning with concepts can be described in a natural way in terms of distances in a space. The framework of this chapter follows the theory presented in my book *Conceptual Spaces: The Geometry of Thought* (Gärdenfors 2000). As we shall see, this kind of model will help clarify the relationship between inductive and nonmonotonic reasoning. Before presenting the conceptual level, I will give some motivations for studying inductive and nonmonotonic reasoning.

2. Three Ways of Describing an Observation

To illustrate the relevance of the three levels of modeling reasoning, let us look at the notion of an *observation* as it is used in inductive reasoning. It is commonplace that induction is going from single observations to generalizations. But this statement loses its air of triviality if one takes seriously the question of *what* an observation is. It is surprising that this question has received very little attention within the philosophy of science.² I want to argue that there is no unique way of characterizing an observation. Indeed, I shall distinguish three levels of accounting for observations corresponding to the three levels of modeling described in the introduction (or, since all levels may be adopted at the same time, they may as well be called perspectives):

1. *The symbolic level:* This way of viewing observations consists of describing them in some specified language. The language is assumed to be equipped with a fixed set of primitive predicates and the denotations of these predicates are taken to be known. An observation is a particular type of *statement* (proposition). The observational statements are supposed to be furnished to the reasoner by incorrigible perceptual mechanisms.
2. *The conceptual level:* On this level observations are not defined in relation to

some language but characterized in terms of some underlying conceptual space. The conceptual space, which is more or less connected to perceptual mechanisms, consists of a number of “quality dimensions” (these will be described later). Using the notion of conceptual spaces, an observation can be defined as *an assignment to an object of a location in a conceptual space*. For example, the observation that is described on the symbolic level as “x is red” is expressed on the conceptual level by assigning x a point in color space. On this level, induction is seen as closely related to *concept formation*. According to the conceptual perspective, inductive inferences show prototype effects, in contrast to the symbolic perspective that operates on Aristotelian concepts (cf. Smith and Medin 1981).³

3. *The subconceptual level*: In the most basic sense an observation is what is received by our sensory organs. In this sense, an observation can be identified with what is received by a set of *receptors*. For human beings and other animals these inputs are provided by the sensory receptors, but one can also talk of a machine making observations of this kind via some measuring instruments serving as receptors. Actually, this is what happens in modern science. Many “observations” never pass a human eye or ear, but are transmitted directly from the measuring devices to a computational database that is then used to evaluate the experiment.

The receptors provide “raw” data in the sense that the information is not assumed to be processed in any way, neither in a conceptual space, nor in the form of some linguistic expression. The observations are thus described as occurring before conceptualization. The inductive process is seen as establishing connections between various types of inputs. One currently popular way of modeling this kind of process is by using artificial neuron networks.

One objective of this chapter is to argue that depending on which approach to observations is adopted, thoroughly different considerations about inductive inferences will come into focus.⁴ In my opinion there is a multitude of aspects of inductive reasoning and not something that can be identified as *the* problem of induction. The upshot is that there is no canonical way of studying induction. What is judged to be the salient

features of the inductive process depends to a large extent on *what* an observation is considered to be and thus on what cognitive level the process is modeled.

3. Nonmonotonic Reasoning

Concepts play an important role in the generation of *inferences*. As Holland et al. (1986: 180) put it: “To know that an instance is a member of a natural category is to have an entry point into an elaborate default hierarchy that provides a wealth of expectations about the instance.” In this section, I will argue that what has been called *nonmonotonic reasoning* is tightly connected to this role of concepts. As I shall argue in Section 7, this form of reasoning is best described on the conceptual level instead of on the symbolic level that has been dominating in the literature.

The deductive reasoning of traditional logic is *monotonic* in the sense that when a proposition *A* can be inferred from a set *S* of sentences, then *A* can be inferred from any set that contains *S*. However, everyday reasoning, which in general is based on assumptions about what is “normally” the case, is often nonmonotonic. For example, if I learn that Gonzo is a bird, then with the aid of the presumption that birds normally fly, I conclude that Gonzo flies. But if I obtain the additional information that Gonzo is an emu, this conclusion is no longer drawn.

Nonmonotonic reasoning has become a central topic within AI.⁵ However, most of the research efforts have been concentrated on finding the appropriate *logical rules* that govern nonmonotonic reasoning. This means that a symbolic representation of the relevant knowledge is already presumed. However, I believe that in order to understand nonmonotonic reasoning one must go below the symbolic level of representation. Strangely enough, the relationship between induction and nonmonotonic reasoning does not seem to have been investigated.

The basic idea of nonmonotonic inferences is that when more information is obtained about an object, some inferences that were earlier reasonable are no longer so. An important point that is often overlooked is that information about an object may be of two kinds: *propositional* and *conceptual*. When the new information is propositional, one learns new *facts* about the object, for example, that x is an emu. When the new information is conceptual, one *categorizes* the object in a new way, for example, x is *seen as* an emu instead of as just a bird. It is important to notice

that describing information as propositional or as conceptual does not mean that these kinds of information are in conflict with one another. On the contrary, they should be seen as different *perspectives* on how information is described.

The theory of nonmonotonic reasoning has focused on propositions; hence it has been seen as a nonmonotonic *logic*. However, in the examples discussed in the literature, the great majority derives from the nonmonotonicity of *concepts*. For example, the *default rules* studied by Reiter (1980) and his followers have been conceived of as inference rules, although a more natural interpretation of “defaults” is to view them as *relations between concepts*. For instance, when something is categorized as a fruit, it will also, by default, be categorized as sweet, even though it is well known that the category contains many exceptions that are not sweet.

It may be argued that there is no harm done in focusing on the symbolic perspective of nonmonotonicity since information about categorization can be quite naturally transferred to propositional information: categorizing x as an emu, for example, can be expressed by the proposition “ x is an emu.” However, this transformation into the symbolic form tends to suppress the internal *structure* of concepts. Once one formalizes categorizations of objects by *predicates* in a first order language, there is a strong tendency to view the predicates as primitive atomic notions and to forget that there are rich relations between concepts that disappear when put into standard logical formalism.

Indeed, in the symbolic paradigm, the fact that the concept of an emu is a subcategory of “bird” is represented by an explicit axiom in the form of a universal sentence “for all x , if x is emu, then x is a bird.” However, if the geometrical structure of concepts, as it is given in a conceptual space, were built into the predicates of the language themselves, such an axiom would be totally redundant because the region representing emus is a subregion of the one representing birds. As we shall see, the inclusion relations between the regions and their domains will, in a sense, become *analytic* in a conceptual space.

To be sure, there is in the literature one well-known theory of nonmonotonic inferences that focuses on conceptual relations, namely *inheritance networks* (see, for example, Touretsky 1986 and Makinson and Schlechta 1991). However, in the theory of inheritance networks, concepts are represented by (nonstructured) *points* without any structure, and their relations by two kinds of links: “is-a” and “is-not-a.” Since these

links say nothing about the structure of concepts, this form of representation is far too meager to handle the relations between concepts that are exploited in inferences, monotonic as well as nonmonotonic. In contrast, I submit that a theory of conceptual structure is necessary in order to understand different kinds of nonmonotonic inferences involving concepts.

As a challenge to any theory about nonmonotonic inferences, I would like to point out the following nonmonotonic aspects of reasoning about concepts:

(a) *Change from a General Category to a Subordinate*

This is the most well known nonmonotonic aspect of concepts. When we shift from applying a “basic” category (a term borrowed from prototype theory) like *bird* to an object x , to applying a “subordinate” category like *emu*, we often give up some of the (default) properties associated with the basic category: a bird is normally small and sings and flies, while an emu has none of these properties.

(b) *Contrast Classes*

In standard uses of first order logic, *combinations* of concepts are expressed by *conjunctions* of predicates. However, there are many different combinations of concepts that cannot be analyzed in this manner. As a matter of fact, nonmonotonicity is ubiquitous in concept combinations. For example, even though “Zinfandel” is a subcategory of “wine” and “wine” is a subcategory of “object,” “white Zinfandel” is not a subcategory of “white wine” (it is a rosé wine) and “white wine” is not a subcategory of “white objects” (it is light yellow).

For another example, consider the seemingly innocent concept *red*. In the *Advanced Learner's Dictionary of Current English*, it is defined as “of the colour of fresh blood, rubies, human lips, the tongue, maple leaves in the autumn, post-office pillar boxes in Gt. Brit.” This definition fits very well with letting *red* correspond to the normal region of the color space (see Section 4). Now consider *red* in the following combinations:

- Red book
- Red wine
- Red hair
- Red skin
- Red soil
- Redwood

Figure 1. Cuplike objects (From Labov 1973).

In the first example, *red* corresponds to the dictionary definition, and it can be combined with *book* in a straightforward extensional way that is expressed by a conjunction of predicates in first-order logic. In contrast, *red* would denote *purple* when predicated of wine, *copper* when used about hair, *tawny* when of skin, and *pinkish brown* when of wood. Thus the class of objects that the concept is applied to, the so-called *contrast class*, changes the meaning of *red* in a non-monotonic fashion (Broström 1994).

(c) Metaphors

Even more drastic combination effects occur in metaphorical uses of concepts. For example, when we talk about a *red newspaper*, we do not expect it to be printed on red paper, only to express a certain political viewpoint. And in everyday metaphors such as the “legs” of a table, the “hands” of a clock, the “mouth” of a river,

we do not think of tables, clocks and rivers as having bodies. The kind of conceptual change involved in a metaphor corresponds to a *revision* of the concept, and thus the inferences involved in metaphorical uses of concepts parallels *belief revisions* that are modeled in propositional systems (Gärdenfors 1988; for a comparison between nonmonotonic inferences and belief revision, see Gärdenfors and Makinson 1994).

Metaphors are notoriously difficult to handle within the symbolic paradigm, since it is assumed that the reference of a predicate is fixed in advance. In most logical theories, these linguistic figures have thus been treated as deviant phenomena and have been ignored or incorporated via special stylistic rules.

(d) Context Effects

Combinations of concepts can result in non-monotonic effects as exemplified by contrast

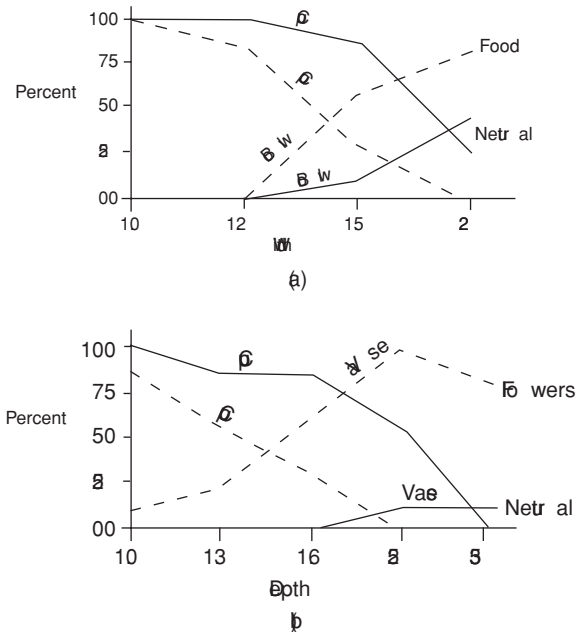

Figure 2. Context effects on the borders between concepts (Labov 1973).

classes and metaphors. Sometimes the mere *context* in which a concept is used may trigger different *associations* that lead to nonmonotonic inferences. Barsalou (1987: 106) gives the following example: "When *animals* is processed in the context of milking, *cow* and *goat* are more typical than *horse* and *mule*. But when *animals* is processed in the context of riding, *horse* and *mule* are more typical than *cow* and *goat*."

Another example of how the context affects the application of concepts is the following, due to Labov (1973). He showed subjects pictures of objects like those in Figure 1 in order to determine how the variations in shape influence the names the subjects use. But he also wanted to see whether the *functions* of the objects also influences naming.⁶ In the "neutral" context, subjects were asked to imagine the object in someone's hand. In a "food" context, they were asked to imagine the object filled with mashed potatoes; and in a "flowers" context, they were told to imagine the object with cut flowers in it.

Figure 2 shows the results, when the *width* of objects 1 to 4 (Figure 2a) and *depth* of objects 1 and 5 to 9 (Figure 2b) varied as is represented on the horizontal axes. The vertical axis represents the percentage of subjects that named the object with a particular word. As can be seen, the names for the objects were heavily influenced by the imagined context.

This example shows that even if the "core" or "prototype" of two concepts like *cup* and *bowl*

remain unchanged, the context may change the *border* between the concepts. Such a change may clearly have nonmonotonic effects on the reasoning involving the concepts.

I have here presented four different kinds of nonmonotonic aspects of reasoning with concepts. It should be obvious that these aspects are interrelated. However, in the literature, the focus has almost exclusively been on what happens when one changes from a general category to a subordinate. I submit that other aspects are equally important and in need of a systematic explanation. Furthermore, the relation to inductive reasoning has been neglected. In the following two sections, I will outline a theory that I believe can shed light on all of the nonmonotonic aspects of concepts discussed here.

4. Conceptual Spaces as a Representational Framework

As a framework for a geometric structure used in describing the cognitive level of reasoning, I have proposed (Gärdenfors 1990a, 1990b, 1992, 2000) the notion of a *conceptual space*. Conceptual spaces represent information by *geometric* structures rather than by symbols. Information is represented by points (standing for individuals or objects), and regions (standing for properties and relations) in dimensional spaces. A great deal of the structure of concepts, for example similarity relations, can be modeled

in a natural way by exploiting *distances* in the space.

A conceptual space consists of a number of *quality dimensions*. Examples of such dimensions are: color, pitch, temperature, weight, and the three ordinary spatial dimensions. I have chosen these dimensions because they are closely connected to what is produced by our sensory receptors (Schiffman 1982). However, there are also quality dimensions that are of an abstract nonsensory character.

The primary role of the dimensions is to represent various "qualities" of objects in different *domains*. Since the notion of a domain is central to my analysis, it should be given a more precise meaning. To do this, I rely on the notions of separable and integral dimensions taken from cognitive psychology (see, e.g., Garner 1974; Maddox 1992; Melara 1992). Certain quality dimensions are *integral* in the sense that one cannot assign an object a value on one dimension without giving it a value on the other. For example, an object cannot be given a hue, without also giving it a brightness value. Or the pitch of a sound always goes along with a loudness. Dimensions that are not integral are said to be *separable*, as for example the size and hue dimensions. Using this distinction, the notion of a *domain* can now be defined as a set of integral dimensions that are separable from all other dimensions.

The domains form the framework used to assign *properties* to objects and to specify *relations* between them (see next section). The dimensions are taken to be independent of symbolic representations in the sense that we can represent the qualities of objects, for example by vectors, without presuming an explicit language in which these qualities are expressed.

The notion of a dimension should be understood literally. It is assumed that each of the quality dimensions is endowed with certain *topological* or *metric* structures. As a first example, I will take the dimension of *time*. In science, time is a one-dimensional structure that is isomorphic to the line of real numbers. If *now* is seen as the zero point on the line, the future corresponds to the infinite positive real line and the past to the infinite negative line. This representation of time is not universal, but is to some extent culturally dependent, so that other cultures have a different time dimension as a part of their cognitive structure. There is thus no unique way of choosing a dimension to represent a particular quality, but in general one has a wide array of possibilities.

In order to separate different uses of quality dimensions, it is important to introduce a distinction between a *psychological* and a *scientific* interpretation. The psychological interpretation concerns how humans (or other organisms) structure their perceptions. The scientific interpretation, by contrast, deals with how different dimensions are presented within a scientific theory. The distinction is relevant when the dimensions are seen as cognitive entities, in which case their topological or metric structure should not be determined by scientific theories, which attempt at giving a "realistic" description of the world, but by *psychophysical* measurements that determine the structure of how our perceptions are represented.

A paradigmatic example of a domain involves *color*. In brief, our cognitive representation of color can be described by three dimensions. The first dimension is *hue*, which is represented by the familiar *color circle*. The topological structure of this dimension is thus different from the quality dimensions representing time or weight which are isomorphic to the real line. One way of illustrating the differences in topology is by noting that we can talk about psychologically *complementary* colors, that is, colors that lie *opposite* to each other on the color circle. In contrast it is *not meaningful* to talk about two points of time or two weights being "opposite" to each other.

The second psychological dimension of color is *saturation*, which ranges from grey (zero color intensity) to increasingly greater intensities. This dimension is isomorphic to an interval of the real line. The third dimension is *brightness*, which varies from white to black and is thus a linear dimension with end points. Together, these three dimensions, one with circular structure and two with linear, constitute the color space which is a subspace of our perceptual conceptual space.

This space is often illustrated by the so-called *color spindle* (see Figure 3). Brightness is shown on the vertical axis. Saturation is represented as the distance from the center of the spindle towards its perimeter. Hue, finally, is represented by the positions along the perimeter of the central circle.

It is impossible to provide a complete list of the quality dimensions involved in the conceptual spaces of humans. Some of the dimensions seem to be *innate* and to some extent hardwired in our nervous system, as for example color, pitch, and probably also ordinary space. Other dimensions are presumably *learned*. Learning

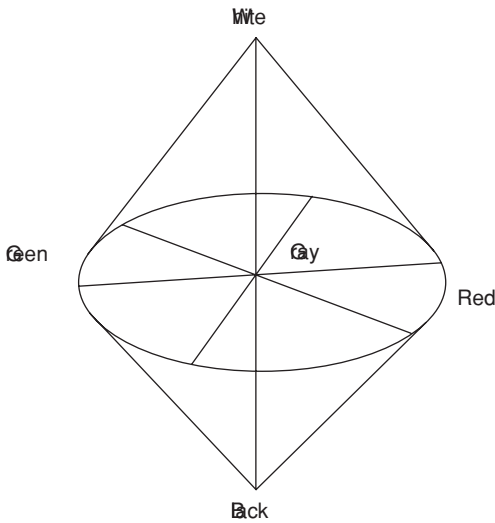

Figure 3. The color spindle.

new concepts often involves expanding one's conceptual space with new quality dimensions. *Functional* properties used for describing artifacts may be an example here. Even if we do not know much about the topological structures of these dimensions, it is quite obvious that there is some such nontrivial structure (see the analyses of functional representation in Vaina 1983 and Gärdenfors 2007). Still other dimensions may be *culturally* dependent. Finally, some quality dimensions are introduced by *science*.

5. Characterizing Concepts

The theory of conceptual spaces will now be used to provide a definition of properties and concepts. In my technical use a property is a concept that concerns only one domain of quality dimensions, while a concept in general connects several kinds of dimensions. I propose the following criterion (Gärdenfors 1990b, 1992, 2000) where the topological characteristics of the quality dimensions are utilized to introduce a spatial structure for properties:

Criterion P: A *natural property* is a convex region in some domain.

The motivation for the criterion is that if some objects which are located at v_1 and v_2 in relation to some quality dimension (or several dimensions) are both examples of the property C , then any object that is located between v_1 and v_2 on the quality dimension(s) will also be an example of C . Criterion P presumes that the notion of

betweenness is meaningful for the relevant quality dimensions. This is, however, a rather weak assumption which demands very little of the underlying geometrical structure. (For a different proposal based on topological properties, see Mormann 1993).

Further motivation for criterion P comes from recent results by Jäger and van Rooij (2007) concerning the emergence of a common semantics in a community. They show that if two persons communicate about a common metric conceptual space, for example the color space, using a finite number of expressions, the most efficient communication results if both of them use the expressions to refer to a set of prototypes in the space and then partition the space according to the so-called Voronoi tessellation. It is well known that such a tessellation always results in convex regions (see Gärdenfors 2000: Sec. 3.9).

Criterion P does not presume that one can identify sharp borders between concepts, but it can also be applied to *fuzzy* concepts or concepts that are defined by *probabilistic* criteria. What convexity requires is that if two object locations v_1 and v_2 both satisfy a certain membership criterion, e.g., has a certain degree or probability of membership, then all objects between v_1 and v_2 also satisfy the criterion.

Most properties expressed by simple words in natural languages seem to be natural properties in the sense specified here. For instance, I conjecture that all *color terms* in natural languages express natural properties with respect to the psychological representation of the three color dimensions. It is well known that different languages carve up the color circle in different ways, but all carvings seems to be done in terms of convex sets (see Berlin and Kay 1969).

Properties, as defined by criterion P, form a special case of *concepts*. I define this distinction by saying that a property is based on a *single* domain, while a concept may be based on *several* domains. The distinction between properties and concepts has been obliterated in the symbolic as well as connectionist representations that have dominated the discussion in the cognitive sciences. In particular, both properties and concepts are represented by *predicates* in first order languages.

The predicates of a first order language correspond to several different grammatical categories in a natural language, most importantly those of adjectives, nouns and verbs. The main semantic difference between adjectives and nouns, on the

one hand, is that adjectives like “red,” “tall,” and “round” normally refer to a single domain and thus represent properties, whereas nouns such as “dog,” “apple,” and “town” normally contain information about several domains and thus represent concepts. Verbs, on the other hand, are characterized by their temporal structure, that is, they essentially involve the time dimension (see Langacker 1987 for conceptual representations of verbs). Using conceptual spaces, one can thus express the fundamental semantic differences between the most important grammatical categories. First order languages do not seem to be sufficiently rich to make these distinctions in a systematic manner.

Let us now focus on the differences between single-domain properties and multi-domain concepts. As a paradigm example of a concept that is represented in several domains, consider “apple” (compare Smith et al. 1988). The first problem when representing a concept is to decide which are the relevant domains. When we encounter apples as children, the first domains that we learn about are presumably color, shape, texture and taste. Later, we learn about apples as (biological) fruits, about their nutritional value, and possibly about some further dimensions. It should be noted that I do not require that a concept should be associated with a closed set of domains. On the contrary, this set may be expanded as one learns about further aspects of a concept.

The next problem is to determine the geometric structure of the domains. Taste space can presumably be represented by the four dimensions sweet, sour, salty, and bitter, and the color domain by hue, saturation, and brightness. Other domains are trickier: it is difficult to say much about, for example, the topological structure of “fruit space.” Some ideas about how “shape space” should be modeled have been discussed in, for example, Marr and Nishihara (1978) and Gärdenfors (1990b, 2000). Instead of giving a detailed presentation of the geometric structures of the different domains, let me represent the “apple” regions verbally as follows:

<i>Dimension</i>	<i>Region</i>
Color	Red-yellow-orange
Shape	Roundish
Texture	Smooth
Taste	Regions of the sweet and sour dimensions
Fruit	Specification of seed structure, flesh and peel type, etc.
Nutrition	Values of sugar content, vitamins, fibers, etc.

When several domains are involved in a representation, some principle for how the different domains are to be *weighed* together must be assumed. These weights influence the distances in the conceptual space. The relative weights of the domains depend on the *context* in which the concept is used. Hence, I assume that in addition to the regions associated with each domain, the concept representation contains information about the *prominence* of the different domains. The prominence values of different domains determine which *associations* can be made and thus which *inferences* can be triggered by a particular use of a concept. The prominence values can change with the context, and with the knowledge and interests of the user. For example, if you are eating an apple, its taste will be more prominent than if you are using an apple as a ball when playing with an infant, which would make the shape domain particularly prominent.

Concepts are not just bundles of properties. The proposed representation for a concept also includes an account of the *correlations* between the regions from different domains that are associated with the concept. In the “apple” example there is a very strong (positive) correlation between the sweetness in the taste domain and the sugar content in the nutrition domain and a weaker correlation between the color red and a sweet taste.

These considerations of prominence and correlations motivate the following definition of concept representation:

Criterion C: A *natural concept* is represented as a set of convex regions in a number of domains together with a prominence assignment to the domains and information about how the regions in different domains are correlated.

Concerning human abilities to detect clusters of properties, it turns out that we are, in general, extremely poor at performing *abstract* correlation assessment tasks (Nisbett and Ross 1980; Kornblith 1993: 96–100). However, work by Billman (1983) and Billman and Knutson (1996) indicates that humans are quite good at detecting correlations that cluster *several dimensions*, in spite of our limitations in detecting isolated correlations between variables. A plausible explanation of this phenomenon is that our perceptions of “natural” concepts (according to Criterion C) do show correlations along multiple dimensions, and, as a result of natural selection, we have developed a competence to detect such clustered correlations.⁷ In brief, we are better

at learning concepts than learning scattered correlations between properties. In line with this, Holland et al. (1986: 183–184) formulate the hypothesis that the *basic level* categories of prototype theory (Rosch 1975, 1978) are characterized by distinctive clusters of correlated properties. If valid, this hypothesis would provide a potent underpinning for that part of prototype theory.

In this analysis of concepts I have tried to bring in elements from other theories in psychology and linguistics. Some related ideas can be found in, among others, Barsalou (1992), Holmqvist (1993), Langacker (1987: 154–166), and Smith et al. (1988). The main difference between these theories and the one presented here is that I put greater emphasis on the geometrical structure of the concept representations, in particular via the requirement of representing by convex regions of quality dimensions. As will be seen in the following sections, these structures are crucial for the analysis of the inductive and nonmonotonic reasoning processes.

6. Induction in Conceptual Spaces

One of the most impressive features of human reasoning is our ability to perform *inductive inferences*. Without any perceived effort, we are prepared, sometimes with overwhelming confidence, to generalize from a very limited number of observations. These inferences concern connections between properties from different domains.

However, we do not perform inductive inferences in an arbitrary manner. Peirce (1932: 476) notes that there are certain forms of *constraints* that delimit the vast class of possible inferences. As he puts it:

Nature is a far vaster and less clearly arranged repertory of facts than a census report; and if men had not come to it with special aptitudes for guessing right, it may well be doubted whether in the ten or twenty thousand years that they may have existed their greatest mind would have attained the amount of knowledge which is actually possessed by the lowest idiot. But, in point of fact, not man merely, but all animals derive by inheritance (presumably by natural selection) two classes of ideas which adapt them to their environment. In the first place, they all have from birth some notions, however crude and concrete, of force, matter, space, and time; and, in the next place, they have some notion of

what sort of objects their fellow-beings are, and how they will act on given occasions.

Here, Peirce hints at an *evolutionary* explanation of why “the human intellect is peculiarly adapted to the comprehension of the laws and facts of nature” (1932: 474). In Quine’s (1969: 125) words: “To trust induction as a way of access to the truths of nature . . . is to suppose, more nearly, that our quality space matches that of cosmos.”

In this section, I shall use conceptual spaces to develop a theory of constraints for inductive reasoning. I shall focus on the problem of *projectibility*, that is, the problem of which properties and concepts may be used in induction.

6.1. Observation Statements and the Riddles of Induction

The most ambitious project of analyzing inductive inferences during the previous century has been that of the logical positivists. According to their program, the basic objects of scientific inquiry are sentences or statements in some formal or natural language. As mentioned in Section 2, the observational statements are taken to be provided by incorrigible perceptual mechanisms.

Ideally, the scientific language is a version of first order logic where a designated subset of the atomic predicates represent observational properties and relations. These observational predicates are taken to be primitive notions. This means that when it comes to inductive reasoning, all observational predicates are treated in the same way. For example, Carnap (1950: Sec. 18B) requires that the primitive predicates of a language be logically independent of each other. The advantage of this, from the point of view of the positivists, is that induction then becomes amenable to logical analysis, which, in the purist form, is the only tool admitted.

However, it became apparent that the methodology of the positivists led to serious problems for their analysis of induction. The most famous ones are Goodman’s (1955) “riddle of induction” and Hempel’s (1965) “paradox of confirmation.” To see the problems for the symbolic paradigm, I will give brief recapitulations of these paradoxes.

Hempel’s paradox of confirmation deals with the problem of what observations would count as inductive support for a general law. Suppose we are interested in a law of the form $(x)(Rx \rightarrow Bx)$ (for example, “all ravens are black”).

The most obvious confirming instances are sentences of the form $Ra \ \& \ Ba$ (black ravens). However, the general law is logically equivalent to $(x) (\neg Bx \rightarrow \neg Rx)$. For symmetry reasons, the observations confirming this law are of the form $\neg Ba \ \& \ \neg Ra$ (nonblack nonravens). But if this is true, we can confirm the law that all ravens are black by gathering green apples, blue suede shoes, and red herrings. This is obviously counterintuitive.

Goodman's puzzle starts from the universal sentence that all emeralds (examined up to 1999) are green. The property "grue" is defined as something that is green before the year 2000 and blue after the beginning of year 2000. Similarly, "bleen" means blue before 2000 and green thereafter. According to the definition, all emeralds examined up to 1999 have been grue. So why should we not expect that the inductive inference that all emeralds are grue is as valid as the seemingly more natural inference that all emeralds are green?

Note that it does not help to say that "green" is a *simpler* predicate than "grue" because it does not involve any reference to a particular point of time. It is true that "grue" can be defined in terms of "green" and "blue" and a time reference, but it is equally true that "green" can be defined as "grue before the year 2000 and bleen thereafter." So from a purely logical point of view, "green" and "grue" are perfectly symmetrical as predicates. And the logical point of view is the only one that counts within the methodology of orthodox logical positivism, which is based on symbolic representations. However, as Goodman and Hempel have shown, such a purist position results in paradoxes concerning induction.

One conclusion to be drawn from these paradoxes is that the symbolic level is not sufficient for a complete understanding of inductive reasoning. What is needed is a *nonlogical* way of distinguishing the predicates that may be used in inductive inferences from those that may not. There are several suggestions for such a distinction in the literature. One idea is that some predicates denote "natural kinds" or "natural properties" while others don't, and it is only the former that may be used in inductive reasoning. Natural kinds are normally interpreted realistically, following the Aristotelian tradition, and thus assumed to represent something that exists in the world independently of human cognition. However, when it comes to inductive *inferences* it is not sufficient that the properties exist out there somewhere, but we must be able to represent the natural kinds in our minds, if they

are to be used in planning and decision making. In other words, what is needed to understand induction, as performed by humans, is an analysis of natural properties on the conceptual level.

6.2. Induction and Natural Concepts

Let us approach the problem by considering how observations are identified on the conceptual level. As discussed in Section 2, an observation can be defined as an assignment to an object of a location in a conceptual space. For example, the observation that is described on the symbolic level as "x is yellow" is represented on the conceptual level by assigning x a point in the yellow region of color space. Since natural languages only divide the color domain into a finite number of categories the information contained in the statements that x is yellow is much less precise than the information furnished by assigning x a location in color space. In this sense, the conceptual level allows much richer instruments for representing observations than the symbolic level.

Let us have a look at how Goodman's predicate "grue" can be modeled in a conceptual space. Given the standard representations of colors as presented in Section 4, "green" and "blue" are natural properties according to Criterion P, while "grue" and "bleen" are not. "Grue" presumes two dimensions, color and time, for its description.

To model the predicate, we can consider the cylindrical space that is generated by taking the Cartesian product of the time dimension and the hue dimension (the color circle). This cylinder is depicted in Figure 4. In this space, "grue" and "bleen" would not represent convex regions, but rather be discontinuous at the point on the time dimension representing the year 2000. In contrast "blue" and "green" would still correspond to convex regions.

Mormann (1993: 230–231) suggests a slightly different solution to Goodman's riddle. The underlying conceptual space is again the "time-color" cylinder of Figure 4. Simplifying Mormann's construction a bit, a closed set is a region $A \times B$ (a Cartesian product) where A is a segment of the time dimension and B a segment of the color circle. In a sense, the closed sets are all the "rectangles" of the time-color cylinder. Mormann proposes the criterion that a natural property on the time-color cylinder is such a closed set. On this criterion, "green" and "blue"

Figure 4. The time-color cylinder.

are again natural properties, while “grue” and “bleen” are not.

Carnap (1971: 70–76) excludes Goodman-type predicates by distinguishing between “locational” and “nonlocational” attributes. “Grue” denotes a locational attribute since it refers to a particular temporal location. However, Carnap’s solution seems rather ad hoc since it does not explain, for example, why a nonlocational predicate like “green or orange” is not regarded as projectible.

Let us take a brief look at the concepts that occur in Hempel’s (1965) paradox of confirmation. As a matter of fact, “nonblack” corresponds to a convex region of the color space since any color between two nonblack colors is also nonblack. I have no firm intuitions on whether “nonblack” is projectible or not. “All nonblack bodies reflect some light” seems to be a completely acceptable generalization. However, the concept “nonraven” would be difficult to count as a natural property according to Criterion P of Section 5. The class of all objects that are nonravens belong to many unrelated domains. Hence, it would be extremely tricky to specify the associated regions in a way that satisfies Criterion P. Even if “nonraven” is restricted to the domain of birds, it depends on the structure of this domain, which to a large extent is unknown, whether “nonraven” corresponds to a convex region.

Even if both F and G denote natural properties, the disjunction “ F or G ” need not denote a natural property (in concordance with this, learning such a non-natural disjunctive property can only be achieved by learning each of the disjuncts); and if F is a natural property, but G is not, then “ F and G ” need not be a natural property. However, if both F and G are natural properties, the conjunction “ F and G ” will also be nat-

ural, since the intersection of two convex regions is again convex.

In line with this, Nolan (1994: 134–137) points out that grue-like predicates cannot be *learned* in the normal way of learning a language. This idea fits well with my emphasis on natural properties. Given a conceptual space, it is much easier to learn a predicate that corresponds to a natural region of the space, than learning something that corresponds to an irregular subset of the space.

The upshot is that Criterion P is proposed as a solution to the problem of projectibility in induction. It provides a way of delimiting the class of properties that can function in inductive reasoning. It should be noted that Criterion P depends on the geometric structure of the conceptual spaces because it involves the notion of convexity, and hence the criterion cannot be expressed on the symbolic level. On the conceptual level of representation, inductive reasoning then consists in finding the relevant connections between natural properties in different domains.

Followers of Goodman could argue that even if predicates like “grue” and its ilk do not correspond to natural properties in our standard conceptual space, it is conceivable that such predicates would correspond to natural properties in some other conceptual space, where, consequently, our predicates “green” and “blue” would denote nonnatural properties. In other words, what counts as a natural property is dependent on the underlying conceptual space. This form of relativism is handled in Gärdenfors (1993) with the aid of evolutionary considerations. In brief, the structure of our conceptual space has been molded by the environment we live in.

Furthermore, a consequence of the analysis presented here that if we assume that the meanings of the predicates are determined by

a mapping into a conceptual space S , Criterion P and the topological structure of different quality dimensions entail that certain statements will become *analytically true*. For example it follows from the linear structure of the length dimension that comparative relations like “earlier than” are *transitive*. This is thus an analytic feature of such a relation (*analytic-in-S*, that is). Similarly, it is analytic that everything that is green is colored (since “green” refers to a region of the color space) and that nothing is both green and blue. Analytic-in- S is thus defined on the basis of the topological and geometrical structure of the conceptual space S . However, different conceptual spaces will yield different notions of analyticity, which leads to a form of relativism that would be foreign to a classical notion of analyticity.

Category-Based Induction

A different tradition of investigating inductions involving concepts rather than properties concerns so-called *categorical inductive inferences* (see, e.g., Osherson et al. 1990; Sloman 1993; Heit 2000; Rips 2001). Osherson et al. (1990) studied two types of inductive arguments: general, where the conclusion concerns a class that is superordinate to those of the premises, and specific, where the class of the conclusion is on the same categorical level as the premises. An example of a general argument is the following:

Grizzly bears love onions
Polar bears love onions

All bears love onions

And an example of a specific argument is:

Robins use serotonin as a neurotransmitter
Bluejays use serotonin as a neurotransmitter

Geese use serotonin as a neurotransmitter

Osherson et al. (1990) investigated thirteen qualitative patterns concerning how subjects judge the confirmation strength of such inductive arguments. For example, the inference

Robins use serotonin as a neurotransmitter
Bluejays use serotonin as a neurotransmitter

Sparrows use serotonin as a neurotransmitter

was considered stronger than the inference

Robins use serotonin as a neurotransmitter
Bluejays use serotonin as a neurotransmitter

Geese use serotonin as a neurotransmitter

The underlying reason is that robins and bluejays resemble sparrows more than they resemble geese. Relations of similarity are thus important for our judgments of the validity of inductive inferences.

Osherson et al. present different kinds of empirical evidence to support the patterns of confirmation that they have identified. The model they put forward claims that the confirmation assigned to categorical inductive inferences “varies directly with the following two variables: a = the degree to which the premise categories resemble the conclusion category; and b = the degree to which the premise categories resemble the members of the lowest level category that includes both the premise and conclusion categories” (1990: 189–190).

This model is challenged by Sloman (1993). Instead of a category-based model, he proposes a feature-based one. Every category in the inductive arguments is described by a vector of real number from the $[0,1]$ interval. Sloman calls each coordinate of the vector a “feature,” but in the present context they may as well be called dimensions. He says that these features “represent a large number of interdependent perceptual and abstract attributes. In general, these values may depend on the context in which categories are presented” (1993: 237).

To explain the patterns of confirmation that were investigated by Osherson et al. (1990), Sloman (1993) develops a connectionist model. Using this model, he is able to explain ten of the previous patterns and three new ones, not treated by Osherson et al. He also presents empirical support for the new patterns. According to Sloman’s model, the strength of an inductive argument can be determined as the proportion of features in the conclusion category that are also included in the premise categories. In the simplest case there is only one premise “All P s are Q ” and a conclusion of the form “All C s are Q .” The premise category P can be represented by a vector $F(P)$ of feature values and the conclusion category C by a corresponding vector $F(C)$. In the single-premise case of Sloman’s model, the strength of the inductive argument is measured by the value $F(P) \cdot F(C) / |F(C)|^2$, where $F(P) \cdot F(C)$ can be seen as a measure of the overlap of the features of P and C and $|F(C)|^2$ a measure of the magnitude of the conclusion category vector.⁸ The strength of the inductive argument is thus measured as the *similarity* between the premise and the conclusion category. Hence, Sloman’s connectionist model could be replaced by a similarity measure in a conceptual

Figure 5. Projections of properties onto domains.

space covering the dimensions of the feature vector.

The results concerning category-based induction show that humans have powerful abilities to handle multiple correlations between different domains, which accords with the discussion at the end of Section 5 (Heit 2000). In the theory of conceptual spaces, this kind of inductive process corresponds to determining *mappings* between the different domains of a space. Using such a mapping, one can then determine correlations between the regions of different domains, by looking at the *projections* of objects onto the domains. Since all objects in Figure 5 that are projected onto the P-region in dimension X are projected onto the Q-region of the dimension Y, “all Ps are Q” is valid. Now if property C on the X dimension is close to (similar to) P, then it is likely that all Cs are Q too.

7. Nonmonotonic Reasoning with Concepts

In this section, the theory of conceptual spaces will be applied to outline explanations for the different kinds of nonmonotonic features of concepts that were presented in Section 3. In the concluding section, I shall then point out some relations between inductive and nonmonotonic reasoning.

(a) Change from General Category to Subordinate

A first observation is that describing properties as convex regions of conceptual spaces fits very well with the so-called *prototype theory* of categorization developed by Rosch and her collaborators (Rosch 1975, 1978; Mervis and Rosch 1981; Lakoff 1987). The main idea of prototype theory is that, within a category of objects, certain

members are judged to be more representative of the category than others. For example robins are judged to be more representative of the category *bird* than are ravens, penguins and emus; and desk chairs are more typical instances of the category *chair* than rocking chairs, deck chairs, and beanbags. The most representative members of a category are called *prototypical* members. It is well known that some properties, like *red* and *bald* have no sharp boundaries and for these it is perhaps not surprising that one finds prototypical effects. However, these effects have been found for most properties including those with comparatively clear boundaries like *bird* and *chair*.

If concepts are described as convex regions of a conceptual space, prototype effects of reasoning are indeed to be expected. In a convex region one can describe positions as being more or less *central*. For example, if color concepts are identified with convex subsets of the color space, the central points of these regions would be the most prototypical examples of the color.

Subordinate concepts may move away from the prototypes of the general concept and thus result in atypical properties. Here the representation of concepts as convex regions in a conceptual space may be useful. If the first thing I ever hear about the individual Gonzo is that it is a bird, I will naturally locate it in the conceptual space as a more or less prototypical bird, that is, at the center of the region representing birds. (The relevant conceptual space may be something like a many-dimensional hierarchical space of coordinates in the style of Marr and Nishihara 1978.) And in that area of the conceptual space, birds do fly, that is, almost all individuals located there also have the ability to fly. However, if I then learn that Gonzo is an emu, I must *revise* my earlier concept location and put Gonzo in the emu region, which is a subset of the bird region but presumably lies at the outskirts of that region. And in the emu region of the conceptual space almost none of the individuals fly. This form of reasoning can thus be described as a *relocation* of an object in a conceptual space.

This simple example only hints at how the *correlation* between different parts of a region representing a property and regions representing other properties can be used in understanding nonmonotonic reasoning. For this analysis, the spatial structure of properties is essential. Such correlations will only be formulated in an *ad hoc* manner if a propositional representation of information is used where the spatial structure cannot be utilized.

Figure 6. The subspace of skin colors embedded in the full color spindle.

(b) Contrast Classes

I have proposed that properties correspond to connected regions of a conceptual space. However, as was noticed in Section 3, a word like “red” has many uses that can result in nonmonotonic inferences: red book, red wine, red hair, red skin, red soil, redwood, etc. “Red book” accords with the dictionary definition, but the other uses don’t fit with the standard color region assigned to red. How can we then explain that the same word is used in so many different contexts?

I don’t see how this phenomenon can be analyzed in a simple way using the symbolic or sub-conceptual approaches. However, the idea of a contrast class can quite easily be given a general interpretation with the aid of conceptual spaces. For each domain, for example skin colors, we can map out the class of possible colors on the color spindle. This mapping will determine a subset of the full color space. The shape of this subset may be rather irregular. However, if the subset is embedded in a space with the *same dimensional structure* as the full space we obtain a picture that looks like Figure 6.

In this smaller spindle, the color words are then used in the same way as in the full space, even if the hues of the color in the smaller space don’t match the hues of the complete space. Thus, *white* is used about the lightest forms of skin, even though white skin is pinkish, *black* refers to the darkest form of skin, even though black skin is brown, and so on. The embeddings into smaller conceptual spaces will natu-

rally result in nonmonotonic effects. For example, from the fact that *x* is a white wine, one cannot conclude that *x* is a white object, even though *person* is subordinate to *object*. This analysis of contrast classes is presented in greater detail in Gärdenfors (2000).

(c) Metaphors

Metaphors have been notoriously difficult to handle within traditional semantic theories, let alone first order logic. In contrast, they are given key positions within cognitive semantics. Not only poetic metaphors but also everyday “dead” metaphors are seen as central semantic features and are given systematic analyses. One of the first works in this area was Lakoff and Johnson (1980).

In Gärdenfors (2000), I have proposed an analysis of metaphors within the theory of conceptual spaces. The core hypothesis is that *a metaphor expresses a similarity in topological or metrical structure between different quality dimensions*. A concept that corresponds to a particular structure in one quality dimension can be used as a metaphor to express a similar structure about another dimension. In this way one can account for how a metaphor can *transfer knowledge* about one conceptual dimension to another.

As a simple example, let us consider the expression “the peak of a career.” The literal meaning of *peak* refers to a structure in physical space, namely the vertically highest point in a horizontally extended (large) object, typically a mountain. This structure thus presumes two spatial dimensions, one horizontal and one vertical (see Figure 7a).

A career is an abstract entity without location in space. So how can a career have a *peak*? I submit that when we metaphorically talk about the peak of a career the same geometrical structure is applied to a two-dimensional space that consists of the *time* dimension (of the career) and a dimension of *social status* (see Figure 7b). The latter dimension is normally conceived of as being vertical: we talk about somebody having a “higher” rank, “climbing” in the hierarchy, and so on (see Lakoff and Johnson 1980).

It can now be seen that the role of different contrast classes for the same concept, as described earlier, is closely related to that of metaphorical uses of a word. A metaphor expresses a similarity in topological or geometrical structure between *different* quality dimensions. Now, in the case of contrast classes, one set of dimensions is not really mapped onto a

Figure 7. The literal and a metaphorical meaning of “peak.”

different set, but it is mapped onto a *subspace* of itself retaining the same topological structure.

(d) Context Effects

The main effect of applying a concept in a particular context is that certain dimensions of the concept are put into focus by the context. In relation to the model given in the previous section, this means that the context determines the *relative saliency* of the dimensions. For example, in a context of moving furniture, the weight dimension becomes highly salient. Hence, the concept *piano* may lead to an inference of *heavy*. In contrast, in a context of musical instruments, the weight dimension is much less salient and an application of the concept *piano* will probably not become associated with *heavy* (Barclay et al. 1974).

Another effect of changes in context is that change in saliency of certain dimensions may result in a shift of the *borders* between different concepts. As was seen in Section 3, once the functionality was put in focus in Labov’s study of the concept *cup*, the border between *cup* and *bowl* changed considerably. Such changes of borders naturally lead to nonmonotonic effects when the concepts are applied in different contexts.

As a matter of fact, also the nonmonotonic effects of contrast classes discussed above can be seen as a context effect. By introducing a concept like *skin* or *wine*, a context is set up in which the contrast class of the objects falling under the concept is focused. Hence it is quite natural that the application of, for example, color concepts become restricted to the contrast class.

When analyzed on the symbolic level, nonmonotonic reasoning has concerned the class of logical *rules* that are valid (Gabbay et al.

1993; Gärdenfors and Makinson 1994). However, when transformed into representations in conceptual spaces one finds several different kinds of processes that produce nonmonotonic features when described symbolically. The conclusion is that nonmonotonic inferences cannot be seen as a unified type of reasoning, but must be broken down into different kinds of processes, as has been argued in this section.

Fodor (1998) criticizes the use of conceptual spaces (vector spaces) to model concepts where “the similarity between your concepts and mine is expressed by the positions in our respective spaces” (1998: 33). He continues:

Suppose, in particular that it is constitutive of the difference between our NIXON concepts that you think Nixon was even more of a crook than I do. Once again, a robust notion of content identity is presupposed since each of our spaces is required to have a dimension that expresses crookedness; a fortiori, both are required to have dimensions which express degrees of the *very same property*. [...] You and I can argue about whether Nixon was merely crooked or very crooked only if the concept of *being crooked* is one that we have in common. (Fodor 1998: 33–34, italics in original)

First of all it should be noticed that Fodor here uses “concept” to denote also what I would classify as individuals (Nixon) and dimensions (crookedness), which complicates the picture. I believe that distinguishing between individuals, properties, concepts and dimensions, as is done in the theory of conceptual spaces, helps in clearing up a lot of meta-conceptual confusion.

Secondly, on my account it is possible to have the same concepts even if we do not have

the same underlying dimensions. It is sufficient that our conceptual spaces partition the world in the same way. Let me give a slightly artificial example to show this: Suppose my classification of *rectangles* is based on the dimensions “length” and “width,” while yours is based on “area” and “side proportion.” So I represent a particular rectangle by the vector $\langle 6, 3 \rangle$ while you represent the same rectangle as $\langle 18, 2 \rangle$. Even though we use different “properties” in Fodor’s sense to classify and identify rectangles, we will nevertheless be in perfect agreement in our communication about the objects. Thus, in contrast to what Fodor claims, the “Publicity constraint” that he puts forward does not entail that we have to sort the world according to identical dimensions.

Thirdly, Fodor also argues that vector space based concepts cannot account for the compositionality of concepts. The best way of countering his argument is to present such an account, which I do in Gärdenfors (2000: Sec. 4.4). The role of contrast classes as discussed above is a special case of this theory.

8. Conclusion

The aim of this chapter has been to present various aspects of inductive and nonmonotonic reasoning about concepts. I have distinguished between three levels of representing reasoning and outlined a theory of conceptual spaces as a tool for representing reasoning on the conceptual level. The theory emphasizes *topological* and *geometrical* structures rather than logical and symbolic. The theory of conceptual spaces provides a viable framework for analyzing various aspects of reasoning about concepts. In particular, it can be used to explain different kinds of inductive and nonmonotonic reasoning. I have aimed at showing that the theory provides better and richer tools for this purpose than do symbolic or connectionist models.

The theory also allows us to elucidate the relationship between inductive and nonmonotonic reasoning. As I have argued in Section 6, inductive reasoning concerns *establishing* the correlations between properties from different domains that are part of concept representations. And in Section 7, I have shown that nonmonotonic reasoning concerns *using* such correlations for various kinds of default conclusions. Thus both types of reasoning processes depend on correlations between properties in different domains. Such correlations also form the basis for our *expectations*. There is much more to learn

about how humans discover such correlations in their inductive reasoning and in what way the correlations are exploited in everyday reasoning, nonmonotonic or not. Nevertheless, I believe that describing these processes on the conceptual level is helpful in bringing out the relations between these kinds of reasoning.

However, the geometric models used in the descriptions of conceptual spaces can also be used in technical applications of reasoning. In particular, the efforts to develop a Semantic Web would benefit from using representations on the conceptual level as I have argued in Gärdenfors (2004). The program I propose there involves a radical shift in focus of what meta-data should be added to the Web. In the current Semantic Web, the information mainly concerns taxonomies and inference rules that are expressed by symbolic information. If conceptual spaces are used as a foundational methodology, the focus will be on describing *domain structures*. This involves, above all, specifying the geometric and topological structure of the domains. Describing domains will require a different programming methodology compared to what exists in the current web languages. Once the relevant information about domain structure and concepts becomes available, the taxonomies that have been in focus of the current Semantic Web will emerge from the domain structure and the symbolic inference mechanism will become more or less superfluous. The type of representing information suggested by conceptual spaces require computations involving vectors, using reasoning based on similarities, rather than inference mechanisms based on tree searching in a rule-based symbolic approach.

Notes

- 1 Some aspects of reasoning about categories are presented in Gärdenfors and Williams (2001).
- 2 One notable exception is Shapere (1982).
- 3 For a presentation of the theory of prototypes, see, for example, Rosch (1975, 1978), Mervis and Rosch (1981), Lakoff (1987).
- 4 I cannot talk about three ways of *describing* observations, because the very notion of “describing” presumes the linguistic level.
- 5 See Gabbay et al. (1993) for a survey of some of the research areas. In Balkenius and Gärdenfors (1991), nonmonotonic reasoning is connected to representations in artificial neuron networks and in Gärdenfors and Makinson (1994), it is connected to expectation structures.
- 6 For an analysis of functional aspects of concepts see Gärdenfors (2007).

- 7 Garcia and Koelling (1966) showed that rats can quickly learn correlations between domains (as, for example, a particular kind of food and sickness) if the connection between the domains has some *ecological validity*. Without such a correlation the rats perform very poorly. Presumably, similar mechanisms operate in humans.
- 8 $F(P) \cdot F(C)$ is the *inner product* of the two vectors, defined as $\sum_i F(P)_i \cdot F(C)_i$ and $|F(C)|^2$ is the inner product of $F(C)$ with itself, defined as $\sum_i F(P)_i^2$.

Chapter 17: Category-Based Induction

DANIEL N. OSHERSON, EDWARD E. SMITH, ORMOND WILKIE,
ALEJANDRO LÓPEZ, AND ELДАР SHAFIR

The Problem of Argument Strength

Fundamental to human thought is the confirmation relation, joining sentences $P_1 \dots P_n$ to another sentence C just in case belief in the former leads to belief in the latter. Theories of confirmation may be cast in the terminology of argument strength, because $P_1 \dots P_n$ confirm C only to the extent that $P_1 \dots P_n / C$ is a strong argument. We here advance a partial theory of argument strength, hence of confirmation.

