Researchers have also linked comparison outcomes to basic self-regulatory strategies (Pennington & Roese, 2003). Specifically, Markman and McMullen (2003) have relied on Higgins's (1998) distinction between *promotion* and *prevention* strategies in predicting likely outcomes of social and other comparisons. "An upward comparison represents a desirable outcome and thus may activate promotion goals to obtain that outcome, whereas a downward comparison represents an undesirable outcome and thus may activate prevention goals so that the outcome does not occur" (Markman & McMullen, 2003, p. 252). Lockwood (2002) found that simulation of the self as like an attainable downward comparison target indeed enhanced *prevention* goals (see also Lockwood, Sadler, Fyman, & Tuck, 2004).

THE IMPORTANCE OF CONSTRUAL

All the findings we have reviewed on the consequences of social comparison highlight the role that construals play in this process. Downward comparison, traditionally thought to be self-enhancing, can have adverse consequences just as upward comparison, traditionally considered detrimental, can have positive consequences. And much of this depends on what one does with the comparison information—one can perceive similarity or not with the comparison other; one can reconstrue information such that the self is protected even in light of negative information (DeVellis et al., 1991). The genius effect—the tendency to perceive those who outperform us as particularly brilliant—provides a very telling example of the importance of construal (Alicke, LoSchiavo, Zerbst, & Zhang, 1997). By "aggrandizing the outperfomer" we can stave off the self-esteem threat posed by underperforming: The "genius" attribution may make the other so discrepant from the self that comparison is not even viable.

Some studies have also documented *differing* effects of the *same* social comparison. For example, married women experienced more *positive* mood (assimilation) but more *negative* evaluations of their own marriage (contrast) when they compared with an upward versus downward comparison standard (another married woman; Buunk & Ybema, 2003). These authors suggest that "the mood evoked by social comparison is primarily a primitive, direct, and automatic response," whereas evaluation of one's marriage is "a separate, cognitive, process"

(p. 614). Thus, one can feel inspired but concerned about one's own marriage when comparison to a better-off other occurs.

Taken as a whole, the literature relevant to comparison consequences leads to the conclusion, in the words of Buunk and colleagues (1990), that either direction of comparison—upward or downward—"has its ups and downs." Furthermore, although we have focused on affective responses in simplistic positive–negative terms, it is also the case that a diverse set of emotions may be experienced in response to social comparison (Smith, 2000). The impact of a comparison will ultimately be determined not by its direction but by the way in which it is perceived and interpreted by the comparer.

SUMMARY AND CONCLUSIONS

This chapter has considered the role of standards in social judgment, focusing on how the use of standards may produce either assimilation or contrast effects. We have conceptualized standards broadly, arguing that they can take the form of contextual cues (as in priming research, or simply in the accumulation of exposure to stimuli), the self, other people, social groups, or internalized guides.

We began with a consideration of how standards are selected, and we emphasized that while standards may often be directly supplied or thrust on the individual, there is also room for the perceiver to actively choose or avoid comparative standards. In this way, particular needs can be met and/or certain outcomes of comparison avoided. Thus, for example, the individual can actively choose to avoid self-awareness (as a means of escaping the negative comparison of the self to standards) or can choose an upward rather than downward comparison target (depending on the desire to self-improve). We next considered a number of models of social judgment that have emerged in recent years. Each focuses largely on *outcomes* of the comparison process and whether and when assimilation versus contrast effects emerge. Finally, we considered specific social judgment phenomena—cases in which social standards guide judgment of self and others—and attempted to relate them to the broader models.

In considering each domain of self- and other judgment, we focused on how assimilation and contrast effects are *both* evident under different conditions, and how these conditions include both cognitive and motivational factors:

1. In the case of self as a standard to judge others, assimilation effects are reflected in the positive relationships between own standing on a trait dimension and judgments of another person's standing (Lambert & Wedell, 1991), and in false consensus effects (Ross et al., 1977; Sherman et al., 1984). But judgments of others can also be contrasted from the self, as in research on egocentric definitions of trait concepts—whereby self and other judgments are negatively related (Dunning & Cohen, 1992), and in false uniqueness effects (Marks, 1984; Suls & Wan, 1987). Contrastive patterns seem to be driven by self-esteem concerns, as they are particularly likely when self-esteem is threatened (e.g., Beauregard & Dunning, 1998), but cognitive factors may be responsible as well. Judgments of unambiguous or *extreme* stimuli, and judgments along dimensions where the self's standing is extreme, are also likely to prompt contrast, as are judgments relative to *distinct* standards—such as one's specific score on the SAT (rather than one's standing on an abstract trait). These features—ambiguity of stimuli, extremity of standard, and distinctness of standard—are highlighted in a number of the judgment models considered earlier in the chapter (perhaps most notably in Stapel and colleagues' ICM).

2. In the case of stereotypes as standards to judge others, the dominant theoretical models and data suggest *assimilation*. Using language from a variety of judgment models we considered, the individual group member is "included" (Schwarz & Bless, 1992a) or "interpreted" (Stapel & Koomen, 1998) in the broad frame of the stereotype, "set" in the context of the stereotype (Martin, 1986), hypothesized to be similar to the broad category (Mussweiler, 2003a, 2003b), "simulated" as a member of the category (Markman & McMullen, 2003), and judged consistently with the group-based "expectation" (Manis & Paskewitz, 1984a, 1984b). At the same time, however, other research suggests that stereotypes can produce contrast effects, as when an African American law school applicant is judged more favorably than a comparable White applicant (Linville & Jones, 1980). These contrast effects are particularly likely when judgments are made on subjective response scales (Biernat et al., 1991), and when targets violate expectancies (Jussim et al., 1987). Again, extremity versus ambiguity of targets is implicated here—ambiguous targets, or those who can be construed in ways that "fit" the category, are assimilated; extreme, nonfitting targets are not. Motivational factors have also been identified in this literature as *diminishing* the assimilative impact of stereotypes. For example, interdependence goals and motivations to avoid stereotyping tend to reduce stereotype-consistent judgments, though they typically do not invoke contrast.

3. Internalized guides operate as standards to judge the self. In research on objective self-awareness theory (Duval & Wicklund, 1972) and self-discrepancy theory (Higgins, 1987), the focus is primarily on *contrast* effects: Comparison of the self to internalized guides or standards typically prompts affective contrast. This is because our actual behavior typically does not meet our high standards or ideals, and the salience of discrepancy prompts negative affect. At the same time, the negative affect produced by becoming aware of the self's discrepancy with a standard has a motivational quality geared toward *assimilative* change—typically, moving the self toward the standard (see Monteith et al., 2002; Silvia & Duval, 2001). Similarly, the construct of possible selves implicates behavioral assimilation (Markus & Nurius, 1986, p. 954), as do models of self-regulation (Carver & Scheier, 1998; Higgins, 1998). Thus, this body of work highlights that an initial *contrastive* outcome (negative affect based on failure to meet standards) can ultimately trigger *assimilation*—the meeting of standards or goals.

4. Finally, we considered the large literature on social comparison theory, in which other individuals are used as standards to judge the self. Historically, this perspective was dominated by a *contrast* perspective: Upward comparisons were generally presumed to prompt negative self-evaluation; downward comparisons to prompt positive self-evaluations (e.g., Morse & Gergen, 1970). And indeed, there is considerable evidence supporting such patterns of contrast. However, evidence of *assimilation* has not been rare, as when cancer patients' downward comparisons prompt negative affect (Taylor & Lobel, 1989), and when upward comparisons are inspiring (Lockwood & Kunda, 1997). Key to social comparison outcomes is the *similarity* principle, highlighted in Mussweiler's (2003a) SAM: To the extent that there is similarity between self and the comparison other—in terms of shared group membership, feature overlap, attainability, or perceived uncontrollability of outcome (such that self could be like the other)—assimilation seems to be the more likely outcome (see also Collins, 1996, 2000). The social comparison literature has also highlighted that motives may affect which comparison other is chosen or even whether or not similarity is perceived. Motives to self-enhance, to improve the self, or even to self-verify may guide all aspects of the comparison process.

In thinking about the "big picture" of standards and judgment, we find ourselves disinclined to conclude this chapter by offering a new or comprehensive model of social judgment. Instead, we suggest a broad framework and a set of factors or considerations that should be taken into account when predicting the outcome of comparative judgment.

First, we suggest that the process of standard use in judgment can be described in terms of three general stages: standard selection/activation, target-standard comparison, and judgment outcome (assimilation or contrast). These stages are similar to those outlined by Mussweiler (2003a, 2003b), and we also agree with Mussweiler that information made accessible at each of the first two stages—information that becomes the focus of attention—is the most proximal contributor to the judgment outcome. We suggest, too, that at each of the first two stages, both "hot" and "cold" factors are operative.

The first stage, standard selection/activation, can involve (1) the explicit choice of a standard—as when participants in a social comparison study select the reference group with whom they would like to compare, (2) a standard being directly thrust upon the perceiver—as when one is told to compare the target X to standard Y, or (3) a standard being subtly activated in the environment—as when a prior context makes a particular category or exemplar salient. Motivations of the perceiver matter most in the first case, when choice of standard takes us toward goals of self-enhancement, accuracy (self-evaluation), self-improvement, self-verification, or a host of other motives (including epistemic goals or curiosity; see Dunning, 2001). But even when a standard is explicitly or subtly activated in a given context, the perceivers' motives may affect their construal of the standard, as when

an upward social comparison standard is viewed as highly similar to the self (presumably reflecting some self-enhancement goals; Wheeler, 1966). In addition, of course, standard activation or selection implicates an array of cognitive features that ultimately contribute to judgment outcomes. Relevant but *extreme* or *distinct* standards set the stage for contrast; more *moderate*, *broad*, or *abstract* standards set the stage for assimilation (e.g., see Herr, Sherman, & Fazio, 1983).

At the second stage, target–standard comparison, motives of the judge may again play a role. When, for example, the self is a relevant standard for judging others, one may project the self on to others to gain validation for one's views, or may distinguish the self from others to establish uniqueness or rarity of favorable qualities (McFarland & Miller, 1990). And, of course, when an internal standard becomes salient, pointing to a self-discrepancy, the individual can choose to escape self-awareness to stop the comparison altogether (Greenberg & Musham, 1981). Again, however, this stage is affected by colder cognitive processes as well. To the extent that the standard and target share features, or can be included in the same category, assimilation is likely; to the extent that the standard is out of awareness but active—as in many priming studies—assimilation is also likely. Ambiguous targets are also more likely to prompt assimilation than extreme or unambiguous targets.

It is through these two paths then—the motives of the perceiver and the cognitive features of the standard, the target, and the standard–target overlap/distinctness—that judgment in the form of assimilation or contrast results. This judgment stage can also be affected by additional factors, such as the language in which judgment is rendered (with *objective* or *common-rule* judgments more likely to produce assimilation; Biernat et al., 1991; Krantz & Campbell, 1961), and motives to *correct* for the (unwanted) influence of a standard on judgment (which typically produces contrast [Martin, 1986], but can produce assimilation [Wegener & Petty, 1997]).

The goal of this chapter has been to make the process and outcomes of standard use a bit more transparent—to highlight basic principles by which standards influence social judgment. We have not considered *non*social judgment here, and thus we have said nothing about how federal agencies decide that drugs are or are not safe, or that cars and toys meet or do not meet safety standards. We have also avoided discussion of legal decision making or admissions policies or ethical standards, where social judgments *are* ultimately involved. In these cases, a variety of factors outside our purview surely contribute to the *development* of standards (what constitutes a safe drug? what is "reasonable doubt" in a criminal case? what are ethical standards of conduct?). And in a number of these cases, judging a stimulus relative to a standard may be a fairly *objective* process (as when initial screening for graduate school applicants requires the applicant achieve some minimum standard on the GRE). At the same time, however, we suspect that motives of the perceiver or judge can influence which standards are activated in a given context, or how information about the standard and target are processed. Features of the standard and

target—including extremity, distinctness, standard–target overlap—also determine the outcome of the comparative process. In short, we suspect that the models and phenomena reviewed in this chapter are broadly applicable to the use of standards in everyday life.

NOTES

1. From a "related attributes" perspective, it has been hypothesized that people should prefer dissimilar others when it comes to evaluating opinions, a prediction that has also received support (e.g., Goethals & Zanna, 1979; Gorenflo & Crano, 1989)

2. This derives from the "maximum–minimum" principle of Gestalt theory: a maximum simplicity of perfect articulation that produces contrast and a minimum simplicity of uniformity that produces assimilation. Stimulus differences are minimized to create homogeneity within a category and maximized to accentuate category differences (see Tajfel & Wilkes, 1963).

3. However, Krueger and Clement (1994) have demonstrated that the false consensus bias remains even after providing participants with other statistical information and educating them about the bias (see also Alicke & Largo, 1995).

4. Krueger (1998) has suggested that an egocentric *perceptual* process underlies the false consensus effect. That is, "the perception of consensus is assumed to be part of the initial encoding of the stimulus rather than the outcomes of subsequent higher level processes" (Krueger, 1998, p. 202). Such an account need not imply motivation or cognition directly.

5. Though most research in the self-discrepancy tradition has focused on failures to meet standards, recent work from a regulatory focus perspective (Higgins, 1997, 1998) discusses the assimilative consequences of meeting ideal standards. Specifically, when promotion-focused, success (the "gain" of meeting an ideal standard) is thought to evoke cheerfulness-related emotions. But when prevention-focused, success (the "nonloss" of meeting an ought standard) is thought to evoke quiescence-related emotions (Higgins, Shah, & Friedman, 1997; Idson, Liberman, & Higgins, 2000). This latter effect is a kind of affective contrast—emotion is more favorable than the undesired (and successfully avoided) outcome.

Decisions Constructed Locally

Some Fundamental Principles of the Psychology of Decision Making

ELDAR SHAFIR

Behavioral research into the making of decisions has been influenced by two popular and rather compelling views of the human agent. The first, "folk psychology" view, consists of our intuitive understanding of the decisions that we make and of the factors that motivate and underlie them. The second, normative, "rational agent model," presents a more analytic, a priori, analysis of what it means to make rational choices and has come to dominate much of economics and the rest of the social sciences, as well as the formulation and conduct of policy. Interestingly, part of what has made the normative treatment so appealing has been its general affinity with intuition. Putting aside certain technical requirements that even the most ardent proponents of the rational model recognize as highly idealized, preferences, according to the normative theory, generally are assumed to respect simple rules of stability and well ordering that most naive respondents, upon a moment's reflection, readily endorse. Similarly, people's intuitions regarding value maximization, self-control, planning, situational influences, and the stability and reliability of preferences are, to a first approximation, aligned with normative expectations, even if folk psychology recognizes certain normative assumptions as extreme.

The empirical findings, on the other hand, are often nonnormative and counterintuitive. Not only are preferences often inconsistent with the normative requirements of decision making, they violate simple intuitive expectations as well. And, as in other areas of empirical investigation, observations that are unexpected and counterintuitive tend to trigger further thinking and

research and can lead to new insight and understanding.

In this chapter, we explore some fundamental insights and general principles that characterize our current understanding of decision making. Some of these principles, while integral to our understanding of decision-making processes, are quite general, forming part of a psychological portrayal of human information processing that is not unique to the making of decisions; other insights pertain more specifically to the decision-making context. As with all reviews of this kind, the perspective provided here is somewhat idiosyncratic, heavily influenced by the author's views and predilections; it by no means provides a complete and definitive summary of this rich and diverse field of investigation. (Some good collections of relevant readings are Goldstein & Hogarth, 1997; Holyoak & Morrison, 2005; Koehler & Harvey, 2004; among others.)

In what follows, we consider the tension between normative and descriptive insights that underlies the modern study of decision making. We begin by discussing two prominent features that render people's decision behavior profoundly different from that envisioned by normative treatments. One is the overwhelming tendency to make "local" as opposed to "global" decisions; the other is our proclivity to "construct" our preferences once a decision needs to be made. Following an initial discussion of these two essential characteristics, we proceed to consider various empirical studies that have explored the logic and consequence of these attitudes, as well as some of the psychological traits or processes that

underlie them. In the third section, we consider a number of features that are integral to the decision-making context, including attitudes toward risk and loss and the repeated and temporal aspects of decision making. In the fourth section, we explore further some of the psychological processes that appear to play a prominent role in people's construction of their preferences. These include response compatibility, decisional conflict, reasons, emotions, and personal identity, as well as unconscious influences and automatic processes. The fifth section provides some concluding remarks.

A PERSONAL ANECDOTE

Consider the following brief personal anecdote. As a graduate student, I would walk a few times a week from home to work, and back, along the streets of Cambridge, Massachusetts. One day, while listening to a lecture on "local optima," I realized that I had been doing something remarkable: I had been taking one route every morning, on the way to work, but a different route in the evening, on the way back home. As it turned out, there was no good reason for this inconsistency: There were no inclines, no views to enjoy, no dark or crowded spaces. Rather, in an attempt to walk around an irregularly shaped parking garage situated en route, I took, in each direction, what felt like the most efficient detour. As portrayed in Figure 14.1, because of how the garage was configured, that detour led to one route on the way to school and to an alternate route on the way back home. Not surprisingly, my old Cambridge map shows one route to be somewhat longer than the other. To the extent that my sole purpose was to cover the distance efficiently, I had taken the "wrong" route half the time.

This anecdote captures the essence of the account of decision making that unfolds in this chapter. It is characterized by two distinguishing features that I shall argue are at the core of decision-making behavior. The first is that decisions are made "locally." In my commuting everyday, I had not bothered to plan my entire route ahead of time. Clearly, had I determined the shortest route from home to work, I could then have opted for the same route back from work to home. Instead, I left home with a clear destination and a general direction and proceeded to make little decisions along the way, intended eventually to lead me to where I wanted to go. My behavior was the outcome not of a "global" plan, intended to maximize efficiency, but rather of a series of local decisions, each looking intuitively right but jointly yielding a suboptimal pattern.

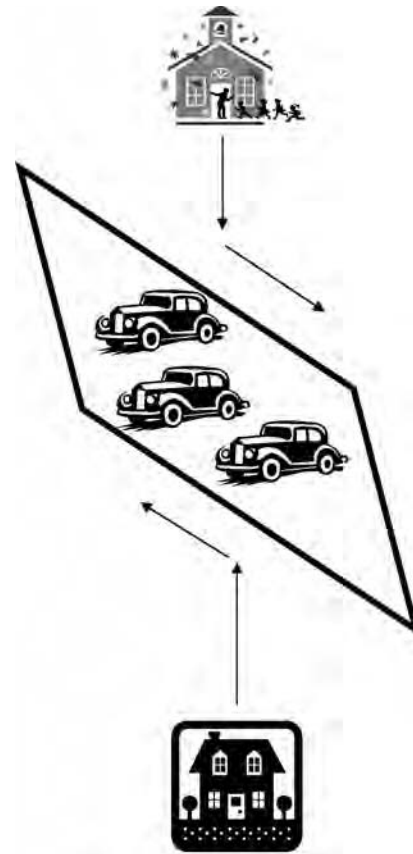
The second characteristic of my commuting experience, closely related to the first, was that at each juncture of the route my preferences were not simply revealed (for I did not yet have any), but rather, these preferences were "constructed" at the moment of having to decide. When I arrived at the parking garage (at least on the first days) I had no memory or other available record to consult about whether I ought to take a right or a left.[1] Instead, only once there, with the strangely shaped garage in full display, did I undertake to decide where to turn,


FIGURE 14.1. Local optimization.

and that decision was heavily influenced by the features of the context that were locally salient.

Normative as well as intuitive analyses require, implicitly if not explicitly, that decisions be considered at a level relevant to the outcomes of interest. When making a choice, the available alternatives ought to be evaluated in terms of their ability to deliver the outcomes of interest, with relative disregard for immaterial detail encountered along the way. If my primary aim is to take the shortest route from home to work, it would be a mistake to end up on a longer route just because I took a quick turn on some random corner. Likewise, when shopping for a car, it would be a mistake to opt for a mediocre alternative when I could do better just because the salesman had a warm smile. Similarly, if I want to save as much as I can for retirement, it would be a mistake to choose an option that is likely to save me less in the long run just because it is expected to do better next week.[2] People, however, tend to make their decisions locally, paying great attention to minor deviations from the status quo rather than to their overall, long-term impact. People tend to consider decisions one at a time, rather than as part of some relevant accumulation over many similar instances. And they let various accidental features of the context—whether an option is in their possession or not, the default option, the presence or absence of comparable alternatives—influence their decision, often with long-term consequences.

SOME BASIC FEATURES OF THE DECISION-MAKING CONTEXT

We begin our survey with some basic terminology and a few observations that are considered "classical" by now. They have been extensively reviewed and amply discussed, and they form the core of a successful program of research commonly referred to as *behavioral decision making*. At the core of this program are fundamental psychological principles that underlie the making of decisions, and that account for the systematic discrepancies that arise between the normative treatment and the empirical findings. We begin with a quick review of these (for further exposition and discussion, see Kahneman & Tversky, 2000; LeBouef & Shafir, 2005b; Payne, Bettman, & Johnson, 1992; Shafir & Tversky, 1995).

Risk and Value

Decisions are often risky, in the sense that their outcomes are not known with certainty. In making decisions under risk, people have to consider two factors, the desirability of the outcomes and their probability of occurrence. Classical decision theory is largely concerned with the question of how these factors are, or should be, combined.

Consider a choice between a risky prospect that offers a 50% chance to win $200 (and 50% chance to win nothing) and the alternative of receiving $100 for sure. As it turns out, most people prefer the sure gain over the gamble, although the two prospects have the same expected value. (The expected value of a gamble is a weighted average where each possible outcome is weighted by its probability of occurrence; the expected value of the gamble above is .50 * $200 + .50 * 0 = $100.) Preference for a sure thing over a gamble of equal expected value is called *risk averse*.

Now suppose that we are forced to choose between a prospect that offers a 50% chance to lose $200 (and 50% chance to lose nothing) versus losing $100 for sure. In this problem, most people reject the sure loss and prefer to take an even chance at losing more or nothing. As in the previous choice involving gains, these prospects have the same expected value. This preference for a risky prospect over a sure outcome that has the same expected value is an instance of *risk seeking*. In fact, with the exception of prospects that involve very small probabilities, risk aversion is generally observed in choices involving gains, whereas risk seeking tends to hold in choices involving losses.

The aforementioned risk tendencies can be explained by the notion of diminishing sensitivity. Just as the impact of a candle is greater when it is brought into a dark room than into a room that is well lit, so the impact of an additional $100 is greater when it is added to a gain of $100 than when it is added to a gain of $800. This principle was first formalized by early 18th-century mathematicians, who proposed that subjective value, or utility, is a concave function of money, and that preferences ought to be described using expected utility instead of expected value. According to expected utility, the worth of a gamble offering a 50% chance to win $200 (and 50% chance to win nothing) is .50 * $u($200), where u is the person's concave utility function (where $u(0) = 0$). It follows from such a function that the subjective value attached to a gain of $100 is more than 50% of the value attached to a gain of $200, which entails preference for the sure $100 gain and, hence, risk aversion.

Risk seeking for losses can be explained by assuming similarly diminishing sensitivity to negative outcomes, yielding a subjective value function for losses that is convex. According to such a function, the worth of a gamble that offers a 50% chance to lose $200 is greater (i.e., less negative) than that of a sure loss of $100. That is, .50 * $u(-$200) > u(-$100)$. This implies a risk-seeking preference for the gamble over the sure loss.

Conjoining the concave and convex functions for the contexts of gains and losses, respectively, yields the S-shaped value function illustrated in Figure 14.2. This function forms part of a descriptive theory of choice, known as prospect theory (Kahneman & Tversky, 1979, 1984; Tversky & Kahneman, 1992). The value function of prospect theory has three important properties: (1) it is defined on gains and losses rather than total wealth; (2) it is steeper for losses than for gains; and (3) it is concave for gains and convex for losses.

The first property is closely related to my daily commute behavior portrayed in Figure 14.1. It captures the fact that people tend to treat outcomes as gains and losses defined relative to a neutral reference point, rather than in terms of total wealth. (Just like I turned left or right based on what felt beneficial at that particular point, not on what would prove most efficient overall.) The second property states that losses generally loom larger than corresponding gains, which is captured in Figure 14.1 by a function that is steeper for losses than for gains (i.e., $u($X) < -u(-$X)$). The third property of the value function captures the aforementioned risk attitudes: risk aversion in the domain of gains and risk seeking in the domain of losses.
FIGURE 14.2. Prospect theory's value function.

Risk Attitudes and Framing

Although there is a presumption that people are entitled to their own preferences and that those described above are as legitimate as any others, people's attitudes toward risk can soon be seen to generate problematic decision patterns, reminiscent of the ones I showed on my way to school. One such pattern is illustrated by the following pair of decisions (where the bracketed numbers indicate the percentage of respondents who chose each option.)

Problem 1 :
Assume yourself richer by $300 than you are today.
You have to choose between
- a sure gain of $100   [72%]
- 50% chance to gain $200 and 50% chance
  to gain nothing   [28%]

Problem 2:
Assume yourself richer by $500 than you are today.
You have to choose between
- a sure loss of $100   [36%]
- 50% chance to lose nothing and 50% chance
  to lose $200   [64%]

Most subjects presented with the choice involving gains in problem 1 are risk averse, whereas most subjects presented with the choice between losses in problem 2 are risk seeking. The two problems, however, are essentially identical: When the initial sums are added to the expected outcomes, both problems amount to a choice between $400 for sure versus an even chance at $300 or $500.

The predictable responses to the two problems capture a fundamental feature of "local" decision making. They show that people do not combine the initial payment with the anticipated choice outcomes as required by normative analysis. (For, if these were combined into a global representation, the two problems would appear indistinguishable.) And, as a consequence of this local decision evaluation, the same choice problem framed in alternative ways leads to systematically different choices (much as different encounters of the same parking garage led me to take alternate routes). When the same problem framed in slightly different but logically equivalent ways leads to different decisions, this is known as a *framing effect*. Framing effects constitute a violation of an essential requirement of the rational theory of choice, known as *description invariance*, according to which equivalent representations of a choice problem should yield the same preferences (Tversky & Kahneman, 1986).

Framing effects are pervasive and can be observed even when the same respondents answer both versions of a problem (LeBouef & Shafir, 2003). Furthermore, they are found in the choices of both naive and sophisticated respondents. For example, experienced physicians were found to be just as susceptible to the effects of framing—concerning alternative treatments for lung cancer described in terms of mortality rates or in terms of survival rates—as were graduate students or clinic patients (McNeil, Pauker, Sox, & Tversky, 1982).

In fact, the tendency to adopt the locally provided frame is quite general and does not depend on the triggering of alternate risk attitudes. It can lead, among others, to "attribute-framing" effects (Levin, Schneider, & Gaeth, 1998). For example, people are more favorably inclined toward medical procedures when their chances of success, rather than failure, are highlighted. Similarly, ground beef, which can be described as 75% lean or 25% fat, tends to be evaluated more favorably under the former than the latter description (Levin, 1987; see also Levin, Schnittjer, & Thee, 1988). And a community with a 3.7% crime rate tends to be allocated greater police resources than one described as 96.3% "crime free" (Quattrone & Tversky, 1988).

Attribute-framing manipulations affect the perceived quality of items through a minor alteration of their description. Part of the impact of such semantic factors may be due to spreading activation (Collins & Loftus, 1975) wherein positive concepts (e.g., "crime free") activate associated positive concepts and negative concepts activate other negative concepts. In addition, because of the psychophysics of number perception, a 96.3% "crime free" rate suggests that virtually all are law-abiding, whereas a 3.7% as opposed to 0% crime rate appears substantial and suggests the need for intervention (Quattrone & Tversky, 1988). In line with the foregoing discussion, such framing effects are the result not of an all-encompassing, context-independent process of evaluation but, rather, of a "situated cognition," built of low-level perception and immediate association, which leaves decisions largely at the mercy of local, and often accidental, features of specific exposure.

Local versus Global Decisions

To further capture the problematic nature of decisions made locally, recall that what typically matters is the person's overall state, not the specific gains and losses encountered along the way. This, however, is often violated when people make their decisions locally, paying great attention to local deviations from the status quo rather than to their overall, long-term impact.

Whereas normative thinking typically preoccupies itself with the most efficient routes, people often optimize "locally," as they navigate around specific obstacles. However, decisions that are compelling locally often add up to inferior overall patterns. Consider, for example, the following two choices, one involving gains and the other involving losses (taken from Tversky & Kahneman, 1981, p. 454):

Imagine that you face the following pair of concurrent decisions. First examine both decisions, then indicate the options you prefer.

Decision (i). Choose between:
  A: a sure gain of $240   [84%]
  B: 25% chance to gain $1000 and 75% chance
      to gain nothing   [16%]

Decision (ii). Choose between:
  C: a sure loss of $750   [13%]
  D: 75% chance to lose $1000 and 25% chance
       to lose nothing   [87%]

As expected from the foregoing discussion, the majority choice in decision (i), involving gains, is risk averse, and the majority choice in decision (ii), involving losses, is risk seeking. Simple calculation, however, shows that the combination of A and D, which is chosen by a majority of respondents, yields a combined outcome (25% chance to win $240 and 75% chance to lose $760) that is strictly inferior to the unchosen alternative (combination B and C; 25% chance to win $250 and 75% chance to lose $750). Two individually compelling local decisions thus lead to a pattern that is globally inferior.

Many patterns of decision inconsistency documented in the literature would not arise were decisions considered from a more global perspective. Various framing manipulations would be of little consequence were people to go beyond the provided frame and represent the decision outcomes in a canonical manner that is description invariant. Interestingly, unlike some more purely cognitive domains (e.g., vision or language) wherein canonical representations are often formed automatically, the representation of decision outcomes does not typically undergo canonical transformation (cf. Kahneman, 2003). As described next, a key ingredient in the local representation of decision outcomes is what are seen as potential losses.

Loss Aversion

Many decisions present trade-offs between gains and losses, and losses generally loom larger than corresponding gains, as captured in Figure 14.2 by the fact that the value function is steeper in the negative than in the positive domain. This asymmetry in the evaluation of positive and negative outcomes, called loss aversion, occurs because the pain associated with giving up a good is greater than the pleasure associated with obtaining it. An immediate implication of loss aversion is that people will not accept an even chance to win or lose $X, because the loss of $X is more aversive than the gain of $X is attractive. (In fact, people will typically accept an even-chance prospect only when the gain is more than twice as large as the loss; Tversky & Kahneman, 1991.) This yields "endowment effects," wherein the mere possession of a good (such that parting with it is rendered a loss) can lead to higher valuation of the good than if it were not in one's possession. A classic experiment illustrates this point (Kahneman, Knetsch, & Thaler, 1990). Participants were arbitrarily assigned to be *sellers* or *choosers*. Sellers were each given an attractive mug, which they could keep, and asked to indicate the lowest amount for which they would sell the mug. Choosers were not given a mug but were instead asked to indicate the amount of money that the mug was worth to them. (Further procedural details were designed to promote truthful estimates: an official market price, $X, was to be revealed; all those who valued the mug at more than $X received a mug, whereas those

who valued the mug below $X received $X.) Note that all participants, sellers and choosers, faced the same decision: determining a price at which they would prefer money over the mug. Because participants were randomly assigned to be sellers or choosers, standard expectations are that the two groups would value the mugs similarly. Loss aversion, however, suggests that the sellers would set a higher price (for what they were about to "lose") than the choosers. Indeed, sellers' median asking price was twice that of choosers.

Another manifestation of loss aversion is a reluctance to trade, illustrated, for example, in a study in which half of the subjects were given a decorated mug and the rest were given a bar of chocolate (Knetsch, 1989). Later, each subject was shown the alternative gift option and offered the opportunity to trade his or her gift for the other. Because the initial gift allocation was arbitrary and transaction costs minimal, economic theory predicts that about half the participants would exchange their gifts. Loss aversion, on the other hand, predicts that most participants would be reluctant to give up a gift in their possession (a loss) to obtain the other (a gain). Indeed, only 10% of participants chose to trade. This contrasts sharply with standard analysis, in which the value of a good does not change when it becomes part of one's endowment.

Loss aversion emerges as an important empirical generalization that has implications for a wide range of decisions. It promotes stability rather than change, because the disadvantages of departing from the status quo loom larger than the advantages presented by the alternative (Samuelson & Zeckhauser, 1988). It has thus been suggested that loss aversion can hinder the negotiated resolution of disputes. If each disputant sees the opponent's concessions as gains but its own concessions as losses, agreement will be hard to reach because each will perceive itself as relinquishing more than it stands to gain (Kahneman & Tversky, 1995.) A skillful mediator may facilitate agreement by framing concessions as bargaining chips rather than as losses, or by setting all sides' reference points low, thus requiring compromises over outcomes that are mostly perceived as gains (cf. Kahneman, 1992).

Note that loss aversion is an attitude inherently confined to a local setting; it is based on departure from a current reference point, not on the conditions reached after the loss. Thus, a person A, who has just lost $1 million in the stock market may be more upset than person B, who has lost only $10,000, despite the fact that, at the end of this bad day for both, person A may be worth twice as much as person B. In my decision to surround the garage in Figure 14.1, a perceived "loss" corresponded to the reluctance to walk backward rather than forward at that particular juncture; concern with losing ground at that point did not allow for the possibility that the avoidance of such loss may ultimately lead to a longer route overall.

Isolated versus Joint Evaluation

An interesting and systematic pattern of local influence is observed when people evaluate options in isolation as

opposed to when they directly compare them. In general, systematic discrepancies in the weighting of option attributes can emerge when options are evaluated in isolation as opposed to when they are compared. Certain attributes, for example, are difficult to evaluate in isolation; others tend to overwhelm in direct comparisons. In one example, capturing what Hsee (1996) has called an evaluability effect, subjects are invited to consider two secondhand music dictionaries, one with 20,000 entries and a cover that's slightly torn, the other with 10,000 entries and a cover that is like new. When evaluating only one dictionary at a time, respondents, who have little notion of how many entries to expect, are willing to pay more for the dictionary with the new rather than the torn cover. In contrast, when these dictionaries are evaluated concurrently most people prefer the dictionary with more entries, despite its inferior cover (Hsee, 1996; Hsee, Loewenstein, Blount, & Bazerman, 1999).

For another example, consider a job that pays $80,000 a year at a firm where one's peers receive $100,000, compared to a job that pays $70,000 while coworkers are paid $50,000. Consistent with the fact that most people prefer higher incomes, a majority of second-year MBA students who compared the two options preferred the job with the higher absolute income, despite the lower pay relative to one's peers. When the jobs are considered separately, however, the precise attractiveness of one's own salary is hard to gauge, whereas earning less than one's peers renders the former job relatively less attractive than the latter. Indeed, the majority of MBA students who evaluated the two jobs separately anticipated higher satisfaction in the job with the lower salary but the higher relative position, obviously putting greater weight on the latter attribute in the context of separate evaluation (Bazerman, Schroth, Shah, Diekmann, & Tenbrunsel, 1994).

In the same vein, decision principles that are hard to apply in isolated settings may prove decisive in direct comparisons, yielding systematic shifts in attribute weights. Kahneman and Ritov (1994), for example, asked participants for the maximum they were willing to contribute to several environmental programs. One program was dedicated to saving dolphins in the Mediterranean Sea; another funded free medical checkups for farmworkers at risk for skin cancer. When asked which program they would rather support, the vast majority chose the medical checkups for farmworkers, presumably based on the principle that human lives matter more than those of animals. However, when asked separately for the largest amount they would be willing to pay for each intervention, respondents, moved by the animals' touching plight, were willing to pay more for the dolphins than for workers' checkups. In a similar application, potential jurors awarded comparable dollar amounts to plaintiffs who had suffered either physical or financial harm when the cases were evaluated separately. However, in concurrent evaluation, award amounts were substantially larger for physical as opposed to financial harms, affirming the notion that personal harm is perceived as the graver offense (Sunstein, Kahneman, Schkade, & Ritov, 2001).

Attribute weights, which are normatively assumed to remain stable, are thus seen to systematically shift and give rise to patterns of inconsistent preferences. Such shifts are largely the outcome of local decision contexts, which can trigger different comparison and evaluation processes, yielding differential relative attribute weights. As with other localized decisions, this process can lead to suboptimal decisions about outcomes that will be experienced in a different future context. A compelling illustration is provided by Hsee and colleagues (1999) in the context of a hypothetical purchasing decision at an audio store. Suppose that a pair of speakers has superior sound but is aesthetically unattractive relative to a second pair, which looks much better but has a slightly less impressive sound. At the store, with the two options in direct comparison, one is likely to opt for the better sounding speaker that, after all, one might reason, matters more than how a speaker looks. But then, at home with only the chosen speakers and nothing to compare them with, the slight superiority in sound is likely to prove inconsequential, whereas the unattractiveness of the speakers may persist and prove quite noticeable.

Discrepancies between separate versus concurrent evaluation may have profound implications for intuition and for policy. Outcomes in everyday life are typically experienced one at a time: A person lives through one scenario or another. Normative intuitions, on the other hand, often arise from comparative introspection: we entertain a scenario along with its alternatives. When an event triggers reactions that partly stem from its being experienced in isolation, important aspects of that experience may be misconstrued by intuitions that arise from comparative evaluation (for further discussion, see Shafir, 2002).

Repeated Decisions

As illustrated in Figure 14.1 and other previous examples, a local approach to decision making can give rise to decisions that are inconsistent with preferences that emerge from a more "global" evaluation. In essence, a global perspective requires one to ignore features of the decision that are momentarily salient in favor of other, often less salient considerations that have long-run repercussions. This tension can be clearly observed in the context of repeated decisions, where local features of a decision can be in tension with considerations that prove to matter more in the long run.

In fact, decisions that occur on a regular basis are often more meaningful when evaluated "in the long run." The decision to diet, to exercise, or to practice a musical instrument makes very little difference on any single occasion and can only be carried out under a long-term perspective that trumps the person's short-term preference for cake over vegetables, for sleeping late rather than jogging early, or for reading a good book rather than rehearsing a boring musical piece. In many instances that are interpreted as involving myopia, impatience, or the lack of self-control, people fail to take a long-term perspective when evaluating instances of recurring decisions, where the repeated perspective might be more ap-

propriate than regarding each choice as an isolated event.

When offered a 50% chance to win $2,000 and a 50% chance to lose $500, most participants refused to play this gamble once, but the majority were happy to play the gamble five times. Furthermore, when given the choice, most preferred to play the gamble six times rather than five. Apparently, fear of possibly losing the single gamble is compensated for by the high likelihood of ending up ahead in the repeated play. Other participants were asked to imagine already having played the gamble five times (outcome as yet unknown) and were given the option to play one additional such gamble: The majority of participants rejected this additional opportunity. Although participants preferred to play the gamble six times rather than five overall, once they had finished playing five and had readjusted their point of reference, the additional opportunity to play one more gamble was immediately "segregated" and treated as a single instance, which—as is known from the single-gamble version—participants prefer to avoid (Redelmeier & Tversky, 1992).

Along similar lines, physicians often can think of their patients "individually" (i.e., a patient at a time) or "globally" (as groups of patients presenting similar problems). In several studies, Redelmeier and Tversky (1990) found that physicians were more likely to take "extra measures," such as ordering an expensive medical test or recommending an in-person consultation, when they considered the treatment of an individual patient than when they considered a larger group of similarly afflicted patients. Personal concerns loom larger when patients are considered individually than when they are considered "in general," with the latter group more likely to highlight efficiency concerns. Because physicians tend to see patients one at a time, this discrepancy predicts a pattern of individual decisions that is often inconsistent with what these physicians would endorse collectively. For a more mundane example, people report greater willingness to wear a seatbelt—and to support pro-seatbelt legislation—when they are shown statistics concerning lifetime risk of being in a fatal accident, instead of the dramatically lower risk associated with any single auto trip (Slovic, Fischoff, & Lichtenstein, 1988).

Related patterns prompted Kahneman and Lovallo (1993) to argue that decision makers often err by treating each decision as unique, rather than as part of a series of similar decisions made over a lifetime (or, in the case of organizations, made by many workers). They distinguish an "inside view" of situations and plans, characterized by a focus on the peculiarities of the case at hand, from an "outside view," guided by analysis of a large number of relevant cases. Whereas the outside view, based, for example, on base rates, tends to lead to more accurate evaluation, people routinely adopt an inside view, which typically overweighs the particulars of the given case at the expense of more general and reliable (e.g., base rate) considerations. The inside view can thus generate overconfidence (Kahneman & Lovallo, 1993), as well as undue optimism, for example, regarding the chances of completing projects by early deadlines (Buehler, Griffin,

& Ross, 1994). In particular, the myopia that emerges from treating repeated decisions as unique leads to overly bold predictions and to the neglect of considerations that ought to matter in the long run. For example, although they know that past product launches have routinely run over budget and behind schedule, managers may convince themselves that this time will be different because the team is excellent and the product exceptional.

Temporal Considerations

A nontrivial task in the making of decisions, and one that is intimately related to considerations of repeated transactions, is the need to decide how much weight to give to outcomes extended into the future relative to if they were to occur right now. Various forms of uncertainty (regarding nature, one's own tastes, etc.) justify some degree of discounting in the calculation of the present value of future goods. The sum of $1,000 received a year from now is typically worth less than $1,000 received today. As it turns out, observed discount rates tend to be unstable and often influenced by factors, such as the size of the good and its temporal distance, that are not subsumed under standard normative analyses (for reviews, see Ainslie, 2001; Frederick, Loewenstein, & Donoghue, 2002; Loewenstein & Thaler, 1989). For example, although many prefer an apple today over two apples tomorrow, virtually nobody prefers one apple in 30 days over two apples in 31 days (Thaler, 1981). Because discount functions are nonexponential, a one-day delay has greater impact when that day is near than when it is far (see also Loewenstein & Prelec, 1992). Similarly, when asked what amount of money in the future would be comparable to receiving a specified amount today, people typically require about $60 in one year to match $15 now, but they are satisfied with $4,000 in a year instead of $3,000 today. This implies discount rates of 300% in the first case and 33% in the second.

Such discrepancy in the discount rates that are applied to small versus large amounts is, again, reminiscent of my excessive concern with the small detour in front of the parking garage while trying to cover a larger distance. To the extent that we engage in numerous transactions through time, imposing great discount rates on small amounts right now ignores the fact that repeated small amounts will add up to be large in the long run. This yields systematic inconsistency in attitudes toward small decisions as opposed to the full trajectory, which in many instances—my walk to school, for example—ought to count for more.

Excessive discounting turns into myopia, which can often be observed in people's attitudes toward future outcomes (see, e.g., Elster, 2000; Elster & Loewenstein, 1992). Loewenstein and Thaler (1989), for example, discuss an intervention in West Virginia in which the high school dropout rate was reduced by one-third when potential dropouts were threatened with the loss of their driving privileges. This immediate threat had a significantly greater impact than the far more serious but more distant socioeconomic implications of failing to graduate

from high school. In a similar vein, physicians apparently lament the fact that warning about the risk of skin cancer from excessive sun exposure has less impact than warning about sun exposure's tendency to cause acne. In fact, "quit smoking" campaigns have begun to stress the immediate benefits of quitting (quick reduction in chances of heart attack, improved ability to taste foods within 2 days, and so on) more prominently than the substantial long-term benefits (American Lung Association, 2003). Similar reasoning applies in the context of medical self-examinations and the promotion of safe-sex practices, where immediate discomfort or gratification can overwhelm much greater, but temporally distant, considerations (see also Schelling 1980, 1984). Myopia presents an extreme case of decisions made locally, with insufficient regard for more distant and global considerations. It stems from strong impulses triggered by local context that tend to overwhelm the construction of future preferences.

Trope and Liberman (2000, 2003) present compelling evidence suggesting that temporal distance systematically alters people's mental representations of future events and that this systematically changes the valuation of those events. They propose that changes in preference occur because temporal distance from actual engagement in an activity changes the way the activity is represented. Specifically, the more temporally distant events are, the more likely they are to be represented in terms of a few abstract features that convey their perceived essence ("high-level construals") rather than in terms of more concrete and secondary details ("low-level construals"), which gain in weight as the events grow closer. Indeed, these authors suggest that construal levels underlie a broad range of evaluative and behavioral consequences of psychological, not merely temporal, distance from events. We next turn to some other, nontemporal features that impact preference construction.

SOME ELEMENTS OF DECISION CONSTRUCTION

In line with construal processes in other areas of psychology, preferences appear to be constructed, not merely revealed, in the making of decisions (Slovic, 1995). The study of choice, as Payne, Bettman, and Schkade (1999) have suggested, often looks more like architecture, with preferences constructed in context, rather than as archaeology, with preferences being merely uncovered. And while this has major implications for the study of normative–descriptive tensions, it also sheds light on the processes that underlie the evaluation of alternatives.

Compatibility

Because people often do not have reliable views about the relative importance of various dimensions, the weights assigned to those dimensions can be influenced by relatively immaterial changes in the task, the description, and the nature of the options under consideration. Even simple monetary gambles, for example, differ on

payoffs and the chance to win. Respondents' preferences among such gambles can be assessed in different, but logically equivalent, ways (see Schkade & Johnson, 1989, for a review). Thus, participants may be asked to choose among the gambles, or, alternatively, they may estimate their maximum willingness to pay for each gamble. Although logically equivalent, these procedures often result in differential weightings of attributes and, consequently, in inconsistent preferences.

In line with the principle of stimulus–response compatibility, long recognized by students of human perception and motor performance (Fitts & Seeger, 1953; Wickens, 1984; see Shafir, 1995, for discussion), the weight given an attribute can be enhanced by its compatibility with a required response. Thus, a gamble's potential payoff can be weighted more heavily in a pricing task (in which both the price and the payoff are expressed in the same—monetary—units) than in choice (Slovic, Griffin, & Tversky, 1990; Tversky, Sattath, & Slovic, 1988; although see Frederick & Shafir, 2005). For example, consider two gambles: one offers an 8/9 chance to win $4 and the other a 1/9 chance to win $40. People typically choose the high-probability gamble but assign a higher price to the high-payoff gamble, thus expressing conflicting preferences (Grether & Plott, 1979; Lichtenstein & Slovic, 1971, 1973; Tversky, Slovic, & Kahneman, 1990). This pattern is known as the *preference reversal phenomenon* (Slovic & Lichtenstein, 1983). It has been replicated among professional gamblers in a Las Vegas casino (Lichtenstein & Slovic, 1973), and it has also been documented in numerous studies involving nonmonetary options, including choice between highway safety programs, job candidates, and interventions intended to address environmental problems (Kahneman & Ritov, 1994; Slovic et al., 1990; Tversky et al., 1988).

For another type of response compatibility, imagine having to choose or, alternatively, having to reject, one of two options. Logically speaking, the two tasks are interchangeable: If people prefer one option they will reject the second, and vice versa. However, people tend to focus on the relative strengths of options (more compatible with choosing) when they choose, and on weaknesses (compatible with rejecting) when they reject. As a result, options' positive features (the pros) loom larger in choice, whereas their negative features (the cons) are weighted relatively more during rejection. In one study, respondents were presented with pairs of options—an enriched option, with various positive and negative features, and an impoverished option, with no real positive or negative features (Shafir, 1993). For example, consider two vacation destinations: one with a variety of positive and negative attributes, such as gorgeous beaches and great sunshine but cold water and strong winds, and another that is neutral in all respects. Some respondents were asked which destination they preferred; others decided which to forgo. Because positive features are weighed more heavily in choice and negative features matter relatively more during rejection, the enriched destination was most frequently chosen and rejected. Overall, its choice and rejection rates summed to 115%, significantly more than the impoverished destination's

85%, and more than the 100% expected if choice and rejection were complementary (see also Downs & Shafir, 1999; but see Wedell, 1997, for an alternative interpretation).

Thinking back to our opening anecdote, it is worth noting that the cognitive principle of compatibility is itself highly "localized" in character. The compatibility between an option's features and the response is a function of the specific features that are locally prominent and the response that is required at the moment of decision. The prominent features may change with time or with perspective, and they may become more or less important with compounding or with frame. But such potential changes are unlikely to have any impact on the compatibility that emerges during the processing of the information that is salient at the moment of decision.

Decisional Conflict

Interestingly, according to the classical normative view, options are each assigned an attractiveness, or "utility" rating. In this view, there is not much room for decisional conflict. Regardless of how utilities are computed, once they have been assigned, independently for each alternative, the person is predicted to choose the option assigned the highest subjective utility. In contrast, according to the picture that emerges from the present discussion, choices can be hard to make. People need to construct their preferences in the context of making a decision, and they often do so by looking for a good reason, compelling rationale, for choosing one option over another. At times, compelling rationales are easy to come by and to articulate, whereas other times no easy rationale presents itself, rendering the conflict between options hard to resolve. Such conflict can prove aversive and can lead people to postpone the decision or to select a "default" alternative. The proclivity to resort to compelling rationales in an attempt to minimize conflict appears benign; nonetheless, it can generate preference patterns that are fundamentally different from those predicted by normative accounts based on value maximization.