To begin, it will be useful to review the terminology of argument strength. By an *argument* is meant a finite list of sentences, the last of which is called the *conclusion* and the others its *premises*. Schematic arguments are written in the form $P_1 \dots P_n / C$, whereas real arguments are written vertically, as in the following examples:

- Grizzly bears love onions.
Polar bears love onions.
----- (1)
All bears love onions.
- Owls prey on small rodents.
----- (2)
Rattlesnakes prey on small rodents.

An argument A is said to be *strong* for a person S just in case S 's believing A 's premises causes S to believe A 's conclusion. Mere belief in the conclusion of an argument (independently of its premises) is not sufficient for argument strength. For this reason, Argument 1 is stronger than Argument 2 for most people, even though the conclusion of Argument 2 is usually considered more probable than that of Argument 1. An extended discussion of the concept of argument

strength is provided in Osherson, Smith, and Shafir (1986). It will be convenient to qualify an argument as strong, without reference to a particular person S , whenever the argument is strong for most people in a target population (e.g., American college students). We also say that $P_1 \dots P_n$ confirm C if $P_1 \dots P_n / C$ is strong.

An illuminating characterization of argument strength would represent a long step toward a theory of belief fixation and revision. Unfortunately, no general theory is yet in sight, and even partial theories are often open to elementary counterexamples (see Osherson et al., 1986). This article offers a hypothesis about the strength of a restricted set of arguments, exemplified by Arguments 1 and 2. The premises and conclusions of such arguments attribute a fixed property (e.g., *preys on small rodents*) to one or more categories (e.g., OWL and RATTLESNAKE).¹ The present study focuses on the role of categories in confirmation; the role of properties is not systematically investigated. In this sense, the model we advance concerns induction that is category based.

Category-based induction was first examined by Rips (1975). He studied the strength of single-premise arguments involving categories such as RABBIT and MOUSE, or EAGLE and BLUEJAY. The present investigation builds on one of the models that Rips discusses and applies it to a larger class of arguments.

Our discussion proceeds as follows. After defining the class of arguments to be considered in this article, and introducing some relevant terminology, we document a set of 13 qualitative phenomena that must be deduced by any

adequate theory of argument strength. Our own theory is then presented and shown to account for all of the phenomena. Next, we describe several experiments designed to test the theory quantitatively. Refinements and alternatives to the theory are discussed in the final section.

Arguments To Be Considered

An argument is called *categorical* just in case its premises and conclusion have the logical form *all members of X have property Y*, where *X* is a (psychologically) simple category like FALCON, VEHICLE, or MAMMAL, and, *Y* remains fixed across premises and conclusion. Arguments 1 and 2 are categorical in this sense. The arguments discussed in this article are all categorical.

The property ascribed to the categories figuring in Argument 1 is *loves onions*. Subjects are likely to have prior beliefs about the kinds of animals that love onions, as well as prior beliefs about properties that are correlated with this one, such as *eats a wide variety of fruits and vegetables*. Beliefs such as these can be expected to weigh heavily on argument strength, defeating our goal of focusing on the role of categories in the transmission of belief from premises to conclusions. For this reason, the arguments to be examined all involve predicates about which subjects in our experiments have few beliefs, such as *requires biotin for hemoglobin synthesis*. Such predicates are called *blank*. Although blank predicates are recognizably scientific in character (in the latter case, biological), they are unlikely to evoke beliefs that cause one argument to have more strength than another.

In summary, the theories discussed below bear on categorical arguments involving natural kinds and blank predicates. An example of such an argument is

Mosquitoes use the neurotransmitter Dihedron.
Ants use the neurotransmitter Dihedron.

Bees use the neurotransmitter Dihedron. (3)

Henceforth, the term *argument* is to be understood in the foregoing sense.

Terminology and Notation

We assume that subjects (and experimenters) largely agree with each other about facts related to the hierarchical level of natural-kind concepts. To illustrate, wide agreement is presup-

posed about the following judgments:

1. FALCON and PELICAN are at the same hierarchical level;
2. BIRD is one level above both FALCON and PELICAN; and
3. ANIMAL is one level above BIRD.

We cannot presuppose universal agreement about such levels. For example, some subjects might take BIRD-OF-PREY to be one level above EAGLE, whereas others (who make fewer distinctions) might take BIRD to be one level above EAGLE. This kind of individual difference about fine-grained categories will be harmless in what follows. It is sufficient that agreement exists about salient categories such as EAGLE, BIRD, and ANIMAL.

Recall that all premises and conclusions to be discussed have the form *all members of X have property Y*. Given such a premise *P* or conclusion *C*, we denote the category that figures in *P* or *C* by $CAT(P)$ or $CAT(C)$. Thus, if *P* is the first premise of Argument 1 above, then $CAT(P) = GRIZZLY BEAR$. If *C* is the conclusion of Argument 3, then $CAT(C) = BEE$.

Let Argument $A = P_1 \dots P_n / C$ be given. *A* is called *general* if $CAT(P_1) \dots CAT(P_n)$ are all properly included in $CAT(C)$. For example, Argument 1 is general. *A* is called *specific* if any category that properly includes one of $CAT(P_1) \dots CAT(P_n)$, $CAT(C)$ also properly includes the others. For example, Argument 3 is specific. By this definition, no argument is both general and specific. *A* is called *mixed* if *A* is neither general nor specific. The following argument is mixed:

Flamingoes require titanium for normal muscle development.

Mice require titanium for normal muscle development.

All mammals require titanium for normal muscle development.

(4)

Argument 4 is not general because FLAMINGO is not included in MAMMAL. It is not specific because BIRD properly includes FLAMINGO but not MOUSE or MAMMAL. Argument 2 is also mixed.

Phenomena

General Remarks

Even within the restricted class of arguments at issue in this article, a variety of phenomena

can be discerned that must be accounted for by any adequate theory of category-based induction. Each phenomenon signals the importance of a given variable in argument strength when other variables are held more or less constant. The phenomena should thus be conceived as tendencies rather than strict laws determining confirmation. We now present 13 such phenomena and illustrate each with a contrasting pair of arguments. The first argument in each pair is claimed to be stronger than the second, in conformity with the phenomenon that the pair illustrates. At the end of this section, we describe a study that empirically documents all of these claims about relative argument strength.

Phenomena Concerning General Arguments

Let general argument $P_1 \dots P_n / C$ be given.

PHENOMENON 1 (PREMISE TYPICALITY)

The more representative or typical $CAT(P_1) \dots CAT(P_n)$ are of $CAT(C)$, the more $P_1 \dots P_n$ confirm C . Because robins are more typical than penguins of BIRD, this phenomenon is illustrated by the following pair of arguments:

Robins have a higher potassium concentration in their blood than humans.

All birds have a higher potassium concentration in their blood than humans.

(5a)

Penguins have a higher potassium concentration in their blood than humans.

All birds have a higher potassium concentration in their blood than humans.

(5b)

The foregoing arguments have single premises. Multiple-premise illustrations of the same point are easy to construct. A premise typicality effect for social categories has been reported by Rothbart and Lewis (1988, see also Collins and Michalski 1989).

PHENOMENON 2 (PREMISE DIVERSITY)

The less similar $CAT(P_1) \dots CAT(P_n)$ are among themselves, the more $P_1 \dots P_n$ confirm C . Thus, since hippos and hamsters differ from each other more than do hippos and rhinos, the following arguments illustrate the premise diversity phenomenon:

Hippopotamuses have a higher sodium concentration in their blood than humans.

Hamsters have a higher sodium concentration in their blood than humans.

All mammals have a higher sodium concentration in their blood than humans.

(6a)

Hippopotamuses have a higher sodium concentration in their blood than humans.

Rhinoceroses have a higher sodium concentration in their blood than humans.

All mammals have a higher sodium concentration in their blood than humans.

(6b)

Observe that Argument 6a is stronger than Argument 6b even though hamsters are less typical than rhinoceroses of MAMMAL. Thus, the greater diversity of the premise categories in Argument 6a outweighs the greater typicality of the premise categories in Argument 6b.

PHENOMENON 3 (CONCLUSION SPECIFICITY)

The more specific is $CAT(C)$, the more C is confirmed by $P_1 \dots P_n$. Thus, because BIRDS is a more specific category than ANIMAL, this phenomenon is illustrated by the following pair of arguments:

Bluejays require Vitamin K for the liver to function.

Falcons require Vitamin K for the liver to function.

All birds require Vitamin K for the liver to function.

(7a)

Bluejays require Vitamin K for the liver to function.

Falcons require Vitamin K for the liver to function.

All animals require Vitamin K for the liver to function.

(7b)

A phenomenon related to conclusion specificity is reported by Gelman (1988, p. 78) in a developmental study.

PHENOMENON 4 (PREMISE MONOTONICITY)

For general arguments, more inclusive sets of premises yield more strength than less inclusive

sets. The following pair of arguments illustrates this kind of monotonicity:

Hawks have sesamoid bones.
 Sparrows have sesamoid bones.
Eagles have sesamoid bones.
 All birds have sesamoid bones. (8a)

Sparrows have sesamoid bones.
 Eagles have sesamoid bones.
All birds have sesamoid bones. (8b)

Premise monotonicity has been investigated by Carey (1985).

Phenomena Concerning Specific Arguments

Let specific argument $P_1 \dots P_n / C$ be given.

PHENOMENON 5 (PREMISE-CONCLUSION SIMILARITY)

The more similar $CAT(P_1) \dots CAT(P_n)$ are to $CAT(C)$, the more $P_1 \dots P_n$ confirm C . Because robins and bluejays resemble sparrows more than they resemble geese, this phenomenon is illustrated by the following pair of arguments:

Robins use serotonin as a neurotransmitter.
 Bluejays use serotonin as a neurotransmitter.
Sparrows use serotonin as a neurotransmitter.
 Sparrows use serotonin as a neurotransmitter. (9a)

Robins use serotonin as a neurotransmitter.
 Bluejays use serotonin as a neurotransmitter.
Geese use serotonin as a neurotransmitter.
 Geese use serotonin as a neurotransmitter. (9b)

The present phenomenon was originally reported by Rips (1975) for single-premise arguments (see also Collins and Michalski 1989).

PHENOMENON 6 (PREMISE DIVERSITY)

The less similar $CAT(P_1) \dots CAT(P_n)$ are among themselves, the more $P_1 \dots P_n$ confirm C . Illustration is provided by the following pair inasmuch as lions are less similar to giraffes than than they are to tigers.

Lions use norepinephrine as a neurotransmitter.
 Giraffes use norepinephrine as a neurotransmitter.
Rabbits use norepinephrine as a neurotransmitter.
 Rabbits use norepinephrine as a neurotransmitter. (10a)

Lions use norepinephrine as a neurotransmitter.
 Tigers use norepinephrine as a neurotransmitter.
Rabbits use norepinephrine as a neurotransmitter.
 Rabbits use norepinephrine as a neurotransmitter. (10b)

Phenomenon 6 corresponds to Phenomenon 2 for general arguments. Observe that Argument 10a is stronger than Argument 10b even though giraffes resemble rabbits no more than do tigers.

PHENOMENON 7 (PREMISE MONOTONICITY)

More inclusive sets of premises yield more strength than less inclusive sets, provided that the new premise is drawn from the lowest level category that includes the old premises and conclusion. The following pair of arguments illustrates this kind of monotonicity.

Foxes use Vitamin K to produce clotting agents in their blood.
 Pigs use Vitamin K to produce clotting agents in their blood.
Wolves use Vitamin K to produce clotting agents in their blood.
 Gorillas use Vitamin K to produce clotting agents in their blood. (11a)

Pigs use Vitamin K to produce clotting agents in their blood.
 Wolves use Vitamin K to produce clotting agents in their blood.
Gorillas use Vitamin K to produce clotting agents in their blood.
 Gorillas use Vitamin K to produce clotting agents in their blood. (11b)

PHENOMENON 8 (PREMISE-CONCLUSION ASYMMETRY)

Single-premise arguments are not symmetric, in the sense that P/C may not have the same strength as C/P . This kind of asymmetry is illustrated by the following pair of arguments:

Mice have a lower body temperature at infancy than at maturity.
Bats have a lower body temperature at infancy than at maturity.
 Bats have a lower body temperature at infancy than at maturity. (12a)

Bats have a lower body temperature at infancy than at maturity.
Mice have a lower body temperature at infancy than at maturity.
 Mice have a lower body temperature at infancy than at maturity. (12b)

Premise–conclusion asymmetry was first discussed by Rips (1975).

Phenomena Concerning Mixed Arguments

PHENOMENON 9 (NONMONOTONICITY, GENERAL)

Some general arguments can be made weaker by adding a premise that converts them into mixed arguments. This kind of nonmonotonicity is illustrated by the following contrast:

Crows secrete uric acid crystals.
Peacocks secrete uric acid crystals.
 All birds secrete uric acid crystals. (13a)

Crows secrete uric acid crystals.
 Peacocks secrete uric acid crystals.
Rabbits secrete uric acid crystals.
 All birds secrete uric acid crystals. (13b)

PHENOMENON 10 (NONMONOTONICITY, SPECIFIC)

Some specific arguments can be made weaker by adding a premise that converts them into mixed arguments. This kind of nonmonotonicity is illustrated as follows.

Flies require trace amounts of magnesium for reproduction.

 Bees require trace amounts of magnesium for reproduction. (14a)

Flies require trace amounts of magnesium for reproduction.
 Orangutans require trace amounts of magnesium for reproduction.

 Bees require trace amounts of magnesium for reproduction. (14b)

A Phenomenon Involving Both General and Specific Arguments

PHENOMENON 11 (INCLUSION FALLACY)

A specific argument can sometimes be made stronger by increasing the generality of its conclusion. Because BIRD includes OSTRICH, this phenomenon is illustrated as follows:

Robins have an ulnar artery.

 Birds have an ulnar artery. (15a)

Robins have an ulnar artery.

 Ostriches have an ulnar artery. (15b)

The choice of Argument 15a as stronger than Argument 15b is counternormative and may be termed an *inclusion fallacy*. For discussion and analysis of inclusion fallacies in another context, see Shafir, Smith, and Osherson (in press).

Two Limiting-Case Phenomena

The last two phenomena to be discussed have an evident character, and no data are needed for their documentation.

PHENOMENON 12 (PREMISE–CONCLUSION IDENTITY)

Any argument of the form Q/Q is perfectly strong. One such argument is as follows:

Pelicans have property Y.
 Pelicans have property Y. (16)

PHENOMENON 13 (PREMISE–CONCLUSION INCLUSION)

Suppose that statements P and C are such that the conclusion category is included in the premise category. Then the argument P/C is perfectly strong. For example:

All animals have property Y.
 All birds have property Y. (17)

Table 1 summarizes all 13 phenomena.

Empirical Documentation of Phenomena 1–11

Two studies were performed to empirically document Phenomena 1–11. In Study 1, subjects were presented a 12-page booklet. The first page contained instructions, and each of the following pages contained one of the contrasting pairs of arguments used above to illustrate Phenomena 1–11. The instructions were as follows:

We are interested in how people evaluate arguments. On each page of your booklet there will be two arguments labeled “a” and “b.” Each will contain one, two, or three statements separated from a conclusion by a line. Assume that the statements above the line are facts, and choose the argument whose facts provide a better reason for believing its conclusion. These are subjective judgments; there are no right or wrong answers.

On each subsequent page, the contrasting pair of arguments was arranged vertically; across all subjects each argument appeared equally

Table 1: Summary of the 13 Phenomena

<i>Phenomenon</i>	<i>Stronger Argument (Version a)</i>	<i>Weaker Argument (Version b)</i>
General arguments		
1. Premise Typicality	ROBIN/BIRD [73]	PENGUIN/BIRD [7]
2. Premise Diversity	HIPPO, HAMSTER/MAMMAL [59]	HIPPO, RHINO/MAMMAL [21]
3. Conclusion Specificity	BLUEJAY, FALCON/BIRD [75]	BLUEJAY, FALCON/ANIMAL [5]
4. Premise Monotonicity	HAWK, SPARROW/EAGLE/BIRD [75]	SPARROW/EAGLE/BIRD [5]
Specific arguments		
5. Premise–Conclusion Similarity	ROBIN, BLUEJAY/SPARROW [76]	ROBIN, BLUEJAY/GOOSE [4]
6. Premise Diversity	LION, GIRAFFE/RABBIT [52]	LION, TIGER/RABBIT [28]
7. Premise Monotonicity	FOX, PIG/WOLF/GORILLA [66]	PIG, WOLF/GORILLA [14]
8. Premise–Conclusion Asymmetry	MICE/BAT [41] (40)	BAT/MICE [39] (20)
Mixed arguments		
9. Nonmonotonicity, General	CROW, PEACOCK/BIRD [68]	CROW, PEACOCK/RABBIT/ BIRD [12]
10. Nonmonotonicity, Specific	FLY/BEE [51]	FLY, ORANGUTAN/BEE [29]
General and specific arguments		
11. Inclusion Fallacy	ROBIN/BIRD [52]	ROBIN/OSTRICH [28]
Limiting-case arguments		
12. Premise–Conclusion Identity		PELICAN/PELICAN
13. Premise–Conclusion Inclusion		ANIMAL/BIRD

Note. Number of subjects in Study 1 preferring each argument is given in brackets. Entries in parentheses are results of Study 2.

often in the upper and lower positions. The order of the argument pairs was randomized anew for each subject. The subjects were 80 University of Michigan undergraduates who were paid for their participation and tested in groups of 20.

The results of Study 1 are presented in Table 1. For each contrasting pair, the number of subjects choosing a given argument is shown in brackets next to the argument. In all cases but one, the majority choice is overwhelmingly for the argument we claimed in the preceding section to be stronger (these differences are significant at the .01 level by a two-tailed sign test). The sole exception is Phenomenon 8, premise–conclusion asymmetry, in which there is roughly an equal preference for the two contrasting arguments.

Postexperimental comments by some subjects suggested that the arguments constituting Phenomenon 8 were treated differently than other arguments. Because the arguments MOUSE/BAT and BAT/MOUSE contain identical statements, subjects apparently reasoned that there could be no difference in strength between them. This metacognitive strategy may have obscured the underlying difference in strength in which we are interested.

To respond to the foregoing difficulty, Study 2 was performed. Subjects were presented with

a four-page booklet in which the first page contained instructions and each of the three test pages contained a contrasting pair of arguments. One contrasting pair was that used above to illustrate premise–conclusion asymmetry (Phenomenon 8) (*viz.*, MOUSE/BAT versus BAT/MOUSE). The other two pairs were fillers. The instructions were designed to suppress the metacognitive strategy. They were the same as the instructions of Study 1, except that the last sentence was replaced by

Although the two arguments in a pair may sometimes seem very similar, there is always a difference in how much reason the facts of an argument give to believe its conclusion. However small this difference may be, we would like you to indicate for which argument the facts provide a better reason to believe the conclusion.

As before, each argument in a pair appeared equally often in the upper and lower positions, and the order of arguments was varied across subjects. The subjects were 60 University of Michigan undergraduates, paid for their participation and tested in groups of 20. None had participated in Study 1.

Most subjects preferred the MOUSE/BAT argument to the BAT/MOUSE argument. The

difference, 40 versus 20, is significant at the .01 level by a sign test (two-tailed).

Replications

We have replicated the foregoing results – including the preference for MOUSE/BAT over BAT/MOUSE – in several studies using sets of argument pairs that overlap those described earlier. In addition, we have documented the phenomena with an alternative methodology, as follows. Forty University of Michigan undergraduates were given 24 arguments in individually randomized order. They were asked to estimate the probability of each conclusion on the assumption that the respective premises were true. Twenty-two of the arguments corresponded to the 11 contrasts of Phenomena 1–11. Illustrating with nonmonotonicity, general (Phenomenon 9), 2 of the arguments were as follows:

Terriers secrete uric acid crystals.
All canines secrete uric acid crystals. (18a)

Terriers secrete uric acid crystals.
Mustangs secrete uric acid crystals.
All canines secrete uric acid crystals. (18b)

Twenty-four of the 40 subjects assigned a higher conditional probability to Argument 18a than to Argument 18b; 10 showed the reverse judgment, and 6 assigned the same conditional probability to each conclusion. This bias in favor of nonmonotonicity is significant by a sign test ($p < .01$, one-tailed). The other phenomena tested in the original experiments have been similarly replicated except for premise–conclusion asymmetry, which was tested without special instructions and yielded only a nonsignificant difference in the predicted direction.

Theory

Two Variables in Confirmation

The theory developed below claims that confirmation varies directly with the following two variables: a = the degree to which the premise categories resemble the conclusion category; and b = the degree to which the premise categories resemble members of the lowest-level category that includes both the premise and conclusion categories. These variables can be illustrated with Argument 9b, in which the premise categories are ROBIN and BLUEJAY and in which the conclusion category is GOOSE. Variable a cor-

responds to the similarity between robins and bluejays on the one hand, and geese on the other. Regarding variable b , observe that BIRD is the lowest-level category that includes ROBIN, BLUEJAY, and GOOSE. Hence, b corresponds to the similarity between robins and bluejays on the one hand, and all birds on the other. This variable is intended to capture the following kind of reasoning:

“Since robins and bluejays have the property, it may be the case that all birds have the property. Geese are birds. So maybe geese have the property too.”

Although we do not claim that such reasoning is consciously produced by the typical subject, we do claim that it represents a thought process that is central to inductive judgment (see also Carey 1985).

Rips (1975) has already proposed that variables a and b are fundamental to category-based induction. Our goal is to formulate this idea in a way that applies to a broader set of arguments than the single-premise, specific arguments considered by Rips. We show that the resulting model is consistent with all 13 phenomena discussed above and provides a reasonable fit of quantitative data described later.

Extended Similarity Functions

Both variables a and b invoke similarity as the underlying mechanism of confirmation judgment. Accordingly, our model rests on an extended notion of similarity. For a given subject S , we suppose the existence of a function SIM , defined on any pair of elements that are at the same hierarchical level within some natural category. Pairs of this kind include (BEE, MOSQUITO), (APPLE, WATERMELON), and (FALCON, CHIMPANZEE) – the last pair consists of elements at the same hierarchical level within the category ANIMAL. Given such a pair (k, g) , $SIM_s(k; g)$ is assumed to return a real number between 0 and 1 that reflects the similarity that S perceives between k and g , where values near 0 and 1 represent low and high similarity, respectively. Although $SIM_s(k; g)$ need not always equal $SIM_s(g; k)$ (see Tversky 1977), symmetry does seem to be approximately true for the stimuli that figure in our discussion.

The SIM function is directly relevant only to single-premise, specific arguments P/C . For such arguments, $SIM_s(CAT(P); CAT(C))$ represents the similarity between the categories in P and C . To be relevant to multiple-premise

arguments, both general and specific, we extend the domain of the SIM function as follows. Let $k_1 \dots k_n$, g be elements that are at the same hierarchical level within some natural category. We define $\text{SIM}_s(k_1 \dots k_n; g)$ to be the maximum of $\{\text{SIM}_s(k_1; g) \dots \text{SIM}_s(k_n; g)\}$. In words, $\text{SIM}_s(k_1 \dots k_n; g)$ is the greatest similarity that S perceives between g and some one of $k_1 \dots k_n$. To illustrate, if S 's intuitions conform to ours, $\text{SIM}_s(\text{robin}, \text{crow}; \text{sparrow}) = \text{SIM}_s(\text{robin}; \text{sparrow})$. When $n = 1$, the extended SIM function reduces to the original one.²

The foregoing use of the MAX function can be motivated by the following considerations about similarity and confirmation. Consider the argument

Rhinos have BCC in their blood.
Antelopes have BCC in their blood. (19)

Although not exceptionally strong, Argument 19 has nonnegligible strength, partly because of the similarity of RHINO to ANTELOPE. The same remarks apply to

Elephants have BCC in their blood.
Antelopes have BCC in their blood. (20)

However, combining the two premises, as in

Rhinos have BCC in their blood.
Elephants have BCC in their blood.
Antelopes have BCC in their blood. (21)

yields an argument that seems to be only slightly stronger than Argument 19 or 20, not twice as strong. The similarity of premise categories to conclusion categories thus appears not to summate when overall confirmation is mentally computed. This lack of additivity cannot be due to a mechanism that averages the similarity of premises to conclusion because averaging is inconsistent with premise monotonicity for specific arguments (see Phenomenon 7). In particular, since elephants resemble antelopes more than do monkeys, an averaging mechanism would render the single-premise Argument 20 stronger than

Elephants have BCC in their blood.
Monkeys have BCC in their blood.
Antelopes have BCC in their blood. (22)

But Argument 22 is clearly stronger than is Argument 20.

These considerations point to a maximizing principle in computing the similarity of multiple premises to a specific conclusion. With regard to

Arguments 19–21, such a principle allows the similarity of RHINO to ANTELOPE to be eclipsed by the greater similarity of ELEPHANT to ANTELOPE (or vice versa, if RHINO is more similar to ANTELOPE than is ELEPHANT), which explains why Argument 21 is not twice as strong as Argument 19.

A theory based on maximization must also account for the greater strength of Argument 22 compared with 20. Our theory achieves this, not by considering the additional similarity of MONKEY to ANTELOPE, but by considering the greater “coverage” of the category MAMMAL by the set {ELEPHANT, MONKEY} than by {ELEPHANT}. In the same way, the somewhat greater coverage by {RHINO, ELEPHANT} compared to {ELEPHANT} of the category MAMMAL accounts for the somewhat greater strength of Argument 21 compared with 20. The need to formalize this notion of coverage leads us to a second extension of the SIM function.

We extend the SIM function so that it applies to tuples of the form $(k_1 \dots k_n; G)$, where $k_1 \dots k_n$ are at the same hierarchical level of some natural category, and G is at a higher level. In this case, we define $\text{SIM}_s(k_1 \dots k_n; G)$ to be the average of

$$\{\text{SIM}_s(k_1 \dots k_n; g) \mid S \text{ believes that } g \text{ is at the same level as } k_1 \dots k_n \text{ and that } g \text{ belongs to } G\}.$$

In words, $\text{SIM}_s(k_1 \dots k_n; G)$ is the average similarity that S perceives between $k_1 \dots k_n$ and members of G at the level of $k_1 \dots k_n$. To illustrate, suppose that all the songbirds that S can think of appear in the list: ROBIN, SPARROW, FINCH, CARDINAL, BLUEJAY, ORIOLE. Then, $\text{SIM}_s(\text{CARDINAL}, \text{SPARROW}; \text{SONGBIRD})$ is the average of

$$\text{MAX}\{\text{SIM}_s(\text{CARDINAL}; \text{ROBIN}), \text{SIM}_s(\text{SPARROW}; \text{ROBIN})\}$$

$$\text{MAX}\{\text{SIM}_s(\text{CARDINAL}; \text{SPARROW}), \text{SIM}_s(\text{SPARROW}; \text{SPARROW})\}$$

$$\text{MAX}\{\text{SIM}_s(\text{CARDINAL}; \text{FINCH}), \text{SIM}_s(\text{SPARROW}; \text{FINCH})\}$$

$$\text{MAX}\{\text{SIM}_s(\text{CARDINAL}; \text{CARDINAL}), \text{SIM}_s(\text{SPARROW}; \text{CARDINAL})\}$$

$$\text{MAX}\{\text{SIM}_s(\text{CARDINAL}; \text{BLUEJAY}), \text{SIM}_s(\text{SPARROW}; \text{BLUEJAY})\}$$

$$\text{MAX}\{\text{SIM}_s(\text{CARDINAL}; \text{ORIOLE}), \text{SIM}_s(\text{SPARROW}; \text{ORIOLE})\}$$

If we make the further supposition that S 's intuitions are like our own, $SIM_s(\text{CARDINAL}, \text{SPARROW}; \text{SONGBIRD})$ equals the average of

- $SIM_s(\text{SPARROW}; \text{ROBIN})$
- $SIM_s(\text{SPARROW}; \text{SPARROW})$
- $SIM_s(\text{SPARROW}; \text{FINCH})$
- $SIM_s(\text{CARDINAL}; \text{CARDINAL})$
- $SIM_s(\text{CARDINAL}; \text{BLUEJAY})$
- $SIM_s(\text{CARDINAL}; \text{ORIOLE})$.

As a second illustration, $SIM_s(\text{RABBIT}; \text{MAMMAL})$ equals the average of $SIM_s(\text{RABBIT}; \text{ELEPHANT})$, $SIM_s(\text{RABBIT}; \text{MOUSE})$, and so forth. $SIM_s(\text{RABBIT}; \text{PACHYDERM})$ does not figure in this average because PACHYDERM is not at the same level as RABBIT .³

It may be helpful to provide an intuitive interpretation of such expressions as $SIM_s(\text{CARDINAL}, \text{SPARROW}; \text{SONGBIRD})$. SIM_s returns a high value on $(\text{CARDINAL}, \text{SPARROW}; \text{SONGBIRD})$ to the extent that every songbird (retrieved by S) is similar to either cardinals or sparrows or both. Conversely, the value is low if there are many songbirds that are similar to neither cardinals nor sparrows. Thinking of similarity (solely as an aid to intuition) as a decreasing function of metric distance in a space of instances, $SIM_s(\text{CARDINAL}, \text{SPARROW}; \text{SONGBIRD})$ is large to the extent that the set $\{\text{CARDINAL}, \text{SPARROW}\}$ "covers" the space of songbirds, in the sense that every songbird is near some member of $\{\text{CARDINAL}, \text{SPARROW}\}$.

Finally, it is worth pointing out that we could not properly reconstruct the coverage conception if we had earlier defined $SIM_s(k_1 \dots k_n; g)$ to be the sum rather than the maximum of $\{SIM_s(k_1; g) \dots SIM_s(k_n; g)\}$. To see this, consider a seven-member category $\Gamma = \{A, B, C, D, E, F, G\}$, the similarities of which are represented (inversely) by linear distance in the following diagram:

AB CDE FG

Intuitively, $\{B, D, F\}$ covers Γ better than $\{C, D, E\}$ does. This intuition conforms to the MAX-version of $SIM_s(k_1 \dots k_n; g)$ because every member of Γ is near some member of $\{B, D, F\}$, whereas some members of Γ – namely, A, B, F , and G – are far from every member of $\{C, D, E\}$. That is, $SIM_s(B, D, F; \Gamma) > SIM_s(C, D, E; \Gamma)$. However, the intuition that $\{B, D, F\}$ covers Γ better than does $\{C, D, E\}$ is violated if $SIM_s(k_1 \dots k_n; g)$ is computed as $SUM\{SIM_s(k_1; g) \dots SIM_s(k_n; g)\}$. For, by measuring distances in

the diagram the reader can verify that if the SUM version is used, the average of $\{SIM_s(C, D, E; \gamma) \mid \gamma \in \Gamma\}$ exceeds the average of $\{SIM_s(B, D, F; \gamma) \mid \gamma \in \Gamma\}$. Thus, the sum version of $SIM_s(k_1 \dots k_n; g)$ counterintuitively declares $\{C, D, E\}$ to provide better coverage of Γ than does $\{B, D, F\}$. The same counterintuitive result is obtained if an average version of $SIM_s(k_1 \dots k_n; g)$ is used.

The Model

Our model is formulated with the help of the following notation. Given a list $k_1 \dots k_m$ of categories, we denote by $[k_1 \dots k_m]$ the lowest level category K such that each of $k_1 \dots k_m$ is a subset of K . For example:

1. $[\text{TROUT}, \text{SHARK}] = \text{FISH}$;
2. $[\text{RABBIT}, \text{ELEPHANT}] = \text{MAMMAL}$;
3. $[\text{LION}, \text{SALMON}] = \text{ANIMAL}$;
4. $[\text{PORCUPINE}, \text{MAMMAL}] = \text{MAMMAL}$;
5. $[\text{HORNET}, \text{COW}, \text{ANIMAL}] = \text{ANIMAL}$.

The similarity–coverage model of argument strength: For every person S there is a positive constant $\alpha \in (0, 1)$ such that for all arguments $A = P_1 \dots P_n / C$, the strength of A for S is given by

$$\alpha SIM_s(\text{CAT}(P_1) \dots \text{CAT}(P_n); \text{CAT}(C)) + (1 - \alpha) SIM_s(\text{CAT}(P_1) \dots \text{CAT}(P_n); [\text{CAT}(P_1) \dots \text{CAT}(P_n), \text{CAT}(C)])$$

Thus, the model allows for individual differences in the relative importance attributed to similarity and coverage in argument strength. Such differences are represented by the parameter α . In contrast, for any given subject it is assumed that a single value of α applies to all arguments evaluated in a given context.

To illustrate the model, consider the argument

Beavers require oxydilic acid for good digestion.
 Raccoons require oxydilic acid for good digestion.

 Bears require oxydilic acid for good digestion. (23)

According to the model, the strength of Argument 23 for a given subject S is a weighted sum of terms a and b , where

$$a = SIM_s(\text{BEAVER}, \text{RACCOON}; \text{BEAR}) \text{ and}$$

$$b = SIM_s(\text{BEAVER}, \text{RACCOON}; [\text{BEAVER}, \text{RACCOON}, \text{BEAR}]).$$

Table 2: Summary of the Similarity–Coverage Model

<i>Theoretical Concept</i>	<i>Explanation</i>
$SIM_s(k; g)$, where k is at the same hierarchical level as g	Similarity according to S of k to g
$SIM_s(k_1 \dots k_n; g)$, where $k_1 \dots k_n$ are at the same hierarchical level as g	Maximum $\{SIM_s(k_i; g) \mid i \leq n\}$
$SIM_s(k_1 \dots k_n; G)$, where $k_1 \dots k_n$ are at the same hierarchical level and G is at a higher level	Average $\{SIM_s(k_1 \dots k_n; g) \mid g \in G\}$ (= average $\{\text{maximum } \{SIM_s(k_i; g) \mid i \leq n\} \mid g \in G\}$)
$[k_1 \dots k_n]$	Lowest level category G such that each of $k_1 \dots k_n$ is a subset of G
$CAT(P), CAT(C)$	Category terms figuring in premise or conclusion
Strength of $P_1 \dots P_n / C = \alpha SIM_s(CAT(P_1) \dots CAT(P_n); CAT(C)) + (1 - \alpha) SIM_s(CAT(P_1) \dots CAT(P_n); [CAT(P_1) \dots CAT(P_n), CAT(C)])$	

Term a is the greater of $SIM_s(\text{BEAVER}; \text{BEAR})$ and $SIM_s(\text{RACCOON}; \text{BEAR})$. By the definition of the bracket notation (i.e., the lowest level category that includes the bracketed categories), $[\text{BEAVER}, \text{RACCOON}, \text{BEAR}] = \text{MAMMAL}$, so Term b amounts to $SIM_s(\text{BEAVER}, \text{RACCOON}; \text{MAMMAL})$. This term represents the coverage of MAMMAL by BEAVER and RACCOON , that is, the average of $\text{MAX}\{SIM_s(\text{BEAVER}; m), SIM_s(\text{RACCOON}; m)\}$ across all mammals m known to S .

Now consider the related argument

Beavers require oxydlic acid for good digestion.
Raccoons require oxydlic acid for good digestion.

All mammals require oxydlic acid for good digestion.

(24)

According to the model, the strength of Argument 24 for a given subject S is given by the sum of a and b , where

$a = \alpha SIM_s(\text{BEAVER}, \text{RACCOON}; \text{MAMMAL})$ and

$b = (1 - \alpha) SIM_s(\text{BEAVER}, \text{RACCOON}; [\text{BEAVER}, \text{RACCOON}, \text{MAMMAL}])$.

By the definition of the bracket notation, $[\text{BEAVER}, \text{RACCOON}, \text{MAMMAL}] = \text{MAMMAL}$, so b may be rewritten as

$b' = (1 - \alpha) SIM_s(\text{BEAVER}, \text{RACCOON}; \text{MAMMAL})$.

The sum of a and b' is $SIM_s(\text{BEAVER}, \text{RACCOON}; \text{MAMMAL})$, regardless of the value of the parameter α . Consequently, according to the model, the strength of Argument 24 for S depends only on the coverage of MAMMAL by $\{\text{BEAVER}, \text{RACCOON}\}$.

The last example motivates the additive form of our model. It is intuitively plausible that the strength of Argument 24 depends only on the

sole variable of coverage. This dependency is deduced by adding terms of the form αX and $(1 - \alpha)X$, where X is the coverage variable. We note as well that the additive combination of similarity and coverage is the simplest hypothesis for a model that invokes both variables. Support for the additive form of the model thus provides better confirmation for its underlying idea (stated in the *Two Variables in Confirmation* section above) than would support for a version of the model that relies on more complicated mechanisms.

Table 2 summarizes the concepts figuring in the similarity coverage model.

The Phenomena Revisited

Given plausible assumptions about the SIM_s function, the similarity–coverage model predicts the 13 phenomena discussed earlier. In this sense, the phenomena provide qualitative support for the model. For each phenomenon we repeat its description, and then apply the similarity–coverage model to the contrasting arguments that were used as illustration. See Table 1 for a synopsis of relevant arguments.

Phenomena Concerning General Arguments

PHENOMENON 1 (PREMISE TYPICALITY)

The more representative or typical $CAT(P_1) \dots CAT(P_n)$ are of $CAT(C)$, the more $P_1 \dots P_n$ confirm C . According to the model, for a given person S , the strengths of Arguments 5a and 5b are given by

$$\alpha SIM_s(\text{ROBIN}; \text{BIRD}) + (1 - \alpha) SIM_s(\text{ROBIN}; [\text{ROBIN}, \text{BIRD}])$$

and

$$\alpha \text{SIM}_s(\text{PENGUIN}; \text{BIRD}) + (1 - \alpha) \text{SIM}_s(\text{PENGUIN}; [\text{PENGUIN}, \text{BIRD}]),$$

respectively. Because $[\text{ROBIN}, \text{BIRD}] = [\text{PENGUIN}, \text{BIRD}] = \text{BIRD}$, the foregoing expressions reduce to $\text{SIM}_s(\text{ROBIN}; \text{BIRD})$ and $\text{SIM}_s(\text{PENGUIN}; \text{BIRD})$, respectively. $\text{SIM}_s(\text{ROBIN}; \text{BIRD})$ equals the average similarity of robins to other birds, whereas $\text{SIM}_s(\text{PENGUIN}; \text{BIRD})$ equals the average similarity of penguins to other birds. It is reasonable to suppose that for a majority of subjects, the former value is greater than the latter, which yields the greater strength of Argument 5a compared with Argument 5b. More generally, the average similarity of an instance to the members of a given category is known as the *typicality* of that instance in the given category (Smith and Medin 1981; Tversky 1977), and the model thus predicts greater strength for general arguments the premises of which are typical rather than atypical (other factors held constant). This generalization captures Phenomenon 1.⁴

PHENOMENON 2 (PREMISE DIVERSITY)

The less similar $\text{CAT}(P_1) \dots \text{CAT}(P_n)$ are among themselves, the more $P_1 \dots P_n$ confirm C . According to the model, for a given person S , the strengths of Arguments 6a and 6b are given by

$$\alpha \text{SIM}_s(\text{HIPPO}, \text{HAMSTER}; \text{MAMMAL}) + (1 - \alpha) \text{SIM}_s(\text{HIPPO}, \text{HAMSTER}; [\text{HIPPO}, \text{HAMSTER}, \text{MAMMAL}])$$

and

$$\alpha \text{SIM}_s(\text{HIPPO}, \text{RHINO}; \text{MAMMAL}) + (1 - \alpha) \text{SIM}_s(\text{HIPPO}, \text{RHINO}; [\text{HIPPO}, \text{RHINO}, \text{MAMMAL}]),$$

respectively. Because $[\text{HIPPO}, \text{HAMSTER}, \text{MAMMAL}] = [\text{HIPPO}, \text{RHINO}, \text{MAMMAL}] = \text{MAMMAL}$, these expressions reduce to $\text{SIM}_s(\text{HIPPO}, \text{HAMSTER}; \text{MAMMAL})$ and $\text{SIM}_s(\text{HIPPO}, \text{RHINO}; \text{MAMMAL})$, respectively. To see that for most persons S , $\text{SIM}_s(\text{HIPPO}, \text{HAMSTER}; \text{MAMMAL})$ is likely to be greater than $\text{SIM}_s(\text{HIPPO}, \text{RHINO}; \text{MAMMAL})$, it suffices to observe that

1. For many $k \in \text{MAMMAL}$ (e.g., LION, ELEPHANT, HORSE), $\text{SIM}_s(\text{HIPPO}, \text{HAMSTER}; k) \approx \text{SIM}_s(\text{HIPPO}, \text{RHINO}; k)$ because most everything that resembles rhinoceroses resembles hippopotamuses as well. (The

use of the MAX interpretation of SIM_s is crucial here.)

2. For no $k \in \text{MAMMAL}$ does $\text{SIM}_s(\text{HIPPO}, \text{RHINO}; k)$ exceed $\text{SIM}_s(\text{HIPPO}, \text{HAMSTER}; k)$ by much because no mammal resembles rhinoceroses much more than it resembles hippopotamuses; and
3. For some $k \in \text{MAMMAL}$ (e.g., MOUSE, SQUIRREL, CHIPMUNK), $\text{SIM}_s(\text{HIPPO}, \text{HAMSTER}; k)$ appreciably exceeds $\text{SIM}_s(\text{HIPPO}, \text{RHINO}; k)$ because these mammals resemble hamsters more than they resemble rhinoceroses.

These facts yield the greater strength of Argument 6a compared with Argument 6b, in conformity with Phenomenon 2.

PHENOMENON 3 (CONCLUSION SPECIFICITY)

The more specific is $\text{CAT}(C)$, the more C is confirmed by $P_1 \dots P_n$. According to the model, the strengths of Arguments 7a and 7b reduce to $\text{SIM}_s(\text{BLUEJAY}, \text{FALCON}; \text{BIRD})$ and $\text{SIM}_s(\text{BLUEJAY}, \text{FALCON}; \text{ANIMAL})$, respectively. The greater homogeneity of BIRD compared to ANIMAL implies that $\{\text{BLUEJAY}, \text{FALCON}\}$ covers the former better than the latter. This implies that Argument 7a is stronger than Argument 7b, in conformity with Phenomenon 3.

PHENOMENON 4 (PREMISE MONOTONICITY)

For general arguments, more inclusive sets of premises yield more strength than less inclusive sets. Similarly to before, the model implies that the strengths of 8a and 8b boil down to $\text{SIM}_s(\text{HAWK}, \text{SPARROW}, \text{EAGLE}; \text{BIRD})$ and $\text{SIM}_s(\text{SPARROW}, \text{EAGLE}; \text{BIRD})$, respectively. Obviously, $\{\text{HAWK}, \text{SPARROW}, \text{EAGLE}\}$ covers BIRD better than $\{\text{SPARROW}, \text{EAGLE}\}$ does. This implies that Argument 8a is stronger than Argument 8b, as required by Phenomenon 4.

Phenomena Concerning Specific Arguments

PHENOMENON 5 (PREMISE-CONCLUSION SIMILARITY)

The more similar $\text{CAT}(P_1) \dots \text{CAT}(P_n)$ are to $\text{CAT}(C)$, the more $P_1 \dots P_n$ confirm C . According to the model, for a given person S , the strengths of Arguments 9a and 9b are given by

$$\alpha \text{SIM}_s(\text{ROBIN}, \text{BLUEJAY}; \text{SPARROW}) + (1 - \alpha) \text{SIM}_s(\text{ROBIN}, \text{BLUEJAY}; [\text{ROBIN}, \text{BLUEJAY}, \text{SPARROW}])$$

and

$$\alpha \text{SIM}_s(\text{ROBIN, BLUEJAY; GOOSE}) \\ + (1 - \alpha) \text{SIM}_s(\text{ROBIN, BLUEJAY; } \\ [\text{ROBIN, BLUEJAY, GOOSE}]),$$

respectively. Because $[\text{ROBIN, BLUEJAY, SPARROW}] = [\text{ROBIN, BLUEJAY, GOOSE}] = \text{BIRD}$, these expressions reduce to

$$\alpha \text{SIM}_s(\text{ROBIN, BLUEJAY; SPARROW}) \\ + (1 - \alpha) \text{SIM}_s(\text{ROBIN, BLUEJAY; BIRD})$$

and

$$\alpha \text{SIM}_s(\text{ROBIN, BLUEJAY; GOOSE}) \\ + (1 - \alpha) \text{SIM}_s(\text{ROBIN, BLUEJAY; BIRD}),$$

respectively. Because the two $(1 - \alpha)$ terms are identical, Argument 9a is predicted to be stronger than Argument 9b if $\text{SIM}_s(\text{ROBIN, BLUEJAY; SPARROW}) > \text{SIM}_s(\text{ROBIN, BLUEJAY; GOOSE})$. Surely this is the case for most subjects. Phenomenon 5 is thereby captured.⁵

PHENOMENON 6 (PREMISE DIVERSITY)

The less similar $\text{CAT}(P_1) \dots \text{CAT}(P_n)$ are among themselves, the more $P_1 \dots P_n$ confirm C . According to the model, for a given person S , the strengths of Arguments 10a and 10b are given by

$$\alpha \text{SIM}_s(\text{LION, GIRAFFE; RABBIT}) \\ + (1 - \alpha) \text{SIM}_s(\text{LION, GIRAFFE; } \\ [\text{LION, GIRAFFE, RABBIT}])$$

and

$$\alpha \text{SIM}_s(\text{LION, TIGER; RABBIT}) \\ + (1 - \alpha) \text{SIM}_s(\text{LION, TIGER; } \\ [\text{LION, TIGER, RABBIT}]),$$

respectively. Because $[\text{LION, GIRAFFE, RABBIT}] = [\text{LION, TIGER, RABBIT}] = \text{MAMMAL}$, these expressions reduce to

$$\alpha \text{SIM}_s(\text{LION, GIRAFFE; RABBIT}) \\ + (1 - \alpha) \text{SIM}_s(\text{LION, GIRAFFE; MAMMAL})$$

and

$$\alpha \text{SIM}_s(\text{LION, TIGER; RABBIT}) \\ + (1 - \alpha) \text{SIM}_s(\text{LION, TIGER; MAMMAL}),$$

respectively. Because $\text{SIM}_s(\text{LION; RABBIT})$ is likely to be no smaller than either $\text{SIM}_s(\text{TIGER; RABBIT})$ or $\text{SIM}_s(\text{GIRAFFE; RABBIT})$, it follows (via the MAX interpretation of SIM_s) that $\text{SIM}_s(\text{LION, GIRAFFE; RABBIT})$ is no smaller than $\text{SIM}_s(\text{LION,$

$\text{TIGER; RABBIT})$ for most persons S . On the other hand, it is clear that $\{\text{LION, GIRAFFE}\}$ covers MAMMAL better than $\{\text{LION, TIGER}\}$ does. Under the assumptions of the model, these facts imply that Argument 10a is stronger than 10b, in conformity with Phenomenon 6.

PHENOMENON 7 (PREMISE MONOTONICITY)

More inclusive sets of premises yield more strength than less inclusive sets, provided that the new premise is drawn from the lowest level category that includes the old premises and conclusion. According to the model, for a given person S , the strengths of Arguments 11a and 11b are given by

$$\alpha \text{SIM}_s(\text{FOX, PIG, WOLF; GORILLA}) \\ + (1 - \alpha) \text{SIM}_s(\text{FOX, PIG, WOLF; } \\ [\text{FOX, PIG, WOLF, GORILLA}])$$

and

$$\alpha \text{SIM}_s(\text{PIG, WOLF; GORILLA}) \\ + (1 - \alpha) \text{SIM}_s(\text{PIG, WOLF; } \\ [\text{PIG, WOLF, GORILLA}]),$$

respectively. Because $[\text{FOX, PIG, WOLF, GORILLA}] = [\text{PIG, WOLF, GORILLA}] = \text{MAMMAL}$, these expressions reduce to

$$\alpha \text{SIM}_s(\text{FOX, PIG, WOLF; GORILLA}) \\ + (1 - \alpha) \text{SIM}_s(\text{FOX, PIG, WOLF; MAMMAL})$$

and

$$\alpha \text{SIM}_s(\text{PIG, WOLF; GORILLA}) \\ + (1 - \alpha) \text{SIM}_s(\text{PIG, WOLF; MAMMAL}),$$

respectively. By the MAX interpretation of SIM_s , $\text{SIM}_s(\text{FOX, PIG, WOLF; GORILLA})$ is at least as great as $\text{SIM}_s(\text{PIG, WOLF; GORILLA})$. Also by MAX, $\{\text{FOX, PIG, WOLF}\}$ covers MAMMAL better than $\{\text{PIG, WOLF}\}$ does. Argument 11a is thereby predicted to be stronger than Argument 11b, in conformity with Phenomenon 7.

PHENOMENON 8 (PREMISE-CONCLUSION ASYMMETRY)

Single-premise arguments are not symmetric, in the sense that P/C may not have the same strength as C/P . According to the model, for a given person S , the strengths of Arguments 12a and 12b are given by

$$\alpha \text{SIM}_s(\text{MOUSE; BAT}) \\ + (1 - \alpha) \text{SIM}_s(\text{MOUSE; } [\text{MOUSE, BAT}])$$

and

$$\alpha \text{SIM}_s(\text{BAT; MOUSE}) + (1 - \alpha) \text{SIM}_s(\text{BAT; [BAT; MOUSE]}),$$

respectively. Because $[\text{MOUSE, BAT}] = [\text{BAT, MOUSE}] = \text{MAMMAL}$, these expressions reduce to

$$\alpha \text{SIM}_s(\text{MOUSE; BAT}) + (1 - \alpha) \text{SIM}_s(\text{MOUSE; MAMMAL})$$

and

$$\alpha \text{SIM}_s(\text{BAT; MOUSE}) + (1 - \alpha) \text{SIM}_s(\text{BAT; MAMMAL}),$$

respectively. It may be assumed that $\text{SIM}_s(\text{BAT; MOUSE})$ is roughly equal to $\text{SIM}_s(\text{MOUSE; BAT})$. On the other hand, the average similarity of mice to other mammals is greater than that of bats to other mammals. Hence, $\text{SIM}_s(\text{MOUSE; MAMMAL}) > \text{SIM}_s(\text{BAT; MAMMAL})$. Putting these facts together yields greater predicted strength for Argument 12a than for 12b, in line with Phenomenon 8. The foregoing derivation also reveals the following prediction of the similarity–coverage model: For a specific argument P/C to exhibit asymmetry, $\text{CAT}(P)$ and $\text{CAT}(C)$ must differ in typicality.

Phenomena Concerning Mixed Arguments

PHENOMENON 9 (NONMONOTONICITY, GENERAL)

Some general arguments can be made weaker by adding a premise that converts them into mixed arguments. According to the model, for a given person S , the strengths of Arguments 13a and 13b are given by

$$\alpha \text{SIM}_s(\text{CROW, PEACOCK; BIRD}) + (1 - \alpha) \text{SIM}_s(\text{CROW, PEACOCK; [CROW, PEACOCK, BIRD]})$$

and

$$\alpha \text{SIM}_s(\text{CROW, PEACOCK, RABBIT; BIRD}) + (1 - \alpha) \text{SIM}_s(\text{CROW, PEACOCK, RABBIT; [CROW, PEACOCK, RABBIT, BIRD]}),$$

respectively. Because $[\text{CROW, PEACOCK, BIRD}] = \text{BIRD}$ and $[\text{CROW, PEACOCK, RABBIT, BIRD}] = \text{ANIMAL}$, these expressions reduce to

$$\alpha \text{SIM}_s(\text{CROW, PEACOCK; BIRD}) + (1 - \alpha) \text{SIM}_s(\text{CROW, PEACOCK; BIRD})$$

and

$$\alpha \text{SIM}_s(\text{CROW, PEACOCK, RABBIT; BIRD}) + (1 - \alpha) \times \text{SIM}_s(\text{CROW, PEACOCK, RABBIT; ANIMAL}),$$

respectively. Regarding α -terms, $\{\text{CROW, PEACOCK}\}$ probably covers BIRD as well as $\{\text{CROW, PEACOCK, RABBIT}\}$ does. Regarding $(1 - \alpha)$ -terms, $\{\text{CROW, PEACOCK}\}$ covers BIRD better than $\{\text{CROW, PEACOCK, RABBIT}\}$ covers ANIMAL , in view of the greater variability among animals compared to the subset birds. Under the assumptions of the model, these facts imply that Argument 13a is stronger than 13b, as specified by Phenomenon 9.

PHENOMENON 10 (NONMONOTONICITY, SPECIFIC)

Some specific arguments can be made weaker by adding a premise that converts them into mixed arguments. According to the model, for a given person S , the strengths of Arguments 14a and 14b are given by

$$\alpha \text{SIM}_s(\text{FLY; BEE}) + (1 - \alpha) \text{SIM}_s(\text{FLY; [FLY, BEE]})$$

and

$$\alpha \text{SIM}_s(\text{FLY, ORANGUTAN; BEE}) + (1 - \alpha) \text{SIM}_s(\text{FLY, ORANGUTAN; [FLY, ORANGUTAN, BEE]}),$$

respectively. Because $[\text{FLY, BEE}] = \text{INSECT}$ and $[\text{FLY, ORANGUTAN, BEE}] = \text{ANIMAL}$, these expressions reduce to

$$\alpha \text{SIM}_s(\text{FLY; BEE}) + (1 - \alpha) \text{SIM}_s(\text{FLY; INSECT})$$

and

$$\alpha \text{SIM}_s(\text{FLY, ORANGUTAN; BEE}) + (1 - \alpha) \text{SIM}_s(\text{FLY, ORANGUTAN; ANIMAL}),$$

respectively. Regarding α -terms, $\text{SIM}_s(\text{FLY; BEE}) > \text{SIM}_s(\text{ORANGUTAN; BEE})$ and, consequently, $\text{SIM}_s(\text{FLY; BEE}) = \text{SIM}_s(\text{FLY, ORANGUTAN; BEE})$. Regarding $(1 - \alpha)$ -terms, $\{\text{FLY}\}$ covers INSECT better than $\{\text{FLY, ORANGUTAN}\}$ covers the varied category ANIMAL . The model thus implies that Argument 14a is stronger than Argument 14b, in conformity with Phenomenon 10.⁶

A Phenomenon Involving Both General and Specific Arguments

PHENOMENON 11 (INCLUSION FALLACY)

A specific argument can sometimes be made stronger by increasing the generality of its conclusion. The model implies that for a given

person S , the strengths of Arguments 15a and 15b are given by

$$\alpha \text{SIM}_s(\text{ROBIN}; \text{BIRD}) \\ + (1 - \alpha) \text{SIM}_s(\text{ROBIN}; [\text{ROBIN}, \text{BIRD}])$$

and

$$\alpha \text{SIM}_s(\text{ROBIN}; \text{OSTRICH}) \\ + (1 - \alpha) \text{SIM}_s(\text{ROBIN}; [\text{ROBIN}, \text{OSTRICH}]),$$

respectively. Because $[\text{ROBIN}, \text{BIRD}] = [\text{ROBIN}, \text{OSTRICH}] = \text{BIRD}$, these expressions reduce to

$$\alpha \text{SIM}_s(\text{ROBIN}; \text{BIRD}) + (1 - \alpha) \text{SIM}_s(\text{ROBIN}; \text{BIRD})$$

and

$$\alpha \text{SIM}_s(\text{ROBIN}; \text{OSTRICH}) \\ + (1 - \alpha) \text{SIM}_s(\text{ROBIN}; \text{BIRD}),$$

respectively. The $1 - \alpha$ terms are identical. Regarding the α -terms, $\text{SIM}_s(\text{ROBIN}; \text{BIRD})$ represents the average similarity of robins to other birds, including songbirds like sparrows, cardinals, and orioles. Because this average is partially weighted by the similar songbirds, $\text{SIM}_s(\text{ROBIN}; \text{BIRD})$ exceeds $\text{SIM}_s(\text{ROBIN}; \text{OSTRICH})$, since ostriches are highly dissimilar to robins. Phenomenon 11 follows. The foregoing derivation also reveals the following prediction of the similarity–coverage model: Arguments P/C and P/C' – with $\text{CAT}(C') \in \text{CAT}(C)$ – can give rise to the inclusion–fallacy phenomenon only if $\text{CAT}(C')$ is an atypical member of $\text{CAT}(C)$.

Two Limiting-Case Phenomena

PHENOMENON 12 (PREMISE–CONCLUSION IDENTITY)

Any argument of the form Q/Q is perfectly strong. According to the model, for a given person S , the strength of Argument 16 is given by

$$\alpha \text{SIM}_s(\text{PELICAN}; \text{PELICAN}) \\ + (1 - \alpha) \text{SIM}_s(\text{PELICAN}; [\text{PELICAN}, \text{PELICAN}]).$$

Because $[\text{PELICAN}, \text{PELICAN}] = \text{PELICAN}$, this expression reduces to $\text{SIM}_s(\text{PELICAN}; \text{PELICAN})$. It is safe to assume that subjects perceive the similarity of pelicans to themselves to be extremely high, thereby accounting for the extreme strength of Argument 16. If we assume that $\text{SIM}_s(\text{PELICAN}; \text{PELICAN})$ is in fact the maximal value 1, then Argument 16 is predicted to be perfectly strong.

PHENOMENON 13 (PREMISE–CONCLUSION INCLUSION)

Suppose that statements P and C are such that the conclusion category is included in the premise category. Then the argument P/C is perfectly strong. We must explain why Argument 17 is at least as strong as any other argument. Let $k_1 \dots k_n$ be all the animals known to S . Then, according to the model, $\text{SIM}_s(\text{ANIMAL}; \text{BIRD})$ equals the average of

$$\{\text{SIM}_s(k_1 \dots k_n; g) \mid S \text{ believes that } g \text{ is a bird}\}$$

Because birds are animals, this expression is the average of terms of the form $\text{SIM}_s(x; x)$. Such an average may be assumed to equal 1, and Phenomenon 13 is explained thereby.⁷

A Related Finding

Gelman and Markman (1986) documented a pattern of inference in young children and adults that may be illustrated as follows. Subjects were told that a pictured flamingo had a right aortic arch, whereas a pictured bat had a left aortic arch. They were then shown a pictured blackbird that resembled the bat in appearance more than it did the flamingo. Subjects nonetheless attributed the flamingolike, right aortic arch to blackbirds rather than the batlike, left aortic arch. Gelman and Markman concluded that category membership rather than similarity governs these kinds of inferences in both young children and adults.

We may represent the Gelman–Markman finding in terms of the strengths of the following arguments.

$$\frac{\text{Flamingos have a right aortic arch.}}{\text{Blackbirds have a right aortic arch.}} \quad (25a)$$

$$\frac{\text{Bats have a left aortic arch.}}{\text{Blackbirds have a left aortic arch.}} \quad (25b)$$

According to the similarity–coverage model, for a given person S , the strengths of Arguments 25a and 25b are given by

$$\alpha \text{SIM}_s(\text{FLAMINGO}; \text{BLACKBIRD}) + (1 - \alpha) \\ \times \text{SIM}_s(\text{FLAMINGO}; [\text{FLAMINGO}, \text{BLACKBIRD}])$$

and

$$\alpha \text{SIM}_s(\text{BAT}; \text{BLACKBIRD}) \\ + (1 - \alpha) \text{SIM}_s(\text{BAT}; [\text{BAT}, \text{BLACKBIRD}]),$$

respectively. Because $[\text{FLAMINGO}, \text{BLACKBIRD}] = \text{BIRD}$ and $[\text{BAT}, \text{BLACKBIRD}] = \text{ANIMAL}$, these expressions reduce to

$$\alpha \text{SIM}_s(\text{FLAMINGO}; \text{BLACKBIRD}) \\ + (1 - \alpha) \text{SIM}_s(\text{FLAMINGO}; \text{BIRD})$$

and

$$\alpha \text{SIM}_s(\text{BAT}; \text{BLACKBIRD}) \\ + (1 - \alpha) \text{SIM}_s(\text{BAT}; \text{ANIMAL}),$$

respectively. Regarding the α -terms, $\text{SIM}_s(\text{FLAMINGO}; \text{BLACKBIRD}) < \text{SIM}_s(\text{BAT}, \text{BLACKBIRD})$. Regarding the $(1 - \alpha)$ -terms, because $\{\text{FLAMINGO}\}$ covers BIRD better than $\{\text{BAT}\}$ covers the varied category ANIMAL , $\text{SIM}_s(\text{FLAMINGO}; \text{BIRD}) > \text{SIM}_s(\text{BAT}; \text{ANIMAL})$. As a consequence, Argument 25 will be judged stronger than Argument 25b if: (1) α is not too large, and (2) the coverage advantage of Argument 25a is not greatly outweighed by the similarity advantage of Argument 25b. We find these latter two assumptions reasonable, and thus believe that the Gelman–Markman finding is explainable in the context of the similarity–coverage model.

Quantitative Test of the Model

We performed 12 experiments designed to obtain quantitative data bearing on the similarity–coverage model. In an initial study, subjects rated the similarity of pairs of mammals in order for us to empirically estimate the SIM function underlying the model. From the approximated SIM function, predictions were derived about the relative strength of an extensive set of arguments. The predictions were then tested against ratings of argument strength provided by an independent group of subjects. The following is a condensed description of these experiments. A full report is available in Smith, Wilkie, López, and Osherson (1989).

Initial Similarity Study

Seven of the experiments were based on the category MAMMAL and the following base set of instances:

HORSE, COW, CHIMP, GORILLA, MOUSE, SQUIRREL, DOLPHIN, SEAL, ELEPHANT, RHINO. (26)

An initial study was performed to obtain similarity judgments for all 45 pairs of distinct mammals drawn from this set. Each pair was

printed on a separate card, and 40 subjects rank ordered all 45 cards in terms of “how similar the mammals appearing on each card are” (no ties allowed). The mean rank of each pair was divided by 45 to obtain a similarity scale between 0 and 1 (1 for perfect similarity, 0 for perfect dissimilarity). In addition, each identity pair (e.g., $(\text{HORSE}, \text{HORSE})$) was assigned a score of 1. Table 3 records these similarity scores.

We used these pairwise similarity scores to approximate $\text{SIM}_s(k; g)$ for each subject S and each pair of instances k, g drawn from the base set shown earlier. Averaging over subjects yields a composite similarity function defined over pairs of instances. This composite function will be denoted by SIM (without subscript), and represents the similarity intuitions of the average subject.

SIM may be extended via the MAX principle discussed earlier so that $\text{SIM}(k_1 \dots k_n; g)$ is defined for any choice of instances $k_1 \dots k_n; g$. However, we have no direct estimate of $\text{SIM}(k_1 \dots k_n; G)$, where G is the given, natural kind category and $k_1 \dots k_n$ are instances of G drawn from the base set. This is because calculation of $\text{SIM}(k_1 \dots k_n; G)$ presupposes the value of $\text{SIM}(k_1 \dots k_n; g)$ for all $g \in G$ that are retrieved by S , and not all of these g figure among the base set of instances (e.g., MOOSE is an instance of MAMMAL retrievable by most subjects, but does not figure in our base set for MAMMAL). An approximation to $\text{SIM}(k_1 \dots k_n; G)$ is therefore necessary. For this purpose, we have replaced G by its base set of instances. For example, to compute $\text{SIM}(\text{SQUIRREL}, \text{HORSE}; \text{MAMMAL})$, we computed $\text{SIM}(\text{SQUIRREL}, \text{HORSE}; G')$, where $G' = \{\text{HORSE}, \text{COW}, \text{CHIMPANZEE}, \text{GORILLA}, \text{MOUSE}, \text{SQUIRREL}, \text{DOLPHIN}, \text{SEAL}, \text{ELEPHANT}, \text{RHINO}\}$. This approximation is crude, but it represents in straightforward fashion the larger set of computations entailed by the model.

Finally, we consider the exact form of the predictions to be tested in the experiments. For a given argument A , the predictor variable of the model has the form $\alpha X_A + (1 - \alpha) Y_A$, where X_A is the model’s similarity term for A and Y_A is its coverage term for A . Both of these terms are empirically estimated from ratings of similarity. Likewise, the predicted variable is estimated from ratings of argument strength. The two rating procedures cannot, however, be relied on to provide identical scales for the two types of judgment. As a result, we take the model to be supported by any observed linear relation between predictor and predicted variables; that is, we test the prediction that for some choice of the

Table 3: Similarity Scores for Pairs of Mammals

<i>Mammals</i>	<i>Score</i>	<i>Mammals</i>	<i>Score</i>

parameter α , constants c and d , and for all arguments A , the empirically determined strength of A equals $c[\alpha X_A + (1 - \alpha)Y_A] + d$. This latter predictor has the form $aX_A + bY_A + d$, so the model predicts a high, multiple correlation between: (1) the empirically obtained estimates of argument strength and (2) approximations to the similarity and coverage variables figuring in the model. Since the similarity-coverage model makes no claims about the average value of the parameter α in the sample of subjects participating in our studies, we leave the a , b , and d coefficients as free parameters.

Confirmation Studies

Separate groups of 20 subjects ranked the strength of arguments based on the instances in the base set. For example, one group ranked 45 arguments of the form

X requires biotin for hemoglobin synthesis.
 Y requires biotin for hemoglobin synthesis.
 Z requires biotin for hemoglobin synthesis.

All mammals require biotin for hemoglobin synthesis.

where X , Y , and Z are distinct mammals drawn from the base set, and different arguments contain distinct trios of mammals in their premises. Together, there are 120 such premise-triples, and 45 were randomly generated to create the 45 arguments. These premise-triples are presented in Table 4.

Four sets of 45 cards were prepared, corresponding to the 45 arguments generated for the experiment. The names of the three mammals figuring in the premises were printed near the top of each card. The four sets differed in the order in which the mammals on a card appeared; four different random patterns were used. The following instructions were used:

We are frequently called upon to make judgments of the likelihood of something being true on the basis of limited information. Consider the following statement:

All mammals require biotin for hemoglobin synthesis.

How likely would you think that this statement is true if you knew, say, that all coyotes required biotin for hemoglobin synthesis? Would your opinion change if, instead of

coyotes, you knew the statement to be true of moles, or anteaters?

In this task you will be helping us to find out more about this type of reasoning. You will be handed a set of 45 cards. On each card will be written the name of the three mammals. For each card, you are to accept it as given that the mammals listed require biotin for hemoglobin synthesis. On the basis of this evidence, you are to determine how likely it is that all mammals require biotin for hemoglobin synthesis. Each card is to be evaluated entirely independently of the others.

Some of the mammals may seem to provide stronger evidence than others. Your task is to arrange the 45 cards in order of increasing strength of evidence.

The mechanics of a ranking procedure were then explained, and it was made explicit that no ties in the ranking were permitted.

The ranks assigned by the 20 subjects were averaged and divided by 45. Each argument thus received an “obtained confirmation score,” namely, a number between 0 and 1, where 1 represents *high* assessed confirmation and 0 repre-

sents *low* assessed confirmation. These obtained confirmation scores are presented in Table 4.

Consider now the predicted confirmation scores. According to the similarity-coverage model, the strength of each of the arguments is given by

$$\alpha \text{SIM}(X, Y, Z; \text{MAMMAL}) + (1 - \alpha) \text{SIM}(X, Y, Z; [X, Y, Z, \text{MAMMAL}]).$$

Because $X, Y,$ and Z are mammals, $[X, Y, Z, \text{MAMMAL}] = \text{MAMMAL}$, so the foregoing expression reduces to $\text{SIM}(X, Y, Z; \text{MAMMAL})$. For each triple X, Y, Z of mammals figuring in the experiment, an approximation to $\text{SIM}(X, Y, Z; \text{MAMMAL})$ was computed by first determining the maximum similarity of each mammal in the base set to $X, Y, Z,$ and then taking the average of these maximum similarities. The correlation between predicted confirmation scores and obtained confirmation scores is .87 ($N = 45, p < .01$).

A replication of the previous study was performed with new subjects using all 45 arguments based on 2 distinct mammals from the base set. The resulting correlation between obtained and predicted confirmation scores was .63 ($N = 45, p < .01$). Another replication used all one-premise arguments derived from the base

set and gave a correlation of .75 ($N = 10$, $p < .01$).

The foregoing experiments provide evidence for the predictive value of the coverage variable of the similarity–coverage model. To evaluate the role of the similarity variable, a second series of studies was performed with specific conclusions. For example, 20 new subjects rated all 36 possible arguments of the form

X requires biotin for hemoglobin synthesis.

Y requires biotin for hemoglobin synthesis.

Horses require biotin for hemoglobin synthesis.

where X and Y are distinct mammals drawn from the base set, neither of them HORSE, and different arguments contain distinct pairs of mammals in their premises. As before, the ranks assigned by the 20 subjects to the 36 arguments were averaged and divided by 36. Table 5 presents these mean ranks.

According to the similarity–coverage model, the strength of each argument is given by

$$\alpha \text{SIM}(X, Y; \text{HORSE}) + (1 - \alpha) \text{SIM}(X, Y; [X, Y, \text{HORSE}]).$$

Because X and Y are mammals, $[X, Y, \text{HORSE}] = \text{MAMMAL}$, so the foregoing expression reduces to

$$\alpha \text{SIM}(X, Y; \text{HORSE}) + (1 - \alpha) \text{SIM}(X, Y; \text{MAMMAL}).$$

For each pair X, Y of mammals figuring in the experiment, the value of $\text{SIM}(X, Y; \text{HORSE})$ was taken directly from the data of the initial similarity study (using the MAX interpretation of $\text{SIM}(X, Y; \text{HORSE})$). Regarding the second term, an approximation to $\text{SIM}(X, Y; \text{MAMMAL})$ was computed as described above. The similarity–coverage model implies that these two predictor variables should predict the obtained confirmation scores up to linearity. In fact, the multiple correlation coefficient between the latter two variables and the obtained confirmation scores is .96 ($N = 45$, $p < .01$).

Can the data be used to provide evidence for both similarity and coverage variables in the strength of specific arguments, that is, is there evidence for both $\text{SIM}(X, Y; \text{HORSE})$ and $\text{SIM}(X, Y; \text{MAMMAL})$ in an argument of form $X, Y/\text{HORSE}$? A natural way to test for the effect of these variables would be to compute the partial correlation between each predictor variable and the obtained confirmation score with the effects of the other predictor variable partialled out. Unfortunately, the interpretation of such an analysis is clouded by the fact that the similarity and coverage variables rely on overlapping facts about SIM. In particular, a high value of $\text{SIM}(X, Y; \text{HORSE})$ increases the value of $\text{SIM}(X, Y; \text{MAMMAL})$. For this reason, instead of partial correlations, we have computed nonpartial, Pearson coefficients between obtained confirmation and

each predictor variable taken alone. The correlation between obtained confirmation scores and the similarity variables $SIM(X, Y; \text{HORSE})$ is .95 ($N = 45, p < .01$). The correlation between obtained confirmation scores and the coverage variable $SIM(X, Y; \text{MAMMAL})$ is .67 ($N = 45, p < .01$). These two coefficients are significantly different ($p < .01$).

The foregoing results suggest that maximum similarity to HORSE is sufficient to account for the obtained confirmation scores. This fact should not be taken to support the view that the strength of specific arguments depends only on the similarity of the premise categories to the conclusion category. Such a hypothesis is contradicted by qualitative phenomena discussed earlier (e.g., premise diversity for specific arguments, see Phenomenon 6).

The foregoing study was replicated three times using different mammals for the conclusion category, and different numbers of premises. The obtained correlations between predicted and observed confirmation scores were all .94 or better.

Other Replications

As a check on the robustness of the preceding findings, five additional studies were performed. Each study involved one or more of the following changes compared to the seven original studies. First, instead of ranking arguments, subjects rated the probability of an argument's conclusion assuming the truth of its premises; in addition, different blank properties were used for every argument. Second, subjects were native French or Spanish speakers, working with translated materials. Third, the category INSECT was used in place of MAMMAL. All correlations in these studies between predicted and observed confirmation scores were significant at the .01 level, with a median correlation of .88. See Smith et al. (1989) for details.

Discussion

The conjunction of qualitative and quantitative evidence discussed in previous sections provides reason to believe that the two terms of the similarity–coverage model reflect genuine psychological processes that are central to confirmation. The model nonetheless remains underdetermined by the data considered in this article. In this section, we take up several proposals for theoretical refinement or amendment.

Weighting of Instances by Availability

Different members of the same category are often differentially available to a person S , even if S can recognize all of them as members of the category. For example, robins may be more accessible than turtledoves in S 's memory as members of the category BIRD. To represent such differential availability, the present version of the similarity–coverage model requires refinement. One way to achieve this is to incorporate relative availability in the computation of coverage. Specifically, for members $k_1 \dots k_n$ of category G , $SIM(k_1 \dots k_n; G)$ can be redefined so that the maximum similarity of $k_1 \dots k_n$ to $g \in G$ is weighted by the availability of g to S .

Although weighting by availability does not affect the model's ability to deduce the 13 qualitative phenomena, it could conceivably improve predictive accuracy in the experiments reported. Accordingly, we examined several principled bases – all derived from rated typicality – for assigning relative availability to the mammals figuring in the experiments. None of these revisions of the model resulted in better overall predictive accuracy. This lack of improvement is probably due to low variability in availability among the mammals used; all were highly typical, and no doubt became even more available by virtue of their continued use in a given experiment.

MAX Versus SUM in $SIM(k_1 \dots k_n; g)$

Consider a specific argument $P_1, P_2/C$. In computing the overall similarity of $CAT(P_1), CAT(P_2)$ to $CAT(C)$, the similarity–coverage model employs a MAX function over the similarities of $CAT(P_1)$ to $CAT(C)$ and $CAT(P_2)$ to $CAT(C)$. Use of maximization was motivated by the observation that the strength of $P_1, P_2/C$ seems not to be the sum of the strengths of P_1/C and P_2/C .

MAX is an extreme example of a nonadditive function, and it is possible that subjects use a function somewhere between MAX and SUM. Indeed, a more elaborate form of the similarity–coverage model might be equipped with another parameter that reflects an individual subject's position in the MAX to SUM continuum. Given this new parameter value β , the model would define $SIM_s(k_1 \dots k_n; g)$ to be

$$\beta \text{MAX}\{SIM_s(k_1, g) \dots SIM_s(k_n, g)\} \\ + (1 - \beta) \text{SUM}\{SIM_s(k_1, g) \dots SIM_s(k_n, g)\}.$$

This parameterized SIM function could then be incorporated into the similarity–coverage model as before, the resulting model having two parameters instead of one.

Diversity Versus Coverage

Philosophers of science underscore the usefulness of diversified data in testing scientific theories. Intuitively, there are fewer plausible alternatives to a theory that predicts phenomena of different sorts compared to one the predictions of which are always of the same kind. (For discussion, see Horwich 1982.) Given subject S and argument $P_1 \dots P_n/C$, the closest variable to diversity in the present model is the coverage by $\{\text{CAT}(P_1) \dots \text{CAT}(P_n)\}$ of the lowest level category that includes the premise and conclusion categories.

What is the relation between diversity in the philosopher's sense, and coverage in the present sense? To answer this question, it is necessary to assign a precise meaning to the diversity concept. Given subject S and set K of instances, we define $\text{DIV}_s(K)$ – the diversity of K (for S) – to be

$$\text{SUM}\{1 - \text{SIM}_s(k_1; k_2) \mid k_1, k_2 \in K\},$$

that is, the sum of the dissimilarities between members of K . Given sets K and G , we define the “diversity of K compared to G (for S)” to be $\text{DIV}_s(K)$ divided by $\text{DIV}_s(G)$. This latter quotient is denoted by $\text{DIV}_s(K; G)$. Observe that if either K or G have less than two members, then $\text{DIV}_s(K; G)$ is not defined.

Now let a subject S , a category G , and two instances k_1, k_2 be given. Then, $\text{SIM}_s(k_1, k_2; G)$ is the coverage of $\{k_1, k_2\}$ in G , and $\text{DIV}_s(\{k_1, k_2\}; G)$ is the diversity of $\{k_1, k_2\}$ compared with G . These two terms may differ considerably. For example, if k_1, k_2 represent highly dissimilar but very eccentric instances of G (e.g., whales and bats in the category MAMMAL), then $\text{DIV}_s(\{k_1, k_2\}; G)$ may be comparatively high but $\text{SIM}_s(k_1, k_2; G)$ may be comparatively low. We may use the similarity data of Table 3 to empirically contrast coverage and diversity. Taking G to be the base set of mammals, we calculated $\text{SIM}(k_1, k_2; G)$ and $\text{DIV}(\{k_1, k_2\}; G)$ over all 45 pairs k_1, k_2 of instances drawn from this set. The correlation of these two variables is only .55.

In terms of the DIV function, the philosopher's intuition about diversity may be stated as the following theory about general arguments involving more than one premise.

The diversity model for general arguments: For every person S and every general argument $A = P_1 \dots P_n/C$ in which $n \geq 2$, the strength of A for S is given by

$$\text{DIV}_s(\{\text{CAT}(P_1) \dots \text{CAT}(P_n)\}; \text{CAT}(C))$$

The reader can verify that the diversity model is compatible with those qualitative phenomena that bear on general arguments having more than one premise, namely, premise diversity, conclusion specificity, and premise monotonicity (Phenomena 2–4). We do not believe, however, that the diversity model is an accurate portrayal of the strength of general arguments. First, the model provides no account of single-premise, general arguments (because individual premises manifest no diversity). As a consequence, incorporating diversity into a more complete theory of category-based induction requires positing separate psychological mechanisms for single- versus multiple-premise arguments. Special provision would also be necessary for mixed arguments, for in such arguments confirmation can decrease rather than increase as premises become more dissimilar (cf. Phenomenon 9, nonmonotonicity, general). In contrast, the similarity–coverage model relies on a single (albeit extended) similarity function, and it applies uniformly to arguments of any number of premises, be they specific, mixed, or general. It may turn out that multiple, independent mechanisms underlie human inductive judgment, even for the restricted class of arguments at issue in this article. But complex models should not be favored over simple ones until required by recalcitrant data.

Also, there is a datum that seems to favor the coverage approach to general arguments over the diversity approach. There are general arguments $P_1, P_2/C$ and $Q_1, Q_2/C$ such that the diversity of $\{Q_1, Q_2\}$ exceeds that of $\{P_1, P_2\}$, but $P_1, P_2/C$ is stronger than $Q_1, Q_2/C$. To provide an example of such a pair of arguments, we note that $\{\text{PELICAN}, \text{ALBATROSS}\}$ is at least as diverse as $\{\text{ROBIN}, \text{SPARROW}\}$. The same experimental procedure used to verify the 11 qualitative phenomena also yields the following contrast.

Robins have a choroid membrane in their eyes.
Sparrows have a choroid membrane in their eyes.

All birds have a choroid membrane in their eyes.

(27a)

Pelicans have a choroid membrane in their eyes.
Albatrosses have a choroid membrane in their eyes.

All birds have a choroid membrane in their eyes.
(27b)

The diversity model is incompatible with this result. In contrast, the similarity–coverage model provides the following explanation for it. According to the model, for a given person *S*, the strengths of Arguments 27a and 27b are given by:

$$\alpha \text{SIM}_s(\text{ROBIN, SPARROW; BIRD}) \\ + (1 - \alpha) \text{SIM}_s(\text{ROBIN, SPARROW; [ROBIN, SPARROW, BIRD]})$$

and

$$\alpha \text{SIM}_s(\text{PELICAN, ALBATROSS; BIRD}) \\ + (1 - \alpha) \text{SIM}_s(\text{PELICAN, ALBATROSS; [PELICAN, ALBATROSS, BIRD]})$$

respectively. Because $[\text{ROBIN, SPARROW, BIRD}] = [\text{PELICAN, ALBATROSS; BIRD}] = \text{BIRD}$, these expressions reduce to $\text{SIM}_s(\text{ROBIN, SPARROW; BIRD})$ and $\text{SIM}_s(\text{PELICAN, ALBATROSS; BIRD})$, respectively. These latter terms represent the coverage by $\{\text{ROBIN, SPARROW}\}$ of BIRD, and the coverage by $\{\text{PELICAN, ALBATROSS}\}$ of BIRD, respectively. $\text{SIM}_s(\text{ROBIN, SPARROW; BIRD})$ equals the average of $\text{MAX}\{\text{SIM}_s(\text{ROBIN; } b), \text{SIM}_s(\text{SPARROW; } b)\}$ over all birds *b* known to *S*. $\text{SIM}_s(\text{PELICAN, ALBATROSS; BIRD})$ equals the average of $\text{MAX}\{\text{SIM}_s(\text{PELICAN; } b), \text{SIM}_s(\text{ALBATROSS; } b)\}$ over all such birds *b*. It is obvious that for most subjects *S*, the former average is greater than the latter, because most birds known to *S* are small, sing, and so forth. The greater strength of Argument 27a compared to 27b is thereby deduced.

The Multiplicity of Categories in Confirmation Judgment

The similarity–coverage model assumes the existence of a preestablished hierarchy of categories that classify the instances figuring in an argument. The success of the model in predicting the qualitative phenomena discussed earlier testifies to the approximate soundness of the model's assumption. Greater predictive accuracy nonetheless requires supplementary principles to describe the variety of categories that subjects may create "on line" when reasoning about argument strength (cf. Barsalou 1983; Kahne-

man and Miller 1986). Thus, the following argument may give rise to the covering category SMALL ANIMAL in the minds of many subjects, despite the absence of this category from their prestored list of animal classes.

Hummingbirds require Vitamin L for carbohydrate breakdown.

Minnnows require Vitamin L for carbohydrate breakdown.

Titmice require Vitamin L for carbohydrate breakdown.

The mental origin of such categories in reasoning about argument strength remains a central problem in the study of confirmation.

Notes

- 1 We use capitals to denote categories. Properties are italicized.
- 2 Outside the context of confirmation judgment, subjects may rate the similarity of a set to an object by averaging rather than by taking MAX. The present definition of $\text{SIM}_s(k_1 \dots k_n; g)$ is not intended to apply outside the domain of confirmation.
- 3 Our present definition of $\text{SIM}_s(k_1 \dots k_n; G)$ does not correctly apply to cases like $\text{SIM}_s(\text{EAST-MEXICAN-CHIHUAHUA; MAMMAL})$ because hardly any members of MAMMAL are at the same level as the very specific category EAST-MEXICAN-CHIHUAHUA. Such cases can be handled by a slight reformulation of our definitions. We do not pause for the details, however, because they are not relevant to the arguments considered in this article.
- 4 A spatial interpretation of similarity helps in understanding why central birds such as robins have greater average similarity to other birds than do peripheral birds such as penguins. Consider again the linearly arranged category Γ from the Extended Similarity Functions section. The reader can verify that the average distance between the peripheral member *B* and the rest of Γ is greater than the average distance between the central member *D* and the rest of Γ .
- 5 For some subjects, $[\text{ROBIN, BLUEJAY, SPARROW}]$ may equal SONGBIRD rather than BIRD. Because $\{\text{ROBIN, BLUEJAY}\}$ covers SONGBIRD even better than it covers BIRD, the model predicts such subjects to prefer Arguments 9a to 9b even more strongly than subjects for which $[\text{ROBIN, BLUEJAY, SPARROW}] = \text{BIRD}$.
- 6 It has been suggested to us that Argument 14b is weaker than Argument 14a because the former contains a pragmatic violation. Specifically, the violation is said to consist in the

fact that the orangutan premise of Argument 14b appears irrelevant to the conclusion, inasmuch as orangutans and bees belong to such different categories. Against this interpretation we may report that 64 of 100 Chilean undergraduates judged Argument 14c, below, to be stronger than Argument 14a, even though more of its premises violate the alleged pragmatic constraint.

Flies require trace amounts of magnesium for reproduction.

Orangutans require trace amounts of magnesium for reproduction.

Salmon require trace amounts of magnesium for reproduction.

Hawks require trace amounts of magnesium for reproduction.

Jellyfish require trace amounts of magnesium for reproduction.

Rattlesnakes require trace amounts of magnesium for reproduction.

Bees require trace amounts of magnesium for reproduction.

(14c)

We leave it to the reader to deduce from the similarity-coverage model the greater strength of Argument 14c compared with Argument 14a.

- 7 We note that this derivation rests on a questionable assumption, namely that a category such as ANIMAL can be mentally construed as a set of instances.

Chapter 18: When Explanations Compete: The Role of Explanatory Coherence on Judgments of Likelihood

STEVEN A. SLOMAN

Introduction

One way to decide whether a proposition is likely to be true is by considering why it might be true. We generate explanations and evaluate their plausibility. If the only available means of evaluating our explanations is in turn to explain them, then we are in danger of an infinite regress which leaves us uncertain as to the truth of the original proposition. But often some other means is available. We can evaluate our explanations by appealing to logic, authority, general knowledge or episodic memory. For example, to establish belief in the proposition

(A) Experienced car mechanics earn in the top quartile of incomes in the United States.

we might generate the explanation that they charge exorbitant and unnecessary labor costs which we can confirm from our own experience. This would increase the subjective likelihood of the proposition.

In the case of inductive inference, where we're deciding whether a proposition (a conclusion) is likely on the basis of knowledge that one or more related propositions (premises) are true, we must often consider not only why the conclusion might hold, but also why the premises do hold, and, most importantly, what implications our explanation for the premises has for the conclusion. One context in which this occurs is when we're reasoning by analogy. For example, consider the proposition concerning car mechanics above given the new information that

(B) Experienced electricians tend to earn in the top quartile of incomes in the United States.

A reasonable strategy would be to try to explain why both electricians and car mechanics would be in such income brackets and then decide whether the explanation for electricians is relevant to car mechanics. We can distinguish two cases. Either the explanations will be the same, if, for example, we ascribe both propositions to our belief that all skilled manual laborers earn that kind of money, or the explanations will be different, as they would be if we attribute the fact about electricians to their skill but we attribute the suggestion about car mechanics to their greed.

If the explanations are identical, we would expect the premise to increase belief in the conclusion. Because we know the premise to be true, any plausible explanation for it gains credibility. This form of reasoning is commonly called *abduction* and can be traced to the philosopher Charles Peirce (Ketner, 1992). Because our explanation has gained credibility, and because it also applies to the conclusion, our belief in the conclusion should increase. In short, a fact which increases the credibility of our explanation for an uncertain proposition should increase the subjective likelihood of that proposition. In other words, the conditional subjective likelihood of proposition A given proposition B, $\Pr\{A|B\}$, should be greater than the unconditional subjective likelihood of proposition A, $\Pr\{A\}$.

But what if our explanations for the premise and conclusion are different? How do people

treat the evidential relation between propositions that they attribute to different causes? One reasonable strategy would be to treat the two propositions as separate and unrelated such that the given proposition does not influence willingness to confirm the other. If we believe that electricians earn as much money as they do because they are skilled and that car mechanics earn money for entirely different reasons, knowledge about electricians might have no bearing on our beliefs concerning the earning potential of car mechanics. If so, $\Pr\{A|B\}$ should be equal to $\Pr\{A\}$. Alternatively, if simply increasing the probability of the value of a property like earned income – by attributing it to electricians – increases the subjective likelihood that that property value will apply to other professions, regardless of our explanations for the propositions, then B should increase belief in A; $\Pr\{A|B\}$ should again be greater than $\Pr\{A\}$.

Explanation Discounting

Finally, different explanations might compete with each other. People may have a tendency to consider only one explanation for a property. The mere presence of an alternative explanation may cause discounting of others. A proposition B that provided a different explanation for the property could reduce confidence in the original explanation for proposition A and thereby decrease A's subjective likelihood. This reduction in confidence could arise in one or both of two ways. The alternative explanation could have its effect directly on the assessment of plausibility. The presence of an alternative could reduce the credibility of the original explanation. Another possibility is that the alternative explanation could reduce the likelihood of generating the original explanation. The presence of an alternative could inhibit the construction or retrieval of other, potentially more convincing explanations. Even if only one of these effects occurs, a proposition would *reduce* belief in another proposition whose explanation is different; $\Pr\{A|B\}$ would be less than $\Pr\{A\}$.

In sum, given an argument with premise B and conclusion A and taking Pr to be a particular person's subjective scale of probability, I hypothesize that $\Pr\{A|B\} > \Pr\{A\}$ if and only if A and B have the same explanation for that person and $\Pr\{A|B\} < \Pr\{A\}$ if and only if that person would explain A and B differently. The hypothesis pertains to the class of arguments in which

a single property is predicated of two categories, one in the premise and the other in the conclusion. To make the hypothesis viable, certain cases must be eliminated. In particular, the hypothesis does not apply to arguments in which the premise and conclusion describe or imply competing outcomes or states of affairs. Consider the argument

Car mechanics claim to be the highest paid manual laborers.

Therefore, skilled electricians claim to be the highest paid manual laborers.

If we explain these statements in the same way, for example by attributing both claims to the two groups' willingness to work hard, then the premise would probably reduce belief in the conclusion because only one claim can be true (car mechanics and skilled electricians cannot both be the highest paid manual laborers). On the other hand, if we explain these statements differently, then the premise could increase belief in the conclusion. For example, if we explain the premise by appealing to a belief that car mechanics are habitual liars but explain the conclusion by attributing it to our belief that skilled electricians work hard, then the premise would be likely to increase belief in the conclusion because, by implying that the car mechanics' claim is false, it reduces the competition skilled electricians have to the title "highest paid manual laborer". Other exceptions to the hypothesis may also exist.

A variety of evidence is consistent with the hypothesis that a premise will decrease the judged probability of a conclusion when the two statements have different explanations. Indeed, the hypothesis is related to Kelley's (1973) discounting principle which states that the role of a given cause in producing a given effect is discounted if other plausible causes are also present (p. 113). The attribution of cause is one form of explanation. Kelley's principle summarizes the results of a number of studies in which subjects evoke compliance from either a lower- or higher-status target person. Subjects are less likely to attribute the lower-status target person's behavior to internal as opposed to external factors than the higher-status person's (although an overall bias to make internal attributions has also been observed; e.g., Ginzler, Jones, & Swann, 1987). The suggestion is that people will discount certain causes, like helpfulness, if other plausible ones, like desire-to-please, are available. As these

studies show, such a heuristic can provide a rational solution to an attribution problem.

Shaklee and Fischhoff (1982) elaborated on this principle by showing that people use a “truncated search” strategy when determining the causes of an event with multiple possible causes. Subjects who knew that a cause was involved in an event chose to learn additional details about the cause rather than learn about other possible causes. They not only discounted alternative causes, they didn’t even want to learn more about them. Knowledge of the relevance of one cause inhibited interest in others.

Finally, evidence suggesting the explanation discounting hypothesis comes from research concerning the psychological strength of arguments containing unfamiliar predicates – predicates which subjects cannot reason about or explain, such as “require trace amounts of magnesium for reproduction”. Using such arguments, Osherson, Smith, Wilkie, Lopez, and Shafir (1990) demonstrated a phenomenon that they called nonmonotonicity. They asked people to choose the stronger of the following two arguments; that is, to choose the argument whose conclusion was made more likely by the premises:

(C) *Flies require trace amounts of magnesium for reproduction.*

Therefore, bees require trace amounts of magnesium for reproduction.

(D) *Flies require trace amounts of magnesium for reproduction.*

Orangutans require trace amounts of magnesium for reproduction.

Therefore, bees require trace amounts of magnesium for reproduction.

Most subjects chose argument C. Adding the premise concerning orangutans to the argument concerning flies and bees actually reduced argument strength. I have suggested (Sloman, 1993) that the strength of such arguments is proportional to feature coverage – the extent to which the features of the premises *cover* those of the conclusion. I have also suggested that the cause of the nonmonotonicity phenomenon is that incompatible premise features compete and inhibit one another, which reduces their coverage of the features of the conclusion. We may have a bias to put greater weight on features that are common to all premises. Because orangutans and flies share few features, the distinctive fea-

tures of orangutans may inhibit those of flies. And because orangutans share few features with bees as well, whereas flies share many, some of those inhibited features will likely be common to flies and bees. Orangutans would reduce the weight of features shared by premises and conclusion without contributing to feature coverage.

What is meant by “feature” in this context? One interpretation is that a feature is a pointer to an explanation; each premise feature can be associated with an explanation for why the predicate applies to that premise category. Under this interpretation, my hypothesis amounts to the claim that explanations compete with and inhibit each other. In the nonmonotonicity example, all the competition happens to take place amongst alternative explanations for the premises. If the principle of explanation discounting holds, then it should apply more generally. Alternative explanations suggested by the premise should also have the effect of reducing the credibility of a conclusion for which a different explanation is readily available.

In sum, three ideas converge to suggest the operation of an explanation discounting principle: Kelley’s (1973) suggestion of a discounting principle, Shaklee and Fischhoff’s (1982) demonstration of the truncated search strategy in causal attribution, and the explanation for the nonmonotonicity phenomenon offered by Sloman (1993). I now report two experiments that test whether this principle operates when people are making inductive inferences concerning meaningful properties.

Experiment 1

I test the hypothesis that explanations compete with each other by comparing the difference between judgements of the probability of a conclusion when presented alone and the conditional probability of the conclusion given some fact, that is, a premise, under two conditions: either the premise and conclusion have the same explanation or they have different explanations. Consider the following argument:

(E) *Many ex-cons are hired as bodyguards.*

Many war veterans are hired as bodyguards.

If both these statements are true, they are likely true for the same reason, namely that both ex-cons and war veterans tend to be tough and

experienced fighters. But the statements of the next argument have different explanations:

- (F) Many ex-cons are unemployed.
Many war veterans are unemployed.

The reason the premise may be true is that ex-cons are often considered untrustworthy. However, the reasons for the conclusion are that war veterans sometimes suffer psychological trauma or that they're social outcasts. Explanation discounting would predict that the conditional probability judgement in the first case, where premise and conclusion explanations are the same, should be greater than the raw conclusion probability judgements. In the second case, where explanations are different, they should be lower.

Method

Sixteen category pairs were chosen. Each pair was used to construct two arguments: one whose premise and conclusion explanations were expected to be the same, and one whose explanations were expected to be different. Arguments were constructed by choosing two predicates: one for the argument in the Same condition and the other for the argument in the Different condition. Twenty Brown University undergraduates, paid for their participation, were tested on each of the resulting 32 arguments. Each subject completed four questionnaires that asked them to, respectively, judge the probability of each premise, judge the probability of each conclusion, judge the conditional probability of each conclusion given its corresponding premise, and provide an explanation for each premise and each conclusion. These explanations were collected in order to verify that explanations were the same for Same-condition arguments and different otherwise.

All subjects first completed the premise probability judgement task. They were shown a scale, from 0 to 1.0 in increments of 0.1, that was labeled "very unlikely" under 0, "completely unsure" under 0.5 and "very likely" under 1.0. They were also shown two examples of statements, unrelated to any of the arguments, with different probabilities filled in and justified. They were instructed to write a number from 0 to 1.0 beside each statement that indicated the likelihood that the statement was true. One group consisting of half the subjects next judged the conditional probabilities and a second group

Table 1: Conclusion and Conditional Likelihood Estimates in Experiment 1 as a Function of Relation Between Explanations

Judgement Task	Premise and Conclusion Explanations	
	Same	Different
$\Pr\{\text{Conclusion}\}$	0.62	0.54
$\Pr\{\text{Conclusion/Premise}\}$	0.66	0.47
$\Pr\{C P\} - \Pr\{C\}$	0.041	-0.071

consisting of the other half judged the conclusion probabilities. In the third phase, the two groups switched tasks. Instructions for the conclusion task were identical to those for the premise task except that no examples were provided. When conclusions were rated second, subjects were requested to ignore the facts from the preceding section. For the conditional ratings, subjects were again shown a scale and asked to rate the probability of the conclusion taking into account the fact that precedes it, whether the fact seems true or not. Each premise was preceded by "Fact:" in bold lettering and each conclusion by "Conclusion:", also in bold format. An example was provided. Finally, each subject provided the most plausible explanation of each statement of each argument as they could. Two example explanations of one sentence each were presented. Subjects were encouraged to be brief. Completing the four tasks took about an hour per subject.

Two orders of items were used. The first consisted of a random order of Same and Different arguments under the constraint that an equal number of Same and Different arguments appeared in the first and second halves of the list. The second order was identical except that the order of the two list halves was reversed. Each order was given to half of each group of subjects. The same order was used for each task. Each subject saw the premises, the conclusions, the arguments and the statements to explain in the order given by the arguments from which they came.

Results and Discussion

As predicted, the difference between conditional and conclusion probabilities was positive for Same-condition arguments and negative for Different-condition arguments, as shown in Table 1. The premise increased subjects' willingness to affirm the conclusion when both statements of the arguments had the same

explanation. For example, they judged the probability that *many war veterans are hired as bodyguards* to be higher when told that *many ex-cons are hired as bodyguards* than when they were not told anything about ex-cons. Furthermore, the premise decreased subjects' willingness to affirm the conclusion when statements had different explanations. The conditional probability that *many war veterans are unemployed* given that many ex-cons are was judged lower than the unconditional probability of war veterans exhibiting the property. This pattern is corroborated by a repeated-measures analysis of variance whose factors were judgement task (conclusion vs. conditional probability) and type of explanation (same or different). Conclusion and conditional probability judgements were not significantly different, $F(1, 19) < 1$. Judgements in the Different condition were significantly lower than those in the Same condition, $F(1, 19) = 68.80$; $p < .0001$, partly because, as expected, conditionals were lower in the Different condition and partly because, by chance, conclusion probabilities were also lower. Most importantly, the interaction between the two variables was significant, $F(1, 19) = 14.29$; $p < .01$. As described above, premises had opposite effects in the two conditions. The analysis across items showed an identical pattern. Furthermore, premises had a significantly positive effect in the Same condition, $t(19) = 2.22$; $p < .05$, and a significantly negative effect in the Different condition, $t(19) = -2.16$; $p < .05$.

The analyses just described collapse over the order in which subjects made the probability judgements and are therefore all within-subjects. However, if we consider only those judgements that were made prior to (and are therefore uncontaminated by) conclusion judgements and those conclusion judgements that were made prior to (and are therefore uncontaminated by) conditionals, an identical pattern of means is observed. Because these two types of judgements were made first by different groups of subjects, this comparison is between-subjects. The difference in the Same condition increased to 0.075 and the difference in the Different condition increased to -0.063 .

Were our intuitions about whether explanations would be the same or different correct? We answered this question by rating subjects' explanations. We categorized as either same or different each pair of explanations (from phase 4 of the experiment) provided by each subject that corresponded to the premise and conclusion of each argument. We thus had 20 ratings of expla-

nation sameness, one from each subject, for each argument. We then asked a naive judge to make these ratings. The judge was instructed to rate the explanations as the same if they had substantially the same content, that is, if a naive person given one explanation would treat it as synonymous with the other. She agreed with 84% of our judgements. The discrepant cases were given to a second naive judge, who made a final decision.

Analysis of these judgements shows that explanations tended to be more different than we had expected. Only 60% of explanations in the Same condition were actually the same whereas 91% in the Different condition were actually different. Most importantly, however, if we condition probability judgements on whether explanations were actually the same or different, we obtain an identical pattern of results to that reported above.

Moreover, the number of explanations consistent with our expectations helps to predict the magnitude of the effect we see across items. If we consider only those items that we expected to have the same explanation, the correlation between the number of times they actually had the same explanation and the difference between the conditional and conclusion probability judgements was .43. In contrast, if we consider only those items for which we expected explanations to be different, the number of actually different explanations helped to predict when we would expect a large negative difference, the correlation being $-.21$. The magnitude of this correlation is fairly low because of range attenuation; the number of actually different explanations was usually very close to 20.

The mean premise probability judgements were 0.60 in the Same condition and 0.63 in the Different condition. Their difference is marginally significant, $t(19) = 2.07$, $.05 < p < .10$, although probably not meaningful. The differential effect of the premise on belief in the conclusion in the two conditions is not easily attributed to differences in either premise or conclusion probabilities because of the double dissociation observed: the premise has a positive effect in one condition but a negative effect in the other. In any case, these attributions are ruled out by the next experiment.

Experiment 2

Because different arguments were used in the Same and Different conditions of Experiment 1 (although categories were held constant), the logical possibility exists that the effects we

observed were the result of our particular choices of premises and conclusions. Perhaps, purely by chance and not because of their underlying explanations, we chose premises in the Same condition that had a positive influence on their conclusions and premises in the Different condition that had a negative influence. Experiment 2 both tests this possibility and attempts to replicate the results of Experiment 1.

To test whether the chosen premises were responsible for the observed interaction, we reversed the condition of each premise. Each premise that was in the Same condition was associated with a new conclusion that we expected would have a different explanation, and each Different-condition premise was associated with a new conclusion that we expected would have the same explanation. The prediction is identical to that above: premises should have a positive effect in the Same condition and a negative effect in the Different condition. Changing the arguments in this way also tests whether the results of Experiment 1 were due to our particular choice of conclusions in that Experiment 2 involves a new set of conclusions.

Method

The method of Experiment 2 was identical to that of Experiment 1 except that a different set of arguments was used. We again tested 20 Brown University undergraduates. The premises in the Same condition were identical to those that appeared in Experiment 1's Different condition and those in the Different condition appeared in the previous experiment's Same condition. New conclusions were constructed to make the explanations for the premise and conclusions the same or different, as desired. For example, consider argument E above from the Same condition. We changed the conclusion category so that the new argument read

- (G) Many ex-cons are hired as bodyguards.
Many bachelors are hired as bodyguards.

Now the explanation for the conclusion will probably be different from that of the premise. Instead of having to do with toughness, it will reflect that bachelors have no attachments and therefore nothing to lose. Similarly, Different-condition argument F above was changed to read

- (H) Many ex-cons are unemployed.
Many people with bad credit histories are unemployed.

Table 2: Conclusion and Conditional Likelihood Estimates in Experiment 2 as a Function of Relation Between Explanations

<i>Judgement Task</i>	<i>Premise and Conclusion Explanations</i>	
	<i>Same</i>	<i>Different</i>
Pr{Conclusion}	0.50	0.58
Pr{Conclusion/Premise}	0.61	0.49
Pr{C P} – Pr{C}	0.11	–0.098

Now both statements are likely to have the same explanation; namely, that those people tend to be treated as bad risks.

Results and Discussion

The results replicated those of Experiment 1 closely except that the difference between the Same and Different conditions was more pronounced. Again as predicted, the difference between conditional and conclusion probabilities was positive for Same-condition arguments and negative for Different-condition arguments, as shown in Table 2. A two-factor repeated-measures analysis of variance across subjects again confirms the reported pattern. This time neither the main effect of judgement task nor of type of explanation was significant, both $F_s < 1$, but the interaction was highly significant, $F(1, 19) = 30.30$; $p < .0001$. The F -ratios across items were substantially similar. The effect of the premise was significantly positive in the Same condition, $t(19) = 5.43$; $p < .001$, and significantly negative in the Different condition, $t(19) = -3.13$; $p < .01$. If we consider only those conditional judgements that were made prior to conclusion judgements and conclusion judgements that were made prior to conditionals – a between-subjects comparison – the pattern of means is identical. The difference in the Same condition increases to 0.14 and in the Different condition to –0.090.