Tversky and Shafir (1992a) presented subjects with pairs of options, such as bets varying in probability and payoff (after they were first invited to familiarize themselves with all options, to avoid the triggering of different expectations). Subjects could choose one of the two options or, instead, they could pay to add an additional option from a set of alternatives observed earlier. One group received the following two options:

Conflict:
x) 65% chance to win $15
y) 30% chance to win $35

Others received a similar choice except that option y was replaced by option x':

Dominance:
x) 65% chance to win $15
x') 65% chance to win $14

Note that gamble x is common to both conditions, whereas x' is strictly dominated by x, whereas y is a viable alternative. A moment's study should reassure the reader that the *conflict* condition presents an objectively superior set of alternatives to those offered in the *dominance* condition.

Subjects were asked to indicate whether they wanted to add another gamble or select between the available alternatives. Their preferred gamble from the resulting set (with or without the added option) was played out and their payoff was proportional to the amount of money they earned minus the fee they paid for the added gambles.

On average, subjects requested an additional alternative 64% of the time in the conflict condition, and only 40% of the time in the dominance condition ($p < .05$). The tendency to search for additional options, in other words, was greater when the choice among alternatives was harder to rationalize, although the quality of available options was superior, than when there was a compelling reason and the decision was easy, despite the fact that the available options were now less good.

According to standard assumptions of value maximization, a person should search for additional alternatives if and only if the expected (subjective) value of searching exceeds that of the best alternative currently available. Because the best alternative offered in the dominance condition was also available in the conflict condition, value maximization implies that the percentage of subjects who seek an additional alternative cannot be greater in the conflict than in the dominance condition.

It appears that the search for additional alternatives depends not only on the value of the best available option but also on the difficulty of choosing among the available options. In situations of dominance, for example, there are clear and indisputable reasons for choosing one option over another (e.g., "This bet offers an equal chance to win more!"). Having a compelling argument for choosing one of the options reduces the temptation to look for additional alternatives. When the choice involves conflict, on the other hand, reasons for choosing any one of the options are less immediately available and the decision is more difficult to justify (e.g., "Should I go for a greater chance to win less, or for a smaller chance to win more?"). In the absence of compelling reasons for choice, there is a greater tendency to search for other alternatives.

As the foregoing pattern clearly illustrates, decision conflict is a sentiment that is largely a feature of the local context; it is determined by the ease or difficulty of the present decision and can be quite independent of the actual worth of the available alternatives. Thus, a good alternative, when placed next to another good alternative, can make for a difficult decision, whereas a weaker alternative, when placed next to one that is substantially worse, can make the decision appear easy. The option the person ends up with, therefore, can be largely an accident of the particular set of alternatives encountered at the moment of decision. Reminiscent of my walk to school (Figure 14.1), where I had optimized not the en-

tire route but, rather, the specific detour around the garage standing in the way, so the subjects above appear to be choosing options as a function not of an overall preference ordering but of the specific decision conflict produced by the locally available alternatives.

Conflict and the Status Quo

One way to avoid conflict in choice is to opt for what appears like no choice at all, namely, the status quo. In one example (Tversky & Shafir, 1992a), participants who were purportedly looking to buy a CD player were presented with a Sony player that was on a 1-day sale for $99, well below the list price. Two-thirds of the participants said they would buy such a CD player. Another group was presented with the same Sony player, and also with a top-of-the-line Aiwa player for $159. In the latter case, only 54% expressed interest in buying either option, and 46% preferred to wait until they learned more about the various models. The addition of an attractive option increased conflict and diminished the number of people who ended up with either player, despite the fact that most preferred the initial alternative to the status quo. This violates what is known as the regularity condition, which states that the "market share" of an existing option—in this case, the status quo—cannot be increased by enlarging the offered set (see also Tversky & Simonson, 1993).

A related pattern was documented in an upscale grocery store, where shoppers encountered tasting booths that offered the opportunity to taste any of 6 jams in one condition, or any of 24 jams in the second (Iyenger & Lepper, 2000). In the 6-jams condition 40% of shoppers stopped to have a taste and, of those, 30% proceeded to purchase a jam. In the 24-jam condition, a full 60% stopped to taste, but a mere 3% purchased. Presumably, the conflict generated by so many options proved hard to resolve. In a similar vein, Huberman, Iyengar, and Jiang (2004) found that employees' participation in 401(k) retirement savings plans drops as the number of fund options proposed by their employer increases.

Decisional conflict tends to favor default alternatives, much as it advantages the status quo. In one study, students agreed to fill out a questionnaire in return for $1.50. Upon completion of the questionnaire, half of the respondents were offered the opportunity to exchange the $1.50 (the default) for one of two prizes: a metal *Zebra* pen, or a pair of plastic *Pilot* pens. The remaining subjects were only offered the opportunity to exchange the $1.50 for the *Zebra*. The pens were shown to subjects, who were informed that each prize regularly costs about $2. The results were as follows. Twenty-five percent opted for the payment over the *Zebra* when the *Zebra* was the only alternative offered, but a reliably greater 53% chose the payment over the *Zebra or* the *Pilot* pens when both options were available (Tversky & Shafir, 1992a). Whereas the majority of subjects took advantage of the opportunity to obtain a valuable alternative when only one was offered, the availability of competing valuable alternatives increased the tendency to retain the default option.

Related effects have been documented in decisions made by expert physicians and legislators (Redelmeier & Shafir, 1995). In one scenario, due to caseload in the operating room, neurologists and neurosurgeons were asked to decide which of several patients awaiting surgery ought to be operated on first. Half the respondents were presented with information about two patients, a woman in her early 50s and a man in his 70s. Others saw the same two patients along with a third, a woman in her early 50s who was highly comparable to the first, so that it was difficult to think of a rationale for choosing either woman over the other. As predicted, more physicians (58%) chose to operate on the older man in the latter version, where the two highly comparable women generated decisional conflict, than in the former version (38%), in which the choice was between only one younger woman and the man. (Note that chance would have acted in the opposite direction.)

Adherence to the default or status quo has also been observed in a couple of naturally occurring "experiments." One was in the context of insurance decisions, when New Jersey and Pennsylvania both introduced the option of a limited right to sue, entitling automobile drivers to lower insurance rates. The two states differed in what was offered as the default option: New Jersey motorists needed to acquire the full right to sue (transaction costs were minimal: a signature), whereas in Pennsylvania, the full right to sue was the default, which could then be forfeited in favor of the limited alternative. Whereas only about 20% of New Jersey drivers chose to acquire the full right to sue, approximately 75% of Pennsylvania drivers chose to retain it. The difference in adoption rates had financial repercussions estimated at nearly $200 million (Johnson, Hershey, Meszaros, & Kunreuther, 1993). A second naturally occurring "experiment" was recently observed in Europeans' decisions regarding being potential organ donors (Johnson & Goldstein, 2003). In some European nations drivers are by default organ donors unless they elect not to be, whereas in other, comparable European nations they are, by default, not donors unless they choose to be. Observed rates of organ donors are almost 98% in the former nations and about 15% in the latter, a remarkable difference given the low transaction costs and the significance of the decision.

The addition of options can generate conflict and increase the tendency to refrain from choosing. Other options, on the other hand, can lower conflict and increase the likelihood of making a choice. *Asymmetric dominance* refers to the fact that in a choice between options A and B, a third option, A′, can be added that is clearly inferior to A (but not to B), thereby increasing the choice likelihood of A (Huber, Payne, & Puto, 1982). For example, a choice between $6 and an elegant pen presents some conflict for participants. But when a less attractive pen is added to the choice set, the superior pen clearly dominates the inferior pen, thus providing a rationale for choosing the elegant alternative and increasing the percentage of those choosing the elegant pen over the cash. Along related lines, a *compromise effect* has been observed

wherein the addition of a third, extreme option makes a previously available option appear as a reasonable compromise, thus increasing its popularity (Simonson, 1989; Simonson & Tversky, 1992).

Standard normative accounts do not deny conflict, nor, however, do they assume any direct influence of conflict on choice. (Under utility maximization, there does not appear to be much room for conflict: Either utility differences are large and the decision is easy, or they are imperceptibly small and the decision is of little import.) In actuality, people are concerned with making the "right" choice, which gives decisional conflict an influence considerably greater than suggested by considerations of value maximization. Conflict is an integral aspect of decision making, and the phenomenology of conflict, which can be altered via the addition or removal of alternatives, yields systematic choice patterns that often violate standard normative predictions.

What is most remarkable, and lies at the heart of the tension with the normative account, is the "local" character, the heavy context dependency, of the observed choices. The normative account assumes a well-behaved ordering of preferences, with any observed choice revealing a glimpse into that order. In contrast, people's actual choices are often the result of the local resolution of conflict between alternatives, with the option chosen often not the option that would have been chosen had context differed by just a little, and often in rather trivial ways. A major contributor to the local construction of preference is people's reliance on what feel like good reasons or compelling rationales for making a decision. We turn to a brief consideration of such reasons next.

Reasons

Reminiscent of the notion of the "need for closure" (Kruglanski & Webster, 1996), people confronted with nontrivial decisions like to feel like they have made the "right choice." In an attempt to make the right choice, people often look for good reasons, for compelling arguments, for choosing one option over another (Shafir, Simonson, & Tversky, 1993). Relying on good reasons seems like sound practice; the converse, making a choice without good reason, seems unwise. At the same time, abiding by this practice can be problematic because the reasons that come to mind often are heavily context dependent, limited to what is introspectively accessible, and not necessarily those that guide, or ought to guide, the decision at hand. For example, participants who were asked to analyze *why* they felt the way that they did about some jams they had a chance to taste showed less agreement with "expert" ratings of the jams than did those who merely stated their preferences without explanation (Wilson & Schooler, 1991). Preference can be altered in line with reasons that come readily to mind, but those reasons may be heavily influenced by salience, availability, or local context. (Further inquiry into the logic of reason salience is likely to bring forth a panoply of other, nuanced considerations, such as the distinction between the availability of reasons—for example, a comparison to other options, which may not be available when the op-

tion is considered in isolation—as opposed to the salience or accessibility of reasons, which may be influenced by description or method of elicitation; see Higgins, 1996.) Focusing on a set of temporarily available or salient reasons can cause one to lose sight of other, perhaps more valid considerations (Wilson, Dunn, Kraft, & Lisle, 1989).

In fact, people are not always aware of their reasons for acting and deciding (see, e.g., Bargh, 1997; Nisbett & Wilson, 1977). In one example, participants, presented with four identical pairs of stockings and asked to select one, showed a marked preference for the option on the right end of the display. However, despite the evidence that choice was governed by position, no participant mentioned position as the reason for his or her choice. Respondents easily generated "reasons" (in which they cited attributes such as texture), but the reasons they provided bore little resemblance to those that actually guided choice (Nisbett & Wilson, 1977). Related work by Schwarz and colleagues on the experience of reason accessibility (e.g., Sanna, Schwarz, & Small, 2002; Schwarz, 1998; Schwarz et al., 1991) has documented paradoxical patterns wherein the availability of a greater number of reasons that felt more difficult to generate yields more reluctant decisions than a small subset of those reasons produced easily.

Because nuanced factors that are salient in the local context can determine which reasons emerge as most apparent, a reliance on reasons can induce great preference malleability. In one study (Tversky & Shafir, 1992b), college students were asked to imagine that having just taken and passed a difficult exam, they now had an opportunity to buy an attractive vacation package over the Christmas holidays at a low price. Respondents faced the following options: They could choose to buy the vacation package, they could forego the vacation package, or they could pay a $5 fee to defer the decision by a day. The majority elected to buy the vacation package, and less than a third elected to delay the decision. A second group was asked to imagine that they had taken the exam and failed and would need to retake it after the Christmas holidays. They were then presented with the same choice, and as before, the majority elected to buy the vacation package, and less than a third preferred to defer. However, when a third group of participants was to suppose they did not know whether they had passed or failed the exam, the majority preferred to pay to defer the decision until the next day, when the exam result would be known, and only a minority were willing to commit to the trip without knowing. Apparently, participants were comfortable booking the trip when they had clear reasons for the decision—celebrating when they passed the exam or recuperating when they had failed—but were reluctant to commit when their reasons for the trip were uncertain. This pattern, which violates the *sure thing principle* (Savage, 1954), has been documented in a variety of contexts, including gambling and strategic interactions as manifested in prisoner's dilemma games (Shafir, 1994; Shafir & Tversky, 1992).

The tendency to focus on information that is unavailable at the moment of decision, as suggested by the fore-

going studies, can lead to delays that have a significant impact. Consider the following scenario (Bastardi & Shafir, 1998):

> For some time, you have considered adding a compact disc (CD) player to your stereo system. You now see an ad for a week-long sale offering a very good CD player for only $120, 50% off the retail price. Recently, however, your amplifier broke. You learn that your warranty has expired and that you have to pay $90 for repairs.

One group (the "simple" condition) was asked whether they would buy the CD player during the sale, and the vast majority (91%) said they would. Another ("uncertain") group was presented with the same scenario but were told that they would not know until the next day whether their warranty covered the $90 repairs. These respondents could opt to wait until the following day (when they knew about the warranty) to decide whether to buy the CD player. Sixty-nine percent elected to wait. Those who chose to wait then learned that the warranty had expired and would not cover repairs. Upon receiving the news, the majority decided not to buy the CD player. Note that this contrasts sharply with the unequivocal choice to buy the CD player when the $90 repair costs were a given. Although they faced the same decision, only 55% (over all those who waited and those who did not) chose to buy the CD player in the uncertain condition, when they did not know but could pursue information about the repair costs, compared with 91% in the certain condition, when repair costs were known from the start. The decision to pursue information that is locally unavailable can focus attention on the information obtained and thereby trigger reasons for making the choice that would have had little impact otherwise, ultimately distorting preference (Bastardi & Shafir, 1998). Similar patterns have been replicated in a variety of contexts, including one involving professional nurses in a renal-failure ward, more of whom expressed willingness to donate a kidney (to a hypothetical relative) when they had purportedly been tested and learned that they were eligible than when they had known they were eligible from the start (Redelmeier, Shafir, & Aujla, 2001). A reliance on reasons in choice renders decision makers susceptible to a variety of contextual, procedural, and circumstantial nuances that make alternative potential reasons salient and thus help shape preferences, often in discrepant and possibly suboptimal ways.

Transient Frames of Mind

Emotions

Emotional reactions are another major facilitator in allowing local contexts to play a prominent role in determining preference. Much of literature and the arts are devoted to the eternal tension between passion and reason and the influence that heightened states of arousal can have on actions that conflict with long-term interests. But at a more mundane level as well, emotional reactions, often undetected, can contribute to a variety of local influences on decision making. Indeed, transient moods influence choice and judgment in ways that neither rationality assumptions nor intuition predicts (Zajonc, 1980; Zajonc & Markus, 1982). Negative moods, for example, can increase the perceived likelihood of bad outcomes and the frequency of undesirable events (such as homicides) and to decrease judged life satisfaction, while positive moods act in the opposite direction (Johnson & Tversky, 1983, Schwarz & Clore, 1983). Furthermore, those in positive moods often engage in attempts at "mood maintenance," among other things through greater risk aversion (Isen & Geva, 1987; Isen, Nygren, & Ashby, 1988). In a related vein, Trope and his colleagues (e.g., Trope, Ferguson, & Raghunathan, 2000) have explored the influence of mood as a resource that serves in coping with emotionally challenging messages. Raghunathan and Trope (2002), for example, document the differential impact of a good mood when processing counterattitudinal messages that are or are not relevant to the decision maker.

Interestingly, moods with the same valence can have differential effects on judgment; for example, anger and fear, both negative emotions, seem to have different effects on individuals' appraisal of control and, consequently, yield optimism and pessimism about future risks, respectively (Lerner & Keltner 2001). Similarly, Raghunathan and Pham (1999) have suggested that sad individuals tend to be more risk prone, whereas anxious individuals are more risk averse. They attribute these tendencies to the notion that anxiety and sadness convey different information to the decision maker and prime different goals, with anxiety promoting an implicit goal of uncertainty reduction and sadness an implicit goal of reward achievement. In fact, the salience of alternate goals, often induced by mood, is another contributor to the effects of local contexts, with different goals often primed by contextual nuances and interim subgoals possibly drawing attention away from goals that are higher in the hierarchical goal structure (Kruglanski et al., 2002; Shah & Kruglanski, 2002; Trope, Igou, & Burke, 2006).

An "affect heuristic" has been proposed, according to which spontaneous and effortless judgments are often made through quick consultation of images marked by positive and negative affective feelings (Finucane, Alhakami, Slovic, & Johnson, 2000; Slovic, Finucane, Peters, & MacGregor, 2002). The role of emotional reactions can be witnessed, for example, in the inverse relationship commonly observed between perceived risks and benefits, such that activities that are thought by people to have great benefits are seen by those same people as presenting few risks, and vice versa. Typical of a heuristic outcome, this unlikely inverse relationship, purportedly mediated by affect, is strengthened under time pressure (Finucane et al., 2000; Fischhoff, Slovic, Lichtenstein, Reid, & Combs, 1978). Because, in line with an affect heuristic, emotional reactions can generate powerful associations, respondents show a relative insensitivity, once emotionally powerful events are considered, to these events' actual probability of occurrence (Rottenstreich & Hsee, 2001). In a similar vein, both the perceived frequency of common events and the perceived likelihood of risks such as nuclear power are re-

lated to the amount of dread that they arouse (Fischhoff et al., 1978; Lichtenstein, Slovic, Fischoff, Layman, & Combs, 1978).

Emotionally evaluative responses can have a non-negligible effect on decision. For one example, mere cognitive effort can generate negative emotions and influence the probability that the alternative producing such effort will be chosen (Garbarino & Edell, 1997). For a different example, participants are apparently willing to pay more to insure, and are more likely to seek compensation for, an item that is emotionally meaningful than for an emotionally neutral but equally valuable item (Hsee & Kunreuther, 2000). More generally, Loewenstein, Weber, Hsee, and Welch (2001) suggest that "anticipatory emotions" (e.g., emotional reactions to potential outcomes in a risky situation) can influence the cognitive appraisal of decision situations and can impact choice. Shiv and Fedorikhin (1999) consider situations in which consumers are influenced by automatically evoked affect as well as by more controlled cognitions, and they present findings suggesting that when processing resources are limited, spontaneous affective reactions have a greater impact relative to cognitions compared to when the availability of processing resources is high.

Transient emotions, often triggered by local contextual factors, can thus influence the construction of preference. Grocery shopping while very hungry, for example, is likely to lead to purchases that would not have been made under normal circumstances (cf. Loewenstein, 1996). But, as with other contextual influences, even when people are aware of being in the grip of a transient emotion, they typically fail to "correct" adequately. In one study, for example, respondents were asked to predict whether they would be more bothered by thirst or by hunger if trapped without food and water. Some were asked before exercising (when they were not especially thirsty) whereas others were approached immediately after exercising (and, thus, were thirsty). Postexercise, 92% indicated that they would be more troubled by thirst than by hunger, whereas preexercise only 61% did (Van Boven & Loewenstein, 2003). In general, people tend to underestimate the degree to which various contextual changes will impact their sentiments and preferences (e.g., Gilbert, Pinel, Wilson, Blumberg, & Wheatley, 1998; Van Boven, Dunning, & Loewenstein, 2000). This contributes to what look like myopic decisions, as people honor present inclinations, not fully appreciating the extent to which these may be attributable to local factors that may soon change.

Automaticity and Priming

A variety of priming effects and automatic processes further contribute to decisions that are responsive to highly local influences, which often have little relevance to eventual consumption. At one extreme are phenomena such as mere priming, where mere repeated exposure to objects, even subliminally, can increase their liking (Bornstein, 1989; Zajonc, 1968). In a classic priming study, participants received a "word perception test" in which either creativity, reliability, or a neutral topic was primed. Participants then completed an ostensibly unrelated "product impression" survey that gauged their opinions of various cameras. Cameras advertised for their creative potential were rated more attractive by those primed for creativity than by those exposed to words related to reliability or a neutral topic (Bettman & Sujan, 1987). Momentary priming can influence ensuing preferences, rendering salient criteria that would otherwise have been considered less important. Due to the highly local nature of such salience effects, product consumption is often likely to occur long after such criterion salience has dissipated (see Mandel & Johnson, 2002; Verplanken & Holland, 2002).

Then, there are a variety of automatic and imperceptible influences, where, for example, a momentary, context-induced physical reaction can influence an ensuing decision. Thus, people who happened to have a waitress touch them lightly on the shoulder are found to tip higher than those who were not touched (Crusco & Wetzel, 1984; Schwarz, 1990, Schwarz & Clore, 1983.) Or, for another example, male participants who encounter a woman on a fear-arousing suspension footbridge are likely, due to misattributed arousal produced by the wobbly bridge, to consider the woman more attractive and are consequently more likely to follow up with a phone call than others who meet the woman before the bridge (Dutton & Aron, 1974). The judged funniness of cartoons can be influenced by the perceived state of one's zygomaticus muscle (involved in smiling) in contexts in which smiling is either facilitated or inhibited, and evaluative processes can be influenced by unrelated tasks such as the Isometric flexion ("approach behavior") or extension ("avoidance behavior") of the upper arm (Neumann & Strack, 2000).

Unavoidable "local" contextual influences occur also during simple interpersonal interaction, and they have been studied, and used, by marketing researchers. Consider, for example, the effects of hypothetical questions on respondents' subsequent decisions. One line of investigation has shown that people's prediction of their future behavior, although inaccurate, can affect their actual behavior. In one experiment (Sherman, 1980), college students were asked to write counterattitudinal essays. In a prior, seemingly unrelated survey, half the students were asked to predict whether they would comply with such a request, and many predicted they would not. The eventual rate of compliance among those who made this prediction was much lower than among those who had not made an earlier prediction. Subjects had thus mispredicted their own behavior (because many would have written the essay had they not been asked to predict in advance). Nonetheless, the actual rate of compliance was close to that predicted. In effect, people went on to decide in a manner consistent with their own mispredictions. Related research has shown the potential role of such self-erasing errors in increasing voter turnout simply by asking people to predict whether they will vote (Greenwald, Carnot, Beach, & Young, 1987).

Even when faced with questions that are purely hypothetical, respondents are unable to prevent a substantial biasing effect on their behavior, particularly when the

questions appear relevant (Fitzsimons & Shiv, 2001). Thus, gauging attitudes toward consumer products can increase attitude accessibility and impact consumer behavior (Chapman, 2001; Fazio, Powell, & Williams, 1989). For example, Morwitz, Johnson, and Schmittlein (1993) found that merely asking consumers whether they intended to purchase an automobile or a personal computer increased their subsequent purchase rate. Follow-up interviews suggest that the effects of hypothetical questions on choice occur beyond awareness and, as a result, are quite difficult to counteract.

A rich and fascinating literature documents the many ways that mere exposure, simple priming, subliminal perception, and unconscious inferences alter judgment and choice. A common theme running through many of these phenomena is the fact that they are heavily context sensitive, induced by nuances that can shift at any moment. The extent to which they impact the local construction of preferences may have little to do with the contexts surrounding consumption. The person touched on the shoulder leaves a larger tip without receiving better service, and the man who calls the person he met on the bridge may be disappointed when they meet again on firm ground. Reminiscent of my detour around the parking garage (Figure 14.1), these are actions that often may prove tangential to one's greater aims and occasionally may cause distortion and error.

Identities

Constructed preferences can further fluctuate as a function of personal identities that happen to be locally salient. A working mother, for example, might think of herself primarily as a mother when in the company of her children but may see herself primarily as a professional while at work. The list of potential identities is extensive (Turner, 1985), with some of a person's identities (e.g., "mother") conjuring up strikingly different values and ideals from others (e.g., "CEO").

Identity salience has been shown to affect various behaviors, including resistance to persuasion (Kelley, 1955), reactions to advertisements (Forehand, Deshpandé, & Reed, 2002), and the rating of consumer products (Reed, 2004). In one study, Asian American women (who hold identities—Asian vs. woman—that entail conflicting expectations about mathematical ability) scored higher on a math test after completing a brief survey that evoked their ethnicity than did those who first completed a survey that evoked gender (Shih, Pittinsky, & Ambady, 1999).

Along similar lines, decisions can be seen to depend on local and happenstance fluctuations in identity salience. In one study, college students whose "academic" identities had been triggered were more likely to opt for more academic periodicals (e.g., *The Economist*) than were those whose "socialite" identities had been made salient. Similarly, Chinese Americans whose American identities were evoked adopted more stereotypically American preferences (e.g., for individuality and competition over collectivism and cooperation) compared to when their Chinese identities had

been triggered (LeBoeuf, 2002; LeBoeuf & Shafir, 2005a).

Whereas these findings are consistent with research on the fluidity of the self-concept (cf. Higgins, 1987; Markus & Kunda, 1986), individual personality traits can also have an impact that depends on local context. As documented by Higgins and his colleagues, the fit between the manner of making a decision and the person's regulatory orientation can influence people's level of engagement with and their evaluation of outcomes. For example, participants assigned a higher price to a coffee mug if they had chosen it using a strategy that fit their orientation (eager strategy/promotion; vigilant strategy/prevention) than a strategy that did not fit (Avnet & Higgins, 2006; Higgins, 2000; Higgins, Idson, Freitas, Spiegel, & Molden, 2003).

Although choice and evaluation are typically expected to reveal stable and coherent patterns that correspond to the person's overall preference rankings, evoked identities tend to activate concepts and priorities that are associated with particular tastes and values, which, in turn assimilate preferences to the evoked identity (cf. Bargh, Chen, & Burrows, 1996; Higgins, Rholes, & Jones, 1977). Preference thus tends to align with currently salient identities, yielding predictable tension anytime there is a mismatch between the identity that does the choosing and the one likely to do the consuming, as when a parent, while at work, commits to an evening meeting only to regret missing her child's soccer game once back at home.

Utility Prediction

Some recent research has explored the question whether people actually maximize the expected experienced utility of a decision (i.e., the hedonic experience that the decision will bring) as opposed to merely the decision utility (i.e., the utility perceived at the moment of decision) (Kahneman, 1994). In general, utility mispredictions are common. When predicting the impact on their lives of various events, people tend to focus too heavily on those specific events, consequently overestimating the impact these will have on their lives and on their life satisfaction (Schkade & Kahneman, 1998; Wilson, Wheatley, Meyers, Gilbert, & Axsom, 2000). In a similar vein, thinking about their own mood appears to increase decision makers' concern with the hedonic consequences of decisions, thereby promoting mood-regulatory activities and altering preference, possibly in favor of otherwise less preferred alternatives (Caruso & Shafir, 2005).

In making such forecasts, people tend, among other things, to neglect the eventual dissipation of satiation (Simonson, 1990); they often misremember options previously encountered due to inferences made at present or to the overweighting of final moments (Kahneman, Frederickson, Schreiber, & Redelmeier, 1993; Mather, Shafir, & Johnson, 2000), and they often fail to anticipate increases in liking due to mere exposure or endowment (Kahneman & Snell, 1992; Van Boven et al., 2000) and tend to underappreciate the extent to which they will be able to maintain a level of satisfaction in the face of ad-

versity (Gilbert et al., 1998, Kahneman, Diener, & Schwarz, 1999).

One common cause for the misprediction of future utility is the tendency to anchor on the present and to focus heavily on the change between how things are now and how they will become, as opposed to how they might be, in steady state, once they have changed. Like preferences, utility predictions are often formed during the decision making process, and present-biased utility expectations are likely to result in courses of action that often fail to maximize future well-being.

CONCLUDING REMARKS

This chapter has considered people's proclivity to make "local" decisions. Such decisions are shaped by considerations and impulses that are triggered by the local context of decision, rather than by a more global evaluation, which—as dictated by a normative analysis—would be guided by foresight and planning and by considerations of compounding and consistency.

At the core of this account lies a classic case of divergence in disciplinary sensitivities. Whereas the notion of "construal" is now second nature to social psychologists, it is far less obvious to common intuition, and even less so in economics. Economic thinking concerns itself with states of the world. The axioms that underlie the normative treatment are stated in terms of extensional outcomes, where each option, representing a state of the world, is clearly and uniquely designated, independently of how precisely it may be described or perceived. The problem with this perspective is a painfully obvious but profoundly consequential fact about human nature: People's decisions are not directly about objective (extensional) states of the world but about the mental (intensional) representations of those states. And the mental representation of states of the world is subject to a rich psychology, involving embellishment, interpretation, and distortion, much of it arising at the time of having to make a decision. As a consequence, trivial contextual features can have an unwarranted impact, and nuanced differences in otherwise logically equivalent representations of options can generate widely different perceptions, trigger different reactions, and yield different preferences.

The implications of this tension are profound. Although people tend to endorse the normative desiderata upon reflection, their decision behaviors, driven as they are by intuitive evaluation, automatic processes, and locally triggered impulses, often violate the normative requirements in systematic and predictable ways (Shafir & LeBoeuf, 2002). We have recently conducted a field experiment in South Africa to assess the relative importance of subtle psychological features compared to price in the decision to take a loan from a local lender (Bertrand, Karlan, Mullainathan, Shafir, & Zinman, 2005). Some 57,000 incumbent clients of the lender were sent letters offering large, short-term loans at randomly chosen interest rates. Consistent with standard economics, those offered higher rates were less likely to take a

loan than those with access to lower rates. In addition, various "psychological" features on the offer letter, which did not affect offer terms or economic content, were also independently randomized. One of the features consisted of the number of sample possible loans displayed: The offer letter displayed either one example of a loan size and term, along with the respective monthly repayment information, or multiple (four) such examples of loan sizes and terms. In contrast with standard economic prediction, and in line with the foregoing discussion regarding decisional conflict and the proliferation of alternatives, we found higher takeup of the loan under the one-example description than under the multiple-example version. The magnitude of this effect was large: The more limited description of the offer had the same positive effect on takeup as dropping the monthly interest on these loans by 2 percentage points. (In a similar vein, Huberman et al., 2004, find that employees' participation in 401(k) plans drops as the number of fund options proposed by their employer increases.) We also randomized the presence or absence of a smiling woman's picture in the bottom corner of the offer letters. For the men in the sample, the presence of that picture had the same positive effect on takeup as dropping the monthly interest on the loans by 4.5 percentage points! On average, any one psychological manipulation we tried had the same effect as a one-half-percentage-point change in the monthly interest rate on loans that averaged one-third of the borrowers' monthly income.

People's decisions are influenced by a variety of factors. Some factors, such as a concern with fairness, the tendency to defer difficult decisions, and even attitudes toward gains and losses, may be, at least in part, conscious and intentional. Others, such as those based on automatic processing, happen entirely out of awareness. Most people who are not well versed in current behavioral research, for example, would most likely be unwilling to entertain the possibility that a touch on the shoulder or a picture in the corner of a letter predispose them to make substantially different economic decisions. Choice behavior is the outcome of a variety of cognitive and affective processes. Some of these—as well as others that are not true about us—we consciously and proudly endorse; others we have no introspective access to or control over. What is common to many of these is that they are creatures of the moment. They arise from a local context and are employed in the construction of preferences we need to form. But local contexts change, and with them the cues and features that impinge upon our valuation of alternatives. As a result of this malleability, our decisions often violate the most basic consistency requirements, including the requirements of independence of irrelevant alternatives, and of independence from irrelevant descriptive or procedural nuances. Also, because these often diverge, the context-sensitive character of our decision making tends to call into question the presumed continuity between the contexts of decision and those surrounding consumption. Normative treatments tend to focus less on specific decisions and more on the aggregate outcomes they produce in combination. Much

of our mental apparatus, on the other hand, both conscious and not, focuses heavily on each decision in turn, with limited attention devoted to aggregate outcomes. Our tendency to construct decisions in context, quirky, often sophisticated, but highly localized, produces some excellent constructions as well as others that are not so good. Typically, however, these occur in the absence of an overall plan, leading to patterns we would have wished to design otherwise had we been able to think about it differently.

NOTES

1. Of course, as time progressed, my commute became habitual and was performed by rote. This, in fact, captures another key feature of many decisions. They are first made under the influence of local context and later become thoughtless and "automatic."
2. Of course, the horizon that ought optimally to be taken in making such decisions can be a matter of some debate and may depend on the options under consideration. Classic economic theories of saving often assume maximization over one's life cycle. For many other decisions—such as how best to plan our Christmas vacation—shorter horizons are sufficient. This issue does not have an impact on the present discussion.

Psychological Distance

Elena Stephan

WHAT IS PSYCHOLOGICAL DISTANCE?

Psychologically distant things (objects, events) are those that are not present in the direct experience of reality. We would like to set aside the philosophical questions regarding the objective existence of reality and focus, instead, on people's subjective experiences of reality, divergence from such experiences, and the consequences of those. People believe that they directly experience themselves and their immediate surroundings at the present moment. Anything that is not present is distal. It may be thought of, constructed, or reconstructed, but it cannot be experienced directly. There are different reasons for things not to be present in the immediate reality experienced by me. Things may belong to the past or to the future (e.g., my first year of marriage, my first year of school), to spatially remote locations (e.g., my parents' house, the North Pole), to other people (the way my best friend or a person from another culture perceives the present situation), and to hypothetical alternatives to reality, what could or might have been but never materialized (e.g., had I married another person or had I had wings). These alternatives to the directly experienced reality define, respectively, four dimensions of psychological distances—temporal distance, spatial distance, social distance, and hypotheticality. In each pair of examples of distal things, the first example is more proximal than the second. We would like to propose that in relation to psychological distance, these various distance dimensions are anchored on a single starting point (zero distance

point), which is my direct experience of the here and now. Anything else—other times, other places, experiences of other people, and hypothetical alternatives to reality—is a mental construct.

This analysis suggests a basic relationship between psychological distance and construal; that is, any distancing (i.e., moving beyond direct experience) involves construal. Based on construal-level theory (CLT; Liberman & Trope, 1998; Trope & Liberman, 2003), we distinguish between extents (levels) of construal and propose that more distal entities, which are more remote from direct experience, are construed on a higher level (i.e., involve more construal). The reason for this change in construal could be that as we move away from direct experience of things, we have less information about those things. Thus, we know less about the more distant future and the more distant past, we know less about more remote places, we know less about acquaintances than about close friends, and, finally, we know less how the world would have been with more remote (i.e., less probable and more difficult to imagine) alternatives to reality. In all those cases, lack of knowledge about the more remote entities—people, events, places, alternatives—requires representing them more abstractly than proximal entities.

Sometimes, in the absence of knowledge about distal entities, one may extrapolate from proximal ones. For example, if I do not know how my friend felt about a movie, I may reason that she is similar to me and assume that her feelings were similar to mine. Ordinarily, simi-

larity decreases with distance (e.g., the distant future becomes increasingly less similar to the present and more distal people are increasingly less similar to ourselves) and with it the ability to project (i.e., extrapolate) direct experience. Schematic construals are employed instead. For example, if I assume that the experiences of a person from another culture are dissimilar to mine, then I need to resort to general schemas in order to construe those experiences. More generally, in the absence of any specific knowledge about either a distal or a proximal entity, the former would be less likely construed in concrete terms than the latter.

We thus propose that because there is less information about distal entities than proximal entities, people typically construe the former more abstractly than the latter. As a result, an association is formed between psychological distance and level of construal, and the use of more abstract construals for more distal entities may be generalized beyond the conditions that initially gave rise to the association. That is, people may construe distal entities at a high level and proximal entities at a low level even when information on these entities is equally available or obtainable. Differential knowledge explains how the association between distance and level of construal was formed, but it does not necessarily explain every specific case of construing distal entities at a high level.

It is important to note that estimations of distance are subjective. What determines level of construal is not the physical distance as measured in meters or temporal distance as measured in seconds but, rather, the subjective experience of distances as large or small. The same objective distance may look differently due to psychological factors, some of which are "cognitive" (e.g., division into more stages may enhance perceived distance), and some are "motivational" (e.g., in the service of self-enhancement, one's negative behaviors may seem more distant than one's positive behaviors). This chapter does not address the question of how objective units of distance translate into subjective experiences. Rather, we address the effects of perceived distance on other outcomes, such as level of construal, prediction, affect, and choice.

PLAN OF THE CHAPTER

The next section discusses in more detail the concept of level of construal and the association between level of construal and psychological distance. That section addresses two implications of this association, namely, that psychological distance would produce higher levels of construal and that, conversely, high levels of construal would enhance perceived distance. The third section examines the effects of psychological distance on confidence in prediction, intensity of affective reactions, and evaluation and choice. We present evidence suggesting that the effects of various distance dimensions are similar to each other and are mediated by level of construal. The fourth section further proposes that the different psychological distances are interrelated and to some extent interchangeable. That is, distancing an object on one dimension may be exchanged for distancing the object on another dimension.

PSYCHOLOGICAL DISTANCE AND LEVEL OF CONSTRUAL

What Is Level of Construal?

Before examining how psychological distance and level of construal affect each other, we discuss in more detail the concept of level of construal. Our basic premise is that high-level construals change the meaning of events by forming more abstract representations of the events. A defining property of concrete representations is that they lend themselves to multiple abstract representations. For example, the concrete action "waving a hand" could be identified more abstractly as threatening or, alternatively, as being friendly (Vallacher & Wegner, 1987), and "a poodle" could be classified as a pet or, alternatively, as a mammal (Rosch & Lloyd, 1978). An abstract representation is selected among different possible abstractions according to context-defined relevance, which, in turn, may be affected by one's goals. Thus, if one's goal is to buy a poodle for a child, then "a pet" is a relevant category and friendliness is relevant, but if one's goal is scientific zoological classification, then "a mammal" is a relevant category and friendliness is of less relevance.

Usually, some aspects of the focal stimulus are more closely related to one interpretation or categorization (the hand movement was relatively fast; poodles are friendly), while other aspects are more closely related to other interpretations or categorizations (the person who waved her hand seemed to smile; poodles are warm blooded). Moving from a concrete representation to an abstract representation involves deciding on one of the alternative abstract representations. This, in turn, means omitting the features that are perceived to be less important while retaining those considered more central or important to the abstract construct in question. For example, in replacing "waving a hand" with the more abstract construal "showing friendliness," the fact that one used one's hand is omitted (Semin & Fiedler, 1988). Similarly, in representing a poodle as a pet, warm-bloodedness is omitted (Rosch & Lloyd, 1978). Like irrelevant details, details that are inconsistent with the chosen abstract representation are omitted from the representation or assimilated into it. For example, the detail that the hand waving was slightly faster than usual would be omitted or modified once the "being friendly" interpretation is chosen.

Because abstract representations necessarily impose one of possibly many alternative interpretations, and because irrelevant or inconsistent details are omitted from the abstract representation or assimilated to it, abstract representations may be expected to be simpler, less ambiguous, and more prototypical than concrete representations (Fiske & Taylor, 1991; Smith, 1998). Abstraction thus involves moving to a more schematic, simple, and coherent representation.

There are multiple levels of abstractness, as one could construct less inclusive or more inclusive categories of objects (e.g., poodle, dog, or mammal). In feature-based theories of categorization, more inclusive categories have fewer features and therefore are simpler than concrete categories (Rosch & Lloyd, 1978). Actions also form hierarchies of abstractness (e.g., giving money, helping, and being a good person) with each level of abstractness containing less concrete details about the specific type of action performed and the objects it involved (Semin & Fiedler, 1988; Trope, 1989). In the same way, traits form hierarchies (e.g., an excellent guitarist, musical, and talented) such that more abstract traits are less detailed about the behaviors, objects, circumstances, and people they involve (Hampson, John, & Goldberg, 1986). Goal-directed actions form hierarchies too, as goals could be translated into more abstract, superordinate goals (Carver & Scheier, 2000; Miller, Galanter, & Pribram, 1960; Vallacher & Wegner, 1987). In such hierarchies, each action (e.g., study for an exam) has a superordinate, abstract level, which answers the question of why the action is performed (e.g., do well) and a subordinate, concrete level, which supplies the details of how the action is to be performed (e.g., read a textbook).

It is important to note that abstract representations are not simply more impoverished than concrete representations. Rather, many times, they contain additional information (i.e., high-level meaning) about the value of the stimulus and its relations to other stimuli. For example, the construal "a mammal" entails many characteristics not directly observed in the original "poodle" stimulus (e.g., ways of reproduction), and it places it within a larger context of living things, thus specifying its relations to other animal species (e.g., it informs us that a poodle is closer to mice than to fish). Thus, the process of abstraction involves not only a loss of specific, idiosyncratic, and incidental information but also ascription of new meaning via the top-down process of induction from stored knowledge. Abstract representations contain less information about the unique instance but might, nevertheless, contain more general information.

In sum, we suggest, in line with other theories of mental construal, that abstract mental models represent the detailed and possibly ambiguous information contained in a real event in a relatively simple and coherent mental model that connects it to stored knowledge. Moreover, it is possible to think about levels of abstractness as a gradual reduction in incidental details and in complexity of representations. We further suggest that higher-level, more abstract and coherent representations are formed of more distal entities.

The rest of this section presents evidence in support of the construal-level hypothesis, which is that distancing produces more abstract, higher-level construals. We also examine the reverse direction of influence, namely, higher-level construals leading to perception of increased psychological distance. To that end, we examine new and existing social psychological literature on future and past temporal distance, physical distance, social distance, and hypotheticality.

The Effect of Psychological Distance on Level of Construal

The Effect of Temporal Distance on Level of Construal

CONSTRUAL OF ACTIONS

Research conducted in the framework of temporal construal theory has examined the effects of future temporal distance on level of construal of actions, objects, other people, and oneself. For example, in one study participants imagined themselves engaging in various activities (e.g., reading a science fiction book) either tomorrow or next year and described these activities (Liberman & Trope, 1998, study 1, part 1). The study found that people used more superordinate, high-level descriptions of distant activities (e.g., "getting entertained") and low-level descriptions for near future activities (e.g., "flipping pages"). A related, forced-choice study used an adapted version of Vallacher and Wegner's (1989) Level of Personal Agency questionnaire that was originally designed to assess stable individual differences in action identification (Liberman & Trope, 1998, study 1, part 2). The questionnaire presents 19 activities (e.g., "locking a door"), each followed by two restatements, one corresponding to the how (low-level) aspects of the activity (e.g., "putting a key in the lock") and the other corresponding to the why (high-level) aspects of the activity (e.g., "securing the house"). As predicted, participants chose significantly more high level, why restatements when the activities were described as occurring in the distant future than when the same activities were described as occurring in the near future.

CATEGORY BREADTH

If the distant future is represented more abstractly, then individuals should use broader categories to classify objects for distant-future situations than for near-future situations. To test this prediction, Liberman, Sagristano, and Trope (2002, study 1) asked participants to imagine an event (e.g., camping trip) in either the upcoming weekend or a weekend a few months later and to classify a given set of 38 objects related to the event (e.g., tent and toothbrush) into as many mutually exclusive and exhaustive groups as they deemed appropriate. Participants were instructed to assume that their classification was final and could not be altered later. The authors simply counted the number of groups into which participants classified the objects from each scenario. The results showed that participants used fewer categories when they imagined the objects in a distant-future scenario than a near-future scenario. This finding is consistent with the CLT assumption that distant-future events are represented in terms of relatively high-level, abstract categories, whereas near-future events are represented in terms of relatively low-level, concrete categories.

PRINCIPLES AND VALUES

Eyal, Liberman, Sagristano, and Trope (2006) found that the distant future is construed in terms of abstract

principles more than the near future. For example, in one study, participants read about distant-future and near-future situations that involved an abstract principle or a dilemma (e.g., "In a few days/in a few years, the university will set to increase the number of minority students") and asked them to choose a description of this situation either in terms of a global principles or in terms of a lower-level action, devoid of moral implications (e.g., "endorsing affirmative action" vs. "making changes to admission lists"). It was found that distant-future situations were perceived in terms of high-level principles more than near-future situations. Presumably, principles more easily apply to the distant future, but as the situation gets closer in time, morals and ideologies seem to lose their relevance.

CAUSAL ATTRIBUTION

A series of studies by Nussbaum, Trope, and Liberman (2003) examined level of construal of social targets as a function of future temporal distance. A considerable amount of person perception research has demonstrated the correspondence bias, namely, the tendency to attribute situationally constrained behavior to the corresponding personal disposition (see Gilbert & Mallone, 1995; Jones, 1979). In terms of CLT, this bias reflects a high-level construal of behavior in terms of abstract, decontextualized dispositions (see Fiedler, Semin, Finkenauer, & Berkel, 1995; Semin & Fiedler, 1988; Semin & Smith, 1999). According to CLT, the correspondence bias would be more likely with more distal social targets.

Nussbaum and colleagues (2003, study 1) used the Jones and Harris (1967) attitude attribution paradigm to test this hypothesis with respect to temporal distance. Student participants from Tel-Aviv University read an essay arguing in favor of Israel's withdrawal from Lebanon. (The study was conducted a few months before Israel's withdrawal from Lebanon in June 2000.) They were told that the essay was written by a student who had been instructed either to express her own opinion (unconstrained condition) or to argue in favor of withdrawal (situationally constrained condition). Participants were asked to estimate the likelihood that the writer would express pro-withdrawal attitudes in a variety of near-future (next day) or distant-future (a year later) situations (e.g., express pro-withdrawal attitudes in a conversation with friends and attend a pro-withdrawal rally). The results showed that the judged likelihoods of essay-consistent (pro-withdrawal) behavior in the near future were moderated in view of the situational constraints, whereas the judged likelihoods for the more distant future were high regardless of situational constraints. Thus, whereas near-future predictions showed substantial situational discounting, distant-future predictions showed little or no situational discounting. These findings demonstrate that the correspondence bias, the tendency to underweight low-level situational constraints on observed behavior, is more pronounced when this behavior is used for predicting the distant future than the near future.

BEHAVIOR CONSISTENCY

CLT predicts that people would expect others to behave more consistently across different situations in the distant future than in the near future. Nussbaum and colleagues (2003, study 2) tested this hypothesis by asking participants to predict an acquaintance's behavior in four different situations (e.g., a birthday party and waiting in line in the supermarket) in either the near future or the distant future. Participants predicted the extent to which their acquaintances would display 15 traits (e.g., behave in a friendly vs. unfriendly manner) representative of the Big Five personality dimensions (extraversion, agreeableness, conscientiousness, emotional stability, intellect). Cross-situational consistency was assessed by computing, for each of the 15 traits, the variance in predicted behavior across the four situations and the correlations among the predicted behaviors in the four situations. As hypothesized, the results showed that participants expected others to behave more consistently across distant-future situations than across near-future situations. This was manifested in both lower cross-situational variance and higher cross-situational correlations for distant-future behavior predictions than for near-future behavior predictions.

CONSTRUAL OF THE SELF

The latter study was replicated with the self as the target. Nussbaum, Liberman, and Trope (2004) made people imagine themselves in different situations, either in the near future or in the distant future, and indicate the extent to which their behavior in those situations would reflect each of the Big Five traits. As with describing other people, it was found that in the distant future people expected themselves to exhibit traits more consistently across situations. This study suggests, in line with CLT, that people are more likely to use abstract, decontextualized trait concepts in predicting distant-future than near-future behaviors of both other people and themselves.

Nussbaum and colleagues (2004) also examined the effect of future temporal distance on the level of construal of self using Linville's (1985) self-complexity paradigm. Participants described themselves to another person, who was expected to read the description in either the near future or the distant future. For that end, they chose cards with self-descriptive adjectives and grouped them into categories. The results indicated that participants used fewer categories and that the categories were more distinct from each other in the distant-future condition than in the near-future condition. It seems, then, that a temporally distal perspective on the self fosters a less complex representation thereof than a proximal temporal perspective.

In sum, extensive research conducted within the framework of temporal construal theory demonstrates that future temporal distance enhances level of construal of actions, situations, objects, and people. Are there similar effects for other dimensions of psycho-

logical distance? We turn now to examine this question.

The Effect of Past Temporal Distance on Level of Construal

Closely related to CLT is the idea that past temporal distance is associated with higher construal levels. Semin and Smith (1999) asked participants to recall significant events from either the distant past (at least a year ago) or the recent past (the last 2 weeks) and analyzed the abstractness level of the responses. They found more abstract language in descriptions of more distant events. The authors suggested that past events are gradually moved into a long-term storage system, which uses an abstract, schematic form of information representation. Consistent with this view is also the research on temporal effects on attribution, which has shown that over time, observers' attributions about an actor's behaviors become more dispositional and less situational, presumably because the specific details of the situations fade away more rapidly than the more general inferences about the actor's personality (Frank & Gilovich, 1989; see also Funder & Van Ness, 1983; Moore, Sherrod, Liu, & Underwood, 1979; Nigro & Neisser, 1983; Peterson, 1980; but see Burger, 1986).