We used subjects' explanations to evaluate whether explanations were actually the same or different in a manner identical to that used in Experiment 1. This time the first naive judge agreed with 90% of our initial judgements. We again overestimated our subjects' tendency to provide the same explanation for two statements although this time we were more accurate. Sixty-eight percent of explanations in the Same condition were actually the same, 85% in the Different condition were actually different.

Again, conditioning probability judgements on whether explanations were actually the same or different makes no substantial difference to the effects we observe.

The number of explanations consistent with our expectations provides an even better prediction of the magnitude of our effect across items relative to Experiment 1. For items that we expected to have the same explanation, the correlation between the number of times they actually had the same explanation and the difference between the conditional and conclusion probability judgements was .54, whereas for items for which we expected explanations to be different, the correlation between the number of actually different explanations and the probability differences was $-.51$.

The mean premise probability judgements were 0.59 in the Same condition and 0.56 in the Different condition. The difference is not significant, $t(19) = 1.09$, n.s. Because no difference was observed and because the order of means is opposite to that of Experiment 1, the differential effect of the premise cannot be attributed to its probability. Analogously, because the order of conclusion probability means was opposite to that of Experiment 1, the effects of the premise cannot be attributed to their relative order.

General Discussion

Two experiments have shown that categorical facts in the context of arguments will tend to increase the subjective likelihood of other categorical statements if their explanations are consistent. They will tend to decrease the subjective likelihood of other statements if their explanations are different. Because all categories and predicates appeared in both explanation conditions, the differential effect of the premises is not due to peculiarities of the statements chosen. These results support the explanation discounting principle, which assumes that the likelihood of a statement is often derived by evaluating the plausibility of its explanation, and posits that people will tend to focus on a single explanation such that alternative explanations compete and inhibit one another.

The results that I have reported cannot be dismissed by attributing to subjects a misunderstanding of the conditional probability rating task. One might argue that, instead of rating the conditional probability of the conclusion given the premise – which combines prior belief in the conclusion with the belief transmitted by the premise – subjects are evaluating the

strength of the argument – which factors out prior belief and reflects only the belief transmitted by the premise. On this view, subjects' relatively low conditional likelihood judgements may simply reflect their belief that arguments in which premise and conclusion have different explanations are weak. This interpretation is unsatisfactory both for empirical and conceptual reasons. First, the correlation between conclusion and conditional probabilities was 0.53 in Experiment 1 and 0.44 in Experiment 2 ($ps < .001$). Such high correlations would be expected on the assumption that subjects were doing what they were asked to do – namely, rate the likelihood of the conclusion given all available evidence. If subjects were actually rating argument strength, the correlation should not differ from 0. More fundamentally, this hypothesis sheds no light on the central question under scrutiny: how are people influenced by the relation between the explanations of a premise and a conclusion when generalizing a property? It simply rephrases the question in terms of the determinants of argument strength.

One implication of my hypothesis is that two statements should have symmetric effects on each other. Given statements A and B whose explanations are different, $\Pr(A|B) < \Pr(A)$ if and only if $\Pr(B|A) < \Pr(B)$. Likewise, given statements A' and B' whose explanations are the same, $\Pr(A'|B') > \Pr(A')$ if and only if $\Pr(B'|A') > \Pr(B')$. My hypothesis thus predicts a property of subjective probability scales that also happens to obtain for probability scales that satisfy the axioms of standard probability theory.

I have suggested two mechanisms that could be responsible for the effects we observe when the explanation of the premise is not consistent with that of the conclusion. First, the presence of the premise explanation could cause subjects to discount their explanation for the conclusion by making them aware that alternative explanations are available. Second, the presence of the premise explanation could inhibit subjects from constructing or retrieving an alternative and more plausible explanation for the conclusion when they are evaluating its likelihood by causing them to perseverate on their explanation for the premise. I do not propose to attempt to distinguish these two hypotheses, not only because both probably capture some aspect of subjects' reasoning, but also because the proposals may not be distinguishable after sufficient elaboration. To illustrate, consider a model of likelihood assessment that states that the credibility of a statement is proportional to the success

of a process which attempts to construct an explanation for the statement that is maximally consistent with one's knowledge and beliefs. Furthermore, the process is competitive in the sense that propositions that cohere with the emerging explanation become more active and those that are incoherent are inhibited so that only a small set of propositions come out as "winners". A natural representation for the plausibility of an explanation in this model would be its degree of activation after a winner has been chosen. Similarly, a natural representation of the degree to which an explanation has been constructed or retrieved in this model would also be its degree of activation. So, by this model, the two hypotheses would be indistinguishable because they would both be represented by the same theoretical construct.

The decisive role played by the explanation of an event in providing a sense of certainty in an outcome is now well established (Sloman, 1990). For example, Koriat, Lichtenstein, and Fischhoff (1980) were able to reduce subjects' probability judgements concerning their answers to general knowledge questions by having them generate reasons contradicting their answers. Indeed, counterexplanation techniques have proved to be one of the few successful methods for reducing certain forms of bias in confidence judgements, such as the confirmation bias (Lord, Lepper, & Preston, 1984) and the hindsight bias (Slovic & Fischhoff, 1977). Ross, Lepper, Strack, and Steinmetz (1977) had subjects explain events in the lives of two psychiatric patients. They then informed subjects that the events were fictitious. Despite this discreditation of the evidence, subjects rated the likelihood of the event higher than did a group who had not generated an explanation. Apparently, explaining an event can be sufficiently convincing to make belief in it independent of data.

Pennington and Hastie (1988) argue that decision-making is "explanation based" (see also Wilson, Dunn, Kraft, & Lisle, 1989). They presented evidence to subjects in a mock courtroom situation either in chronological order, in which subjects were able to construct a story of the event in question, or in random (witness) order. Subjects were swayed more by evidence presented in story order than in witness order. Again, construction of a single coherent explanation for an event made it more credible, which is consistent with the present result that making different explanations simultaneously available

reduced confidence. People try to generate an internally consistent organizational structure to evaluate the likelihood of an event in a way that can override the desire to be as complete as possible in the consideration of alternatives. Explanation discounting may be less a product of an active competitive process than a side-effect of our tendency to try to capture relevant information in one coherent package. The very act of constructing an explanation may cause us to neglect others.

The notion of "explanation" is not unambiguous and a complete analysis is not yet available. One illustrative attribute of an explanation is that it must not presuppose the statement that it is explaining (see Osherson, Smith, & Shafir, 1986, for a fuller discussion of related issues). At minimum, a convincing explanation can be characterized as one which reduces a statement to others which can be independently confirmed through some form of logic, memory, or appeal to authority.

The experiments that I describe do not distinguish explanations that are inconsistent from those that are merely different. I have shown that, under the present conditions, $\Pr(A|B) < \Pr(A)$ if and only if A and B are related through the sharing of a predicate (and possibly otherwise related) and they have different explanations. The effect may have emerged because subjects treated the explanations as inconsistent. The possibility remains open that statements which are completely unrelated and have different explanations will not influence each other, $\Pr(A|B) = \Pr(A)$.

Variations of the conditional probability rating task employed in this research have been used to study the process of inductive inference in both children (e.g., Carey, 1985) and adults (e.g., Rips, 1975). This work has demonstrated a variety of systematicities in the inductive process, most of which are summarized by the dozen phenomena described by Osherson et al. (1990) and Sloman (1993) concerning judgements of the strength of arguments that use statements with unfamiliar predicates. An example phenomenon is nonmonotonicity, described above, which states that adding a premise will sometimes decrease the strength of an argument.

The work has also spawned a variety of theories of the process of inductive inference, including two computational models (Osherson et al., 1990; Sloman, 1993). Osherson et al. explain the nonmonotonicity phenomenon by positing

that people consider a higher-level, inclusive category which they draw from a stable category hierarchy when judging argument strength. Their model predicts nonmonotonicities whenever the additional premise category is not included in the higher-level category under consideration because people then have to consider an even higher-level, more inclusive category. This rule has some exceptions. See Osherson et al. (1990). In Experiment 1 of this paper, arguments in both the Same and Different conditions used the same categories. Therefore, cases in which the premise reduced confidence in the conclusion cannot be attributed to a change in the inclusive category under consideration. Apparently, we cannot always appeal to category-inclusion hierarchies to understand the conditions under which premises make a conclusion seem less plausible.

An alternative hypothesis, implemented in the feature-based model of Sloman (1993), is that the strength of an argument is directly related to feature coverage – the proportion of the conclusion category's features or attributes that it shares with the premise categories. The model is implemented as a simple connectionist network that takes advantage of the automatic generalization properties of distributed representations so that the links between categories and the predicate in the premises will automatically transfer to the conclusion by way of common features. As stated, this model has no way of accounting for nonmonotonicities. However, I explain them in Sloman (1993), as described above, by essentially invoking the principle of explanation discounting and discuss one of several ways to implement it in the model.

People's tendency to discount explanations when alternatives are available is an effective strategy for reducing uncertainty in a variety of situations. For example, we saw above how it helped to elucidate the motivation behind a person's behavior. When you ask someone over whom you have power to do you a favor, a reasonable conclusion is that their agreement to do so does not imply that they are intrinsically helpful. Similarly, if Alaska's leading cause of death were pneumonia, we could reasonably increase our degree of belief that pneumonia is associated with a cold climate, which in turn would make it less likely that Mexico's leading cause of death is pneumonia. However, an unrestrained use of such a strategy can also lead us astray. We found that the claim that many furniture movers have bad backs made subjects less

likely to believe that many secretaries have bad backs. The explanation discounting hypothesis explains this on the basis of the fact that secretaries will have bad backs from sitting over a desk for too long whereas furniture movers will have bad backs as a result of heavy lifting. If the hypothesis is right, then the different explanations compete and inhibit one another. But should they? Presumably humans can have bad backs for several reasons. The mere fact that heavy lifting can cause back problems should have no bearing on whether sitting too long at a desk can also cause back problems. Our hesitancy to consider multiple explanations for a property can lead us to underestimate the likelihood of propositions that can be true for multiple reasons.

Chapter 19: Properties of Inductive Reasoning

EVAN HEIT

Imagine that during an evening while you are out at the theater, your home is broken into and several personal items are stolen. This sudden event, in addition to having practical and possibly emotional consequences, is going to lead to changes in your beliefs and predictions about the future. Whereas you may have previously thought that your home was secure, you may now believe, on the basis of this one event, that it is rather likely that your home will be burgled again.

In the terms of inductive reasoning, you may well see similarities between one case – your home on this particular evening – and future cases – that is, your home on other, future evenings – leading you to project a predicate – being burgled – from the one case to the others. Of course, carrying out this sort of inductive reasoning would be more complicated, because there are the many past cases of evenings on which your home has not been burgled, and these cases too seem to have implications for the future. In addition, other information may be useful, such as whether or not nearby homes have been burgled recently. It seems that due to the similarity in location, knowing the history of other homes would help you to predict the safety of your own home.

This paper addresses how people project information from known cases to the unknown. The aim is to integrate the findings from a large number of psychological studies conducted over the past 25 years, on adults as well as children. From a tradition starting with Rips (1975), psychological experiments on inductive reasoning have typically addressed how people make inferences about predicates or properties of things such as animals – for example, about whether

a dog is susceptible to a particular kind of disease – rather than idiosyncratic events such as home burglaries. One reason for the extensive study of reasoning using animal categories rather than individual personal events is that we have a rich and well-documented categorical structure for representing animals and other living things.

It is possible to think of many cognitive activities as containing an element of inductive reasoning, using the known to predict the unknown; such activities range from problem solving to social interaction to motor control. However, this paper will focus on a narrower range of phenomena, concerning how people evaluate inductive arguments such as the following example:

Goldfish thrive in sunlight

Tunas thrive in sunlight.

The information above the line is taken as a premise that is assumed to be true; the task is to evaluate the likelihood or strength of the conclusion, below the line. There are several possible variants of this task. For example, the premise and conclusion could be presented as sentences or in pictures. There could be more than one premise. In addition, information in the premises could be provided for a category, such as all goldfish, or for an individual, such as one particular fish. Likewise, the conclusion could refer to a category or a specific individual. Finally, there are several ways to collect judgments about the conclusion; one could, for example, require responses on a scale of probability or inductive strength, or forced-choice judgments, in which subjects must choose between different

conclusions. Indeed, some studies could be described as collecting behavioral judgments rather than asking questions. For example, in some infant studies, induction is measured in terms of what action the child performs with a particular toy. Generally speaking, not all the results reported in this paper have been documented for all the different task variants, because researchers have typically assumed that the different variants address the same underlying processing. However, when systematic differences between different task versions have been reported, these will be highlighted.

This paper is intended to answer a number of questions about inductive reasoning, using the current findings from psychological research. The first three questions are factual and empirical, concerning how people respond to various kinds of inductive arguments. First, what makes a case generalizable? That is, when does an observation that something has a certain property promote the inference that something else has that property? Second, what makes a set of cases generalizable? The evidence shows that simply putting together a list of the most convincing, or induction-promoting, cases does not necessarily lead to the strongest possible ensemble of cases. The interesting result is that sometimes a set of individually weak cases can make a strong case together. Third, what makes a property projectable? That is, when we observe an object with various properties, which properties of the object are more likely to be projected to another case or inferred than others? Many psychological studies of inductive reasoning have addressed more than one of these questions. Therefore, different facets of the results of these studies will be described at different points in this paper.

The final question to be addressed is as follows: What are the psychological models of inductive reasoning? In the fourth main section of this paper, formal models of inductive reasoning will be discussed. Rather than present all of these accounts in detail, these accounts will be described just in terms of how they address the results covered by the first three questions. In Table 1, the touchstone results from psychological experiments on inductive reasoning will be listed, and the models of induction will be assessed against this list.

However, before proceeding with this review of psychological work on inductive reasoning, it is worth acknowledging that the study of induction has a longer history in other fields such as philosophy. Perhaps the best-known analysis

Table 1: Touchstone Results in Inductive Reasoning

Inferences From Single Cases

1. Similarity between premise and conclusion categories promotes induction.
2. Typicality of the premise category promotes induction. (No corresponding findings for the conclusion category.)
3. Homogeneity of the conclusion category promotes induction. (No corresponding findings for the premise category.)

Inferences From Multiple Cases

4. Greater number of observations, or premises, promotes induction (although the evidence is weak for children).
5. Greater diversity of observations, or premises, promotes induction (although the evidence is mixed for children, and too much diversity may not help even for adults).

Influence of Properties

6. There is widespread evidence that people draw inferences differently depending on the property being projected (found in adults and children).
 7. Some properties are idiosyncratic or transient, with a narrow scope for inferences, whereas other properties are more broadly projected.
 8. The assessment of similarity between categories in an argument depends on the property being projected.
-

from philosophy is Hume's (1748/1988) argument against the logical justification of induction. Hume argued that, unlike deductive inference, there is no basis for establishing the validity of a method for drawing inductive inferences. Although psychological work on induction has not directly addressed this traditional problem of induction, psychological research does paint a somewhat more optimistic picture, emphasizing how inductive reasoning is widespread in human thought and how people perform this reasoning very systematically. Psychological research has uncovered a rich and interesting set of phenomena that reveal much about cognitive processes. Furthermore, although they fall short of a complete logical justification for induction, some psychological accounts have addressed whether people's patterns of inductive reasoning do meet basic cognitive goals and to what extent people are subject to fallacies or internal contradictions. As the psychological phenomena are reviewed in this paper, when there have been related philosophical analyses these will be presented as well.

What Makes a Good Case?

The first issue to be addressed is why do we more readily draw inferences from some cases than others? For example, hearing about a burglary 2 miles away normally would have more effect than a burglary 100 miles away, on inferences about the security of one's own home. In fact, the notion of proximity is central to understanding induction, because similarity between cases has been found to be one of the main determinants of inductive strength. Actually, in this section, two questions will be covered. First, what is it about a premise category that promotes inferences to a conclusion category? Second, what makes a conclusion category itself seem like a good target for inferences? All of the results in this section will refer to situations where there is a single premise provided, because there is a well-established set of central phenomena for single-premise arguments. In the next section of this paper, inferences using multiple premises will be considered.

Initial Adult Studies

The seminal study of inductive reasoning was that of Rips (1975). This work looked at how adults project properties of one category of animals to another. Subjects were told to assume that on a small island, it had been discovered that all members of a particular species (of birds or mammals) had a new type of contagious disease. Then the subjects judged for various other species what proportion would also have the disease. For example, if all rabbits had this disease, what proportion of dogs would have it? Rips used a variety of animal categories in the premise and conclusion roles, with the categories having a known similarity structure derived using multidimensional scaling techniques. It was found that two factors consistently promoted inferences from a premise category to a conclusion category.

First, similarity between premises and conclusions promoted strong inferences. For example, subjects made stronger inferences from rabbits to dogs than from rabbits to bears. Second, the typicality of the premise, with respect to its superordinate category, was critical in promoting inferences. (Typicality of *rabbit*, for example, would be measured in terms of its distance from the representation of its superordinate, *mammal*, in a multidimensional scaling solution.) The result was that more typical premise

categories led to stronger inferences than did atypical premise categories. For example, with the bird stimuli, having *bluejay* as a premise category led to stronger inferences overall than did having *goose* as a premise category. Using multiple regression analyses, Rips (1975) found distinct contributions of premise–conclusion similarity and premise typicality. Interestingly, there was no evidence for a role of conclusion typicality. For example, all other things being equal, people would be as willing to draw a conclusion about a bluejay or about a goose, despite the difference in typicality of these two categories. It is important to keep these three findings in mind, because they recur in many subsequent studies of inductive reasoning – namely, that premise–conclusion similarity and premise typicality promote induction, but that typicality of the conclusion category does not seem to affect inductive strength.

Chronologically speaking, the next major study in this paradigm was done by Nisbett, Krantz, Jepson, and Kunda (1983), who also asked subjects to draw inferences about items (animals, people, and objects) found on a remote island. For example, subjects were told to imagine that one member of the Barratos tribe was observed to be obese, and they estimated the proportion of all members of this group that would be obese. Likewise, the subjects were told that one sample of the substance “floridium” was observed to conduct electricity, and they estimated the proportion of all members of this set that would conduct electricity. There were several interesting findings from the Nisbett et al. study, but for our present purposes the most relevant is that the subjects were very sensitive to perceived variability of the conclusion category. For a variable category such as Barratos people (and their potential obesity), the subjects were rather unwilling to make strong inferences about other Barratos, after just one case. But for a homogenous category such as floridium samples, the subjects were willing to generalize the observation of electrical conductance to most or all of the population.

This result, that subjects were more willing to draw inferences about homogenous conclusion categories, makes a striking comparison to the results of Rips (1975). Whereas Rips found that typicality of the conclusion did not affect inductive strength, the results of Nisbett et al. (1983) results show that conclusion categories do matter, at least in terms of their variability. The criteria for what makes a good premise

category are different than the criteria for what makes a good conclusion category.

Studies with Children on Use of Shared Category Membership

The Rips (1975) task has been adapted for testing with children, first by Carey (1985). There are a number of important reasons to study inductive reasoning in children. Such studies could show how inductive abilities develop, perhaps guiding or constraining accounts of fully developed, adult inductive reasoning. In comparing two models that equally account for adult data, if one model can also give an explanation of the course of development, then that model ought to be favored. Also, the performance of children on induction tasks can help the researcher determine what children know about a particular domain. For example, a pattern of age-related changes in reasoning about animals could reflect the growth of children's knowledge or theories about living things. Of course, with these different reasons for studying the development of induction, there is always the challenge of whether to attribute a change in performance to development of reasoning processes or development of knowledge.

Carey (1985) used an induction task with pictures of humans, animals, plants, and other things. Children, as young as age 4, were shown a picture of a premise item, such as a picture of a person, and told that it had some property, such as that of having a spleen inside.¹ Then the child was shown several pictures of other things, such as dogs, bees, and flowers, and was asked whether each also had the same property – for example, that of having a spleen. A number of results showed what makes a good case, from the point of view of young children. For children of age 6 and under, information about persons, as premises, tended to promote strong inductions. For example, when told that a person had a spleen, children were inclined to judge that dogs and bees had spleens as well. On the other hand, other animals did not make good cases, or were considered weak premises. For example, projection from dogs to humans was much weaker than projection from humans to dogs. This result maps well onto the finding of typicality effects by Rips (1975), given the assumption that children consider humans to be very typical animals.

Some of the other results from Carey (1985) also map well onto past results, in particular that similarity effects were also found. A fact about

humans was projected most strongly to other mammals, then to other animals such as birds and bees, and progressively less to plants and inanimate objects. Children as young as age 4 showed this pattern, but the steepness of the generalization gradient was greater in older children, suggesting greater sensitivity to similarity between categories.

On their own, these results from Carey (1985) would perhaps be described best as resulting from a change in knowledge rather than a change in processing. That is, as children get older, they lessen their use of humans as a prototype, and they increase the steepness of their generalization gradient when using information about similarity between various animals, plants, and inanimate objects. These changes could well reflect a maturing conception of things in the living world, and an increasing differentiation between various categories, rather than changes in how inductive reasoning is actually performed. However, this issue will be revisited as other results are described.

Chronologically, the Carey (1985) study was followed by several studies by Gelman and colleagues (Gelman 1988; Gelman and Coley 1990; Gelman and Markman 1986; Gelman and O'Reilly 1988). In these experiments, similar procedures to Carey's were used, with children being told a property of some animal or object in a picture and then judging whether or not other animals or objects would also have this property. Gelman and Markman tested children as young as age 4, with the particular aim of looking at the nature of similarity effects. Although Carey did find similarity effects in young children, there are various ways in which animals and other things could be considered similar, and it is important to understand what kind of conception of similarity is guiding inductive inferences. Gelman and Markman contrasted similarity based on perceptual appearances with similarity based on underlying shared category membership. For example, a blackbird and a bat may look fairly similar, whereas a blackbird and a flamingo may not appear too similar, but the latter two share many internal characteristics because they are both birds. Using questions about unfamiliar internal properties, Gelman and Markman found that young children preferred to project between pairs of items with shared category membership, even when the members of the pair were less similar on the surface than those of some other pair. Therefore it was concluded that children used a fairly sophisticated conception of similarity to guide inductive reasoning, with deeper

similarities such as category membership overriding more superficial similarities.

Gelman (1988) examined inductive reasoning at different levels of a taxonomic hierarchy (cf. Rosch, Mervis, Gray, Johnson, and Boyes-Braem 1976). For example, given the premise that a daffodil has some novel property, children were asked whether the property would be true of another daffodil (same subordinate level category), a rose (same basic level category), a houseplant (same superordinate level category), and a bowl (unrelated category). Children as young as age 4 showed a generalization gradient that was similar to that for the results of Carey (1985), with the most projections within the subordinate level, and decreasing projections at higher levels of the taxonomy. Gelman pointed out that the results could reflect not only similarity-based reasoning but also sensitivity to category variability or homogeneity (as in Nisbett et al. 1983), with lower level categories being more homogeneous. Indeed in some cases adult judgments of category homogeneity were significantly correlated with likelihood of children's inferences to that category. In a second study done by Gelman (1988), children were asked to generate their own familiar properties for the premise category and were then asked to judge whether this property held for the various conclusion categories as well. It was found that judgments about familiar properties followed the same patterns as did judgments about novel properties, suggesting that subjects might make inferences about novel properties by considering the distribution of known properties (see Heit 1998).

As in Gelman's (1988) experiments, Gelman and O'Reilly (1988) looked at inductive reasoning at different points in a taxonomic hierarchy, but the focus was at higher or more superordinate levels of the taxonomy. Again, the pattern of results consisted in a decreasing likelihood of inferences at progressively higher taxonomic levels. This study also showed that children were equally willing to make inferences to typical superordinate category members and atypical superordinate category members, as in Rips (1975).

Gelman and Coley (1990) tried to extend the main results from older children to 2-year-olds, using a somewhat simpler procedure. The key findings were that children were able to use shared category membership to guide inferences, even when it conflicted with surface similarity, and that, again, the typicality of conclusion categories did not affect induction. In a useful control condition, it was found that the sharing of

a category label, such as "bird," was critical to obtaining these results. Shared transient properties, such as "wet," did not serve as a reliable basis for induction.

At this point, it is worth mentioning parenthetically that despite this evidence for shared category membership as a basis for induction, in preference to perceptual similarity and other shared attributes, there is indeed evidence that perceptual similarity and other shared attributes do have some role in promoting inductive reasoning. That is, if two things look alike, you may still want to project a property from one to another on this basis, despite different category membership. In studies with children (as young as age 3) and adults, Florian (1994) found effects of perceptual similarity and shared attributes on induction, beyond effects of category membership. (See also Loose and Mareschal 1999.)

Keeping with the progression of finding category membership as a basis for induction at increasingly younger ages, it is interesting to consider the relevant studies done with infants. Children as young as 3 or 4 years have shown a rather sophisticated use of similarity and category membership to guide induction. How well does this ability extend to even younger children? Again, induction tasks with infants could reflect their inductive reasoning abilities as well as their knowledge base for a particular domain of categories. Baldwin, Markman, and Melartin (1993) examined inductive inference in infants between 9 and 14 months of age, using an exploratory play task. The children learned, after a brief exposure of 30 seconds about a property of a novel toy – for example, that a can would make a wailing sound when squeezed. The test was whether children would expect another toy of similar appearance to have this property as well. Children played for a longer time with a second object that did not have the target property (e.g., a can that did not wail) in comparison with appropriate control conditions, suggesting that the infants had inferred that the second toy would be like the first toy and were surprised that it did not have the same property. This study showed that some of the inductive ability in older children is also present with infants, but it was not designed to look at whether or not children use a taxonomy of categories to support induction.

Mandler and McDonough (1996) also looked at induction with infants, but focused more on use of established taxonomies of categories. They looked especially at the use of the superordinates *animal* and *vehicle*. The infants were

taught an action to perform on an object, such as giving a (toy) dog a drink; then they were tested on whether this action was generalized to other objects in the same superordinate category (e.g., a rabbit) and the other superordinate category (e.g., a bus). The children's pattern of play respected the boundaries of superordinate categories, with actions taught on one animal being extended to other animals but not to other vehicles, and likewise actions taught on one vehicle extended to other vehicles but not animals. However, there was not evidence for much sensitivity to distinctions within the superordinate category. That is, infants did not project more between similar items (e.g., *dog* and *rabbit*) than between dissimilar items (e.g., *dog* and *fish*), as long as all items were in the same superordinate category. There are a number of ways to conceive of this result. As in Gelman and Markman (1986), it shows the primacy of shared (superordinate) category membership. Unlike Gelman (1988), Mandler and McDonough (1996) did not address shared subordinate or basic level category membership, so it is difficult to say whether inductions would have been even stronger with subordinate or basic level categories than with superordinate categories (but see Mandler and McDonough 2000). Would the inferences have been even stronger from one kind of dog to another? Finally, the dissimilar conclusion categories in Mandler and McDonough (1996) tended to be atypical of the superordinate category (e.g., fish are less typical animals than are rabbits), so the lack of distinctions among various conclusion categories within a particular superordinate category could be taken as a replication of the finding that conclusion typicality does not affect induction (Carey 1985; Gelman and O'Reilly 1988; Rips 1975).

Perhaps the best way to summarize the Baldwin et al. (1993) and Mandler and McDonough (1996) studies is that they documented an important subset of the known results for older children, using ordinary infant behaviors (playing with toys) as a means of measuring induction rather than other forms of the task which would require explicit judgments.

Further Phenomena Involving Typicality, Similarity, and Specificity

One of the advantages of studying induction in adults rather than children is that it is possible to present a greater number of problems in one session and potentially address a greater

range of phenomena. Indeed, Osherson, Smith, Wilkie, López, and Shafir (1990) have made a substantial and influential contribution to the study of inductive reasoning by documenting a set of important phenomena (see also Osherson, Stern, Wilkie, Stob, and Smith 1991). Several of these phenomena involve reasoning from just a single premise category, whereas the remainder involve multiple premises and will be described in a later section of this paper. The experiments of Osherson et al. (1990) involved giving subjects pairs of inductive arguments such as the following:

Robins use serotonin as a neurotransmitter

Sparrows use serotonin as a neurotransmitter

and

Robins use serotonin as a neurotransmitter

Geese use serotonin as a neurotransmitter.

Subjects would tend to choose the first argument as stronger than the second, illustrating the premise–conclusion similarity phenomenon (reported by Rips 1975, and subsequently others). In addition, Osherson et al. (1990) documented the premise typicality effect, reported by Rips and others. As an extension of this result, Osherson et al. (1990) described the premise–conclusion asymmetry phenomenon; for example, the argument from robins to geese above would be stronger than the reversed argument, from geese to robins (see also Carey 1985, for an example of asymmetry). This phenomenon follows from the premise typicality effect, because whenever an argument has a premise category more typical than its conclusion category, the reversed argument should be weaker than the original argument.

Next, Osherson et al. (1990) documented the conclusion specificity phenomenon. It was found that arguments with a more specific conclusion category, such as *bird*, were considered stronger than arguments with a more general conclusion category, such as *animal*. This result makes sense from a logical perspective, in that more evidence should be needed to support a more sweeping conclusion about a relatively superordinate category, in comparison with a narrow conclusion about a more subordinate category. (See also McDonald, Samuels, and Rispoli 1996, for correlational evidence that over a range of arguments, scope of conclusion category is one of three good predictors of inductive strength.) This phenomenon can also be

tied to the Nisbett et al. (1983) result showing that people make stronger inferences about more homogenous categories. In general, superordinate categories should be more variable than their subordinate categories, because the superordinate includes its own subordinates.

One of the important contributions of Osherson et al. (1990) was that they began to show where people's inductive inferences diverge from normative patterns. Rather than take the Humean approach of addressing whether induction can be justified, Osherson et al. (1990) aimed to show examples in which people's inductive inferences were clearly not justified – for example, because they violated axioms of probability. One relevant phenomenon is the inclusion fallacy, illustrated in the following arguments:

Robins secrete uric acid crystals

All birds secrete uric acid crystals

and

Robins secrete uric acid crystals

Ostriches secrete uric acid crystals.

People choose the first argument as stronger than the second, even though the first conclusion logically implies the second. Because the second conclusion is implied by the first conclusion, the probability of the second conclusion should not be lower than the probability of the first conclusion. The inclusion fallacy seems to reflect the use of similarity between the premise and conclusion in making judgments. If the representations of *robin* and *bird* are quite similar (due to the typicality of *robin*), but *ostrich* has a quite different representation than *robin*, then the second argument could seem weaker than the first. However, it should be noted that the more general result is the conclusion specificity phenomenon, in which arguments with more specific conclusion categories are considered stronger. The inclusion fallacy would seem to apply only in cases such as the example above involving a pair of category members, one very typical, such as *robin*, and one atypical, such as *ostrich*.

Also, using picture versions of the Osherson et al. (1990) tasks, López, Gelman, Gutheil, and Smith (1992) found evidence for a number of the Osherson et al. (1990) single-premise phenomena with children ranging from ages 5 to 9. In addition to typicality effects, López et al. (1992) found conclusion specificity effects; for

example, inferences were weaker for a conclusion about animals and plants than for a conclusion about just animals. This result, again, can be taken as support for the Nisbett et al. (1983) findings of poor generalization to variable categories, here with young children. Likewise, the López et al. (1992) result converges nicely with the Gelman (1988) and Gelman and O'Reilly (1988) results that children draw strong inferences between items that are both members of a relatively specific, subordinate category.

Furthermore, Sloman (1993, 1998) extended the findings of the inclusion fallacy by demonstrating another phenomenon, inclusion similarity. As in the inclusion fallacy, the inclusion similarity phenomenon shows an effect of similarity between premise and conclusion categories, in an apparently nonnormative way. However, Sloman reported these effects even more dramatically, for deductively valid, perfectly strong arguments. Subjects found arguments of the form *Animals/Mammals* (i.e., with *animal* as the premise category and *mammal* as the conclusion category) stronger than arguments like *Animals/Reptiles*. Notably, both of these arguments are equally, and perfectly, valid. That is, anything true of all animals must necessarily be true of all mammals and all reptiles as well. However, an argument such as *Animals/Reptiles* may get a low strength rating because of relatively low similarity between the respective representations of *animal* and *reptile*.

Sloman (1998) documented a related phenomenon, called *premise specificity*, which also shows compellingly the influences of similarity on people's evaluations of inductive arguments. This phenomenon is well illustrated by the following example: People will prefer an argument with the form *Birds/Sparrows* over an argument with the form *Animals/Sparrows*. As in the inclusion similarity phenomenon, each argument is perfectly valid – there is no difference in the probability of the conclusion for one argument versus the other. Still, subjects describe the first argument, with a narrow premise category, as being stronger than the second, with a broad premise category. Sloman (1998) reported that the inclusion similarity and premise specificity findings were fairly robust over variations in procedure, but it is possible to prevent subjects from drawing such fallacious inferences by making the category inclusion relations explicit – for example, by reminding subjects that all sparrows are animals. It is also interesting to compare the premise specificity phenomenon with the conclusion specificity phenomenon

(Osherson et al. 1990), in which people draw stronger inferences about a narrower conclusion, such as *bird* in comparison with *animal*. In contrast, conclusion specificity does seem to be compatible with axioms of probability theory.

Effects of Expertise on Induction

Developmental research on induction is important because, potentially, both knowledge and cognitive capacities are changing as children get older, allowing researchers to collect a very rich set of data. However, as mentioned, it can be difficult to attribute a developmental change uniquely to a change in knowledge or a change in cognitive mechanism. At the other end of the developmental continuum, adults are acquiring expertise on various topics suited to their living conditions or working needs. Although adults with different areas of expertise, or from different cultures, could possibly differ in terms of cognitive processing, it is plausible to attribute expertise differences in inductive reasoning largely to differences in knowledge. A recent, exciting trend consists of research on experts' inductive reasoning, going beyond past studies which had mainly looked at reasoning in American college students and American children. Coley, Medin, and Atran (1997) and López, Atran, Coley, Medin, and Smith (1997) studied inductive reasoning by Itzaj Mayans in the rainforest of Guatemala, people with great expertise regarding local plants and animals. Medin, Lynch, Coley, and Atran (1997) looked at inductive reasoning about categories of plants, by various kinds of tree experts.

Coley et al. (1997) looked at inductive reasoning at different levels of the taxonomic hierarchy of animals and plants. The purpose of this work was to see whether some taxonomic level is "privileged" or specially favored for inductive inferences, and whether this privileged level varies on the basis of expertise. For example, subjects were told to assume that all black vultures (a subspecies) are susceptible to a particular disease and were asked the likelihood that all vultures (a species, or strictly speaking a folk-generic category) would be susceptible to this disease. Coley et al. (1997) tested various premise-conclusion pairs, including the pairings of varietal and subspecies, subspecies and species, subspecies and lifeform (e.g., birds), species and lifeform, and lifeform and kingdom (e.g., animals). The key result, for both Itzaj and American college students, was that there was a sharp drop in strength of inferences when

conclusion categories were beyond the species level. That is, inferences regarding subspecies and species conclusion categories were quite strong, whereas inferences regarding the lifeform and kingdom level were much weaker. Coley et al. (1997) interpreted this result as showing that the species level is privileged, in that it is the broadest taxonomic level that supports strong inferences. However, specificity of the premise category did not seem to have much effect on induction, to the extent that Coley et al. (1997) compared premise categories at different taxonomic levels.

This study can be tied to a number of past results. First, the general result of weaker inferences for broader or more variable conclusion categories recapitulates the findings of Nisbett et al. (1983) and more recently the conclusion specificity phenomenon in Osherson et al. (1990) and López et al. (1992). Also there is some similarity between the study of Coley et al. (1997) and the work done by Carey as well as Gelman and colleagues, showing weaker inferences to the extent that the category encompassing the premise and conclusion items is more general or superordinate. However, the specific finding of Coley et al. (1997), that the species level is privileged, would not necessarily be predicted on the basis of past work. Indeed, it is surprising that the same level of privileged inference was found for the Itzaj and American college students, considering the knowledge differences – the far greater daily experience of plants and animals among the Itzaj. Coley et al. (1997) suggested that beliefs about categories' usefulness for induction could go beyond actually known facts and experiences. For example, American college students could simply have a belief that different species of animals have their own characteristic anatomies, diseases, and so forth, without any more specific knowledge to this effect (see also Heit 1998, Shipley 1993), so someone could treat a particular level as being privileged without detailed knowledge to support this distinction.

López et al. (1997) also compared induction by the Itzaj and by American college students and, in contrast to Coley et al. (1997), found more widespread influences of knowledge on patterns of inductive reasoning. They examined similarity and typicality effects and found that the patterns of inductions differed between the two cultures in cases where their category representations diverged. For example, the Itzaj reported foxes as being more similar to cats than to dogs, whereas American students

stated that foxes are more similar to dogs. This pattern was reflected by choices in a task where subjects saw pairs of inductive arguments. Itzaj subjects stated that arguments of the form Foxes/Cats were stronger, whereas Americans stated that those of the form Foxes/Dogs were stronger. Although Coley et al. (1997) did not find cross-cultural differences in the privileged level of conclusion categories, it is clear from López et al. (1997) that indeed there are some cultural, or knowledge-derived, differences.

Further evidence for effects of knowledge on induction comes from Medin et al. (1997), who looked at inferences about plant categories for three kinds of (American) tree experts: taxonomists, landscapers, and tree maintenance workers. Medin et al. were mainly interested in effects of similarity or shared category membership, for groups that differed among themselves regarding preferred taxonomic membership and, on occasion, differed with regard to standard scientific taxonomies. For example, on a free sorting task, landscapers and maintenance workers tended to organize tree species in terms of their shape or utility for various landscaping tasks. Medin et al. (1997) devised questions on a test of inductive reasoning that pitted scientific matches against alternative, functional category structures. For example, two tree species might be distant in terms of the scientific taxonomy, but they could both be useful for providing shade. The test items for the inductive inferences used biological properties concerning reproduction, disease, or physiology. It was found that taxonomists (not surprisingly) sorted trees on the basis of scientific taxonomy and likewise favored inductive arguments between categories that were close in the scientific taxonomy. Maintenance workers seemed to favor a more functional category organization for both sorting and reasoning. Landscapers seemed to be more flexible and possibly more conversant with multiple category structures; they tended to prefer functional organization for sorting but their biological inferences reflected knowledge of the scientific taxonomy. In sum, these three groups of experts generally showed the similarity effects that have been documented in other populations, but the groups' knowledge about trees mediated these similarity effects. (See also Proffitt, Coley, and Medin 2000.)

Discussion

The study of inductive arguments with a single premise category has produced a number

of interesting and consistent results. What promotes an inference from one case to another? The three key factors that promote inductive inferences are similarity between premise and conclusion category (in terms of a taxonomic hierarchy rather than superficial similarities), typicality of the premise category, and homogeneity of the conclusion category. Returning to the example at the start of this paper, how would these variables affect inferences about home burglaries? Similar cases should promote inference, so a burglary that is particularly near your home, or a recent burglary as opposed to one from the distant past, should increase the perceived risk for your own home. In addition, typicality of the given case should affect inferences, beyond any given effect of similarity. For example, if your neighborhood consists mainly of houses, a burglary in a houseboat should not generalize well to burglaries in other homes. The relation between houses and houseboats could well be asymmetrical, reflecting this difference in typicality. That is, characteristics of houses may seem to generalize to characteristics of houseboats better than characteristics of houseboats would generalize to those of houses. Finally, variability of the conclusion category should lead to weaker inferences. For example, a home that is sequentially occupied by different people with different habits and different possessions and is sometimes completely unoccupied would be relatively difficult to make predictions about, compared with a more stable conclusion item.

These three results have ties to past philosophical work on induction. Similarity effects, or the idea that seeing some commonalities between two items should promote the inference of further commonalities, has been a longstanding position in philosophy (see, e.g., Mill 1874). However, Goodman (1972) has argued that similarity itself may not be a primitive notion; for example, the features that are used to assess similarity can be context dependent (see Hahn and Chater 1997, and Medin, Goldstone, and Gentner 1993, for reviews of related psychological results). Likewise, Gelman and Markman (1986) made an important distinction between inductions based on internal similarity and those based on external, perceptual similarity. This issue will be returned to in the third section, which describes results in which the use of similarity depends on the property being projected.

Furthermore, Shipley (1993) has applied Goodman's (1955) work on induction to several results in psychology. The idea that some

categories, such as more typical categories, are particularly good for promoting inferences, in part because of their past frequency of use, is related to Goodman's (1955) idea of entrenchment of predicates, with some predicates (or categories) promoting inferences more than others. However, this analysis does not explain why entrenchment, or typicality, of premise categories matters but typicality of conclusion categories does not. Again, the point could be made that typicality is not a primitive concept any more than similarity, and there could be several determinants of typicality such as frequency of use, centrality, similarity to other category members, and nearness to an ideal (cf. Barsalou 1985).

Finally, the use of beliefs about variability of conclusion categories, or beliefs that some taxonomic level may be privileged for induction, is tied to Goodman's (1955) concept of overhypotheses. Overhypotheses are general beliefs that guide inference, without necessarily having much specific content. For example, a person can believe that samples of a particular kind of metal will be homogenous in terms of whether they conduct electricity, without any more specific knowledge of whether this kind of metal does in fact conduct electricity. The sensitivity to conclusion variability in Nisbett et al. (1983) can be explained in terms of use of overhypotheses about different kinds of categories (metals, people, etc.).

To conclude, it is interesting to note the results that have not been reported. For example, there have been no reports to date of independent effects of the typicality of the conclusion category as opposed to the premise category. Indeed, it would seem useful for any account of induction to address why conclusion typicality does *not* matter, even as it explains why premise typicality does matter. Another nonresult relates to the homogeneity or variability of a premise category. It is clear that conclusion homogeneity promotes inferences, but no studies have directly addressed the effects of homogeneity of a single premise category. (Sloman's, 1998, premise specificity effect comes the closest, but this result seems to have depended heavily on similarity between the premise and conclusion categories, rather than on the homogeneity of the premise category.) This issue may be somewhat easier to study with multiple premise categories, because the diversity within, say, a pair of premise categories can be manipulated easily by choosing similar versus different pairings. The next section will address

premise diversity as well as several other important results that have been obtained by studying induction with multiple categories.

What Makes a Good Set of Cases?

When people try to make an inference about some object or event, they are typically faced with a great deal of information. Rather than just one past case being available or relevant, in many realistic situations there will be an extensive set of cases that could be relied on. How do people draw inductive inferences from multiple cases? What makes a set of cases or precedents seem strong, compelling, or useful for promoting inferences? One factor is numerosity. For example, the more homes that have been broken into on your street, the greater the perceived risk for your own home. However, one of the fascinating characteristics of human inductive inference is that people do not simply add up evidence from individual cases. That is, putting together two cases that are strong on their own does not necessarily lead to an even stronger argument based on both cases. In the first part of this section, the evidence for when numerosity does increase inductive strength will be covered, then the evidence for more complex and subtle phenomena, dependent on the diversity and variability of cases rather than their numerosity, will be reviewed.

Number of Cases

In their study involving inferences about people and objects on an island, Nisbett et al. (1983) systematically varied the given number of observations. For example, subjects were told that one, three, or twenty obese members of the Barratos group had been observed and were asked what proportion of all Barratos are obese. In general, inferences were stronger with increased sample size. However, this effect interacted with homogeneity of the conclusion category. If the conclusion category was perceived as very homogenous (e.g., floridium samples with respect to electrical conductivity), then just one case was enough for subjects to generalize to the whole population (or nearly 100%). Therefore there was something of a ceiling effect, and increases in sample size did not always lead to higher estimates.

Osherson et al. (1990) referred to the sample size effect as *premise monotonicity* – namely, a monotonic relation between the number of premise categories in an inductive argument and

rated inductive strength. Although they found interesting exceptions to this phenomenon, to be described shortly, the overall trend supported this generalization. Likewise, McDonald et al. (1996) measured inductive strength for a variety of arguments and found that the number of premise categories in the argument was one of the reliable predictors of strength.

Not only does sample size or number of premise categories serve as a robust determinant of inductive strength in adults, but in some cases children's inductive inferences appear to be sensitive to sample size. In particular, both López et al. (1992) and Gutheil and Gelman (1997) found some evidence for sample size effects in 9-year-olds. López et al. (1992) used a picture version of the Osherson et al. (1990) task, and found that 9-year-olds favored an argument of the form Raccoon, Leopard, Skunk, Tiger, Giraffe/Animal over the form Skunk, Tiger, Giraffe/Animal. More premise categories led to greater inductive strength. However, the sample size effect was not entirely robust, even in 9-year-olds. Children of this age did not show sample size effects for similar arguments with a more specific conclusion category – that is, *bear* rather than *animal*. López et al. (1992) interpreted this difference between more general and more specific conclusion categories in terms of the account proposed by Osherson et al. (1990). According to Osherson et al. (1990), evaluating an argument with a specific conclusion category such as *bear* would require the generation of a superordinate category, such as *animal* or *mammal*. Therefore the arguments with a specific conclusion would require more cognitive processing and hence would be more difficult overall, masking any sensitivity to sample size. In contrast, López et al. (1992) failed to find any sensitivity to sample size among 5-year-olds for both general and specific arguments, even in a task in which the experimenter counted the number of premise categories for the child. At present, there seems to be no evidence that children younger than 9 use sample size evidence in inductive reasoning, although it is tempting to imagine that sample size is such a central element of reasoning that in the future procedures might be devised to find sensitivity in younger children.

Gutheil and Gelman (1997) also looked at sample size effects in 9-year-olds. As in López et al. (1992), there was actually mixed evidence, with the children failing to show sensitivity to sample size in some cases. Gutheil and Gelman

used a similar procedure to that of López et al. (1992), describing hidden properties of animals, but with categories at a somewhat lower taxonomic level. All of the premise items were in the same basic level category (e.g., they were all frogs). On the basis of past work (e.g., Gelman and O'Reilly 1988) showing that children's inferences are stronger at lower taxonomic levels, it was hoped that the sample size effect would be more evident at lower levels. Gutheil and Gelman used a specific conclusion (e.g., a picture of another frog), and in their first attempt they did not find sample size effects in 9-year-olds, essentially replicating López et al. (1992). In a second study, however, they simplified the task by not showing the picture of the conclusion item but simply describing it. Here, Gutheil and Gelman found sample size effects – namely, stronger inferences based on five premise items as opposed to one premise item.

Diversity of Cases

Although sheer numerosity of cases does have some effect on induction, there is also substantial evidence that variability or diversity of cases affects inductive strength. Intuitively, repeating the same evidence, or highly similar pieces of evidence, again and again should not be much more convincing than just giving the evidence once. On the other hand, if different kinds of converging evidence come from different sources, then potentially a stronger or broader case can be made. This result, that more variable observations promote broader or stronger generalizations, is now considered a truism in areas of research near to induction, such as categorization (e.g., Fried and Holyoak 1984; Homa and Vosburgh 1976; Posner and Keele 1968).

The first study of diversity-based reasoning in induction was a developmental one by Carey (1985), comparing 6-year-olds and adults. Carey looked at patterns of inductive projection, given the premises that two diverse animals, dogs and bees, have some biological property. The purpose of this study was to see whether subjects would reason that "if two such disparate animals as dogs and bees" had this property then "all complex animals must" (p. 141). Indeed, adults made broad inferences to all animals, extending the property not only to things that were close to the premises (other mammals and insects) but also to other members of the *animal* category (such as birds and worms). In contrast, the children seemed to treat each premise separately;

they drew inferences to close matches such as other mammals and insects, but they did not use the diversity information to draw a more general conclusion about animals. Therefore, in this first attempt there was evidence for effects of diversity in adults but not children. However, Carey was simultaneously interested in development of reasoning as well as development of the *animal* concept. The nonappearance of the diversity effect in children could have been due to an undeveloped *animal* concept in 6-year-olds, rather than different or incomplete processing.

In a follow-up study, Carey (1985) looked at diversity effects based on the concept *living thing* rather than *animal*. The most relevant result was that subjects were taught a biological fact either about dogs and bees or about dogs and flowers, with the latter being even more diverse than the former. Given a fact about dogs and flowers, children did tend to generalize fairly broadly, suggesting that children may have some sensitivity to diversity of premise categories. However, if anything, they tended to overgeneralize, extending the property not only to other living things but often to inanimate objects as well. Therefore Carey concluded that 6-year-old children did not quite have a developed *living thing* concept serving as the basis for induction. Still, there was suggestive evidence for the impact of diversity of premise categories in this study.

Continuing along this line of research that looks for diversity effects in children, López et al. (1992) found limited evidence for 9-year-olds and no evidence for 5-year-olds. For the 5-year-olds, choices in a picture-based task did not show any sensitivity to diversity of premise categories, even when the diversity was explicitly mentioned by the experimenter. However, 9-year-olds did show sensitivity to diversity of premises, but only for arguments with a general conclusion category such as *animal* rather than a specific conclusion category such as *kangaroo*. Again, López et al. (1992) explained this result in terms of arguments with specific conclusion categories' requiring more stages of cognitive processing than are needed for arguments with general conclusion categories.

Gutheil and Gelman (1997) attempted to find evidence of diversity-based reasoning for specific conclusions in 9-year-olds, using category members at lower taxonomic levels, which would presumably enhance reasoning. However, like López et al. (1992), Gutheil and Gelman did not find diversity effects in 9-year-olds, although

in a control condition with adults, there was robust evidence for diversity effects.

More recently, however, Heit and Hahn (1999) reported diversity effects in children younger than 9 years, in experiments with pictures of people and everyday objects as stimuli rather than animals with hidden properties. For example, children were shown a diverse set of dolls (a china doll, a stuffed doll, and a Cabbage Patch doll), all being played with by a girl named Jane. Also children were shown a nondiverse set: three pictures of Barbie dolls, being played with by Danielle. The critical test item was another kind of doll, a baby doll, and the question was, Who would like to play with this doll? In another stimulus condition, there was a diverse set of hats worn by one person, and a nondiverse set worn by another person, and again, the critical question was whether another hat would belong to the person with diverse hats or the person with nondiverse hats. For 74% of these critical test items, children 5 to 8 years of age made the diverse choice rather than the nondiverse choice. It seems from the Heit and Hahn experiments that children can follow the diversity principle at some level. However, it will take further work to establish the critical differences that led the past studies not to find diversity effects in children.

Indeed for adults, or at least American college students, there has been considerable evidence for diversity-based reasoning. Osherson et al. (1990) documented diversity effects in adults, for written arguments with general as well as specific conclusion categories. López (1995) devised a stricter test of diversity-based reasoning, in which people chose premise categories rather than simply evaluate arguments given a set of premises. In other words, would people's choices of premises reveal that they valued diverse evidence? Subjects were given a fact about one mammal category, and they were asked to evaluate whether all mammals had this property. In aid of this task, the subjects were allowed to test one other category of mammals. For example, subjects would be told that lions had some property, and then they were asked whether they would test leopards or goats as well. The result was that subjects consistently preferred to test the more dissimilar item (e.g., goats rather than leopards). It appears on the basis of López that for inductive arguments about animals, subjects do make robust use of diversity in not only evaluating evidence but also seeking evidence. (See also Spellman, López,

and Smith 1999, for a comparison with other reasoning tasks involving evidence selection.)

Do adults in other cultures show evidence of diversity-based reasoning? One might think that, just as diversity effects are age-dependent, they might also depend on knowledge or cultural experience. Choi, Nisbett, and Smith (1997) reported diversity effects in Korean university students, for both animal categories and categories of people. However, in their study of Itzaj adults in Guatemala, López et al. (1997) did not find evidence for diversity-based reasoning, using arguments with various categories of living things and questions about disease transmission. Indeed, sometimes Itzaj subjects reliably chose arguments with homogenous premise categories over arguments with diverse categories. (See also Coley, Medin, Proffitt, Lynch, and Atran 1999.) From the subjects' explanations, it seems that they were using other knowledge about disease transmission that conflicted with diversity-based reasoning. For example, given a nondiverse argument, that two similar kinds of tall palm trees could get a certain disease, one subject claimed that it would be easy for the shorter kinds of palm trees, below, to get the disease as well. This issue, of how knowledge about properties guides induction beyond the structural effects of the categories themselves, will be discussed extensively in the next section on what makes a good property for induction. It does appear that the appearance of diversity may depend on relevant supporting knowledge's being accessed. In a follow-up study, López et al. (1997) found that the Itzaj did show diversity-based reasoning effects in some contexts. For example, Itzaj subjects were told to imagine buying several bags of corn. The question was whether it would be better to inspect two corn cobs from one bag, or one corn cob from each of two different bags. (See Nagel 1939, p. 72, for a related example.) The subjects tended to prefer the latter, more diverse choice. This important result suggests, following Carey (1985), that diversity-based reasoning depends not only on processing but on knowledge.

Exceptions to Diversity Effects

The lack of diversity effects found in the Itzaj people suggests that there may well be other systematic responses to diverse information, and that in some cases diverse premise categories may not lead to a very convincing argument. In their influential work, Osherson et al.

(1990) documented situations in which more diverse premise categories actually led to weaker inferences, referring to these as *nonmonotonicity effects*. For example, consider the following pair of arguments:

Flies require trace amounts of magnesium for reproduction	
Bees require trace amounts of magnesium for reproduction	
and	
Flies require trace amounts of magnesium for reproduction	
Orangutans require trace amounts of magnesium for reproduction	
Bees require trace amounts of magnesium for reproduction.	

Adult subjects tended to judge the first argument as stronger than the second, in apparent contradiction to both the sample size and diversity phenomena. According to Osherson et al. (1990), the reason why the second argument seems weaker is that it brings to mind a broader superordinate context, animals rather than insects. Whereas flies are highly typical insects, in the context of animals, flies are much less typical and orangutans are not prototypical either. Hence the second argument would be weaker because of lower typicality of premise categories.

Sloman (1993) reported a related violation of diversity, referred to as the *feature exclusion effect*. It was found that most subjects found an argument of the form Foxes, Deer/Weasels to be stronger than an argument of the form Foxes, Rhinos/Weasels, despite the greater diversity of the latter set of premises. According to Sloman (1993), the reason for this result was that rhinos and weasels have so few features in common (i.e., they are so dissimilar) that adding information about rhinos to a statement about foxes just does not warrant any further conclusions about weasels.

Finally, it is useful to mention that this nonmonotonicity effect has been replicated with Korean undergraduates (Choi et al. 1997), and furthermore that López et al. (1992) found some evidence for nonmonotonicity effects in 5-year-olds and even more consistent evidence with 9-year-olds. Perhaps the best conclusion to be drawn from nonmonotonicity effects as well as feature exclusion effects is that although diverse

premises promote induction, too much diversity can actually hurt rather than help.

Discussion

When multiple premises are used to evaluate an inductive argument, the associated phenomena are rather interesting and varied. The key results can be summarized in terms of two main findings as well as the exceptions to these findings. The main findings are, again, that higher numbers of premise categories, as well as diversity of premise categories, promote inferences. The sample size effect seems to be robust, although its empirical status could be clarified for children of age 9 and younger. The diversity effect seems to be less robust, in that there are cultural or knowledge-based differences as well as a number of negative results with children. Some of the negative findings with respect to sample size and diversity seem consistent enough to treat as phenomena in their own right – for example, nonmonotonicity effects (Osherson et al. 1990) and feature exclusion effects (Sloman 1993).

Because the results are particularly variable for diversity effects, it is useful to systematically enumerate why in a particular situation a person, whether child or adult, may not show diversity-based reasoning (see Coley et al. 1999 for a further discussion). This question is especially interesting, considering that it seems normative to draw stronger inferences from more diverse observations. This claim has been made by philosophers such as Nagel (1939) in the context of probability theory and Hempel (1966) in the context of scientific inference from experiments (see also Bacon 1620/1898; Heit 1998; López 1995). Note that the point of these claims was not to provide a complete justification for inductive inference, but rather to argue that diverse evidence may be more likely to satisfy particular goals. For example, Hempel claimed that conducting diverse experiments is compatible with a falsifying strategy in testing a scientific theory, compared with conducting a series of similar experiments.

One class of explanation for a lack of diversity effects, say in children, would consist of processing differences. For example, López et al. (1992) suggested, following the model of Osherson et al. (1990), that adults carry out a two-stage procedure in assessing inductive strength, assessing premise-to-conclusion similarity as well as the diversity of the premise categories (or how well they cover a generated superordinate). The

lack of diversity effects in children could be due to an abbreviated procedure in which they complete the first stage but not the second. Processing explanations bring up the question of whether processing in children is truly different from adult processing, or simply more fragile. Perhaps under the right conditions – for example, with simple materials that minimize task demands – children could show the same processing as do adults.

Another class of explanation comprises knowledge differences, which was highlighted by the cross-cultural studies of López et al. (1997), who showed domain differences in diversity for Itzaj adults in Guatemala. Likewise, Carey (1985) treated the diversity task as a measure of the maturity of various concepts such as *living thing* and *animal*.

Finally, it is possible that when a group of subjects, say children, fail to show diversity effects, they do so because there is a mixture of systematic responses. For example, about half of the time the children might be showing diversity effects, whereas for various reasons the other half of the time they could be doing something else systematically, such as being affected by the feature exclusion effect. Indeed, there are borderline results in both López et al. (1992) and Gutheil and Gelman (1997) that are opposite to diversity, suggesting the possibility that children were systematically doing something different rather than simply guessing. For a particular nonfinding of diversity, explanations due to missing processing mechanisms, performance difficulties, knowledge effects, or other systematic effects would all be possible. It is suggested that a future goal of studies on diversity should be not only to document when diversity-based reasoning does and does not occur, but to specifically aim at distinguishing among different explanations for its nonoccurrence.

As mentioned in the section on single-premise arguments, the studies of premise diversity effects facilitate the comparison with studies on conclusion variability (e.g., Nisbett et al. 1983). Whereas having a variable or broad conclusion category leads to weaker inferences, it now seems that having a variable or broad set of premise categories generally leads to stronger inferences (at least in American adults). It seems that people are concerned about breadth of categories for both premises and conclusions of inductive arguments, but breadth of premises leads to the opposite result of breadth of the conclusion category. It would be very interesting for models of induction to address directly why

this variable has different effects for premise categories and conclusion categories.

In conclusion, to return to the example of homes and burglaries, it is useful to consider what would make a set of cases likely to promote inferences about another burglary. The effect of sample size has an intuitive effect; the more burglaries on your street, the higher your perceived risk. Can diversity effects be tied to the home burglary example? Perhaps. Say that it is the first of February. If there were a dozen burglaries on your street last year, one in each month, that may seem to indicate a fair risk for your own home. On the other hand, what if there were a dozen burglaries, all taking place on Christmas Eve? This situation would involve more recent events, but they seem to form a localized or restricted cluster. The other situation, with a greater diversity of burglary occasions over the span of a year, all more distant from the present date, might promote a stronger inference about the present situation.

What Makes a Good Property?

So far, this review has focused on the effects of categories on induction; that is, what makes a set of categories promote inductive inference? This emphasis has followed the historical emphasis of the field; for example, three of the most influential studies of induction (Carey 1985; Osherson et al. 1990; Rips 1975) also focused on categories. However, properties or predicates also have a crucial role in inductive reasoning – the end part of a statement, such as *thrives in sunlight* or *secretes uric acid crystals*, has considerable effects on how people respond to inductive arguments. In the example of homes, it makes intuitive sense that different predicates will have different patterns of projection. For example, if your neighbor's home is burglarized, the perceived risk for your own home seems greater. The proximity between the two homes promotes this inference. However, if your neighbor's home is painted blue, that does not seem to increase the risk that your own home will be painted blue. For this predicate, proximity does not have much predictive value. In this section, several ways that properties matter will be reviewed. A number of past results on property effects can be described as relating to the scope of the property. For example, house color is a stable or consistent property for one house, but it tends to vary more within a group of nearby houses. Other property effects could be attributed to differing use of similarity informa-

tion for different properties. In many past studies already reviewed, subjects have seemed to reason about biological properties of animals in terms of some notion of internal similarity – projecting, for example, more readily from horses to cows rather than to lizards. But for other properties, such as house burglaries, the relevant measure of similarity might be physical proximity. Finally, a number of other ways that the content of properties influences inductive reasoning will be reviewed.

Scope of Properties

The Nisbett et al. (1983) study is a good first illustration of how knowledge about the scope of a property affects inductive inference. As already reviewed, seeing that just one member of the Barratos group is obese does not seem to promote the inference that other people in this group will be obese. Obesity seems to be more of an individual characteristic rather than a group characteristic. On the other hand, Nisbett et al. found that people make stronger inferences for the same category but another property, skin color. Here, seeing the skin color of just one Barratos promotes inferences about other members of this group, on the assumption that members of the same ethnic group will likely have some shared physical characteristics. In another study with adults, Gutheil and Gelman (1997) reported property effects like those found by Nisbett et al., but for a wider range of properties. In the terminology of Goodman (1955), it appears that some properties are more projectable than others.

This use of knowledge about scope of properties is not limited to adults but is clearly evident in young children as well. For example, Gelman (1988) compared stable, internal properties with more transient or idiosyncratic properties, in reasoning tasks performed by children as young as age 4. For projectable properties such as *has pectin inside*, children's inferences showed similarity effects, reflecting the taxonomic hierarchy of categories. But for properties such as *has a little scratch on it*, children showed chance patterns of reasoning, indicating that for properties with an idiosyncratic scope, they did not have a systematic basis of projection. (Also, see Springer 1992 for similar results, in which children used kinship information to project biological properties, but projected idiosyncratic properties at a chance level.)

Young children's reasoning about the scope of properties is surprisingly sophisticated. A study

by Macario, Shipley, and Billman (1990) showed rather subtle use of information about property variability by 4-year-olds. In particular, children were able to use the variability of one property to infer the variability of another property. The task was to learn about groups of objects that were preferred by one puppet or another. For example, children would see that the objects in one group all were blue and that a contrast category had one red member. Then the children were presented with a set of transfer items for classification, and on the basis of these choices it appeared they had inferred that the contrast category's other members would all be red. Likewise, after seeing that one category's members varied in shape, children inferred that the contrast category's members would also vary in shape. As in Nisbett et al. (1983), it was demonstrated that children would more readily base their inferences on a homogenous property as opposed to a property that varied across category members. But in addition it was shown that children could infer the variability or scope of a property in a sensible and productive manner.

More recently, Waxman, Lynch, Casey, and Baer (1997) have looked at knowledge about scope of properties for real animal categories. In an initial experiment, Waxman et al. found that given a property of, say, a collie, young children tended to extend this property to other members of the same subordinate category (other collies) as well as other members of the same basic level category (other dogs). As in Macario et al. (1990), the question was whether children could learn about scope of properties, and in particular whether they would infer that some properties were distinctive for different subordinate categories, but homogenous within each subordinate. Children were taught facts about two subcategories, such as that one breed of dog was used to find birds and another breed of dog was used to pull sleds. Then the children were taught that a dog of a third kind had another characteristic, such as that of being used to help take care of sheep. Finally, the children were tested on whether this third characteristic would extend to a variety of dogs and other animals. Unlike in the initial experiment, when this training was provided the children tended to restrict the scope of their inferences to the original subordinate category. With a small amount of training, 4-year-old children were able to learn about the scope of a property and use this information in a consistent way.

It seems that even infants show evidence for increasing sophistication about the scope

of properties. Mandler and McDonough (1998) used an imitation task to compare 14-month-olds and 20-month-olds on inferences with properties that would have a scope at the basic level of categorization (e.g., chewing on bones would apply to dogs but not other animals such as birds). It was found that the 14-month-olds were willing to project properties rather widely, such as projecting bone-chewing to birds, but that the 20-month-olds were more restricted in the breadth of their generalizations, suggesting that they were sensitive to the scope of these properties.

Properties and Similarity

Although it might seem from the previous section that some properties have a wide scope for projection whereas other properties are simply idiosyncratic and harder to project, the picture is actually more complicated and more interesting. Depending on the argument – that is, depending on the categories in an inductive argument – a particular property may be projectable, nonprojectable, or somewhere in between. Consider the following example, from Heit and Rubinstein (1994). For a typical blank anatomical property, such as *has a liver with two chambers*, people will make stronger inferences from chickens to hawks than from tigers to hawks. Because chickens and hawks are from the same biological category and share many internal properties, people are quite willing to project a novel anatomical property from one bird to another. But since tigers and hawks differ in terms of many known internal biological properties, it seems less likely that a novel anatomical property will project from one to the other. This result illustrates the priority of biological categories that has been observed in induction (e.g., Carey 1985; Gelman 1988). However, now consider the behavioral property *prefers to feed at night*. Heit and Rubinstein found that inferences for behavioral properties concerning feeding and predation were weaker between the categories *chicken* and *hawk* than between the categories *tiger* and *hawk* – the opposite of the result for anatomical properties. Here, it seems that despite the considerable biological differences between tigers and hawks, people were influenced by the known similarities between these two animals in terms of predatory behavior, thus making strong inferences about a novel behavioral property. In comparison, chickens and hawks differ in terms of predatory behavior (with chickens tending to

be pacifists), so that people were less willing to project a novel behavioral property between these two animals. Together, these results suggest that each property is more projectable for a different pair of animals. (Also see Choi et al. 1997 for a comparison between anatomical and behavioral properties.) It is not simply the case that some properties are always more projectable than other properties. Instead, there was a crossover interaction pattern between properties and premise–conclusion matches.

Recently, Ross and Murphy (1999) have also provided evidence for the flexibility of people's reasoning about different kinds of properties. Ross and Murphy's interest was the domain of foods, which perhaps in comparison with other domains such as the animal kingdom leads more readily to cross-classification. For example, a bagel can be considered as part of the breads category (a taxonomic organization) or as a breakfast food (a script-based organization). (See also Murphy and Ross 1999.) Ross and Murphy compared two kinds of properties: biochemical properties and situational properties relating to how a food might be used. It was found that for biochemical properties, subjects preferred inferences based on taxonomic matches, whereas for situational properties, subjects preferred script-based matches. Just as in Heit and Rubinstein (1994), any account of induction that does not take into account the property being projected could not account for these results. In particular, inductive inference cannot be reduced to simply assessing the similarity between premise and conclusion categories, unless a flexible conception of similarity is allowed, in which similarity depends on the property being projected. For example, inferences about behavioral or situational properties might lead to behavioral or situational features being emphasized in similarity computations. Smith, Shafir, and Osherson (1993) referred to such an effect as *feature potentiation* (and see Heit 1997 for a review of related work). However, this term in itself does not give an account of how the process would take place. It seems likely that feature potentiation would rely on other mechanisms of memory (of which inferences have been successful in the past) as well as explanatory reasoning (about which features might be useful).

There is also some evidence that this kind of property effect occurs in children's reasoning as well. Gelman and Markman (1986) provided children with a property for one item (e.g., a blackbird) and then asked them whether the property would be true for a perceptually sim-

ilar item (e.g., a bat) or an item that was a taxonomic match but less similar perceptually (e.g., a flamingo). It was found that for biological properties (e.g., referring to eating habits), the children preferred the taxonomic match, but that for perceptual properties (e.g., texture), they were at chance level or in some cases they showed a tendency to choose the perceptual match, suggesting that different features might have been potentiated for perceptual inferences.

Using a somewhat different task, Kalish and Gelman (1992) have looked at property inferences based on novel combined categories, such as *glass scissors*. Children were given facts about one of these categories, such as *used for partitioning* (a functional property) or *will get fractured if put in really cold water* (a dispositional property). The subjects were asked whether these properties would be true of other items as well, such as metal scissors and a glass bottle. The children (age 4) preferred matches in terms of object kind (e.g., both scissors) when projecting a novel functional property, but they preferred matches in terms of composition (e.g., both glass) when projecting a novel dispositional property, showing an impressive degree of sophistication about inferences.

Moving to even younger ages, Mandler and McDonough (1996, 1998) reported sensitivity to different kinds of properties for infants. Using a task in which 14-month-old children imitated actions performed on various objects, they found that the children were sensitive to the difference between animal actions (e.g., giving a drink) and vehicle actions (e.g., opening with a key). The children were less likely to repeat animal actions performed on a vehicle or vehicle actions performed on an animal than they were to repeat actions that matched the items. Again, there was evidence that quite young children are sensitive to the idea that there are different kinds of properties, with differing relevant criteria for projecting these properties. At no point during the course of their development has it been demonstrated that children treat all properties as the same – the default seems to be to show property effects of some kind.

Other Property Effects

In addition to the property effects just reviewed, researchers have documented a number of other interesting phenomena deriving from the content of properties. The diversity of these phenomena attests to the importance and prevalence of property effects, touching on several

aspects of inductive reasoning. What these phenomena have in common, however, is that they all point to the limitations of similarity as a basis for inductive inference. Smith et al. (1993; see also Osherson, Smith, Myers, Shafir, and Stob 1994) provided an important example in which inferences go in the opposite direction of what overall similarity would predict. Consider the following two arguments:

Poodles can bite through barbed wire

German shepherds can bite through barbed wire

and

Dobermans can bite through barbed wire

German shepherds can bite through barbed wire.

Clearly there is greater similarity between Dobermans and German shepherds than there is between poodles and German shepherds. Yet people find the first argument stronger than the second. An informal way to justify this reasoning is that if poodles, a rather weak and tame kind of dog, can bite through barbed wire, then obviously German shepherds, which are much stronger and more ferocious, must be able to bite through barbed wire as well. This property, *can bite through barbed wire*, seems to depend on the magnitude of other dimensions such as strength and ferocity. Again, informally, it seems that subjects are trying to explain how the various animals could bite through barbed wire, in terms of known facts about these animals.

However, this result could be explained alternatively in terms of the diversity effect, on the assumption that in addition to the premises provided to subjects, people use their own prior knowledge to create additional, hidden premises. For example, people might already believe that another large, ferocious kind of dog, such as a Rottweiler, can bite through wire. This belief could serve as a hidden premise that would affect judgments about the conclusion. In this situation, supplying the premise that poodles can bite through barbed wire would lead to a diverse range of premise categories, Rottweilers and poodles. In contrast, supplying the premise that Dobermans can bite through barbed wire would represent a fairly narrow set of premises, Rottweilers and Dobermans. Hence, following the already established diversity effect, the premise with poodles should lead to a stronger conclusion.

Sloman (1994, 1997) has investigated the role of explanations in inductive reasoning more directly. Sloman has concluded that people are highly sensitive to the content of properties being projected, coming up with an explanation of the manifested property as a means of assessing inductive strength. An argument will be strong to the extent that premise and conclusion statements have the same explanations. For example, consider the following.

Many ex-cons are hired as bodyguards

Many war veterans are hired as bodyguards

and

Many ex-cons are unemployed

Many war veterans are unemployed.

According to Sloman (1994), the first argument is strong because both statements have the same explanation – namely, that ex-convicts and war veterans are hired as bodyguards because in both cases they are tough and experienced fighters. The second argument is weaker because the two statements would have different explanations – namely, that ex-convicts might be unemployed for different reasons than war veterans. (Sloman, 1997, investigated this phenomenon further, distinguishing between unrelated explanations and conflicting explanations.) As in the Smith et al. (1993) results, and for that matter the results of Heit and Rubinstein (1994) and Ross and Murphy (1999), it seems that inductive inference with meaningful properties critically depends on determining which known characteristics of the categories are causally related to or predictive of the property to be projected. Indeed, when Lassaline (1996) made various causal relations explicit to subjects, she found that they were particularly sensitive to causal relations between characteristics of the premise category and the property to be projected. (See also Hadjichristidis, Sloman, Stevenson, and Over 1999, and Wu and Gentner 1998).

Finally, as possibly converging evidence for the role of explanations, McDonald et al. (1996) found that number of conclusions suggested by a set of premises was negatively correlated with perceived inductive strength. Perhaps when a set of premises all have the same explanation, it leads to a single, clear, and strong conclusion, but when there are multiple conclusions it is reflective of conflicting possible explanations, and thus any particular inference will be weak.

Discussion

The main conclusion from this section is that properties matter, a great deal! In addition to factors such as similarity between premise and conclusion categories, and typicality and diversity of premise categories, the content of the property being projected from premise to conclusion has a central role in inductive inference. Perhaps most dramatically, idiosyncratic properties such as being obese or having a scratch do not lead to widespread, systematic inferences. In addition, Smith et al. (1993) showed that for some properties, similarity between premise and conclusion categories is negatively correlated with inductive strength, although this result could also be explained in terms of diversity. To account for other results (e.g., those of Heit and Rubinstein 1994), one must assume that different kinds of similarity would be used for inferences about different properties, fitting with Goodman's (1972) points about the flexibility of similarity. Sensitivity to different kinds of properties has been observed in young children and even infants. If one thing is clear, it is that any complete account of inductive reasoning needs to address property effects. Many valuable and systematic results, reviewed in the first two sections of this paper, have been obtained from studies in which properties were not varied systematically, but it seems that these studies were looking at only a restricted range of human abilities. Just as it is possible to learn more about the cognitive processes underlying induction by using arguments with multiple premises rather than a single premise, it is possible to learn yet more about induction by comparing performance with different properties.

In all three sections of this paper so far, a few themes have emerged repeatedly. One is that, as Goodman (1955) noted, categories and properties vary in terms of their entrenchment. Some categories and some properties seem to be more suitable for inductive reasoning than others. Although Goodman referred to this issue as a "riddle," it seems that humans are rather systematic in terms of what they treat as more or less entrenched; typical categories, for example, tend to be good for induction whereas transient properties tend to be bad for induction. Another theme is that for categories as well as properties, there is a sense that scope or variability is critical to induction. A varied set of premise categories will promote induction, but it is easier to draw an inference about a narrow conclusion category than about a broad conclusion cate-

gory. Properties in an inductive argument seem to have a breadth or scope of their own, with some properties being restricted to a particular place or time and other properties seeming to generalize easily to many cases. Even 4-year-old children seem to have a sophisticated awareness about the scope of properties (Waxman et al. 1997). The final theme is that similarity is a crucial concept. Just as similarity between premise and conclusion categories promotes induction, dissimilarity within a set of premise categories also promotes induction. (Indeed, the diversity effect can be thought of as a kind of similarity effect. Because similar categories are expected to share properties, learning that two diverse categories share a property seems more surprising or informative than learning that two similar categories share a property.) Even typicality effects can be explained in terms of similarity, because a category's typicality is highly correlated with its similarity to the representation of its superordinate.

The property effects described here are interesting because they place limits on the use of similarity as an account for inductive inference: Different measures of similarity would be needed for different properties, and in some cases, it is clear that other constructs such as explanations are needed in order to account for human inference. Sloman (1994, 1997) explicitly investigated explanation-based reasoning in induction, and the other studies on property effects (e.g., Heit and Rubinstein 1994, and Smith et al. 1993) also point, indirectly, to reasoning processes beyond straightforward assessment of similarity.

How Do Psychological Models of Induction Address These Results?

Now that these main results in inductive reasoning have been presented (see Table 1 for a list of key results), it is time to move to the models of induction that have been developed by psychologists. Choosing these models for presentation requires some degree of focus. After all, any theoretical account or explanation of inductive reasoning could be considered a model in some sense. However, for comparability, the focus will be on formal models that are either mathematical or computational descriptions. Also, this section will focus on whether the various models can account for the main results, rather than provide complete presentations of the models themselves (for which the reader is referred to the original sources).

Rips (1975)

Chronologically speaking, the first formal model of induction was that of Rips (1975). This modeling effort was performed by deriving multidimensional scaling solutions for different categories of animals, so that similarity and typicality measures could be derived from the animals' positions on a scaling solution. Then Rips applied a set of multiple regression equations to look at various predictors of inductive strength, such as premise–conclusion similarity, premise typicality, and conclusion typicality. The resulting regression model, which included the first two predictors, can account for some of the main results with adult subjects and single-premise arguments – namely, similarity and premise typicality effects.

Potentially, this model could also be applied to some of the developmental trends that have been reviewed, with the assumption that adults and children of different ages would have different multidimensional representations of their knowledge of animals. For example, some of the differences in projection for children and adults reported by Carey (1985) could be explained in terms of *human* being more typical (or central) for children than for adults. Likewise the greater sensitivity to similarity for older children could be captured in terms of greater differentiation in the multidimensional representation for older children, or a greater coefficient for similarity in the regression equation. In principle, this model could be applied to expertise differences as well; the cultural differences found by López et al. (1997), for example, could again be explained in terms of different representations of animal categories being used by American college students and Itzaj subjects.

To evaluate whether this model can account for differences due to development and expertise, it would be necessary to perform multidimensional scaling for the relevant subject population. The model predicts that inductive judgments will be strongly related to these derived similarity measures. However, Medin et al. (1997) did find some dissociations between similarity judgments and inductive judgments for different kinds of tree experts, so the model would have some trouble with these results. Likewise, the results that showed people overriding similarity (e.g., those in Lassaline 1996 and Smith et al. 1993), would be out of bounds for this model.

Without further assumptions, the model does not seem to be sensitive to property effects.

For example, Heit and Rubinstein (1994) and Ross and Murphy (1999) showed that different measures of similarity were used for predicting different properties. But if the Rips (1975) model relies on a fixed multidimensional scaling solution, then it would predict the same use of similarity information for different properties. In addition, the model does not really address the difference between projectable and non-projectable properties, or why permanent characteristics seem to project better than idiosyncratic properties.

Which other results can the Rips (1975) model not address? This model was aimed only at single-premise arguments, so it does not address any of the phenomena with multiple-premise categories. Also, the model does not account for one of the most basic results with single-premise arguments – namely, that specificity or homogeneity of the conclusion category promotes induction (Nisbett et al. 1983; Osherson et al. 1990). This model derives its predictions from points represented in multidimensional space. If, for example, *robins* and *birds* are located very near each other in conceptual space because of their similar representations, then the regression model will make similar predictions for inferences about these two categories. In contrast, people will make weaker inferences about the more general category, *birds*. More generally, the model does not make a distinction between categories and individuals. For example, an individual robin would have about the same multidimensional representation as would the *robin* category. Therefore, the model can be applied equally well to reasoning about individuals and about categories, but the model cannot account for any systematic differences that might be found.

Finally, the Rips (1975) model was used to make one of the important discoveries in this area, that typicality of the conclusion category does not affect inductive strength. However, the model itself does not give an explanation as to why conclusion typicality has no effect. Table 1 shows that the Rips model makes a good start toward addressing Results 1 and 2 and could even account for some group differences such as developmental or expert–novice differences. Otherwise the model does not address these results. Out of fairness, though, it must be said that this model was the first formal psychological account in this area, and it predates most of the results in the table! The Rips model, as will be seen, was influential for subsequent modeling work.

Osherson et al. (1990)

The next model of induction, that of Osherson et al. (1990), simultaneously takes a major qualitative leap beyond the Rips (1975) model, now addressing multiple-premise arguments, while at the same time including the Rips model as a special case for single-premise arguments. Just as the Rips model used similarity and typicality as predictors, the Osherson et al. (1990) model has two main components. The first component assesses the similarity between the premise categories and the conclusion category. However, the similarity measure is derived from overlap in a featural representation, rather than from a multidimensional scaling solution. The model can be applied to individuals or to categories, as long as as they can be described in terms of feature sets. The second component measures how well the premise categories cover the superordinate category that includes all the categories mentioned in an argument. For single-premise arguments, coverage more or less reduces to typicality, but for multiple-premise arguments, coverage gives something closer to a measure of diversity. Coverage is best explained in terms of a series of examples (although Osherson et al. do give a computational formulation):

- (A) Squirrels have property X
Cows have property X
- (B) Cows have property X
Squirrels have property X
- (C) Cows have property X
Tunas have property X
- (D) Dogs have property X
Cats have property X
Cows have property X
- (E) Dogs have property X
Elephants have property X
Cows have property X
- (F) Dogs have property X
Elephants have property X
Roses have property X.

For Arguments A and B, the lowest level superordinate that includes all the categories is *mammal*. Coverage is assessed in terms of the average similarity of the premise category to members of the superordinate. To the extent

that cows are more typical mammals than squirrels are, and therefore more similar to other kinds of mammals, Argument B will have greater coverage than Argument A. This is how the model addresses typicality effects. Next, consider Argument C. The lowest level superordinate including all the categories would be *animal* rather than *mammal*. On average, cows are less similar to various kinds of animals, in comparison with the similarity between cows and just mammals. Therefore, Argument C has worse coverage than Argument B does.

The remaining arguments have multiple premises. In assessing similarity between members of the superordinate category and the multiple premises, only the maximum similarity for any one premise category is considered. So, for Argument D, small mammals tend to be similar to dogs and cats, and large mammals tend not to be similar to dogs and cats. So including *cat* as a premise category does not add much information beyond just having *dog* as a premise category alone. In contrast, for Argument E, some mammals are similar to dogs and other mammals are similar to elephants. Therefore, the *elephant* premise adds information, and the coverage for Argument E is greater than that for Argument D. In this way, the model of Osherson et al. (1990) addresses diversity effects, to the extent that greater coverage is correlated with greater diversity. Finally, the model addresses some exceptions to diversity. For example, in Argument F, the inclusive superordinate category would be *living things* rather than *mammals*. In terms of this much wider category, dogs and elephants do not provide particularly good coverage. Hence there would not be much of a diversity effect for Argument F.

The Osherson et al. (1990) model can address all the single-premise phenomena listed above for the Rips (1975) model, and likewise has many of the same limitations, such as not really addressing property effects at all. But in addition the model can address conclusion specificity to some extent. For example, the model can predict stronger inferences with *bird* as a conclusion category rather than *animal*, to the extent that *animal* suggests a broader superordinate category and a lower measure of coverage for the premise category or categories. With a similar rationale, the model might be applied to the conclusion variability results of Nisbett et al. (1983). For example, a narrow category such as “floridium samples” might be easier to cover than a broader category such as “people in the Barratos tribe.” However, further investigation

would be needed to see whether the model can address the whole pattern of results. In addition, the model as formulated would not make different predictions for obesity versus skin color of the Barratos. In sum, further assumptions would be needed for this model to fully address the effects of homogeneity of the conclusion category.

Another characteristic of the Osherson et al. (1990) model is that it depends on people generating a useful superordinate to include all the categories presented in an argument. Potentially, different people might generate different superordinates. Indeed, López et al. (1992) suggested that there could be developmental changes in the ability to generate superordinates, so that children might show more adult-like patterns of reasoning when a superordinate is provided, in comparison with situations where they need to generate their own superordinate. This issue of having to generate a superordinate is also implicit in the Rips (1975) model, where typicality assessments must be made relative to some superordinate category.

The Osherson et al. (1990) model is particularly useful for addressing multiple-premise arguments. The second, coverage-based component is valuable for explaining sample size and diversity effects, and some of the exceptions. It is also appealing to explain any lack of sample size and diversity effects in young children as being due to an underdeveloped mechanism for assessing coverage. More generally, one of the advantages of the Osherson et al. (1990) model over the Rips (1975) model is that it seems to give more of a mechanistic explanation rather than simply provide a means for fitting data. Also, particularly for multiple-premise arguments, the Osherson et al. (1990) model is complex enough and well-specified enough to predict a rich and interesting set of phenomena, profitably addressed by Osherson et al. (1990) themselves.

The Osherson et al. (1990) model gives an account of the first two results in Table 1 and addresses Result 3 to some extent. By assuming that different groups of people, such as children and adults, have different featural representations, the model could account for some group differences in these basic results. The coverage component allows the model to account for sample size and diversity effects, Results 4 and 5. Without further assumptions, the model does not address the remaining results, concerning property effects.

Sloman (1993)

This model was implemented as a connectionist network, and perhaps its most important difference from the Osherson et al. (1990) model is that it relies solely on feature overlap without a second mechanism assessing coverage of a superordinate category. Indeed, the Sloman model is especially valuable because it shows how much can be accomplished without this second mechanism, bringing into focus what the second mechanism might actually contribute. The Sloman (1993) model can account for many of the same phenomena as can the Osherson et al. (1990) model, and it likewise has many of the same limitations, so mainly the differences will be covered here. In brief, the way this model works is that premises of an argument are encoded by training the connectionist network to learn associations between input nodes representing the features of the premise categories and an output node for the property to be considered. Then the model is tested by presenting the features of the conclusion category and measuring the activation of the same output node. The model accounts for similarity effects, because training and testing on similar input vectors will lead to strong outputs during testing. The model accounts for diversity effects, because training on a diverse set of categories will tend to strengthen a greater number of connections than will training on a narrow range of categories. It would be interesting to see whether the Sloman model could address the apparent developmental changes in diversity effects that can be accounted for rather naturally by the Osherson et al. (1990) model.

The treatment of typicality effects is somewhat less straightforward. Although Rips (1975) found a distinctive contribution of premise typicality beyond similarity, and, more generally, typicality effects have been one of the most robust findings in inductive reasoning, the Sloman (1993) model does not always predict typicality effects. For arguments with general conclusion categories, for example, an argument such as Cows/Mammals being stronger than Squirrels/Mammals, the model would account for any typicality effect in terms of feature overlap. That is, *cows* would be more typical of *mammal* as well as being more similar to the representation of *mammal*, and hence the first argument would be stronger. Although the model does predict some premise-conclusion asymmetries (p. 256), it does not predict an

independent effect of premise typicality on arguments with specific conclusion categories (e.g., *dog* rather than *mammal*) – that is, independent of any effect of feature overlap or representation of the conclusion category. More precisely, imagine that category A is more typical than category B, but that these two categories have equal feature overlap to category C. On the basis of the results from Rips (1975), we would expect an argument with the form A/C to be stronger than B/C, but this model would not predict any difference between the two arguments. Indeed, the model seems to predict independent effects of typicality of the conclusion category, a result that has not been reported elsewhere.

One of the advantages of the reliance on feature overlap by the Sloman (1993) model is that it can readily account for nonnormative human results that seem to be heavily influenced by similarity, such as the inclusion fallacy and the inclusion similarity effect. An example of the inclusion similarity effect is that the argument Animals/Mammals seems stronger than Animals/Reptiles, despite the two arguments being equally valid. The Sloman model accounts for this result readily in terms of greater feature overlap between animals and mammals, whereas the Osherson et al. (1990) model predicts that the two arguments would be equally (and perfectly) strong.

Again, in terms of Table 1, the Sloman (1993) model addresses similarity effects, and to an incomplete extent, typicality effects. Like the Osherson et al. (1990) model, the Sloman model can address some effects of different taxonomic levels of the conclusion category, partly addressing Result 3, but it is not clear whether it fully addresses the effects of conclusion variability as described by Nisbett et al. (1983). The model gives a good account for Results 4 and 5, going beyond the Osherson et al. model in terms of explaining some exceptions to diversity effects. Like the previous two models, without further assumptions the Sloman model does not address property effects, Results 6, 7, and 8.

Smith et al. (1993)

Unlike the previous three models which did not really address property effects, the “gap” model of Smith et al. (1993) was explicitly intended to address some of the effects of properties on induction. To illustrate this model, it is best to refer to the example in which the premise that poodles can bite through wire is considered

stronger than the premise that German shepherds can bite through wire, for the conclusion that Dobermans can bite through wire. According to the gap model, the first step is that the property *biting through wire* potentiates a set of relevant features or dimensions (e.g., size and strength) and a criterion is set for possessing this property (e.g., a minimum size and strength necessary). Then the premise category is compared with this criterion. In the case of poodles biting through wire, the criterion for the property *biting through wire* would be lowered because there is a large gap between previous beliefs about poodles and what has been expected about biting through wire. The result is that Dobermans biting through wire becomes more plausible, owing to a lowered criterion. In comparison, given the premise about German shepherds, the gap would be so small that beliefs would not change much. This premise would not really lead to changes in the plausibility of the conclusion.

Perhaps what is most appealing about the gap model is that it explicitly includes a stage for potentiating features that are relevant to inferences about a particular property. Unlike in the three previous models, there is no default assumption that different properties will be treated the same. Still, the model does not provide an account of the feature potentiation process, but simply assumes that it would be there. The gap model does include a similarity component as well. Thus the model could account for basic similarity effects, and to an initial extent addresses results such as those of Heit and Robinstein (1994), who found use of different similarity measures for different properties. However, it is not obvious how the model would capture differences between projectable and nonprojectable properties – that is, why some properties are not projected at all or are just projected randomly. Furthermore, the model does not seem to address typicality effects. Even so, the model does allow for multiple-premise categories to be combined and explains sample size effects, but it is unclear whether the model would account for diversity effects or nonmonotonicity effects (see Smith et al. 1993, p. 84).

In sum, in several ways the gap model is an important advance over the Osherson et al. (1990) model, but in other ways the model is somewhat simplified and some key phenomena are left out. In terms of Table 1, the model addresses Results 1, 4, 6, and 8.

Table 2: Sample Application of the Bayesian Model

<i>Hypothesis</i>	<i>Range</i>	<i>Degree of Prior Belief</i> $P(H_i)$	$P(D H_i)$	<i>Posterior Belief</i> $P(H_i D)$
1	Cow → True Sheep → True	.70	1	.93
2	Cow → True Sheep → False	.05	1	.07
3	Cow → False Sheep → True	.05	0	.00
4	Cow → False Sheep → False	.20	0	.00

Note – Cases in which the property is true for a category are in boldface.

Heit (1998)

The final model to be discussed is the Bayesian model proposed by Heit (1998). The Bayesian model differs somewhat from the other models in that it perhaps is less of a processing-level account. This model was intended to be a computational-level analysis of what, given certain assumptions, would be normative for inductive inferences. The Bayesian model is an attempt to address normative issues in the spirit of Anderson's (1990) rational analysis of cognition. That is, after specifying the goals of a system, the optimal computational means for attaining these goals are considered. Note that the Bayesian model is by no means an attempt to provide logical justification for inductive inferences or to explain why induction is successful in the real world. It is simply an analysis of the steps that could be taken in a probability estimation task.

According to the Bayesian model, evaluating an inductive argument is conceived of as learning about a property, in particular learning for which categories the property is true or false. For example, in argument

Cows can get disease X

Sheep can get disease X,

the goal is to learn which animals can get this disease and which animals cannot. The model assumes that for a novel property such as the one in this example, people would rely on prior knowledge about familiar properties in order to derive a set of hypotheses about what the novel property might be like. For example, people know some facts that are true of all mammals, including cows and sheep, but they also know some facts that are true just of cows and likewise some facts that are true just of sheep. The

question is, Which of these known kinds of properties does the novel property *can get disease X* resemble most? Is it a cow-and-sheep property, a cow-only property, or a sheep-only property? To answer this question, the Bayesian model treats the premise or premises in an inductive argument as evidence, which is used to revise beliefs about the prior hypotheses according to Bayes's theorem. Once these beliefs have been revised, the plausibility of the conclusion is estimated.

It will be helpful to present more details of the model in the context of this example. People know quite a few properties of animals, but these known properties must fall into four types: properties that are true of cows and sheep, properties that are true of cows but not sheep, properties that are true of sheep but not cows, and properties that are not true of either cows or sheep. These four types of known properties can serve as four hypotheses when one is reasoning about novel properties, because any new property must also be one of these four types. These four types of properties are listed in Table 2, with cases in which the property is true for a category shown in boldface for emphasis.

As is shown in Table 2, a person would have prior beliefs about these hypotheses. For example, the value of .70 for Hypothesis 1 represents the belief that there is a 70% chance that a new property would be true of both cows and sheep. This high value could reflect the high degree of similarity between cows and sheep and that people know many other animal properties that are true of both cows and sheep. (The particular numbers are used only for illustration at this point.) However, the person might see a 5% chance that a new property would be true of cows and not sheep, a 5% chance that a new property would be true of sheep and not cows, and a 20% chance that the property is true of neither category. Note that because

the four hypotheses are exhaustive and mutually exclusive, their corresponding prior beliefs add up to 1.

This table describes prior beliefs not only about the four hypotheses but also about the two categories. If we combine Hypotheses 1 and 2, it appears that the person believes that there is a 75% chance that cows would have the new property; likewise, if we combine Hypotheses 1 and 3, the person believes that there is a 75% chance that sheep have the new property.

The next step is to combine these prior beliefs with new evidence, using Bayes's theorem. The given premise, *Cows have Property P*, is used to update beliefs about the four hypotheses, so that a better evaluation of the conclusion, *Sheep have Property P*, may be achieved. When we apply Bayes's theorem (Equation 1), the premise is treated as the data, D . The prior degree of belief in each hypothesis is indicated by $P(H_i)$. (Note that there are four hypotheses, so $n = 4$ here.) The task is to estimate $P(H_i | D)$ – that is, the posterior degree of belief in each hypothesis, given the data.

$$P(H_i | D) = \frac{P(H_i)P(D|H_i)}{\sum_{j=1}^n P(H_j)P(D|H_j)} \quad (1)$$

In Table 2, the calculations are shown for all four hypotheses, given the data that *Cows have Property P*. The calculation of $P(D | H_i)$ is quite easy. Under Hypotheses 1 and 2, cows have the property in question, so obtaining the data (that cows have the property) has a probability of 1. But under Hypotheses 3 and 4, cows do not have the property, so the probability of obtaining the data must be 0 under these hypotheses. The final column, indicating the posterior beliefs in the four types of properties, has been calculated with Equation 1. Notably, Hypothesis 1, that cows and sheep have the property, and Hypothesis 2, that just cows have the property, have been strengthened. The two remaining hypotheses have been eliminated from contention, because they are inconsistent with the data or premise that cows have the property.

Finally, the values in Table 2 may be used to evaluate the conclusion, that sheep have Property P. The degree of belief in this conclusion is simply the sum of the posterior beliefs for Hypotheses 1 and 3, or .93. Recall that before the introduction of evidence that cows have the property, the prior belief that sheep have the property was only .75. Thus, the premise that cows have the property led to an increase in the belief that horses have the property.

This illustration raises the important issue of how the prior beliefs, such as the numbers in the third column of Table 2, might be derived. Are the exact values of the priors important? These questions are fundamental issues for Bayesian statistics (see, e.g., Box and Tiao 1973; Raiffa and Schlaifer 1961; see also Heit and Bott 2000). For the purposes of Heit (1998), it was assumed that the priors would be determined by the number of known properties of each type that are brought to mind in the context of evaluating the inductive argument. It might be said that the prior beliefs for new properties are estimated with the use of something like an availability heuristic (Tversky and Kahneman 1973) based on known properties. The basic idea is that when reasoning about novel animal properties, people would retrieve a set of familiar animal properties from memory. Then they would count up how many known properties are consistent with each of the four properties – for example, how many known properties of animals are true of both cows and horses. The priors in Tables 2, for example, are consistent with the idea that 20 known properties are brought to mind: 14 of Type 1, 1 of Type 2, 1 of Type 3, and 4 of Type 4.

In addition, Heit (1998) argued that the exact values for the prior beliefs are not critical in many cases. For instance, in the present example, the initial degree of belief in Hypothesis Type 4, that neither cows nor horses have the property, was not at all important. The posterior belief in Hypothesis 1, $P(H_1 | D)$, can be calculated simply from the prior beliefs in Hypotheses 1 and 2, $P(H_1 | D) = P(H_1) / [P(H_1) + P(H_2)]$, or $.93 = .70 / (.70 + .05)$. The posterior belief in Hypothesis 1 would be the same regardless of the value of $P(H_4)$, as long as $P(H_1)$ and $P(H_2)$ maintain the same ratio to each other.

The Bayesian model addresses many of the key phenomena reviewed in this paper. For example, the model predicts similarity effects, because novel properties would be assumed to follow the same distributions as would familiar properties. The argument Cows/Sheep seems strong, because many known properties are true of both categories. In contrast, Hedgehogs/Sheep seems weaker, because prior knowledge indicates that there are fewer properties in common for these two categories. The Bayesian model also addresses typicality effects, under the assumption that according to prior beliefs, atypical categories such as *hedgehog* would have a number of idiosyncratic features. Hence a premise asserting a novel property about hedgehogs would suggest that this property is likewise

idiosyncratic and not to be widely projected. In contrast, prior beliefs about typical categories would indicate that they have many features in common with other categories, and hence a novel property of a typical category should generalize well to other categories. (In comparison with the Sloman 1993 model, the Bayesian model predicts an independent influence of premise typicality, rather than conclusion typicality, beyond feature overlap.)

The Bayesian model also addresses diversity effects, with a rationale similar to that for typicality effects. An argument with two similar premise categories, such as *cows* and *horses*, could bring to mind a lot of idiosyncratic properties that are true just of large farm animals. Therefore a novel property of cows and horses might seem idiosyncratic as well. In contrast, an argument with two diverse premise categories, such as *cows* and *hedgehogs*, could not bring to mind familiar idiosyncratic properties that are true of just these two animals. Instead, the prior hypotheses would be derived from known properties that are true of all mammals or all animals. Hence a novel property of cows and hedgehogs should generalize fairly broadly. This is a quite strong prediction of the Bayesian model, and it is not yet clear how the model would account for any lack of diversity in children. Likewise, it would take further investigation to see whether the Bayesian model would apply to other exceptions to diversity such as the nonmonotonicity effect reported by Osherson et al. (1990) as well as other nonnormative results such as the inclusion fallacy (Osherson et al. 1990) and the inclusion similarity effect (Sloman 1993, 1998). It could be the case that the Bayesian model has difficulty explaining these nonnormative results. On the other hand, to the extent that people can rely on different priors for answering different questions, the apparent inconsistencies in reasoning might be due to the knowledge that is retrieved for answering particular questions rather than the reasoning process itself.

The Bayesian model can address conclusion homogeneity effects, as in Nisbett et al. (1983). For example, Nisbett et al. found that after a single observation, people were fairly willing to generalize that all floridium samples conduct electricity. The result can be explained in terms of people's initially entertaining two hypotheses: All floridium samples do not conduct electricity, and all floridium samples do conduct electricity. Observing just a single sample of floridium that conducts electricity fits with the second hypothesis and rules out the first hypothesis; hence a

strong generalization proceeds rapidly. In contrast, the result for Barratos and obesity was that seeing just one obese Barratos did not promote strong inferences about the whole group. In this case, people might entertain a whole distribution of prior hypotheses—for example, 0% of Barratos are obese, 1% are obese, 2% are obese, . . . , 50% are obese, 51% are obese, . . . , 99% are obese, 100% are obese. Observing one obese Barratos would rule out the 0% hypothesis, and it might cast doubt on the 1% hypothesis; but it would not license the strong inference that all Barratos are obese.

In a similar way, an idiosyncratic property such as *has a scratch on it* could lead people to entertain a diffuse set of prior hypotheses, so that a single observation would not lead to strong inferences. More generally, because the essence of the Bayesian model is that it derives inferences based on prior knowledge of familiar properties, it should be highly sensitive to content effects such as property differences and effects of expertise. The key idea is that the novel property in an argument serves as a cue for retrieving familiar properties. Most psychology experiments on inductive reasoning have used novel properties that sounded at least vaguely biological or internal. In addition, people may retrieve familiar biological properties as a default, for animal categories. So unless the novel property suggests otherwise, people would tend to rely on distributional information about known biological properties.

To give another example, when reasoning about the anatomical and behavioral properties in Heit and Rubinstein (1994), subjects could have drawn on different priors for the two kinds of properties. As in many other experiments, reasoning about anatomical properties led people to rely on prior knowledge about familiar anatomical properties. In contrast, when reasoning about a behavioral property such as *prefers to feed at night*, the prior hypotheses could be drawn from knowledge about familiar behavioral properties. These priors would tend to promote inferences between animals such as hawks and tigers that are similar behaviorally rather than anatomically.

To conclude, the Bayesian model has the potential to address all of the phenomena listed in Table 1. However, the main drawback of this model is that it has not been fully tested. Heit (1998) presented illustrations of how the model might account for a variety of phenomena, but the model has not been directly applied to human data. To test the Bayesian model properly, it would be necessary to collect data

about people's beliefs about a large number of familiar properties and then use these data to predict judgments about novel properties. Of course, the other models also depend on collected data such as property listings or similarity ratings, in order to generate predictions. One difference is that the Bayesian model can also respond to beliefs about hidden essences (cf. Medin and Ortony 1989); for example, the belief that all pieces of limestone have got something unique and distinctive in common, even if one cannot specify exactly what that is. These beliefs might not be easily measured from property listings. Still, the Bayesian model does begin to address a broader range of phenomena than those addressed by the other models.

Discussion

To some extent, there has been a developmental trend among psychological models of induction, with more recent models not surprisingly taking on a wider range of results. Still, perhaps what all the models have in common is more important than their differences, with some notion of similarity (in terms of feature overlap or proximity in multidimensional space) and some notion of diversity (in terms of category coverage or feature overlap) driving many of the predictions. Given the commonalities among all the models, the main value of the Bayesian analyses by Heit (1998) may be that they highlight the normative basis for the models' predictions. Although it does not address property effects, the Osherson et al. (1990) model has been most influential because it does bring together a lot of phenomena and make interesting predictions of further results.

If one can project from past trends, future models of induction may address content and property effects to a further extent, in light of results showing effects of expertise on induction and widespread property effects even with very young children. Certainly, the wide range of phenomena addressed by the Heit (1998) model, even at an initial stage, should encourage future models to go further. Ideally, future models will give a better process-level account of what Smith et al. (1993) referred to as *feature potentiation* – that is, selecting features that are relevant to a particular inference. Also, to the extent that induction involves explanatory or causal reasoning as suggested by the studies of Sloman (1994) and others, it must be admitted that none of the existing models gives a satisfying account of explanatory reasoning.

Conclusion: Future Directions for Empirical Research

Although much progress has been made in empirical work on inductive reasoning in the past 25 years, by reading between the lines in this review one can see areas of incompleteness that might be profitably investigated in future studies. Perhaps the clearest way to look at inductive reasoning is to do so in terms of the various phenomena, such as typicality effects and diversity effects, that appear in Table 1. As one considers these results, it is natural to be interested in whether they appear in different groups of people, such as children or adults, and Western cultures or non-Western or traditional cultures. Work that addresses such questions is well under way, although there are still many interesting questions to be addressed, such as why diversity-based reasoning seems to be harder to find in some groups.

Another way to think about induction is to do so in terms of the various tasks and responses that would require inductive reasoning. For example, in the experiments described in this review researchers have used response measures such as probability judgments, judgments of inductive strength, forced-choice predictions, and behaviors such as how an infant plays with a toy. The tasks varied in another important way as well. In some experiments, the premises gave information about individuals (e.g., a particular bird has some property) and in other experiments, the premises gave information about categories (e.g., a kind of bird has some property). Possibly there was even some ambiguity in some experiments whether the premises referred to individuals or categories. This problem could particularly come up when premises are presented in picture form, if it is unclear whether a picture of some individual is meant to stand for a class of items. It would be important to establish whether the various phenomena of inductive reasoning, listed in Table 1, do appear for different versions of the task. For example, all of the models of induction described here can apparently be applied to inferences about individuals or categories. Systematic research could potentially show differences in reasoning about individuals as opposed to categories, and these differences might or might not correspond to the models' predictions.