These findings are consistent with memory consolidation, namely, the tendency for concrete details to fade away from memory more rapidly than general abstractions, which makes memories of the distant past more abstract than memories of the recent past (Bartlett, 1932; Wyer & Srull, 1986). However, assuming that memory is an active, reconstructive process, CLT proposes that increasing past temporal distance is associated not only with a loss of specific details but also with an increased use of high-level, schematic construals (Ross, 1989). For example, Ross (1989) found that young adults tend to think that their personal adjustment (i.e., their sense of personal worth and self-reliance) and social skills improve with age. In an actual assessment, however, these scores appeared relatively stable, with the same average self-ratings between the ages of 25 and 45 (Woodruff & Birren, 1972). Interestingly, at age 45 people tended to rate their adjustment at the age of 25 as much lower than it actually was, presumably because they subscribed to a general theory that adjustment and social skills increase over the years (Ross, 1989). Thus, it is not only the case that information about their actual standing at 25 was lost, but it was also replaced with schema-derived inferences. Consistent with this idea, McDonald and Hirt (1997) showed that over time, student participants not only forgot a fellow student's grades but also were more likely to infer those from overall expectancies and general attitudes toward that person, thus producing a more coherent picture of the target person over time. Similarly, Mitchell, Thompson, Peterson, and Cronk (1997) found that people's recollections of a bicycle trip or a trip to Europe became more positive over time, presumably as the details of these events faded from memory and were replaced with a more general, schematic (and, in

this case, positive) representation. It seems, then, that the passage of time produces not only a passive loss of detail but also an active reconstruction characteristic of higher-level construals.

The Effect of Spatial Distance on Level of Construal

Spatial distance from an object ordinarily determines the amount and kind of information that is available about the object. As one gets closer to an object, the information becomes more accurate and detailed. From the distance we see a forest; as we get closer we begin seeing the trees. A more pertinent question, however, is whether, as would be predicted by CLT, the same information about an object would be represented differently depending on whether the object is thought to be in a close or a distant location. A study by Fujita, Henderson, Eng, Trope, and Liberman (2006) examined how perceivers construe a social interaction believed to take place in either a spatially close or a distant location. New York University student participants watched and then described a video of two other NYU students casually conversing about their schooling, hobbies, and families. They were told that the video was filmed either at NYU Study Abroad in Florence, Italy (distant location), or at NYU in New York City (proximal location). Content analysis based on Semin and Fiedler's (1988) linguistic categorization model (LCM) served as to assess the level of abstractness of the descriptions. As expected, the descriptions of the taped interaction were more abstract when the interaction was said to take place in Florence than in New York City. Participants thus formed more abstract representations of the same observed social interaction when its location was said to be distant rather than near. It should be pointed out that the effect of the location was unrelated to participants' sense of familiarity with or similarity to the interactants, which was also measured in this study. These findings demonstrate the idea that spatial distance, like temporal distance, leads to higher-level construal of the information at hand.

The Effect of Social Distance on Level of Construal

The distinctions between self and other, similar and dissimilar others, familiar and unfamiliar others, ingroup members and outgroup members, and status differences, all may be considered as instances of social distance. We now review social psychological research documenting higher-level construals of more distant social targets. We then discuss the case of politeness as an indicator of social distance and examine its effects on level of construal. Finally, we examine the possibility of relating cultural differences in construal to CLT.

SELF VERSUS OTHER

Perhaps the best documented difference in construal between self and other is the actor–observer effect in attribution (Jones & Nisbett, 1972; for a review, see Gilbert, 1998). This research shows that a person's view of his or

her behavior emphasizes the role of concrete situational factors that operate at the moment of action, whereas his or her view of other people emphasizes the causal role of stable, general dispositional properties of the actor. For example, Robins, Spranca, and Mendelson (1996) found that participants in a "getting acquainted" conversation task tended to see their own behavior as caused by their partner but their partner's behavior as caused by his or her personality (see also Nisbett, Caputo, Legant, & Marecek, 1973; Saulnier & Perlman, 1981; for a review, see Watson, 1982).

Similar to what CLT suggests, Semin and Fiedler (1989) argued that the actor–observer effect reflects different levels of abstraction of action representation. In support of this proposal, Semin and Fiedler (1989; see also Fiedler et al., 1995) made participants describe either their own or another person's behaviors in a number of situations (e.g., a successful party or a failure at school) and coded their responses for abstractness. The analysis employed the LCM (Semin & Fiedler, 1988) described earlier. The results showed that observers' descriptions of behaviors had a higher proportion of abstract verbs than actors' descriptions. The reverse pattern was found for the rate of specific context supplements (e.g., space and time). From the perspective of CLT, these findings demonstrate a higher construal level of distal social targets (another person) than a proximal social target (the self).

Self–other differences might be explained as being due to differences in knowledge (people know more about themselves and the variability of their behavior over situations than about others) and differences in the salience of behaviors versus situations (the latter is more salient from one's own perspective, the former from the observer's perspective). The differential knowledge explanation is consistent with the CLT notion of how high level of construal came to be associated with distant entities, but it does not necessarily exemplify the notion of construal level. Would differences in construal emerge when knowledge is identical for near and distal social targets? Research relating abstractness of memories to the perspective in which they are recalled seems to offer a positive answer. It has been shown, for example, that personal memories of behaviors that were recalled from a third-person perspective (e.g., "try to remember your first day at school, as if you are now watching the kid you were") rather than from a first-person perspective ("try to remember your first day at school, as if you are a kid again") tended to employ dispositional (as opposed to situational) terms (Frank & Gilovich, 1989; Nigro & Neisser, 1983). In a similar vein, Libby and Eibach (2002, study 4) found that imagining performing an activity (e.g., rock climbing and playing drums) from a third-person perspective produced less vivid and rich reports of the activity than imagining the same activity in a first-person perspective. In terms of CLT, this means that a third-person perspective, which imposes more distance than a first-person perspective, induced a higher level of construal.

A third-person perspective on oneself may be induced by a situational manipulation of self-awareness, such as the presence of a mirror or a camera (Duval & Wicklund, 1972; Wicklund, 1975) but may also express a dispositional tendency for public self-consciousness (Fenigstein, Scheir, & Buss, 1975). Both sources of self-awareness seem to increase people's tendency to behave in a way that corresponds to their own personal values and socially accepted ideals (e.g., Macrae, Bodenhausen, & Milne, 1998; for a review, see Gibbons, 1990). From our perspective, values and ideals are high-level constructs (Eyal, 2005). The finding that self-awareness increases behavior–value correspondence is therefore consistent with the idea that increased distance from oneself increases the impact of high-level constructs on one's behavior. Self-awareness also decreases the effect of situational factors on behavior. For example, self-aware individuals are better able to resist situational inducements to commit moral transgressions under the cover of anonymity (Beaman, Klentz, Diener, & Svanum, 1979). Moreover, both situationally manipulated self-awareness and dispositional self-consciousness seem to enhance dispositional attributions and diminish situational attributions for one's own actions, presumably because these variables engender a view on oneself that is akin to that of an external observer (Gibbons, 1990). As noted before, general dispositions are typically more abstract than situational attributions and, therefore, constitute a higher level of construal.

In sum, people tend to construe others in higher-level terms than themselves and, in addition, to construe themselves in higher-level terms when taking the perspective of another person. Both of these effects are consistent with CLT. The latter effect is particularly informative because it is hard to interpret in terms of differential knowledge about the target.

INGROUPS VERSUS OUTGROUPS

A considerable amount of research on group perception suggests that people form higher-level construals of outgroups than their ingroups. Compared with ingroups, outgroups are described in more abstract terms (Fiedler et al., 1995; Werkman, Wigboldus, & Semin, 1999) and are perceived as more homogenous (Jones, Wood, & Quattrone, 1981; Park & Judd, 1990; Park & Rothbart, 1982), less differentiated into subgroups (Brewer & Lui, 1984; Linville, 1982; Park, Ryan, & Judd, 1992), and as possessing more structured, predictable sets of properties (Linville, Fischer, & Yoon, 1996). From the perspective of CLT, we construe outgroups more abstractly than ingroups because we typically have less direct experience with outgroups and thus perceive them as more distant. We might also have less information about the outgroup. We propose, however, that a generalized sense of greater psychological distance from the outgroup than the ingroup may independently affect construal. Support for this proposal comes from the Jones and colleagues (1981) study on ingroup heterogeneity/outgroup homogeneity. These researchers asked students, who were members of four selective clubs, to characterize members of different clubs (their own club and each of the three other groups) on a number of per-

sonal characteristics, such as introverted–extraverted, refined–crude, and athletic–nonathletic. On each trait scale, participants marked the position of the average member of each group, two values between which they believed 50% of the group members would fall, and two scale values between which they believed all group members would fall. As predicted, participants indicated wider ranges for their own club than the three other clubs, indicating more perceived variability within the ingroup as opposed to the outgroup. Importantly, this tendency was unrelated to the number of ingroup or outgroup members known, suggesting that the more abstract construals of the outgroup than the ingroup may be independent of amount of knowledge about those groups.

SOCIAL POWER

Almost any relationship can be characterized in terms of the amount of control an individual has over others' outcomes relative to the amount of control others' have over the individual's outcomes (Thibaut & Kelley, 1959). A considerable amount of social psychological research has shown that social power affects a broad range of social cognitive and self-regulatory phenomena (Fiske, 1993; Keltner, Gruenfeld, & Anderson, 2003). Does social power also affect social distance among individuals? Based on the definition of power in terms of outcome dependence, Smith and Trope (2006) recently proposed that the more powerful individuals feel more independent of others and, therefore, more distinct and separate from them. Indeed, there is evidence that individuals with more power see themselves as more different from, and thus distant from, other people than people with less power (e.g., Lee & Tiedens, 2001; Snyder & Fromkin, 1980). For example, group leaders tend to be distinctive relative to their fellow group members, and over time they become even more psychologically separate from the rest of the group (see Hogg, 2001; Hogg & Reid, 2001).

If power entails more social distance, then CLT would predict that it would predispose the more powerful individuals to form high-level construals of relevant situations. Powerful individuals might, as a result, focus on the central, most important aspects of the situation and disregard secondary, more peripheral aspects, thus forming an unequivocal orientation toward the situation. In a study related to this prediction, Overbeck and Park (2001) asked high- and low-power participants to interact via email with targets who held the opposite power role. Some of the information participants received was relevant to the task at hand and some was irrelevant. At the end of these interactions, participants were asked to list as much information from the emails as they could remember. Not only did participants in the high-power role recall overall more information from these interactions, but they were especially superior at recalling information that was relevant. Thus, high-power participants were better at distinguishing between primary and secondary information, a hallmark of abstract processing.

Powerful people also seem to use more abstract language. Guinote (2001) found that Portuguese participants used more abstract language to describe both their ethnic group and an outgroup when they were part of the majority (i.e., they were living in Portugal: higher-power group) than when they were part of a minority (i.e., they were immigrants living in Germany: lower-power group). Similarly, participants who played the role of judges used more abstract, trait-like language in referring to themselves than did participants who were workers (Guinote, Judd, & Brauer, 2002).

Smith and Trope (2006) examined how priming power affects participants' ability to abstract visual stimuli in perceptual tasks. For example, one of the studies examined participants' performance on an embedded-figures task in which a specified pattern has to be found and traced within a complex geometrical figure (Witkin, Oltman, Raskin, & Karp, 1971). As predicted, participants who were primed with high power performed better than participants who were primed with low power. Subsequent studies by Smith and Trope found that power-primed participants were (1) better at detecting patterns and thus more accurately detected the amount of covariation in a series of data; (2) focused more on primary features, making more superordinate categorizations; and (3) more accurate at detecting structure, making responses that better fit the data at hand, in a Gestalt completion task. These effects of power on level of construal were not mediated by participants' reported mood, efficacy, or effort.

It has been argued that powerful individuals are susceptible to heuristic thinking and uninhibited reliance on superficial stereotype-consistent cues (Fiske, 1993; Keltner et al., 2003). The present analysis suggests an interesting alternative to this view. Power does not seem to reduce overall attention to and utilization of the available information. Instead, it seems to focus individuals on its central, high-level aspects. It is possible, then, that the distal perspective activated by the possession of social power promotes going beyond the information given, detecting the underlying structure, and abstracting from it superordinate, central features. This power-driven construal may support the kind of long-term planning and goal pursuit that are often required of individuals in positions of power.

POLITENESS

The way individuals communicate with each other might be indicative of the social distance between them (Argyle, 1970). One general aspect of interpersonal communication is the extent to which the speaker addresses a recipient politely. Research conducted across different cultures has found that politeness is closely related to social distance. That is, speakers tend to address more politely socially distant listeners than socially close listeners (see Brown & Levinson, 1987; Holtgraves, 2002). Politeness may thus serve as an indicator of social distance and, like social distance, act to produce higher construal levels of the situation.

A series of studies by Stephan (2005) tested this hypothesis. For example, one study examined how the intention to be very polite as opposed to less polite affects the abstractness of one's language. Participants were asked to indicate how a student would address a classmate (e.g., ask for his or her notes) in a very polite way, a moderately polite way, or a less polite way. The open-ended responses were analyzed for abstractness according to the Semin and Fiedler's (1988) LCM. As predicted, abstract verbs were used more frequently and concrete verbs were used less frequently with increasing levels of politeness. Another study examined how the intention to be very polite versus less polite affected level of construal of actions. Participants imagined a person performing an action and then described it in either a polite way or a less polite way by choosing between a high-level, "why" description and a low-level, "how" description of the action (Vallacher & Wegner, 1989). For example, participants chose between describing "Shelly is reading a book" as "Shelly is gaining knowledge" or as "Shelly is following lines of print." As predicted, high-level restatements were chosen more frequently for polite descriptions than for less polite descriptions. Both studies demonstrate, then, that an increase in level of politeness resulted in higher-level construals of actions.

CULTURE

Research on cross-cultural psychology distinguishes between independent and interdependent cultures. This research suggests that Asian and South American cultures, compared to West European and North American cultures, emphasize more the interdependence and interconnectedness of the individual with the collective, rather than his or her independence from others (Berry, 1976; Markus & Kitayama, 1994). Thus, participants from China, India, Africa, and Mexico often explicitly acknowledge the importance of other people, of relations, and of the participatory, responsive, interpersonal nature of behavior. In terms of social distance, interdependent cultures may be characterized as maintaining more proximity between a person and his or her social surrounding (Markus & Kitayama, 1994). If others are more proximal in interdependent cultures, then CLT would predict that in these cultures, people would be predisposed to using low-level construals of persons, objects, and events.

Indeed, a large amount of research has documented a reduced tendency in interdependent cultures to construe others in high-level, dispositional terms, and an enhanced tendency to construe them in lower-level, situation-specific and relational terms (Miller, 1984; Morris & Peng, 1994; for a review, see Choi, Nisbett, & Norenzayan, 1999). For example, Morris and Peng (1994) found that Chinese participants explain a murder crime in situational terms (e.g., the murdered was just fired from work) whereas European Americans explain a similar crime in dispositional terms (e.g., the murderer could not control himself). Interestingly, it seems that the differences in construal between independent and interdependent cultures apply not only to people, but also to a wide range of nonsocial stimuli. Nisbett, Peng, Choi, and Norenzayan (2001) suggest, more broadly, that individuals from interdependent cultures process stimuli in a contextual manner, attend to the relationships between the focal object and the field, explain and predict events on the basis of such relationships, and rely on experience-based knowledge rather than on abstract logic. In contrast, individuals from independent cultures presumably process the same stimuli as isolated from the immediate context, focus on attributes of the object and assign it to categories, use rules about the categories to explain and predict the object's behavior, and use formal logic. For example, these researchers report a study in which Japanese and American participants were shown pictures of fish and other underwater objects and reported what they had seen. This study found that Japanese participants made more statements about background elements than did American participants. Interestingly, Nisbett and colleagues suggested that these differences in perception and cognitive styles may be traced to structural differences in the socioeconomic systems that have evolved in different cultures. Social structure presumably shapes cognition because perception of social objects is generalized to the inanimate world, and because reasoning develops in the service of solving interpersonal conflicts. Based on this assumption, Nisbett and colleagues argue more specifically that social interdependence and close social ties give rise to attention to relations between objects and to experience-based knowledge, whereas social independence gives rise to isolating objects, attending to their attributes, and assigning them to abstract categories. This idea is consistent with the CLT proposal that social distance affects level of construal.

The Effect of Level of Construal on Psychological Distance

As indicated earlier, psychological distance may not only affect construal but may be affected by construal. We argued that the association of distance to high construal levels becomes generalized beyond situations in which distance entails less knowledge. We further suggest that through this association process, the connection also became bidirectional, so that high levels of construal induce perceptions of greater distance from stimuli. We therefore predict that highly construed stimuli would be perceived as more distant in time and space, as more distant socially, and as less real.

The Effects of Level of Construal on Future Temporal Distance

Liberman, Trope, McCrae, and Sherman (in press) examined the effect of construal level on the temporal distance of activity enactment. In one of their studies, participants were first asked to indicate either "why" (i.e., high-level construal) or "how" (i.e., low-level construal) a person would perform an activity (e.g., "Ron is considering opening a bank account. Why (How) would Ron do that?") and were then asked to estimate how much time

from now the person would do the activity. As predicted, participants indicated more distant enactment times after a high-level "why" construal than after a low-level "how" construal. The authors found similar effects with other manipulations of level of construal, and with participants' estimates of the enactment time of their own activities.

The Effects of Level of Construal on Past Temporal Distance

Semin and Smith (1999, studies 2 and 3) studied the effect of linguistic abstractness on event age. They provided participants with retrieval cues of varying abstractness and examined how distant were the events that they recalled. For example, participants recalled either an occasion on which they helped somebody (i.e., concrete retrieval cue) or an occasion on which they displayed a trait of helpfulness (i.e., abstract retrieval cue). As predicted, an abstract retrieval cue prompted memories that were more than 8 months older than memories that were prompted by a concrete retrieval cue. Thus, abstractness of representation affected past temporal distance.

Semin and Smith (1999) suggest that abstract terms mark distant events and concrete terms mark recent events. They relate their findings to the existence of two separate learning and memory systems: a fast learning system and a slow learning system (McClelland, McNaughton, & O'Reilly, 1995). According to this model, the slow learning (schematic) system records repeatedly encountered regularities in the environment and uses them to fill in unobserved details and interpret new information. It uses, therefore, more abstract representations. In contrast, the fast learning (episodic) memory system uses more concrete representations and records specific events together with information about their context. From our perspective these findings demonstrate a more general principle, which is that high-level construals foster a perception of more distant past events.

The Effects of Level of Construal on Social Distance

Stephan (2005) conducted a series of studies to examine the effect of level of construal on politeness and familiarity, which were conceptualized as indicators of social distance. It was predicted that an increase in level of construal would produce a corresponding increase in perceived politeness and a decrease in perceived familiarity of a social target. For example, one study asked participants to provide either dispositional, high-level explanations or situational, low-level explanations for an actor's behavior (e.g., "Danny is explaining the class materials to another student. What aspects of Danny's personality, character, or dispositions [in the situation or the setting] could explain Danny's behavior?"). The researchers then measured the perceived familiarity of the target person. Consistent with the prediction, politeness and familiarity were higher after participants generated low-level, situational attributions than high-level, dispositional attributions. These results suggest that an increase

in level of construal produces an increase in perceived social distance, as indicated by reduction in perceived familiarity as well as in increased politeness.

The Effects of Level of Construal on Hypotheticality and Probability

A low-level construal of hypothetical events, more than a high-level construal, makes them seem more likely to become real, or, in other words, makes them seem more probable (for reviews, see Koehler, 1991; Nisbett, 1993). For example, a study by Sherman, Chialdini, Schwartzman, and Reynolds (1985) presented participants with information about a disease that supposedly was becoming prevalent on campus and asked them to imagine actually contracting the disease. For some subjects, symptoms were concrete (low energy level, muscle aches, severe headaches), whereas for others the symptoms were described more abstractly (disorientation, malfunctioning nervous system). A control group read the descriptions of the disease but did not engage in imagining contracting the disease. The results indicated that subjects who imagined contracting the disease with the concrete symptoms estimated that the likelihood of actually contracting it was greater than the control subjects imagined, who, in turn, gave higher likelihood estimates than the group of subjects who imagined abstract symptoms. Thus, construing something on a lower level makes it seem more likely. Koehler (1991) argued that low-level, detailed construals allow a more confirmatory information search. It is possible, however, that the mere existence of low-level, concrete details creates a feeling of greater reality, veridicality, and likelihood.

The literature on source monitoring in memory (Johnson, Hashtroudi, & Lindsay, 1993) is also closely related to the connection between level of construal and veridicality. One of the questions that this literature has addressed is how people know if a mental representation corresponds to reality rather than to fantasy. In other words, how do people decide that something they remember actually happened as opposed to being imagined, dreamt, or considered (e.g., did I really visit my aunt's house or did I only consider going there?). According to source monitoring theory, certain memory characteristics enhance people's confidence in an event's reality. These include perceptual detail, such as sound, smell, touch, and taste, as well as contextual information, such as the hour, day, year and season the event took place, and the relative spatial arrangement of people and of objects (Johnson, Foley, Suengas, & Raye, 1988). For example, I might think I remember the color of the floor my aunt stood on and the smell of the cooking meal in her kitchen and thus conclude that it must be the case that I really visited her house. In terms of CLT, these details pertain to a low-level construal and the process of inferring the reality of a mental representation involves using the existence of low-level details as an indication of higher likelihood and veridicality.

It is noteworthy that representations of imagined actions do actually appear to have less perceptual and contextual features than observed events (Suengas & John-

son, 1988). Stern and Rotello (2000) made participants perform some actions and imagine others (e.g., eating crackers and tying a ribbon around a pencil) and examined the memory characteristics of these actions both immediately and 1 week later. They found that performed events were clearer and richer in sensory and contextual detail than imagined events. Thus, it appears that the relation between hypotheticality and level of construal is bidirectional: not only that people infer realism (i.e., probability) from level of construal but also that realism affects level of construal. Interestingly, in the study by Stern and Rotello, the level of perceptual and contextual features of both imagined and performed events deteriorated over a period of 1 week (see Johnson et al., 1988, for a comparable effect of time on autobiographical memories), making the level of these features similar between immediate imagined actions and performed actions 1 week later. It seems, therefore, that temporal distance has an effect on level of construal that is similar to the effect of hypotheticality.

Implicit Associations between Psychological Distance and Level of Construal

Recently, Bar-Anan, Liberman, and Trope (in press) examined associations between level of construal and psychological distance using an Implicit Associations Test. Similar to other assessments of implicit associations (e.g., between stereotyped group members and stereotypical attributes; Greenwald, McGhee, & Schwartz, 1998), participants in these studies were presented with stimuli from four categories: stimuli pertaining to high-level construal (e.g., category names such as "drinks"), stimuli pertaining to low-level construal (e.g., exemplar names such as "coke"), stimuli pertaining to low psychological distance (e.g., the word "ours" or the word "friend" for the social distance), stimuli pertaining to high psychological distance (e.g., the word "theirs" or the word "stranger"). In the critical trials participants mapped stimuli from these four categories on two responses, pressing either a left key or a right key on the computer keyboard. On CLT-congruent trials, high-level stimuli were paired with distant stimuli and low-level stimuli were paired with proximal stimuli, whereas on CLT-incongruent trials high-level stimuli were paired with proximal stimuli and low-level stimuli were paired with distal stimuli. Reaction times were compared between congruent and incongruent trials to test the prediction of CLT that reaction would be faster on congruent than on incongruent trials. Each study examined one of four dimensions of psychological distance—temporal distance, spatial distance, social distance, and hypotheticality. With all four dimensions it was found that participants are faster with congruent than with incongruent pairings, suggesting that participants implicitly associate psychological distance with high-level construal and psychological proximity with low-level construal.

This set of studies extends previous lines of research on the association between level of construal and psychological distance in several important respects. First, it shows that this association cannot be explained by differential knowledge about proximal versus distal targets. Second, the research demonstrates similar effects across the four dimensions of psychological distance (temporal, spatial, social, and hypotheticality), thus suggesting that they all share a common meaning as instances of psychological distance. Third, it suggests that the association between psychological distance and construal level can be activated automatically without conscious deliberation.

COGNITIVE, AFFECTIVE, AND BEHAVIORAL EFFECTS OF PSYCHOLOGICAL DISTANCE

How does psychological distance from an event affect people's affect, cognitions, and behaviors toward those events? Research conducted in the framework of temporal construal theory addressed this question with respect to future time perspective. This section reviews the research, integrates it with literatures suggestive of similar effects of other distance dimensions, and offers new predictions for these dimensions. As in the previous section, we examine the effects of future temporal distance, past temporal distance, hypotheticality, and social distance. We also examine the effects of level of construal. As demonstrated in the previous section, level of construal is closely related to psychological distance, and therefore CLT postulates that its effects on prediction, evaluation, and choice would resemble those of psychological distancing.

Prediction

The French anthropologist Claude Levi Strauss once noted that in the Western sciences, the most distal topics (e.g., astronomy and geography) developed first whereas those that look at more proximal entities (e.g., psychology) were last to develop (Levi Strauss, 1978). We would like to propose, consistent with this observation, that abstract theoretical reasoning is easier to apply to distal targets than to proximal targets. More specifically, CLT proposes that increasing psychological distance from a future situation would make it more likely that predictions about this situation would be based on the implications of high-level rather than low-level construals. In theory-based predictions, the theory constitutes a high-level construct that promotes confident predictions, whereas low-level features, associated with incidental deviations and noise, undermine confidence. In these cases, psychological distancing, because it enhances the effects of high-level constructs and reduces the effects of low-level constructs, would enhance confidence. For example, economic theory posits that increasing interest rates causes the stock market to decline. The theory acknowledges that other factors might also affect the stock market but treats them as noise. According to CLT, psychological distancing would promote confidence in predicting that if interest rates are raised, then the stock market would fall. Thus, economists would be more confident in their prediction when considering the more distant future, when making predictions about more geographically distant markets, when making forecasts

about the investments of other people, and when the predictions concern a hypothetical or unlikely scenario.

Normatively, predictions about more distant entities should be made with less confidence because less is known about them. For example, one knows less about another person than about oneself, and hence one should be less confident when predicting the other's than one's own behavior. However, if high-level construals promote greater confidence, then people may feel no less and even more confident in predicting distal outcomes. For example, because stable personality traits and dispositions are more readily inferred about another person than about oneself (Jones & Nisbett, 1972), one may be more confident in predicting another person's correspondent behaviors than one's own (Pronin, Kruger, Savtisky, & Ross, 2001). This logic of CLT is consistent with the claim that overconfident predictions stem from relying on oversimplified representations of situations.

A great deal of social cognitive research has identified mental construal as underlying a wide range of prediction errors, including overconfidence (Dunning, Griffin, Milojkovic, & Ross, 1990; Griffin, Dunning, & Ross, 1990), the planning fallacy (Buehler, Griffin, & Ross, 1994; Kahneman & Lovallo, 1991; Kahneman & Tversky, 1979), affective forecasting errors (Dunn, Wilson, & Gilbert, 2003; Gilbert, Morewedge, Risen, & Wilson, 2004; Gilbert, Pinel, Wilson, Blumberg, & Wheatley, 1998; Gilbert & Wilson, 2000; Kahneman & Snell, 1990, 1992; Wilson, Meyers, & Gilbert, 2001). This research has shown that people often have unwarranted confidence in their prediction because their mental models of future situations are schematic and oversimplified. For example, people typically underestimate task completion times because they base their estimates on schemas of how things unfold and fail to take into consideration nonschematic events (Buehler et al., 1994). Thus, the schema of writing a paper includes reading relevant literature, analyzing data, and communicating with colleagues, but it does not include a visit from one's in-laws. Therefore, the latter, even if known in advance, would not be taken into account in predicting how much time it takes to write a paper. As another example, focalism involves overconfident prediction of one's own reactions to emotional events (e.g., how sad I am going to be if my team loses the game) due to an underestimation of the diluting effect of low-level, situational factors (i.e., underestimation of the fact that most of life remains unaffected by the game; Wilson, Wheatley, Meyers, Gilbert, & Axsom, 2000).

In all these lines of research, predictions are compared to actual outcomes (i.e., predicted completion times are compared to actual completion times), whereas CLT focuses on comparing predictions for proximal versus distal entities (e.g., estimations of completion times in the distant future vs. the near future). This difference notwithstanding, we would like to note that explaining the discrepancy between prediction and reality as a consequence of construal is in line with our assumption that distances are anchored on one's direct experience and that any distancing entails construal. Let us now turn to

examine the effects of psychological distance on prediction, which, we believe, are mediated by differences in construal in much the same way as differences between predicted and actual outcomes.

Future Temporal Distance and Confidence in Prediction

Direct evidence for these hypotheses comes from research on the effect of temporal distance on predictions of social and nonsocial events (Nussbaum et al., 2004; see also Nussbaum et al., 2003). One study examined the confidence of advanced psychology students in replicating classic findings in psychology in either the near future or the distant future (Nussbaum et al., 2004, study 1). For example, participants imagined entering a class at the university, either the next day or a year later (depending on the experimental condition), handing the students a list of words to memorize and then testing how well they remember it after moving some of the students to a different room. Participants estimated how likely it is that those tested in the same room would outperform, on average, those who were moved to a different room, thus replicating the encoding specificity effect. Participants were more confident in replicating encoding specificity when they imagined conducting the experiment in the distant future than in the near future. The same pattern of results occurred also with other classic findings in social, cognitive, and developmental psychology.

Several other studies assessed confidence in predicting one's own performance on a general knowledge quiz expected to take place either on the same day or 2 months later (Nussbaum et al., 2004, study 3). These studies used the same questions but in either a relatively easy or hard question format, which we assumed is a low-level aspect of performance. Specifically, in one study, the quiz consisted of either multiple-choice questions (relatively easy format) or open-ended questions (relatively hard format). In another study, the quiz consisted of questions with either two response alternatives (relatively easy) or four response alternatives (relatively hard). We also assessed participants' perceived ability in each knowledge domain (how knowledgeable one is in geography, history, etc.). The results showed that the difficult question format appropriately reduced confidence in near-future performance but failed to reduce confidence in distant-future performance. We think that this was the case because question format was a low-level aspect of the situation that, consistent with CLT, affected confidence in near-future outcomes more than in distant-future outcomes. Our results also indicated that participants' beliefs about their general knowledge in different domains predicted their confidence in that domain in the distant future better than in the near future. We think that this was the case because such beliefs constitute a high-level consideration, as they are perceived to be more central to the quiz.

The Nussbaum and colleagues (2003) studies on the effect of future temporal distance on dispositional attribution, discussed in the first section of this chapter as an example of the effect of future temporal distance on level of construal, are also relevant to prediction. They show

that people base their predictions of others' more distant-future behavior more on high-level, dispositional attributions and less on low-level, situational attributions.

In sum, there seems to be considerable empirical support for the idea that temporal distance increases the impact of high-level information (e.g., theories, prototypes, self-beliefs, and personal dispositions) and decreases the impact of low-level information (e.g., irregular outcomes and specific situational and task characteristics) on prediction. Thus, two complementary processes may contribute to the unwarrantedly higher confidence levels associated with distant-future predictions: underweighting of the uncertainty associated with low-level information and overweighting of the certainty associated with high-level information.

Confidence Regarding Past Events

How does confidence about past events change over time? Bearing on this question is research on the hindsight bias, namely, people's tendency to exaggerate their past estimated likelihoods of an event after it had occurred (Fischhoff, 1975; for a review, see Christensen-Szalanski, & Willham, 1991). For example, after January 1, 2000, people reported that before that date they estimated the likelihood of no disaster happening as quite high, higher than the estimates they actually gave before that date (Pease, McCabe, Brannon, & Tagler, 2003). Interestingly, one of the explanations for the hindsight bias is akin to construal. Specifically, it has been proposed that people construct a theory to explain the outcome (e.g., 9/11 events were foreseeable given the frustration of the Muslim world), which makes the outcome seem inevitable.

CLT predicts that the hindsight bias and, more generally, theory-driven confidence in the inevitability of past events would increase over time. The research literature provides some support for this prediction. For example, Bryant and Guilbault (2002) found that hindsight about President Bill Clinton's acquittal in the Monica Lewinsky case increased from 4 days after the verdict to 11 days after the verdict. Obviously, more research is needed to examine in more detail the hypothesis that hindsight would increase over time and to specify the conditions under which this would occur. For example, it would be interesting to examine whether confidence in the inevitability of historical events increases over large time spans (e.g., how inevitable were the events of September 11, 2001, or how inevitable was World War II) and whether an increase in confidence is associated with holding general theories that explain those events. It would also be interesting to manipulate the salience of local, low-level theories (e.g., 9/11 happened because the FBI failed to arrest the suicide pilots) as opposed to global, high-level theories (the Muslim world felt outraged toward the United States), and examine whether the salience of the latter, more than the former, would make the effect of hindsight increase over temporal distance. Such results, if obtained, would suggest that past events that are explained in global and abstract terms seem increasingly inevitable over the course of time, more than past events that are attributed to specific, low-level events. In other words, the more global one's theories, the more the distant past would seem inevitable and the distant future would seem foreseeable.

Summary: Psychological Distance and Confidence

We reviewed research on the effect of future and past temporal distance on confidence in prediction. This research demonstrates that distancing enhances confidence in predictions that are based on high-level features, such as theories and schemas, but not confidence in predictions that are not based on high-level constructs. Would similar effects obtain also for social distance and for hypothetical versus actual scenarios? We could not find any research that directly addresses this question and could only speculate about such effects. A possible prediction would be, for example, that remote hypothetical models (e.g., a model of the effects of a meteorite hitting earth) would make more confident and clear-cut predictions than models of more realistic and likely events (e.g., a model of the effects of global warming). One could also predict that as a precondition of a theoretical prediction becomes more probable (e.g., as the likelihood of a meteorite hitting earth would increase), confidence in one's predictions would decline.

Preferences

How do people evaluate and make choices about distant future outcomes, as opposed to near future outcomes? How is advice given to others different from one's own choice? How does uncertainty about a situation change the way it is evaluated? And does level of construal change decisions? All these are questions we now address. As before, the most direct evidence bearing on these questions comes from research on the effects of future temporal distance, but findings related to other distances are discussed as well.

Future Temporal Perspective and Preferences

How the value of outcomes changes with temporal distancing has been a question of central importance in psychology (e.g., Ainslie, 1975; Ainslie & Haslam, 1992; Baumeister & Heatherton, 1996; Metcalfe & Mischel, 1999; Rachlin, Brown, & Cross, 2000; Read & Loewenstein, 2000), behavioral economics (e.g., O'Donoghue & Rabin, 2000), and political science (e.g., Elster, 1977; Schelling, 1984). All these behavioral sciences have generally assumed that the value of outcomes is discounted or diminished as temporal distance from the outcomes increases. Indeed, a considerable amount of research suggests that individuals often place higher value on a near-future reward than on a distant-future reward, even when the distant-future reward is larger (e.g., Ainslie & Haslam, 1992; Elster & Loewenstein, 1992; Mischel, Grusec, & Masters, 1969; Mischel, Shoda & Rodriguez, 1989; Read & Loewenstein, 2000).

Contrary to the claim of overall time discounting, CLT proposes that the effect of temporal distance would de-

pend on the level of construal with which value is associated. In this view, temporal changes in the attractiveness of an option depend on the value associated with the high-level construal of the option (high-level value) and the value associated with the low-level construal of the option (low-level value). Temporal distance should increase the weight of high-level value and decrease the weight of low-level value. As a result, temporal distance should shift the overall attractiveness of an option closer to its high-level value than to its low-level value. When the low-level value of an option is more positive than its high-level value, the option should be more attractive in the near future (time discounting). However, when the high-level value of an option is more positive, the option should be more attractive in the distant future (time augmentation).

We examined this hypothesis with different manipulations of high versus low levels of construal: primary, goal-related versus secondary, goal-irrelevant sources of value; feasibility versus desirability and expectancy versus value in gambles; arguments in favor versus arguments against an action; and abstract and primary attitudes and values versus concrete and secondary attitudes and values. This literature was reviewed elsewhere (Liberman & Trope, 1998; Sagristano, Trope, & Liberman, 2002; Trope & Liberman, 2000; see Trope & Liberman, 2003), and is only briefly summarized here. We return to the general question of discounting after we review the effects of different psychological distances on evaluation and choice.

PRIMARY VERSUS SECONDARY ASPECTS OF OBJECTS

Consider an activity consisting of two parts: a main task, which is the goal of the activity, and an unrelated filler task to be performed during a break in the main task. Because the main task is the primary goal of the activity, it is part of a high-level construal of the activity, and because the filler task is a secondary aspect of the activity, it is part of a low-level construal of the activity. CLT therefore predicts that temporal distance will increase the weight of the value of the main task relative to the weight of the value of the filler task in determining the overall attractiveness of the activity. When the main task is more attractive than the filler task, the overall activity would become more attractive over temporal distance. In contrast, when the main task is less attractive than the filler, the overall activity would become less attractive over temporal distance.

Trope and Liberman (2000, study 4) presented participants with activities consisting of either an interesting main task and a boring filler or a boring main task and an interesting filler. Each activity was described as consisting of three sessions of performing the main task, with the filler task performed between these sessions to provide rest and distraction from the main task. For example, an activity titled "Judging Humor" was described as follows: "The main task is judging humor, and will ask you to evaluate the funniness of cartoons. The filler task in between the three sessions is checking data, and will ask you to compare two lists of numbers to check for dis-

crepancies." When the chosen activity was said to take place in a few weeks, participants strongly preferred the activity with an interesting main task to the activity with a boring main task. However, when the chosen activity was said to take place in the same experimental session, this preference was significantly weaker. Thus, as predicted by CLT, temporal distance enhanced the tendency to evaluate activities in terms of goal-relevant rather than incidental aspects, so that with time delay the activity with an interesting main task (but boring filler) became more attractive and the activity with a boring main task (but interesting filler) became less attractive. The same temporal changes in preference were found for evaluations of products with primary and secondary features (Trope & Liberman, 2000, study 3).

FEASIBILITY AND DESIRABILITY

An important difference between high-level and low-level construals of goal-directed action is their emphasis on the desirability versus feasibility of outcomes. Desirability refers to the value of an action's end state, whereas feasibility refers to the ease or difficulty of reaching the end state. For example, desirability concerns the value of receiving a job offer, whereas feasibility concerns the amount of time and effort one has to invest to get the job offer. Given this assumption, CLT predicts that desirability considerations are more likely to guide distant-future preferences, whereas feasibility considerations are more likely to guide near-future preferences.

Liberman and Trope (1998) tested these predictions in a number of studies. One of the studies (study 4) used a realistic choice situation. Tel Aviv University students taking an introductory social psychology course were presented with a choice among several course assignments. The assignments were either easy (based on readings in Hebrew, the students' native language) or difficult (based on readings in English, a foreign language for these students) and either on an interesting topic (e.g., romantic love) or on an uninteresting topic (e.g., history of social psychology). In this situation, the difficulty of the assignment represents a feasibility consideration and the interest level of the assignment represents a desirability consideration. Students had to submit both a near-future and a distant-future assignment. They were told that they would have 1 week to work on each assignment but that the near-future assignment (reading materials and essay questions) would be given immediately whereas the distant-future assignment would be given 9 weeks later. Consistent with CLT, students' preferences showed that time delay decreased the effect of the difficulty of the assignments and increased the effect of the interest level of the topic of the assignments. The preference for the easy but uninteresting assignment decreased over time, whereas the preference for the hard but interesting assignment increased over time. Thus, in selecting a near-future assignment, students were willing to sacrifice interest for the sake of ease. In contrast, in selecting a distant-future assignment, students were willing to sacrifice ease for the sake of interest, thus committing themselves to a desirable but less feasible task. A similar tem-

poral pattern was obtained with various other options (Liberman & Trope, 1998, study 2).

Feedback seeking is another important decision that often pits feasibility against desirability concerns. Freitas, Salovey, and Liberman (2001) reasoned that feedback seeking involves a conflict between the goal of gaining information about oneself (a desirability consideration) and the difficulty of being exposed to self-evaluation (a feasibility consideration). They therefore predicted and actually found that distant future feedback preferences depended on the accuracy of the offered feedback, whereas near-future feedback preferences depended on the evaluative implications of the feedback. Informative but unflattering feedback was preferred for the distant future, whereas uninformative but flattering feedback was preferred for the near future.

An interesting implication of CLT's view on feasibility and desirability concerns the effect of temporal distance on planning. Liberman and Trope (1998, study 5) conceptualized time constraints as a feasibility aspect of an activity and investigated the role of time constraints and desirability of activities in near- and distant-future planning. They showed that plans for the distant future tend to reflect desirability of activities and disregard time constraints, thus creating a tendency to overcommit. It appears that in making distant-future plans, individuals consider each activity in isolation and fail to take into account that each activity they plan comes at the expense of some other activities in which they may want to engage at the same time.

PROBABILITY AND VALUE

The distinction between feasibility and desirability may be extended to games of chance—gambles characterized by probability of winning and the monetary payoff associated with winning. According to CLT, payoff is the superordinate consideration because the payoff determines the desirability of the end state of a gamble. The probability of winning is a subordinate consideration having to do with the properties of the random mechanism, device, or procedure that determines the feasibility of winning. In the normative expected utility model, probability and payoffs combine multiplicatively and therefore have symmetric weight in determining the attractiveness of gambles. However, our studies have demonstrated that people view the probability of winning as subordinated to the payoff; that is, they think that probability is important only if the payoff is high, but that payoff is important regardless of whether the probability of winning is high or low (Sagristano et al., 2002, study 1). This establishes payoffs as pertaining to a higher construal level than probabilities, and entails a prediction by CLT that people would assign more weight to payoffs and less weight to probabilities in deciding for the more distant future.

A series of studies on preference for near- and distant-future gambles tested this prediction (Sagristano et al., 2002). For example, one of the studies assessed monetary bids for gambles to be played on the same day or 2 months later. Participants were presented with a set of 20 bets that varied in probability of winning and expected value and were asked to state the amount of money they were willing to bid to play each gamble. As expected, preference among near-future gambles was primarily based on probability of winning, whereas preference among distant-future gambles was primarily based on the payoffs associated with winning. Thus, for near-future gambles, bids were highest for high-probability–low-payoff bets (i.e., relatively safe bets), whereas for distant-future gambles, bids were highest for low-probability–high-payoff bets (i.e., risky bets). These findings extend CLT to uncontrollable, random outcomes.

ARGUMENTS IN FAVOR OF AND AGAINST AN ACTION

In deciding whether to undertake an action, cons are subordinate to pros. This is because the subjective importance of cons depends on whether or not pros are present more than the subjective importance of pros depends on whether or not cons are present. For example, consider a decision to undergo a medical treatment. If we know that the treatment has some health benefit for us, we would inquire about its potential side effects before making a decision. But if the treatment has no benefits for us, we would decide against taking it without further inquiry about its side effects. In contrast, we would inquire whether a medical treatment has health benefits whether or not it has side effects—when the treatment is known to have no side effect, information about its benefits may tell us whether the treatment is worth taking; when the treatment is known to have some side effects, we may still inquire about the benefits of the treatment in order to determine whether they outweigh its side effects. Thus, the importance of side effects depends on whether the treatment is known to have benefits, but the importance of benefits is independent of whether the treatment is known to have side effects.

After establishing these subordination relations in a series of studies (Eyal, Liberman, Trope, & Walther, 2004, studies 1a and 1b), the authors proceeded to examine an obvious implication that follows from CLT: If cons are subordinate to pros, then pros should become more salient as temporal distance from the action increases, whereas cons should become less salient as temporal distance from the action increases. A series of studies tested this prediction by asking participants to generate arguments in favor and against new (i.e., nonroutine) near-future or distant-future actions. As predicted, participants generated relatively more pro arguments and fewer con arguments when the actions were to take place in the more distant future. The proposed action involved new exam procedures (e.g., switching to open-ended questions instead of multiple-choice questions; study 2), social policies (e.g., restricting private cars in the city center; study 3), and a variety of personal and interpersonal behaviors (e.g., approaching a fellow student and offering to write an assignment together; studies 4–6). In all the studies, participants generated more pros and less cons as temporal distance from the actions increased.

PREDICTING BEHAVIORAL INTENTIONS FROM ATTITUDES AND VALUES

Personal attitudes and values are commonly viewed as transsituational guides (Schwartz & Bilsky, 1987), as abstract structures that provide continuity and meaning under changing environmental circumstances (Feather, 1995), and as stable meaning-producing superordinate cognitive structure (Rohan, 2000). Based on CLT, we propose that attitudes and values, because of their relatively abstract and decontextualized nature, will be more readily applied to and guide choice in psychologically distant situations. As one gets closer to a situation, choices are increasingly more likely to be based on secondary, low-level considerations.

Initial evidence for this analysis was recently obtained by Sagristano, Eyal, Trope, and Liberman (2006). The first session of the study assessed participants' general attitudes toward blood donation, volunteering for psychology experiments, and physical fitness advisement. In the second, purportedly unrelated session, participants were offered an opportunity to actually engage in those activities either in the next 2 days or several weeks later, and their behavioral intentions were assessed. As expected, participants' general attitudes better predicted their intention for the distant future than for the near future.

Another set of studies examined temporal changes in forming value-consistent intentions and applied Schwartz's (1992) value questionnaire to assess the importance participants assign to a wide range of values (e.g., power, benevolence, and hedonism). For example, one study asked participants to imagine 30 behaviors (e.g., rest as much as I can) and to indicate the likelihood of performing each behavior either in the near future or in the distant future. The researchers then correlated the rated importance of each value and the mean likelihood for performing the behaviors corresponding to that value. As predicted, these correlations were higher when the behaviors were planned for the distant future than when they were planned for the near future (Sagristano et al., 2006).

It is also possible to distinguish between values that are central to an individual and more peripheral, secondary values. When a situation is related to a number of different values, the individual's central values are more likely to guide choice from a psychologically distant than a proximal perspective, whereas the individual's secondary values are more likely to guide their choice from the psychologically proximal than the distant perspective. To examine this prediction, Eyal, Liberman, Sagristano, and Trope (2006) measured or manipulated the centrality of values and examined how they predict behavioral intentions. For example, one study assessed the relative centrality of achievement versus altruism values and examined near and distant intentions of solving a dilemma between getting ahead by working extra hours or helping a friend. Results indicated that people who were predominantly achievement oriented planned to be achieving in the distant future more than in the near future, whereas people who were predominantly altruistic planned to be more cooperative in the distant future than in the near future. In other words, participants solved the conflict in favor of the more central value in their own value priorities in the distant future more than in the near future. These results imply that distant-future decisions reflect predominant values whereas in near-future decisions secondary values are also brought into consideration. Interestingly, these results also suggest that individuals with different values are quite similar to each other with respect to their near-future plans but differ considerably in their plans for the distant future. Inasmuch as actual behavior is closer to near-future plans than to distant-future plans, it is also possible to contend that individual differences in values are reflected in distant plans more than in real behavior. This would be reminiscent of the basic notion of social psychology that individual differences often fail to materialize in actual behavior, despite the common intuition that such differences are essential, central, and important. Possibly, people feel that individual differences in values guide behavioral choice because we tend to think of behavioral plans for temporally distant or hypothetical situations.

COMPENSATORY STRATEGIES IN DECISION MAKING

Our choice findings may be interpreted as suggesting that choice for the near future is based on more dimensions and is more compensatory, whereas choice for the distant future gives more weight to a smaller number of dimensions and is, therefore, less compensatory. Decision-making research views looking at attributes within each alternative as the hallmark of compensatory search, because compensation requires summing, within each alternative, the contribution of each attribute to the overall value. Looking at each attribute across alternatives, on the other hand, typically characterizes noncompensatory choice strategies, such as elimination by aspect (Payne, Bettman, & Johnson, 1988). We think that, generally, looking within alternatives across attributes constitutes a lower-level construal than looking at attributes across alternatives, because alternatives are directly experienced entities whereas attributes are abstracted. Moreover, a comparison of alternatives requires construal, or transcending the directly experienced situation (e.g., one cannot experience simultaneously a number of apartments and compare by experience their level of noise), but many attributes of a single alternative may be experienced simultaneously and thus do not require transcendence (see Hsee & Zhang, 2004, for a related distinction between joint and separate evaluation). From this perspective, too, compensatory evaluation of alternatives and within-alternative search would be associated with low-level construal and would characterize processing of proximal decision situations, whereas noncompensatory evaluation and within-attribute search would be associated with high-level construal and therefore would characterize processing of distal decision situations.

This idea was recently tested in an information search study by Borovoy, Liberman, and Trope (2004). Partici-

pants were presented with a matrix of information in which rows represented alternatives (e.g., different apartments), columns represented attributes (e.g., price, location, and noise), and cells represented the standing of each alternative on the corresponding attribute. Participants searched this matrix by exposing the information in each cell, one at the time (see Payne et al., 1988, for a review of this paradigm). We told some participants that they are making a choice for the near future (e.g., that they are choosing an apartment to rent in the next 2 weeks) whereas other participants were told that they are making a decision for the distant future (e.g., that they are choosing an apartment to rent 1 year later). We counted the number of within-alternative steps (i.e., the number of cells that were opened immediately after opening a cell in the same row) and within-attribute steps (i.e., the number of cells that were opened immediately after opening a cell in the same column). As expected, we found more within-alternative steps and less within-attribute steps for more near-future decisions. Moreover, we found that participants opened an equal number of cells and invested a similar amount of time in both temporal distance conditions. Thus, they did not perform a more heuristic search for the distant future sets.