A related issue is how well the laboratory-based tasks reported here match up to inductive reasoning as manifested by everyday judgments and decisions. How well do the phenomena

reviewed here correspond to everyday reasoning? It is hoped that most of the key results in Table 1 would occur outside of the laboratory as well. Perhaps the more contentious results would be the fallacies reported by Osherson et al. (1990) and Sloman (1993, 1998), in which people violate basic laws of probability. It would be valuable to study whether these reasoning fallacies are robust enough to appear in the real world and in everyday choices, or whether they are dependent on the characteristics of experimental settings and survey methodology.

Still another way to think about the phenomena of inductive reasoning is to consider whether they might be different for various domains of knowledge or different kinds of categories – for example, natural kinds, artifacts, social categories, event categories, ad hoc categories (Barsalou 1983). Again, this is an intriguing possibility that would need to be investigated more systematically in future research. Some studies have been done with different kinds of categories, but the majority of published experiments have used animal categories (and animals' biological properties). Although there could be many reasons for this focus on categories of animals, the risk remains that the results might be different in other domains or with other kinds of categories. It is unclear whether the emphasis on animal categories in published papers simply reflects the choices of experimenters in creating stimuli, or whether there is some nonpublication bias because experiments with other stimuli did not yield interpretable results.

Therefore, after 25 years of psychological research on inductive reasoning, it is time both to acknowledge the extensive progress that has been made, especially in terms of the regularities that have been documented, and to acknowledge that future empirical work needs to be more ambitious, ideally guided by more ambitious models as well.

Note

1 Quite a few studies, including parts of Carey (1985), have looked at attribution tasks rather than projection tasks. In an attribution task, the subject, typically a child, states whether some familiar item has some familiar property, such as whether dogs sleep. The contribution of inductive reasoning to attribution tasks is unclear, because in many cases the subject would be able to answer on the basis of established knowledge or observations without a major role for induc-

tive inference. Therefore, this paper will focus on projection tasks, which involve unfamiliar categories and/or properties.

Section 5: Dual and Integrative Approaches

Chapter 20: Human Reasoning and Argumentation: The Probabilistic Approach

MIKE OAKSFORD, NICK CHATER, AND ULRIKE HAHN

When compared to standard logic, research in the psychology of deductive reasoning has found that people make large and systematic (i.e., non-random) errors (Manktelow 1999), which suggests that humans may be irrational (Stein 1996; Stich 1985). However, the probabilistic approach argues against this interpretation. Rather than view this behaviour as errorful, it is argued that performance may have been compared to the wrong normative standard. When compared to probability theory rather than logic, participants' reasoning may be seen in a more positive light.

The probabilistic approach contrasts with mental logic (e.g., Rips 1994) and mental model theories (e.g. Johnson-Laird and Byrne 1991) which both argue that systematic deviations from logic represent unavoidable performance errors. In both theories working memory limitations restrict people's reasoning abilities. These approaches are hard to reconcile with the high error rates seen in some tasks, for example, up to 96 percent in Wason's selection task, and the fact that everyday thought and action seems to be highly successful. How can this success be understood if peoples' reasoning system is prone to so much error? The probabilistic approach resolves this problem by adopting a different normative theory (Oaksford and Chater 1998b; Stanovich and West 2000) and by considering the role of the environment in reasoning (Anderson 1990, 1991; Chater and Oaksford 1999b; Oaksford and Chater 1998a).

The goal of this chapter is to review recent primarily empirical developments¹ in the probabilistic approach to explaining the core tasks in the area, conditional inference, data selection in the Wason selection task, and syllogis-

tic reasoning. We also look at how the probabilistic approach has been generalised to *argumentation*, that is, the process of persuading others of a, possibly controversial, standpoint, which is arguably the more general human activity of which deductive reasoning is but a part. We first provide an overview of our approach which links the three areas of reasoning we look at and which addresses some of the standard criticisms.

Overview

We look first at conditional inference, i.e., inferences involving the expression *if... then*. In psychological experiments on conditional inference, participants are provided with a conditional premise, for example, *if something is a bird then it flies*, and a categorical premise, for example, *Tweety is a bird*. They are often told to assume that the premises are true. On this assumption, they are then asked whether *Tweety flies* can be inferred from the premises. This inference is the logically valid inference form of *modus ponens* (MP). So, if they reason logically, they should endorse this inference. When simple alphanumeric stimuli are used (*if A then 2, A, therefore 2?*), participants typically endorse this inference, but when everyday materials are used, like in our example, they tend to endorse it less. Moreover, even with alphanumeric stimuli, people endorse another logically valid inference, *modus tollens* (MT, categorical premise: *Tweety does not fly*, conclusion: *Tweety is not a bird*) far less than MP.

According to the probabilistic approach these findings relate to the fact that inferences involving everyday conditionals are *defeasible*, i.e.,

adding premises can lose conclusions. So if you then learn that *Tweety is an Ostrich* the MP inference above is *defeated*, that is, adding a premise has lost a conclusion (this behaviour is called *non-monotonicity*). There are a variety of logical proposals to get around this problem but none appear to succeed (see Chater and Oaksford 1993; Oaksford and Chater 1991, 1992, 1993, 1995, 1998b). However, probability theory simply *is* non-monotonic and so handles cases like these with ease, that is, the probability that birds fly is high ($P(\textit{flies}(x) | \textit{bird}(x)) = .9$) but the probability of a bird flying given that it is also an ostrich is near 0 ($P(\textit{flies}(x) | \textit{bird}(x), \textit{ostrich}(x)) \approx 0$). Treating conditionals as expressing conditional probabilities was proposed in philosophy by Adams (1966, 1975, 1998), and has been used in artificial intelligence by Pearl (1988, 2000).

As we have just indicated, the primary motivation for the probabilistic approach is that the introduction of probabilities provides a potential solution to the problem of non-monotonicity in real human reasoning. Our original critiques of *logician* cognitive science (Chater and Oaksford 1990; Oaksford and Chater 1991) in general and of *logician* psychological theories of human reasoning in particular (Chater and Oaksford, 1993; Oaksford and Chater 1993, 1995, 1998) focussed on the inability of accounts, like those proposed by Fodor (1987) and by mental logics and mental models theories, to deal with non-monotonicity. Subsequent research within the probabilistic approach has been aimed at showing how probability theory, which deals with this problem head-on, may also provide better accounts of human reasoning data and may also preserve human rationality. In artificial intelligence, probability theory (Pearl 1988, 2000) or other uncertainty formalisms (see Prakken and Vreeswijk 2002, for a recent overview) have become the dominant approach to providing practical systems that deal with defeasibility. Providing practical artificial reasoning systems that deal with the computational problems surrounding defeasible inference requires something like probability theory. Our hunch is that natural reasoning systems have evolved a similar solution.

Our approach to the other areas of human reasoning that we discuss in this chapter follows on directly from adopting the conditional probability interpretation of the conditional (Adams 1998; Bennett 2003). In the Wason selection task (Wason 1966, 1968), participants must

select the best types of evidence to determine whether a conditional rule is true or false. This task is interpreted as selecting the evidence that best distinguishes a conditional hypothesis, *if p then q* , where $P(q | p)$ is high and in particular higher than $P(q)$, from a foil hypothesis where $P(q | p) = P(q)$. The evidence that best distinguishes these possibilities turns out to depend on the priors $P(p)$ and $P(q)$. If these are low, what Oaksford and Chater (1994) called “the rarity assumption,” then the theory of *optimal data selection* predicts the empirically observed pattern of evidence selection, which can not therefore be regarded as irrational.

In syllogistic reasoning, people must draw conclusions from two *quantified* premises, for example, *All beekeepers are artists, Some beekeepers are chemists, therefore, Some artists are chemists*. The probabilistic analysis of these inferences starts from the observation that many conditionals in natural language are implicitly quantified. So the logical form of *birds fly* could be *for all x if x is a bird then x flies*. Chater and Oaksford (1999), therefore, interpreted the quantifier in *all p are q* to mean that $P(q | p) = 1$. They then provided interpretations based on conditional probability for the other quantified statements, for example, *some p are q* means $P(q | p) > 0$. This approach importantly allowed interpretations for quantifiers that had not been used in reasoning experiments. For example, the case where $P(q | p)$ is high but less than 1, provides the interpretation for *most p are q* . *Most birds fly* seems to be the most appropriate interpretation of *birds fly* but one that is unavailable in standard logic. Using these interpretations of the quantifiers allows the *probabilistic validity* of syllogistic inferences to be defined including those involving *generalized* quantifiers (Barwise and Cooper 1981) like *most* and *few*. Moreover, a simple set of probabilistic heuristics can be described that reliably identifies the *p*-valid conclusion if there is one.

We have seen how a simple interpretation of the conditional as conditional probability runs through our whole approach to human reasoning. This approach might be characterised as arguing that although people are poor at logical reasoning they are nonetheless good at probabilistic reasoning. However, this claim seems to be at odds with established results apparently showing that people are also very poor probabilistic reasoners (e.g., Tversky and Kahneman 1974; Kahneman, Slovic and Tversky 1982). For example, people seem to be insensitive to base

rates, that is, in applying Bayes's theorem people often provide estimates of posterior probabilities that seem to reflect only the likelihoods and not the priors. People also seem to be overconfident in their probability judgements, that is, they do not seem to be well calibrated to the actual frequencies of events in the world. Moreover, people also seem prone to the conjunction fallacy. That is, they violate the probabilistic law that the joint probability of any two events can not be greater than either individual event, i.e., $P(A) \geq P(A, B) \leq P(B)$.

There are several points to make here. Our accounts of human reasoning are framed at the computational level, that is, they characterise what is being computed not how (although we do provide a process account in terms of *probabilistic heuristics* for syllogistic reasoning). That people's behaviour well approximates the norms provided by these models, which are thereby descriptively adequate, does not necessarily mean that people are doing complex probabilistic computations in their heads. As Oaksford and Chater (1994) argued, people could approximate these norms using a small set of hard wired heuristics (Gigerenzer and Goldstein 1996). To the extent that this is the case we would expect people to be relatively insensitive to probabilistic manipulations (see Oaksford et al. 1997). However, as we will see, people are sensitive to a variety of probabilistic manipulations in these tasks. Consequently it would appear that people may be performing some forms of rudimentary probabilistic calculations. Again these may bear no direct relation to the explicit manipulation of probability values using the rules of probability theory represented in our model. However, if people are responding appropriately to probabilistic manipulations then this behaviour does seem inconsistent with their systematically falling into error on probabilistic reasoning tasks.

But there are good reasons to suspect that Kahneman and Tversky's assessment of people's probabilistic reasoning abilities was premature (McKenzie 2005). According to recent analyses many of the apparent errors and biases observed in probabilistic reasoning are a consequence of presenting the probabilistic information in an unnatural format (Gigerenzer and Hoffrage 1995). Most often in experiments of this type people are given the probabilistic information in terms of explicit probability statements or percentages, for example, .05 or 5 percent. However, Gigerenzer and Hoffrage (1995)

argue that this is unnatural given the normal sampling situation where we build up frequency information as a result of multiple encounters with objects and events. What you discover by such a process is, for example, that something like ninety-five out of the one hundred ravens you have examined are black. A wide variety of replications of Kahneman and Tversky's original experiments now show that when a frequency format is used to express the probabilities, far fewer deviations from probability theory are observed.

Moreover, there are many recent (Bovens and Hartmann 2003; and indeed older, e.g., Birnbaum 1983) normative analyses showing that apparent deviations from normative probability can be readily explained without recourse to inaccurate heuristics. In particular, Bovens and Hartmann (2003) have recently shown that by construing the information in the conjunction problem as deriving from more or less reliable witnesses a Bayesian network can be constructed in which it is possible for the probability of the report of a joint event to be more likely than a report of one of the conjuncts. For example, given the background information in the Linda problem, she is more likely to be active in the feminist movement than a bank teller. Under these conditions, one is more likely to believe a witness who tells you that Linda is active in the feminist movement and a bank teller than one who only tells you that Linda is a bank teller. If people construe the conjunction task in this way, they need be doing nothing irrational.

We have dealt here with perhaps the most obvious objection to a probabilistic approach to human reasoning. However, we do not want to pretend that the probabilistic approach is without problems. Many issues are discussed in Oaksford and Chater (1998: 279–291) and they mainly involve how probabilities are assigned to whole bodies of knowledge and how changes are tracked through such large knowledge bases. These are profound problems but we are optimistic that recent research into Bayes nets that introduce structure, via strong independence assumptions, into such knowledge bases may resolve some of these issues. Moreover, the move to probabilistic and related approaches in artificial intelligence has been motivated by even more profound problems for the logicist approach (Chater and Oaksford 1990; Oaksford and Chater 1991, 1993, 1995, 1998). Again, our hunch is that the natural reasoning system has evolved a similar solution.

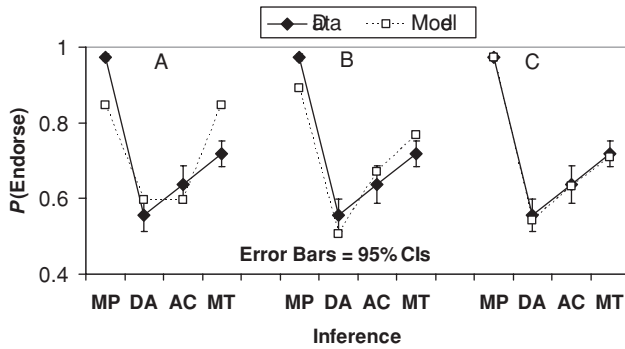

Figure 1. The probability that each inference is endorsed showing the fits of standard logic (Panel A), the conditional probability model (Panel B), and the revised probability model (Panel C) to the data from Schroyens and Schaeken’s (2003) meta-analysis.

We now turn to each of the three domains of reasoning research before showing how the probabilistic approach may also apply to the more general human activity of argumentation.

Conditional Inference

The conditional inference task involves presenting participants with a conditional premise, *if p then q* ($p \rightarrow q$), and one of four categorical premises, p , $\neg p$, q , or $\neg q$. If people interpret the everyday conditional of natural language (“ \rightarrow ”) as the material conditional of standard logic (“ \supset ”), then they should endorse the logical rules of inference, *modus ponens* (“MP”) and *modus tollens* (“MT”):

$$\text{MP} \quad \frac{p \supset q, p}{\therefore q} \quad \text{MT} \quad \frac{p \supset q, \neg q}{\therefore \neg p} \quad (1)$$

These inference schemata read that if the propositions above the line are true, then it can be inferred that the propositions below the line are true. Moreover, they should *not* endorse the logical fallacies of *denying the antecedent* (“DA”) and *affirming the consequent* (“AC”):

$$\text{DA} \quad \frac{p \supset q, \neg p}{\therefore \neg q} \quad \text{AC} \quad \frac{p \supset q, q}{\therefore p} \quad (2)$$

So logically participants should endorse MP and MT equally and they should refuse to endorse DA or AC. However, they endorse MP significantly more than MT and they endorse DA and AC at levels significantly above zero. Figure 1, Panel A, shows the results of a recent meta-analysis of conditional inference (Schroyens and Schaeken 2003) together with the best fits obtainable by standard logic (for how this fit was

obtained, see Oaksford and Chater 2003a). In the next section we outline the theory of conditional inference developed in the probabilistic approach.

Theory

Following other researchers in this area (e.g., Anderson 1995; Chan and Chua 1994; George 1997, 1999; Liu 2003; Liu, Lo, and Wu 1996; Politzer 2005; Stevenson and Over 1995), we proposed a model of conditional reasoning based on conditional probability (Oaksford and Chater 2003a, 2003b, 2003c, 2003d; Oaksford, Chater, and Larkin 2000). The probability of the conditional, $P(p \rightarrow q)$, is the conditional probability, $P(q | p)$. This is what Edgington (1991) calls *The Equation*. The greater the probability of the conclusion given the premises the more it should be endorsed. The constraints on conditional inference were specified in a 2×2 contingency table as in Oaksford and Chater (1998c). A notational variant of this table is shown in Table 1, in which $a = P(q | p)$, $b = P(p)$, and $c = P(q)$.²

Oaksford et al. (2000) derived conditional probabilities of the conclusion for each inference MP, MT, AC, and DA. Oaksford and Chater (2007, 2008) recently showed that this account of conditional inference is equivalent to the *dynamic* approach to conditional inference in *probability logic* (Adams 1998). From this perspective, conditionals allow people to update their beliefs (prior probability distributions) given new information. So if a high probability is assigned to *if x is a bird, x flies*, then on acquiring the new information that *Tweety is a bird*, one’s degree of belief in *Tweety flies* should be revised to one’s degree of belief in *Tweety flies given Tweety is a bird*, i.e., one’s degree of belief in the conditional. So using P_0

Table 1: The Contingency Table for a Conditional Rule If p Then q , Where There is a Dependency Between the p and q that May Admit Exceptions, $a = P(q|p)$, $b = P(p)$, and $c = P(q)$

	q	$\neg q$	
p	ab	$b(1-a)$	b
$\neg p$	$c-ab$	$1-c-b(1-a)$	$1-b$
	c	$1-c$	

to indicate *prior* degree of belief and P_1 to indicate *posterior* degree of belief, then:

$$P_1(q) = P_0(q|p), \quad \text{when } P_1(p) = 1. \quad (3)$$

Thus according to this account, the probability with which someone should endorse the MP inference is the conditional probability, exactly as in Oaksford et al. (2000).

However, as Oaksford and Chater (2007, 2008) pointed out there is a problem with

extending this account to MT, DA and AC (Sober 2002). The appropriate conditional probabilities for the categorical premise of these inferences to conditionalize on are $P(\neg p|\neg q)$, $P(\neg q|\neg p)$, and $P(p|q)$ respectively. However, the premises of MT and the fallacies do not entail values for these conditional probabilities (Sober 2002, 2004; Wagner 2004). Oaksford et al. (2000) suggested that people had prior knowledge of the marginals, $P(p)$ and $P(q)$, which together with $P(q|p)$ do entail appropriate values (see, Wagner [2004] for a similar approach):

$$\text{MP} \quad P_1(q) = P_0(q|p) = a \quad (4)$$

$$\text{DA} \quad P_1(\neg q) = P_0(\neg q|\neg p) = \frac{1-c-(1-a)b}{1-b} \quad (5)$$

$$\text{AC} \quad P_1(p) = P_0(p|q) = \frac{ab}{c} \quad (6)$$

$$\text{MT} \quad P_1(\neg p) = P_0(\neg p|\neg q) = \frac{1-c-(1-a)b}{1-c} \quad (7)$$

Equations (4) to (7) show the posterior probabilities of the conclusion of each inference assuming the posterior probability of the categorical premise is 1. The behavior of this account is shown in Figure 2. By using Jeffrey conditionalization, these cases can be readily generalized to when the probability of the categorical premise

Figure 2. How the probability that a conclusion should be drawn varies as a function of the prior probabilities of the categorical premise and conclusion for DA, for AC, and for MT.

is less than 1. For example, for MP:

$$P_1(q) = P_0(q | p)P_1(p) + P_0(q | \neg p)P_1(\neg p). \quad (8)$$

An important constraint on Jeffrey conditionalization is the *rigidity condition*:

$$\text{Rigidity Condition: } P_1(q | p) = P_0(q | p) \quad (9)$$

That is, discovering the posterior probability of the categorical premise does not alter the estimate of the probability of the conditional. The possible effects of the failure of rigidity can be illustrated using a concrete example, that is, what happens if you believe that *if you turn the key (p) the car starts (q)* and that on this occasion *the car didn't start*. There would seem to be little reason to expect the car to start unless one was reasonably confident that the key had been turned. Put another way, the assertion of the categorical premise of MT only seems to be informative against a background where the car was expected to start. Normally this is only a reasonable expectation if it is known that the key has been turned. So this seems like a case in which rigidity might be violated. That is, the effect of a failure of rigidity is to suggest the possibility of a counterexample to the conditional, that is, the categorical premise of MT suggests a case where the key has been turned but the car has not started ($p, \neg q$).

Oaksford and Chater (2007, 2008) suggested that because rigidity violations indicated the possibility of a counterexample, people adjust $P_0(q | p)$ to a revised value, $P_0^R(q | p)$, by Bayesian revision, assuming a model where turning keys and cars starting are independent as a foil hypothesis (Oaksford and Chater 1994, 1996, 2003e).³ This adjustment means that the value of the conditional probability used to calculate the posterior probabilities for DA, AC, and MT is lower than for MP. As we now see, Oaksford (2005) showed how this revision provided a much better account of the baseline rates of endorsement for the conditional inferences investigated in the psychology of reasoning. In the next section, we outline some of the evidence that this account can explain.

The Evidence

In this section, we first discuss the *inferential asymmetries* in the base-line results. We then discuss the recent evidence on the probability of the conditional before returning to the older

data on *negative conclusion bias* and *suppression effects*.

THE INFERENTIAL ASYMMETRIES

Oaksford and Chater (2007, 2008) observed that the first hurdles any account of conditional inference must get over are the empirical asymmetries observed between MP and MT, that is, MP is endorsed more than MT, and between DA and AC, AC is endorsed more than DA (see Figure 1). Figure 1 Panel B shows the fit of the original Oaksford et al. (2000) model. It is clear that it *underestimates* the magnitude of the MP–MT asymmetry and *overestimates* the magnitude of the DA–AC asymmetry. This fact has recently been used to argue against Oaksford et al.'s (2000) probabilistic approach (Evans and Over 2004; Schroyens and Schaeken 2003).

Oaksford and Chater (2003b) showed that the original model, despite its limitations, did not provide significantly worse fits to the data than other theories like mental models (Johnson-Laird and Byrne 1991, 2002) or mental logic (e.g., Rips 1994). Consequently, there is no need to invoke processing limitations at the algorithmic level like those invoked by these theories to explain the mismatch between the data and the computational level theory they adopt for this task, that is, standard logic. Oaksford and Chater (2003a, 2003b) suggested that concentrating on the algorithmic level may lead to better fits.

Schroyens and Schaeken (2003) provided an alternative mental models account, in which people seek for counterexamples from long term memory to putative conclusions suggested by their initial mental models. They showed that a parameterised version of this model provided better fits to the data in Figure 1 than Oaksford et al.'s (2000) model. The parameters of this model corresponded to the probabilities of retrieving the p and $\neg q$, $\neg p$ and q , and the $\neg p$ and $\neg q$ cases from long term memory. Oaksford and Chater (2003a) argued that there were several conceptual problems with this account. For example, Schroyens and Schaeken suggested that it may be consistent with a probabilistic construal of rationality. This might be true if the three parameters of their model corresponded to the joint probabilities, $P(p, \neg q)$, $P(\neg p, q)$ and $P(\neg p, \neg q)$. However, the best fit values of their parameters summed to greater than 1, implying that $P(p, q) < 0$. Thus, their account is forced to attribute people with probabilistically inconsistent beliefs. Moreover, Oaksford and Chater (2003c) showed

that when fitted to data where probabilities are explicitly manipulated (Oaksford et al. 2000), Schroyens and Schaeken's model provided worse fits than the original conditional probability model.

However, the magnitude of the inferential asymmetries observed in the conditional inference task remained unexplained. Oaksford and Chater's (2007, 2008) invocation of rigidity violations may explain the magnitude of these asymmetries at the computational level. Rigidity violations suggest a lower revised value for the conditional probability, that is, $P_0^R(q|p)$. It is this lower value that is used to estimate the relevant conditional probabilities for the categorical premises of DA, AC, and MT to conditionalize on. Oaksford and Chater (2007, 2008) fitted a model to the same data in Figure 1, where a lower value was used (but which had the same number of free parameters) and the fits were significantly better (see Figure 1, Panel C). The relationship between the revised value, $P_0^R(q|p)$, and $P_0(q|p)$ was also consistent with Bayesian revision on one counterexample. These results seem to show that the magnitude of the MP–MT asymmetry can also be explained from a Bayesian perspective.

EVIDENCE FOR "THE EQUATION"

Recent evidence shows that people do regard the probability of a conditional to be the conditional probability (i.e., *The Equation* [Edgington 1991; see also Bennett 2003]) as the probabilistic account presupposes (Evans et al. 2003; Oberauer and Wilhelm 2003; Over et al. 2005). We focus on Evans et al. (2003), who assessed people's probabilistic interpretations of conditional rules and their contrapositives (*if $\neg q$ then $\neg p$*). They tested three possibilities. First, material implication predicts that the probability of a conditional should be $1 - P(p, \neg q)$, that is, 1 minus the probability of finding a falsifying case. Second, the conditional probability account predicts that the probability of a conditional should be $P(q|p)$. Finally, in the defective truth table account (Johnson-Laird and Tagart 1969), where false antecedent cases are irrelevant, the probability of a conditional should be the joint probability, $P(p, q)$. According to material implication, conditionals and their contrapositives should be endorsed equally because they are logically equivalent. Consequently, there should be a strong correlation between ratings of how likely the conditional and its contrapositive are to be true. However, according to the conditional probability account,

$P(q|p)$ and $P(\neg p|\neg q)$ can differ considerably and would not be expected to reveal a perfect correlation.

Evans et al. (2003) varied $P(q|p)$, $P(\neg q|p)$ and $P(\neg p)$ by describing the distribution of cards in packs of varying sizes. For example, given a conditional *if the card is yellow then it has a circle printed on it*, participants could be told that there are four yellow circles, one yellow diamond, sixteen red circles and sixteen red diamonds (Oaksford et al. [2000] used similar manipulations).⁴ So $P(q|p) = .8$, $P(\neg q|p) = .2$ and $P(\neg p) = 32/3$. On material implication, increases in $P(\neg p)$ should increase ratings of $P(\textit{if the card is yellow then it has a circle printed on it})$; according to conditional probability, they should be independent of $P(\neg p)$; and according to conjunction interpretation, they should decrease with increases in $P(\neg p)$. The evidence supported conditional probability with some evidence for a joint probability interpretation.

Recently, Over et al. (2005) replicated these findings for everyday conditionals pretested for $P(p)$ and $P(q)$ as in Oaksford, Chater, and Grainger (1999) and Oaksford et al. (2000: Exp. 3). They also found that for these conditionals the conjunctive interpretation was not adopted by a significant proportion of participants unlike in Evans et al. (2003). Consequently, the conjunctive interpretation is probably an artefact of unrealistic stimuli. Similar results have been found by Oberauer and Wilhelm (2003). Moreover, Ohm and Thompson (in press) also have shown that people's inferential behaviour corresponds closely to the probabilistic approaches predictions given their conditional probability interpretations.

Oberauer, Weidenfeld, and Hörnig (2004) had participants learn about the probabilities of the antecedent and consequent of a conditional but observed no effects on the conditional inference task. This result is not consistent with the large range of probabilistic effects in conditional inference (Chan and Chua 1994; George 1997, 1999; Liu 2003; Liu, Lo, and Wu 1996; Ohm and Thompson in press; Stevenson and Over 1995). It also appears inconsistent with these authors' own findings on the probability of the conditional (Oberauer and Wilhelm 2003). Unless, that is, people's probabilistic interpretation of the conditional has absolutely no consequences for their inferential behaviour.

NEGATIVE CONCLUSION BIAS

The behaviour of the model shown in Figure 2 explains *negative conclusion bias*, which

arises in *Evans' negations paradigm* (Evans 1977; Evans, Clibbens, and Rood 1995; Evans and Handley 1999). Here negations are used in the antecedents and consequents of the rules to create four task rules (A: Affirmative; N: Negative): *if p then q* (AA), *if p then ¬q* (AN), *if ¬p then q* (NA), and *if ¬p then ¬q* (NN). This manipulation means that half the conclusions of any inference, MP, DA, AC, or MT, will be affirmative and half of them will be negative. *Negative conclusion bias* is observed when participants endorse more inferences with a negative conclusion than with an affirmative conclusion. Negated categories have a higher probability than their affirmative counterparts, for example, $P(x \text{ is a dog}) < P(x \text{ is not a dog})$ (Oaksford and Stenning 1992; Oaksford and Chater 1994). Consequently if a conclusion is negated then it corresponds to a high probability conclusion. The probability of the conclusion is on the *x*-axis in Figure 2. It is clear that as this probability increases so the probability with which the model predicts an inference should be endorsed also increases.

This account was confirmed by Oaksford et al. (2000) who varied the probabilities of the antecedents, $P(p)$, and consequents, $P(q)$, to produce four variants analogous to those in the negations paradigm but with high probabilities in place of negations. The four rules were (L: low probability; H: high probability), LL, LH, HL, and HH corresponded to the AA, AN, NA, and NN rules respectively. Oaksford et al. (2000) observed a significant high probability conclusion effect directly analogous to negative conclusion bias (see also Schroyens, Schaeken, Fias, and d'Ydewalle 2000; Schroyens, Verschueren, Schaeken, and d'Ydewalle 2000).

SUPPRESSION EFFECTS

Suppression effects occur when further information reduces the degree to which an inference is endorsed. For example, if someone is told that *if the key is turned the car starts* and that *the key is turned*, they are likely to infer that *the car starts* by MP. However, if they are also told that *if the petrol tank is not empty the car starts*, then they are less likely to endorse this conclusion because the car may not start if the petrol tank is empty (Byrne 1989). The petrol tank being empty provides an *exception* to the rule. These cases have been called "additional antecedents." Their presence suppresses the valid inferences MP and MT (Byrne 1989). These effects are predicted by the probabilistic model. Additional antecedents increase the probability of $P(p, \neg q)$ cases and so reduce the conditional probability, $P(q|p)$,

and hence the probability of drawing the MP inference. The model predicts a similar effect for MT which is also observed. More counter-intuitively the model predicts that decrease in $P(q|p)$ should also decrease endorsements of DA and AC (Oaksford and Chater 2003d), and this effect has been observed (George 1997). Oaksford and Chater (2003d) also discuss a variety of other suppression effects consistent with the conditional probability model (e.g., Chan and Chua 1994; Cummins 1995; Cummins, Lubarts, Alksnis, and Rist 1991; George 1997; Liu, Wo, and Wu 1996; Stevenson and Over 1995; Thompson 1994; Thompson and Mann 1995). Bonnefon and Hilton (2004; see also Bonnefon 2004) also report results on the suppression effect that they argue are best explained by the probabilistic approach.

Further Theoretical Issues

We conclude this section on conditional inference by addressing three further theoretical issues that have arisen in the recent literature on conditional inference surrounding the probabilistic approach. First, we look at the theoretical differences between the probabilistic approach and recent accounts of conditional reasoning that preserve the logical approach but supplement it with a search for counterexamples in long-term memory. Second, we look at Liu's (2003) recent *two-step conditionalisation* model and whether it differs significantly from the account in (4)–(7) above. Finally, we suggest the future direction of conditional reasoning research, in particular at the algorithmic level.

LOGIC AND LONG-TERM MEMORY SEARCH

The definition of conditional probability in Adams's (1998) account and Oaksford et al.'s (2000) is based on the subjective definition provided by the Ramsey Test (Ramsey 1990, originally 1931; see footnote 1). That is, the antecedent is added to one's stock of beliefs, appropriate revisions are made, and the resulting degree of belief in the consequent is the conditional probability. The Ramsey test clearly relies on an account of how knowledge is stored and accessed. Oaksford and Chater (2003a; see also Sellen, Oaksford, and Gray 2005) observed that this reliance means that the probabilistic approach to the MP–MT and DA–AC asymmetries is very similar to some other approaches (Markovits and Barrouillet 2002; Markovits and Quinn 2002; Markovits, Fleury, Quinn, and Venet 1998; Quinn and Markovits 1998; Quinn and Markovits 2002; Schroyens, Schaeken, and

d'Ydewalle 2001a, 2001b). These approaches suggest that people search long-term memory for counterexamples and if they find them they reduce the ratings they assign to an inference or do not endorse it at all. According to Oaksford and Chater's (2007, 2008) account, counterexamples are often suggested to DA, AC, and MT inferences because of possible rigidity violations (Sobel 2004). This results in revising the conditional probability for these inferences. One difference is that the probabilistic approach provides a normatively consistent account of what people do when they consider a counterexample, that is, they revise down $P(q|p)$ by Bayesian revision. As we now show, these other approaches seem to encounter all the problems of defeasible inference that motivated our original adoption of probability theory.

The problem centers on the continued adherence of these approaches to a truth functional view of the conditional. People are proposed to initially interpret the conditional as true, that is, they must assume there can be no counterexamples. On this assumption, they draw the appropriate logical inference. According to the extension of mental models theory, proposed by Schroyens and Schaeken (2003), people then search for counterexamples to the conclusion and conclude the conditional is false if they find one. So given the nonlogical axiom, *if x is a bird, x flies*, and the claim that *Tweety is a bird*, it is concluded validly that *Tweety can fly*, but when the proposition that *Tweety is an ostrich* is retrieved it is concluded that *if x is a bird, x flies* is false (presumably because it is also known that *if x is an ostrich, x can not fly*). This argument has the form of a logically acceptable *reductio ad absurdum* of this conditional claim. However, it has the unacceptable consequence that most conditional knowledge is strictly false because it is defeasible.

This consequence is unproblematic from a probabilistic point of view because probability theory is *non-monotonic* (see *Introduction*) and hence on this view most conditional knowledge, while highly probable, is strictly false. However, it means that people can not have a deductive reasoning system of the kind proposed by mental models. Schroyens and Schaeken (2003) do not say what they think happens to the proposition that *if x is a bird, x flies* when people infer that it is false. There are two options: Retain it as an axiom or expunge it from long-term memory. Only the latter option is logically consistent because if it is nonetheless retained as an axiom, then contradictions will result. For example, on subsequently learning that *Chirpy is a bird and an ostrich*, the axioms about birds

and ostriches above lead to the conclusion that *Chirpy can fly and Chirpy can not fly*, that is, a logical contradiction. To avoid this situation, the conditional claim needs to be expunged from long-term memory. But then this very useful generalization is no longer available to draw reasonable inferences about the world!

TWO-STEP CONDITIONALISATION

Liu, Wo, and Wu (1996; see also Liu 2003) presented participants with two conditions. In one participants might be asked, *if I tell you this is a rock, would you infer it is hard* (a *reduced* problem), which contains no conditional premise. In another condition they would be asked, *if I tell you that if something is a rock it is hard and that this is a rock, would you infer that it is hard* (a *complete* problem). The pattern of results was very similar. So even without a conditional premise, as long as the materials can access appropriate world knowledge, performance is very much the same. However, while the general pattern of responding is unchanged, adding the conditional premise leads to systematic increases in the endorsement of the inferences. This could be because people engage a logical reasoning mechanism when explicit premises are provided.

However, Liu (2003) favors a probabilistic interpretation involving two steps of conditionalisation. So, for MP, people first update their probability that q is true by conditionalising on the truth of p , that is, the categorical premise, to arrive at $P(q|p)$. This is what Liu (2003) calls the "proportionality hypothesis," which he attributes to Oaksford et al. (2000). According to this hypothesis, people disregard the conditional premise. In the second step of conditionalisation, people take the conditional premise into account to evaluate $P(q|p, \text{if } p \text{ then } q)$. This second step explains the differences observed between the two conditions of Liu's (2003) experiments.

A problem for two-step conditionalisation is that the second step seems redundant. The first step conditionalises on the categorical premise. To do this an estimate of $P(q|p)$ is derived from long-term memory for world knowledge for $P(p) = 1$ to conditionalise on. By the Ramsey test this is estimated by adding p to world knowledge, adjusting, and reading off the degree of belief in q . But then the second step is redundant. The second premise is *if p then q* and $P(\text{if } p \text{ then } q) = P(q|p)$, which must be estimated in *exactly the same way as in the first step*. So it seems unlikely that the second-step conditionalisation could alter the results of the first step.

Pragmatically it could be that the act of asserting the conditional for a complete problem provides further evidence that p is sufficient for q , that is, $P(q|p)$ is higher than just considering one's own world knowledge would suggest.⁵ However, this would seem to violate the constraints on Jeffrey conditionalization, which works by keeping the relationships between cells in the joint probability distribution constant, that is, the conditional probabilities do not change. As we have seen, this is called the rigidity condition in Jeffrey conditionalization, that is, $P_0(q|p) = P_1(q|p)$. Liu's second step argues that conditionalizing on the conditional premise leads to an increase in this conditional probability, that is, $P_2(q|p) > P_1(q|p)$. But by Jeffrey conditionalization these should remain the same, that is, $P_0(q|p) = P_1(q|p) = P_2(q|p)$.

It seems that the only effect the assertion of the conditional premise could have is to provide additional *evidence* that q and p are related which increases the assessment of $P_2(q|p)$ because *people now know more than they did before*, although this violates the rigidity condition. That is, Liu's (2003) second step can not be described as just another application of Jeffrey conditionalization. We therefore see no advantage in Liu's (2003) two-step approach. Our original account (Oaksford et al. 2000) did not disregard the conditional premise but assumed that people conditionalize on it (see (4)–(7) above). Consequently, people were assumed to take the extra knowledge, that in this context the conditional premise is asserted into account and therefore $P(q|p)$ is higher than their prior world knowledge would predict. When reduced problems are presented participants are not provided with the extra knowledge that the dependency described in the conditional rule holds in this context.

FUTURE DIRECTIONS: THE RAMSEY TEST

The analysis provided here and by probability logic (e.g., Adams 1998) shows that the principle effort in the psychology of conditional inference should be directed at delineating the cognitive processes underlying the Ramsey test. Our best philosophical understanding of conditional probability is given by this test which essentially invokes a currently unarticulated mental process (Bennett 2003). Moreover, recent appeals to the Ramsey test (Evans and Over 2004) treat it as a primitive mental operation and deal only with the mental representations that may result from having performed one.

In contrast, Oaksford (2004) presented an algorithmic account of conditional inference

based on the probability conditional using a simple constraint satisfaction neural network (McClelland 1998; Rumelhart, Smolensky, McClelland, and Hinton 1986). In such a framework, performing a Ramsey test amounts to clamping on (or off) the node corresponding to the categorical premise and reading off the activation level of the node corresponding to the conclusion. As the Ramsey test requires, this process is *conservative*, that is, it involves minimal changes, as all the connection weights remain the same. Given certain constraints (McClelland 1998), for MP this operation corresponds to computing the real posterior probability, that is, $P_0(q|p,K)$, where K stands for the other knowledge embedded in the connections between nodes. K will also include $P_0(p)$ and $P_0(q)$ which are represented as bias terms.

This framework also may capture the contrast between MP and MT. For MP people may simply perform the Ramsey test without considering other possibilities. However, as it has been argued, the conditions under which the categorical premise of MT can be asserted suggests a counterexample. Consequently, people may not just clamp off the q -node to perform the Ramsey test but may also consider the possibility where the q -node is clamped off and the p -node is clamped on. This can lead to updating of the connection weight by local learning (which would need to be reversible as people are only *supposing*, after all).⁶ The q -node is then clamped off and the posterior probability, $P_0(\neg p | \neg q, K)$ (with the revised $P_0(q|p, K)$), read off. The results of these operations would also need to be stored in working memory, perhaps as "mental models." While the constraints that guarantee this probabilistic interpretation of the network's operation may be unrealistic (McClelland 1998), this seems at least a promising avenue to pursue to provide an algorithmic level account of inference based on probability logic and the Ramsey test.

This account of the Ramsey test suggests that future theorising in the psychology of reasoning must address the storage and representation of world knowledge and how this interacts with reasoning process, a point made many times before (Oaksford and Chater 1991, 1993, 1998a). However, with the advent of probabilistic approaches with their emphasis on the Ramsey test (see also Evans and Over 2004) and the interpretation of neural networks as Bayesian statistical analyzers (McClelland 1998), how this can be achieved is perhaps clearer than it once was.

Data Selection

The probabilistic approach was originally applied to Wason's (1968) selection task, where participants must select cards to find out whether a rule, e.g., *if there is an A on one side (p) there is a 2 on the other side (q)*, is true or false (Oaksford and Chater 1994, 1996). That is, they must select the data most relevant to judging this hypothesis. Participants see four cards, one with A showing (p), one with K ($\neg p$), one with 2 (q) and one with 7 ($\neg q$). They are then told to select only those they must turn. Logically participants should select only the p and $\neg q$ cards. However, Figure 4, Panel A (Data), shows the results of a meta-analysis of selection task results (Oaksford and Chater 1994) showing clearly that the logical response does not occur. People generally select the p card alone of the more commonly the p and the q card.

This task was originally introduced into the literature as a task involving scientific inference to establish the truth of a general hypothesis (Wason and Johnson-Laird 1972). More recently, some authors have assumed that it is a purely deductive task. By assuming that that rule only applies to the four cards and not the unlimited domains of a scientific hypothesis (*all ravens are black* applies to all swans that have, do, and will exist), a purely deductive solution to this task is possible (e.g., Feeney and Handley 2000; Feeney, Handley, and Kentridge 2003; Handley, Feeney, and Harper 2002). Oaksford and Chater (1994, 1996, 1998c, 2003e) treated the task as it was originally introduced, as one of scientific hypothesis testing and their approach was in the spirit of recent Bayesian accounts of scientific inference in the philosophy of science (Earman 1992; Howson and Urbach 1989). As in the section on conditional inference, we first introduce the theory and then consider the evidence.

Theory

In the *information gain or optimal data selection* model⁶, people are assumed to select evidence (i.e., turn cards) to determine whether q depends on p , as in Table 1 in the section on conditional inference (the *dependence hypothesis*, H_D), or whether p and q are statistically independent (the *independence hypothesis*, H_I). Participants are looking for evidence that provides the most discrimination between these two hypotheses. Initially participants are maximally uncertain about which is true, that is, the prior

probabilities of H_D and H_I are .5. Participants' goal is to select evidence (turn cards) that would be expected to produce the greatest reduction in this uncertainty. This involves calculating the posterior probabilities of the hypotheses, H_D or H_I , being true given some evidence. These probabilities are calculated using Bayes' theorem which requires information about prior probabilities ($P(H_D) = P(H_I) = .5$) and the likelihoods of evidence given a hypothesis, e.g., the probability of finding an A when turning the 2 card assuming H_D ($P[A | 2, H_D]$). These likelihoods can be calculated directly from the contingency tables for each hypothesis: for H_D , Table 1, and for H_I , the independence model where the cell values are simply the products of the marginals. The expected reduction in uncertainty by turning any of the four cards can then be calculated.

A brief more formal explication can be presented by exploiting the equivalence between expected information gain and *mutual information* (Cover and Thomas 1991) noted by Oaksford and Chater (1996) and Hattori (2002). Hattori (1999, 2002) also proposed a logistic selection tendency function that maps this quantity into a probability that a card will be selected. Below we show the equation for the probability of checking ravens to assess their colour (i.e., turning the p card).

$$P(p \text{ card}) = \frac{1}{1 + e^{-2.37 + 9.06M(p)}}, \quad (10)$$

$$\text{where } M(p) = \frac{I(p)}{\sum_i I(x_i)}, \quad (11)$$

$$\text{and } I(p) = \sum_{ij} P(q_i, H_j | p) \log_2 \left(\frac{P(q_i, H_j | p)}{P(q_i | p)P(H_j | p)} \right) \quad (12)$$

(10) is the selection tendency function. The parameters 2.37 and 9.06 were derived from Hattori (1999). They provide the best fit between the expected information gains and the probability of selecting a card in a meta-analysis of past data. In (11) x_i ranges over the four cards in the task. $M(p)$ is consequently the proportion of the overall information gain available represented by checking a raven for its colour (i.e., turning the p card). (12) is the equation for expected mutual information. In (12) q_i ranges over the possible other sides of the p card, for example, whether a raven is black or some other colour, and H_j ranges over the two possible

Figure 3. The probabilities with which a card should be selected as a function of the probabilities of the antecedent ($P(p)$, x -axes) and the consequent ($P(q)$, y -axes) according to the revised information gain model. The lighter the region, the greater the probability that a card should be selected. These probabilities were calculated by transforming the information gains using a logistic selection tendency function. The prior probabilities ($P(M_I)$ and $P(M_D)$) were set to .5 and the exceptions parameter (ϵ) was set to .1. Points in the lower triangular region in black violate the assumptions of the dependence model that $P(q) > P(p)P(q|p)$.

hypotheses, H_D and H_I . With some rearrangement, the probabilities in (12) can all be calculated from Table 1 and the corresponding independence model.

We show the behaviour of the revised model in Figure 3. Each panel represents a card using a density plot with the probability of the antecedent ($P(p)$) on the x -axis and the probability of the consequent ($P(q)$) on the y -axis. The third dimension, shown by shading, corresponds to the probability that the card should be selected, $P(T_x)$; the lighter the shading the higher the probability that a card should be

selected. As in Oaksford and Chater's (1994) original model, the prior probabilities do not affect the ordering over the probabilities with which each card should be selected. So the prior probabilities were set to the same value, that is, $P(H_D) = P(H_I) = .5$. $P(q|p)$ was set to .9. Points in the lower triangular region in black violate the assumption of the dependence model that $P(q) > P(q|p)P(p)$. As Figure 3 shows, when the marginal probabilities $P(p)$ and $P(q)$ are small (the "rarity assumption"), the p and the q cards are expected to provide the greatest reduction in uncertainty about which hypothesis was

Figure 4. The probability that each card is selected in the standard selection task showing the fit of the optimal data selection model (Panel A) and mental models (Panel B).

true. Consequently, the selection of cards apparently demonstrating human irrationality may reflect a rational data selection strategy. Indeed in an environment where most properties are rare, this may be the optimal strategy (but see Klauer 1999; Laming 1996; Chater and Oaksford 1999c; see Oaksford and Chater 1996, for a reply).

The Evidence

Oaksford and Chater (1994) showed how the original model was consistent with a range of previously observed results. We will not review all this material again but concentrate in this section on briefly surveying the more recent evidence for the information gain or optimal data selection model.⁷

BASE-LINE RESULTS

The base-line results are shown in Figure 4 (data). Oaksford and Chater (2003e) fitted the model in (10)–(12) to these results. Figure 4, Panel A (Model) shows that the fit to the data was very good. Oaksford and Chater (2003e) also fitted the mental models theory to these data and the fits are shown in Panel B. The fits look comparable. However, the predicted values are means calculated from individual fits to the thirty-four studies in the meta-analysis. In fact, the mental models account was rejected as a model of these data as overall, that is, across all studies, it produced a significantly poorer fit than a saturated model.

Across the studies in Oaksford and Chater's (1994) meta-analysis, the mean value of the probability of the p card, $P(p)$, was .22 (SE = .019) and the mean value of the probability of the q card, $P(q)$, was .27 (SE = .022). These values were very close to the expected prior probability of a cause (.25) and of an effect (.27) found by Anderson (1990) when modeling

causal estimation tasks (Schustack and Stemberg 1981). It would seem that participants bring very similar prior expectations to bear in both tasks. This suggests that in the selection task, people by default adopt values for the probability of the antecedent and consequent which are analogous to their knowledge and causes and effects.

MATCHING BIAS

Evans' negations paradigm, which we met in the discussion of conditional inference, was originally used in the selection task (Evans and Lynch 1973). Exactly the same four rules are used – AA, AN, NA, and NN. Rules with a negated consequent: *if p, then ¬q*, and *if ¬p, then ¬q* produce selections more consistent with falsification (Evans 1983, 1984, 1989; Evans and Lynch 1973). Participants select more consequent cards that can make the rule false (i.e., false consequent, or FC, cards) than consequent cards that can make it true (i.e., true consequent, or TC, cards). For example, for the *if p, then ¬q* rule participants select the q card (FC). Evans (e.g., 1998) explains this finding by people "matching," that is, they display a *matching bias*. Participants ignore the negations and match the items named in the rule to the corresponding cards. Thus, no sudden insight into logic is required to explain why, for example, people select the falsifying q card for the *if p, then ¬q* rule. The cards that falsify or confirm vary between rules. So the convention has been adopted of referring to the cards using the labels: true antecedent (TA), false antecedent (FA), true consequent (TC) and false consequent (FC). For example, for the *if ¬p, then ¬q* rule, TA is the $¬p$ card, FA is the p card, TC is the $¬q$ card, and FC is the q card.

As for the conditional inference, Oaksford and Chater (1994; see also Oaksford

Figure 5. The probability that each card is selected in the negations paradigm selection task showing the fit of the optimal data selection model for, if p then q (Panel A), if p then not- q (Panel B), if not- p then q (Panel C), and if not- p then not- q (Panel D).

2002a) argued that these effects can be rationally explained by negations defining higher probability contrast classes (Oaksford and Stenning 1992). Recently, Oaksford and Chater (2003e) fitted the information gain model to a meta-analysis of results on the negations paradigm selection task and the fits are shown in Figure 5. They also fitted a mental models account of these results and found very similar fits. However, as Oaksford and Chater (2003b) argued, the information gain model explains why people behave as they do. In their normal environment where properties are rare, selecting confirming evidence is more likely to be informative. However, they are also sensitive to the fact that negations define higher probability contrast sets which alters the probabilities of the antecedent and consequent. So despite the change in logical status people are always looking for the rare evidence, that is, the p and q cards.

Yama (2001) pitted the matching bias explanation against the contrast class approach. He did this by using rules like *if p then q* and *if p then $\neg q$* where the q category was binary and related to the blood types, Rh+ and Rh-. People were told that one of these categories, Rh-, was rare. Therefore, by the contrast class account the rule *if p then $\neg Rh+$* should lead to selecting the rare Rh- card but according to matching they should select the Rh+ card: In four experiments, the predictions of optimal data selection and matching were confirmed, although as Oaksford (2002) argued there was most support for optimal data selection. In a recent experiment Oaksford and Moussakowski (2004) replicated Yama's (2001) Experiment 4, which provides most evidence for the matching account, but used a *natural sampling* method (see later) to convey the probability information. In this

experiment, the detailed predictions of the optimal data selection and contrast class account were strongly confirmed. Moreover, the model provided good fits to the data.

EVIDENCE FOR THE RARITY ASSUMPTION

The rarity assumption is a key element in the rational explanation of the selection task. Recently, it has been shown that rarity is the default when people are testing (Anderson and Sheu 1995; McKenzie and Mikkelsen 2000) or framing hypotheses (McKenzie, Ferreira, Mikkelsen, McDermott, and Skrable 2001). McKenzie and Mikkelsen (2000) showed that people regard rare evidence as more relevant to supporting a hypothesis than common evidence. So for example, logically both black ravens and non-black non-ravens (e.g., pink flamingos) confirm the hypothesis that *if it's a raven, then it's black*. However, people regard black ravens as more supportive of this hypothesis (see also Oaksford and Chater 1996). Moreover, rare observations were often selected even when they were not mentioned in the hypothesis.

It could be argued that people are simply matching the salient named items (see Evans 1998). However, McKenzie et al. (2001) showed that hypotheses are normally phrased in terms of rare events so that such a matching strategy is invariably the rational thing to do. They showed participants data about a group of students' SAT scores and whether these students were admitted to a select university. Only one student was admitted and this was the only student with a high SAT score. When asked to fill in a sentence frame describing this situation, "If ____, then ____, " participants strongly preferred the phrasing "if applicants have high SAT scores, they will be accepted" over "if applicants

have low SAT scores, they will be rejected" even though both are equally legitimate ways to complete the statement. Crucially, when given the information that most students were accepted, and that few applicants had low SAT scores, this finding reversed, that is, they now preferred the second phrasing. In both cases, participants preferred to frame a hypothesis in terms of rare rather than common events. In sum, the rarity assumption not only makes conceptual sense of the literature in the philosophy of science (see Mackie 1963; Oaksford and Chater 1996), it is also a part of people's normal expectations about the hypotheses they formulate and test about their everyday world.