SUMMARY: THE EFFECT OF FUTURE TEMPORAL PERSPECTIVE ON PREFERENCES

Together, the studies reviewed here support the CLT analysis of temporal changes in the effects of high-level and low-level information on preference. A distant-future activity was chosen according to the main task, but a near-future activity was chosen more according to a secondary, filler task. Diagnostic value was the prime determinant of preferences regarding distant-future self-relevant feedback, but pleasantness of the feedback was influential in preferences for the near future. Distant future time planning, but not planning for the near future, was guided by desirability concerns without taking into account time constraints. A future gamble was chosen according to the value of the outcome, whereas a near-future gamble was chosen according to the probability of the outcome. A distant-future action alternative was represented in terms of pro arguments, whereas a near-future action alternative included a representation of more con arguments. Finally, behavioral intentions for the more distant future, more than intentions for the near future, corresponded to abstract and central attitudes and values, whereas more specific and secondary attitudes and values showed the reverse intertemporal pattern.

In many of these cases, an irreversible decision was made at the same point in time regarding near- or distant-future options. Moreover, at the time of the decision, similar low- and high-level information was available for both the near- and distant-future options. Nevertheless, low-level information was more influential in decisions regarding near-future options, whereas high-level information was more influential in decisions regarding distant-future options. Thus, these findings cannot be explained by temporal differences in availability of high- versus low-level information or by the ability to postpone the use of one of these types of information when it pertains to distant-future options.

Notably, our studies do not show more regressive choices for the more distant future. To the contrary, choices for the distant future tend to discriminate more clearly both between alternatives and between individuals. Thus, our participants were not simply uncertain or indifferent in their choices for the distant future, but, to the contrary, exhibited more differentiation and decisiveness regarding distant-future choices. We think that this was the case because they based distant-future preferences on higher-level construals, which are often more simple and schematic than construals of the near future. Our studies on information search and memory explicitly show that participants did not invest less effort and did not engage in shallower processing when thinking about more distant-future decisions. They did, however, apply a less compensatory, more attribute-based, rather than alternative-based, strategy in making decisions for the more distant future. We believe that this was the case because compensation and within-alternative search are based on a lower-level construal of the decision situation than looking within attributes. It is this noncompensatory strategy, we believe, that in many cases gives rise to more clear-cut preferences for the more distant future.

Past Temporal Distance and Preferences

Gilovich and Medvec (1995) found that people regret action in the recent past but inaction in the distant past. For example, when asked about regrets they have about their college years, students would say that they regret majoring in psychology, but older people would say that they regret not taking art classes. One explanation that Gilovich and Medvec proposed for their finding was that reasons for an action are more schematic and essential for the action (e.g., I like art) than reasons against an action (e.g., I am too busy) and therefore are better retained in memory. As a result, with time, the reasons for not taking an action become unclear, and a failure to act becomes less understandable and more regrettable. This explanation is consistent with our findings that pro arguments become more salient over temporal distance whereas con arguments become less salient over distance. Thus, the tendency to increasingly regret inaction over time distance may be explained within CLT as a result of the pro arguments being superordinate to con arguments (see above), and thus more salient at a larger distance.

Social Distance and Preferences

ADVISING VERSUS MAKING DECISIONS: PRIMARY AND SECONDARY ASPECTS

Kray and Gonzalez (1999) and Kray (2000) compared participants' own choices to the advice they gave to close and remote others. They found that in advising others, especially to more socially remote others, participants tended to give more weight to a single attribute that they

designated as the most important and less weight to other, more peripheral attributes. For example, when advising another person about choosing between two jobs, participants gave more weight to personal satisfaction (the most important dimension) and less weight to salary and location (the less important dimensions) than when choosing for themselves (study 2). In two other studies, conceptually similar results were shown to be stronger with a more distant social target (a student in another department) than with a closer target (a student in one's own class). Moreover, it was found that when rating the importance of attributes, advisories to others tend to give more polarized ratings, favoring central attributes and discounting unimportant ones, whereas decisions for oneself tend to have a more balanced view, in which more similar importance ratings are assigned to both important and less important attributes. Kray also found that participants reported more responsibility and potential regret, a larger number of generated decision-relevant attributes, and less regressive choice when making decisions for others than for oneself, from which she concludes that it is implausible that people simply invested less effort in advising others than in deciding for themselves. In our terms, these findings demonstrate choosing according to more central, high-level aspects for more socially remote targets and applying less compensatory strategies for others than for oneself. Both of these results parallel our findings on future temporal perspective and, we believe, may be similarly explained within the framework of CLT.

THE EFFECT OF POWER ON WEIGHTING PRIMARY AND SECONDARY ASPECTS

As discussed earlier, theory and research suggest that powerful individuals feel more independent of others and, therefore, more distinct and distant from others than people with less power (e.g., Hogg, 2001; Hogg & Reid, 2001; Lee & Tiedens, 2001; Snyder & Fromkin, 1980). We also argued that this predisposes the more powerful individuals to adopt a distal perspective on the immediate situation and to form high-level construals of information about the situation (see Smith & Trope, 2006) and therefore to be more attuned to the primary outcomes the situation affords. In contrast, powerless individuals would divide their attention between central and peripheral aspects of the situation and would, therefore, be less likely to form an unequivocal action orientation in line with what the situation affords.

Initial evidence in support of this idea comes from a series of studies by Guinote and Trope (2004). One of these studies assigned participants to the roles of judges or workers. The judges evaluated the performance of the workers and controlled their payment and thus constituted a higher-power role. Before starting this task, in a purportedly unrelated experiment, participants were asked to imagine themselves in two situations, and to describe 1 day in their lives while in those situations. One situation described a friend visiting, whereas the other situation described doing an internship. Both situations provided opportunities to engage in work and social activities, but in the internship situation work activities are more central, whereas in the friend visit situation social activities are more central. The results showed that participants planned more work-related than social-related activities in the internship situation and more social-related than work activities in the friend visit situation. More important here, this difference was stronger for participants in the more powerful role than for participants in the less powerful role. As predicted, then, the more powerful individuals seemed more responsive to primary aspects of the situation and less responsive to secondary aspects of the situation. These findings are consistent with the assumption that greater social power increases the weight of high-level construals in individuals' behavioral choices. Positions of social power often require individuals to take a global orientation, plan ahead, and take decisive action. By promoting high-level construals, social power may naturally support such requirement.

CHOOSING VERSUS PREDICTING OTHERS' CHOICES: PROBABILITY AND VALUE

We argued earlier that in positive bets, payoffs may be conceptualized as being at a higher-level construal than probabilities. If this is true, then the weight of payoffs would increase over distance whereas the weight of probabilities would show the reverse effect. Consequently, people would take more risky (i.e., lower-probability, higher-value) distant bets but more conservative (i.e., high-probability, low-payoff) proximal bets. Self–other differences in choice of positive bets seems to support this prediction. Hsee and Weber (1997) asked participants to make a series of choices between a sure outcome and a risky outcome (e.g., getting $800 for sure vs. a 50% chance to get $2,000) and also to predict the choice that other people would make. They found that people thought that others would take more risky bets than themselves. Moreover, the discrepancy between one's own risk preferences and the predicted risk preferences of others was related to the abstraction of the other person: It was stronger for abstract others, of whom participants had no image, than for concrete individuals, whom participants could see but did not know. Hsee and Weber explained their results in terms of the risk-as-feeling hypothesis according to which people's risk preferences are dependent on their feelings toward risk. They contended that people are more likely to empathize with a more concrete individual and perceive his or her feelings as similar to their own. Consistent with this view, CLT suggests that others, and particularly distant others, are construed more abstractly. Therefore, in predicting their preferences, people give more weight to value and less weight to probability.

Probability and Preference

CLT predicts that increasing the likelihood of an event would decrease the weight of desirability-related features relative to the weight of feasibility-related features in decisions, thereby decreasing (or even reversing) the pref-

erence for a more desirable but less feasible outcome over a less desirable but more feasible outcome. A recent series of studies by Todorov, Goren, and Trope (in press) tested this prediction. In one study, participants were told that a number of companies in New York had started promotional campaigns for their products and services, and that some of them had offered a special promotional plan to NYU students. In the high-probability condition, participants were told that if they signed up for the campaign, they were almost certain to receive a voucher for the company's products. In the low-probability condition, participants were told that they would have about a 1 in 100 chance of receiving a voucher. In both probability conditions, the campaign was described as offering either a highly desirable but less feasible outcome or a less desirable but highly feasible outcome. For example, the highly desirable outcome was receiving 10 CDs from a Tower Record store, but to claim the CDs, the voucher had to be presented at a store at an inconvenient location. The less desirable outcome was receiving one CD that could be claimed at a convenient location.

Participants indicated their willingness to sign up for the campaign. The results showed that whereas under low probability, participants preferred the highly desirable but less feasible alternative to the less desirable but highly feasible alternative, under high probability this preference was reversed. Similar results were obtained with a variety of other prospects pitting desirability and feasibility. In all these cases, participants gave more weight to the outcome's desirability than to its feasibility when the outcome was improbable, but not when it was highly probable. It seems then that that probability changes the weights of outcome feasibility and desirability in much the same way as temporal proximity does.

Construal Level and Preference

As mentioned earlier, we believe that psychological distancing affects preference via construal, by enhancing the weight assigned to high-level value relative to low-level value. It is also possible to examine directly the effects of construal level on preference—although level of construal is not conceptualized as a dimension of distance, CLT predicts the effect of higher-level construal to be similar to that of psychological distancing. Evidence in the domains of risk taking and self-control seems to support this claim. We turn now to examine it.

RISK TAKING

Level of construal appears to have a crucial effect on the relative weight of probabilities and expected utility in risky choice, particularly in natural, real-life decisions. For many decision situations, one can choose whether to view them as one in a series of similar events or rather as unique, one-time occurrences. For example, when facing a decision on whether to invest in developing a new herbal treatment based on dried violets for stress-related headaches, an executive of a drug company may view the decision as one in series of decisions about novel medicines, or, alternatively, as a unique, one-time decision about applying dried violets for treating stress-related headaches. Note that abstraction is needed in order to adopt the former view, as it requires ignoring specific, incidental, and contextual features. From that perspective, viewing the decision as one in a series of similar decisions constitutes a high-level construal of the situation.

Kahneman and Lovallo (1991) proposed that risk avoidance in real life often stems from a narrow categorization of the decision situation as a unique, one-time event. In our example, if the decision is construed with all of its rich specific and contextual details, it will be viewed as unique and would produce risk avoidance. If, on the other hand, the manager would think of the product as one of a series of developments, and one of a series of risks that the company and she personally are to take, then her willingness to take the risk would increase. This is because normatively, the outcome of aggregated gambles is more likely to be close to its expected utility than the outcome of a single gamble. In other words, risk is reduced with repetition (see Lopes, 1996). In our terms, Kahneman and Lovallo's analysis suggests that less risk aversion (in fact, less weight for the dimension of risk and more weight for expected utility) ensues from a higher level of construal, a notion that is compatible with the findings on the enhancing effects of psychological distance on risk taking reviewed earlier. More generally, in series of risky events, a high-level construal may correspond to aggregation, whereas a low-level construal may be related to a viewing each event separately. Because aggregation reduces risk aversion, it follows that high-level construal of risky events would be associated with reduced risk aversion.

SELF-CONTROL

Situations that require self-control involve a conflict between two opposing motivations (e.g., a desire to go out with friends and a need to study for an exam). Recently, Fujita, Trope, Liberman, and Levin-Sagi (2006) proposed an analysis of self-control conflicts as conflicts between behavioral implications of high-level construal (i.e., value that is related to primary, central, goal-relevant, superordinate considerations) and behavioral implications of low-level construal (i.e., value that is related to secondary, incidental, goal-irrelevant, subordinated, features). Failure of self-control, according to this proposal, is succumbing to the motivation implied by the low-level value. For example, if studying for an exam is related to more superordinate goals than going out with friends, then the latter behavior would represent a failure of self-control. Consistent with this analysis, a series of studies by Fujita and colleagues demonstrated that higher-level construals increased self-control. In one study, participants first completed a task in which they indicated either why or how they would maintain good physical health. This task was designed to induce a high- or low-level construal mindset, respectively. Participants were then asked to hold a handgrip while connected to bogus electrodes, os-

tensibly as part of a psychophysiological assessment of personality. Participants were told that the longer they hold the handgrip, the more diagnostic was the information obtained from the apparatus. Thus, the situation presented a conflict between a desire to get diagnostic, self-relevant information (high-level value) and the inconvenience of holding the handgrip (low-level value). The results indicated, as predicted, that participants in the high-level construal condition held the handgrip longer than those in the low-level construal condition.

The finding that high-level construal produces greater self-control than low-level construal is consistent with the conceptualization of self-control as involving a conflict between behavioral implications of low-level versus high-level value. CLT further predicts that temporal, spatial, and social distancing would also enhance self-control. Consistent with this prediction, extant research on temporal distance has shown that people are better able to commit to self-control a long time in advance than a short time in advance (Ainslie & Haslam, 1992; Frederick, Loewenstein, & O'Donoghue, 2003), and when the temptation is physically distance than when it is near (Metcalfe & Mischel, 1999; Mischel et al., 1989).

Summary: Psychological Distance and Preference

It seems ironic that when outcomes become psychologically proximal and likely to materialize, people tend to overweight secondary considerations in their choices. Conversely, it is when outcomes seem unlikely or remote or refer to distant times that people's primary concerns are more likely to guide their preferences. In other words, people appear to be better able to act according to their priorities with respect to distal options than proximal options. This counternormative (and perhaps counterintuitive) conclusion raises interesting self-regulatory questions regarding people's ability to express core aspects of their self-identity in remote versus proximal situations.

We demonstrated effects of psychological distance on evaluation and choice, and we believe that these effects are mediated by the effects of psychological distance on construal. It is important to note, however, that psychological distance may affect not only the perceived value of outcomes but also the motivation to pursue the outcomes, by affecting the outcomes' expectancy. The effects of distance on expectancy are outside the scope of CLT but are worth discussion in order to prevent possible confusion. It is to that discussion that we now turn briefly.

Motivation researchers have related expectancy to uncontrollable probability of outcomes (e.g., in bets; Edwards, 1955), task difficulty (Atkinson, 1957), controllability (Locke & Latham, 1990; Rotter, 1966), and self-efficacy (Bandura, 1982). For our purposes, it is instructive to note that psychological distance may often reduce expectancy in these various forms. For example, people typically have less control over more socially distant individuals. People typically control others less than themselves and strangers less than friends and relatives. Control also diminishes with spatial distance, as it is often

more difficult to do something about things that are farther away. Events in the distant future (e.g., a distant-future rebate) typically involve some uncertainty (e.g., would the company still be around to pay the rebate), which increases with time distance, as noted already by Keren and Roelofsma, 1995 (see also Frederick et al., 2003, and Prelec & Loewenstein, 1991, for a proposed similarity between the effects of time and probability). Proximity also increases efficacy by making action more crucial for achieving an outcome. For example, a long time before an exam, failing to study may be compensated by studying more intensely later, but a short time before the exam, when only a few hours remain, such possibility no longer exists. As another example, failing to help a stranger may be compensated by help by another stranger, but failing to help a close friend is less likely to be compensated by someone else, because people typically have fewer close friends than strangers around them.

Psychological distance may thus decrease motivation due to changes in expectancy. For example, students may be more motivated to study for a close exam than for a distant exam because not studying is easier to compensate for at a distance, or people may be more motivated to help a close friend than a stranger, because in the latter case, their lack of help is more likely to be compensated by others. These changes in motivation do not reflect changes in value (i.e., it is not necessary to assume that the value of a success on the exam increases closer to it) although such changes may, of course, exist. Moreover, changes in expectancy over psychological distance are not mediated by construal but, rather, are real, objective changes (e.g., opportunities for compensation really decrease closer to an outcome) that do not require a psychological theory to explain them. For that reason, they fall outside the scope of CLT (see Liberman & Trope, 2003, for a detailed discussion of that point with respect to temporal perspective).

It is possible however, that motivation contaminates measures of value. For example, it is possible that one's motivation to study for an exam and one's arousal or level of energy would affect one's answer to a question about the importance of succeeding in an exam. If contaminated with motivation, measures of value would show discounting over psychological distance. It is possible that this is one of the reasons for the widespread assumption that value is discounted over psychological distance. CLT proposes, however, that if value is measured independently of motivation and thus is not affected by possible changes in expectancy, then both discounting and augmentation over psychological distance become possible, depending on the construal level with which value is associated.

Affect

How does psychological distance influence affective responses? It is commonly assumed that the intensity of affective reactions decreases with psychological distance. People typically react more strongly to events that are

closer to them in time and space, to events that happen to themselves than to others, and to events that are real more than to hypothetical events. It seems that the effect of the various dimensions of psychological distance is similar and involves reduction in the intensity of affective responses. Theoretically, CLT would predict that affective responses are diminished over temporal distance only if they are low level, and, contrary to that, high-level affective responses may be augmented over time. But is there high-level affect?

Indeed, emotion researchers typically identify affective responses with low-level, concrete processing and contrast them with cognitive responses, which are considered to be more abstract and high level (Loewenstein, 1996; Metcalfe & Mischel, 1999). It is possible, however, that there are different types of affect, and that some may be characterized as more abstract and higher level than others. An interesting possibility would be to distinguish between high- and low-level affect by the extent to which they require going beyond one's direct experience here and now (i.e., the extent to which they necessitate distancing and construal). For example, social emotions such as pride and guilt involve considering the perspective of other people and hope involves considering the future; counterfactual emotions, such as disappointment and regret, involve considering alternatives to reality. Interestingly, it has been suggested that anxiety, contrary to fear, is an apprehension of a potential source of danger at a location other than the immediate (Gray & McNaughton, 2000). All these emotions are distinct from hunger, thirst, pain, anger, happiness, sadness, and fear, which do not necessitate transcending one's direct experience (but, of course, allow for such transcendence, as one can, for example, become angry by thinking of a hypothetical event). We refer to this distinction in terms of level: higher-level emotions are those that require more distancing and construal, whereas lower-level emotions are those that do not necessarily require as much distancing and construal. This distinction between levels of emotion partly overlaps with extant distinctions in the literature between basic emotions and other emotions (Ekman, 1992; Izard, 1977, 1992; but see Ortony & Turner, 1990, for questioning the validity of this distinction). Interestingly, in these theories, emotions are called basic because they are assumed to have innate neural substrates, innate and universal expressions, and unique motivational states. These criteria are very different from the construal versus experience criterion that we propose here. Thus, although the distinctions proposed in these theories overlap to some extent, the theoretical basis that underlies the distinction is different.

The classification of emotions according to level is content based, as it distinguishes between qualitatively different emotions. Besides this distinction, according to CLT, the level of the exact same emotion can differ depending on the situation in which it occurs. For example, as noted before, central aspects of situations constitute higher-level construals than do peripheral aspects. Therefore, affective aspects that are made central (e.g., by virtue of being goal relevant) would be of a higher level than similar aspects that are made peripheral (e.g., irrelevant to the main goal). For exam-

ple, in a funeral, sadness about the transience of life and compassion are central and thus constitute high-level emotions, but happiness upon seeing old friends is peripheral and thus constitutes a low-level, peripheral emotion. In a birthday party, however, the centrality of these emotions reverses.

For both content-based and situationally based variations of level of affective responses, CLT proposes that low-level affective responses, more than high-level affective responses, would be diminished over psychological distance. The latter, we think, may be discounted less or even augmented with distance. Let us now review literature on the effect of various distance dimensions on affective responses.

Future Temporal Perspective and Affect

It is commonly assumed that temporal distance diminishes affective reactions. Research on delay of gratification (Mischel et al., 1989; Mischel, Ayduk, & Mendoza-Denton, 2003) and self-control (Baumeister & Heatherton, 1996; Loewenstein, 1996; Metcalfe & Mischel, 1999) has documented that from a distance, people underestimate their affective reaction and overestimate their ability to make "cold," rational, unemotional decisions. For example, the positive value of watching a funny movie is affective or "hot," whereas the positive value of studying for an exam is cognitive. If the value of watching the movie is discounted more steeply than the value of studying, a temporally inconsistent pattern of preferences emerges wherein studying is preferred a long time in advance but watching the film seems more attractive from a closer perspective. According to this approach, then, temporal distance should always increase the relative weight of cognitive (vs. affective) value in preference.

As noted before, an interesting prediction of CLT is that both affective and cognitive types of value could be either high level or low level and, therefore, could be both augmented and discounted over time perspective. This prediction was tested in a study that independently manipulated the affective–cognitive dimension and level of construal (Trope & Liberman, 2000, study 5). In this study, we assessed desirability ratings of four films varying in affective value (funniness) and cognitive value (informativeness). The films were, thus, funny and informative, funny but uninformative, not funny but informative, or neither funny nor informative. Some of our participants expected to watch the films in the same experimental session, whereas other participants expected to watch them in the second session of the study, 2 months later. The goal of watching the films was also manipulated: It was either affective (getting oneself into a good mood) or cognitive (learning about a topic). We assumed that the features of the film that are related to the goal would be more central than the goal-irrelevant features and thus would constitute a high-level construal of the film. Thus, depending on the goal, either affective features or cognitive features of the films were more central (constituted the high-level construal of the films), whereas the other type of features was rendered goal irrelevant and thus part of the low-level construal of the films.

We examined how time perspective, goal, affective value, and cognitive value influenced the desirability ratings of the films. Consistent with the predictions of CLT, we found that temporal distance increased the influence of the informativeness versus the funniness of the films when the goal was cognitive but decreased the influence of informativeness versus the funniness of the films when the goal was affective. Thus, the effect of high-level, goal-relevant value increased over delay relative to the effect of low-level, goal-irrelevant value.

Social Distance and Affect

A large amount of social psychological research suggests that liking, love, hate, and empathy decrease with social distance. For example, reducing similarity reduces liking and empathy toward a social target (Byrne, 1971; Newcomb, 1961). In terms of CLT, liking and empathy are low level, because they do not require construal or transcending one's direct experiences. We would predict that higher-level interpersonal emotions, such as shame and guilt, would be less discounted over social distance. For example, we would predict that reducing similarity would not reduce and may even increase one's feelings of shame regarding another person.

Interestingly, the literature on empathy distinguishes between cognitive empathy, which involves taking a perspective of another person, and emotional empathy, which involves contagion with another person's emotions and does not involve perspective taking (Davis, Hull, Young, & Warren, 1987; Preston & de Waal, 2002). For example, cognitive empathy involves understanding the difficulties faced by another person, whereas affective empathy involves feeling the other person's pain. In our terms, cognitive empathy pertains to a higher level of construal than emotional empathy. CLT therefore predicts that emotional empathy would be discounted over social distance (and, in fact, any psychological distance) more than cognitive empathy.

Physical Distance and Affect

Closely related to empathy is the ability to experience another person's pain and take it into consideration in one's actions. As discussed previously, experiencing another's pain is an emotional contagion and thus would be classified as emotional empathy, or, in our terms, low-level empathy. We would therefore predict that it would decrease over physical distance. Milgram's (1965) studies on obedience are consistent with this prediction, as they show that physical proximity to the victim reduced the willingness to obey an order to inflict pain on him. It is possible that this was the case because physical proximity enhanced participants' emotional empathy toward the victim. In other situations, too, physical proximity plays a major role in empathic concern. For example, it has been suggested that the cruelty of war has intensified with introduction of weapons that are remotely operated (e.g., aerial bombardment). Indeed, Latané's (1981) social impact theory specifies physical distance as one determinant of social impact in general and emotional impact in particular.

The Effect of Level of Construal on Affect

As with the effects of social distance on evaluation and choice, we believe that the effects of distancing on affect are mediated by its effects on construal. Thus, it would be interesting to examine evidence for the effects of construal level on affect. According to Metcalfe and Mischel (1999), stimuli can be mentally represented either in terms of their emotionally arousing "hot" features or their cognitive, informational, "cool" features. These representations are intrinsically connected to two regulatory systems: hot representations elicit emotionally driven, reflexive, "hot" responses that are predominantly under stimulus control and generate automatic approach–avoidance behaviors. Cool representations, on the other hand, elicit cognitively driven, reflective, "cool" system responses whose functioning requires more effortful and conscious control. Effective self-regulation of reflexive responses associated with the hot system is possible to the extent that individuals have and can access cognitive representations (i.e., distraction, reappraisal, and abstraction) that help cool intrinsically hot stimuli. In this view, then, abstract representations are associated with cool, less affective responses. Mischel's (1974) work on delay of gratification provides support for this idea. It demonstrates that an effective way to overcome immediate temptations and successfully delay gratification is to turn attention away from the concrete qualities of the immediate temptation (e.g., a tasty cookie) and focus on its abstract qualities (Mischel et al., 1989; see also Mischel et al., 2003).

A recent study by Kross, Ayduk, and Mischel (2004) examined the joint effects of construal level and social distance on people's ability to reduce experienced negative emotions. In the study, participants recalled a past interpersonal experience in which they felt overwhelming anger and hostility. Type of perspective was manipulated by making some participants think of what emotions are being felt and other participants on why they are experiencing those emotions. In our terms, the former corresponds to a low-level construal whereas the latter corresponds to a high-construal level. They also manipulated the type of perspective, by asking some people to be immersed in the experience, or taking a first-person perspective, and other participants to take a perspective of a distanced observer. In our terms, this corresponds to a manipulation of social distance. The authors hypothesized that a low-level, "what" focus would activate relatively concrete, hot representations of the specific emotions and thus should be associated with a high level of negative affect whereas a high-level, "why" focus may produce either hot representations or cool representations, depending on the type of people's perspective. Specifically, they predicted that a "why" focus would attenuate negative affect only in a self-distanced perspective but not in a self-immersed perspective.

Emotional response of anger was measured implicitly, by a word completion task, and explicitly, by asking par-

ticipants about their mood. The results showed, as predicted, that participants who focused on the reasons underlying their feelings (a high-level, why construal) and maintained a distanced social perspective (an increased social distance) manifested the lowest levels of anger on both explicit and implicit measures. In our terms, these results indicate an interactive effect of construal level and social distancing, such that emotions decrease when both are high. It would be interesting to repeat this study with higher-level emotions such as guilt. CLT would predict that in that case, distance would not attenuate emotional reaction but might in fact increase it.

Theories on affective reactions to exemplars versus categories also suggest that the former elicit more intense affective reactions than the latter (Sherman, Beike, & Ryalls, 1999). For example, while the idea of "saving whales" leaves people relatively unemotional, "saving Willy" (a concrete whale) often touches them deeply and is reflected in an enhanced willingness to donate money to that end (Kogut & Ritov, 2004; Sherman et al., 1999). As in other cases of distance effects on emotion, we predict this to be the case with low-level emotions more than with high-level emotions. Thus, we predict that compassion toward a single whale may be paradoxically reduced if one thinks about an entire category of suffering whales, but that feelings of guilt and shame (e.g., for polluting water) would not be reduced by shifting one's attention from one concrete victim to an entire category of suffering victims.

Summary: The Effect of Psychological Distance on Affect

A considerable amount of theoretical and empirical work suggests that psychological distance reduces the intensity of affective responses. People react less strongly to temporally and physically distant events than to close events. They feel less for more socially distant individuals and react less strongly to less likely occurrences. CLT not only provides a unifying framework for these various effects but also posits that these effects would be weaker for emotions that are of a higher level of construal either because they are central or because they require transcending the immediate experience. Thus, CLT suggests that the effects of distance on affect depend on level of construal, in the same way that the effect of distance on prediction and evaluation depends on level of construal.

Creativity

The last area in which we examine the implications of CLT is creativity. Creativity has been assumed to profit from abstract thinking (e.g., Finke, 1995; Ward, 1995), and performance on a variety of creativity tasks seems to depend on more abstract construals of problem components. For example, creativity on alternative-uses tests (e.g., generating reasons why to greet somebody; Friedman & Förster, 2002; Schoppe, 1975) should be enhanced by construing the action more abstractly (e.g., as a gesture of communication) rather than more concretely (e.g., as "saying hello"). Therefore, whereas the former might lead to solutions that are more remote and diverse from the actual object, the latter might render common associates accessible, impeding innovation (see Marsh, Ward, & Landau, 1999). If creativity is enhanced by abstract representation of problem elements and if, as discussed earlier, distant perspectives engenders higher-level construals, then psychological distancing may promote creative thinking.

The Effect of Future Temporal Perspective on Creativity

In a series of studies, Förster, Friedman, and Liberman (2004) tested the idea that distancing would enhance creativity by manipulating distant versus near-future time perspective and gauging performance on a variety of creativity tasks. One of the studies assessed performance on insight problems. The following is an example: "A prisoner was attempting to escape from a tower. He found a rope in his cell that was half as long enough to permit him to reach the ground safely. He divided the rope in half, tied the two parts together, and escaped. How could he have done this? [Solution: He unraveled the rope lengthwise and tied the remaining strands together]." The natural way to imagine "cutting the rope in half" does not involve unraveling it. One needs to abandon this concrete image and represent the action more abstractly in order to construe this action in an alternative way. Förster and colleagues asked participants to think about themselves and their lives as they would be a year later (or the next day) and then imagine working on the insight problems at that time. For three such problems, participants displayed more insight in the distant-future condition than in the near-future condition. Interestingly, Förster and colleagues (2004, studies 2 and 3) found that temporal distancing facilitated insight not only in verbal tasks but also in visual tasks, which require abstraction of coherent images from fragmented or "noisy" visual input (e.g., the Snowy Picture Test and the Gestalt Completion Test; see Friedman & Förster, 2000, 2002). Other studies demonstrated that temporal distancing facilitates abstract reasoning but not concrete reasoning (Förster et al., 2004, studies 4 and 5).

Creative Insight and Other Psychological Distances

Anecdotal evidence and some research findings suggest that other dimensions of distance might produce similar effects on creativity. People sometime feel that they had their most ingenious ideas in circumstances quite distant from and dissimilar to their usual working environment. "Incubation" may also testify to a similar connection between distancing and creative insight. Sometimes, after repeated and fruitless attempts to solve a problem, the solution may pop up after one takes some distance from the problem by leaving the problem for a while and doing other things (temporal distancing) or by changing the physical context (spatial distancing). It has been argued that one could become more innovative in solving technological problems by imagining oneself as a little dwarf entering the subject matter of the problem at hand (e.g., entering the computer chip, to solve the problem of their overheating), or to change one's physical location to a

very atypical one (e.g., sitting under one's office desk) in order to "break set" and achieve a fresh look at the problem (Helfman, 1992). Adams (1986) and de Bono (1985; see also Butler & Kline, 1998) suggest that considering the perspective of other people who are involved in a problem might help generate better and more creative solutions. Systematic research on these issues is lacking, and further research is needed to better understand the effect of psychological distancing on creativity and reasoning.

Distancing, decontextualization, and abstraction seem to play a role not only in creative problem solving but also in production and perception of art. In art in general and in modern art in particular, distancing oneself from the concrete shape or material of a piece of art or from its mundane nature appears to be an important prerequisite for appreciating its artistic value. What is true for the perception of art also holds for its production: Deciding that a mundane object is or can be an object of art affords some abstraction. In fact, artistic perception requires abstraction of new meaning from concrete, directly experienced percepts, a meaning that is oftentimes different than the most common and usual abstractions people apply in everyday life. In that, artistic perception is similar to solving insight problems (Arnheim, 1969). Thus, although not empirically tested, distancing and abstraction seem to play a major role in creative problem solving, creative perception, and creative production. We believe that empirically exploring this possibility would be a fruitful avenue for future research.

INTERRELATIONS AMONG DIMENSIONS OF PSYCHOLOGICAL DISTANCE

In the final section of this chapter we examine the idea that all the dimensions of psychological distance are interrelated. We think that this should be the case because they share the feature of being distances from the same thing—one's direct experience—and because, as a consequence of diverging from direct experience, they have similar effects on construal. This section reviews empirical evidence regarding explicit and implicit associations among distance dimensions.

Social Distance and Other Dimensions of Psychological Distance

We now review research testing the interchangeability of social distances dimensions. We examine research on the effects of temporal distance and spatial distance on social distance and then turn to research on the reverse effect, namely, the effect of social distance on temporal and spatial distances.

The Effect of Temporal Distance on Social Distance

A series of studies by Stephan (2004) examined the effect of temporal distance on social distance. We predicted that an increase in temporal distance would produce a corresponding increase in social distance. One study, for

example, used politeness as an indicator of social distance. As mentioned in the first section of this chapter, research on politeness assumes that politeness varies as a function of social distance (Brown & Levinson, 1987). Therefore, the degree of politeness a speaker chooses may be used as an indicator of his or her perceived social distance from the recipient of the message. In our study, participants wrote instructions for a person who was expected to read them either in the near future or in the distant future. For example, participants wrote sightseeing suggestions for a tourist who was supposed to arrive on the following day or 1 year later. Then, participants rated how polite they intended to be in phrasing their suggestions. As predicted, participants indicated higher levels of politeness for the tourist who was expected in the more distant future.

The Effect of Spatial Distance on Social Distance

Spatial distance has been recognized for a long time as a major factor in creating and maintaining social ties (Festinger, 1951). For example, it has been shown that friendship is more likely to develop among spatially close than distant individuals, unless an initial antagonism has existed in the relationships (Festinger, 1951; Schiffenbauer & Schiavo, 1976). This is hardly surprising, as increasing physical proximity may create opportunities for social interaction and expose people to similar experiences (see Festinger, Schachter, & Black, 1950; Priest & Sawyer, 1967). Would a similar relation hold if distance is manipulated independently of these additional factors?

In a study aimed to answer this question, Reichman and Ben Arie (2004) examined the effect of actual sitting distance on politeness. They entered the first meeting of a SAT preparation course. The participants were adults who did not know each other in advance. Participants were asked to write two notes (one explaining how to use the course web site, and the other asking for advice on how to prepare for an exam) to a person sitting next to them, to a person sitting in another class, behind the wall, or to a person in a similar class in another town. After writing the notes, participants rated their own responses for intended politeness. We found that participants addressed more politely others who were in another class or in another city compared to others who were in the same class. Thus, spatial distance affected social distance, which was expressed, in this study, by the chosen level of politeness.

The Effect of Social Distance on Temporal Distance

Stephan (2005) conducted a study to examine the effect of social distance on temporal distance, using politeness to manipulate perceived social distance. Participants were asked to imagine two people conversing and one of them telling about an action he or she intended to perform. Participants then read a statement that was phrased in either normative language or colloquial language. For example participants in the colloquial (normative) condition read: "Sharon decided to keep an eye

on Lisa's baby (to watch Lisa's baby more carefully)." Colloquial utterances are less polite and indicate greater social proximity than normative utterances. Participants indicated how much time later the protagonist would perform the action. Consistent with our prediction, the mean enactment time for the colloquially phrased statements was nearer than for the normatively phrased statements, indicating that closer social distances produced a perception of sooner enactment times.

The Effect of Social Distance on Spatial Distance

Studies on personal space show that social distance affects the spatial distance people prefer to keep from each other. The more familiar and comfortable people are with each other, the closer the physical distance they maintain from each other (for a review, see Hayduk, 1983). People also tend to physically distance themselves from feared or stigmatized others (e.g., AIDS patients—Mooney, Cohn, & Swift, 1992; stereotyped groups—Macrae, Bodenhausen, Milne, & Jetten, 1994; Worthington, 1974). In these studies, however, socially distant targets were also less attractive. To distinguish between these two factors, we manipulated social distance as the degree of politeness used between interlocutors. In our study, participants received a sketch on which the location of the speaker was marked and read a phrase that the speaker said to the addressee. The phrase was either colloquial or normative, for example, "My brother is taking our family car, so the rest of us will stay at home (will be stuck at home)." Participants indicated on the sketch the location of the addressee. As predicted, the use of more polite (normative) language by the speaker produced a perception of a greater physical distance between the interlocutors, as compared to the use of less polite (colloquial) language. Thus, this study demonstrates that people who address each other more politely are expected to communicate across greater spatial distances. Colloquial language, which signified social closeness, produced estimates of smaller spatial distances.

Automatic Associations among Distance Dimensions

We claim that different dimensions of psychological distance share an important aspect of meaning, namely, that they all are distances from direct experience and as such require construal. Moreover, it is possible to assume that psychological distance would be an important aspect of stimuli that would be spontaneously encoded. The Stroop paradigm (Stroop, 1935) offers an apt way to examine these predictions. In a typical Stroop task, participants are faster at naming the ink color of semantically compatible words (the word "blue" or the word "sky" printed in blue ink; the words "green" or the word "grass" printed in green ink) than at naming the ink color of semantically incompatible words (the word "blue" or the word "sky" printed in green ink; the word "green" or the word "grass" printed in blue ink). These results are interpreted as suggesting that reading the words and assessing their semantic meaning is automatic (happens spontaneously, without participants' intention and despite the fact that it does not help in performing the experimental task), and that there is shared meaning between the two dimensions of the task (ink color, the semantic meaning of the words).

A series of experiments by Bar-Anan, Liberman, Trope, and Algom (2005) demonstrated a similar effect with distance-compatible versus distance-incompatible stimuli. The experiments applied a picture–word version of the Stroop task, in which the participants discriminate between cues of one psychological distance dimension while ignoring cues of another psychological distance dimension. We reasoned that if psychological distance is a shared meaning of spatial distance and the other three dimensions, then it would be easier to perform the task when the relevant and the irrelevant cues are congruent in psychological distance than when the relevant and irrelevant cues are incongruent in terms of psychological distance. For example, we predict that participants would identify a stimulus as spatially proximal faster when the irrelevant stimulus is a word that denotes psychological proximity (e.g., the word "we," which represents social proximity, printed on a spatially proximal object) rather than a word that denotes psychological distance (e.g., the word "others," which represents social distance, printed on a spatially proximal object).

Bar-Anan and colleagues (2005) used perspective pictures (e.g., a picture of an alley of trees or a picture of rolling hills). An arrow pointing to either a proximal or a distal point on the landscape was shown on the picture, and a word denoting a psychologically proximal entity ("tomorrow," "friend," "we," or "sure") or a psychologically distal entity ("year," "enemy," "others," or "maybe") was printed on the arrow (see Figure 15.1). In some of the experiments, the task was spatial discrimination, namely, participants indicated whether the arrow pointed to a spatially proximal or distal location. In other experiments, the task was semantic discrimination, namely, participants indicated whether the word on the arrow was, for example, "we" or "others." In both types of tasks, and across all four dimensions of distance, participants were faster in responding to distance-congruent than to distance-incongruent stimuli. These results demonstrate that people assess the psychological distance of stimuli that pertain to spatial distance, temporal distance, social distance, or hypotheticality, even when this information is irrelevant to their current goal and that these various distances share a common aspect of meaning. We interpret these results as initial evidence that psychological distance is a basic, automatically activated aspect of each of these dimensions.

CONCLUSION

As this review illustrates, there is a large amount of research across the behavioral sciences on how people respond to events from the recent versus distant past, near versus distant future, to spatially near versus far objects, to themselves versus others, and to real versus hypothetical, probable versus improbable events. Different theoretical approaches and research paradigms have been
FIGURE 15.1. Stimuli used in the Stroop task, examining associations between spatial distance and hypotheticality. Reaction times in both distance discrimination and word discrimination tasks were faster with congruent pairs (distant with "maybe"; proximal with "sure") than with incongruent pairs (distant with "maybe"; proximal with "sure").

proposed for each of those dimensions. Without denying the uniqueness of each dimension, we propose that they also have something in common, that they all constitute dimensions of psychological distance. At their point of origin is one's direct experience of the "here and now." Transcending this point entails constructing mental models of what is not directly experienced, and the farther removed an object is from direct experience on any distance dimension, the higher (more abstract) the level of construal of that object.

Consistent with this proposal, the research reviewed in this chapter suggests that different distance dimensions are interrelated. For example, distancing an object on one dimension may make it seem more distant on other dimensions, and the psychological distance of objects is assessed spontaneously, across different dimensions. Moreover, a large body of research shows that temporal distance, spatial distance, social distance (e.g., self vs. other and ingroup vs. outgroup), hypotheticality, and (im)probability are all associated with higher levels of construal. That is, the same information about more distant objects is represented more schematically in terms of few superordinate, core features of the object. These construals, in turn, expand one's horizons and guide prediction, evaluation, and action with respect to psychologically more distant entities. Indeed, the present review shows, for example, that distancing an event may increase or decrease one's confidence in predicting the event depending on whether the event is more likely or

less likely under high-level construals than low-level construals. Correspondingly, distancing an event may increase or decrease its attractiveness depending on whether the high-level value of the event is more positive or less positive than its low-level value. Again, these effects appear to hold across different distance dimensions.

The present review suggests, then, that (1) different distance dimensions are related to each other, (2) distancing on any of these dimensions is associated with higher levels of construal, and (3) they are, at least to some extent, interchangeable in their effects on prediction, evaluation, and choice. These three sets of findings suggest that psychological distance, as conceptualized here, may capture a fundamental aspect of meaning and may provide a unifying framework for understanding a wide range of seemingly unrelated social psychological phenomena.

PART III

PERSONAL MOTIVATIONAL SYSTEM

CHAPTER 16

Feelings and Phenomenal Experiences

NORBERT SCHWARZ
GERALD L. CLORE

Following an initial emphasis on "cold" cognitive processes, which could be conceptualized within the computer metaphor of the information-processing paradigm, social cognition researchers rediscovered "hot" cognition in the 1980s. Two decades later, their interest in the interplay of feeling and thinking is shared by researchers in decision making, cognitive psychology, and related fields. This chapter reviews what has been learned; it focuses on basic theoretical principles and empirical regularities rather than complete coverage of the literature. We first introduce three broad approaches to the interface of feeling and thinking and subsequently evaluate them in light of empirical findings in three key domains, namely, human judgment, strategies of information processing, and memory. Throughout, we emphasize the influence of feelings on cognitive processes; the reverse influence of cognition on emotion is reviewed by Clore, Schwarz, and Conway (1994) and Ellsworth and Scherer (2003).

APPROACHES TO FEELING AND THINKING

Three general approaches to the role of feelings in human cognition focus on the experiential, cognitive, and somatic components of feelings, respectively. The first approach emphasizes the experiential quality of feelings and addresses their informational functions. A second approach emphasizes the thoughts that accompany feelings, whereas a third approach emphasizes hardwired processes, focusing on the somatic components of affective states.

The Experiential Component of Feelings: Feelings as a Source of Information

Central to the experiential approach is the assumption that feelings can serve as a source of information in their own right. This assumption is consistent with traditional theorizing on emotions and has been fruitfully extended to other subjective experiences.

Affective, Bodily, and Cognitive Experiences

Social psychologists often subsume moods and emotions under the generic term "affect." This term, however, can also refer simply to valence—the positive and negative aspect of things. All emotions are affective, but not all affective things are emotions. *Emotions* arise in response to ongoing, implicit appraisals of situations with respect to positive or negative implications for one's goals and concerns (e.g., Ellsworth & Scherer, 2003; Ortony, Clore, & Collins, 1988). They have an identifiable referent (what the emotion is "about"), a sharp rise time, limited duration, and often high intensity. Emotion researchers commonly assume that "emotions exist for the sake of signaling states of the world that have to be responded to, or that no longer need response and action" (Frijda, 1988, p. 354). What exactly emotions signal can be derived from their underlying appraisal patterns. Sadness, for example, signals a loss or lack of reward that is not attributed to the causal action of another agent; when it is attributed to the causal action of another agent, it gives rise to anger. Accordingly, sadness and anger inform us about not only a loss but also about its likely cause, giving

rise to different attributions in judgment studies (e.g., Keltner, Ellsworth, & Edwards, 1993).

Moods, on the other hand, lack a clear referent, may come about gradually, may last for an extended time, and are often of low intensity (Morris, 1989). The experience of a positive or negative emotion may also leave us in a positive or negative mood after the emotion dissipates and its specific cause is no longer attended to (Bollnow, 1956). This difference between moods and emotions is apparent in ordinary language when we say that we are angry "about" something but that we are "in" a bad mood. Hence, moods mostly convey generic valence information that has no clear referent, which accounts for their pervasive influence.

Bodily experiences include feelings such as hunger, pain, and physiological arousal, which inform us about specific states of the organism. These experiences can be informative in their own right, and induced physical arousal (e.g., Zillman, 1978) or proprioceptive feedback from facial expressions (e.g., Strack, Martin, & Stepper, 1988) and arm flexion and extension (Friedman & Förster, 2000) can convey information that influences judgment and information processing.

Finally, *cognitive experiences* such as surprise, amazement, boredom, or feelings of familiarity inform us about knowledge states. Two cognitive experiences that received particular attention are the metacognitive experiences of accessibility and processing fluency. *Accessibility experiences* refer to the ease or difficulty with which information can be brought to mind or thoughts can be generated. They can serve as input into a large variety of judgments; their specific impact is highly malleable and depends on which naive theory of mental processes is brought to bear on the task (Schwarz, 2004).

Processing fluency refers to the ease or difficulty with which new, external information can be processed. Variables like figure–ground contrast, presentation duration, or the amount of previous exposure to the stimulus affect the speed and accuracy of low-level processes concerned with the identification of a stimulus's physical identity and form; they influence *perceptual fluency* (e.g., Jacoby, Kelley, & Dywan, 1989). Variables such as the consistency between the stimulus and its context or the availability of appropriate mental concepts for stimulus classification affect the speed and accuracy of high-level processes concerned with the identification of stimulus meaning and its relation to semantic knowledge structures; they influence *conceptual fluency* (e.g., Whittlesea, 1993). Empirically, both types of fluency show parallel influences on judgment (for a review, see Winkielman, Schwarz, Fazendeiro, & Reber, 2003) and can be subsumed under the general term "processing fluency." Which inferences people draw from experienced processing fluency again depends on the naive theory of mental processes that they bring to bear on the task (Schwarz, 2004). In addition, high fluency is experienced as hedonically positive (as captured by psychophysiological measures; Winkielman & Cacioppo, 2001), and this affective response can itself serve as a basis of judgment (Winkielman et al., 2003).

As our review indicates, all these experiences can influence how we evaluate a stimulus and which strategy of information processing we adopt; they also receive increasing attention in the study of memory.

Judgment

Central to the feelings-as-information approach is the assumption that people draw on their affective, cognitive, and bodily experiences as a source of information. In the case of moods and emotions, people may use their apparent affective response to a target as information in forming an evaluative judgment (e.g., Schwarz & Clore, 1983; Wyer & Carlston, 1979). This possibility is most obvious when the judgment refers, by definition, to one's affective reaction to the stimulus. For example, when asked how much we like a person, we may base the judgment on our feelings toward the person rather than on a review of his or her attributes. Also, when a judgment does not refer directly to our feelings but poses a task that is particularly complex and demanding, we may simplify the task by asking ourselves, "How do I feel about it?" (Schwarz & Clore, 1988). When the apparent affective response is indeed elicited by the target, it provides meaningful information that is relevant to the judgment at hand. Pham, Cohen, Pracejus, and Hughes (2001) observed that people can monitor and report the feelings elicited by moderately complex targets, like pictures or advertisements, very rapidly—in fact, more rapidly than their cognitive responses, consistent with Zajonc's (1980) affective primacy hypothesis.

Because we have only one window on our experience, it is difficult to distinguish *integral* feelings, elicited by the target, from *incidental* feelings that happen to be present at the time. Hence, we may mistake incidental feelings, like a preexisting mood, as part of our reaction to the target. This results in judgments that are congruent with the implications of our feelings, most notably in more positive evaluations under happy rather than sad moods. To disentangle the contributions of the perceiver's feelings from other information about the target, experimental tests of the feelings-as-information hypothesis usually rely on the induction of incidental affect. This gave rise to the erroneous conclusion that "affect can only serve as a heuristic cue due to mistaken inferences," suggesting that reliance on one's feelings "is an ineffective and dysfunctional strategy" (Forgas, 2001, p. 104). This assertion confuses the operational and theoretical level and is at odds with a long tradition of theorizing that emphasizes the signaling functions of affective responses (see Frijda, 1988; Zajonc, 1980). Feelings can serve as a basis of accurate as well as mistaken inferences, depending on the relationship between the feeling and the target. In fact, a growing body of work (see Damasio, 1994; Feldman-Barrett & Salovey, 2002) indicates the adaptive value of attending to one's feelings in judgment and decision making.

However, our feelings only influence judgment when they seem relevant to the task at hand. Hence, their influence is *eliminated* when we, correctly or incorrectly, as-

sume that they are indeed incidental, thus calling their informational value into question (e.g., Schwarz & Clore, 1983). Note that this proposition does *not* imply that mood effects on evaluative judgments require a conscious attribution of one's feelings to the target, in contrast to what some interpreters (e.g., Forgas, 1995a) suggested (for a discussion, see Schwarz, 2001). People usually consider their experiences, ranging from their feelings to the thoughts that come to mind, to be "about" whatever is in the focus of their attention. This observation has been termed the "aboutness" (Higgins, 1998) or "immediacy" principle (Clore et al., 2001); it is reminiscent of the Gestalt observation that stimuli presented in close temporal or spatial proximity are experienced as connected (Heider, 1958). Accordingly, reliance on our thoughts and feelings is the automatic default operation and does not require a conscious attribution, whereas discrediting thoughts and feelings does.

The differences between moods and emotions, noted earlier, suggest that people are more likely to be aware of the cause of their emotions than of the cause of their diffuse moods; this limits the likelihood that they misread their emotions as a response to an unrelated target. Moreover, emotions reflect specific appraisal patterns and hence provide more specific information than global moods, which mostly indicate valence. Finally, the same basic logic applies to bodily sensations as well as accessibility and fluency experiences. As our chapter indicates, people only draw on these experiences as a source of information when their informational value is not discredited.

Processing Style

Moods, emotions, and bodily sensations have also been found to influence people's processing strategies. From the feelings-as-information perspective, these experiences inform us about the benign or problematic nature of the current situation. This, in turn, influences which processing strategy we adopt, consistent with the assumption that human cognition is situated and adaptively tuned to meet situational requirements (see Schwarz, 2002).

Feelings that signal a problematic environment foster systematic, bottom-up processing with considerable attention to detail. As Wegner and Vallacher (1986) noted, this style of reasoning is adaptive when we encounter problems in the pursuit of our goals. We also adopt it when bodily avoidance feedback (e.g., Friedman & Förster, 2000) or emotions that entail a high uncertainty appraisal (e.g., Tiedens & Linton, 2001), correctly or incorrectly, provide an experiential "problem" signal. Conversely, feelings that signal a benign environment are typically associated with more heuristic processing and increased reliance on the top-down use of preexisting knowledge structures, unless otherwise required by the task at hand (e.g., Bless et al., 1996). As predicted by the feelings-as-information approach, these differences in processing style are eliminated when the informational value of the feeling is called into question through attribution manipulations (e.g., Sinclair, Mark, & Clore, 1994).

Empirically, influences of feelings on processing style have been observed across a wide range of tasks, including problem solving (for a review, see Schwarz & Skurnik, 2003), stereotyping (for a review, see Bless, Schwarz, & Kemmelmeier, 1996), and persuasion (for a review, see Schwarz, Bless, & Bohner, 1991). We address distinctions between several related conceptual models in our review of the evidence.

Memory

Experiential considerations played a key role in early treatments of memory processes but have lost popularity and were rediscovered only recently (Brewer, 1992). The accumulating work (for a review, see Kelley & Rhodes, 2002) documents a pervasive role of feelings of familiarity, which arise from processing fluency. For example, Jacoby and Dallas (1981) observed that participants could accurately recognize previously shown rare words but provided numerous false alarms in response to common words. Apparently, they misattributed the familiarity resulting from their frequent exposure to common words to the recency of exposure, erroneously concluding that the word was part of the preceding learning task. Such findings parallel the role of processing fluency in judgment. However, other memorial activities, like retrieving facts from long-term memory, do not involve phenomenal experiences (Brewer, 1992).

Whereas the role of cognitive experiences in memory is increasingly well understood, the influence of moods and emotions on memory has rarely been addressed from an experiential perspective. One approach to this issue (e.g., Bless, 1996) assumes that mood-congruent recall may arise from initial mood effects on evaluative judgment. When asked to recall events from our kindergarten days, for example, we may first wonder what they were like. When in a good mood, we may arrive at a more pleasant assessment, which may then serve as input into reconstructive memory processes (Ross, 1989), resulting in the "recall" of more pleasant events.

The Cognitive Component of Feelings: What Comes to Mind

An alternative approach traces the influence of feelings to the thoughts that accompany moods and emotions. In a pioneering series of studies, Isen, Shalker, Clark, and Karp (1978) observed pronounced mood effects on evaluative judgments. To account for them, they suggested a "cognitive loop" in the form of higher accessibility of mood-congruent information stored in memory. At the same time, Bower (1981; Bower, Monteiro, & Gilligan, 1978) conceptualized the operation of affective states in a general network model of human memory. He represented emotions as central nodes in an associative network, which are linked to related ideas, events of corresponding valence, autonomic activity, and muscular and expressive patterns. When new material is learned, it

is associated with the nodes that are active at the time of learning, including the respective emotion nodes. When an emotion node is stimulated later on, activation spreads along the pathways, increasing the activation of other, connected nodes; activation of a node above a certain threshold brings the represented material into consciousness.

Memory

Bower's (1981) model and related conceptualizations (e.g., Isen et al., 1978; Spies & Hesse, 1986; Wyer & Srull, 1989) generate two key predictions. A *state-dependent learning and recall* hypothesis holds that material learned in one affective or bodily state is more likely to be recalled when we are in the same rather than another state. Whereas this prediction pertains to matching states at learning and recall, a *mood-congruency hypothesis* pertains to matching valences of the affective state and the to-be-recalled material. It holds that positively (negatively) valenced material is more likely to be recalled in positive (negative) moods. Although these hypotheses are conceptually distinct, they are often difficult to distinguish empirically (Morris, 1989). In fact, mood-congruent recall has been most reliably observed in the domain of autobiographical memory, with happy events being more likely to be recalled under happy than sad moods (see Blaney, 1986, for a review). However, happy events are likely to have put one into a happy mood at the time they occurred. Accordingly, mood congruency in autobiographical recall could be due to either state dependency or mood congruency.

Critics of Bower's (1981) model questioned the plausibility of the assumed links between positive (negative) moods and *all* positive (negative) material stored in memory; this structure should reduce the activation of any given node as a function of the overall number of nodes activated. Moreover, an extensive review of relevant experiments (Wyer, Clore, & Isbell, 1999) concluded that reported effects of mood on the recall of valence-congruent semantic concepts in memory may be due to the inadvertent activation of mood-relevant concepts as part of the mood-induction procedure, rather than to mood per se.

Judgment

If some aspect of mood does affect the recall of valenced material, it should also affect tasks to which the material may be relevant. Accordingly, a *mood-congruent encoding* hypothesis suggests that ambiguous material would be encoded in terms of mood-congruent concepts. Moreover, associations that come to mind subsequently (regardless of the ambiguity of the material) may also be mood congruent, resulting in *mood-congruent elaboration*. By the same token, mood-congruent recall of infomation about the target is assumed to result in *mood-congruent judgments.* Finally, any impact of mood-congruent recall and elaboration is predicted to be more pronounced the more the judgment involves substantive thought (Forgas,

1995a), that is, under conditions of high processing motivation and low time pressure.

Processing Style

Mood-congruent recall assumptions can also be used to predict affective influences on styles of information processing. If a given affective state brings a large amount of congruent information into consciousness, it may limit the *cognitive resources* required for working on other tasks. However, it is unclear which mood is most likely to constrain resources. On the one hand, negative affective states are associated with intruding thoughts and ruminations (e.g., Martin & Tesser, 1989) and people in an induced or chronic negative mood have difficulty suppressing mood-congruent material when instructed to do so (e.g., Wenzlaff, Wegner, & Roper, 1988). Hence, Ellis and Ashbrook (1988) suggested in their resource allocation model that *negative* affective states interfere with information processing. On the other hand, Isen (1987) hypothesized that positive material in memory "is more extensive and at the same time better integrated, so that positive affect is able to cue a wide range of thoughts" (p. 217). Accordingly, Mackie and Worth (1989) proposed that *positive* affective states can limit attentional resources due to intruding positive thoughts. Neither proposal can account for the bulk of the available findings, as reviewed below.

Finally, we note that models focusing on *what* comes to mind do not provide an easy way to conceptualize the role of cognitive experiences. Although they can account for affective influences on ease of recall and fluency of processing, the judgment effects of experienced accessibility and fluency cannot be conceptualized without making assumptions extraneous to associative network models.

The Somatic Component of Feelings: A Hard Interface?

The somatic component of feelings has been addressed in two different ways. As Zajonc and Markus (1984) noted, most theories postulate some form of experiential mediation between somatic processes and judgments or other outcomes (e.g., Izard, 1977; Leventhal, 1982; Schachter & Singer, 1962; Tomkins, 1962). Hence, we treat such theories in the context of experiential approaches. As an alternative, Zajonc and Markus suggested that the impact of somatic processes may be hardwired instead of experientially mediated. For example, Zajonc and collaborators emphasized possible representational functions of the motor system (e.g., Adelman & Zajonc, 1989) and suggested a crucial role for the vascular system of the head in emotion regulation (Zajonc, Murphy, & Inglehart, 1989). Much of this work focuses on somatic processes as determinants of emotion and little is known about their role in mediating the consequences of emotions. Reflecting the paucity of research that bears on this mediational issue, and the limits of our expertise, we do not address this perspective in this chap-

ter, which focuses on feelings (i.e., subjective experiences).

FEELINGS AND JUDGMENT

Next, we review research on the impact of different feelings on social judgment and highlight similarities in the informative functions of affective, cognitive, and bodily experiences. Where applicable, we contrast predictions derived from the general approaches discussed previously.

Moods

All models predict more positive judgments under happy than sad moods. This prediction is well supported, with exceptions addressed below. From a feelings-as-information perspective (Schwarz & Clore, 1983, 1988; Wyer & Carlston, 1979), mood-congruent judgments arise because people misread incidental moods as part of their apparent affective reaction to the target; from a mood-congruent recall perspective (Bower, 1981), they arise because moods bring different associations to mind. These perspectives lead to different predictions about the conditions under which mood-congruent judgment should be observed.

Perceived Informational Value

If feelings serve as a source of information, their impact should depend on their perceived informational value. We should discount our feelings as a source of information when there is reason to assume that they may not reflect our reaction to the target but should see them as particularly informative when our apparent reaction to the target contradicts the plausible impact of other influences. Such discounting and augmentation effects (Kelley, 1972) cannot be derived from the assumption that moods or emotions affect judgment through the selective recall of information from memory (e.g., Bower, 1981) or by hardwired processes (e.g., Zajonc & Markus, 1984). These assumptions predict main effects of affective states, whereas the feelings-as-information hypothesis predicts an interaction between affective states and the perception of their likely causes.

Supporting this interaction prediction, Schwarz and Clore (1983) observed that the influence of mood on judgments of life satisfaction was eliminated when participants attributed their current feelings either correctly or incorrectly to a transient source. For example, participants reported higher life satisfaction and a more elated current mood in telephone interviews when called on sunny rather than rainy days. This difference was eliminated when the interviewer mentioned the weather as part of a private aside, thus directing participants' attention to this source of their feelings. Similarly, recalling a sad life event did not influence participants' judgments of life satisfaction when they could misattribute the resulting sad feelings to the alleged impact of the experi-

mental room. In addition, current mood, as assessed at the end of each experiment, was more strongly correlated with judgments of life satisfaction when participants' attention was *not* directed to a transient source of their feelings than when it was. Conceptual replications of these attributional effects have been reported by Gorn, Goldberg, and Basu (1993), Keltner, Locke, and Audrain (1993), Savitsky, Medvec, Charlton, and Gilovich (1998), Schwarz, Servay, and Kumpf (1985), and Siemer and Reisenzein (1998), among others.

Further highlighting that people assess the informational value of their feelings, Avnet and Pham (2004) manipulated participants' perception of the extent to which they can trust their feelings. As expected, induced moods influenced evaluative judgments more when participants were primed to trust rather than distrust their feelings. Finally, augmentation and discounting effects are more reliably obtained under the systematic processing strategy fostered by negative moods (Schwarz & Clore, 1983), which prompts more elaborate causal reasoning (Bohner, Bless, Schwarz, & Strack, 1988).

Perceived Relevance

Even when we perceive our feelings as informative, the information they provide may seem more germane to some judgments than to others. For example, Pham (1998) observed more pronounced mood effects when participants evaluated activities with experiential rather than instrumental goals in mind (see also Adaval, 2001; Yeung & Wyer, 2004). He concluded (Pham, 2004) that we consider our feelings more relevant "for assessing the potential fulfillment of experiential goals (e.g., 'Would I have fun at this movie?') than for assessing the potential fulfillment of instrumental goals (e.g., 'Would seeing this movie help me for the project?')" (p. 366). Similarly, we consider our feelings more relevant when judging our own preferences than when judging the preferences of others. Accordingly, Raghunathan and Pham (1999) found stronger mood effects when individuals made decisions for themselves rather than for others.

Finally, people are less likely to rely on their moods when they have high expertise in the domain of judgment (e.g., Ottati & Isbell, 1996; Sedikides, 1995). High expertise presumably facilitates the assessment of the relevance of one's feelings and renders other, relatively more diagnostic inputs easily accessible. Conversely, being under time pressure increases reliance on one's feelings (Siemer & Reisenzein, 1998), presumably because it interferes with relevance assessments and the search for alternative inputs.

In sum, the use of feelings as information follows the same principles as the use of other information (Feldman & Lynch, 1988): We only rely on them when their informational value is not discredited and when they seem relevant to the judgment at hand. Moreover, their impact decreases when other, more relevant, inputs are accessible.

Feeling versus Content

According to mood-congruent recall models, the impact of moods should increase when the mood induction is thematically related to the target judgment. Suppose, for example, that a depressed mood is induced by thoughts about a serious illness. If so, the valence of the mood *and* the content of the mood induction should facilitate the recall of illness-related material from memory (e.g., Bower, 1981). Hence, illness-related judgments should be more likely to show mood effects than judgments pertaining to other content domains. Empirically, this is not the case (e.g., Johnson & Tversky, 1983; Mayer, Gaschke, Braverman, & Evans, 1992).

For example, Johnson and Tversky (1983) observed that reading descriptions of negative events, which presumably induced a depressed and slightly anxious mood, increased judgments of risk. This effect was independent of the object of judgment or the content by which the mood was induced. Reading about cancer, for example, affected judgments of the risk of cancer but had equally strong effects on judgments of the risk of accidents and divorce. Such generalized effects, undiminished over dissimilar content domains, are incompatible with models of mood-congruent recall. However, they are consistent with the feelings-as-information hypothesis. From this perspective, participants inferred higher risk from their depressed and anxious feelings, thus simplifying an otherwise difficult task (for an extended discussion of the role of feelings in judgments of risk, see Loewenstein, Weber, Hsee, & Welch, 2001).

In addition, other researchers observed mood effects on evaluative judgments in the absence of any evidence for mood effects on the recall of relevant information from memory (e.g., Fiedler, Pampe, & Scherf, 1986). More fundamentally, a general review of the mood and memory literature (Wyer, et al., 1999) suggests that most instances of mood-congruent recall in the literature are ambiguous as to whether they result from mood per se or from the inadvertent activation of mood-relevant concepts. Most mood-induction procedures involve the activation of positive and negative concepts as well as of positive and negative feelings, raising the possibility that mood-congruent recall may often be concept-congruent recall.

Mood-Incongruent Judgments

When we ask ourselves, "How do I feel about it?," our happy or sad moods convey that we feel good or bad about whatever the "it" is. In most cases, this results in mood-congruent judgments, as in the foregoing examples. Nevertheless, mood-incongruent judgments can be observed under specific conditions.

First, suppose you are asked to read a sad story and to evaluate how successful it is at making you feel sad. If you find yourself happy after reading the story, you are likely to conclude that it was a poor sad story—a condition under which positive feelings result in a negative judgment. Empirically this is the case, as Martin, Abend, Sedikides, and Green (1997) demonstrated. In our read-ing, such findings reflect changes in the criterion of judgment rather than changes in the information conveyed by the mood.

Second, mood-incongruent judgments can result from the logic of discounting effects themselves (e.g., Isbell & Wyer, 1999; Ottati & Isbell, 1996). Suppose that you are evaluating a job candidate but are aware that you have been in a miserable mood all day due to an earlier event. How much of your negative affect reflects your reaction to the candidate and how much is due to the earlier event? If you fully attribute your bad feelings to the earlier event, you may arrive at an unduly positive assessment of the candidate. Empirically, attempts to correct for a perceived influence often result in overcorrections of this type (Strack & Hannover, 1996; Wilson & Brekke, 1994), unless the person can draw on other accessible inputs as an alternative route to judgment. Accordingly, (mis)attribution manipulations may eliminate mood effects when diagnostic alternative inputs are available but may foster overcorrection, and hence mood-incongruent judgments, when they are not.

Finally, mood-inducing events can elicit contrast effects in the evaluation of closely related targets by serving as extreme standards of comparison. For example, Schwarz, Strack, Kommer, and Wagner (1987) induced happy or sad moods by conducting an experiment in a very pleasant or unpleasant room. Consistent with the induced moods, their student participants reported higher life satisfaction in the pleasant than unpleasant room. When asked to report their housing satisfaction, however, this pattern reversed, presumably because even modest dorm rooms seemed luxurious compared to the salient standard introduced by the unpleasant room. Theoretically, such comparison-based contrast effects should be limited to judgments for which the mood-inducing event can serve as a highly relevant standard.

Specific Emotions

The general logic outlined for moods also applies to the use of specific emotions as a source of information. For example, Schwarz and colleagues (1985) observed that the impact of a fear-arousing communication on participants' attitudes was eliminated when participants attributed their subjective experience to the arousing side effects of a pill but was enhanced when they assumed the pill would have tranquilizing effects. However, the informational value of specific emotions differs from the informational value of global moods in two important ways.

First, emotions are specific reactions to specific events, whereas moods are of a diffuse and unfocused nature (Morris, 1989). Because of their unfocused nature, moods can be misread as a response to wide range of different targets—but once we attribute the mood to specific cause, its impact on unrelated judgments vanishes (Schwarz & Clore, 1983). In contrast, the source of a specific emotion is more likely to be in the focus of attention from the onset, thus limiting the emotion's informational value for unrelated judgments. Accordingly, Keltner, Locke, and colleagues (1993) observed that hav-

ing participants label their current feelings with specific emotion terms was as efficient in eliminating mood effects on subsequent judgments as a standard misattribution manipulation. Their findings are also an important methodological warning: Using specific emotion terms as manipulation checks invites causal attributions to determine the specific emotion, which can eliminate the expected effect.

Second, emotions reflect an underlying appraisal (e.g., Ellsworth & Scherer, 2003; Ortony et al., 1988) and the experience of a specific emotion implies that a specific set of appraisal criteria has been met. Anger, for example, informs us that somebody did us wrong and hence provides more specific information than a diffuse negative mood. If so, different emotions of the same valence should have differential effects, which can be predicted on the basis of the underlying appraisals (e.g., Lerner & Keltner, 2000). A growing body of literature supports this reasoning (for a review, see Han, Lerner, & Keltner, in press).

In an early study, Gallagher and Clore (1985) showed that feelings of fear affected judgments of risk but not of blame, whereas feelings of anger affected judgments of blame but not of risk. Similarly, Lerner, Gonzalez, Small, and Fischhoff (2003) observed in a national survey during the immediate aftermath of the terrorist attacks of September 11, 2001, that inducing participants to focus on the experienced fear increased risk estimates and plans for precautionary behavior, whereas focusing on the experienced anger did the reverse. Studying attributions of responsibility, Keltner, Ellsworth, and colleagues (1993) observed that angry participants assigned more responsibility to human agents than to impersonal circumstances, whereas sad participants assigned more responsibility to impersonal circumstances than to human agents, again consistent with the underlying appraisal patterns. Using a minimal group paradigm, DeSteno, Dasgupta, Bartlett, and Cajdric (2004) found that anger elicited more negative automatic evaluations of the outgroup, whereas sadness did not affect outgroup evaluations relative to a neutral mood control.

Going beyond judgment effects, several studies documented effects of emotions on goal-oriented behavior. Raghunathan and Pham (1999) suggested that sadness, a common response to the loss or absence of a reward, may prompt the goal of reward acquisition; in contrast, anxiety, a response to threats, may prompt a goal of uncertainty reduction. To test these predictions, they provided sad or anxious participants with a choice that required a trade-off between risk and rewards. As expected, sad individuals pursued reward acquisition and preferred high reward options, even though they came at the cost of high risk. Conversely, anxious individuals pursued uncertainty reduction and preferred low-risk options, even though they came at the cost of low reward. Similarly, Lerner, Small, and Loewenstein (2004) showed that induced disgust and sadness can affect economic decisions. Compared to a neutral emotion condition, disgusted participants sold goods they owned at a lower price and offered less money to acquire new goods, presumably because disgust prompts "expel" and "intake avoidance"

goals. Sad participants, on the other hand, offered more money to acquire goods, consistent with Raghunathan and Pham's (1999) observation that sadness motivates reward acquisition; however, they also sold what they had at a lower price, in contrast to what this account would predict. Lerner and colleagues attribute both findings to participants' desire to change their sad circumstances, which would motivate pricing decisions that facilitate the sale of what one owns and the acquisition of what one wants.

In combination, these findings indicate that specific emotions influence judgments in ways that are consistent with the underlying appraisals. Moreover, emotions give rise to specific goals, which influence subsequent behavior. Attributing the emotion to an unrelated event would presumably eliminate these effects (e.g., Schwarz et al., 1985).

Bodily Sensations

The research on mood and emotions indicates that incidental feelings influence judgment only when the nature of the feelings, the salience of their causes, or other aspects of the situation allow them to be experienced as reactions to the target of judgment. The available research suggests that this conclusion also applies to bodily sensations.

Arousal States

Exploring the impact of heightened excitation levels, Zillman (1978) had participants engage in various forms of exercise. Shortly after the exercise, no impact of increased excitation level was observed, presumably because participants were still aware of its source. After some delay, however, subsequent judgments were affected by the residual arousal. Apparently, participants misinterpreted their arousal as a reaction to the target, once the temporal distance of the exercise rendered this alternative source less accessible and plausible. Similarly, Zanna and Cooper (1976) observed in their classic misattribution experiments that cognitive dissonance effects were eliminated when participants could attribute the resulting arousal state to some other source.

These lines of research indicate that individuals draw on their perceived arousal state as a source of information, unless its informational value is called into question, as we have seen for other feelings. Moreover, apparent "excitation" effects can be obtained in the absence of any actual arousal, based on false feedback (e.g., Valins, 1974). This is incompatible with the assumption that some actual arousal needs to be present to be "transferred" (Zillman, 1978) and highlights the informational value of *perceived* arousal as the crucial ingredient.

Facial Feedback

Darwin (1872/1965) noted that "most of our emotions are so closely connected with their expression that they hardly exist if the body remains passive" (p. 257). Taking a more extreme view, James (1890) maintained that emotions were, in fact, nothing more the awareness of

our expressions: "We feel sorry because we cry, angry because we strike, and afraid because we tremble" (p. 243). Experimental research provided some support for the assumption that emotional expressions may elicit distinctive emotional experiences. For example, Ekman, Levenson, and Friesen (1983) found that posing different facial expressions of emotion triggered different patterns of autonomic activity (e.g., changes in heart rate, skin temperature, and skin conductance). Hence, the impact of facial expressions on judgment may involve autonomic activity as well as proprioceptive feedback.

For example, Keltner, Ellsworth, and colleagues (1993) induced participants to take on a sad or angry facial expression, without labeling the expression in emotion terms. These expressions affected attributions of responsibility in the same way previously discussed for recall-induced sadness and anger. In fact, the influence of facial expressions alone was larger than the influence of facial expressions combined with an emotional recall task, perhaps because the influence of the expression itself was less transparent. Using a particularly subtle manipulation, Strack and colleagues (1988) had participants rate the funniness of cartoons while holding a pen in their mouths in such a manner that a smile was either facilitated or inhibited. Holding a pen between one's teeth requires that one contract the same muscles that are used when one smiles, while holding a pen between one's lips results in pursing the lips, rendering a smile impossible. As expected, participants reported greater amusement at the cartoons when the muscle contractions resembled rather than inhibited a smile. Stepper and Strack (1993) further showed that such processes are not limited to facial feedback. Their participants reported higher pride when they received positive performance feedback in an upright posture rather than a slumped posture.

As observed for moods and emotions, the impact of emotional expressions can be discounted and augmented by suitable attributional manipulations (Olson & Roese, 1995). Moreover, bodily experiences are perceived as a response to whatever is in the focus of one's attention, rendering their influence more context dependent than has often been assumed. For example, Tamir, Robinson, Clore, Martin, and Whitaker (2004) observed that brow (vs. cheek) tension reduced preferences in an easy judgment context but increased preferences in a difficult context. Similarly, head shaking (vs. nodding) either increased or decreased prosocial affect, depending on the context in which the judged character was presented. Finally, a subliminal smile (vs. frown) led to higher self-ratings of performance when paired with one's own actions but to lower self-ratings of performance when paired with a competitor's actions.

Other research documented effects of bodily sensations beyond the affective domain. For example, contracting the corrugator muscle elicits a feeling of effort that can affect judgment in ways that parallel the effect of difficulty of recall or thought generation (e.g., Sanna, Schwarz, & Small, 2002; Stepper & Strack, 1993). Similarly, arm flexion and arm extension can provide approach and avoidance feedback that influences processing style in ways that parallel the influence of happy and sad moods (e.g., Friedman & Förster, 2000). We address these findings in the respective sections that follow.

Cognitive Experiences

The same principles hold for metacognitive experiences, which only influence individuals' judgments if their informational value is not called into question.

Accessibility Experiences

According to most models of judgment, we should evaluate an object more favorably when we bring many rather than few positive attributes to mind; similarly, we should consider an event more likely when we generate many rather than few reasons for its occurrence. Empirically, this is often *not* the case (e.g., Sanna, Schwarz, & Small, 2002; Sanna, Schwarz, & Stocker, 2002; Wänke, Bohner, & Jurkowitsch, 1997). Recalling many attributes or generating many reasons is more difficult than recalling or generating only a few, and these metacognitive accessibility experiences are informative in their own right. What people conclude from them is more malleable than the conclusions drawn from moods and emotions and depends on which of many naive theories of mental functioning they apply (Schwarz, 2004).

THE ACCESSIBILITY–FREQUENCY LINK

One naive theory links recall experiences to characteristics of the external world and holds, "The more exemplars exist, the easier it is to bring some to mind." This correct belief is at the heart of Tversky and Kahneman's (1973) availability heuristic and people infer higher frequency and probability when examples are easy rather than difficult to bring to mind. Because frequent exemplars are also more typical for their category, ease of recall further suggests high typicality. Accordingly, people infer that they use their bicycles more often after recalling few rather than many instances (Aarts & Dijksterhuis, 1999); rate themselves as more assertive after recalling few rather than many of their own assertive behaviors (Schwarz, Bless, Strack, et al., 1991); and hold an attitude with more confidence after generating few rather than many supporting arguments (Haddock, Rothman, Reber, & Schwarz, 1999).

When people apply this naive theory, their inferences are consistent with the implications of *what* comes to mind when recall or thought generation is experienced as easy but opposite to these implications when it is experienced as difficult. These effects cannot be traced to differences in the quality of the recalled examples but are eliminated when the subjective experience is misattributed to an external influence. In the latter case, participants draw on accessible content, reversing the otherwise observed pattern (e.g., Haddock et al., 1999; Sanna, Schwarz, & Small, 2002; Schwarz, Bless, Strack, et al., 1991). Moreover, yoked participants, who merely read the thoughts generated by another and are hence deprived of the generation experience, are more influenced when their partner lists many rather than few argu-

ments, in contrast to the person who lists them (e.g., Wänke, Bless, & Biller, 1996). Finally, the same effect can be observed when all participants list the same number of thoughts and their subjective experience of difficulty is manipulated through facial feedback in the form of corrugator contraction, an expression associated with mental effort (e.g., Sanna, Schwarz, & Small, 2002; Stepper & Strack, 1993). Thus, merely furrowing one's brow can be sufficient to arrive at conclusions that are opposite to the content of one's thoughts.

Experienced difficulty of thought generation can thwart the success of popular debiasing strategies, which encourage people to guard against overconfidence, hindsight bias, and similar fallacies by thinking about counterfactual alternatives. Such strategies only work when generating counterfactuals is experienced as easy but backfire when it is experienced as difficult (Sanna & Schwarz, 2004; Schwarz, Sanna, Skurnik, & Yoon, 2007).

OTHER NAIVE THEORIES

While the accessibility–frequency link has received most attention, people hold a variety of other naive theories about memory and thought generation, rendering the inferences from accessibility experiences highly malleable (for a review, see Schwarz, 2004). For example, they correctly assume that details of recent events are easier to recall than details of distant events, and details of important events easier than details of unimportant ones. Which of these theories they apply depends on the task posed. Xu and Schwarz (2005) had participants recall details of the Oklahoma City bombing. When first asked to date the event, participants inferred that it was more recent after recalling 2 rather than 10 details; when first asked how important the event was to them at the time, they inferred higher importance after recalling 2 rather than 10 details. More important, application of a given theory entails an attribution of the experience to a specific cause (here, recency or importance), which can change the implications of the experience for subsequent judgments (Schwarz, 2004). Hence, participants who initially attributed the difficulty of recalling many details to the event's temporal distance subsequently reported that the event was quite important to them— presumably because they could still recall details even though the event had apparently happened long ago. Conversely, participants who initially attributed difficulty of recall to low personal importance subsequently dated the event as closer in time—presumably because they could still recall details despite the event's low personal importance.

PROCESSING MOTIVATION

Finally, people are more likely to rely on their accessibility experiences under conditions that commonly foster heuristic processing but to turn to accessible content under conditions that commonly foster systematic processing. Rothman and Schwarz (1998) asked men to recall few or many behaviors that increase or decrease their risk of heart disease. Men without a family history of heart disease relied on their accessibility experiences and inferred *higher* risk after recalling few risk-increasing or many risk-decreasing behaviors. In contrast, men with a family history relied on recalled content and inferred *lower* risk under these conditions. Apparently, the personal relevance of the task, indicated by their family history, influenced the processing strategy used (see also Grayson & Schwarz, 1999). Similarly, Ruder and Bless (2003) observed that being in a good mood, a condition that fosters heuristic processing as reviewed below, increased reliance on accessibility experiences. Conversely, being in a sad mood, a condition that fosters systematic processing, increased reliance on recalled content.

In combination, these findings challenge the widely shared assumption that we can predict people's judgments by knowing *what* comes to mind. Unless we take the person's metacognitive experiences, relevant naive theories, and processing motivation into account, our predictions will often be erroneous (Schwarz, 2004).

Processing Fluency

Numerous variables can influence the fluency with which new information can be processed, ranging from visual characteristics of the presentation (like figure–ground contrast or print font) to the semantic relatedness of the material and the frequency and recency of previous exposure. Because these variables result in similar phenomenological experiences of fluent processing, the meaning of the experience is open to interpretation. Which interpretation people choose and which inferences they draw again depend on the naive theory they bring to bear. Applicable theories are recruited by the task and application of one theory usually renders the experience uninformative for inferences that require a different theory (Schwarz, 2004).

Some naive theories pertain to presentation conditions; people assume that material is easier to process when shown for long rather than short durations, with high rather than low clarity, and so on. Other theories pertain to one's state of knowledge; people assume, for example, that familiar material is easier to process than unfamiliar material. When fluency deriving from one's state of knowledge is brought to bear on judgments of presentation characteristics, it results in *illusions of perception*. Thus, people infer that a stimulus was presented for a longer duration, or with higher clarity, when it is easy to process due to earlier exposures (e.g., Whittlesea, Jacoby, & Girard, 1990; Witherspoon & Allan, 1985). Conversely, when fluency deriving from favorable presentation conditions is brought to bear on judgments of one's knowledge, it results in *illusions of memory* and people erroneously infer that the stimulus is familiar (e.g., Whittlesea et al., 1990), resulting in false recognition judgments.

Even when processing fluency is due to previous exposure, and correctly attributed to this source, it may result in erroneous judgments when perceivers misidentify the specific instance of exposure. For example, learning the names of nonfamous individuals in an experimental session may later result in erroneous judgments of fame when one of the names seems familiar and one cannot re-

call the context in which it was initially encountered (e.g., Jacoby, Kelley, Brown, & Jasechko, 1989). As in the case of accessibility experiences, bodily sensations that convey mental effort can mirror low fluency. Strack and Neumann (2000) observed in a conceptual replication of Jacoby and colleagues' (1989) fame study that contracting the corrugator muscle can protect against illusions of fame, presumably by conveying low fluency. Finally, the impact of fluency experiences is eliminated when people (mis)attribute fluency to an unrelated source (for a review, see Kelley & Rhodes, 2002), as observed for other feelings.

Several consequences of fluency are of particular interest to social psychologists. First, fluency affects *judgments of truth*. Presumably, the sense of familiarity that arises from high fluency suggests that one has heard the statement before, which may serve as a consensus cue—if many people believe it, there is probably something to it (Weaver, Garcia, Schwarz, & Miller, in press). This is most apparent when fluency results from repeated exposure and numerous studies obtained robust "illusions of truth" under these conditions (e.g., Begg, Anas, & Farinacci, 1992; Hasher, Goldstein, & Toppino, 1977). After some delay, illusions of truth can even emerge when the statement is explicitly marked as "false" (e.g., Skurnik, Yoon, Park, & Schwarz, 2005). This poses major problems for education campaigns and rumor control, as Allport and Lepkin (1945) noted decades ago: Corrections of false information often entail a reiteration of the false statement, thus increasing its fluency and later acceptance. More surprisingly, simply presenting statements with good figure–ground contrast (Reber & Schwarz, 1999), or in a rhyming form (McGlone & Tofighbakhsh, 2000), is sufficient to increase their acceptance as true. This suggests that any variable that increases fluency may also increase perceived truth.

Second, fluency affects judgments of *liking*, *preference*, and *beauty*. As Zajonc (1968) demonstrated, repeated exposure to an initially neutral stimulus, without any reinforcement, leads to gradual increases in liking (for a review, see Bornstein, 1989). Several authors suggested that this mere exposure effect may be due to increased fluency (e.g., Seamon, Brody, & Kauff, 1983). Supporting this hypothesis, a growing body of findings indicates that *any* variable that facilitates fluent processing increases liking, even under conditions of a single exposure. For example, people like the same stimulus more when it is preceded by a visual (Reber, Winkielman, & Schwarz, 1998) or semantic (Winkielman et al., 2003) prime that facilitates fluent processing and less when it is preceded by primes that impede fluent processing. In fact, the influence of many variables long known to affect liking and aesthetic preference, from figure–ground contrast to symmetry and prototypicality, can be can be traced to increased processing fluency (Reber, Schwarz, & Winkielman, 2004).

The available evidence suggests that fluency itself is hedonically marked and elicits a positive affective response that can be captured with psychophysiological measures (Winkielman & Cacioppo, 2001). This affective response presumably mediates the effect of fluency

on preference judgments. Supporting this assumption, Winkielman and Fazendeiro (reported in Winkielman et al., 2003) observed that the influence of fluency on liking was eliminated when participants misattributed their positive affect to music played in the background. What is less clear is *why* processing fluency is experienced as affectively positive. Relevant proposals range from the adaptive value of a preference for familiar stimuli (Freitas, Azizan, Travers, & Berry, 2005; Zajonc, 1968) to the adaptive value of fast stimulus identification (Winkielman, Schwarz, & Nowak, 2002).

The parallel effects of processing fluency on judgments of truth and aesthetic preference also shed new light on Keats's famous assertion that "beauty is truth, truth is beauty"—both judgments are based, in part, on the same experiential information. Moreover, the relationship between familiarity and affective response is bidirectional. Stimuli that evoke positive affect also seem more familiar, even when processing fluency is controlled for (Monin, 2003), as do novel arguments when people are in elated moods (Garcia-Marques & Mackie, 2001). Once again, the single window we have on our subjective experiences makes it difficult to distinguish between commonly related experiences and facilitates misattributions.

Priming as a Misattribution Process

The same attribution logic holds for our thoughts (Clore, 1992; Clore & Colcombe, 2003). We usually assume that the thoughts that come to mind are "about" whatever we are thinking about (Higgins, 1998)—or why else would they come to mind now? When we are aware that our thoughts may have been prompted by an unrelated influence, we discount them as a source of information. Hence, priming procedures work best when they are subtle and embedded in other tasks (e.g., Higgins, Rholes, & Jones, 1977), allowing us to misread the primed thoughts as a response to the target. But priming manipulations backfire when they are blatant (e.g., Martin, 1986) or participants' attention is drawn to them (e.g., Strack, Schwarz, Bless, Kübler, & Wänke, 1993), making people aware that their thoughts may not be "about" the target. In these cases, people attempt to correct for the perceived influence, often resulting in overcorrection (Strack & Hannover, 1996; Wilson & Brekke, 1994). This experiential perspective on the influence of thought content blurs the lines between the experiential and cognitive accounts described earlier. It suggests, for example, that even if judgment effects were to involve mood-congruent recall from memory, they might be attenuated or eliminated if people became aware that these thoughts had come to mind only because the people were in a good or bad mood.

Summary

In sum, people assume that their thoughts and feelings are "about" what is in the focus of their attention. They draw on their apparent responses to the target as relevant information, unless they are aware that their experi-

ences may be due to another source. In the latter case, they may attempt to correct for their likely influence; this often results in theory-driven overcorrection, unless alternative diagnostic inputs are available. Reliance on one's affective feelings is particularly likely when the judgment is affective in nature (e.g., preference or well-being), which often renders one's feelings the most diagnostic source of information available; when little other information is accessible; when the judgment is overly complex and cumbersome to make on the basis of a piecemeal information processing strategy; or when time constraints or competing task demands limit the attention that may be devoted to evaluating the informational value of one's feelings or to searching for alternative inputs. The same logic applies to specific emotions, bodily sensations, and metacognitive experiences, with the qualifications noted previously. Hence, forming judgments on the basis of one's feelings may sometimes be thought of as a simplifying heuristic strategy. Note, however, that this strategy entails assessments of the informational value of one's feelings and of their relevance to the task at hand, as well as the use of naive theories as inference rules.

The feelings-as-information approach provides a parsimonious and unifying framework for conceptualizing the influence of a wide variety of phenomenological experiences; it is the only available conceptualization for the influence of cognitive experiences. Moreover, its predictions are consistent with the bulk of the evidence. Obviously, this supportive evidence, by itself, does not rule out other pathways of influence. This issue is particularly contentious for the influence of moods, which other researchers are inclined to attribute primarily to mood-congruent recall (for extensive reviews, see Forgas, 1995a, 2001, 2003). Mood-congruent recall could, in principle, provide a plausible pathway for mood effects on judgment even under conditions in which the feeling itself is discredited as a source of information and people engage in an effortful, piece-meal judgment strategy. However, in the absence of (mis)attribution manipulations that discredit the informational value of participants' current feelings, it is difficult to determine which process drives a particular instance of mood effects on evaluative judgment.

FEELINGS AND STRATEGIES OF INFORMATION PROCESSING

Numerous findings indicate that feelings may influence individuals' spontaneous adoption of heuristic or systematic strategies of information processing. While the evidence is uncontroversial, there is less agreement on the underlying process. Moreover, most of the conceptualizations focus on the influence of happy or sad moods. One approach attributes affect-induced differences in processing strategy to differences in attentional resources, although some researchers assume that negative moods limit resources (e.g., Ellis & Ashbrook, 1988), whereas others assume that positive moods do so (e.g., Mackie & Worth, 1989). A second approach attributes

differences in processing style to the informational functions of moods. Variants of this approach assume that our feelings inform us about the state of the environment (Schwarz, 1990; Weary, Marsh, Gleicher, & Edwards, 1993), the contingency of hedonically relevant rewards (Wegener & Petty, 1994), or the progress made in goal pursuit (Clore et al., 2001), or that they serve as input into specific performance decisions (Martin, Ward, Achee, & Wyer, 1993). A third approach focuses on mood maintenance and repair. It assumes that we protect our pleasant affect by avoiding excessive mental effort when we feel happy (mood maintenance) but engage in effortful thought to distract ourselves and to improve our mood when we feel sad (mood repair; e.g., Clark & Isen, 1982; Erber & Erber, 2001). These different accounts gave rise to a lively debate (see the contributions in Martin & Clore, 2001). However, their exclusive focus on the influence of moods captures only part of the accumulating evidence. As reviewed next, proprioceptive approach or avoidance feedback (Friedman & Förster, 2000, 2002) is functionally equivalent to being in a happy or sad mood, as are environmental cues, like smiling or frowning faces (Ottati, Terkildsen, & Hubbard, 1997) and even the color of the paper on which a task is presented (Soldat, Sinclair, & Mark, 1997). We therefore attempt to provide an integrative account that captures these commonalities while maintaining core assumptions of previous conceptualizations (presented in Martin & Clore, 2001).

Situated Cognition: Cognitive Processes Are Tuned to Meet Situational Requirements

"My thinking is first and last and always for the sake of my doing," noted William James (1890, p. 333) more than a century ago. To serve our doing in adaptive ways, our cognitive processes are responsive to the environment in which we pursue our goals, as a growing body of research into situated cognition indicates (see Smith & Semin, 2004). We propose that the adaptively tuned nature of human cognition is at the heart of the observed shifts in processing strategy (Schwarz, 2002). If so, we should observe that external and internal cues that signal a benign and unproblematic environment are functionally equivalent, as are external and internal cues that signal a problematic environment. These signals have cognitive and motivational consequences, which are highly adaptive under most circumstances.

When facing a problematic situation, we are usually motivated to do something about it. Any attempt to change the situation requires a careful assessment of its features, an analysis of their causal links, detailed explorations of possible mechanisms of change, and anticipation of the potential outcomes of any action that might be initiated. Consistent with these conjectures, negative affective states are associated with a narrowed focus of attention (e.g., Broadbent, 1971; Easterbrook, 1959) and a higher level of spontaneous causal reasoning (e.g., Bohner et al., 1988), paralleling the observation that failure to obtain a desired outcome shifts attention to a lower level of abstraction (e.g., Wegner & Vallacher,

1986). These influences foster vigilance and bottom-up, data-driven processing (Bless, 1997; Schwarz, 1990), in particular when the negative feeling entails a high uncertainty appraisal, as is the case for sadness (Tiedens & Linton, 2001). Moreover, it may seem unwise to rely on one's usual routines and preexisting general knowledge structures under these conditions, thus discouraging top-down strategies. Finally, we may be unlikely to take risks in a situation that is already marked problematic and may therefore avoid simple heuristics and uncertain solutions.

Conversely, when we face a benign situation that poses no particular problem, we may see little need to engage in detailed analyses and may rely on our usual routines and preexisting knowledge structures, which have served us well in the past (Bless, 1997; Schwarz, 1990). This encourages less effortful, top-down processing as a default, *unless* current goals require otherwise. In pursuing such goals, we may be willing to take some risk, given that the general situation is considered safe. As a result, we may prefer simple heuristics over more effortful, detail-oriented judgmental strategies, and may explore new procedures and possibilities and pursue unusual, creative associations.

In combination, these conjectures suggest that our cognitive processes are tuned to meet the situational requirements signaled by our feelings. In contrast to earlier conceptualizations, which pertained exclusively to the influence of moods, this cognitive tuning hypothesis does *not* entail that happy individuals are somehow unable (Mackie & Worth, 1989) or unwilling (Schwarz & Bless, 1991) to engage in systematic processing. Rather, it merely entails that the happy mood *itself* does not signal a situation that poses particular processing requirements. Hence, the spontaneously adopted heuristic processing style and reliance on preexisting knowledge structures should be easy to override, rendering processing under happy moods more flexible than processing under sad moods. In contrast, the systematic processing style fostered by negative moods should be difficult to override, reflecting that it would be maladaptive to ignore a potential "problem" signal (Bless & Schwarz, 1999). Moreover, any variable that can signal a benign or problematic situation should have effects that parallel the influence of happy or sad moods. Finally, specific emotions provide information that goes beyond global benign/problem signals and elicit processing strategies that are specifically tuned to meet the requirements entailed in the underlying appraisal pattern.

The feelings-as-information logic further predicts that feelings should exert no influence on processing style when their informational value is called into question. Empirically this is the case, as Sinclair and colleagues (1994) and Gasper (2004) observed for the case of moods, in contrast to what other approaches would predict.

This conceptualization does not preclude other influences. Recent negative events, for example, may temporarily preoccupy the person to an extent that interferes with systematic processing, despite the presence of negative affect (Ellis & Ashbrook, 1988). Similarly, people may indeed engage in mood repair when they feel bad (Erber & Erber, 2001). But it would be maladaptive to do so at the expense of attention to the causes of one's feelings. Hence, we would expect mood maintenance and repair to take priority only after the person concluded that little could be done or when the laboratory task seems irrelevant to begin with. Also, mood maintenance and repair would be expected when pleasant affect (rather than performance) is a primary goal, as might be expected when experimental instructions suggest so (e.g., Wegener, Petty, & Smith, 1995).

Feelings and Cognitive Performance

We first illustrate the interplay of feelings and task requirements in the choice of processing strategies. Subsequently, we review prototypical findings, highlighting the functional equivalence of different feelings and environmental cues.

Feelings and Task Requirements: Moods, Scripts, and Concentration Tests

If happy moods increase, and sad moods decrease, our tendency to rely on the "usual routines," people should be more likely to rely on an applicable script (Schank & Abelson, 1977) when they are in a happy rather than sad mood. Empirically, this is the case. Employing a dual-task paradigm, Bless, Clore, and colleagues (1996) had participants listen to a tape-recorded restaurant story that contained script-consistent and script-inconsistent information. While listening to the story, participants worked on a concentration test that required them to mark certain letters on a work sheet. Good performance on this test requires detail-oriented processing; in contrast, the restaurant story can be understood by engaging *either* in script-driven top-down processing or in data-driven bottom-up processing. As predicted, happy participants were likely to recognize previously heard script-inconsistent information but showed high rates of erroneous recognition of script-consistent information—the classic pattern of schema-guided memory. Neither of these effects was obtained for sad participants, indicating that they were less likely to draw on the script. Given that top-down processing is less taxing than bottom-up processing, we may further expect that happy participants do better on a secondary task. Confirming this prediction, happy participants outperformed sad participants on the concentration test.

In combination, these findings indicate that moods influence the spontaneously adopted processing style under conditions in which different processing styles are compatible with the individual's goals and task demands, as was the case for comprehending the restaurant story. Under these conditions, sad individuals are likely to spontaneously adopt a systematic, bottom-up strategy, whereas happy individuals rely on a less effortful top-down strategy. But when task demands (as in the case of the aforementioned concentration test) or explicit instructions (e.g., Bless, Bohner, Schwarz, & Strack, 1990)

require detail-oriented processing, happy individuals are able and willing to engage in the effort. The latter observation is inconsistent with the proposal that happy moods limit cognitive resources (e.g., Mackie &Worth, 1989), or generally impair processing motivation (e.g., Schwarz & Bless, 1991).

Categorization

The detail-oriented, bottom-up processing style associated with sad moods fosters the formation of fine-grained, narrow categories, whereas the top-down, heuristic processing style associated with happy moods fosters the formation of more inclusive categories (Isen, 1987). Thus, happy participants are more likely to include unusual exemplars in a category than participants in a neutral mood, assigning, for example, "feet" to the category "vehicles" and "cane" to the category "clothing" (Isen & Daubman, 1984). They also list more unusual exemplars when given a category prompt (Hirt, Levine, McDonald, Melton, & Martin, 1997) and match geometric figures on the basis of global rather than local similarities (Gasper & Clore, 2002). Finally, Beukeboom and Semin (2005) observed that sad participants identified behaviors at a lower level of abstractness than happy participants, paralleling the impact of actual obstacles (Wegner & Vallacher, 1986).

Similar effects have been obtained with other manipulations that signal a benign or problematic situation. Using a subtle bodily feedback manipulation, Friedman and Förster (2000, 2002) asked participants to either press their hand downward against the top of the table (arm extension) or upward against the bottom of the table (arm flexion). Arm extension (as in pushing something away) is usually associated with avoidance behavior, whereas arm flexion (as in pulling something closer) is associated with approach behavior. The proprioceptive feedback of the involved muscle activation is sufficient to influence processing style: Relative to a control, participants who flexed their arms provided more inclusive categorizations, whereas those who extended their arms provided less inclusive categorizations.

Creative Problem Solving

As may be expected on the basis of the categorization findings, happy individuals typically outperform sad or neutral-mood individuals on creativity tasks, like the Remote Associates Test (e.g., Isen, Daubman, & Nowicki, 1987) or Duncker's candle problem (Isen & Daubman, 1984). Again, studies using arm flexion or extension to provide bodily approach–avoidance feedback obtained parallel results (Friedman & Förster, 2000). Participants who flexed their arms were more likely to break the set than participants who extended their arms, resulting in better performance on tests that require the identification of targets hidden in complex visual patterns. Performance on such tasks is facilitated by the application of familiar concepts to the hidden targets, while disregarding irrelevant detail and breaking the set imposed by the

distractor—requirements that give top-down processing an advantage over bottom-up processing.

Analytic Reasoning Tasks

If sad moods foster systematic, detail-oriented processing, they should facilitate performance on analytic reasoning tasks. The bulk of the available evidence is consistent with this prediction (see Schwarz & Skurnik, 2003, for a review). For example, Fiedler (1988) reported that sad participants produced fewer inconsistencies in multiattribute decision tasks than happy participants. Specifically, the latter were twice as likely than the former to violate transitivity by producing inconsistent triads of the form A > B and B > C, but A < C. Similarly, Melton (1995) observed that happy participants performed worse on syllogisms than participants in a neutral mood. Again, the influence of bodily approach–avoidance signals parallels these effects. Using analytical reasoning tasks taken from the graduate record exam (GRE), Friedman and Förster (2000) observed that participants who extended their arms (avoidance) solved nearly twice as many problems correctly as participants who flexed their arms (approach).