EVIDENCE FOR INFORMATION GAIN

As Evans and Over (1996) pointed out there are many different measures of the informativeness of data to test a hypothesis other than information gain. Oaksford and Chater (1996) argued that information gain seemed to have some nice properties not shared with measures like diagnosticity; for example, it does not go to infinity as a type of evidence becomes unlikely and it extends naturally to the case in which there are more than two competing hypotheses. Recently, Nelson (2005) has tested a variety of putative data selection norms that have been appealed to in the psychological literature, including Bayesian diagnosticity (Evans and Over 1996; McKenzie and Mikkelsen in press), information gain (mutual information) (Oaksford and Chater 1994, 1996, 2003e; Hattori 2002), Kullback-Liebler distance (Klauer 1999; Oaksford and Chater 1996), probability gain (error minimization) (Baron 1981, 1985), and impact (absolute change) (Nickerson 1996).

Nelson used a combination of computer simulation and experiment to assess the theoretical and empirical adequacy of these norms. First, he showed that they disagree on the best data to select under certain circumstances. For example, diagnosticity differs from all the other sampling norms when the probabilities of evidence are very low and so diagnosticity approaches infinity. Nelson then took a range of cases where the norms differ on the ordering in the informativeness of data and conducted an experiment to see what order people would adopt. He found the strongest correlations with information gain (.78) and probability gain (.69) which is the same as impact (Nickerson 1996). Correlations with diagnosticity (-.22) and log diagnosticity (-.41) were actually *negative*, strongly contradicting the view

that people's data selection behaviour can be modelled using these norms, *pace*, for example, Evans and Over (1996). The agreement between information gain and impact mirrored Oaksford, Chater, and Grainger's (1999) experimental results on the selection task, which failed to discriminate between these measures while being able to reject the alternative measures proposed by Evans and Over (1996) and Klauer (1999).

MANIPULATING PROBABILITIES

Just as for conditional inference, the main prediction of the information gain model is that systematically varying $P(p)$ and $P(q)$ should also alter people's data selection behaviour in a way that mirrors the effects of negations. There has now accumulated a substantial body of evidence showing that probability manipulations do indeed have the predicted effects in the selection task (Green and Over 1997, 1998, 2000; Green, Over, and Pyne 1997; Hattori 1999, 2002; Kirby 1994; Oaksford, Chater, and Grainger 1999; Oaksford, Chater, Grainger, and Larkin 1997; Oaksford and Moussakowski 2003; Oaksford and Wakefield 2004; Yama 2001). This evidence is discussed in detail in Oaksford and Chater (2003e) and seems to support the view expressed by Green and Over (2000; 66) that "...no account of the selection task is sufficiently general if it cannot take account of the set size of p and the set size of q or the probability judgements which reflect these." That is, any explanation of the selection task must take a probabilistic approach like that embodied in the information gain model or the other probabilistic approaches to data selection suggested in the literature (Evans and Over 1996; Klauer 1999; Nickerson 1996; but see Nelson 2005).

However, there has been some evidence cited as being inconsistent with the optimal data selection account. Some of this evidence shows that more logiclike performance can arise without varying probabilities (Almor and Sloman 1996; Gebauer and Laming 1997; Moshman and Geil 1998; Osman and Laming 2001). Other evidence apparently reveals an effect not predicted by optimal data selection (Hardman 1998; Feeney and Handley 2000). Oaksford and Chater (1996) addressed some of these results. For example, the logical responses in Almor and Sloman (1996) occurred for rules expressing analytic truths, for example, "if a large object is stored then a large container must be used," for which evidence is irrelevant. It is part of the meaning of "large object" that if it is stored, a

large container must be used.⁸ As this has to be true there is no uncertainty to be reduced, so the optimal data selection account cannot apply. Oaksford and Chater (2003e) discuss most of the other cases and make similar observations.

Other experiments have attempted to explicitly manipulate probabilities and have failed to find effects (Feeney, Handley, and Kentridge 2003; Handley, Feeney, and Harper 2002; Oberauer, Wilhelm, and Diaz 1999; Oberauer, Weidenfeld, and Hörnig 2004). We outline several reasons why these data do not significantly challenge the optimal selection model.

First, and perhaps most important, these apparent failures to replicate have to confront the accumulated evidence, listed earlier, showing that probabilistic manipulations do affect data selection performance on Wason's task. Against this background, it is difficult to interpret failures to replicate like Oberauer, Wilhelm, and Diaz (1999), and Oberauer, Weidenfeld, and Hörnig (2004). Moreover, in none of these papers is a systematic attempt to explain away the experiments showing successful probability manipulations. It is all too easy not to find effects if your hypothesis is that they should not occur.

Second, Feeney and Handley's (2000) original experiments were only inconsistent with the original model presented in Oaksford and Chater (1994) in which the $\neg p$ card was always uninformative. However, Oaksford (2002b) showed that this card can be informative using the contingency table in Table 1 (introduced by Oaksford et al. 2000) and that this model provides very good fits to Feeney and Handley's (2000). Similarly, when Oaksford and Chater (2003e) fitted the model to the data from Oberauer et al.'s (1999) Experiment 1 they actually found very good fits.

Third, Handley et al. (2002) repeated these experiments and also manipulated $P(q)$. Feeney et al. (2003) also fitted the optimal data selection model to these data and showed poor fits. However, by the same standards adopted in Oaksford and Chater (2003e), the model could not be rejected for thirteen out of the eighteen conditions in Handley et al. (2002). Although when participants' estimates of $P(q)$ were used rather than allowing this to be a free parameter, the model could be rejected for all eighteen conditions. But as Oaksford and Wakefield (2003) and Over et al. (2005) have observed, estimates such as these need to be obtained more indirectly.

Fourth, Feeney and colleagues do not show that their own theory provided better fits to the

data. This runs counter to the standard logic of model fitting: the idea is to do better than the competition. Our original model fitting exercise responded to an explicit claim that optimal data selection couldn't explain Feeney and Handley's (2000) data and showed that it could. However, as they are advocating an alternative model, the burden of proof is on them to show that their model provides better fits.⁹

Fifth, there is recent evidence contradicting Feeney et al.'s main claim that variations in $\neg p$ card selections supports deductive processing in the selection task (Lucas and Ball 2005). They argue that this card is selected when participants assume a bi-conditional interpretation and infer there is $\neg q$ on the other side. So given the rule *if A then 2* participants who turn the *L* card infer that the hidden face is, for example, a 7. However, they are then told that *if L then 2*, and now they tend not to turn this card because they now know that there is very likely to be a 2 on the other side, that is, they now know that the presence of an A is not necessary for there to be a 2 on the other side. This explanation means that people select this card because they contemplate that the hidden side should be a number that does not match the number in the rule, that is, a number other than 2. However, using protocol analysis, Lucas and Ball (2005) found that for all selected cards the hidden sides participants mention match those stated in the rule. So rather than consider the 7 on the hidden face, as Feeney and Handley (2000; Handley et al. 2002; Feeney et al. 2003) predict, they consider the 2. Lucas and Ball (2005) observe that this "secondary matching" effect (Wason and Evans 1975) is inconsistent with Feeney and Handley (2000), but that it is consistent with the optimal data selection model because it predicts that people should seek the rare cases, which are always the matching cases.

Finally, it would be premature to speculate further on what Feeney and colleagues' experiments reveal about human reasoning, partly because some of the probability manipulations also seemed to be particularly weak. This was also a criticism made by Oaksford and Wakefield (2003) of some experiments reported by Oberauer, Wilhelm, and Diaz (1999). Oaksford and Wakefield (2003; see also Oaksford and Moussakowski 2004) used the same materials as Oberauer et al.'s (1999) Experiment 3 but provided probability information via "natural sampling," which should lead to a stronger probability manipulation (Gigerenzer and Hoffrage,

1995). Participants were shown forty cards one at a time. The proportion of p , $\neg p$, q , and $\neg q$ cards reflected the probability information. Strong probability effects were observed. Probability estimates were also obtained from participants *indirectly*. They classified fifty cards “drawn” from the pack into the four possible card types: p and q , p and $\neg q$, $\neg p$ and q , and $\neg p$ and $\neg q$ (see also Over et al. 2005). These were used to provide parameter free fits to the selection task data, which were very good. The indirect estimates overestimated the low probabilities and underestimated the high probabilities mirroring a π -function (Kahneman and Tversky 1979) relating the experimentally given probabilities to the best-fit estimates. Critically, Oaksford and Wakefield (2003) confirmed a unique prediction of the model that for the HH rule in this experiment, the $\neg p$ card should be selected more than the q card.¹⁰

Syllogistic Reasoning

The probabilistic approach has also been extended to syllogistic reasoning, for example, *Some of the artists are beekeepers, All the beekeepers are chemists*, therefore, *Some of the artists are chemists*. As before, we start with the theory which Chater and Oaksford (1999) called the *probability heuristics model* (PHM).

Theory

In the probability heuristics model (Chater and Oaksford, 1999a), PHM, the probabilistic interpretation of conditionals is extended to quantified claims: *All*, *Some*, *None*, and *Some . . . not*. In Table 1, if there are no exceptions, then the probability of the consequent given the antecedent, $P[q|p]$, is 1. The conditional and the universal quantifier *All* have the same underlying logical form: $\forall x(\text{if } P(x) \text{ then } Q(x))$. Consequently, universal claims such *All Ps are Qs*, were interpreted as asserting that the probability of the predicate term (Q) given the subject term (P) is 1, that is, $P(Q|P) = 1$. Probabilistic meanings for the other quantifiers are then easily defined: *None*, $P(Q|P) = 0$; *Some*, $P(Q|P) > 0$; *Some . . . not*, $P(Q|P) < 1$. Given these probabilistic interpretations it is possible to prove what conclusions follow probabilistically for all sixty-four syllogisms (i.e., which syllogisms are “ p -valid”).

Moreover, given these interpretations and again making the rarity assumption (see earlier,

on the selection task), the quantifiers can be ordered in terms of how *informative* they are: *All* > *Some* > *None* > *Some . . . not*. A quantified statement is informative to extent that it is surprising, that is, its probability is low. Basic level natural language categories usually only refer to a small subset of objects. So if two predicates were selected at random it is rarely the case that they cross classify an object. For example, “table” and “toupees” never apply to the same object. Consequently the statement most likely to be true of an object given two randomly selected predicates X and Y is that *No X are Y*. The rarest case is when *All X are Y*, which is therefore the most informative. Moreover as long as the probability of *No X are Y* is less than .5, *Some . . . not* is the least informative.

A simple set of heuristics defined over the informativeness of the premises can successfully predict the p -valid conclusion if there is one.

There are three generation heuristics in the PHM:

(G1) The *min*-heuristic: Choose the quantifier of the conclusion to be the same as the quantifier in the least informative premise (the *min*-premise).

The most informative conclusions that can validly follow almost always follow this rule. Some conclusions probabilistically entail (“ p -entail”) other conclusions. For example, if *All X are Y*, then it is probable that *Some X are Y* (this will follow as long as there are some Xs). Thus the second heuristic is:

(G2) P -entailments: The next most preferred conclusion will be the p -entailment of the conclusion predicted by the *min*-heuristic (the “*min*-conclusion”).

Heuristics (G1) and (G2) specify the quantifier of the conclusion. The third heuristic, the *attachment*-heuristic, specifies the order of end terms in the conclusion:

(G3) *Attachment*-heuristic: If just one of the possible conclusion subject noun phrases matches the subject noun phrase of just one premise, then the conclusion has that subject noun phrase¹.

Where subject noun is: *All X, All Z, Some X, Some Z*, etc. Crucially, *Some X are not Z* and *Some X are Z* have the *same* subject noun phrase “*Some X*.” We illustrate these heuristics with an example (where “_” stands as a place holder for

a subject of predicate term in the mental representation of the putative conclusion):

All Y are X	(<i>min</i> -premise)
Some Z are Y	(<i>max</i> -premise)
Some _ are _	(by <i>min</i>)
Some Z are X	(by <i>attachment</i>)
Some _ are not _	(by <i>p</i> -entailment)
Some Z are not X	(by <i>attachment</i>)

By the *min*-heuristic, the conclusion is *Some*. The *min*-premise has an end term (Z) as its subject. Therefore, by *attachment*, the conclusion will have Z as its subject term, and the form *Some Z are X*. The *p*-entailment of the *min*-conclusion is *Some Z are not X* which is predicted to be the next most endorsed conclusion.

G1–G3 generate syllogistic conclusions. It is assumed that people are rarely able to test these conclusions for *p*-validity (or, for that matter, logical validity). However, it is argued that people employ two test heuristics that provide a fast and frugal estimate of how likely the conclusion generated by G1–G3 is to be informative and *p*-valid (Chater and Oaksford 1999a):

- (T1) The *max*-heuristic: Be confident in the conclusion generated by G1–G3 in proportion to the informativeness of the most informative premise (the *max*-premise).
- (T2) The *Some...not*-heuristic: Avoid producing or accepting *Some...not* conclusions, because they are so uninformative relative to other conclusions.

The most important heuristic is the *min*-heuristic, which states that the conclusion will have the form of the least informative premise. So for example, a *p*-valid syllogism such as, *All B are A, Some B are not C*, yields the conclusion *Some A are not C*. This simple heuristic captures the form of the conclusion for most *p*-valid syllogisms. Moreover, if over-generalised to the invalid syllogisms, the conclusions it suggests match the empirical data very well.

The most important feature of PHM is that it can generalise to syllogisms containing quantifiers such as *Most* and *Few* that have no logical interpretation. In terms of Table 1 these quantifiers are used when there are some (*Most*) or many (*Few*) exceptions. So the meaning of *Most* is: $1 - \Delta < P(Q|P) < 1$, and the meaning of *Few* is: $0 < P(Q|P) < \Delta$, where Δ is small. These interpretations lead to the following order of informativeness: *All* > *Most* > *Few* > *Some* > *None* > *Some...not*. Consequently,

PHM uniquely makes predictions for the 144 syllogisms that are produced when *Most* and *Few* are combined with the standard logical quantifiers. Chater and Oaksford (1999) showed that these heuristics pick out the *p*-valid conclusions for these new syllogisms, and they report experiments confirming the predictions of PHM when *Most* and *Few* are used in syllogistic arguments.

The Evidence

For syllogisms, the base-line results are provided by the previous research carried out with the standard logical quantifiers, *All*, *Some*, *Some-not*, and *None*. We discuss these data first before moving on to how the model generalises to *Most* and *Few*. We then look at work on informativeness orders (Oaksford, Roberts, and Chater 2002) and other data PMH can explain on strong and weak possible conclusions. As before we discuss other data claimed to be inconsistent with the model.

BASE-LINE DATA

Table 2 shows the results of a meta-analysis showing the weighted average of correct responses to the logically valid syllogisms in all the studies using all sixty-four syllogisms that had been published up until then (Dickstein 1978; Johnson-Laird and Bara 1984; Johnson-Laird and Steedman 1978). The pairs, for example, (X,Z), in the syllogistic premises are ordered to show their status as the subject (first) or the predicate (second) term. The logically valid conclusion and the number of mental models required to reach that conclusion are also shown.

These data reveal how the heuristics of PHM can explain the data. Note that all the syllogisms above the double line are drawn more often than all those below it (with one exception). Moreover, all the syllogisms above the single line are drawn more often than all of those below it. All the syllogisms above the double line conform perfectly to the *min*-heuristic (G1), those below, although not violating the *min*-heuristic (the conclusion is *less* informative than the *min*-conclusion), do not conform to it. All those syllogisms that are below the single line only have a very uninformative *Some...not* conclusion (T2) and interestingly this conclusion is drawn only as often as *None* which is the *min*-conclusion. Moreover, *Some...not* is a *p*-entailment of *None* (G2). Finally, all those syllogisms above the double line also have very uninformative *max*-premises (T1). Thus it would seem that

Table 2: Meta-Analysis of the Logically Valid Syllogisms Showing the Form of the Conclusion, the Number of Mental Models Needed to Reach that Conclusion, and the Percentage of Times the Valid Conclusion was Drawn in Each of the Five Experiments Analyzed by Chater and Oaksford (1995)

<i>Syllogism</i>	<i>Conc.</i>	<i>MMS</i>	<i>Mean</i>
<i>All</i> (Y,X), <i>All</i> (Z,Y)	<i>All</i>	1	89.87
<i>All</i> (X,Y), <i>All</i> (Y,Z)	<i>All</i>	1	75.32
<i>All</i> (Y,X), <i>Some</i> (Z,Y)	<i>Some</i>	1	86.71
<i>Some</i> (Y,X), <i>All</i> (Y,Z)	<i>Some</i>	1	87.97
<i>All</i> (Y,X), <i>Some</i> (Y,Z)	<i>Some</i>	1	88.61
<i>Some</i> (X,Y), <i>All</i> (Y,Z)	<i>Some</i>	1	86.71
<i>No</i> (Y,X), <i>All</i> (Z,Y)	<i>No</i>	1	92.41
<i>All</i> (X,Y), <i>No</i> (Z,Y)	<i>No</i>	1	84.81
<i>No</i> (X,Y), <i>All</i> (Z,Y)	<i>No</i>	1	88.61
<i>All</i> (X,Y), <i>No</i> (Y,Z)	<i>No</i>	1	91.14
<i>All</i> (X,Y), <i>Some...not</i> (Z,Y)	<i>Some...not</i>	2	67.09
<i>Some...not</i> (X,Y), <i>All</i> (Z,Y)	<i>Some...not</i>	2	56.33
<i>All</i> (Y,X), <i>Some...not</i> (Y,Z)	<i>Some...not</i>	2	66.46
<i>Some...not</i> (Y,X), <i>All</i> (Y,Z)	<i>Some...not</i>	2	68.99
<i>Some</i> (Y,X), <i>No</i> (Z,Y)	<i>Some...not</i>	3	16.46
<i>No</i> (Y,X), <i>Some</i> (Z,Y)	<i>Some...not</i>	3	66.46
<i>Some</i> (X,Y), <i>No</i> (Z,Y)	<i>Some...not</i>	3	30.38
<i>No</i> (X,Y), <i>Some</i> (Z,Y)	<i>Some...not</i>	3	51.90
<i>Some</i> (Y,X), <i>No</i> (Y,Z)	<i>Some...not</i>	3	32.91
<i>No</i> (Y,X), <i>Some</i> (Y,Z)	<i>Some...not</i>	3	48.10
<i>Some</i> (X,Y), <i>No</i> (Y,Z)	<i>Some...not</i>	3	44.30
<i>No</i> (X,Y), <i>Some</i> (Y,Z)	<i>Some...not</i>	3	26.58

Note. The means in the final column are weighted by sample size.

a set of very simple heuristics defined over the informativeness of the premises can explain the differences in performance for the logically valid syllogisms.

GENERALISED QUANTIFIERS

Chater and Oaksford also conducted two experiments where they introduced the generalised quantifiers *Most* and *Few* into syllogistic arguments with the other logical quantifiers. In their Experiment 1 they used the quantifiers, *All*, *Most*, *Few*, and *Some...not* and in their Experiment 2 they used the quantifiers, *Most*, *Few*, *Some*, and *None*. No other theory of syllogistic reasoning task performance makes any predictions for the extra 80 syllogisms introduced by this manipulation. However, PHM predicts business as usual, that is, given the informational ordering, *All* > *Most* > *Few* > *Some* > *None* > *Some...not*, participants should simply apply the heuristics as we have seen they do for the logical quantifiers. The results of Chater and Oaksford (1999) confirmed these predictions. For each syllogism type the modal response is that predicted by the *min*-heuristic and the next

most frequent response is its *p*-entailment(s). So for example, for *All-Few* the modal response was *Few* and the next most frequent response was *Some...not*. Moreover, for *All...Some...not*, the weak *p*-entailments¹¹ of *Some...not*, *most* and *few*, are both endorsed more frequently than *All*. This pattern confirms the predictions of PHM's probabilistic semantics for the generalised quantifiers. These experiments show that PHM applies successfully across all 144 possible syllogisms involving the quantifiers, *All*, *Most*, *Few*, *Some*, *None*, *Some...not* (although not with all possible conclusion types). The uniform pattern in these data across the generalized and the standard logical quantifiers challenges other theories of syllogistic reasoning, which currently apply only to the logical quantifiers, to generalize to these data.

INFORMATIVENESS ORDERS

Some of the results of Chater and Oaksford's (1999) experiments were unexpected from the perspective of their theory. In particular the results seemed to question a core assumption of the model concerning the ordering in the

informativeness of the quantifiers. For example, for *Few-Some . . . not* (*Some . . . not-Few*) syllogisms, the *min*-heuristic predicts a *Some . . . not* conclusion. However, in Chater and Oaksford's Experiment 1 there was no significant difference in mean percentage endorsements of *Few* and *Some . . . not*, although they were both endorsed significantly more often than the other possible response. Moreover, for *Few-Some* (*Some-Few*) syllogisms, the *min*-heuristic predicts a *Some* conclusion. However, in Chater and Oaksford's Experiment 2 there was no significant difference in mean percentage endorsements of *Few* and *Some*, although they were both endorsed significantly more often than the other possible response options. These results suggest that in Chater and Oaksford's Experiment 1, *Few* was regarded as having the same informativeness as *Some . . . not*, whereas in their Experiment 2, *Few* was regarded as having the same informativeness as *Some*.

Oaksford, Roberts, and Chater (2002) address this apparent discrepancy. By appeal to the pragmatics literature (Moxey and Sanford 1987, 1993), they argued that *few* is ambiguous and that given the different range of quantifiers available in each of the experiments in Chater and Oaksford (1999) a different interpretation would have dominated in each experiment. Oaksford et al. (2002) conducted a series of experiments to see if under the probabilistic interpretations assigned to each version of *few* they could emulate Chater and Oaksford's (1999) results. Their experiments permitted them to calculate the informativeness of each quantifier for each participant, so they could compare the informativeness of the two versions of *few* with *some* and *some-not*. Under the appropriate interpretation one version of *few* did not differ significantly from *some* and the other did not differ significantly from *some-not*. Consequently, some minor revision of the model is required to take into account the two possible interpretations of *few* but this serves only to improve the fit to the data.

STRONG AND WEAK POSSIBLE CONCLUSIONS

The *min*-heuristic captures the novel distinction between strong and weak possible conclusions (Evans, Handley, Harper, and Johnson-Laird 1999). Take the syllogism *All Y are X*, *Some Z are Y*. The conclusion *Some Z are X*, follows *necessarily* from these premises; *No Z are X*, is *impossible*; but *Some Z are not X* and *All Z are X* are *possible*. Some possible conclusions are endorsed as strongly as necessary con-

clusions (e.g., *Some Z are not X*) and some are endorsed as weakly as impossible conclusions (e.g., *All Z are X*). Possible strong conclusions all conform to the *min*-heuristic, that is, they either match the *min*-premise or are less informative than the *min*-premise. Possible weak conclusions all violate the *min*-heuristic (bar one), that is, they have conclusions that are more informative than the *min*-premise. Mental models theory may explain this result. Strong possible conclusions are licensed in the initial model but not in subsequent models. Weak possible conclusions are licensed only in noninitial models. This means that the conclusions recommended by the *min*-heuristic correspond to those licensed by initial mental models. This is an interesting coincidence as neither theory was constructed with the distinction between strong and weak possible conclusions in mind. However, it is unclear why mental models licenses these initial models. The only suggestion is that it is an "emergent property" of the computer program embodying the mental models theory. But no account of the principles underlying initial model construction that can explain why this property emerges has been forthcoming.

ALTERNATIVE CONCLUSIONS

In a series of experiments designed to test the claim that syllogism difficulty is determined by the number of alternative mental models constructed, Newstead, Handley, and Buck (1999) found evidence consistent with PHM. Participants were asked to indicate the alternative conclusions they considered for different syllogisms or were asked to draw diagrams consistent with the premises. According to mental models theory more alternative conclusions and more diagrams should be produced for multiple model syllogisms than for single model syllogisms. However, Newstead et al. found no relationship between the number of models a syllogism requires for its solution and the number of conclusions or diagrams participants produced. This is consistent with PHM where it is argued that test procedures are rarely invoked. In all Newstead et al.'s experiments, participants' responses also agreed with those predicted by the *min*- and *attachment*-heuristics. Furthermore, according to PHM there should be no differences in task difficulty dependent on figure, a prediction that is inconsistent with mental models theory. Consistent with PHM, in two of Newstead's et al.'s experiments where figure was an independent variable, they found no effect of figure on syllogism difficulty. As they point out,

their findings clearly favour PHM over mental models.

However, Newstead et al. (1999) argue that some other aspects of their results sit less well with PHM. We look at what we consider the most important here and refer the reader to Oaksford and Chater (in press) for further discussion. Newstead et al. argue that PHM predicts that people would consider more conclusions when they are less confident in the *min*-conclusion. Consequently, they argue there should be a linear trend in the number of alternative conclusions considered such that $All < Some < Some-not \approx None$. However, they found no such result. We are unsure how Newstead et al. derived this prediction. The only way that PHM allows alternative conclusions to be generated is via *p*-entailments. However, in modelling the data from their meta-analysis, Chater and Oaksford (1999) argued that *p*-entailments were endorsed in a fixed proportion across all syllogisms. In their meta-analysis, this proportion was .09. Thus, for each *max*-premise type, PHM predicts one conclusion predicted by the *min*-heuristic to be considered plus this small proportion of *p*-entailments, leading to approximately 1.09 conclusions considered. For *All max*-premise type syllogisms Newstead et al. observed an average of 1.05 and for the other *max*-premise type syllogisms they observed an average of 1.13. Thus their findings seem completely consistent with PHM.

WORKING MEMORY AND SYLLOGISTIC REASONING

Copeland and Radvansky (2004) have recently observed that there have been few experiments directly relating memory span measures to syllogistic reasoning performance. They therefore took a variety of working memory span measures and then had participants perform a computerised version of the standard syllogistic reasoning task. They also compared the predictions of the mental models theory and PHM. PHM makes similar predictions to mental models theory because it too can account for the difference in accuracy on the 1-, 2-, and 3-model syllogisms. Getting the valid conclusion requires the use of different numbers of heuristics. For 1-model syllogisms, just the *min*-heuristic and attachment is required. For 2-model syllogisms, the *min*-heuristic, attachment and the *Some...not*-heuristic are invoked (because the conclusion is always *some...not*, so the *some...not*-heuristic is invoked, leading to fewer correct selections).¹² For 3-model syl-

logisms, a *p*-entailment has to be drawn, the *min*-heuristic and attachment applied and the *some-not*-heuristic invoked. Thus, for 1-model syllogisms two heuristics are invoked, for 2-model syllogisms three are invoked, and for 3-model syllogisms four are invoked. The generation heuristics operate over a mental representation of the premises to generate a conclusion, the test heuristics determine confidence that will be related to RTs. The more mental operations that need to be performed the more complex the inference. People with high IQs are likely to be better at more complex processes and WM span and IQ are highly correlated. Thus, it seems that the analyses in terms of the number mental models are consistent with PHM.

Consistent with this analysis Copeland and Radvansky (2004) found significant correlations between working memory span and strategy use for both mental models and PHM. Moreover there were no differences between mental models and PHM on the percentage of responses made that agreed with the predictions of each model. Consequently, although these data did not discriminate between theories, they confirmed the predictions that each theory independently makes for the complexity of syllogistic reasoning and its relation to working memory span.

ACTIVATION OF END TERMS

As with conditional inference and data selection, there have also been some work that it is claimed is not consistent with PHM. Here we consider some experiments by Espino, Santamaria, and Garcia-Madruga (2000). They reported the results of studies investigating the time to respond to a probe word that has or has not occurred in the premises of a syllogistic argument. They derived predictions from mental models theory that they compared to the predictions of the other leading theories in this area including PHM. In their Experiments 2 to 5, they claimed to have found conclusive evidence for the mental models account of syllogistic reasoning and against all these contenders.

We focus on one of their results (more discussion can be found in Oaksford 2001). In their Experiments 2 to 4, Espino et al. found that for Figure 4 syllogisms (e.g., *All the X are Y, All the Y are Z*) responses were faster when the end term *Z* was used as the probe than when the end term *X* was used as the probe. However, this reversed for Figure 1 syllogisms (e.g., *All the Y are X, All the Z are Y*). Espino et al. argued that this finding is consistent with mental models theory

because the end term responded to the fastest is the last item in the mental model. In theories of language comprehension, the last mentioned item in an integrated representation of a multicausal sentence is the most active because this item is where further information must be attached. Espino et al. argued that PHM makes the opposite prediction because the *attachment*-heuristic, determining the order of end terms in the conclusion, must attach to the end term in subject position, that is, X for Figure 4 and Z for Figure 1.

Espino et al. assumed that the heuristics of PHM are applied to the premises during the comprehension stage. The heuristics of PHM operate over representations of the premises (see Chater and Oaksford 1999a: 236) to build a representation of the conclusion. For example, take the Figure 4 syllogism, All the X are Y, All the Y are Z, the *min*-heuristic selects the frame "All _ are _" as the form of the conclusion with place holders for the end terms. The *attachment*-heuristic selects the subject term of the *min*-premise (as long as it is an end term) as the subject term of the conclusion: All X are _. This representation is incomplete. The final operation is to place the other end term in the remaining place holder: All X are Z. That is, the last item to enter the representation in Figure 4 is Z. Consequently, consistent with existing accounts of language comprehension, PHM makes exactly the same predictions as mental models. Therefore, PHM is consistent with Espino et al.'s most robust finding.

DISPELLING THE ATMOSPHERE EFFECT

Shaw and Johnson-Laird (1998) provide evidence and arguments that they take to conclusively dispel accounts of syllogistic reasoning like PHM which argue that the conclusion will be affected by the surface form of the premises. The first such account was called the "atmosphere effect," which has two parts. First, if one or both premises are negative (*None* or *Some . . . not*), the conclusion should be negative, otherwise it is positive (*All* or *Some*). Second, if one or both premises are particular (*Some* or *Some . . . not*), then the conclusion will be particular, otherwise it is universal (*All* or *None*).

Shaw and Johnson-Laird (1998) argue that some conclusions do not fit any form of the atmosphere effect. For example, in Johnson-Laird and Steedman (1978), the most frequent response to the *All-None*[3] syllogism was *Some X are not Z*. This conclusion does not violate the *min*-heuristic because this conclusion is less

informative than the *min*-conclusion (*None*). This point is an example of picking the result to suit the argument. Although *Some . . . not* was the most frequent response to this syllogism in Johnson-Laird and Steedman (1978), in Chater and Oaksford's (1999) meta-analysis (which included this study), the *None* conclusion, licensed by the *min*-heuristic, was endorsed by 61.39% of participants versus only 13.29% who endorsed *Some . . . not*. Consequently, this finding does not question PHM.

Shaw and Johnson-Laird also argued that for every syllogism there is a conclusion that is consistent with atmosphere and so, counter-evidentially, there should be no "no valid conclusion" responses. However, according to the *max*-heuristic, this response will be more likely as the informativeness of the *max*-premise decreases. So PHM does predict "no valid conclusion" responses. Shaw and Johnson-Laird also report an experiment on multiply quantified sentences apparently showing that responses matching one of the premises reduce for multiple model syllogisms. They argue that an initial model is always generated where a conclusion can be read off that matches one of the premises, that is, there is a conclusion consistent with the *min*-heuristic. This conclusion can not be refuted in one-model syllogisms but it can be in multiple model syllogisms where people can seek alternative models. However, the balance of evidence (Evans et al. 1999; Klauer, Musch, and Naumer 2000; Newstead et al. 1999; Schroyens, Schaeken, Fias, and d'Ydewalle 2000) indicates that people rarely construct more than one model, which renders this explanation improbable. PHM explains these results in terms of multiple model syllogisms leading to less informative conclusions, and consequently an increase in no valid conclusion responses. In sum, Shaw and Johnson-Laird's attempt to dispel the atmosphere hypothesis may succeed but it does nothing to dispel PHM.

Argumentation and the Fallacies

Reasoning typically takes place in the service of argumentation, i.e., the attempt to persuade yourself or others of a particular, perhaps controversial, position (van Eemeren and Grootendorst 1992). Argumentation is the overarching human activity that studies of deductive reasoning, inductive reasoning, judgment and decision making are really required to explain. So one might attempt to persuade someone else to accept a controversial standpoint *p* by

trying to persuade them that p is actually a logical consequence of their prior beliefs or current commitments; or that p has strong inductive support; or, where p is an action, that p will help to achieve their current goals. By extending the probabilistic approach to at least some aspects of argumentation, we hope to show that it can generalize beyond the narrow confines of most current psychology of reasoning to the real human activity of which deduction, induction and decision making are but a small part.

Fallacies, or arguments that seem correct but aren't, for example, DA and AC, have been a longstanding focus of debate. Catalogues of reasoning and argumentation fallacies originate with Aristotle and populate books on logic and informal reasoning to this day. The classic tool brought to the analysis of fallacies such as the argument from ignorance is formal logic and it is widely acknowledged to have failed in providing a satisfactory account. Testament to this is the fact that fallacies figure in logic textbooks under the header of "informal reasoning fallacies" (see, e.g., Hamblin 1970) – an acknowledgment of the inability to provide a sufficient formal logical treatment. In particular, logical accounts have proved unable to capture the seeming exceptions to fallacies that arise with simple changes in content that leave the structure of the argument unaffected. This suggests that either it is not formal aspects of fallacies that make them fallacious, or else that the relevant formal aspects are not being tapped into by classical logics.

Oaksford and Hahn (2004; see also Hahn and Oaksford; 2006, 2007; Hahn, Oaksford, and Bayinder 2005; Hahn, Oaksford, and Corner 2005) provide evidence of such variation and put forward an alternative, Bayesian account: Individual arguments are composed of a conclusion and premises expressing evidence for that conclusion. Both conclusion and premises have associated probabilities which are viewed as expressions of subjective degrees of belief. Bayes' theorem then provides an update rule for the degree of belief associated with the conclusion in light of the evidence. *Argument strength*, then, on this account is a function of the degree of prior conviction, the probability of evidence, and the relationship between the claim and the evidence, in particular how much more likely the evidence would be if the claim were true. That is, different instances of argumentative fallacies may vary in argument strength conceived of as the probability of the conclusion given the premises. Oaksford and Hahn (2007) also show how the concept of argument strength in argumentation is

related to the probabilistic analysis of the conditional (see above) and recent discussion in Rips (2001). We now illustrate this approach by appeal to a particular informal reasoning fallacy: the argument from ignorance.

Theory: The Argument from Ignorance

A classic informal argument fallacy, which dates back to John Locke, is the so-called argument from ignorance, or *argumentum ad ignorantiam*.

Ghosts exist, because nobody has proven that they don't. (13)

This argument does indeed seem weak. One would hesitate in positing the existence of all manner of things whose non-existence simply had not been proven, whether these be UFOs or flying pigs with purple stripes. However, is it really the general structure of this argument that makes it weak, and if so what aspect of it is responsible? Other arguments from negative evidence are routine in scientific and everyday discourse and seem perfectly acceptable:

This drug is safe, because no-one has found any toxic effects. (14)

Should all arguments from negative evidence be avoided, or can a systematic difference between the two examples be recognized and explained?

A Bayesian account can capture the difference between (13) and (14) as we show below. Moreover, it can capture the difference between positive and negative evidence which allows one to capture the intuition that the positive argument (15) is stronger than the negative argument (16):¹³

Drug A is toxic because a toxic effect was observed (positive argument) (15)

Drug A is not toxic because no toxic effects were observed (negative argument, i.e., the argument from ignorance). (16)

Although (16), too, can be acceptable where a legitimate test has been performed, that is,

If drug A were toxic, it would produce toxic effects in legitimate tests.

Drug A has not produced toxic effects in such tests

Therefore, A is not toxic

Demonstrating the relevance of Bayesian inference for negative vs. positive arguments involves defining the conditions for a legitimate

test. Let e stand for an experiment in which a toxic effect is observed and $\neg e$ stands for an experiment where a toxic effect is not observed; likewise let T stand for the hypothesis that the drug produces a toxic effect and $\neg T$ stand for the alternative hypothesis that the drug does not produce toxic effects. The strength of the argument from ignorance is given by the conditional probability that the hypothesis, T , is false given that a negative test result, $\neg e$, is found, $P(\neg T | \neg e)$. This probability is referred to as negative test validity. The strength of the argument we wish to compare with the argument from ignorance is given by positive test validity, that is, the probability that the hypothesis, T , is true given that a positive test result, e , is found, $P(T | e)$. These probabilities can be calculated from the sensitivity ($P(e | T)$) and the selectivity ($P(\neg e | \neg T)$) of the test and the prior belief that T is true ($P(T)$) using Bayes's theorem. Let n denote sensitivity, that is, $n = P(e | T)$, l denote selectivity, that is, $l = P(\neg e | \neg T)$, and h denote the prior probability of drug A being toxic, that is, $h = P(T)$, then,

$$p(T | e) = \frac{nh}{nh + (1-l)(1-h)} \quad (17)$$

$$p(\neg T | \neg e) = \frac{l(1-h)}{l(1-h) + (1-n)h} \quad (18)$$

Sensitivity corresponds to the "hit rate" of the test and 1 minus the selectivity corresponds to the "false positive rate."

Positive test validity is greater than negative test validity as long as the following inequality holds:

$$h^2(n - n^2) > (1 - h)^2(l - l^2) \quad (19)$$

Assuming maximal uncertainty about the toxicity of drug A , that is, $P(T) = .5 = h$, this means that positive test validity, $P(T | e)$, is greater than negative test validity, $P(\neg T | \neg e)$, when selectivity (l) is higher than sensitivity. As Oaksford and Hahn (2004) argue this is often a condition met in practice for a variety of clinical and psychological tests. Therefore, in a variety of settings, positive arguments are stronger than negative arguments.

The Evidence

Oaksford and Hahn (2004) also provide experimental evidence to the effect that positive arguments such as (15) are indeed viewed as

more convincing than their negative counterparts under the conditions just described. The evidence from their experiment further shows that people are sensitive to manipulations in the amount of evidence (one versus fifty studies or tests) as predicted by the account. Finally, participants' in their experiment displayed sensitivity to the degree of prior belief a character in a dialogue initially displayed toward the conclusion as the Bayesian account predicts. This finding captures the "audience dependence" of argumentation assumed in the rhetorical research tradition (e.g., Perelman and Olbrechts-Tyteca 1969).

Hahn, Oaksford, and Bayindir (2005) generalized this account to other versions of the argument from ignorance and addressed an outstanding problem. The ghosts example (20) differs from Oaksford and Hahn's (2004) experimental materials in one, possibly important way. The argument for ghosts not only involves negative evidence, but also a flip in polarity between evidence and conclusion: Negative evidence is provided to support the *positive* existence of something. In other words, the inference is of the form:

$$\text{not proven (not exist)} \rightarrow \text{exist} \quad (20)$$

as opposed to merely:

$$\text{not proven (exist)} \rightarrow \text{not exist} \quad (21)$$

The examples in Oaksford and Hahn (2004) have the structure in (21) not the structure in (20). But it may be the opposite polarity case (20) that constitutes the true fallacy of the argument from ignorance.

Classical logic licenses an inference from $\text{not(not } p)$ to p , but not the inference underlying (20) which might be rendered as:

$$\text{not says (not } p) \rightarrow ? \quad (22)$$

This is because when one has not said "not p ," one can either have said " p " or not spoken about " p " at all. For example, in an argument one might defend oneself with the claim "I didn't say you were rude," which could be true either because one had specifically claimed the opposite or because one had not mentioned rudeness at all. So maybe nothing at all can be inferred in such cases?

Hahn, Oaksford, and Bayindir (2005) established that (22) can be a strong argument by using a form of the argument from ignorance based on *epistemic closure* which is related to the negation as failure procedure in artificial intelligence (Clark 1978). The case can be made with

an informal example: imagine your work colleagues are having a staff picnic. You ask the picnic organizer whether your colleague Smith is coming and receive the reply that "Smith hasn't said that he's not coming." Should this allow you to infer that he is in fact coming, or has he simply failed to send the required reply by e-mail? Your confidence that Smith will be attending will vary depending on the number of people that have replied. If you are told that no one has replied so far, assuming Smith's attendance seems premature; if by contrast you are told that everyone has replied, you would be assured of his presence. In between these two extremes your degree of confidence will be scaled: the more people have replied the more confident you will be. In other words, the epistemic closure of the database in question (the e-mail inbox of the organizer) can vary from no closure whatsoever to complete closure, giving rise to corresponding changes in the probability that *not says (not p)* does in fact suggest that *p*.

Hahn, Oaksford, and Bayindir's (2005) experiments confirmed that people are sensitive to variations in the epistemic closure of a database and that this affects their willingness to endorse argument like (22). Moreover, they found that arguments like (22) can be regarded as stronger than the standard negative evidence case (21). Therefore, as our example suggested, there would seem to be nothing in the structure of arguments like the Ghosts example that make them inherently unacceptable.

The real reasons why negative evidence on ghosts is weak, that is, why (13) is a weaker argument than (14), are the lack of sensitivity (ability to detect ghosts) of our tests as well as our low prior belief in their existence, that is, (13) is weak because of the probabilistic factors that affect the strength of the argument. Hahn and Oaksford (2006, 2007) have shown how this account generalises to other inferential fallacies, such as *circularity* and the *slippery slope* argument.

In summary, in this section we have shown how the concept of argument strength can resolve the problem of why some instances of informal argument fallacies nonetheless seem like perfectly acceptable arguments that should rationally persuade an audience of the conclusion.

Conclusion

In this chapter, we have reviewed the evidence that has recently accumulated for the probabilistic approach to human reasoning. Across the

three core areas of the psychology of deductive reasoning there is now considerable support for the view that people utilise probabilistic strategies to draw reasonable inferences about the uncertain world in which they live. We have also replied to occasional critiques of the probabilistic approach and shown how it can be extended to argumentation, which is the more general human activity of which deductive reasoning is but a small part. This review shows that a probabilistic approach to human reasoning (Oaksford and Chater 1994, 1996, 1998, 2001) may be able to explain the seeming paradox of why such a successful organism occasionally seems so irrational in the laboratory: The wrong normative standard has been applied.

Notes

- 1 For a more detailed look at some of the theoretical and conceptual issues surrounding this approach see, Oaksford and Hahn (2007) and Oaksford and Chater (2007).
- 2 According to Adams (1998) probability logic, indicative conditionals of natural language are not candidates for truth or falsity (see Oaksford and Hahn 2007 for more discussion). Consequently standard rules that apply to the material conditional, such as when *if p then q is true, then $P(q|p) = 1$* , do not apply to the indicative conditional of everyday language. It also means that rules like transitivity do not generally apply, that is, *if p then q, if q then r, therefore, if p then r*. However, as Pearl (1988: 493–497) observes, if the conditional probabilities associated with these conditionals are sufficiently extreme, then transitivity may hold to an approximation (assuming also that the transitive chain is not too long).
- 3 On Adams (1998) account and that endorsed here (see also Evans and Over 2004), the meaning of the conditional probability is given by the Ramsey (1990, originally 1931) test, in which people *suppose* the antecedent of a conditional to be true, adjust their other beliefs accordingly, and read off their new degree of belief in the consequent. That people only *suppose* the antecedent to be true is important and implies that the cognitive system can undo any revisions made and crucially does not cause people to act on a supposition in the way they would act on a belief: For example, no action is required to avoid death on *supposing* I am on the deck of the *Titanic* as it sinks but if I believed this I would have to take action and would probably need the help of a mental health professional.
- 4 One might argue that these materials produce a binary situation, for example, a card that is not yellow is definitively red. This could lead to

- affirmative re-interpretations of negated cases, that is, for the contrapositives. This distinction is known to affect people's interpretation of conditionals (see Oaksford 2002; Oaksford and Stenning 1992; Schroyens et al. 2000). However, these results have been replicated with everyday materials (Over et al. 2003).
- 5 On this account, the probability of tacit conditionals, that is, ones that are not explicitly asserted but that are implicit in a text (spoken or written), would be assigned a probability based on prior knowledge. For example, suppose you hear someone state that "So Arsenal will win tonight" (Arsenal is a U.K. football club) in response to their interlocutor just saying "It will rain tonight." The truth of the first person's utterance depends on the truth of the tacit conditional, "if it rains, Arsenal win." Having no other information to go on you would probably only assign this conditional a probability at chance levels. However, if someone actually asserted this conditional, it seems that to obey pragmatic rules of conversation, they may have some concrete evidence for this assertion and so on the basis of the assertion alone it would make sense to assign a higher probability to this conditional.
 - 6 This is again a *conservative* option as it only requires altering a single weight. However, it does imply the existence of a control mechanism capable of holding all else constant while this one weight is adjusted, that is, neural network learning algorithms where the weights are learned from repeated presentations of whole patterns over the network are not being invoked.
 - 7 We also do not discuss the probabilistic decision theoretic account that Oaksford and Chater (1994) supplied for *deontic* versions of the selection task. Many of the predictions of this account have recently been confirmed by Perham and Oaksford (2005).
 - 8 One might object that large objects might be folded, disassembled and so on. This point is well taken but it simply reflects the ambiguity in the philosophical literature over the term "analytic." The classic example of an analytic claim is that "bachelor" means "unmarried man." This claim could be expressed as a meaning postulate *if someone is a bachelor then they are an unmarried man*. But there are counterexamples, just as here. For example, someone who has a bachelor's degree is not necessarily an unmarried man. Our view in these cases is that the distinction is a matter of degree, that is, the probability of the consequent given the antecedent is so high that there is only an infinitesimal chance that the antecedent is not accompanied by the consequent.
 - 9 Given Feeney and colleagues manipulations it is also difficult to determine how to appropriately parameterise the mental models theory, to which they appeal, to derive quantitative fits. In these cases mental models "wins by vagueness." That is, the representations it proposes are claimed to explain some qualitative feature of the evidence but it is impossible to quantitatively assess whether this is actually the case.
 - 10 Oaksford and Chater (1995) explain the relationship between Sperber, Cara, and Girotto's (1995) relevance account and the ODS model.
 - 11 *Weak p*-entailments are where the overlap on the probability interval is not one of perfect inclusion. So, for example, *Some* is a strong *p*-entailment of *Most* because the interval $[1-\Delta, 1]$ is included in the interval $(0, 1)$. However, *Most* is only a weak *p*-entailment of *Some* because while the converse inclusion is not true the intervals overlap to an extent depending on Δ .
 - 12 It could be questioned how the *some...not*-heuristic can lead to better performance. The reason is that many invalid syllogisms can potentially lead to this conclusion via the *min*-heuristic or *p*-entailments and, consequently, a general heuristic against endorsing such conclusions does help discriminate valid from invalid syllogisms in general.
 - 13 One might argue that (15) and (16) are problematic because replacing "not toxic" with "safe" would alter the status of these arguments. This is not the case because we do not have a concept of a "safe effect." The *tests* are tests for *toxic* effects. So (16) could be rephrased as, "Drug A is safe because no toxic effects were observed," but not as, "Drug A is safe because *safe* effects were observed." As the observation of toxic effects is driving these distinctions, what "safe" means in this context must be defined in terms of toxicity in order to define the relevant probabilities.

Chapter 21: Individual Differences in Reasoning and the Algorithmic/Intentional Level Distinction in Cognitive Science

KEITH E. STANOVICH

When a layperson thinks of individual differences in reasoning they think of IQ tests. It is quite natural that this is their primary associate, because IQ tests are among the most publicized products of psychological research. This association is not entirely inaccurate either, because intelligence – as measured using IQ-like instruments – is correlated with performance on a host of reasoning tasks (Ackerman, Kyllonen, and Roberts 1999; Carroll 1993; Hunt 1999; Lohman 2000; Lubinski 2004; Rips and Conrad 1983; Sternberg 1977, 1985). Nonetheless, a major theme of this chapter will be that certain very important classes of individual differences in thinking are ignored if only intelligence-related variance is the primary focus. A number of these ignored classes of individual differences are those relating to rational thought.

In this chapter, I will argue that intelligence-related individual differences in thinking are largely the result of differences at the algorithmic level of cognitive control. Intelligence tests thus largely fail to tap processes at the intentional level of control. Because understanding rational behavior necessitates understanding processes operating at both levels, an exclusive focus on intelligence-related individual differences will tend to obscure important differences in human thinking.

This argument obviously depends strongly on differentiating the algorithmic from the intentional level of analysis. Therefore, in the next section I will outline the sources that I rely on for this conceptual distinction and how I will utilize the distinction to provide a framework for thinking about individual differences in reasoning.

Levels of Analysis in Cognitive Science

Levels of analysis in cognitive theory have been discussed by numerous theorists (Anderson 1990, 1991; Bermudez 2001; Davies 2000; Dennett 1978, 1987; Horgan and Tienson 1993; Levelt 1995; Marr 1982; Newell 1982, 1990; Oaksford and Chater 1995; Pylyshyn 1984; A. Sloman 1993; Sterelny 1990, 2001). For example, Anderson (1990) defines four levels of theorizing in cognitive science. At bottom is a biological level that is inaccessible to cognitive theorizing. Just above is an implementation level which is basically a comprehensible shorthand approximation to the biological. Next comes the so-called algorithmic level which is concerned with the computational processes and information processing operations necessary to carry out a task. The cognitive psychologist works largely at this level by showing that human performance can be explained by positing certain information processing mechanisms in the brain (input coding mechanisms, perceptual registration mechanisms, short- and long-term-memory storage systems, etc.). For example, a simple letter pronunciation task might entail encoding the letter, storing it in short-term memory, comparing it with information stored in long-term memory, if a match occurs making a response decision, and then executing a motor response.

Finally, in Anderson's (1990) scheme, there is the rational level where the issues of biological constitution and algorithmic processing sequence are set aside and predictions are made by attempting to provide a specification of the *goals* of the system's computations (*what* the

Table 1: Different Levels of Cognitive Theory as Characterized by Several Investigators and in This Chapter

<i>Anderson</i>	<i>Marr</i>	<i>Newell</i>	<i>Dennett</i>	<i>This Chapter</i>
Rational Level	Computational Level	Knowledge Level	Intentional Stance	Intentional Level
Algorithmic Level	Representation and Algorithm	Program Symbol Level	Design Stance	Algorithmic Level
Implementation Level		Register Transfer Level		
Biological Level	Hardware Implementation	Device	Physical Stance	Biological Level

system is attempting to compute and *why*) and its knowledge structure. The rational level of analysis is concerned with the goals of the system, beliefs relevant to those goals, and the choice of action that is rational given the system's goals and beliefs (Bratman, Israel, and Pollock 1991; Dennett 1987; Newell 1982, 1990; Pollock 1995).

Many similar taxonomies exist in the literature (Sterelny 1990: 46, warns of the "bewildering variety of terms" used to describe these levels of analysis). Indeed, Anderson's (1990) draws heavily on the work of Marr (1982) and Newell (1982). Table 1 presents the alternative, but similar, schemes of Anderson (1990), Marr (1982), Newell (1982), Dennett (1987), and a compromise scheme that I used in a 1999 volume (Stanovich 1999) and that will be used in this chapter. The first level of analysis is termed the biological level in my taxonomy because I will be largely concerned with human information processing rather than computational devices in general. My scheme follows Marr (1982) and Dennett (1987) in collapsing Anderson's algorithmic and implementation levels into one because for the purposes of the present discussion the distinction between these two levels is not important. This second level is termed algorithmic – a term that is relatively uncontroversial.

In contrast, the proper term for the third level is variable and controversial. Borrowing from Dennett (1987), I have termed this level of analysis the intentional level for the following reasons. First, Anderson (1990) has argued that Marr's (1982) terminology is confusing and inapt because "his level of computational theory is not really about computation but rather about the goals of the computation. His basic point is that one should state these goals and understand their implications before one worries about their

computation, which is really the concern of the lower levels of his theory" (p. 6). Dennett (1987) makes the same critique of Marr's terminology by noting that "the highest level, which he misleadingly calls computational, is in fact not at all concerned with computational processes but strictly (and more abstractly) with the question of what function the system in question is serving" (pp. 74–75). The term chosen by Newell (1982) – the knowledge level – is equally inapt in not signaling that this level is concerned with action selection based on expected goal attainment in light of current beliefs. Instead, I have adapted Dennett's terminology and referred to this level as the intentional level of analysis.

Although Sterelny (1990: 45) argues that this level of analysis is not necessarily tied to an intentional psychology, it is an important part of my usage that I *do* want to conjoin the two. So, in the present case, the term is apt. Importantly, intentional level states in my framework have more conceptual reality than in Dennett's view where they are imputed by someone taking an intentional stance toward another organism. The view taken here is more like that of Newell (1982) than that of Dennett. In discussing the differences between their two positions, Newell (1982) notes that Dennett "does not, as noted, assign reality to the different system levels, but keeps them in the eye of the beholder" (p. 123; see Brook and Ross 2002; Elton 2003; Mirolli 2002; Ross 2000, for discussions of the complexities in Dennett's evolving position; and Davies 2000 for a discussion of personal and subpersonal constructs).

Intentional-level processes would, in my view, be exemplified in models such as A. Slovic's (1993) where desires function as control states that can produce behavior either directly or through a complex control hierarchy by changing intermediate desire-states. He views

dispositions (high-level attitudes, ideals, and personality traits) as long-term desire states that “work through a control hierarchy, for instance, by changing other desire-like states rather than triggering behaviour” (p. 85). For the purposes of the present discussion, intentional-level psychological constructs consist of control states that regulate behavior at a high level of generality, epistemic dispositions that likewise operate very indirectly to alter information pickup tendencies, and cognitive regulatory systems that alter thresholds for things such as belief consistency checks. Importantly, these high-level control states and epistemic dispositions implicate issues of rationality (both practical and theoretical rationality).

To summarize, each level of analysis in cognitive theory frames a somewhat different issue. At the algorithmic level, the key issue is one of computational efficiency, and at the biological level the paramount issue is whether the physical mechanism has the potential to instantiate certain complex algorithms. In contrast, it is at the intentional level that issues of rationality arise.

Intelligence, Rationality, and Levels of Analysis

Work in the psychology of individual differences has long recognized a distinction between cognitive capacities (intelligence) and thinking dispositions (e.g., Baron 1985; Ennis 1987; Moshman 1994; Nickerson 2004; Norris 1992; Perkins 1995; Sinatra and Pintrich 2003; Sternberg 1997, 2003). It is important to realize that the psychological constructs identified by this distinction exist at different conceptual levels in cognitive theory: Measures of cognitive capacities primarily index individual differences at the algorithmic level and measures of thinking dispositions largely index individual differences at the intentional level. For example, cognitive psychologists have focused on the type of algorithmic-level cognitive capacities that underlie traditional psychometric intelligence: perceptual speed, discrimination accuracy, working memory capacity, goal maintenance, and the efficiency of the retrieval of information stored in long-term memory (Ackerman et al. 1999; Carpenter, Just, and Shell 1990; Deary 2000; Hunt 1987, 1999; Kane and Engle 2002; Lohman 2000; Sternberg 1977, 1985, 2000).

In contrast to cognitive psychologists, who have focused largely on cognitive capacities, personality psychologists have focused on think-

ing dispositions and cognitive styles. Generally, thinking dispositions are seen as more malleable than cognitive capacities: “Although you cannot improve working memory by instruction, you can tell someone to spend more time on problems before she gives up, and if she is so inclined, she can do what you say” (Baron 1985: 15). The important point for the argument of this chapter is that thinking dispositions, as studied by psychologists, are largely intentional-level constructs. For example, many concern beliefs, belief structure, and, importantly, attitudes toward forming and changing beliefs. Other cognitive styles that have been identified in the literature concern a person’s goals and goal hierarchy.

I will focus in this chapter on thinking dispositions and cognitive styles that operate to foster reasoning and rational thinking. That is, although cognitive styles relevant to many aspects of personality have been studied (Austin and Deary 2002; Matthews and Deary 1998; McCrae and Costa 1997), the focus here is on those that relate most closely to human rationality – those that relate to the adequacy of belief formation and decision making, things like “the disposition to weigh new evidence against a favored belief heavily (or lightly), the disposition to spend a great deal of time (or very little) on a problem before giving up, or the disposition to weigh heavily the opinions of others in forming one’s own” (Baron 1985: 15).

These, then, are the distinctions to be used in my subsequent discussion. Individual differences in omnibus measures of cognitive capacities such as intelligence tests will be understood as primarily indexing individual differences in the efficiency of processing at the algorithmic level. In contrast, thinking dispositions as traditionally studied in psychology (e.g., Cacioppo, Petty, Feinstein, and Jarvis 1996; Klaczynski, Gordon, and Fauth 1997; Kruglanski and Webster 1996; Schommer-Aikins 2004; Sinatra and Pintrich 2003; Stanovich 2002, 2008; Sternberg 1997, 2003) index individual differences at the intentional level of analysis. Thinking disposition measures are telling us about the individual’s goals and epistemic values – and they are indexing broad tendencies of pragmatic and epistemic self-regulation.

These distinctions capture the important sense in which rationality is a more encompassing construct than intelligence. The reason is that rationality is an organismic-level concept. It concerns the actions of an entity in its environment that serve its goals. It concerns both levels

of analysis – the algorithmic and the intentional level. To be rational, an organism must have well-calibrated beliefs (intentional level) and must act appropriately on those beliefs to achieve its goals (intentional level). The organism must, of course, have the algorithmic-level machinery that enables it to carry out the actions and to process the environment in a way that enables the correct beliefs to be fixed.

Thus, individual differences in rational thought and action can arise because of individual differences in intelligence (an algorithmic-level construct) or because of individual differences in thinking dispositions (an intentional-level construct). To put it simply, the concept of rationality encompasses two things (thinking dispositions and algorithmic-level capacity) whereas the concept of intelligence – at least as it is commonly operationalized – is largely confined to algorithmic-level capacity.¹ As long as variation in thinking dispositions is not perfectly correlated with intelligence, then there is the statistical possibility of dissociations between rationality and intelligence. As will be discussed later, there is in fact a considerable amount of evidence indicating that individual differences in thinking dispositions are substantially dissociated from intelligence.

What Intelligence Tests Leave Out and Why

The tasks on tests of cognitive capacities (intelligence tests or other aptitude measures) are often quite similar to those on tests of critical thinking (in the educational literature, the term critical thinking is often used to cover tasks and mental operations that a cognitive scientist would term indicators of rational thought). An outsider to psychometrics or cognitive science might deem the classification of tasks into one category or the other somewhat arbitrary. In fact, it is far from arbitrary and actually reflects a distinction that is important from the standpoint of both the field of psychometrics and the field of cognitive science.

Psychometricians have long distinguished typical performance situations from optimal (sometimes termed maximal) performance situations (Ackerman 1994, 1996; Ackerman and Heggstad 1997; Cronbach 1949; Matthews, Zeidner, and Roberts 2002). Typical performance situations are unconstrained in that no overt instructions to maximize performance are given, and the task interpretation is determined to some extent by the participant. In contrast,

optimal performance situations are those where the task interpretation is determined externally (not left to the participant), the participant is instructed to maximize performance, and is told how to do so. All tests of intelligence or cognitive aptitude are optimal performance assessments, whereas measures of critical or rational thinking are often assessed under typical performance conditions.

Using the terminology for cognitive levels introduced previously, a way to capture this difference in the language of cognitive science is to say that tests of intelligence are constrained at the intentional level (an attempt is made to specify the task demands so explicitly that variation in intentional level thinking dispositions are minimally influential). In contrast, tests of critical or rational thinking are not constrained at the intentional level (or at least are much less constrained). Tasks of the latter but not the former type allow high-level personal goals and their regulation to become implicated in performance, as well as tendencies to change beliefs in the face of contrary evidence (or tendencies to exhaustively or nonexhaustively think through problem possibilities).

Consider the type of syllogistic reasoning item usually examined by cognitive psychologists studying belief bias effects:

Premise 1: All living things need water

Premise 2: Roses need water

Therefore, Roses are living things

Approximately 70 percent of the university students who have been given this problem incorrectly think that the conclusion is valid (Markovits and Nantel 1989; Sá, West, and Stanovich 1999; Stanovich and West 1998c). That the believability of the conclusion is interfering with the assessment of logical validity is clear from the fact that virtually all of the same students correctly judge the following structurally similar syllogism to be invalid:

Premise 1: All insects need oxygen

Premise 2: Mice need oxygen

Therefore, Mice are insects

A substantial number of people deeming the “rose” syllogism valid now switch and call the “mice” syllogism invalid. What is happening here has been studied extensively by investigators who have examined belief bias effects (e.g., Dias, Roazzi, and Harris 2005; Evans 2002; Evans, Barston, and Pollard 1983; Evans and Feeney

2004; Goel and Dolan 2003; Nickerson 1998; Simoneau and Markovits 2003; Stanovich and West 1997). Prior belief in the conclusion is becoming implicated in the judgment of logical validity.

The important point for the present discussion is that it would not be surprising to see an item such as the “rose” syllogism (that is, an item that pitted prior belief against logical validity) on a critical thinking test. Such tests measure performance under typical conditions, do not constrain intentional-level thinking dispositions, and in fact attempt to probe and assess the nature of such cognitive tendencies to bias judgments in the direction of prior belief or to trump prior belief with new evidence. Thus, for example, an exercise on the *Watson-Glaser Critical Thinking Appraisal* (Watson and Glaser 1980) requires that respondents reason regarding the proposition: Groups in this country who are opposed to some of our government’s policies should be permitted unrestricted freedom of press and speech. Obviously, this is an issue on which prior opinion might be strong. However, to do well on a test such as this, one has to set aside prior opinion because one must evaluate whether arguments relevant to the proposition are strong or weak. When such tests are well designed, strong and weak arguments are presented supporting both the “pro” side of the proposition and the “anti” side of the proposition. Regardless of prior opinion, on some items the respondent is presented with a conflict between prior opinion and argument strength. Thus, the respondent must regulate how much to weigh the structure of the argument versus the prior belief. The test directly taps intentional-level epistemic regulation.

In using items with such content, critical thinking tests such as the Watson-Glaser create (even if the instructions attempt to disambiguate) ambiguity about what feature of the problem to rely on – ambiguity that is resolved differently by individuals with different epistemic dispositions. The point is that on an intelligence test, there would be no epistemic ambiguity created in the first place. Such tests attempt to constrain intentional-level functioning in order to isolate processing abilities at the algorithmic level of analysis. It is the efficiency of computational abilities under optimal (not typical) conditions that is the focus of IQ tests. Variation in intentional-level thinking dispositions would contaminate this algorithmic-level assessment.² Thus, you will not find an item like the “rose” syllogism on an intelligence test

(or any aptitude measure or cognitive capacity measure). If syllogistic reasoning abilities are to be assessed, the content of the syllogism will be stripped (all As are Bs, etc.) or unfamiliar content will be used, such as this example with the same form as the “rose” syllogism:

Premise 1: All animals of the hudon class are ferocious

Premise 2: Wampets are ferocious

Therefore, Wampets are animals of the hudon class

Items like this strip away the belief bias component and thus eliminate the intentional-level conflict between epistemic tendencies to preserve logical validity and the tendency to project prior knowledge. They constrain the intentional level and thus are candidates for the measurement of algorithmic-level computational capacities.

The Key Algorithmic-Level Operation Behind Psychometric g

Although tests of intelligence leave out critical intentional-level factors, they do in fact assess a mental capacity that is of considerable importance for rational thought. For decades psychologists have searched for the common mental operation(s) underlying the positive correlations (psychometric g) among algorithmic-level cognitive measures (Deary 2000; Sternberg and Grigorenko 2002). Only recently has there been some convergence on what this factor is and why it is important for human functioning. That extremely important mental operation is the decoupling of cognitive representations. My conception of cognitive decoupling relies on a synthesis of two literatures in cognitive science – the literature on the evolution and development of mental representations and the literature on individual differences in cognitive control and executive function.

Cognitive decoupling supports one of our most important mental functions: hypothetical thinking. Hypothetical reasoning involves representing possible states of the world rather than actual states of affairs and it is involved in myriad reasoning tasks, from deductive reasoning, to decision making, to scientific thinking (Carruthers, Stich, and Siegal 2002; Currie and Ravenscroft 2002; Evans and Over 1999, 2004; Nichols and Stich 2003; Sterelny 2001). For example, deductive reasoning involves hypotheticality when the premises are not things

the individual knows but instead assumptions about the world; utilitarian or consequentialist decision making involves representing possible future states of the world (necessarily not actual states) so that optimal actions can be chosen; and alternative hypotheses in scientific thinking are imagined causes from which consequences can be deduced for testing.

In order to reason hypothetically, a person must be able to represent a belief as separate from the world it is representing. It is decoupling ability that allows us to mark a belief as a hypothetical state of the world rather than a real one, an ability that has been stressed by numerous cognitive theorists (e.g., Carruthers 2002; Cosmides and Tooby 2000; Dienes and Perner 1999; Evans and Over 2004; Geary 2005; Glenberg 1997; Jackendoff 1996; Leslie 1987; Lillard 2001; Nichols and Stich 2003; Perner 1991; Povinelli and Giambrone 2001; Stanovich 2004). Decoupling skills prevent our representations of the real world from becoming confused with representations of imaginary situations that we create on a temporary basis in order predict the effects of future actions or think about causal models of the world that are different from those we currently hold. Dienes and Perner (1999) emphasize the importance of the mental separation between facts in one's knowledge base from one's attitude toward those facts for cognitive control. For example, when considering an alternative goal state different from the current goal state, one needs to be able to represent both and not confuse which is which. This is an exercise in cognitive control, and thus it is not surprising that decoupling skill has been linked to issues of executive functioning (Dempster and Corkill 1999; Duncan, Emslie, Williams, Johnson, and Freer 1996; Handley, Capon, Beveridge, Dennis, and Evans 2004; Harnishfeger and Bjorklund 1994; Markovits and Doyon 2004; Moutier, Angeard, and Houde 2002; Muller, Zelazo, Hood, Leone, and Rohrer 2004; Norman and Shallice 1986; Simoneau and Markovits 2003; Zelazo 2004).

Language provides the discrete representational medium that greatly enables decoupling and thus allows hypotheticality to flourish as a culturally acquired mode of thought (Evans and Over 2004; Jackendoff 1996; Povinelli and Bering 2002; Povinelli and Giambrone 2001; Tomasello 1999). For example, hypothetical thought involves representing assumptions, and linguistic forms such as conditionals provide a medium for such representations. Increases in representational complexity, and the con-

comitant increase in decoupling potential, are greatly fostered by the acquisition of language. Tacit learning can take place without decoupling, but explicit learning is dependent on it. This is why intelligence is such a good correlate of explicit learning but not tacit learning (Reber, Walkenfeld, and Hernstadt 1991; Sternberg 2003; Wagner 2002; Wagner and Sternberg 1985).

Decoupling skills vary in their recursiveness and complexity. The skills discussed thus far are those that are necessary for creating what Perner (1991) calls secondary representations – the decoupled representations that are the multiple models of the world that enable hypothetical thought. At a certain level of development, decoupling becomes used for so-called meta-representation – thinking about thinking itself (there are many subtleties surrounding the concept of meta-representation; see Dennett 1984; Nichols and Stich 2003; Perner 1991; Sperber 2000; Sterelny 2003; Suddendorf and Whiten 2001; Whiten 2001). Meta-representation – the representation of one's own representations – is what enables the self-critical stances that are a unique aspect of human cognition (Dennett 1984, 1996; Frankfurt 1971; Stanovich 2004; Tomasello 1999). We form beliefs about how well we are forming beliefs, just as we have desires about our desires, and possess the ability to desire to desire differently. Decoupling processes enable one to distance oneself from one's own tendencies to represent the world so that they can be reflected on and potentially improved.

The ability to distance ourselves from thoughts and try them out internally as models of the world makes human beings the supreme hypothesis testers in the animal kingdom and variation in this ability is a contributor to individual differences in assessed intelligence. This is because decoupling – outside of certain domains such as behavioral prediction (so-called theory of mind) – is a cognitively demanding operation. It now appears that perhaps the key operation underlying intelligence is the ability to maintain decoupling among representations while carrying out mental simulation.³ This is becoming clear from converging work on executive function (Baddeley 1992; Baddeley, Chincotta, and Adlam 2001; Duncan et al. 2000; Fuster 1990; Gernsbacher and Faust 1991; Goldman-Rakic 1992; Gray, Chabris, and Braver 2003; Hasher, Zacks, and May 1999; Kane 2003; Kane and Engle 2002; Salthouse, Atkinson, and Berish 2003) and working memory (Colom,

Rebollo, Palacios, Juan-Espinosa, and Kyllonen 2004; Conway, Cowan, Bunting, Theriault, and Minkoff 2002; Conway, Kane, and Engle 2003; Engle 2002; Engle, Tuholski, Laughlin, and Conway 1999; Kane, Bleckley, Conway, and Engle 2001; Kane and Engle 2003; Kane, Hambrick, Tuholski, Wilhelm, Payne, and Engle 2004; Sub et al. 2002). First, there is a startling degree of overlap in individual differences on working memory tasks and individual differences in measures of fluid intelligence. Second, it is becoming clear that working memory tasks are only incidentally about memory. Or, as Engle (2002) puts it, "WM capacity is just as important in retention of a single representation, such as the representation of a goal or of the status of a changing variable, as it is in determining how many representations can be maintained. WM capacity is not directly about memory – it is about using attention to maintain or suppress information. WM capacity is about memory only indirectly. Greater WM capacity does mean that more items can be maintained as active, but this is a result of greater ability to control attention, not a larger memory store" (p. 20).

Engle (2002) goes on to review evidence indicating that working memory tasks really tap the preservation of internal representations in the presence of distraction or, as I have termed it – the ability to decouple a secondary representation (or meta-representation) from a primary representation and manipulate the former. For example, he describes an experiment using the so-called antisaccade task. Subjects must look at the middle of a computer screen and respond to a target stimulus that will appear on the left or right of the screen. Before the target appears, a cue is flashed on the opposite side of the screen. Subjects must resist the attention-capturing cue and respond to the target on the opposite side when it appears. Subjects scoring low on working memory tasks were more likely to make an eye movement (saccade) in the direction of the distracting cue than were subjects who scored high on working memory task.

That the antisaccade task has very little to do with memory is an indication of why investigators have reconceptualized the individual difference variables that working memory tasks are tapping. Individual differences on such tasks are now described with a variety of different terms (attentional control, resistance to distraction, executive control), but the critical operation needed to succeed in them – and the reason they are the prime indicator of fluid intelligence – is that they reflect the ability to sustain

decoupled representations. Such decoupling is an important aspect of behavioral control that is related to rationality, as will be discussed below.

Why Intelligence Correlates with Reasoning Tasks

Given the previous discussion, it is no surprise that intelligence should correlate with performance on a variety of constrained reasoning tasks (that is, tasks that constrain the operation of the intentional level of processing). Virtually all of the higher-level constrained reasoning tasks in the literature require the respondent to construct hypothetical models of situations and mentally manipulate these models; in short, to run mental simulations while maintaining decoupled representations. That this critical mental operation underlies psychometric *g* explains why general intelligence (or intelligence proxies, such as working memory measures, see Colom et al. 2004) correlates robustly with a variety of reasoning tasks such as deductive reasoning, performance on analogies tasks, syllogistic reasoning, matrix completion, and spatial reasoning (see Bara, Bucciarelli, and Johnson-Laird 1995; Copeland and Radvansky 2004; Gilhooly 2004; Hambrick and Engle 2003; Handley et al. 2004; Lohman 2000; Rips 1994; Rips and Conrad 1983; Stanovich and West 1998c; Sternberg 1977; Verschueren, Schaeken, and D'Ydewalle 2005).

A more difficult theoretical challenge is presented by data on unconstrained reasoning tasks. Here there is more to explain, because it has been found that intelligence sometimes correlates with unconstrained reasoning tasks and sometimes it does not. My theoretical explanation for these on-again, off-again correlations makes use of a dual-process theory of cognition, of which there are many in the literature (I listed twenty-two such theories in a recent book, and that was not an exhaustive list; for reviews, see Evans 2003; Feldman Barrett, Tugade, and Engle 2004; Kahneman and Frederick 2002, 2005; Osman 2004; S. Sloman 2002; Stanovich 1999, 2004). Briefly, these models distinguish between autonomous processing and nonautonomous processing.

There are many different autonomous systems in the brain, and to signal this plurality I have suggested the acronym TASS (for The Autonomous Set of Systems, see Stanovich 2004). These processes are termed autonomous because: (1) their execution is rapid, (2) their execution is mandatory when the triggering

stimuli are encountered, (3) they do not put a heavy load on central processing capacity, (4) they are not dependent on input from high-level control systems, and (5) they can operate in parallel. Included in TASS are processes of implicit learning, overlearned associations practiced to automaticity, processes of behavioral regulation by the emotions, and the encapsulated modules for solving specific adaptive problems that have been posited by the evolutionary psychologists (on the types of processes in TASS, see Atran 1998; Carruthers 2002; Cosmides and Tooby 1992; Evans 2003; Mithen 1996; Pinker 1997; Sperber 1994; Stanovich 2004).

The nonautonomous system(s) – sometimes going under the name of analytic processing – have the contrasting set of properties. Analytic cognitive processes are serial (as opposed to parallel), rule-based, often language-based, and computationally expensive. The analytic system is the one responsible for the decoupled cognitive simulation abilities discussed previously.⁴ It can create temporary models of the world – for example, by retrieving goals and beliefs from long-term memory as well as stored procedures for operating on the goals and beliefs and testing the outcomes of imaginary actions (see Currie and Ravenscroft 2002; Nichols and Stich 2003; Perner 1991).

An important function of the decoupling system is that it can override responses primed by an autonomous system by taking early representations triggered by TASS offline and substituting better responses that have survived the cognitive selection process of simulation (McClure, Laibson, Loewenstein, and Cohen 2004; Nichols and Stich 2003). It is the necessity of the operation of this override function that determines whether an unconstrained rational thinking task will show correlations with general intelligence. For example, many unconstrained thinking tasks are tasks in which the optimal responses determined by TASS and by the analytic system are designed to be different (assuming, in the latter case, that the analytic system is actually engaged to run a simulation). I have argued (Stanovich 1999; Stanovich and West 2000) that is just such situations that will generate significant correlations between intelligence and task performance.⁵ This correlation might arise for two reasons. First, some subjects are more likely to operate entirely with TASS systems and these are more likely to be the low IQ subjects. Second, even within the sample of subjects experiencing response conflict,⁶ it is assumed that the subjects of higher intelligence will be more likely

to resolve the conflict in favor of the response generated by the analytic system.

Many tasks in the heuristics and biases literature are of the type that create such significant correlations, because many were specifically constructed⁷ so as to pit a TASS subsystem against the analytic system (Kahneman and Frederick 2002, 2005; Kahneman and Tversky 1996). A classic example is presented in a problem that is famous in the literature of cognitive psychology, the so-called Linda problem (Tversky and Kahneman 1983):

Linda is 31 years old, single, outspoken, and very bright. She majored in philosophy. As a student, she was deeply concerned with issues of discrimination and social justice, and also participated in anti-nuclear demonstrations. Please rank the following statements by their probability, using 1 for the most probable and 8 for the least probable.

- a. Linda is a teacher in an elementary school ____
- b. Linda works in a bookstore and takes Yoga classes ____
- c. Linda is active in the feminist movement ____
- d. Linda is a psychiatric social worker ____
- e. Linda is a member of the League of Women Voters ____
- f. Linda is a bank teller ____
- g. Linda is an insurance salesperson ____
- h. Linda is a bank teller and is active in the feminist movement ____

Because alternative h is the conjunction of alternatives c and f, the probability of h cannot be higher than that of either c or f. Yet 85 percent of the participants in Tversky and Kahneman's (1983) study (and in dozens of replications) rated alternative h as more probable than f, thus displaying what is termed a conjunction fallacy. Tversky and Kahneman (1983) argued that logical reasoning (analytic system processing) on the problem is overwhelmed by a TASS heuristic based on so-called representativeness.⁸ Representativeness primes answers to problems based on an assessment of similarity (a feminist bank teller seems to overlap more with the description of Linda than does the alternative "bank teller"). Of course, logic dictates that the subset (feminist bank teller), superset (bank teller) relationship should trump assessments of representativeness when judgments of probability are at issue.

S. Sloman (1996) views the Linda Problem as the quintessence of dual-process conflict. He quotes Stephen Gould's introspection that

"I know the [conjunction] is least probable, yet a little homunculus in my head continues to jump up and down, shouting at me – 'but she can't be a bank teller; read the description'" (Gould 1991: 469). According to Sloman (1996), the associative system responds to the similarity in the conjunction; whereas the rule-based system engages probabilistic concepts which dictate that bank teller is more probable. Thus, in the Linda problem, we have a case of a TASS response tendency (a similarity-based judgment of representativeness) being pitted against an analytic system response tendency (the logic of subset/superset relations). As Kahneman and Tversky (1996) note, "the within-subjects design addresses the question of how the conflict between the heuristic and the rule is resolved" (p. 587).

That 85 percent of respondents answer the Linda conjunction problem incorrectly indicates that, for most people, analytic processes are not very firmly in control of their judgments. Nevertheless, because a TASS-override is necessary for normative responding, it might be expected that making the normative response would be associated with more algorithmic computational capacity, and this is indeed the case. In one study (Stanovich and West 1998b), we examined the performance of 150 subjects on the Linda Problem. Consistent with the results of previous experiments on this problem (Tversky and Kahneman 1983), 80.7 percent of our sample displayed the conjunction fallacy – they rated the feminist bank teller alternative as more probable than the bank teller alternative. However, the mean SAT score of the 121 subjects who committed the conjunction fallacy was 82 points *lower* than the mean score of the 29 who avoided the fallacy. This difference was highly significant and it translated into an effect size of .746 (which Rosenthal and Rosnow, 1991, classify as large).⁹

Similar results obtain with other tasks from the heuristics and bias literature that pit TASS-processes against analytic reasoning. For example, consider the experiments conducted by Seymour Epstein and colleagues (Denes-Raj and Epstein 1994; Kirkpatrick and Epstein 1992; Pacini and Epstein 1999a, 1999b). Participants in these experiments were presented with two bowls of jelly beans. In the first were nine white jelly beans and one red jelly bean. In the second were ninety-two white jelly beans and eight red. A random draw was to be made from one of the two bowls and if the red jelly bean was picked, the participant would receive a dollar.

The participant could choose which bowl to draw from. Although the two bowls clearly represent a 10 percent and an 8 percent chance of winning a dollar, many participants chose the one-hundred bean jar, thus reducing their chance of winning.¹⁰ Although most were aware that the large bowl was statistically a worse bet, that bowl also contained more enticing winning beans – the eight red ones. Many could not resist trying the bowl with more winners despite some knowledge of its poorer probability. That many participants were aware of the poorer probability but could, nonetheless, not resist picking the large bowl is indicated by comments from some of them such as the following: "I picked the ones with more red jelly beans because it looked like there were more ways to get a winner, even though I knew there were also more whites, and that the percents were against me" (Denes-Raj and Epstein 1994: 823). In short, the simpler TASS tendency to respond to the absolute number of winners trumps the more analytic process of calculating a ratio for a surprising number of participants. Nevertheless, parallel to our findings with the Linda conjunction task, my research group (e.g., Kokis, Macpherson, Toplak, West, and Stanovich 2002) has found that making the normative higher percentage response in the Epstein task is positively correlated with cognitive ability.

There are many more examples from the heuristics and biases literature that display the same pattern (see Stanovich and West 2000; West and Stanovich 2003). For example, the avoidance of the belief bias effect in syllogistic reasoning discussed previously is correlated with cognitive ability (Evans and Perry 1995; Handley et al. 2004; Markovits and Doyon 2004; Newstead, Handley, Harley, Wright, and Farrelly 2004; Sá et al. 1999) as is normatively correct responding on the Wason four-card selection task (DeShon, Smith, Chan, and Schmitt 1998; Stanovich and West, 1998a; Valentine 1975; but see Newstead et al. 2004). These situations are cognitively quite varied, and it is more likely than not that they are not of the same cognitive or neurophysiological class. Their only commonality may be the status of these tasks as presenting situations where a TASS response, if not overcome, will lead to a nonoptimal outcome.

For all categories of suboptimal TASS priming, successful override is achieved only through the coordinated operation of intentional-level functioning (recognizing the need for override of TASS processes) and algorithmic-level functioning (carrying out the cognitive decoupling

operations necessary to cancel the TASS-primed response). Because measures of intelligence or cognitive ability tap primarily individual differences in the latter, conceptually, there is room for individual differences in intentional-level thinking dispositions to predict differences in unconstrained reasoning tasks.¹¹ In the remainder of this chapter, I will illustrate how evidence supports the existence of such an association, and I will explore the philosophical implications of the existence of variance on unconstrained reasoning tasks that can be predicted by measures other than intelligence.

Thinking Dispositions as Predictors of Performance on Unconstrained Reasoning Tasks

In light of the emphasis in the critical thinking literature on the importance of evaluating arguments independently of prior belief (e.g., Nickerson 1998; Paul 1984, 1987; Perkins 1995), it is noteworthy that there are increasing indications in the research literature that individual differences in this skill can be predicted by thinking dispositions even after differences in general cognitive ability have been partialled out. For example, Schommer (1990) found that a measure of the disposition to believe in certain knowledge predicted the tendency to draw one-sided conclusions from ambiguous evidence even after verbal ability was controlled. Kardash and Scholes (1996) found that the tendency to properly draw inconclusive inferences from mixed evidence was related to belief in certain knowledge and to a measure of need for cognition (Cacioppo et al. 1996). Furthermore, these relationships were not mediated by verbal ability because a vocabulary measure was essentially unrelated to evidence evaluation. Likewise, Klaczynski (1997; see also Klaczynski and Gordon 1996; Klaczynski et al. 1997; Klaczynski and Lavallee 2005; Klaczynski and Robinson 2000) found that the degree to which participants criticized belief-inconsistent evidence more than belief-consistent evidence was unrelated to cognitive ability.

Results from my own laboratory have converged with those of Schommer (1990) and Kardash and Scholes (1996) in indicating that thinking dispositions can predict argument evaluation skill once cognitive ability is partialled out. We have developed an argument evaluation task in which we derive an index of the degree to which argument evaluation is associated with argument quality independent of prior

belief (see Stanovich and West 1997, 1998c; Sá et al. 1999). We have consistently found that, even after controlling for cognitive ability, individual differences on our index of argument-driven processing can be predicted by measures of dogmatism and absolutism (Rokeach 1960), categorical thinking (Epstein and Meier 1989), openness (Costa and McCrae 1992), flexible thinking (Stanovich and West 1997), belief identification (Sá et al. 1999), counterfactual thinking, superstitious thinking (Stanovich 1989; Tobacyk and Milford 1983), and actively open-minded thinking (Sá, Kelley, Ho, and Stanovich 2005; Stanovich and West 1997).

These findings support a conceptualization of human cognition that emphasizes the potential separability of cognitive capacities and thinking styles/dispositions as predictors of reasoning skill. Such a separation in psychological constructs makes sense if indeed they do map on to different levels of analysis in cognitive theory. I proposed earlier that variation in cognitive ability indexes individual differences in the efficiency of processing at the algorithmic level. In contrast, thinking dispositions index individual differences at the intentional level. They are telling us about the individual's goals and epistemic values. For example, consider an individual who scores high on our measures of actively open-minded thinking and low on measures of dogmatism and absolutism – a person who agrees with statements such as “People should always take into consideration evidence that goes against their beliefs” and who disagrees with statements such as “No one can talk me out of something I know is right.” Such a response pattern is indicating that this person values belief change in order to get closer to the truth. This individual is signaling that they value being an accurate *belief forming system* more than they value holding on to the beliefs they currently have (see Cederblom 1989 for an insightful discussion of this distinction and our scale based on this notion in Sá et al. 1999).

In contrast, consider a person scoring low on actively open-minded thinking measures and high on measures of absolutism and categorical thinking – a person who disagrees with statements such as “A person should always consider new possibilities” and who agrees with statements such as “There are a number of people I have come to hate because of the things they stand for.” Such a response pattern is indicating that retaining current beliefs is an important goal for this person. This individual is signaling that they value highly the beliefs they currently

have and that they put a very small premium on mechanisms that might improve belief accuracy (but that involve belief change). In short, thinking dispositions of this type provide information about epistemic goals at the intentional level of analysis. Within such a conceptualization, we can perhaps better understand why such thinking dispositions predict additional variance in argument evaluation even after cognitive ability is partialled out. This result may be indicating that to understand variation in reasoning in such a task we need to examine more than just differences at the algorithmic level (computational capacity) – we must know something about the epistemic goals of the reasoners.

Thus, performance on tasks requiring reasoning about previously held beliefs, while certainly somewhat dependent on the cognitive capacity of the subject, also depends on the balance of epistemic goals held by the reasoners. The instructions for many tasks which require reasoning in the face of belief bias (e.g., Baron 1995; Evans, Newstead, Allen, and Pollard 1994; Handley et al. 2004; Oakhill, Johnson-Laird, and Garnham 1989; Stanovich and West 1997) dictate that prior belief be totally discounted in evaluating the argument. But individuals may differ in their willingness as well as their ability to adapt to such instructions. Some individuals may put a low priority on allocating computational capacity to evaluate the argument. Instead, for them, capacity is engaged to assess whether the conclusion is compatible with prior beliefs (Evans, Barston, and Pollard 1983; Evans et al. 1994). Other individuals – of equal cognitive ability – may marshal their cognitive resources to decouple argument evaluation from their prior beliefs as the instructions demand. These individuals may easily engage in such a processing strategy because it does not conflict with their epistemic goals. Tasks unconstrained at the intentional level are the type of tasks able to detect such individual differences. Tasks constrained at the intentional level, such as IQ tests, are largely unable to detect these differences.

Thus, to fully understand variation in evidence evaluation performance, we need to consider variation at the intentional level as well as at the algorithmic level of cognitive analysis. Indeed, this seems to be true for other tasks in the heuristics and biases literature as well. For example, we have linked various measures of thinking dispositions to statistical reasoning tasks of various types (Kokis et al. 2002; Stanovich 1999; Stanovich and West 1998c, 1999, 2000). One such task derives from the work of Nis-

bett and Ross (1980), who studied the tendency of human judgment to be overly influenced by vivid but unrepresentative personal and testimonial evidence and to be underinfluenced by more representative and diagnostic statistical evidence. Studying the variation in this response tendency is important because Griffin and Tversky (1992) argue that “the tendency to prefer an individual or ‘inside’ view rather than a statistical or ‘outside’ view represents one of the major departures of intuitive judgment from normative theory” (pp. 431–432). The quintessential problem (see Fong, Krantz, and Nisbett 1986) involves choosing between contradictory car purchase recommendations – one from a large-sample survey of car buyers and the other the heartfelt and emotional testimony of a single friend. Fong et al. (1986) and Jepson, Krantz, and Nisbett (1983) have studied a variety of such problems and we have examined a number of them in our own research. We have consistently found that, even though these problems are presented to participants as having no right or wrong answers, dispositions toward actively open-minded thinking are consistently associated with reliance on the statistical evidence rather than the testimonial evidence. Furthermore, this association remains even after cognitive ability has been controlled.

We have examined a variety of other critical and rational thinking tasks and have consistently found the same pattern. For example, we have examined the phenomenon of outcome bias in decision evaluation (Baron and Hershey 1988) – the tendency to rate decision quality according to the outcome of the decision even when the outcome provides no cues to the information available to the decision maker. We again found that the ability to avoid outcome bias was associated with dispositions toward actively open-minded thinking and that this tendency was not due solely to differences in cognitive ability. Similar results were found for a variety of other hypothesis testing and reasoning tasks (Kokis et al. 2002; Stanovich 1999, 2004; Stanovich and West 1998c, 2000; Toplak and Stanovich 2002). I have argued elsewhere that the thinking dispositions that serve as good independent predictors in these studies tend to be those that reflect a tendency toward cognition decontextualization – the tendency to strip unnecessary context from problems (Stanovich 2003, 2004). Such dispositions serve to counter one aspect of what I have termed the fundamental computational bias of human cognition. That aspect is the tendency to contextualize a problem with

as much prior knowledge as is easily accessible. This fundamental computational bias was useful in our evolutionary history, but modern bureaucratic societies often require that this bias be overridden. Many tasks in the heuristics and biases literature tap the ease with which we recognize this necessity.

In summary, throughout several of our studies, normative responding on a variety of problems from the heuristics and biases literature was moderately correlated with cognitive ability. Nevertheless, the magnitude of the associations with cognitive ability left considerable room for the possibility that the remaining reliable variance might indicate that there are systematic variation in intentional-level psychology. It was rarely the case that once capacity limitations had been controlled, the remaining variations from normative responding were unpredictable (which would have indicated that the residual variance consisted largely of random error). In several studies, we have shown that there was significant covariance among the scores from a variety of tasks in the heuristics and biases literature after they had been residualized on measures of cognitive ability (Stanovich 1999; see also Parker and Fischhoff 2005). And, as I have just reviewed, the residual variance (after partialling cognitive ability) also was systematically associated with questionnaire responses that were conceptualized as intentional-level styles relating to epistemic regulation. Both of these findings are indications that the residual variance is systematic.

Why Intentional-Level Individual Differences Are Controversial

In this chapter, it has been proposed that thinking dispositions should be distinguished from cognitive capacities because the two constructs are at different levels of analysis in cognitive theory and do separate explanatory work. This distinction motivates interest in a consistent empirical finding in the literature reviewed in the last section: that thinking dispositions can predict performance on reasoning and rational thinking tasks even after individual differences in measures of general cognitive ability have been partialled out. Finding systematic variance in intentional-level functioning that is not explained by computational capacity has implications for what has been termed the great rationality debate in cognitive science – a debate that has generated an enormous literature and a high degree of contention (e.g., Adler 1991, 1998;

Cohen 1981; Evans and Over 1996; Gigerenzer 1996; Johnson-Laird 1999; Kahneman and Frederick 2005; Kahneman and Tversky 1996, 2000; Kuhberger 2002; Lopes 1991; Manktelow 2004; Margolis 1987; Over 2002; Samuels and Stich 2004; Samuels, Stich, and Bishop 2002; Shafir and LeBoeuf 2002, 2005; Stanovich 1999, 2004; Stein 1996; Tetlock and Mellers 2002).

This debate has pitted the heuristics and bias researchers and their claims of empirically demonstrated irrational behavior against a host of so-called Panglossian positions that argue against the possibility of actual (as opposed to apparent) variation in the optimality of intentional-level functioning (for extensive discussions of these various positions, see Samuels and Stich 2004; Stanovich 1999, 2004; Stein 1996). None of these Panglossian positions has difficulty with the finding of zero-order correlations between performance on heuristics and biases tasks and intelligence as long as intelligence is viewed as a proxy for algorithmic-level computational capacity. This is because theorists on all sides of the rationality debate take seriously the stricture that to characterize a sub-optimal behavior as irrational, it must be the case that the normative model is computable in the cognitive mechanism under study (Cherniak 1986; Stich 1990). The intelligence correlations might simply be reflecting the fact that variability in performance on tasks from the heuristics and bias literature may be just a combination of varying computational limitations and random error. Such a view is undermined, however, by findings indicating that there is systematic variability in responding over and above that accounted for by intelligence. That there is systematic variability remaining necessarily means that at least some individuals are characterized by intentional-level functioning that is less than optimal.

The systematic variance in intentional-level function isolated in the experiments reviewed here has perhaps not received sufficient attention because of the heavy reliance on the competence/performance distinction in philosophical treatments of rational thought. In such views, all of the important psychological mechanisms are allocated to the competence side of the dichotomy. For example, Rescher (1988) argues that “to construe the data of these interesting experimental studies [of probabilistic reasoning] to mean that people are systematically programmed to fallacious processes of reasoning – rather than merely that they are inclined to a variety of (occasionally questionable)

substantive suppositions – is a very questionable step. . . . While all (normal) people are to be credited with the capacity to reason, they frequently do not exercise it well” (p. 196). There are two parts to Rescher’s (1988) point here: the “systematically programmed” part and the “inclination toward questionable suppositions” part. As Rips (1994) notes, such views frame the rationality debate in terms of “whether incorrect reasoning is a ‘systematically programmed’ part of thinking [or] just a peccadillo” (p. 394).

Rescher’s (1988) focus is on the issue of how humans are “systematically programmed.” It seems that “inclinations toward questionable suppositions” are only of interest to those in these philosophical debates as mechanisms that allow one to drive a wedge between competence and performance – thus maintaining a theory of near-optimal human rational competence in the face of a host of responses that seemingly defy explanation in terms of standard normative models. For example, like Rescher, Cohen (1982) argues that there really are only two factors affecting performance on rational thinking tasks: “normatively correct mechanisms on the one side, and adventitious causes of error on the other” (p. 252). Not surprisingly given such a conceptualization, the processes contributing to error (“adventitious causes”) are of little interest to Cohen (1981, 1982). On this view, human performance arises from an intrinsic human competence that is impeccably rational, but responses occasionally deviate from normative correctness due to inattention, memory lapses, lack of motivation, and other fluctuating but basically unimportant causes (e.g., “performance” errors). There is nothing in such a view that would motivate any interest in patterns of errors or individual differences in such errors because it is strongly implied that the errors are random. It is just this assumption that is challenged by the research reviewed in this chapter. Beyond variation in computational capacity, there is systematic variance in human intentional psychology – in high-level control states that are related to epistemic and practical rationality.

One of the purposes of the present chapter is to reverse the figure and ground in the rationality debate, which has tended to be dominated by the particular way that philosophers frame the competence/performance distinction. From a psychological standpoint, there may be important implications in precisely the aspects of performance that have been backgrounded in this controversy (“adventitious causes,” “peccadillos”). That is, whatever the outcome of

the disputes about how humans are “systematically programmed,” variation in the “inclination toward questionable suppositions” is of psychological interest as a topic of study in its own right (see Margolis 1987). The experiments discussed in this chapter provide at least tentative indications that the “inclination toward questionable suppositions” has some degree of domain generality and that it is predicted by thinking dispositions that concern the epistemic and pragmatic goals of the individual and that are part of people’s intentional-level psychology.

Consider that the search for counterexamples or alternative theories is the key to normative thinking in domains as varied as decision making, logical reasoning, practical reasoning, and scientific thinking (Carruthers, Stich, and Siegal 2002; Evans 2005; Evans and Over 1999, 2004; Johnson-Laird 1999, 2005; Kahneman and Miller 1986; Rips 1994; Roese 1997; Tor and Bazerman 2003). Many models of thinking in these domains have not historically been focused on individual differences and thus have not emphasized the fact that there may be systematic control features that determine the extent of the search for alternatives and counterexamples – and that there may be predictable variance in these higher-level control functions. I would argue that the work reviewed above on epistemically related cognitive dispositions may in fact be reflecting just such higher-level control features. Individual differences in the extensiveness of the search for alternative models could arise from a variety of cognitive factors that may be far from “adventitious” – factors such as dispositions toward premature closure, cognitive confidence, reflectivity, dispositions toward confirmation bias, ideational generativity, and so on.

I argued previously that this panoply of thinking dispositions is particularly related to the cognitive decontextualization that commonly results when TASS processes are overridden by the analytic system. The decontextualized nature of many normative responses is a feature that is actually emphasized by many *critics* of the heuristics and biases literature who, nevertheless, fail to see it as implying a research program for differential psychology. For example, if to contextualize a problem is the natural and nearly universal reasoning style of human beings (what I have called the fundamental computational bias, see Stanovich 2003, 2004), then it is not surprising that many people respond incorrectly when attempting a psychological task that is explicitly designed to require a decontextualized reasoning style (contrary-to-fact

syllogisms, argument evaluation, etc.). But the fact that some people *do* give the decontextualized response means that at least some people have available a larger repertoire of reasoning styles (they can flexibly reason so as to override the fundamental computational bias if the situation requires).

For example, Rescher (1988) defends responses that exhibit the gambler's fallacy on the grounds that people assume a model of saturation that is valid in other domains (e.g., food ingestion, sleep) and that "the issue may well be one of a mistaken factual supposition rather than one of fallacious reasoning" (pp. 195–196) and he stresses the enthymematic character of much human reasoning. But, again, the fact remains that many people do *not* reason enthymematically in this or other reasoning problems and instead give the normative response. This implies that at least some people have available a larger repertoire of reasoning styles (they can flexibly reason enthymematically and nonenthymematically as the task requires). Or, at the very least, it means that certain people are more easily shifted out of their natural enthymematic reasoning style. Research reviewed here would support the conclusion that having such thinking tendencies can improve performance on many reasoning and decision making tasks regardless of the level of a person's algorithmic-level capacity (intelligence). This is one important implication of the fact that intentional-level cognitive constructs are independent predictors of reasoning skill.

Notes

- 1 My use of the algorithmic/intentional distinction here parallels somewhat the way that Bermudez (2001) has characterized the difference between neuropsychological disorders and psychiatric disorders. Most neuropsychological disorders (unilateral neglect, agnosias, etc.) involve impairment restricted to algorithmic-level functioning (most often in a modular component of the autonomous set of systems, see discussion later). Bermudez (2001) notes that they are traditionally explained by recourse to subpersonal functions. Psychiatric disorders (particularly those such as delusions), in contrast, implicate intentional-level functioning. Bermudez (2001) argues that the "impairments in which they manifest themselves are of the sort that would standardly be explained at the personal level, rather than at the subpersonal level. In the terms of Fodor's dichotomy, psychiatric disorders seem to be disorders of central process-
- ing rather than peripheral modules. . . . Many of the symptoms of psychiatric disorders involve impairments of rationality – and consequently that the norms of rationality must be taken to play a vital role in the understanding of psychiatric disorders" (pp. 460, 461).
- 2 I do not wish to argue that intelligence tests are entirely successful in this respect – that they entirely eliminate intentional-level factors; only that the constructors of the tests *attempt* to do so. Additionally, it is certainly the case that some higher-level strategic control is exercised on intelligence test items, but this tends to be a type of micro-level control rather than the activation of macro-strategies that are engaged by critical thinking tests. For example, on multiple-choice IQ-test items, the respondent is certainly engaging in a variety of control processes such as suppressing responses to identified distractor items. Nonetheless, if the test is properly designed, they are not engaging in the type of macro-level strategizing that is common on critical thinking tests – for example, deciding how to construe the task or how to allocate effort across differing construals.
- 3 More technically, it is probably a key correlate of fluid intelligence and not crystallized intelligence. The term fluid intelligence refers to one of the major two factors underlying intelligence in the so-called Cattell/Horn/Carroll theory of intelligence – as close as there is to a consensus view in the field of intelligence research (Carroll 1993; Cattell 1963, 1998; Daniel 2000; Geary 2005; Horn and Cattell 1967; Horn and Noll 1997; McGrew 1997; McGrew and Woodcock 2001; Taub and McGrew 2004). Sometimes called the theory of fluid and crystallized intelligence (symbolized Gf-Gc theory), this theory posits that tests of mental ability tap a small number of broad factors, of which two are dominant. Fluid intelligence (Gf) reflects reasoning abilities operating across of variety of domains – including novel ones. It is measured by tasks such as figural analogies, Raven Matrices, and series completion. Crystallized intelligence (Gc) reflects declarative knowledge acquired from acculturated learning experiences. It is measured by vocabulary tasks, verbal comprehension, and general knowledge measures. Ackerman (1996) discusses how the two dominant factors in the Cattell/Horn/Carroll theory reflect a long history of considering two aspects of intelligence: intelligence-as-process (Gf) and intelligence-as-knowledge (Gc).
- 4 My view of individual differences in this type of cognitive decoupling as the key operation assessed by measures of intelligence was anticipated by Thurstone (1927), who also stressed that decoupling is related to inhibition of automatic responses: "Intelligence is therefore the capacity of abstraction, which is an inhibitory

- process. In the intelligent moment the impulse is inhibited while it is still only partially specified, while it is still only loosely organized. . . . The trial-and-error choice and elimination, in intelligent conduct, is carried out with alternatives that are so incomplete and so loosely organized that they point only toward types of behaviour without specifying the behaviour in detail" (p. 159).
- 5 This is because intelligence indexes differences in analytic system processing but not the algorithmic-level processes in TASS – primarily because individual differences in the latter are severely restricted (Anderson 1992, 1998; Baron-Cohen 1995; Reber 1992, 1993; Reber, Walkenfeld, and Hernstadt 1991; Saffran, Aslin, and Newport 1996; Vinter and Detable 2003; Vinter and Perruchet 2000; Zacks, Hasher, and Sanft 1982).
 - 6 The conflict need not always be conscious, although dual-process conflict will be especially strong when it is (see S. Sloman 1996).
 - 7 Note that in the vast majority of cases, the response primed by TASS will coincide with that determined by the analytic system – that is, in most cases, TASS does in fact prime the rational response. The minority of instances in which it does not may be situations of some import, however (see Stanovich 1999, 2004).
 - 8 Current understanding of representativeness interprets it as a form of attribute substitution (see Kahneman and Frederick, 2002). Other TASS heuristics have been proposed as the cause of the conjunction error in this problem – many involving conversational assumptions that are automatically applied to the problem (on this by now quite large literature, see Adler 1984, 1991; Dulany and Hilton 1991; Giroto 2004; Hilton 1995; Mellers, Hertwig, and Kahneman 2001; Politzer and Macchi 2000; Politzer and Noveck 1991; Slugoski and Wilson 1998).
 - 9 As mentioned previously, this correlation with intelligence might arise for two reasons. First, some subjects may operate solely on the basis of representativeness and these are more likely to be the low IQ subjects. Secondly, even within the sample of subjects who experienced conflict between representativeness and the subset/superset relationship, the subjects of higher intelligence might have been more likely to resolve the conflict in favor of the latter.
 - 10 The Epstein results are not inconsistent with the findings of Fetherstonhaugh, Slovic, Johnson, and Friedrich (1997) that people's willingness to intervene to save lives was more determined by the proportion of lives saved than by the absolute number. The vividness that is the common cause of the normatively inappropriate response patterns in the two experimental situations operates differently in the two cases.

Stimulus situations in this experimental area are subtly and importantly different (see also Yamagishi 1997). Which aspect of the situation will dominate because of vividness depends greatly on the comparative aspects of the experimental situation (see Slovic, Finucane, Peters, and MacGregor 2002).

- 11 There is a slightly different way of stating these two conclusions that might clarify the model I am developing here. First, there is a correlation between intelligence and performance on these tasks because once the need for override is recognized, the probability of carrying out the sustained decoupling required by override is higher for those with more algorithmic-level cognitive capacity. Nevertheless, the correlation is substantially less than perfect because the mere cognitive capacity for decoupling is alone not enough – the need for override must be recognized, and this depends on intentional-level thinking dispositions of the type discussed in the next section.