Finally, external cues can serve the same function. Soldat and colleagues (1997) presented analytic reasoning tasks, also taken from the GRE, on paper of an upbeat red, or a somewhat depressing blue, hue. Across several replications, participants performed better when the tasks were printed on blue rather than red paper, with white paper falling in between. The performance advantage of blue paper was most pronounced for complex tasks, which posed higher processing demands. Paralleling these laboratory findings, Sinclair, Soldat, and Mark (1998) found that students did better on an exam when printed on blue rather than red paper, in particular for difficult questions.

In contrast to the foregoing findings, mostly based on tasks taken from the GRE, other studies revealed performance deficits under depressed affect on complex logic and mathematics tasks (for a review, see Clore et al., 1994). Theoretically, mixed findings are to be expected for such tasks because none of the hypothesized processes will *necessarily* result in improved performance. For example, greater attention to detail per se will not improve performance when the task requires the application of an unknown algorithm, and it may impede performance when the person gets sidetracked by irrelevant details. Similarly, top-down processing strategies may facilitate as well as impede performance, depending on whether the available heuristic is applicable to the current task. It is therefore not surprising that the most consistent findings have been obtained with common social reasoning tasks, like persuasion and impression formation, with which people are highly familiar.

Persuasion

In general, strong arguments are more persuasive than weak arguments when recipients engage in systematic

processing, whereas argument strength exerts little influence under heuristic processing (for a review, see Petty & Cacioppo, 1986). Accordingly, the impact of argument strength can serve as a diagnostic tool for assessing processing strategy. Studies using this strategy consistently found that happy recipients engage in less, and sad recipients in more, elaboration of counterattitudinal messages than recipients in a nonmanipulated mood (e.g., Bless et al., 1990; see Schwarz, Bless, & Bohner, 1991, for a review). Hence, happy recipients are moderately and equally persuaded by strong as well as weak arguments, whereas sad recipients are strongly persuaded by strong arguments and not persuaded by weak arguments. Conversely, Worth and Mackie (1987) observed that happy recipients were more likely than sad recipients to rely on heuristic strategies in assessing the validity of the message, paying attention to cues such as the communicator's status or expertise in forming a judgment. Consistent with the feelings-as-information logic, these effects are eliminated when recipients are aware that their mood is due to an unrelated source (Sinclair et al., 1994).

As noted previously, however, the impact of moods can be overridden by other variables; hence explicit instructions to pay attention to the arguments (e.g., Bless et al., 1990), or the promise that carefully thinking about the message would make one feel good (e.g., Wegener et al., 1995), have been found to elicit systematic message processing in happy recipients. What characterizes the information processing of happy individuals is not a general cognitive or motivational impairment but a tendency to spontaneously rely on heuristic strategies and general knowledge structures in the absence of goals that require otherwise.

Paralleling the effects of recipients' moods, Ottati and colleagues (1997) observed that the same message is less likely to be scrutinized when presented by a communicator with a smiling, happy face than when presented by a communicator with a neutral, somber face. They suggested that the communicator's conveyed affect can serve informative functions that parallel recipients' own affect. Further illustrating the power of environmental affective cues, Soldat and Sinclair (2001) had participants read persuasive messages printed on colored paper. Participants were persuaded by strong arguments, but not by weak arguments, when the message was presented on paper of depressing blue hue. However, both types of arguments were similarly persuasive when the paper had an upbeat red hue.

Stereotyping and Impression Formation

Paralleling the persuasion findings, numerous studies indicate that perceivers in a sad mood are more likely to elaborate individuating information about the target person, whereas perceivers in a happy mood are more likely to draw on the person's category membership as a heuristic cue. This results in more stereotypical judgments under happy than under sad moods (e.g., Bodenhausen, Kramer, & Süsser, 1994; Isbell, 2004; for a review, see Bless, Schwarz, & Kemmelmeier, 1996). Related research on the influence of brand names on product evaluations

similarly shows higher reliance on brand information under happy than sad moods (e.g., Adaval, 2001). Individual differences in chronic affect parallel these findings. Mildly depressed perceivers attend more to individuating information than do nondepressed perceivers (e.g., Edwards & Weary, 1993) and seek more, and more diagnostic, information (Hildebrandt-Saints & Weary, 1989). Finally, happy individuals' reliance on category membership information can again be overridden by manipulations that increase their processing motivation, such as personal accountability for one's judgment (Bodenhausen et al., 1994) or anticipated interaction with the target person (e.g., Hildebrandt-Saints & Weary, 1989).

Summary

In sum, internal and external cues that signal a benign or problematic situation have cognitive and motivational consequences. Human cognition is tuned to meet situational requirements and problem signals foster vigilance and the adoption of a detail-oriented bottom-up processing style, which is usually adaptive. Signals that characterize the situation as benign, on the other hand, are not, by themselves, associated with particular processing requirements. They foster reliance on preexisting knowledge structures and top-down processing, *unless* goals or task demands require otherwise. Which processing strategy facilitates or impedes performance depends on the specific task. The bulk of the evidence is compatible with this framework (Schwarz, 2002), which offers a unified conceptualization of the operation of internal and external signals in the context of situated cognition.

This does not preclude the operation of other pathways under specific conditions. Sometimes people's preoccupation with recent happy or sad events will indeed limit their cognitive resources (Ellis & Ashbrook, 1988; Mackie & Worth, 1991), although it is difficult to separate the impact of affect per se from the impact of event-related thoughts. Other times, people will indeed attempt to focus on something else to improve a bad mood (e.g., Wegener et al., 1995) or avoid mental effort to maintain a good mood (e.g., Clark & Isen, 1982), although dealing with current problems will probably take precedence in naturalistic contexts. Similarly, moods may serve as input into specific performance decisions (Martin, 2001) and may influence which material comes to mind when we work on a problem (Forgas, 2001). None of these mood-related processes, however, is sufficiently general to account for the observed parallel effects of affective, bodily, and cognitive cues that signal a benign or problematic environment.

Finally, we note that the reviewed findings provide little support for assumptions that positive feelings will have mostly "positive" effects (Fredrickson, 2001). Instead, their effect depends on the specific task at hand and positive feelings can facilitate positive outcomes (such as increased creativity or resiliency; see Fredrickson, 2001) as well as negative ones (such as increased stereotyping and impaired logical problem solving), in contrast to what positive psychologists seem to hope for.

FEELINGS AND MEMORY

Historically, conscious experiences that accompany the process of remembering played an important role in the study of memory, until they went out of fashion with the behaviorist revolution (for reviews, see Brewer, 1992; Roediger, 1996). Over the last two decades, cognitive psychologists have begun to correct the resulting pervasive "neglect of conscious experience" (Tulving, 1989, p. 4) by rediscovering some of the historic themes. This rediscovery is part of a shift from a quantity-oriented "storehouse" metaphor of memory to an accuracy-oriented "correspondence" metaphor of memory (Koriat, Goldsmith, & Pansky, 2000). The storehouse metaphor is exemplified by the list-learning paradigm, with a focus on how many previously learned items can be recovered. Within this metaphor, the role of subjective experiences is conceptualized in terms of a storage architecture, as illustrated by Bower's (1981) model that treats moods and emotions as nodes in a network. The correspondence metaphor treats memory as a "perception of the past" and focuses on whether "this perception is veridical or illusory" (Koriat et al., 2000, p. 484). Inference processes play a key role in this approach. They can be intuitive or analytic, paralleling dual-process distinctions in social cognition, and based on phenomenal experiences that accompany the remembering process as well as other information. For example, the source monitoring approach (Johnson, Hashtroudi, & Lindsay, 1993) assumes that remembering includes inferences about the source of the memories that come to mind, which are based on their phenomenal qualities. From this perspective, all memory failures (except omissions) are based on a failure of source monitoring (i.e., an inferential process). Cognitive experiences in the form of perceptual and conceptual fluency are central to Jacoby and Kelley's (e.g., 1998) attributional approach to memory, which "conceives of remembering as a combination of fluent processing of an event with the mental set that attributes the fluency to past experience " (Roediger, 1996, p. 88).

To date, research into the role of cognitive experiences in memory has almost exclusively taken an approach that is consistent with the feelings-as-information logic. In contrast, research into the role of moods and emotions in memory has mostly been guided by the architectural assumptions of Bower's (1981) network model and has paid little attention to inferential processes, which figure more prominently in judgment research. Next, we review prototypical findings.

Cognitive Experiences

In our review of fluency effects in judgment, we noted that fluency due to one's state of knowledge can result in perceptual illusions when applied to judgments about the presentation of material. Conversely, fluency due to the conditions of presentation can result in memory illusions when applied to judgments of one's knowledge (for reviews, see Kelley & Rhodes, 2002; Koriat et al., 2000). For example, in *recognition* tests, people are more likely to identify a new stimulus as old when its processing

is facilitated by a preceding prime (e.g., Jacoby & Whitehouse, 1989), higher visual clarity of the presentation (e.g., Whittlesea et al., 1990), or a highly related semantic context (Whittlesea, 1993). Paralleling effects observed in judgments of truth and beauty, Rhodes and Kelley (2003) also observed erroneous recognition when the test items were preceded by a rhyming rather than nonrhyming prime. Such enhanced fluency from an unrecognized source presumably also underlies *déjà vu* experiences, where something new seems strangely familiar (Jacoby & Whitehouse, 1989). The observation that bodily sensations of effort can affect fluency-based fame judgments (Strack & Neumann, 2000) further suggests that bodily feedback may also influence recognition, although relevant data are not yet available. Finally, fluency effects on recognition and feelings of familiarity are not obtained when participants attribute fluency to a source other than previous exposure—for example, because they are aware of the prime (Jacoby & Whitehouse, 1989) or realize that clarity of presentation is being manipulated (Whittlesea et al., 1990).

Models that focus solely on *what* comes to mind cannot account for the reviewed phenomena, nor can they account for related research into feelings of knowing and judgments of learning (for a review, see Koriat & Levy-Sadot, 1999). At the same time, it is apparent that the experiential approach is relatively silent with regard to *what* comes to mind and instead focuses on the conditions under which we consider whatever comes to mind a reflection of past events.

Mood

Moods may influence memory at the encoding as well as retrieval stage. Extending the investigation of mood effects on processing style, Storbeck and Clore (2005) demonstrated that happy participants are more likely than sad participants to produce false memories. Drawing on Roediger and McDermott's (1995) paradigm, they presented participants with lists of words (bed, pillow, rest, etc.) that are highly associated with a critical lure (e.g., sleep). Participants typically recall having seen the critical lures, even though they were never presented. This effect depends on engaging in gist processing (in addition to item-specific processing) and is hence more pronounced under happy than sad moods, reflecting the differences in processing style discussed previously. Additional manipulations located this effect at the encoding rather than at the retrieval stage, as theoretically expected.

The lion's share of research into mood and memory, however, has addressed mood effects on recall in the context of Bower's (1981) model, reviewed earlier. This model predicts that material learned while in a given affective state should be better recalled when in the same rather than a different state. Support for this *state-dependent recall* hypothesis has been obtained in several studies that used a "two-list interference paradigm," where list A is learned while in a happy mood and list B is learned while in a sad mood. Being in the same mood at the time of recall facilitated recall in several studies, whereas being in the opposite mood inhibited recall

(e.g., Bower et al., 1978; Schare, Lisman, & Spear, 1984). However, other studies (e.g., Bower & Mayer, 1985; Marshall-Garcia & Beck, 1985) failed to replicate this pattern, even when using the same materials. Bower and Mayer (1985) concluded from their own non-replications that "mood-dependent retrieval is an evanescent will-o'-the-wisp, and not the robust outcome suggested by earlier reports" (p. 42).

A second prediction holds that positive moods facilitate recall of positively valenced material and inhibit recall of negatively valenced material; the reverse is expected for negative moods. Note that this *mood-congruency* prediction pertains to the match of mood at recall and valence of the to-be-recalled material, independent of the mood at the time of learning. Unfortunately, the conceptually straightforward distinction between state dependency and mood congruency is difficult to sustain in the domain that produced the most supportive findings, namely, the recall of autobiographical information (for reviews, see Blaney, 1986; Morris, 1989; Singer & Salovey, 1988), as discussed earlier. In addition, mood congruency may be limited to relatively unstructured material and tends to be difficult to find when positive and negative elements are closely interconnected in a narrative (Hasher, Rose, Zack, Sanft, & Doren, 1985; Mecklenbräuker & Hager, 1984), consistent with the logic of network models.

Empirically, participants' recall often shows a marked asymmetry (e.g., Natale & Hantas, 1982; see Blaney, 1986; Singer & Salovey, 1988, for reviews). Participants in a happy mood recall more happy, and fewer sad, memories than do participants in a neutral mood, indicating facilitative as well as inhibitive effects of happy moods. In contrast, sad participants recall fewer happy events, but not more sad events, suggesting inhibitive but not facilitative effects of sad moods. Three different accounts have been offered for this asymmetry. One proposal holds that positive material is more interconnected in memory than negative material (e.g., Isen, 1984; Matlin & Stang, 1979). If so, a given mood-related association would spread to a larger amount of similarly valenced material under positive rather than negative moods. However, data bearing directly on these structural assumptions are not available. Moreover, others (e.g., Higgins, Van Hook, & Dorfman, 1988) proposed that negative events are more likely to be interconnected in memory, given that they elicit more explanatory activity (Bohner et al., 1988). A second proposal attributes the observed asymmetry to mood repair efforts (Clark & Isen, 1982). According to this hypothesis, sad participants attempt to improve their mood by avoiding further negative thoughts. One might expect, however, that recalling happy memories is an even more effective strategy for mood repair, yet such mood-incongruent recall is rarely observed (for an exception, see Parrott & Sabini, 1990, who found mood-incongruent recall under happy as well as sad moods, in contrast to what the mood repair logic would predict).

As a third possibility, Schnall, Clore, and Ryan (2005) suggested that the usually obtained asymmetry may be due to mood induced differences in processing style.

Using the original materials of Bower, Gilligan, and Monteiro (1981), they crossed happy and sad moods with positive and negative conceptual primes. They observed that happy participants used the primes in recall, regardless of whether they were positive or negative, whereas sad participants did not. Given that happy moods are usually induced by positive conceptual content (either as a function of the mood manipulation or a naturally occurring event), reliance on this accessible conceptual content as a recall cue would produce a pattern of content-congruent recall that looks like mood-congruent recall. Because sad moods promote item-specific processing and discourage reliance on other accessible content, less congruency would be observed under this condition, fostering the familiar asymmetry.

Emotions

Research on the impact of specific emotions on memory has also been guided by the assumption that emotions should activate emotion-congruent material (Bower, 1981). Hence, emotion-congruent material should be easier to recall, more readily perceived, and more likely to interfere with competing material when one experiences the respective emotion. However, the available data, mostly pertaining to anxiety, do not provide strong support for the operation of some general form of emotion congruency (see Mathews & MacLeod, 1994, for an extensive review). Instead, emotions seem to elicit a focus on material that is content relevant rather than on material that is simply feeling consistent. For example, Mogg, Mathews, and Eysenck (1992) observed in an attentional paradigm that anxious participants were only faster in responding to threatening words when the word pertained to their specific domain of worry. Similarly, Mathews and Klug (1993) crossed the valence of a set of words with whether the content was or was not related to the concerns of anxious patients. Content-related words interfered more than did content-unrelated words—and did so regardless of their valence. Mathews and MacLeod (1994) therefore concluded, "It is the match with current domain of concern, rather than emotional valence or congruence in a general sense, that determines the information that is given processing priority" (p. 37). This conclusion is compatible with the assumption that feelings inform us about the current situation, directing our attention to features that are likely to make us anxious.

From Memory to Judgment

Social psychologists' interest in affective influences on memory is mostly motivated by the assumption that affect-related differences in memory mediate affect-related differences in judgment. To do so, the information that comes to mind must seem to be "about" the target of judgment (e.g., Higgins, 1998). If people are aware that it may only come to mind due to their current mood, for example, accessible thought content may be likely to be discounted, as discussed earlier. Surprisingly, this conjecture has not received direct testing.

WHAT HOLDS WHEN?

Consistent with goals of this handbook, our review of the interplay of feeling and thinking focused on basic principles that apply to more than one type of feeling. Each of the reviewed mechanisms can account for some, but not all, of the available data. Moreover, many of the process assumptions are not mutually exclusive and each one may hold under some conditions. In a commendable integrative effort, Forgas (1995a, 2001) proposed a multiprocess affect infusion model (AIM) that focuses on mood effects and does not address other feelings. The AIM incorporates the theoretical approaches discussed earlier and can accommodate any mood effect predicted by its component theories. The model's original contribution is an attempt to specify the conditions under which previously identified processes are likely to hold. While we agree with many AIM predictions, a selective discussion of some of its ambiguities suggests that an integrative conceptualization remains a challenging task.

The AIM distinguishes four different processing strategies. If the target is familiar and a previously formed judgment is accessible in memory, people are assumed to rely on a *direct access* strategy, provided that the judgment is not personally relevant. Mood is not assumed to play a role in this case. The prototypical example given (Forgas, 2001, Fig. 5.1) is stereotyping, which is assumed to reflect the recall of a previously formed impression of a group. But as reviewed earlier, people are more likely to rely on stereotypes when they are in a good rather than bad mood (e.g., Bodenhausen et al., 1994). Moreover, they are more likely to draw on a previously formed judgment when in a good mood, following a direct access strategy, but to form a new judgment based on currently accessible details when in a bad mood (Bless, Mackie, & Schwarz, 1992). Hence, moods influence the use of a direct access strategy in the first place.

As a second possibility, the AIM introduces a *motivated processing* strategy, which people may employ when they want to reach a certain conclusion, potentially in the interest of mood management goals. To arrive at the desired conclusion, they may engage in a selective information search, which may override mood effects on judgment. We assume that this strategy is less likely when the situation is perceived as problematic, again introducing affective influences.

A third possibility pertains to a *substantive processing* strategy. It is based on extensive memory search and elaboration, giving rise to the influence of mood-congruent recall. People are assumed to use this strategy primarily under conditions of unconstrained processing capacity and high accuracy motivation to form judgments that are demanding (as exemplified by atypical, unusual, or complex targets) and of some importance to them. Being in a sad mood is assumed to facilitate the adoption of this strategy via increased accuracy motivation but may impede its adoption via decreased cognitive capacity. The mood-congruency component of this strategy suggests that mood effects on judgment should follow the pattern of mood effects on recall. Empirically, this does not appear to be the case. The judgment effects

attributed to substantive processing show a largely symmetrical impact of happy and sad moods (see Forgas, 1992, for a review), whereas mood-congruent recall is mostly limited to happy participants in memory experiments, as reviewed earlier. The strategy further suggests, for example, that cognitive responses to a persuasive message should reflect mood-congruent elaboration. Empirically, this is not the case. Sad recipients generate more negative responses to weak arguments, but more positive responses to strong arguments, than do happy recipients (Schwarz, Bless, & Bohner, 1991), which is consistent with differential accuracy motivation but not with mood-congruent elaboration. More complex judgments, however, have often been observed to show stronger mood effects (e.g., Forgas, 1995b; Schwarz et al., 1987). But in the absence of attributional manipulations we cannot tell whether participants simplified a complex task by relying on their feelings as information or engaged in mood-congruent substantive processing. In support of substantive processing, Forgas (2001) emphasizes that participants spend more time perusing the information when it is complex but are subsequently fast in providing a judgment. This pattern is also compatible with the possibility that they ponder a complex task and opt for a heuristic shortcut once they realize how burdensome it would otherwise be. Similarly, the observation of mood-congruent recall *after* the judgment is made does not necessarily imply that it mediated the judgment. Instead, the previously formed judgment may itself serve as a cue in reconstructive memory (for an example, see Bless, 1996). As these conjectures indicate, process identification is riddled by uncertainties and diagnostic evidence is often unavailable.

Finally, the AIM's fourth possibility pertains to a *heuristic processing* strategy, based on one's current feelings as a source of information (e.g., Schwarz & Clore, 1983). People are assumed to use this strategy under conditions of limited processing capacity and low accuracy motivation to form judgments that are simple and/or of limited importance to them. From this perspective, any judgment that is susceptible to misattribution effects pertains, by definition, to simple targets of low importance, which is difficult to reconcile with the available evidence. Being in a good mood is predicted to facilitate the adoption of this processing strategy via decreased accuracy motivation, consistent with mood effects on processing style. Finally, the strategy is assumed to be "ineffective and dysfunctional" because "affect can only serve as a heuristic cue due to mistaken inferences" (Forgas, 2001, p. 104), a conclusion that ignores integral affect and the advantages conveyed by fast and efficient affective reactions to the environment (Frijda, 1988; Zajonc, 1980).

Despite such shortcomings, the AIM predicts the correct outcomes more often than not, which makes it a useful guide for considering the possible influence of moods in many applied contexts. This the case because the AIM can accommodate any of the results predicted by its component theories and because different process assumptions often converge on the same outcome prediction, as the next section illustrates.

FEELINGS AND BEHAVIOR

To appreciate how different mood-related processes can result in the same outcome, suppose that Jane encounters an opportunity to help Mary. Jane may consider how much she likes Mary, whether she has the resources to help her, whether that experience would be pleasant, or how much good her help might do. If she applies the "How-do-I-feel-about-it?" heuristic to any of these questions, she will arrive at more positive assessments when in a good rather than bad mood, making helping more likely. If her moods influence what comes to mind, her elaborations will be more positive when in a good rather than bad mood, again making helping more likely. If Mary is an unknown other, a good mood may facilitate her inclusion in the ingroup through broader categorization, again making helping more likely. If the helping task is not very demanding, it may also provide Jane with a good opportunity to maintain her pleasant mood. Hence, the feelings-as-information, mood-congruent recall, and mood maintenance approaches make the same prediction for positive moods, unless the helping task is highly demanding, which would render it an unlikely avenue for mood maintenance (Schaller & Cialdini, 1990). Moreover, only the mood maintenance approach differs in the predictions for negative moods, as helping may provide an opportunity to improve a bad mood, provided the benevolent act is not too costly. Not surprisingly, positive moods are, indeed, reliably related to prosocial behavior, whereas "the effect of negative moods on benevolence is less consistent," as Eisenberg, Losoya, and Spinrad (2003, p. 797) concluded after a comprehensive review. This overdetermined nature of many mood effects precludes inferences about the underlying processes in the absence of additional process information.

Consistent with social psychologists' preferred theorizing, all influences of moods on prosocial behavior were mediated by cognition or motivation in the foregoing example. In contrast, many emotion theorists (e.g., Frijda, 1988; Leventhal, 1982) believe that emotions affect behavior in more direct ways. For example, fear is assumed to involve behavioral tendencies to escape, anger to involve activation of aggressive responses, and so on. In our reading, the direct effects of emotions are more likely to be motivational, changing the accessibility and priority of goals. The likely goals of fearful or angry persons, for example, are much easier to predict than the likely behaviors. Fear clearly involves a desire to avoid harm or loss, but from knowing only that they are afraid, we cannot predict whether people will sell their stocks, listen to the weather report, or start running. The immediate effects of emotion, therefore, are more mental than behavioral, emphasizing the importance of the processes that were the focus of this chapter.

CONCLUDING REMARKS

The proliferation of research into the interplay of feeling and thinking has resulted in a multitude of findings. Most of them can be framed in terms of two global approaches: an experiential approach that focuses on the informational value of subjective experiences, which include moods, emotions, bodily sensations, and cognitive experiences; and a cognitive approach that focuses on the impact of moods and emotions on the content of the thoughts that come to mind rather than the experience of having the thoughts. Each of these approaches is supported by a number of unique findings, whereas many other findings are compatible with both. For the latter, diagnostic process evidence that would convince advocates of the respective other approach is often missing (as a comparison of this chapter and Forgas, 2003, will aptly illustrate). While researchers working within each approach are able to produce many of the core effects with considerable reliability, the interplay of the underlying processes is awaiting an encompassing conceptualization. We hope that our accentuation of the principles underlying each approach will help in tackling this formidable task.

The Role of Impulse in Social Behavior

FRITZ STRACK
ROLAND DEUTSCH

THE TWO HORSES OF HUMAN BEHAVIOR

One of the most famous metaphors in philosophy is Plato's model of the soul in terms of a chariot with his two horses (Plato, 1998). They are vividly described in his dialogue "Phaedrus" where a chariot is drawn by a beautiful and upright white horse that needs no whip and is guided only by the charioteer's commands. The second horse, in contrast, is dark in color, ugly, crooked, and hard of hearing. It is scarcely controlled with a combination of whip and goad. Despite their different character, the two horses are capable of jointly and forcefully moving the vehicle forward. However, it may also be the case that one horse will be dominant and determine the course of the chariot. Of course, this picture aptly symbolizes the two forces of human behavior. The white horse depicts reason and reflection, the dark horse passion and impulse.

The metaphor of the two horses is present in many models of human behavior. In some of them, one of the two horses is portrayed as the *dominant* driving power while the second horse is following suit. Other models, however, focus on a potential *conflict* between the two horses. Plato himself had hoped that the white horse of reason was the most frequent force behind human action. Much later, this dominance was elaborated in the so-called rational model (Hume, 1739/2000) that is still the conceptual basis of economics (e.g., Becker, 1962) and part of the social and psychological sciences (e.g., Fishbein & Ajzen, 1975).

More important for present purposes, the metaphor of the chariot and the horses is a first attempt at describing the dual determination of human behavior. Moreover, it resembles its conceptual successors in that one determinant stands in the foreground and is explained in considerable detail while the other is relegated to a secondary status and is described predominantly by negating the characteristics of the primary determinant. This chapter is meant to focus on a type of behavioral determination that has received little attention from research in social psychology. In particular, we would like to shed some light on the nature of impulse and to identify some of the mechanisms that generate impulsive behaviors. Interestingly, such behaviors are often described by using negations, such as "not caused by intention, judgment or decision," "irresistible," "irrational," "irresponsible," and "undifferentiated" and are often accompanied or driven by strong affect (e.g., Le Bon, 1895). Therefore, we begin by considering those nonimpulsive accounts that serve as a reference point for impulsive behavior and point out their shortcomings.

RATIONAL MODELS OF HUMAN BEHAVIOR

In most of its variants, the rational model holds that behavior is a consequence of people's reflective thoughts and not of their feelings. In addition, there are certain contents that are in its focus. According to the rational model, actors are assumed to anticipate and evaluate the

consequences of what they do. As a result, behavior is construed as a decision that is based on what people expect as a result of what they do and on their beliefs if this is good or bad. For the Greek philosophers, these values were derived from basic virtues (like wisdom, courage, and moderation). Moreover, Socrates assumed that aberrations from the path of virtue were merely due to a lack of knowledge. In other words, if actors knew what is good or bad, their actions would necessarily fall in line.

After more than 2000 years, Socrates's model was extended by Adam Smith (1776/1981), the founder of modern economics. He has argued that there is no need to invoke fundamental virtues in order to derive the values that guide behavior. Instead, he believed that recognizing and pursuing one's own interest will be sufficient to maximize the common good. More recently, economists (e.g., Becker, 1976) have proposed that *all* human behavior is caused by decisions that maximize a person's advantage (or, utility). And as in Socrates's notion, seeming exceptions to this rule were understood as the result of incomplete information.

In modern social psychology, the "rational model" has also influenced theorizing. A prominent example is Fishbein and Ajzen's (1975) theory of reasoned action in which people's attitudes toward a behavioral outcome determine what people decide to do. Once again, reflection is the fundamental mechanism. Elements of the rational model can also be found in Bandura's (1977) theory of social learning, which explains human behavior as a function of its anticipated consequences. To predict what people do, it is necessary to understand how they acquire knowledge about what is good or bad. Bandura has described various mechanisms, among them observing others' behaviors.

ABERRATIONS FROM THE PATH OF REASON: IMPULSIVE DETERMINANTS OF HUMAN BEHAVIOR

The Roots of Impulse in Greek Philosophy and in the Christian Tradition

While for the rational theories of human behavior, the white horse is clearly in charge, its dark companion may either trot along or help to pull the carriage into the predetermined direction. Psychologically speaking, human behavior was seen as the result of reflection, while impulsive mechanisms had no major role beyond energizing the execution of reflective decisions.

However, this Socratic view of human behavior did not go undisputed. In Western philosophy, Plato and Aristotle were the first to recognize the unique quality of impulsive determinants of behavior. In particular, passion was identified as the force that would lead people astray. In marked contrast to the implications of the rational model, knowing what is virtuous or good was not enough. In fact, passion was seen to cause people to do what they knew was wrong. In general, behavior driven by passion was seen to be bad for one's own well-being.

Built on Aristotle's ethics (Bywater, 1984), the Christian tradition also proclaimed virtues as guides for behav-

ior (Aquinas, 2002). Deviations from the path of virtue were understood as violations of God's will. Such sins are caused by an evil force with which humans are endowed. Although sinning was understood to be part of human nature, guilt had to be felt if a behavior was recognized to be inconsistent with religious values. Fortunately, however, the church offers to gracefully remove these unpleasant experiences from its faithful. From a psychological perspective, it is important to note that the Christian doctrine includes effective mechanisms of self-regulation that operate through the recognition of inconsistency, negative affect (guilt, shame, contrition, and regret) and institutions that are capable of resetting the person into his or her previous state. In return, recipients are expected to show faith in the redeemer and fight the forces that led them astray.

In Plato's metaphoric picture, the Christian view is a permanent struggle between reason and passion, or between reflection and impulse. The institutions of the church serve to strengthen the impact of reflective processes within the constraints that are provided by the religious values. Pleasant feelings that are associated with impulsive sinning are framed to elicit guilt and shame. Fortunately, these negative feelings can be prevented by engaging in religious exercises, such as praying and fasting. Alternatively, a pleasant hedonic experience may be purified by embedding it into a religiously accepted institution. This becomes particularly apparent in the case of sex, which must either be entirely abandoned by some representatives of the religion or is only allowed as part of reproduction within marriage.

The Roots of Impulse in the History of Psychology

In the history of psychology, Gustave Le Bon (1895) was perhaps the first to describe the perils of impulse. Moreover, he identified the eliciting circumstances and explained the underlying psychological mechanisms. Specifically, Le Bon asserted two states that cause the person to behave according to different psychological principles. When by themselves, individuals were assumed to act according to reason and responsibility; when in groups, they would lose their "conscious personality," and their behavior was seen as the result of impulses that are suggestively transmitted by other group members. Even more drastically, Le Bon depicted the social group to be the "slave of impulses" (*esclave des impulsions*) that are elicited by hypnotically suggestive influences, which only a "strong personality" would be able to resist. In detail, the major characteristics of group behavior were identified as impulsivity, irritability, lack of logical thinking, deficiency of critical judgment, and an exaggeration of feelings. These determinants of behavior along with the mechanism of hypnotic suggestion were localized in what Le Bon called the "group mind," which would lead to uncivilized manifestations of human behavior. Because they are deprived of the capacity of critical reasoning, individuals in social contexts would be the victims of social influences, and their uninhibited emotions would elicit destructive violence and aggression but also acts of exceptional bravery and sacrifice. According to Le Bon,

this is because social behavior, unlike non-social behavior, is not determined by the actors' personal interest but by the forces previously described.

In this first dual-process model of social behavior, Le Bon has directed the readers' attention to the possibility that under certain conditions, human behavior may not be guided by a reflected evaluation of its outcome but by impulsive forces that obey different rules and regularities. Moreover, such impulsive behaviors were not seen as exceptional deviations but as the normal manifestations of behavior in social situations. Thus, persons' actions were understood to be determined either by the forces of impulse or by those of reason. A joint influence of both operating principles was not part of Le Bon's model, and consequentially, there was no conflict between them.

Le Bon's account has not gone uncriticized. Most prominently, Sigmund Freud (1921) disapproved of Le Bon's concept of a group mind and of hypnotic suggestion as a mechanism of social influence. To explain the behavioral phenomena described by Le Bon, he proposed the model of a mental apparatus in which reflection and impulses were interrelated and in which conflicts between the two may arise. His approach was probably the first attempt at describing mental processes and behavior as the result of an interaction of different systems that operate on the basis of different psychological processes. As a result, human behavior has both reflective and impulsive components, the degree of which depends on the type of interaction between what Freud called the ego, the id, and the superego. In Freud's psychoanalytic model, the id was mainly located in the domain of the unconscious. Even elements of the conscious ego were given the potential to be "repressed" to the unconscious (Freud, 1920). Moreover, the ego uses defense mechanisms to deal with unconscious impulses and much of what the defense mechanisms do is unconscious, thereby producing clinical symptoms. Unlike Le Bon's model, Freud's theory was based on the assumption that inputs from the different aspects of the mental apparatus would *jointly* exert their influence on thinking, feeling and acting. Therefore, conflicts are preprogrammed and the target of therapeutic intervention, which consists of raising unconscious contents, including ego's defense mechanisms, to consciousness. Despite these differences, Freud and Le Bon agreed in their assumption that human behavior is not only determined by a rational anticipation of its outcome. In addition, nonreflective forces were seen to play an important role. Also, both theorists believed that intense affect and emotions would play a central role in undermining reflective control.

The Revival of Impulse in Modern Social Psychology

In many explanations in social psychology, the rational model plays an important role. This seems to be mainly due to the dominant role of attitudes as precursors of behavior. Specifically, the interpretation of attitudes as evaluations led to theoretical models in which behavior was conceived as a decision that was based on what was judged to be good or bad (Ajzen, 1991). Decisions were seen to be reached either by cognitive mechanisms that were modeled after normative procedures (e.g., Kelley, 1967) or by simplified mechanisms that take the bounded rationality (Simon, 1991) of human judgments into account (Nisbett & Ross, 1980; Tversky & Kahneman, 1974). Behavioral deviations from preceding judgments were seen to be punished by negative affect, which was then regulated by various processes of rationalization and justification (e.g., Festinger, 1957).

Despite this predominant orientation, there are a few lines of research in which behavior is explained in a way that is not oriented toward the rational model. One is Berkowitz's theory of aggression (e.g., Berkowitz, 1974) in which aggressive behavior is understood to be determined not by expectations of its outcome but by impulsive mechanisms. Negative affect in combination with the mere accessibility of violent thoughts were found to be sufficient to elicit aggression (see also Berkowitz, 2004).

Another relevant line of research comes from Mischel and his colleagues (e.g., Mischel, Ebbesen, & Zeiss, 1972) who have created an experimental paradigm in which children were required to choose between immediately consuming a small reward and waiting for a much larger reward. While the children typically preferred the larger outcome and started waiting for it, the majority of them interrupted the waiting period and forwent the larger reward for the smaller one. More recently, this inability to delay gratification was explained by Metcalfe and Mischel (1999) within a "hot/cool framework" in which a "cool system" specializes in thoughtful processing of knowledge whereas a "hot system" is in charge of emotional processing and reflexive operations. The authors list a number of features that describe the divergent types of processing in the two systems, identify conditions under which one of the systems assumes a dominant role, and describe ways in which the hot and the cool system interact in different psychological situations. Children's failure to wait for the reward was attributed to the predominance of the hot system that facilitated "reflexive" mechanisms that are driven by stimuli that are tangible in the situation.

Applied to adult behavior, the "irrational" preference for immediate rewards has been studied by economists under the name of "temporal discounting" (e.g., Frederick, Loewenstein, & O'Donoghue, 2002), which follows a hyperbolic utility function (Loewenstein & Elster, 1992). The underlying psychological processes, however, were described as "viscerally" driven and accompanied by the experience of "craving" (Loewenstein, 2001). Recently, Trope and colleagues (Liberman & Trope, 2003) tried to explain the hyperbolic nature of temporal discounting by pointing at the different mental construals of immediate and remote events and at the affective and judgmental consequences.

Most important, however, is a more recent development in the domain of social cognition that advanced the thesis that the controlled judgmental processes that were found to generate behavior had the potential to be executed in an automatic fashion. This notion is based on

the fact that a stimulus can cause behavior not only through generating an evaluative judgment and forming a specific goal but also through a direct and automatic connection to the behavior itself. This "perception–behavior link;" (Bargh, 1997) has its roots in William James's (1890; see also Lotze, 1852) "ideomotor principle" and the concept of "habit" from the behaviorist tradition (Thorndike, 1911; see also Bargh & Ferguson, 2000).

The possibility of a nonreflective determination of behavior has reemerged in modern social psychology mainly as the study of cognitive habituation. Specifically, it has been argued that the repetition of mental processes will allow them to be performed in an automatic fashion that is outside awareness, relatively effortless, unintentional, autonomous, and even involuntary or uncontrollable (Bargh, 1989). Moreover, such automatic processes may directly elicit behaviors without the actor being aware of their specific quality and meaning (Bargh & Ferguson, 2000; Oulette & Wood, 1998; Verplanken & Aarts, 1999) while affect is not seen to play a major role. Most important, perhaps, the reflective and automatically impulsive processes were seen to obey the same underlying mechanisms. In other words, it was deemed possible for *all* reflective operations to be delegated to automaticity if they are executed with a sufficient frequency. Because reflection is a scarce commodity, this flexibility was seen to have adaptive advantages. That is, if a behavior can be performed automatically, reflection may focus on new and more complex behavioral decisions.

VARIANTS OF IMPULSIVE DETERMINATION

This historic review suggests that although reflective determination of social behavior was regarded to be normal or typical, psychological theories have repeatedly pointed at alternative mechanisms. However, it becomes apparent that the nonreflective nature of such determinants provides no common mechanism that would underlie the behavior. For example, nonreflective processes may be driven by passion and affect, as Le Bon and Freud would assume, and would be described as "hot" in Metcalfe and Mischel's (1999) model and as "experiential" in Epstein's (e.g., 2003) conceptualization. Alternatively, they may also be seen as a function of the frequency and the recency with which different pieces of information co-occur (Verplanken, Aarts, & Van Knippenberg, 1997).

Driven by affect or habituation, a stimulus may elicit specific response. The same reaction, however, may also be triggered by a category to which this stimulus belongs. In the social domain, the activation of a stereotype may cause impulsive reactions (Bargh, 1997).

THE ROLE OF IMPULSE IN DIFFERENT AREAS OF PSYCHOLOGY

After having discussed some historic roots of impulsive determinants of social behavior, we turn now to areas of psychology in which both reflection and impulse play a major role in accounting for the phenomena in question.

Attitudes

In social psychology, attitudes are seen as precursors of behavior. Therefore, to know a person's evaluation is an efficient way of predicting this person's behavior. However, it is not clear if the influence of attitudes on behaviors takes a reflective or an impulsive path. This ambiguity is reflected by different definitions. Thurstone (1931), for instance, saw in an attitude the affect for or against a psychological object. A little later, Gordon Allport (1935) defined an attitude as a "mental or neural state of readiness" that exerts a "directive or dynamic influence on the individual's response" (p. 1) while Smith, Bruner, and White (1956) identified attitudes as predispositions that influence experience, motivation, and action toward a class of objects.

While these definitions point to impulsive influences, processes of reflection were in the focus of subsequent definitions. For example, Eagly and Chaiken (1993) described an attitude as "a psychological tendency that is expressed by evaluating a particular entity with some degree of favor or disfavor" (p. 1). It is important to note that authors who agree that evaluations (as opposed to experienced affect) are at the core of the attitude concept differ in whether these evaluations should be understood as declarative representations in memory (Pratkanis, 1989). For example, Schwarz (2000) proposed that attitudes should be understood as judgments that are not stored in memory but are generated on demand.

If this is the case, the question arises how the information that provides the basis for attitudinal judgments is accessed. Moreover, the nature of the internal representations of valence and their structure must be understood. Most important, the question arises if those internal evaluative representations may influence human behavior without mediating judgments.

Accessibility as a Determinant of Attitudinal Judgments

An important development in the study of attitudes psychology is the rise of social cognition (e.g., Bless, Fiedler, & Strack, 2004). Through the adoption of the information-processing paradigm, the mechanisms underlying attitude formation came into the focus of research. Among them were mechanisms whose execution occurs in an automatic fashion. One is the recall of relevant information from memory. Under the label of "accessibility" (Higgins, Rholes, & Jones, 1977), it has been demonstrated that the generation of judgments greatly depends on the likelihood with which a particular information comes to mind. This "activation potential" (Higgins, 1996) is influenced by the frequency and recency of a prior activation (see Srull & Wyer, 1979, 1980). Accessibility has also been shown to provide an important link between evaluative concepts that are stored in memory and the generation of evaluative judgments. It is impor-

tant to recognize that the activation of evaluative contents does not imply any endorsement of their application to the target. Still, this basic mechanism affects not only what people believe but also, as a consequence, how they behave (e.g., Fazio, Powell, & Williams, 1989). In other words, behavior is not only a function of an evaluative judgment but also a function of the probability with which the underlying information is brought to mind. Although the latter component occurs without awareness and is not controllable in a direct fashion, it is also subject to psychological laws.

Within the area of social cognition, automatic processes have come into the focus of investigation for the accessibility of information in evaluative (and nonevaluative) judgments. Also, inferential processes were claimed to consist partly of "spontaneous" (e.g., Newman & Uleman, 1989) and automatic mechanisms (Gilbert, 1989). Thus, the generation of attitudinal judgments was no longer understood as a domain of processes that are entirely under the person's conscious and intentional control. Instead, it was recognized that unconscious and automatic mechanisms play an important role. Primarily, experimental interventions to influence automatic processes consisted of priming procedures that were applied to increase the activation potential of a specific information (for a recent review, see DeCoster & Claypool, 2004). Thus, early research on automatic influences was predominantly focused on independent variables that affected judgments in an uncontrolled fashion while the dependent variables remained the same as in previous research. As a result, whereas nonreflective influences were identified as judgmental determinants, the last step to behavior is still reflective in nature. Consistent with this argument is the "judged usability" phase of knowledge activation and use (Higgins, 1996). However, subsequent study of nonreflective components of attitudes led to further discoveries of which two seem particularly important: the rise of "implicit attitudes" and the "direct link to behavior."

Implicit Attitudes

Whereas automaticity was originally studied by focusing on both its determinants and its effects on conventional expressions of attitudes, the focus of research has shifted more recently toward consequences that do not manifest themselves in measures such as self-reports. This was partly due to the insight that attitudes may not manifest themselves only in "explicit" evaluative expressions. Rather, and in line with earlier definitions of attitudes as "mental readiness" (Allport, 1935), they were found to be effective in an indirect or "implicit" fashion. Moreover, explicit/direct and implicit/indirect measures of attitudes were often unrelated and seem to tap into different evaluative representations. This reasoning has its roots in research by Patricia Devine (1989) on prejudice, which was found to be low if people were given the opportunity to explicitly endorse components of the negative stereotype about African Americans. However, if the same people were subtly primed with words referring to the nega-

tively evaluated group, an ambiguously described target person was subsequently more likely to be assigned the negative characteristics (e.g., hostility) of the stereotyped group. Moreover, this indirect influence did not depend on the degree to which the prejudice was endorsed (Devine, 1989).

This finding suggests that beyond prejudice, evaluations in general may have components that are not reflected in self-reports but may be captured by more indirect measures. Examples are "affective priming" (Fazio, 2001) and the Implicit Association Test (IAT) (Greenwald, McGhee, & Schwartz, 1998), which has initiated a new era of attitude research. On a behavioral level, the IAT measures the ease of generating a categorical response as a function of its evaluative compatibility. For example, participants have to indicate if a name appearing on a computer screen is characteristic for Blacks or Whites by pressing the same (or a different) key that they have been using to indicate that a word is pleasant or unpleasant. Replicated across a great number of content domains, it has been found that it is more difficult (as reflected in longer response latencies and subjective reports) to assign a target to a category with a negative valence if the same response has been used to categorize another target as "positive" (and vice versa) than to assign a target to a category using a response that has been used for a judgment of the valence that is also a feature of the category. The difference in the ease of generating a categorical response for evaluatively compatible and incompatible responses became known as the IAT effect. It partly reflects the strength of evaluative associations and serves as perhaps the most widespread "implicit" measure of attitudes.

Because the IAT and other implicit measures (for a review, see Fazio & Olson, 2003) are only moderately correlated with self-reported attitudes (Nosek, Greenwald, & Banaji, 2005), the existence of implicit attitudes has been postulated. They were defined both operationally and in contrast to "explicit" attitudes. That is, implicit attitudes are what implicit tests measure, and this is different from the evaluations people report if they are asked to indicate their attitudes (e.g., Banaji, 2001; Wilson, Lindsey, & Schooler, 2000). More specifically, implicit attitudes are assigned the characteristics of automatic processing in that they involve components that are outside awareness, are unintentionally formed in a relatively effortless fashion, are autonomous, and are difficult to control.

Obviously, this reflects a swing in the conceptualization of attitudes toward Allport's (1935) definition. A "mental state of readiness" that exerts a "directive influence on the individual's response" describes a different link between attitude and behavior than an evaluation of the outcome of a particular behavior. However, in this definition, "attitudes" are defined by their behavioral consequences but not by a characteristic that leads to the behavior. If the behavioral determinants of attitudes are related to valence, the question arises how valence can be represented other than as a belief about what is good or bad. This is discussed at a later point in this chapter.

Concept–Behavior Links

Independent of evaluative components, impulsive mechanisms have been invoked to account for the impact of conceptual representations on behavior. For example, it has been demonstrated that without the person's awareness, activating a particular stereotype facilitates stereotype-consistent behaviors (Bargh, Chen, & Burrows, 1996). Similarly, it has been shown that the imitation of others' behaviors may occur outside the imitating person's awareness (Chartrand & Bargh, 1999). More recent evidence suggests that priming participants with a stereotype facilitates consistent reactions. Specifically, Payne (2001) found that flashing a photo of a Black person was more likely to categorize an object that was presented immediately after the photos as a handgun whereas flashing the picture of a White person facilitated the categorization of objects as tools. Moreover, additional analyses suggest that this tendency was based on automatic processes and not on controlled mechanisms. While the basic finding was replicated, new evidence suggests that this effect was not driven by a global facilitation of evaluatively consistent categorizations but by the specific contents of the stereotype (Correll, Park, Judd, & Wittenbrink, 2002; Judd, Blair, & Chapleau, 2004).

Derived from the work on automatic processes, behavior has become the theme of yet another line of research. In particular, it has been argued that goals may operate not only if they are in the focus of the actor's attention but also without the person's awareness. Under the title of "unconscious goal pursuit" (Bargh & Gollwitzer, 1994), it has been demonstrated that priming a certain goal may influence people's behavior. As a consequence, nonconsciously operating goals are seen to enable people to control behavior "without invoking conscious choice or control processes" (Fitzsimons & Bargh, 2003, p. 152). However, one might suspect that the guidance of behavior by goal pursuit differs systematically from a behavioral control that is mediated by the activation of thought contents or the exposure to specific stimuli in the situation. For example, a goal is typically understood to be a concept that is embedded in a hierarchical structure, which provides means to circumvent obstacles. This is not necessarily the case for a behavior that is elicited by perceptual or imaginal stimuli. When it comes to automatization of goal pursuit, the question arises if those characteristics are maintained. In other words, how will people react to the blocking of a goal under conditions of automatic goal pursuit? These issues are discussed in more detail at a later point.

Taken together, under the influence of the concept of attitudes, social behavior was largely understood as the result of mental operations that can be described as reflective evaluation. More recently, as the focus of research has shifted toward automatic processes, mechanisms beyond reflection were included into the theorizing. In particular, an attitude's accessibility was recognized as an important determinant. Moreover, direct links between cognitive contents and behavior were identified. In a related development, the concept of attitudes as a content of consciousness was supplemented by an "implicit" variant that operates without the person's awareness.

These developments are a move toward an understanding of social behavior that increasingly acknowledges the impact of impulsive components. At the same time, however, it is obvious that automaticity is not the only component that describes impulsive behaviors. In addition, affect seems to be an important ingredient. In fact, some theories (e.g., Frijda, Kuipers, & Ter Schure, 1989) have argued that different emotions are associated with different types of action readiness. Fear, for example, is often related to flight whereas anger is linked to aggression. Interestingly, there is evidence that the causal relationship between behavior and emotion may be bidirectional. On the one hand, negative affect has been found to trigger aggressive behaviors (Berkowitz, 1993); on the other hand, facial or postural actions have been demonstrated to influence emotional experiences (Stepper & Strack, 1993; Strack, Martin, & Stepper, 1988). Interestingly, affective components may be an important ingredient even in experimental situations that seem to be driven by purely associative mechanisms. For example, Cesario, Plaks, and Higgins (2005) have demonstrated that the behavior that is elicited by the exposure to stereotyped category members (e.g., to elderly people) is modified by the affect toward the category. These researchers found that when "elderly" was primed, participants later walked more slowly if they (implicitly) liked the elderly but walked more quickly if they disliked the elderly.

However, in the reflectively dominated spirit of social psychological theorizing, affect has lost some of its zest and was domesticated into the ruling paradigm. Emotions were understood as attributed arousal (Schachter & Singer, 1962) and affect became a "source of information" (Schwarz & Clore, 1983) that would enter into inferences like any other piece of knowledge. Aggressive behaviors were seen to be largely controlled by their anticipated consequences (Bandura, 1973) and helping behavior was construed as a series of decision at various stages of information processing (Latané & Darley, 1970).

BIOLOGICAL ACCOUNTS OF IMPULSIVE BEHAVIOR

What are the biological factors that correspond to impulsive responding? Research on this issue has focused particularly on quick behaviors that are driven by perception, as well as on shortsighted behaviors. More specifically, psychological mechanisms that have been studied extensively include decreased inhibitory control and a strong attraction of rewards (Cardinal, Robbins, & Everitt, 2003; Winstanley, Theobald, Dalley, Glennon, & Robbins, 2004).

Inhibition

One integral aspect of impulsivity is the efficiency or ability to inhibit situationally triggered responses. A labora-

tory example of inhibition is the stop task, in which participants have to respond as quickly as possible to a go signal (e.g., a red light) unless the go signal is immediately followed by a stop signal (e.g., a tone). The ability to stop the response if a go signal is present serves as an index of inhibition and correlates with general tendencies of impulsive responding (Shachar, Tannock, & Logan, 1993). There are many studies linking inhibition to the neurotransmitter *serotonin* (Cardinal, Daw, Robbins, & Everitt, 2002; Soubrie, 1986; Winstanley et al., 2004). For instance, Winstanley and colleagues (2004) destroyed the serotonergic system of rats. As a consequence, these rats showed a starkly diminished inhibitory control in various behavioral tasks (see also Harrison, Everitt, & Robbins, 1999). Comparable results were obtained with human participants. Manipulating central serotonin levels pharmacologically, Walderhaug and colleagues (2002) observed less inhibitory control in a speed-accuracy test when serotonin was reduced (cf. Craen, Richards, & de Wit, 2002). Serotonin has also been linked to disinhibited behavior in a more general sense. For instance, low levels of serotonin facilitate aggressive behavior in humans (e.g., Berman, Tracy, & Coccaro, 1997; Bjork, Dougherty, Moeller, Cherek, & Swann, 1999; Bjork, Dougherty, Moeller, & Swann, 2000; Young & Leyton, 2002), and pharmacologically augmenting serotonin may reduce aggression (Cherek & Lane, 1999). Correlational data indicate that low levels of serotonin are tied to violence and impulsiveness in suicides (e.g., Asberg, Thoren, Traskman, Bertilsson, & Ringberger, 1976) or criminal offenses.

In addition to neurotransmitters, anatomical structures of the brain can also be related to inhibition. In a broad sense, many frontal-lobe functions involve the inhibition of triggered or ongoing responses (Gazzaniga, Ivry, & Mangun, 2002; Hawkins & Bender, 2002). One extreme form of frontal disinhibition is *utilization behavior*, a syndrome in which patients compulsively imitate other persons' behavior and immediately use objects independent of intentions, such as grabbing a cup and leading it to the mouth even if it contains no liquid (Lhermitte, 1983). The anterior cingulate cortex (ACC) seems to be involved in several executive functions such as directing attention, detecting action errors, or resolving conflict between action tendencies (Banfield, Wyland, Macrae, Münte, & Heatherton, 2004; Cardinal, Parkinson, Hall, & Everitt, 2002). Particularly, it is involved in suppressing externally triggered behaviors (Paus, 2001). For instance, lesions to the ACC cause failures to suppress no longer rewarded responses (Cardinal, Winstanley, Robbins, & Everitt, 2004). Likewise, lesions to the orbitofrontal cortex (OFC) induce disinhibited behavior in several behavioral tasks (e.g., Berlin, Rolls, & Kischka, 2004). Supplementing the link between serotonin depletion and impulsive aggression, there are also indications that frontal dysfunction may enhance aggression and antisocial behavior (e.g., Hawkins & Trobst, 2000; Paschall & Fishbein, 2002; Raine, Lencz, Bihrle, LaCasse, & Colletti, 2000). There is, however, growing evidence not only that inhibition is a function of the fron-

tal lobes but also that other brain systems may contribute to this function (for a review, see Andrés, 2003).

Attraction/Repulsion

Action without foresight implies a strong attraction toward intermediate rewards and/or weak inhibition. Many studies have addressed the tolerance of delayed reward as an index of impulsive action. Waiting for a delayed reward presupposes knowledge of the reward contingencies, the ability to inhibit the impulse of immediate consumption, and a motivational preparedness to sustain the waiting. Preferences for small immediate rewards over large but later rewards has been linked to low levels of serotonin (Bizot, Bihan, Puéch, Hamon, & Thiébot, 1999; Bizot, Thiébot, le-Bihan, Soubrie, & Simon, 1988; Liu, Wilkinson, & Robbins, 2004; Wolff & Leander, 2002). For instance, Wolff and Leander (2002) found that central serotonin levels that were pharmacologically elevated in pigeons increased the animals' preference for a larger but delayed reward over a smaller but immediate one. In a study by Cherek and Lane (1999), high doses of a drug mimicking the effect of serotonin increased the readiness of human participants to wait for a large but later reward. Given its strong link to inhibition, serotonin may influence the preparedness to wait by the same route.

In addition to serotonin, the neurotransmitter *dopamine* is also related to impulses of approach and reward (Cardinal, Robbins, & Everitt, 2002; Kelley & Berridge, 2002; Parkinson et al., 2002). Much of the evidence relating dopamine and approach behavior stems from the finding that amphetamines reduce the symptoms of attention-deficit/hyperactivity disorder (ADHD), which is characterized by lack of inhibitory control and strong discounting of delayed rewards. Amphetamines, at the same time, are drugs that increase dopamine in the brain (Cardinal, Robbins, & Everitt, 2002). Interestingly, amphetamine also influences animals' preparedness to wait for larger but delayed rewards. Particularly, Cardinal (2000) had rats choose between small immediate and large delayed rewards, while in one group the delay between choice and reward was bridged by the appearance of a light cue and in the other group no cue was present when the animals had to wait. Subsequently, animals were tested under the influence of methamphetamine, which is an amphetamine derivate. Methamphetamine decreased impulsive choices if a cue was present but increased impulsive choice if no cue was present. While introducing cues during delay generally helps bridge the temporal gap, dopamine presumably increases the power of such incentive cues and thus facilitates waiting (see also Dickinson, Smith, & Mirenowicz, 2000; Richards, Mitchell, De Wit, & Seyden, 1997; Wyvell & Berridge, 2000). Under many conditions, however, there are few consistent incentive cues to larger later rewards, but instead the immediate reward is cued. In the case of drugs, for instance, frequent consumption usually establishes many drug cues, which signal the positive effect of consumption. Hence, incentive cues, and thus dopa-

mine activation, may increase impulsive responding (cf. Evenden, 1999; Robinson & Berridge, 2003). It should be noted that amphetamines also elevate serotonin immediately but may lead to serotonin depletion as a proximate effect and thereby cause impulsivity and aggression in the long run (e.g., Moeller & Dougherty, 2002; Richards, Sabol, & de Wit, 1999; Verheyden, Hadfield, Calin, & Curran, 2002).

A brain structure strongly associated with attraction and repulsion is the nucleus accumbens (Acb) (Cardinal et al., 2004). Stimulation of this structure causes pleasure and is rewarding (Berridge, 2002; Ikemoto & Panksepp, 1999). In rats, destruction of the Acb leads to a reluctance to wait for a delayed reward (Cardinal, Pennicott, Sugathapala, Robbins, & Everitt, 2001). Importantly, it has been linked to reward prediction (McClure, York, & Montague, 2004), particularly to learning the incentive value of Pavlovian conditioned stimuli (Cardinal, Parkinson, et al., 2002). For instance, if an animal has learned to press a lever for food, the presentation of a cue that has been previously paired with the food will enhance pressing. In other words, the cue has an incentive function and motivates instrumental responding. Lesions of the Acb eliminate this incentive learning (Cardinal, Parkinson, et al., 2002), and stimulating the Acb exaggerates the motivating power of incentive cues (Wyvell & Berridge, 2000). At least partially, the Acb may play an important role in addictive behavior, which is often triggered by drug cues that cause an aberrant wanting of the drug (Cardinal, Parkinson, et al., 2002; Robinson & Berridge, 2003). A second important brain structure related to attraction and repulsion is the OFC. The OFC has been associated with learning reward contingencies in a flexible manner (e.g., Cardinal et al., 2004). It may thus be a structure promoting reflected choice adapted to complex and changing contingencies (Cardinal, Parkinson, et al., 2002; Rolls, 2000). Damage to the OFC leads to perseverance of responses, which are no longer rewarded or even punished (e.g., Berlin et al., 2004). It also causes a tendency in animals to prefer small but immediate over larger and later rewards (Mobini et al., 2002). In human subjects, OFC damage has been related to a lack of anticipatory fear in risky choices (e.g., Bechara, Damasio, & Damasio, 2000).

Summary

The selective review indicates that hot impulsive responding and its inhibition can be traced to particular brain systems. Up to now, research has primarily focused on impulsive motor responding and increased temporal discounting. Also, aggressive behavior (e.g., Berman, 1997; Brennan & Raine, 1997) and addiction (e.g., Kelley & Berridge, 2002) and fear-related impulses have undergone extensive research (e.g., Öhman & Mineka, 2001). The present review of biological processes underlying impulsive responding is by no means exhaustive. There are other brain structures involved in the mechanisms discussed previously, such as the amygdala (e.g., Winstanley et al., 2004), and the functions of the de-

scribed structures are more complex (for reviews, see Cardinal, Parkinson, et al., 2002; Rolls, 2000). In addition, we have excluded the biological bases of "cool" impulses (see Bargh, 2005). The endeavor of social cognitive neuroscience has just begun to relate more complex social impulses to their biological roots.

IMPULSIVE MECHANISMS DESCRIBED IN OTHER FIELDS OF PSYCHOLOGY

While nonreflective mechanisms have only recently moved into the focus of social psychology, other areas have long acknowledged that possibility of an impulsive determination of behavior. One example is personality psychology, where the concept of "impulse" is a core component in various dispositional frameworks (see Carver, 2005).

Personality

As mentioned earlier in this chapter, Freud's (1920) dynamic model of the person included impulse as the behavioral principle of the id, which had to be controlled by the forces of the ego. Thus, the dispositional strength of the ego was negatively related to impulsive manifestations of behavior. As a consequence, assessing the functions of the ego would be an indirect way of measuring impulsivity. This approach was adopted by Block (e.g., 2002), for whom ego control was the central organizing construct of personality functioning. This dimensional construct was defined by the poles "ego undercontrol" and "ego overcontrol." In terms of behavioral manifestations, undercontrollers were seen to seek immediate gratification, readily express emotions, and be "distractable, spontaneous, energetic, uninhibited, uncompulsive, gregarious, and easily influenced by environmental contingencies" (Kremen & Block, 1998, p. 1062). In contrast, overcontrollers are expected to overly delay gratifications, to inhibit emotional responses, and to be "constrained, nondistractible, persistent, perseverative, rarely obsessive, uncomfortable with ambiguities and uncertainties" (Kremen & Block, 1998, p. 1062).

A second control system in Block's theory is called ego resilience. It has the function to select the appropriate level of ego control in a given situation. In this system, behavioral adaptiveness does not hinge on the form of ego control but on the flexibility (or rigidity) with which it is applied to a given situation. Empirical evidence suggests that ego control and ego resilience are not entirely independent. In particular, it has been demonstrated that extreme levels of ego control are tied to low ego resilience (e.g., Asendorpf & van Aken, 1999). In fact, ego control is related to various manifestations of behavioral restraint. Among them are alcohol and drug use (Jones, 1971; Shedler & Block, 1990) and the ability to delay gratification (Funder & Block, 1989).

Another dispositional characteristic that is related to impulsive behaviors is the trait of conscientiousness in the five-factor model of personality (e.g., McCrae &

Costa, 1997). Conscientiousness is partly defined by a lack of impulsiveness and spontaneity and a tendency to engage in critical thinking (Hogan & Ones, 1997). The other endpoint of the dimension is impulsivity, which is described as a tendency to act without thoroughly considering possible options and consequences (Ashton & Lee, 2001). This may be dysfunctional if the task requires planning ahead and making decisions or functional if the task calls for quick thinking and taking advantage of unexpected opportunities (Ashton & Lee, 2001). The trait of conscientiousness was found to be related to different behaviors ranging from the preference for negotiations as a means of conflict resolution (hi C) (Jensen-Campbell & Graziano, 2001) to the aggressive use of humor (lo C) (Martin, Puhlik-Doris, Larsen, Gray, & Weir, 2003), to fewer arrests among prisoners (hi C) (Clower & Bothwell, 2001). There is even evidence that highly conscientious people live longer, because they may take better care of themselves (Friedman et al., 1995).

In his review of the literature on impulse and constraint in personality psychology, Carver (2005) points out that another trait in the five-factor model that may be relevant to impulsive behavior is agreeableness in its component of inhibiting negative affect. Both conscientiousness and agreeableness contribute to the factor psychoticism in Eysenck's (1970) three-factor theory of personality, whereas in Tellegen's (1985) three-factor model, it is his name for a trait that is related to conscientiousness. Behavioral data converge with the previous findings but also have negative emotional components. Specifically, psychoticism is related to antisocial behaviors (Eysenck, 1992) and respondents with low constraint were more likely to show criminal behavior (Krueger, 2002).

As impulsive behaviors are driven by the stimuli that are present in a given situation (and not by their more remote consequences), it seems plausible to look at people's habitual tendency to seek out stimulation as another dispositional basis. Zuckerman and his colleagues have identified "impulsive sensation seeking (ImpSS)" as a trait dimension that predicts people's willingness to take risks for the sake of having novel, varied, and intense experiences (Zuckerman, 1984). This dispositional characteristic had been frequently linked to risk behaviors such as substance use and risky sex (Wagner, 2001). Horvarth and Zuckerman (1993) found strong relations to risky violations of social and interpersonal norms, particularly in the domain of criminal behavior. Among adjudicated adolescents, alcohol problems and the failure to use condoms were found to be highly correlated with IMPSS (Robbins, & Bryan, 2004).

Impulsive Behavior from a Developmental Perspective

Jerome Kagan (e.g., Kagan, 1965), was probably the first psychologist who suggested a dispositional dimension whose poles were described as *impulsive* and *reflective*. His work on cognitive styles has predominantly focused on children's solutions of intellectual tasks where reflectives tended to show long decision times and low error rates because of their examination of all alternatives in a problem situation, whereas impulsives showed fast decision times and higher error rates. Implications of this construct have also been explored for particular learning disorders, reading disability, and hyperactivity (Messer, 1976).

From a more dynamic developmental perspective, impulsive behaviors have been studied in the context of their regulation and control by the person. Whereas Kagan described reflectivity as a function of both socialization and temperament, the temperamental explanation has subsequently assumed a more dominant role in developmental models. Most prominently, Rothbart and Derryberry (1981) differentiated between two components of temperament, namely, reactivity and self-regulation. In particular, reactivity (described as the more impulsive aspects of behavior) was understood to be modulated by self-regulation (or control), which serves to promote "subdominant" responses at the expense of dominant ones (Rothbart & Bates, 1998). This may occur in either an effortful or a reactive fashion. Eisenberg and colleagues (2003) have linked the latter to Block's (Block & Block, 1980) concept of ego control and have applied this notion together with effortful control in a longitudinal study of the development of social adaptation. Although the results are complex and mediated by the intensity of negative emotions, the findings suggest that both effortful and social control have an impact on social status through their positive effect on resiliency.

Impulsive Behavior from a Self-Regulation Perspective

Most attempts dealing with dynamic aspects of impulsive behavior have focused on the antagonism between spontaneous impulses and more enduring goals of the actor. They have suggested several mechanisms how the unwanted forces can be suppressed, constrained, or at least regulated. Thus, impulsive behavior is often understood as an unwanted outcome that needs to be corrected by appropriate interventions.

Under the label "self-regulation," "efforts by the human self" are studied that attempt to "alter any of its own states or responses" (Baumeister & Vohs, 2004, p. 2). In particular, these efforts focus on people's attentional processes, thoughts, feelings, and behaviors. Typically, the self is seen as either a regulating subject that is endowed with strength and willpower (e.g., Schmeichel & Baumeister, 2004) or an object of regulatory processes that follow cybernetic principles (e.g., Carver, 2004). In the first case, the question arises if this agent acts autonomously under the principle of free will. If this is the case, searching for the determinants of regulation cannot be a scientific endeavor. In the second case, it is not clear why the "self" is included to describe the process. If cybernetic mechanisms operate in the same fashion as other principles of thought, affect, and behavior, the addition of the "self" is at least misleading as it also suggests the existence of an autonomous agent.

In both cases, however, there is the—explicit or implicit—presupposition that there are two types of psy-

chological processes: superordinate processes that regulate and subordinate processes that are regulated. Most important, the execution of the superordinate process is assumed to consume energy in order to keep the subordinate process at bay (Baumeister, 2002). Because the supply for this energy is limited, excessive use will deplete it. However, its source will be replenished as a function of time and rest.

A similar dichotomy has been described on the judgmental dimension. Specifically, uncontrolled or "intuitive" processes are often seen to require correction (Strack & Hannover, 1996). Frequently, two processes are invoked that are specialized to either generate a response or to adjust or recompute it according to some superordinate standards of correctness. For example, the so-called anchoring heuristic (Tversky & Kahneman, 1974) has been explained originally by a more automatic response that is elicited by the anchor value and a more deliberative adjustment process that is often insufficient. In the domain of person perception, the characteristic of an observed act has been assumed to automatically activate a category to form an impression of the actor. Given the necessary capacity, the initial impression may be modified or corrected by taking the situational circumstances of the behavior into account (Gilbert & Malone, 1995; Trope, 1986). Beyond improving the accuracy of factual judgments, norms of political correctness were found to modify the judgments of other people. In particular, it has been demonstrated that persons' need to be unprejudiced reduced the influence of stereotypes on explicit judgments (Devine, Plant, Amodio, Harmon-Jones, & Vance, 2002; Dunton & Fazio, 1997; Plant & Devine, 1998).

It is important to note that these models are based on the assumption that only one of the two processes is operating at the same time. That is, depending on the requirements of the task, a more automatic and intuitive type of processing or a more controlled and systematic type of processing will be invoked (e.g., Chaiken, 1987; for a collection of various dual-process models, see Chaiken & Trope, 1999).

Applied to the general theme of this chapter, it can be argued that dual-process models may contribute to a better understanding of the dynamics of impulse by focusing on the uncontrolled component of information processing. In fact, if impulsivity is defined as a characteristic that includes a loss of control, mechanisms that operate in an uncontrolled fashion may be central components/precursors of impulsive behavior. However, most dual-process models (for a recent summary, see Smith & DeCoster, 2000) have no explicit link to behavior. Also, they do not include motivational mechanisms that may play a role in impulsive behavior. Therefore, we focus the remainder of this chapter on a recent dual-systems model that was particularly designed by the authors of this chapter (Strack & Deutsch, 2004) to explain social behavior and to identify its underlying mechanisms. In particular, this model is meant to explain the behavioral dynamics of impulsivity by focusing on the interaction of a reflective and an impulsive mental system. However, before we start discussing the reflective–impulsive model (RIM) in more detail, we would like to briefly discuss two models that are conceptually related to the RIM. However, despite their similarities, the current conceptualization either differs in important aspects or goes beyond the previous models.

Related Frameworks

Mainly based on research on delay of gratification (e.g., Mischel & Ebbesen, 1970), Metcalfe and Mischel (1999) have offered a "hot/cool-system analysis" of human behavior. As in the RIM, the hot and the cool systems operate in parallel and determine behavior in an interactive fashion. Unlike the RIM, however, the two systems are primarily defined by the presence or absence of affect. Specifically, the hot system is described as emotional in nature while the cool system's major characteristic is "cognitive." Although there are other distinctive features of the two systems, the affective quality of the hot system has a dominant role. As a consequence, impulsive behaviors are understood to be affectively driven and to be regulated by the force of willpower, which resides in the cool system.

Although affect is a possible ingredient of the impulsive system in the Strack/Deutsch model, it is not a necessary component. Because we define impulsive processing by the underlying operating characteristics, it does not hinge on the presence of affect. For example, the nonaffective operation of habits is understood to be a possible manifestation of impulsive behavior.

Despite their similarities, the RIM seems to be more general than the hot–cool model. Beyond phenomena of temptation and self-regulation, it is capable of accounting for habitual behaviors and of cognitive phenomena such as selective accessibility and judgmental heuristics.

Although described by its author as a global theory of personality, Epstein (e.g., 1994, 2003) has formulated a cognitive–experiential self-theory (CEST) that shares many basic characteristics of the RIM. Specifically, it proposes two interacting modes of information processing: a rule-based rational system and an emotionally driven experiential system. Moreover, the two models share the same operating principles for the two systems. That is, associative mechanisms for the "experiential" and the "impulsive" system and inferential mechanisms for the "rational" and the "reflective" system (see also Sloman, 1996).

At the same time, there are some important differences that need to be noted. While CEST assumes that the experiential system represents reality in the form of images, metaphors, or narratives and processes them in a "holistic" fashion, the impulsive system of the RIM adopts the structure of an associative network as it is assumed in many cognitive theories of human memory (e.g., Baddeley & Baddeley, 1990), which includes symbolic and abstract representations. Also, the RIM only invokes the two basic determinants of associative processing, namely, the frequency and recency of prior activation. As a consequence, the interactions between the reflective and the impulsive system are based on narrowly circumscribed mechanisms of cognitive accessibil-

ity that allow a precise identification of the cognitive operations that underlie judgmental phenomena (e.g., Mussweiler & Strack, 1999a; Strack & Mussweiler, 1997). Most important, perhaps, the RIM attempts to specify the mental operations in a sequential order to exactly predict their cognitive and behavioral consequences on a microlevel. For example, the RIM was able to generate predictions about different ways of processing negations in the reflective and the impulsive system (Deutsch, Gawronski, & Strack, 2005). In the domain of behavior, the RIM is endowed with mechanisms that describe specific links between the evaluative quality of information and the locomotive quality of the behavior. On this basis, it is possible to integrate findings about the influence of behavior on the selective processing of information (e.g., Förster & Strack, 1996; Strack et al., 1988) and about the facilitation of approach versus avoidance as a function of the valence of the processed information (see Neumann, Förster, & Strack, 2003).

In summary, there is no doubt that the two models are compatible in many of their components. At the same time, the CEST and its characteristics seem to be linked more to the global aspects of psychodynamics and personality theory while the RIM attempts to harness the findings from cognitive and social psychology to identify the precise mechanisms that are constituent elements of the general model.

THE DYNAMICS OF IMPULSIVE BEHAVIOR: THE REFLECTIVE–IMPULSIVE MODEL

To account for impulsive behavior, the RIM (see Strack & Deutsch, 2004, 2005) deviates from the widespread notion that behaviors may be classified into different types on the basis of the underlying process (see also Kruglanski & Thompson, 1999). Instead, it rests on the assumption that each human behavior is the joint result of two independent systems that have different operational principles. One system is called impulsive, the other reflective. Although their operations are described on a mental level of analysis, it is worth noting that neuroscientists have proposed a similar distinction. For example, Bechara (2005) has identified two neural systems that he describes as "impulsive, amygdala dependent" and "reflective, orbifrontal dependent."

The second assumption that is inherent in this model is that the two systems interact at different stages of the processing. In other words, impulsive and reflective processing occurs in parallel and not in a mutually exclusive fashion. More precisely, the impulsive system is assumed to be permanently active while the parallel operation of the reflective system depends on the cognitive capacity that is available. The following sections describe the operating characteristics of the two systems.

Elements of the Impulsive System

The most basic version of the impulsive system is identical to James's (1890) ideomotor principle (see also Lotze, 1852). That is, a perceived or imagined content may elicit

a behavior without a person's intention or goal. In line with recent neurological evidence on mirror neurons (Gallese, Fadiga, Fogassi, & Rizzolattti, 1996), the ideomotor principle can be extended to concepts that include a motor component. Specifically, it has been found in monkeys that the perception of movements activates neurons in the premotor cortex. From the perspective of the present model, the input goes to a behavioral schema that generates the appropriate motor execution on a muscular level. The activity is not executed if there exist competing influences in the impulsive system or a superordinate regulation.

However, the link between perceptual or conceptual input and the behavior may also operate in a less immediate fashion. Specifically, the behavioral implications of a concept may be activated by a concept (or an image) that is only indirectly connected to a behavioral schema. For example, Bargh and colleagues (1996) found that having been exposed to a stereotype about elderly persons caused people to walk more slowly (see also Cesario et al., 2005). If such behaviors are not assumed to be elicited by a decision or a goal, this requires a more complex structure of the impulsive system. In fact, the RIM assumes that in the impulsive system, the perceptual input is linked to the behavioral output by an associative network that is the result of past operations. Specifically, it represents previous inputs and provides a structure by linking it to other contents. Thereby, this network serves as a memory that connects the past to the present. Its most basic principles are associative in nature. It is assumed that like other associative-network models (see Smith, 1998), a link between elements is created by their joint activation, and its strength is a function of the frequency and the recency with which the activation has occurred. Thus, each element has acquired a specific activation potential (Higgins, 1996). The likelihood that the activation of one element will spread to another therefore depends on the existence of a link between the two and on its strength. The activation of a particular element may originate from one element with which it is strongly associated (like "black" and "white") or from several other elements that are activated at the same time. Thus, in the Bargh and colleagues study, it was not sufficient to activate the elderly stereotype to induce the slow walking; in addition, participants had to be induced by other means to engage in walking. Therefore, it seems likely that it was this joint activation that resulted in the behavioral effect.

Advantages and Disadvantages of Creating Habits

As may be apparent already from the present description, operations of the impulsive system require little effort. As a function of frequency and recency, the mere exposure to the appropriate stimulus seems to suffice to elicit a behavior. And if these principles are employed by practicing more complex sequences, the execution of behavior is greatly facilitated. In other words, a behavior has become habitualized and can be performed without much attention. However, the advantage of effortless execution is accompanied by a serious disadvantage,

namely, the slowness with which stable links are created (Devine, Plant, & Buswell, 2000) and particularly their rigidity and perseverance against change. Thus, the benefits a formerly effortful task enjoys if it is "made a habit" are matched by the effort that is needed to "break it" if it turns out to be undesirable.

The Role of Affect and Valence

While behavior can be effectively generated through a strong link to a behavioral schema, another mechanism is equally powerful. It is based on the valence that is experienced in the course of its execution. Specifically, a behavior that is associated with feeling better is more likely to be elicited than a behavior linked to feeling worse. This hedonic experience obeys the same associative principles. As a result, a stimulus associated with the behavior may be sufficient to elicit the feeling that will have a facilitating or an inhibitory function.

In general, the impulsive system is assumed to be oriented toward approach or avoidance, and this "motivational orientation" (Cacioppo, Priester, & Berntson, 1993) may be triggered by the experience of positive or negative affect, the perception of approach or avoidance, or the execution of such behaviors, as well as by the processing of positive stimuli. In the RIM, approach orientation is defined as a preparedness to decrease the distance between the person and an aspect of the environment. This may occur in an actual locomotion or as a symbolic operation (see Markman & Brendl, 2005) or an imagination. Similarly, avoidance orientation is defined as a preparedness to increase the distance between the person and an aspect of the environment. It can be achieved by either moving away from a target (flight) or by causing the target to be removed (fight). Within both motivational orientations, the specific type of response is determined by other influences.

The mechanism of motivational orientation is further described by two operating principles, namely, compatibility and bidirectionality. The compatibility principle states that the processing of information, the experience of affect, and the execution of behavior are facilitated if they are compatible with the prevailing motivational orientation. The bidirectionality principle states that this influence operates in both directions. Thus, behavior may influence affect and evaluation, and vice versa.

Research on regulatory fit (Higgins, 2000) involving promotion and prevention focus (Higgins, 1997) provides a good example of the importance of both motivational orientation and one kind of compatibility. When people have promotion focus concerns with accomplishment and advancement they prefer eager approach strategies to pursue their goals. In contrast, when people have prevention focus concerns with security and responsibilities they prefer vigilant avoidant strategies to pursue their goals. Regulatory fit occurs when individuals pursue goals in a manner that sustains (vs. disrupts) their current motivation orientation. Thus, goal pursuit with eager approach strategies fits a promotion focus but disrupts a prevention focus, and the opposite is true for vigilant avoidant strategies. The value of activities and outcomes can be intensified when people pursue goals under conditions of regulatory fit (e.g., Higgins, Idson, Freitas, Spiegel, & Molden, 2003).

In a general manner, these principles would probably not be too surprising. For example, self-perception theory (Bem, 1967) has long posited that behavior may influence attitudes. However, the underlying mechanisms are quite different. Specifically, this theory assumes that people use their behavior and the situational context to draw inferences about the underlying attitudes. More colloquially, they ask themselves what their attitudes must be if they behave in a particular manner. In contrast, the impulsive mechanisms of the RIM operate without drawing such inferences. The described facilitative effects are predicted to occur even if the meaning of a behavior is not apparent (e.g., Strack et al., 1988). Thus, the motivational orientation can be understood as a global predisposition of the impulsive system that facilitates the processing of information and the execution of behavior in a specific manner. There exists ample evidence for the postulated influences in both causal directions (Strack & Deutsch, 2004).

Although this general principle is a central element in the architecture of the impulsive system, it is important to acknowledge individual differences. One reason may be found in the divergent experiences to which people are exposed. Another reason, however, may lie in inborn temperamental factors. As Kagan and Snidman (1991) have demonstrated, infants differ in their tendencies to approach or avoid unfamiliar situations. And these different "temperaments" were found to influence people's subsequent development. Although their specific structure may be more complex than initially assumed (see Putnam & Stifter, 2005), the finding that innate tendencies toward approach or avoidance play an important role and shape personality characteristics is undisputed. It should also be noted that individual differences in motivational orientation not only concern the tendency to approach desired end states or avoid undesired end states but also occur at the strategic level, such as the tendency mentioned earlier for promotion-focused individuals to use eager strategic means of goal pursuit and prevention-focused individuals to use vigilant strategic means (Higgins, 1997).

At the same time, it is obvious that an adaptive processing system also needs to be oriented toward the specific requirements for the survival of the organism. This should be true for the survival of individuals and their genetic endowment (i.e., for nutrition and reproduction). For example, the impulsive system of people who are deprived of food should facilitate approaching responses toward stimuli that are food related. Similarly, sexual stimuli should elicit attraction particularly under circumstances that lead to reproduction. In fact, evidence (Seibt, Häfner, & Deutsch, 2005) suggests that people who are hungry react faster to food-related words if the required response consists of moving a lever toward the stimulus and react slower if the response is a movement in the opposite direction.

In sum, the impulsive system is specialized to adjust to the organism to the environment in a fast and automatic

manner. Its architecture is determined by a shared genetic endowment that is shaped by adaptive mechanisms, by an inborn disposition toward approach versus avoidance, and by the idiosyncratic history of impulsive operations.

The Reflective System

The advantages of the impulsive system are also accompanied by distinctive shortcomings. That is, its fast and effortless processing goes hand in hand with a considerable rigidity and a failure to perform certain tasks. Specifically, the principle of frequency impairs influences that come from a single piece of information. Similarly, the recency principle causes a distinct disadvantage for information whose impact lies in the past. Moreover, the process of adaptation would be greatly accelerated if changes did not require being personally exposed to the relevant stimuli but allowed learning from others' experiences. Particularly, learning from others' mistakes without suffering the negative consequences of their errors is a great advantage over having to have the negative experience oneself.

To achieve these benefits, there exists a second, reflective system whose operating principles differ from those of the impulsive system. Specifically, the reflective system is based on the generation and transformation of knowledge. That is, the reflective system assigns truth values to information that is contained in associative links and transforms these truth values through syllogistic operations. For example, the perception of a particular person may elicit the characteristic "old" in the impulsive systems. In addition, the reflective system would create a relationship between the perceptual input and the characteristic and assign it the value "true." On the basis of such a propositional categorization, further transformations can be performed. For example, the truth value can be reversed by applying the operation of a negation. Or inferences about other characteristics of a target may be inferred from information that is contained in the category to which it has been assigned.

The reflective system consists of a series of operations that are involved in this epistemic process. At the outset, a deictic procedure ("pointing and referring") assigns an input that may result from either perception or imagery to a category. Through syllogistic reasoning, the "propositional categorization" may become the basis of a "noetic decision" that has a factual and an evaluative component. That is, the reflective system creates knowledge about what is the case or what is good or bad. Structurally, the two variants do not differ and may often be inextricably intertwined. However, the evaluative component of the noetic decision may become the basis of a "behavioral decision" or a behavioral goal. Unlike decisions about facts and values, a behavioral decision focuses on the reduction of a discrepancy between a current state of the self and a positively evaluated possibility. The link between a behavioral decision to actual execution of the behavior is a process named "intending" (e.g., Gollwitzer, 1999), which is terminated if the behavior is executed or if the receding behavioral decision is already met.

Reflective–Impulsive Interactions

Up to this point, the two systems have been described in the major elements and in operational principles. Under the assumption that they function in an either–or fashion, we could continue describing their selective application to various tasks (e.g., Petty & Cacioppo, 1986). However, the RIM posits that the two do not operate by themselves but in close interaction. That is, at the various stages of processing, both systems influence one another. The degree of this influence, however, depends on the conditions that allow the reflective system to contribute. Specifically, it is assumed that the impulsive system is always operating while the parallel reflective operations depend on sufficient capacity and motivation. If they are not available, the impulsive system will have the upper hand.

In the following paragraphs, the interaction of the two systems is described in its general characteristics and in its manifestation at various stages of processing. First and foremost, the reflective operations that lead to the various decisions need an informational basis. Because this information is typically not part of the perceptual input, it must come from a preexistent store. The RIM assumes that the two systems provide different types of memories. The reflective system has a working memory with a very limited capacity and the possibility to directly address its contents (Baddeley, 1986). In contrast, the associative structures that are slowly formed by the impulsive system form a simple long-term store with an unlimited capacity (e.g., Johnson & Hirst, 1991).

This associative store plays an important role for the functioning of the reflective system. On the one hand, it provides the contents that are used for its syllogistic operations. On the simplest level, a propositional categorization can be performed only if the category is already available. That is, the label "elderly" can only be assigned if it is retrieved from storage. Similarly, inferences from a general knowledge about the elderly can only be drawn if an appropriate schema can be found in memory.

This retrieval may be triggered by the input. That is, if the input is strongly associated with a given category, it will most likely be activated and used for further processing in both the impulsive and the reflective system. As a second possibility, there may be no strong link between the input and a category. Then, the activation that is spreading along the associative links may trickle away. However, operations in the reflective system may require the input to be categorized. For this purpose, categorical information from the associative store must be retrieved. Then, the outcome of the retrieval depends not only on the search cue but also on the accessibility of the information. Specifically, we assume that each piece of information has a specific activation potential (Higgins, 1996) that describes the probability with which the information enters into reflective operations. The activation potential depends on the frequency and recency of prior activa-

tion. Thus, processes in the impulsive system may exert a strong influence on reflective operations. For example, people may categorize a target person as "reckless" simply because they had previously been exposed to this category in a different context (Higgins et al., 1977). However, the use of the activated category for a given target also depends on the category's "judged usability" (Higgins, 1996; see also Strack, 1992), which requires an operation that is part of the reflective system.

However, the activation potential of a piece of information is not only determined by the frequency and recency with which the impulsive system is exposed to a stimulus but also by its prior use in the reflective system. In other words, thinking about content will increase the probability that the same (or related) information will be retrieved at a later time. This may have severe consequences on judgment and decision making. For example, if a preceding judgment leads to a selective search of a particular type of information, a subsequent judgment may become biased by the selectively increased accessibility.

This mechanism of selective accessibility was identified to be a cause of judgmental influences under the name of "anchoring heuristic" (Tversky & Kahneman, 1974). That is, the observation that an absolute judgment will be assimilated toward the standard of a preceding relative judgment has been demonstrated to be a function of an increased semantic accessibility (e.g., Mussweiler & Strack, 1999a; Strack & Mussweiler, 1997). Specifically, it was shown (for reviews, see Mussweiler & Strack, 1999b; Strack & Mussweiler, 2003) that forming a comparative judgment had the characteristics of testing an hypothesis in that the standard is entertained as a possibility and in that information is being sought that is consistent with the standard. Even if the information that is found is not sufficient to warrant the acceptance of the hypothesis, the probability that this information will be activated at a later time has been greatly increased. If an absolute judgment about the target has to be formed after the comparative judgment, the previously used information will be more likely to enter into the judgment. As a consequence, the resulting judgment will be assimilated toward the standard of the comparative task. Thus, this anchoring distortion is not due to a direct influence of the anchor value but to the consequences of a specific cognitive operation that is used to generate a comparative judgment. Most important, this influence is introspectively inaccessible and cannot be prevented (Wilson, Houston, Etling, & Brekke, 1996).

These mechanisms exemplify a second type of interaction between the two systems. While a given activation potential in the associative store determines the likelihood that the information is used for reflective purposes, reflective processes modify the activation potential in the associative store, which may become manifest in subsequent operations. Moreover, reflective operations may change associative structures based on the same principles as direct input to the impulsive system. That is, the frequency and recency of co-occurrence in reflective operations determines the likelihood that activation spreads from one element to another in the same way as the frequency and recency of co-occurrence in perceptual exposure.

Synergisms and Antagonisms in the Determination of Behavior

In the RIM, the two systems converge in the final pathway to behavior. That is, the different operational mechanisms contribute to behavioral outcome. To understand the synergistic and antagonistic interplay between the two systems, a closer look at the immediate precursors of the behavior seems to be appropriate.

In the reflective system, behavior is caused by reasoning that generates a noetic decision about the desirability and feasibility of a particular action (cf. Ajzen, 1991; Bandura, 1977). As discussed before, the impulsive system may have already had its effect on those decisions through the accessibility of the activated information. However, a behavioral decision may not immediately result in a goal-directed behavior. Instead, the impulsive system may activate other behavioral schemas that are incompatible with the behavioral decision. Alternatively, the behavioral decision may refer to a later point in time. These issues are examined in turn.

From the previous discussion, it follows that the effect on the behavior depends on the compatibility of the input from both systems. That is, if both systems contribute to an activation of the same schema, the behavior will be facilitated. The execution may be smoothed even further because the contribution of the impulsive system will ease the execution and create a feeling of fluency and positive affect (Csikszentmihalyi, 1988; Winkielman & Cacioppo, 2001). The motivational implications of the cooperation between the two systems are obvious.

However, the two systems may also stand in competition if they activate incompatible schemas or if the execution of impulsive behaviors is inhibited by the reflective system. To take an example from regulatory focus theory (Higgins, 1997), one could imagine a situation in which the impulsive system experiences threat that instigates a prevention-focus preference for vigilant avoidant means but a strategic analysis in the reflection system concludes that eager approach means are preferable. Such antagonistic activation may elicit feelings of temptation and conflict. To gain the upper hand, the reflective system may apply knowledge about the impulsive mechanisms. In particular, it may divert attention from the tempting stimulus. Finally, it should be noted that although both systems may contribute to the execution of a behavior, the impulsive system can take on primary control if the operating conditions for the reflective system are fulfilled. As a consequence, it will be less likely that the behavior will be determined by assessments of feasibility and future consequences than by its immediate associations and the hedonic quality. Under certain circumstances, this may be of great adaptive value. In other situations, however, such impulsive determination may be disruptive and even damaging.

The second issue is about the delay of the execution of a behavioral decision, which is necessary if certain preconditions need to be fulfilled before the behavior can be performed. As a consequence, the temporal gap between the behavioral decision and the execution must be bridged. One possibility would be the permanent activation of the behavioral schemas. However, this would absorb a large amount of cognitive capacity. In addition, this would increase the risk that the behavior would be prematurely executed as a function of ideomotor processes. Because such a mechanism of rehearsal would be maladaptive, we suggest that the gap is being bridged by a process of intending (e.g., Gollwitzer, 1999) that automatically reactivates the behavioral decision, which in turn activates the behavioral schemas that are conducive in the situation. Following its original conceptualization, we also assume the intending process to be self-terminating in that it will be turned off if the goal of the decision has been fulfilled.

Intending also plays an important role if a current behavioral access to a goal is blocked. While the impulsive system will cause emotions like anger, which may result in destructive behaviors, the mechanism of intending may check the instrumentality of the obstructed goal in relation to a superordinate end and choose a different way to achieve the same objective. As with negation, we assume that the impulsive system may circumvent obstacles only through trial and error but not through circumventing obstacles by initiating a new operation of intending.

The Downside of Automaticity

The described transition from effortful reflective operations to effortless associative processing seems to imply a great potential for saving cognitive capacity. In fact, this possibility greatly facilitates the execution of myriad tasks (e.g., Salvucci, 2005) and allows the allocation of the scarce resource to novel tasks. The adaptive value of practice can therefore not be overestimated.

Recently, some researchers (e.g., Bargh, 1997) have even proposed that *all* "controlled" cognitive activities can be automatized. From the present perspective, this optimism is not shared. Rather, the different representational principles of the two systems suggest that some cannot be delegated to the impulsive system. In particular, this applies to representations of what is not the case.

As explained in the previous sections, the memory store of the impulsive system consists of associative structures in which different contents are linked. The only operation is the spread of activation along those links as a function of their strength. Although syllogistic operations occur in the reflective system, their outcomes may establish new links in the associative store. For example, the simplest operation of negating content may create a new characteristic that will then be linked to the original content. Thus, the information that a person is not guilty may lead to the conclusion that he is innocent. Thus, as a function of the reversal of the truth value of a simple propositional representation, a new associative represen-

tation will be formed. Through frequent association of the term with affirmative concepts, a negated term may acquire its own meaning (e.g., "not guilty" in a court of law). But if this link has not been established yet, the impulsive system cannot generate the implications of the negation. Instead, it may process the affirmative content.

Evidence for this possibility comes from various sources. Under a different theoretical framework, Wegner, Ansfield, and Pilloff (1998) had instructed participants to hold a pendulum and prevent it from moving. In another condition, they were specifically told not to let the pendulum swing along a line that was drawn on a piece of paper. Orthogonally to these conditions, participants had to perform a secondary task that required mental effort, a secondary task that required physical effort, or no secondary task as a control condition. The results of this study suggest that the negation that was implied in the experimenter's request was less likely to be processed if participants' attention was directed to another task. However, the affirmative base of the request remained effective. As a consequence, participants in the distraction conditions were more likely to do exactly what they were instructed to prevent. From the present theoretical perspective, this finding supports the notion that negations are generated in the reflective system while the impulsive system processes their affirmative bases. As a result, conditions that impair the reflective system will prevent negations from being formed and facilitate those behaviors that are implied by their affirmative bases. It is important to note that these affirmative influences are generated by the impulsive system, which is not affected by attentional load.

These mechanisms have important implications for any attempts at influencing people's behavior by using negations. For example, in the domain of advertising (Grant, Malaviya, & Sternthal, 2004) it was found that under limited cognitive resources, a brand was evaluated more positively if it was described by a negation that was negatively valenced ("not easy to use") than by a negation that was positively valenced ("not difficult to use"). In a related vein, written advice for elderly users of prescription drugs was not only less effective if it attempted to communicate what users were *not* supposed to do, it even caused users to remember the opposite implications (Skurnik, Yoon, Park, & Schwarz, 2005).

As a consequence, getting people not only to say "no" (or, "not") but also to think and act accordingly seems to work only under conditions that allow the reflective system to be operating. If these conditions are not met, the impulsive system will take over and the influence attempt will backfire. This should particularly be the case if negations are directed toward behaviors that are driven by needs and desires. As the described mechanisms of approach reside in the impulsive system, the reflective system may be at a disadvantage to begin with. As a consequence, negations should be particularly ineffective and even counterproductive under circumstances in which strong needs and desires are activated.

In fact, evidence suggests that this is the case. Generally, research has established that negated statements

are often (falsely) remembered as being true (e.g., Gilbert, 1991), that understanding negated statements consumes more cognitive resources (e.g., Mayo, Schul, & Burnstein 2004), and that automatic responses to negated information direct cognition and behavior in the opposite direction of what was implied logically (e.g., Deutsch et al., 2005; Wegner et al., 1998). More specifically, there are some studies demonstrating such paradoxical effects of negations in situations in which self-regulation is intended. Farrelly and colleagues (2002) compared the effectiveness of antismoking campaigns that used negations (e.g., *Don't smoke*) versus affirmative expressions (e.g., *Tobacco kills*). Exposed to negations, young adults were even more open to the idea of smoking, whereas the affirmative campaign positively changed attitudes toward tobacco. Similarly, drug-related intentions containing negations (e.g., *I will not touch these cigarettes*) will enhance the activation of the negated concept in memory (Palfai, Monti, Colby, & Rohsenow, 1997), thereby pushing behavior toward consumption.

Finally, evidence exists that governmental programs to promote sexual abstinence among teenagers may backfire. In a study that was reported in the news (e.g., newsobserver.com, January 31, 2005), researchers from Texas A&M University collected data suggesting that juveniles who had participated in abstinence-only programs were subsequently more likely to engage in sexual intercourse than those who had not. Although the original data are not published yet, these are consistent with predictions from the RIM. Specifically, it follows from the model that negating the possibility of sexual behavior increases the activation potential of sexual concepts. In a situation of temptation, those concepts will be more likely to be activated and the their impulsive consequence will determine the behavior.

Another characteristic of impulsive responding (i.e., shortsightedness) may be deeply rooted in the characteristics of associative processing. Particularly, representations of the past and the future require propositions (Roberts, 2002). For instance, thinking about a party that happened last month requires ascribing the temporal qualifier *last month* to the representation of the party. Hence, without reflection, processing stops at activating concepts. For instance, thinking of either a past or a future party is predicted to elicit similar impulses. At the same time, research on associative learning indicates that associations that are acquired without insight have a very short time horizon. For instance, Clark and Squire (1998) demonstrated the automatic acquisition of classically conditioned eye-blink responses only when the conditioned and unconditioned stimuli overlapped but not if there was a gap between the two stimuli. In the latter case, conditioned reflexes were only observable for participants who had gained insight into the contingency between conditioned and unconditioned stimuli. There are, however, some nonreflective mechanisms that support future-oriented behavior (Roberts, 2002). However, they appear to be limited to specific and inherited behaviors (such as hoarding in animals) or to depend on extended learning.

BEYOND "IMPLICIT ATTITUDES": IMPULSIVE INFLUENCES ON PSYCHOLOGICAL PHENOMENA

It is obvious that in many aspects, the dynamics of implicit phenomena resemble the processes of the impulsive system. However, the RIM has some features that are not shared by most accounts of implicit/explicit phenomena. First, reflective and impulsive processes in the RIM are assumed to run in parallel, and not in an either–or fashion. As a consequence, it is possible to identify interactions between the two systems at different stages of the processing. Second, reflective and impulsive processes are oriented toward behavior. Although it has been proposed that implicit and explicit phenomena may use different routes to behavior (e.g., Dovidio, Kawakami, Johnson, Johnson, & Howard, 1997; Wilson et al., 2000), few models specify the cognitive and motivational structures of such influences.

Different Types of Processing

Through their direct link to behavior, the impulsive mechanisms that are specified in the RIM are distinct from other dual-process models contrasting two systems that are specialized in either systematic or intuitive/heuristic processing (e.g., Chaiken, 1987; Kahneman & Frederick, 2002). While "systematic" processing is largely compatible with reflective operations, "intuitive/heuristic" processing is not necessarily "impulsive." The influence of affect on behavior exemplifies this point. In the RIM, the relation between affect and behavior is at least twofold. On the one hand, the experienced affect may enter into reflective operations "as information" (Schwarz & Clore, 1983) by being propositionally categorized. Then, its impact may depend on its representativeness (Strack, 1992). At the same time, an affective state may exert a much more direct impact on behavior through the impulsive system by influencing the motivational orientation and facilitating approach or avoidance.

From a RIM perspective, even intuitive or heuristic processing occurs in the reflective system. In other words, although a judgment may be simplified (e.g., by using an affective experience), it is still based on knowledge that obeys syllogistic mechanisms. Therefore, impulsive behaviors and intuitive judgments are conceptually distinct and should not be confused in dual-process models. As a consequence, the contribution of the RIM to a better understanding of heuristics is not that it provides a separate processing system for heuristic judgments but that it describes how input from the impulsive system enters into reflective operations and thereby simplifies judgment and decision making. Thus, judgments that are categorized as "systematic" have impulsive components. This has been demonstrated in the context of the anchoring effect, where the "systematic" generation of a comparative judgment increases the activation potential of standard-consistent information. As a consequence, the equally "systematic" generation of a subse-

quent absolute judgment is influenced in an inadvertent and uncontrollable fashion because the recall of the preactivated information will be "impulsively" facilitated (Strack & Mussweiler, 1997). Similarly, a motivational orientation will exert a facilitating effect on the recall of information that is compatible with a given behavior. The same is expected to be true for the influence of deprivational states (see Seibt et al., 2005). Therefore, the absence of system purity precludes a dichotomy of processes that is tied to characteristics of the judgment task. Rather, the RIM implies that depending on the specific circumstances, both the impulsive and the reflective system contribute to the generation of a judgment. Deeper understanding is reached not by classifying judgments as either "impulsive" or "reflective" but by identifying the relative contributions of both systems and by explaining their specific interactions.

Determinants of Counterattitudinal Behaviors

Although the suggested conceptual integration of impulsive mechanisms adds to a deeper understanding of judgmental processes, its main benefit lies in the explanation of behaviors that are inconsistent with people's attitudinal evaluations. We have mentioned before that such behaviors have primarily served the function of an independent variable in theories of cognitive consistency while its determinants remained largely unexplored. As a consequence, certain types of behavior have been given a marginal status or even been neglected in theorizing of social psychological theorizing. We discuss two examples in the concluding paragraphs.

Aggression

No doubt, aggressive behaviors have an enormous impact on social interaction. Moreover, they do so not only in massive outbreaks of violence but also in more subtle manifestations in everyday encounters. Given the pervasiveness of aggression, the relative scarcity of research may be due to the divergent conceptualizations of the phenomenon (see Anderson & Bushman, 2002). In fact, most accounts of aggressive behavior have been influenced by two theoretical orientations that invoke entirely different psychological mechanisms.

From the perspective of Bandura's (1977) social learning theory, aggression was understood as a behavior that was not counterattitudinal but guided by its anticipated and evaluated consequences. For example, it has been shown that the imitation of aggressive behaviors was reduced if the witnessed aggression was punished (Bandura, 1973), while children who observed assaulting conduct consistently rewarded were most aggressive (Rosekrans & Hartup, 1967). In this perspective, aggressive behaviors are a rational means of gaining a desired result, which do not differ from other instrumental behaviors. This view has specific implications for intervention, namely, to teach people that aggression "does not pay" and is a miscalculation of the expected outcome.

This account stands in stark contrast to an alternative explanation that has its roots in psychoanalytic theory (Freud, 1920). Specifically, aggression is understood as an emotional reaction that is not subject to computations of utility. In experimental psychology, this view has first become known as the frustration–aggression hypothesis (Dollard, Miller, Doob, Mowrer, & Sears, 1939), which has undergone various modifications. In the spirit of this perspective, Berkowitz developed a theory that combines affective antecedents with the accessibility of contents to predict aggressive behaviors. In his "neo-associationist" (Berkowitz, 1990) account, the encounter of negative effect and appropriate behavioral cognitions will automatically elicit aggressive behavior. To reduce aggression, it is not sufficient to influence people's beliefs about behavioral contingencies. Rather, an effective intervention must focus on either the emotional antecedents or the activation potential of aggressive thoughts.

Obviously, the mechanisms described in Berkowitz's theory are akin to impulsive processes whereas Bandura's social learning account is based on reflective principles. There were several attempts at combining these divergent perspectives. For example, a widely accepted distinction exists between "hostile" and "instrumental" aggression (Berkowitz, 1993). Whereas "hostile aggression" was described as emotionally driven, the "instrumental" variant was meant to be a thoughtfully chosen action to reach a goal beyond afflicting harm to the victim. Although this distinction captures the different mechanisms to some extent, it seems possible that hostility may delivered in a deliberate fashion and emotional aggression may not necessarily be driven by an intention to afflict harm. More recently, Anderson and Bushman (2002) have proposed to distinguish between two types of goals that are pursued through aggressive action. Specifically, they suggest that any aggression is based on an intention to harm a victim while some types also have ulterior goals, like the acquisition of some valuables in a robbery.

From the perspective of a two-systems model, it seems more meaningful to use the different qualities of the underlying psychological processes as the major criterion. That is, "impulsive aggression" can be defined as a harmful behavior that is not guided by a particular goal but is driven by a negative emotion, predominantly by anger. In contrast, "reflective aggression" is a goal-directed behavior to either afflict harm or reach an ultimate objective while accepting that harm is being afflicted. Of course, in the execution of the behavior, both types of aggression may blend. For example, anger and impulsive aggression may arise if obstacles prevent the actor from attaining the ultimate goal.

Psychologically, it might be questioned if it is useful to categorize a behavior by its consequences. In this case, if afflicting harm is a goal that is pursued by a person choosing the most appropriate means, why should the operational principles differ from other behaviors that are based on rational choice? Thus, if aggression is meant to express a unique psychological quality, it may make sense to reserve this term for a behavior that is not only harmful but also driven by negative emotion (i.e., driven by the impulsive system).

Temptation

An even clearer type of behavior that does not fit into the general perspective of attitudinal determination is that of temptation. Temptation is often defined as a power that directs behavior into an unwanted direction. In other words, it causes a behavior that is negatively evaluated. Typically, temptation is accompanied by a subjective experience that has been described as "craving" (e.g., Loewenstein, 2001). After having "fallen" into temptation, resuming the attitudinal direction of the behavior is often preceded by emotions of regret and even contrition. Temptation can be counteracted not by focusing on people's evaluative beliefs but by interfering with the impulsive mechanisms. For example, this may be achieved by blocking the perceptual input.

If temptation prevents people from doing what is good for them, it is not surprising that it promotes unhealthy behaviors. This is perhaps most obvious in the domain of drug consumption where people engage in a behavior they know to have severe negative consequences. Other examples are unprotected sex and overeating. Some temptations may eventually turn into addictions that are difficult to reverse. Still, research on these important phenomena is rare in social psychology or psychology in general. However, there are some exceptions.

One line of research that has addressed such issues was Walter Mischel's work on delay of gratification (e.g., Mischel, 1973). Using children as experimental participants, Mischel and his collaborators demonstrated the difficulty and often their failure to forgo a smaller but immediate reward for a larger but delayed gratification. Moreover, these researchers identified some conditions that prevent or foster the capability to delay. In particular, it has been found that directing the children's attention toward the larger delayed reward does not necessarily increase their ability to wait. Instead, it was found that children were even more likely to fall for the immediate reward (Mischel, 1973). This result flies in the face of theorists of rational choice (e.g., Frederick et al., 2002), who have argued that preferences for a smaller immediate gratification are due to a disproportionate discounting of the future outcome. Drawing people's attention to this outcome certainly reminds them of the value and reduces tendencies of discounting. At the same time, however, it increases impulsive tendencies of approaching the positively valued outcome, which is only possible for the immediate outcome. Thus, to understand participants' "irrationality" in intertemporal choice, it is not sufficient to assess people's evaluation of the outcome. Rather, it is necessary to take impulsive mechanisms that are not guided by knowledge or beliefs into account.

The second line of research that addresses the issue of temptation is self-regulation (e.g., Baumeister & Vohs, 2004). Here, temptation is seen as a force that has to be counteracted by the "power of the will" (Baumeister & Vohs, 2003). Specifically, willpower is fueled by a source of energy that will be depleted if too much of it is spent. This notion of energy depletion goes beyond mere attentional models in that it also postulates sequential effects. That is, the power of the will continues to be weakened after it has been employed to ward off tempting forces. While this notion of energy is certainly useful for a better understanding of self-regulation, it says very little about the mental processes that are involved if people resist or yield to tempting influences. It seems that recent research on implicit mechanisms may open a new avenue of research that has important clinical implications for the study of addiction (e.g., Deutsch & Strack, 2006; Wiers, Van de Luitgaarden, Van den Wildenberg, & Smulders, 2005).

CONCLUSION

This chapter has attempted to direct readers' attention to behavioral influences that are acknowledged less frequently in current social psychology than in other domains. In particular, the possibility that a behavior may be determined not only by the evaluation of its anticipated consequences has been recognized more often in the areas of personality and developmental and biological psychology than by social psychologists. Human behaviors that are influenced by factors exerting a more direct influence, and sometimes even standing in conflict with what people believe is good for them, have often been called impulsive, and the same label has been used to describe stable personality characteristics. Moreover, specific neuronal mechanisms have been identified that are in charge of impulsive (as opposed to reflective) processing.

In this contribution, we tried to reintegrate impulsive variants of social behavior into social psychology and used our own two-systems theory as a conceptual frame. In closing, we would like to suggest a taxonomy to classify impulsive behaviors. It has two dimensions that seem to be relevant. First, an impulsive behavior may be a manifestation of a *general* behavioral tendency or may be *specifically* directed at a more narrow class of stimuli. At the same time, the impulsive behavior may be *hot* or *cold*; that is, it may be accompanied by affect or valence or not. The resulting table consists of four cells that can be described as follows.

Impulsive behaviors that fall into the category of "general" and "hot" are illustrated by the results of a motivational orientation. The facilitation of a behavior that is accompanied by positive affect would be an example. The "specific" and "hot" combination is best illustrated by behaviors that originate from a homeostatic dysregulation, like hunger and thirst. Habits, in contrast, can be described as "specific" and "cold." Finally, the cell resulting from "general" and "cold" describes a behavioral disposition toward approach and avoidance. As mentioned earlier, it is also important to distinguish between behavioral dispositions toward approaching something desirable versus avoiding something undesirable and motivational orientations toward using eager approach strategies versus using vigilant avoidance strategies (Higgins, 1997).

The RIM that we have proposed as a conceptual framework to understand impulsive mechanisms is only a start. Beyond integrating aspects of human actions that are not

captured by studying the actors' beliefs about facts and values, the RIM attempts to shed light on phenomena that have been largely neglected by social psychologists. Because some of these behaviors (e.g., addictive or compulsive behaviors) may transcend the traditional borders of the field, both social and abnormal psychology may profit from a closer collaboration. On the one hand, insights from social psychology may provide a more basic understanding of the mechanisms underlying behavioral disorders. Equally important, abnormal behavioral manifestations may shed light on the processes that produce regular social phenomena. Just as visual illusions led to a deeper understanding of human perception, and judgmental biases led to identifying basic mechanisms of judgment and decision making, behavioral disorders have the potential to help us discover important processes that underlie social behavior.

CHAPTER 18

Social Identity and Self-Regulation

DAPHNA OYSERMAN

More than simply a store of autobiographical knowledge, self-concept is one's theory about oneself (Brown, 1998). It functions to organize past and present experience, illuminate one's future possibilities, sustain motivation, and control behavior in pursuit of the selves one might become. It provides answers to the basic self questions "Who am I?" and "How do I fit in?" and functions as a roadmap detailing how one goes about being oneself. Self-concept both feels stable, allowing one to answer the "Who am I" question by responding "Me," but is also fluid. Fluidity is experienced both as open potential—allowing one to believe in one's ability to grow, improve, and change—and as the result of automatic responsivity to situational cues. In this sense, who one is depends on what is relevant in the situation and what people who are like oneself seem to be doing.

A basic premise of this chapter is that motivation is identity based. Situational cues about how to be a self are assimilated into one's working self-concept except when these cues set up a contrasting standard of things "they" but not "we" do, feel, or strive to achieve. Individuals are motivated to pursue the goals ingroup members pursue using the means ingroup members use. What these goals and strategies are is something that is contextually cued.

This chapter focuses on an aspect of self-concept—social identity—and an aspect of the process of being a self—self-regulation. Self-regulation is the coordination of affective and behavioral processes to maintain a reasonably positive sense of oneself while behaving in a socially appropriate manner and working toward one's goals. Whether conceptualized in terms of action or inac-

tion, self-regulation links the present, one's current self and current behavior, with the future, one's possible selves and longer-term goal pursuit (Oyserman, Bybee, Terry, & Hart-Johnson, 2004). Self-regulation involves individuals engaging in or refraining from behavior in the immediate or ongoing present to increase the odds of attaining self-relevant goals later. Thus, self-regulation evokes both behavioral inhibition and behavioral activation systems (Avila, 2001). Individuals are motivated to do what ingroup members do and to avoid doing that which ingroup members do not do. In that sense social identity is central to self-regulation.

By using a social identity perspective (Abrams, 1999; Onorato & Turner, 2002) and explicitly connecting social identity and cultural psychology perspectives (Triandis, 1989) a basic convergent outline of social identity emerges. From both cultural and social identity perspectives, the self-concept is conceived of as fundamentally social. Social contexts influence content of self-concept, and one of the major goals of self-concept is to provide a sense of fit with and integration into a larger social whole. While social identity theories emphasize momentary shifts in situation and cross-situation differences in salience of personal versus social role-based identities, cultural psychology theories place more emphasis on chronic or stable situations and cross-national differences in salience of personal identities versus social role-based identities. By integrating these separate but compatible theories, their complementary theoretical assumptions about the social nature of self-concept can be joined. However, because neither cultural nor social

identity frameworks were intended as process models of how social identities influence self-regulation, an integration of these two models alone is insufficient as a process model of how social identity influences self-regulation. To create a process model, an identity-based motivation model is proposed. It is based in a self-schema framework (Markus, 1977) and links cultural and social identity perspectives to a broader social cognition framework (Higgins, 1996; Schwarz & Bless, in press) that outlines how social contexts influence social identities in ways likely to shift motivation and self-regulatory success.

The basic principles that guide this chapter are (1) that individuals are influenced by what comes to mind when making a judgment and (2) that what it is that comes to mind can be contextually or chronically cued. All things being equal, individuals assume that what comes to mind is relevant; in the case of social identity and self-regulation, what comes to mind is assumed relevant to the things "we" do, feel, or believe. What this "we" is, is perceived as stable and even central to identity but may shift over time. Images of what "we" do provide an outline of one's possible future, sketching out both the possible selves "we" can become and the kinds of strategies "we" use to attain these self-relevant goals. When possible selves thus articulated are linked with effective strategies they improve self-regulatory success. Conversely, when the possible selves thus articulated are linked with ineffective strategies they undermine self-regulatory success. In this way, social identities turn on self-regulation by turning on motivation to act like an ingroup member and engage in the pursuits that characterize ingroup members. Social identities provide both reasons to act and reasons not to act, and also ways to act or avoid action to attain goals. They not only cue us to try but also suggest standards for what trying looks like—what we do, what constitutes sufficient effort for us, and so on.

This basic perspective is congruent with current social identity models that suggest that social identities incorporate both positively valenced feelings of connection and specific group-defining attributes. It is also congruent with parallel arguments presented from a cultural perspective that cuing social connection makes salient social aspects of identity. Integrating these perspectives with a social cognition model allows for new predictions. Using an identity-based motivation perspective provides a mechanism to begin to explore otherwise puzzling discrepancies between espoused goals and self-regulatory behavior. While a social identity perspective proposes that all individuals have chronic propensity to make and maintain social connections and to define themselves in terms of these connections, a cultural psychology perspective emphasizes between-person and between-culture chronic differences in the propensity to focus on social connections. Neither perspective alone provides an articulation of how social situations cue self-judgments, when cued information will be included in or excluded from self-judgments, and how this influences self-relevant action over time.

Cultural psychology has proposed relatively stable differences (based in history, socialization, and social institutions) in the propensity to define the self and the social world in terms of groups and embeddedness within groups as well as relatively stable differences in the kinds of groups that are self-defining (e.g., friendship, family, religious, and tribal). Accumulating evidence suggests that chronic differences do exist but within a more malleable context than a stable differences perspective would allow. Moreover, while a cultural perspective suggests a dichotomized perspective in which the self is defined as either social or personal, an identity-based motivation perspective fills out what is meant by a "social" identity—suggesting that these identities also contain traits, propensities, and characteristics that motivate action. It seems likely, as suggested by social identity perspectives, that when social identities are cued, self-defining traits, propensities, and characteristics are those assumed to be ingroup defining.

This is an important advance because it suggests that motivation is not either personal or social but rather simultaneously socially based and personalized. Unfortunately, cultural psychology has not moved much beyond documenting that social identities may be more central to self-definitions in some cultures (and situations) than others. While, as outlined in the following sections, this lack of progress in cultural psychology may be due to the nature of the tasks cultural psychologists use to study self-concept, it is clear that when socially primed, social identities are evoked and these social identities are likely to contain attributes that feel ingroup congruent.

Perhaps most important, while socially based ingroup defining attributes feel distinct, they may or may not be different from attributes characterizing other groups. In some cases, these ingroup defining attributes may be defined explicitly as the opposite of or in direct contrast to the attributes of another social identity group. However, this is likely to be a special case rather than the norm. Indeed, when self-definition requires contrast with another social group, it can be undermining of self-regulatory ability if the other social group has control of important social goals or of effective strategies to attain these goals.

Just as ingroup defining attributes and valued goals may actually be common across groups, so may be strategies to attain them. Of particular interest are situations in which goals are common but ingroups differ in the extent that various strategies are seen as ingroup-relevant ways to attain these goals. For example, both men and women may be able to claim leadership goals as ingroup defining. However, to the extent that effective assertive or aggressive strategies to pursue this goal are "male," women may be more likely to use less effective strategies—and fall short of their leadership goal. Similarly, both boys and girls may be able to claim academic success as an ingroup defining goal. However, to the extent that effective strategies to attain this goal—studying, paying attention in class, following teacher instructions, handing in assignments that are neat and tidy, asking for help—are considered "female" things to do, then boys may be more likely to use less effective strategies—and fall short of their successful-in-school goal.

These are issues that can only be studied by thinking about the power of social identities. Individual women may want to lead and individual boys may want to do well

in school and may in fact be aware of appropriate strategies to effectively attain their goals. However, once social identities are contextually evoked, effective strategies may no longer feel appropriate. In this sense, social identities can be considered the most basic way in which we define ourselves. Once cued, evoked, or turned on, they override individual goals and aspirations unless individual goals and aspirations are sensed as congruent with social identities. In much the same way, social identities seen as more basic can override other social identities unless the various social identities are construed as compatible. Rather than being a woman or a leader, a boy or a scholar, compound social identities—female leader, athlete scholar, or future leader of one's community— allow for integration of goals and otherwise group-incompatible strategies. In each of the following sections, I outline how social identity has been approached, the additional utility of incorporating a cultural psychology framework, and advances made by integrating social identity, cultural psychology, and social cognition perspectives into an identity-based motivation model.

SOCIAL IDENTITY

Social identity theories have historically assumed a distinction between the self as defined by group memberships (the collective or social self) and the self as defined individually (the private self) (Hogg, 2003). All individuals can and do define themselves in both ways, switching between levels of self-definition depending on social contextual cues as to which level is relevant or useful in the moment (Turner & Oakes, 1986). Rather than describing identities as simply social as opposed to personal or private, social identities can be separated into those that focus on memberships in larger groups—collective identities—and those that focus on specific, face-to-face or personal relationships—termed "relational identities" (Brewer, 1991; Brewer & Gardner, 1996).

Collective social self-concepts contain information about the social categories to which one belongs, one's group memberships, as well as information about what members of one's groups are like, how they act, what they care about, and what their goals and values are (Abrams, 1994). Relational social self-concepts contain information about the specific relationships one is part of as well as how one is defined in relation to these specific others (Cross, Gore, & Morris, 2003; Cross, Morris, & Gore, 2002). Collective social identities focus on larger group identities such as those connected to memberships in a gender, racial–ethnic, nationality, religious, tribal, social class, or regional group. Relational identities focus on memberships in particular relationships— friendships, family, marital, peer, or work groups. Some social identities such as sports fan, fraternity member, student, or employee highlight the ambiguity of these distinctions in that any social identity could define both a particular relational identity and a general collective identity.

According to social identity theorists, social identities are at the heart of self-concept (Tajfel, 1972; Turner & Oakes, 1989). From a social identity perspective, we first attempt to make sense of the social world in terms of social categories and social category memberships and use individuating information only if category membership does not apply. For example, men are faster at responding "not me" to words previously rated as feminine after being primed to think of "I," "me," or "my" in a lexical decision task, presumably because thinking of themselves brings to mind their belongingness to the social category "men" and carries with it all the things that men are and are not (Mussweiler & Bodenhausen, 2002).

Social identities are hot social categories. They include a positive feeling of being included in some groups, a valenced affective response to being excluded from other groups, and concomitant positive feelings about ingroup defining attributes and negative feelings about outgroup defining attributes. That which is included in one's social identity is rated more positively than that which is excluded from it. For example, Reed (2004) showed that being primed to think of "we" increased liking for objects associated with ingroup. After using the "we" priming paradigm, a palm pilot described as a way to stay connected with family was more liked than when the palm pilot was not linked to family. Similarly, participants primed with "we" rated ambiguous statements as more similar to their own beliefs than participants primed with "they" (Brewer & Gardner, 1996).

In addition to gender and family, racial–ethnic, religious, and other social groups or categories may be incorporated into self-concept as social identities. Research has demonstrated influences on self-esteem, motivation, and self-regulation from categorizing oneself in terms of membership in a diverse array of groups including racial–ethnic groups (Oyserman, Gant, & Ager, 1995), gender (Schmader, 2002), cultural groups (Seeley & Gardner, 2003), and other culturally meaningful groups, such as blondes or athletes (Seibt & Förster, 2004). In each of these cases, positive and negative social stereotypes about in- and outgroup members exist.

In this way, social identities can be thought of as self-stereotypes in that they are generalizations about groups to which one belongs that influence the sense one makes of who one is and can become and one's place in the social world (Sherman, Judd, & Parke, 1989; Wilson & Dunn, 2004). Because social identities are part of self-concept, they can be used to make predictions about how others will respond to the self as well as what is likely to feel good and what one is likely to do well at. To be useful as the basis of predictions, social identities have to feel stable just as personal identities do (Swann, 1990). This preference for stability of social identity content was demonstrated by Chen, Chen, and Shaw (2004), following Swann's (1990) self-verification model. Chen and colleagues created social group identities in the lab. They demonstrated that participants preferred to interact with others who viewed their ingroup as they did, even if the social identity of their ingroup was negative.

Although research on social identities typically focuses on a particular social identity, self-concepts are assumed to contain multiple social and personal identities. Individuals can categorize themselves at various levels of ab-

stractness and can define themselves in terms of multiple social identities that connect and intersect in different ways (Burke, 2003; Roccas & Brewer, 2002). Moreover, social identities are not simply self-definitions in terms of social category memberships (e.g., "I am a girl" or "I am a Midwestern democrat"). Social identities also include the traits that come with the categories of gender, social class, political affiliation, and so on (Oyserman, Kemmelmeier, Fryberg, Brosh, & Hart-Johnson, 2003). Thus if being Black or African American is defined in terms of academic engagement then the social identity "I am Black" includes academic engagement so that behaviors such as studying, asking questions after class, or persisting at difficult schoolwork are part of one's self-definition. Generally, traits and characteristics seen as ingroup defining are more likely to be accepted as potential self-definitions as well.

In addition to highlighting the importance of one's group memberships in self-concept, social identity theory clarifies the contingent nature of self-concept content (Hogg, 2003). That is, depending on the situation, the self can be seen as separate, unique, and distinct from others, as part of a single social identity, as part of multiple, overlapping, or conflicting identities, or as part of a merged and connected set of identities. Group memberships provide not only a sense of what or who one is but also a way of locating oneself in relation to in- and outgroups (Hogg, 2003). Who one is includes the totality of self-definitions one has, including traits one has or may acquire because they are ingroup defining and traits one does not have or cannot acquire because they are outgroup defining. The totality of one's group memberships creates a distinct self (Hogg, 2003).

Some traits and characteristics are part of multiple ingroup definitions; for example, doing well in school is part of ingroup definition of a number of racial–ethnic groups. However, sometimes social groups vie to claim the same positive domains as defining their ingroup. A number of social identity theorists have noted that given unequal social power, majority groups are likely to be more successful in claiming valued domains as ingroup defining than minority groups so that minorities must develop alternative means of maintaining positive ingroup identity (for reviews, see Blanton, Christie, & Dye 2002; Branscombe & Ellemers, 1998). This between-group tension is likely to be particularly intense in areas that are critical for social advancement and social power. A group may be willing to concede some domains as defining an outgroup more than an ingroup (e.g., athleticism or prowess in sports, rhythm or talent in music) but not others (e.g., intelligence or academic performance). Thus, by highlighting the between-group tension or struggle to define one's group in terms that are both positive and sufficiently distinct from other groups, social identity theory clarifies that a socially constructed self is constructed from those ways of being that have been claimed by one's ingroup.

To maintain positive identities and avoid incorporating negative outgroup appraisals or stereotypes into concept of social identity, minority groups can reframe their ingroup identity in a number of ways. They can devalue the domains that define the outgroup, discount negative feedback about performance in outgroup defining domains, or take a more blanket approach and use ingroup rather than outgroup both for definitions of success and for feedback about progress toward self-relevant goals (e.g., Branscombe, Schmitt, & Harvey, 1999; Crocker & Major, 1989; Crocker, Voelkl, Testa, & Major, 1991; Osborne, 1995; Tajfel & Turner, 1986). All these ways of defining one's social groups are likely to have consequences for how one sees oneself and the goals one is likely to pursue, though social identity theory does not itself provide a process model of how content of social identity is likely to influence ongoing self-regulation.

Social Identity from the Perspective of Cultural Psychology

Compared with social identity-based descriptions, with some exceptions, cultural psychological models of the self have paid less attention to the traits contained within an interdependent conceptualization of the self. Rather, cultural psychology has emphasized the impact of cultural milieu on propensity to define the self in terms of the private and personal as compared to the social and collective (Markus & Kitayama, 1991). While social identity theories do not explicitly connect content of identity to cultural milieu, social identity reasoning is clearly relevant to differences in cultural milieu. Because cultures are shared systems of meaning that are intergenerational, they are likely to shape which groups are meaningful and how they are characterized, and in that sense culture is basic to social identities. Cultures provide standards of meaning so that members of a culture share not only a common language and location but also shared beliefs, perceptions, evaluations, and ways of acting (Oyserman & Lee, in press).

Although there are likely to be multiple dimensions on which cultures differ that are relevant to content of social identity and the process of self-regulation, the two organizing dimensions that have received the most attention are individualism and collectivism. Individualism has been defined as a focus on rights above duties, concern for oneself and immediate family, emphasis on personal autonomy and self-fulfillment, and basing one's identity on one's personal accomplishments (Hofstede, 1980). It is a worldview that centralizes the personal—personal goals, personal uniqueness, and personal control—and peripheralizes the social (e.g., Kâgitçibasi, 1994; Oyserman, Kemmelmeier, & Coon, 2002; Triandis, 1995). Individualism is contrasted with collectivism; whereas individualism focuses on the personal, collectivism focuses on groups and relations that bind and mutually obligate individuals.

According to a cultural perspective on the self, cultures can be divided into those that highlight values of individualism and those that highlight values of collectivism in socialization practices (see Oyserman, Coon, & Kemmelmeier, 2002, for a review). Societies that centralize individualism in socialization practices are more likely to promote parenting and other social institutional practices that bolster an individual or personal identity-

focused form of self-concept in which the self is seen as an independent, separate, and causal agent. Societies that centralize collectivism in socialization practices are more likely promote parenting and other practices that bolster a related, social or collective identity-focused form of self-concept in which the self is seen as part of social groups and having meaning and agency through group memberships (Kâgitçibasi, 2002).

Like social identity theorists, cultural psychologists have assumed that the self can be defined in terms of both social and personal identities. However, cultural psychologists have focused on between-culture differences in the likelihood that the self is social or personal in focus (Markus & Kitayama, 1991). Individualism implies a personal self-focus, that feeling good about oneself, being unique or distinctive (Oyserman & Markus, 1993; Triandis, 1995), and defining the self with abstract traits as opposed to social or situational descriptors are central to self-definition (Fiske, Kitayama, Markus, & Nisbett, 1998). Conversely, collectivism implies a group or collective self-focus, that group membership is a central aspect of identity (Hofstede, 1980) and that the valued personal traits contained in self-concept reflect the goals of collectivism, such as sacrifice for the common good and maintaining harmonious relationships with close others (Markus & Kitayama, 1991; Oyserman, 1993; Triandis, 1995).

As articulated by Markus and Kitayama (1991), this distinction has been described as differing models of the self, the self as "independent" and as "interdependent." Whereas the initial independent–interdependent self model drew from examples of differences between Japanese and Americans and has been criticized by researchers unable to empirically validate this particular cross-national difference in content of self-concept (e.g., Matsumoto, 1999), follow-up use of the model has moved well beyond a particular cross-national comparison. Indeed, the idea that self-concepts differ in foci parallels earlier work on gender differences in self-concept that documented differences in tendency to define the self in terms of agency versus connection (for reviews, see Cross & Madson, 1997; Markus & Oyserman, 1989). Whether due to gender- or culture-based socialization, it seems reasonable to assume between-person differences in the likelihood that one will conceive of oneself as an agentic entity that is separate or independent of others or as a part embedded within a relational web (Markus & Kitayama, 1991; Oyserman & Markus, 1993).

Although sometimes simplified as if to describe the self as either independent or interdependent, cultural psychologists do explicitly describe the self as defined in both ways (e.g., Trafimow, Triandis, & Goto, 1991; Triandis, 1989). That is, across all societies, both independent and interdependent elements are incorporated into self-concepts (Oyserman, Kemmelmeier, & Coon, 2002). What is likely to differ cross-culturally and across societies is the number of everyday moment-to-moment contexts that cue or turn on one or another aspect of self-concept. An emerging literature shows that when reminded to think of oneself as a social entity (part of a "we" group) or as a separate entity (a singular

"I") individuals do respond differently to social cues (Haberstroh, Oyserman, Schwarz, Kühnen, & Ji, 2002) and process and remember information differently (Kühnen & Oyserman, 2002; Oyserman & Lee, in press).

It seems reasonable that social identity and cultural perspectives be integrated to provide an identity-based sociocultural model of motivation, in which content of self-concept differs both chronically (based on differences in cultural milieu) and momentarily (based on momentary salience of social roles or group memberships). Whether due to chronic or momentary focus, when social roles or group memberships are salient, individuals should define themselves in terms of these roles and the traits and ways of being relevant to these. When individual difference is made salient, individuals should define themselves in terms of their traits and individual preferences. In both cases, motivation to act or refrain from acting will be identity based.

Unfortunately, the empirical base for such integration is as yet limited. An earlier review found that most cultural and cross-cultural research on content of self-concept was correlational and used as the dependent variable content coding from Kuhn and McPartland's (1954) Twenty Statements Task (see Oyserman, Coon, & Kemmelmeier, 2002, for a review). Although, as outlined below, quite a few priming studies were published in the past few years, these studies still rely on content coding of the Twenty Statements Task as the single dependent variable (see Oyserman & Lee, in press, for a review). While taken together, results of these studies do support the notion that content of salient or online self-concept shifts when one is primed to take into account social groups as opposed to individual differences, the Twenty Statements methodology does not lend itself to understanding the traits, characteristics, and future self-goals nested within social identities. To understand why this is so, the specific instructions and coding methods are outlined below. As will be seen, though at first seeming to be a reasonable method for highlighting content difference, the method does not live up to its promise.

Task instructions follow the form "In the twenty blanks below please make twenty different statements in response to the simple question (addressed to yourself), 'Who am I?' Answer as if you are giving the answers to yourself, not to somebody else. Write your answers in the order they occur to you. Don't worry about logic or importance. Go along fairly fast." These instructions are followed by 20 blank lines beginning with the words "I am." In some versions (e.g., Cousins, 1989), respondents are then told to go back over their responses and mark the five responses that are most important to them. Across all the studies using the Twenty Statements Task to study content of self-concept, respondents were primed with personal versus social self-focus, then generated responses to an "I am . . . " stem.

In a classic study, Cousins (1989) found that whereas Americans described themselves in terms of traits more than Japanese students when using the standard (decontextualized) version of the Twenty Statements Task, this tendency was reversed when the task was modified to ask for self-descriptions in context. Once contextualized,

that is, when instructions were to describe oneself "at home," "at school," and "with close friends," Japanese were more likely to use trait descriptors than Americans. Cousins shows that, instead of having decontextualized trait-based selves, Japanese participants had a set of contextualized trait-based selves. The idea that the traits and attributes that are part of a social identity (e.g., student) should become self-defining when that social identity is made salient is basic to social identity theory. However, this way of thinking about content of self-concept is not standard within a cultural psychology framework. Thus, this study was an important first step in making the link between cultural and social identity frameworks; cultural and social identity perspectives converge in predicting first that Japanese would be more likely to describe themselves in terms of the social identities (in this case as child, student, friend) and that once a social identity is made salient, relevant traits and attributes would come to mind. This interesting methodology has not been replicated by other cultural psychology researchers, with the exception of a conceptual replication is by Kanagawa, Cross, and Markus (2001), which unfortunately had inconclusive results.

Further cultural psychology research on content of self-concept used three different priming tasks. Trafimow and colleagues (1991) developed two of these priming tasks. In one priming task, participants read about a Sumerian warrior who needs to choose a general. The criteria he is described as using are the basis of the prime. In one condition, he makes the choice based on the general's traits (meant to be an individual self-prime). In the other condition, he makes the choice based on the general's ingroup connections to family and tribe (meant to be a collective self-prime). Participants read the paragraph and then respond to dependent variables. In the second priming task developed by Trafimow and colleagues, rather than read a passage, participants are asked to take a moment to think about either their similarities to or their differences from family and friends. The authors argue that thinking about difference should prime the private or personal self, while thinking about similarities should prime the collective, relational, or interdependent self. The third priming task involves a more subtle manipulation. Brewer and Gardner (1996) asked participants to read a paragraph and circle either first-person plural ("we") pronouns in a paragraph or third-person ("they") pronouns. This task was revised by Gardner, Gabriel, and Lee (1999). They created a paragraph-length story about a trip to the city in which pronouns to be circled were either first person singular pronouns (I, me, mine) or first person plural pronouns (we, our, us). Circling first-person singular pronouns was the independent self-prime whereas circling first-person plural pronouns was the interdependent self-prime.

Across studies using these primes to assess content of self-concept, the Twenty Statements Task was almost always used as the dependent variable. To determine whether an interdependent (social) self was evoked, content coding focused on collective or group-level self-descriptors (e.g., I am a woman or I am a student). The count or proportion of collective self-descriptors was pre-

dicted to increase following interdependent self-prime. To determine whether an independent (personal) self was evoked, content coding focused on personal trait self-descriptors (e.g., I am determined or I am smart). The count or proportion of trait-focused self-descriptors was predicted to increase following independent self-prime.

Across all studies, the modal response focused on traits (e.g., "I am smart"), coded as "private" self, with many fewer responses focused on group memberships (e.g., "I am a boy" or "I am a student"), coded as "collective" self. Less commonly coded for (or reported on) are responses focused on interpersonal aspects of self-concept (e.g., "I am shy"), those traits that explicitly require the presence of others. Some authors have suggested that these results imply that personal aspects of identity are always more motivationally powerful than social aspects of identity (Gaertner, Sedikides, Vevea, & Iuzzini, 2002). However, it is not possible to infer from the large preponderance of trait descriptors that content of self-concept is mostly focused on personal identities because, as demonstrated in Cousins's (1989) study and as argued by social identity theory, having primed social identities should increase the salience of traits relevant to the social identity. Because researchers in the described studies that follow focus on significant increase in collective identities but do not report on any attempt to code for social identity-relevant traits, it is not possible to tell if the traits brought to mind are appropriately thought of as part of personal or social identity aspects of self-concept.

Thus, six studies using the Sumerian warrior task show an increase in collective self-descriptors in the Twenty Statements Task when the collective versus the individual prime was used (between-subjects design). Participants were U.S. college students (Trafimow et al., 1991), Native American adults (Trafimow & Smith, 1998), European American college students (Ybarra & Trafimow, 1998), a nonspecified U.S. sample (Mandel, 2003), Hong Kong Chinese high school students and adults (Trafimow, Silverman, Fan, & Law, 1997), and European American and Asian American students (Gardner, Gabriel, & Dean, 2004).

In the latter study, "we" priming resulted in a significantly larger increase in responses focused on collective identity for Asian Americans compared to European Americans (Gardner et al., 2004). This may reflect the chronic propensity of people socialized in Asian cultures to conceive of the self in terms of social identities. Language used in each case was English, which may be an important contextual feature of the prime; Trafimow and colleagues (1997) found no effect of priming when materials were presented in Chinese. When responding in Chinese, about three-quarters of the responses were categorized as private and about one-quarter of the responses were categorized as social or collective. Of course, it is possible that responses in Chinese showed more subtle effects—traits may have been those relevant to the social identity brought to mind by the prime— though information about the identity the warrior prime brought to mind was not obtained.

Similarly, three studies using the similarities to/differences from family and friends prime show increase in collective self descriptors in the Twenty Statements Task when the collective versus the individual prime was used (between-subjects design). Participants are European American and Chinese college students in the United States (Trafimow et al., 1991), Hong Kong Chinese high school and college students (Trafimow et al., 1997), and female U.S. college students (Vohs & Heatherton, 2001). Language used in each case was English. As with the Sumerian prime, when Chinese was used in the Hong Kong-based sample, no effects of priming were found. However, effects do not appear to be limited to English. A fourth study conducted in German found significant results using as the dependent variable three collective self-items from the Singelis (1994) self-construal scale. Collective responses increased among German college students in the similarities to friends and family condition (Kühnen, Hannover, & Schubert, 2001). Because this study used a different dependent variable, it is not entirely clear whether effects would have been found with the Twenty Statements Task, again raising the question of whether current methods are adequate to detect effects.

The final set of studies shows shift in self-concept content following the pronoun-circling prime. In studies with European American participants the "we" prime increased interpersonal and collective self-descriptions compared with a "they" prime (Brewer & Gardner, 1996) as well as compared with the "I" prime (Gardner et al., 1999, 2004; Gardner, Gabriel, & Hochschild, 2002). Gardner and colleagues (2004) also showed effects with Asian American participants, effects that were significantly larger than in their European American sample; effects were of the same size whether the Sumerian warrior or the pronoun-circling tasks were used.

Thus, across prime type, "we" priming did shift content of self-concept toward social identities, suggesting that momentary contextual effects influence working or online self-concept. Thus, evidence supports a sociocultural approach to when social identity is cued or made salient. Evidence is limited by the fact that almost all the research involves American samples, and perhaps more importantly, by the method of combining all trait responses into a "private" self code. Studies were not set up to examine the content of primed social identities. It is possible that the traits described are those relevant to the primed social identity. This is a main feature of the social identity approach and is in fact congruent with a cultural psychology approach that would posit that the traits chosen to define the self are those that are culturally valued. Individuals who endorse individualistic cultural values are indeed more likely to describe themselves in terms of individualistically oriented traits, while individuals who endorse collectivistic values are more likely to describe themselves in terms of collectivistically oriented traits (Oyserman, 1993). Given that both perspectives would posit that individuals are motivated to take on the traits and characteristics valued by ingroups, the lack of research that could examine this assumption is particularly puzzling.

While cultural and social identity approaches both suggest that content of self-concept is cued by relevant contextual cues, neither approach provides explicit models of the process by which self-concept influences self-regulation. This process-level framing of self-concept has been articulated within a self-schema approach. As reviewed in the next section, a self-schema approach is highly compatible with a social identity framework and could be integrated within a cultural perspective, together creating an identity-based motivation process model.

IDENTITY-BASED MOTIVATION: A SELF-SCHEMA APPROACH

Social identity approaches assume a hierarchical organization to self-concept, suggesting that content of self-concept is organized within a series of hierarchically organized identities that may or may not feel connected with one another (Roccas & Brewer, 2002). The notion of hierarchical structure is not emphasized in the self-schema model; rather, this approach focuses attention on self-concept process and function (Markus, 1977; Markus & Wurf, 1987). Within a self-schema approach, self-concept is assumed to be made up of cognitive schemas about the self that mediate perception and regulate affect, motivation, and behavior, lending meaning and organization to thoughts, feelings, and actions and motivating action by providing incentives, standards, plans, strategies, and scripts for behavior (Oyserman & Markus, 1993). Rather than focus on hierarchical organization, this approach emphasizes temporal flow. Self-concept content includes an articulation of how one was in the past, is in the present, and might possibly be in the future. These temporal selves include both content relevant to social categories and social roles and content relevant to individual attributes.

The schema approach has already been adapted to a cultural frame (Oyserman & Markus, 1993). How the self is described, which content is included in self-concept, and the incentives, strategies, and scripts adopted to motivation and regulate the self are all likely to be culturally framed (Oyserman & Markus, 1993). That is, individuals are not schematic for all of the characteristics, traits, skills, and abilities that are true or observable about them (Markus, 1977). Instead, self-schemas reflect meaningful domains, those domains that are valued or marked as important in one's social context (Oyserman & Markus, 1993). Thus not all self-relevant content and knowledge becomes integrated into a self-schema, some images or conceptions about the self are tentative, fleeting, peripheral, or not well integrated, while others are more highly elaborated and more chronically accessible. It is these latter selves that function as enduring meaning-making interpretive structures, fostering coherence and forming the core of self-concept.

These salient identities (Burke, 2003; Stryker & Burke, 2000) or self-schemas (Markus, 1977) are packages of self-knowledge reflecting what an individual cares and thinks about and spends time and energy on, dimensions

along which individuals hold clear and distinct perceptions about themselves. They are domain-specific organized cognitive structures that provide generalizations about one's past and present and claims about one's possible future characteristics, actions, and skills (Montepare & Clements, 2001; Oyserman & Markus, 1993). As cognitive structures, self-schemas direct attention to self-relevant information and so influence what is perceived in the environment (Markus & Sentis, 1982). They direct memory and so influence what is remembered and what cues are recalled (Markus, 1977).

Information is assimilated into existing schemas where possible. Individuals process schema-relevant information more quickly and more efficiently than schema-irrelevant information (Markus, Smith, & Moreland, 1985) and are likely to misremember information in ways that reflect their own schemas (Markus, Crane, Bernstein, & Siladi, 1982; Markus & Wurf, 1987). Information irrelevant to self-schemas is likely to be disregarded (Markus, Hamill, & Sentis, 1987); ambiguous information is likely to be framed in ways relevant to self-schemas (Catrambone & Markus, 1987). When a domain becomes self-schematic, it becomes important to maintain a particular view of the self within this domain. Individuals are more likely to challenge, disbelieve, or try to refute negative or disconfirming schema-relevant rather than schema-irrelevant feedback (Markus, 1977). Negative or disconfirming feedback that is schema irrelevant is unlikely to result in mobilization of effort and resources to combat it.

Self-schema research has typically focused on self-concept at the level of personal or individual identities and has been criticized for being explicitly individually focused (Onorato & Turner, 2002). However, while the initial research focused on an individual trait (e.g., defining the self as "independent"), the self-schema conceptualization itself is not limited to personal identities (Oyserman et al., 2003). A self-schema approach has been used to examine the impact of self-concept defined in terms of social category memberships, such as being a man or a woman, being heavyweight and being a member of one's age category. This research shows that not all men and women have gender self-schemas (Markus et al., 1982), not all heavyweight people have "fat" self-schemas (Markus et al., 1987), and not everyone is schematic for his or her age (Montepare & Clements, 2001). Across each of these domains, those who are schematic are more likely to organize information in terms of these schemas and are better able than aschematic individuals to defend the self from negative schema-relevant feedback. Because they are likely to be chronically salient, social identity self-schemas, like personal identity self-schemas, are likely to influence ongoing meaning making, motivation, and persistence.

Following this logic, not all social roles and social categories to which one belongs will become schemas. For example, with regard to minority race and ethnicity a number of authors have argued that one's membership in a minority racial or ethnic group are likely to shift from being simply facts about the self to being important social identities only if life experiences make them central (e.g.,

Cross & Fhagen-Smith, 1996). When one's minority race–ethnicity is salient and contextually valued or marked, it is likely that self-schemas focused on this race or ethnicity will develop. Even when race–ethnicity is culturally marked, not everyone will have a racial or ethnic self-schema, just as not everyone has a gender self-schema (Oyserman, Brickman, & Rhodes, in press; Oyserman et al., 2003). Those who are aschematic will make sense of who they are without spontaneously thinking about race–ethnicity. Those who have a racial–ethnic schema are likely to make sense of themselves and their possibilities through the lens of this schema when it is made momentarily or chronically salient by social contexts. Like other self-schemas, racial–ethnic self-schemas (RES) are stable processing structures that guide the perception, encoding, and retrieval of information relevant to one's racial–ethnic group membership and the connection between membership in this ingroup and membership in larger society (Oyserman et al., 2003).

Following the self-schema model, race–ethnicity aschematic individuals will be more vulnerable to negative feedback based on race–ethnicity, including stereotypes or situational factors emphasizing their otherness, because they lack a cognitive structure to automatically process and fend off the negative self-relevant implications of racially tinged information. Those who define themselves in terms of their racial–ethnic ingroup are RES schematic and will make sense of their circumstance and focus their self-regulatory effort in terms of the content of the schema. Given that many groups would prefer to self-define in terms of generally valued traits and goals such as academic success, to the extent that RES does not explicitly contain links to these goals, schema-based processing carries the risk of disengaging effort from these goals (Oyserman et al., 1995, 2003; Rhodes, Oyserman, & Brickman, 2006).

Oyserman and her colleagues (2003) found evidence that racial–ethnic self-schemas function like other self-schemas in that they focused self-regulatory effort; when primed, RES that contained focus on school as ingroup defining improved academic persistence. When students' RES "bridged" ingroup and larger society by explicitly taking both into account, students were more academically engaged and fared better in school than when their RES focused on the ingroup only or they were RES aschematic. Controlling for prior grades, over the course of the school year, grades of low-income African American and Latino middle school students did not exhibit decline when their racial–ethnic identity schema contained both ingroup and larger society but did decline when they were aschematic for race–ethnicity and when their racial–ethnic identity schema was focused only on the ingroup.

Two subsequent studies of low-income middle and high school–age African American and Latino students also showed that content of RES influenced self-regulation (Rhodes et al., 2006). An experimental manipulation demonstrates the causal process: When content of RES was experimentally primed by having students write about what it means to be a member of their racial–ethnic group either before or after doing a math task, ef-

fects of bridging RES were found. That is, when RES was primed and content of RES focused on both positive connection to ingroup and bridge to larger society, math persistence improved (Oyserman et al., 2003). Thinking about motivation as identity-based clarifies the underlying process. When ingroup identity is contextually cued, individuals are motivated to engage in ingroup-relevant behaviors. If the ingroup is seen as linked with larger society, then larger societal goals like school attainment are cued. The impact of cuing larger societal goals and strategies should be positive—indeed increased persistance was found across various groups, including American Indians, African Americans, and Arab Israelis.

The notion that content of racial–ethnic identity self-schemas influences important behaviors was further explored in a series of studies examining the extent that health promotion behaviors are or are not included in social identity (Oyserman, Fryberg, & Yoder, 2006). Oyserman and her colleagues (2006) posed two questions:

1. Does racial–ethnic social identity include health promotion (such as exercising regularly) or unhealthy lifestyle behaviors (such as smoking or eating candy)?
2. How does content of racial–ethnic social identity influence cognitions and perceptions about health?

Minority college students rated health behaviors as White and middle-class things to do and were more likely to rate unhealthy than healthy behaviors as racial–ethnic ingroup things to do.

Not only did unhealthy behavior appear to be part of RES, but this content, when made salient, seems to have motivational consequences. When primed with race–ethnicity and social class, college and middle school students who are African American, Mexican American, and American Indian are significantly more likely to endorse a fatalistic perspective about health than in the control condition when social class and race–ethnicity are not made salient. A follow-up study with middle school students showed that priming RES also makes health information less cognitively accessible for low-income minority middle school students as compared to control condition. Follow-up studies with American Indian college students and reservation adults demonstrate that the undermining affects of making RES salient occur only when unhealthy behavior is incorporated into RES. Thus, an integration of social identity and self-schema approaches is fruitful in beginning to understand how social identities influence motivation and self-regulation.

Both sociocultural identity and self-schema approaches assume that content of self-concept is socially derived and demonstrate that when social contexts bring social groups or relational ways to thinking about the self to mind, social identities and social self-schemas are primed. However, neither social identity nor self-schema approaches provide an explicit process model of how social contextual information is incorporated into self-concept. To begin to build an identity-based motivation process model that articulates how social contextual information is incorporated into self-concept, it is necessary to turn to social cognition approaches.

Identity-Based Motivation: Integrating a Social Self-Schema Approach with Social Cognition Frameworks

A social cognition framework is a useful starting point in making predictions about the influence of contextual factors on salient content of self-concept and the influence of salient self-concepts on self-regulation and behaviors. In particular, the inclusion–exclusion (Schwarz & Bless, 1992, in press) or assimilation–contrast (Blanton, 2001; Schwarz, Bless, Wänke, & Winkielman, 2003) model provides insight into when social information is likely to be assimilated into one's judgment of who one is and what one might become and when this social information is likely to be used as a standard, excluded from self-concept, such that one's own successes or failures are judged relative to the standard. Because we live in a social world, social comparisons are ubiquitous. Answering the "who am I" and "how do I fit in" questions necessarily involves others, as role models, as yardsticks, or as parts of how we define ourselves.

The social comparison literature has classically proposed that individuals contrast themselves with others, feeling good when another is doing comparatively worse (a downward social comparison) and bad when another is doing comparatively better (an upward social comparison) (see Blanton, 2001; Collins, 1996, for reviews). Much research has focused on the use of downward social comparisons to improve self-evaluation (Gilbert, Giesler, & Morris, 1995; Pelham & Wachsmuth, 1995; Wills, 1981). These comparisons to a worse-off target provide a pleasing reminder of one's own superiority, especially if one cannot easily generate plausible parallels between the other's fate and one's own (Brewer & Weber, 1994). Downward comparisons are equally effective when the comparison target is an individual or a group; indeed, social identity theorists argue that downward outgroup comparisons contribute positively to social identity and that a primary function of social identities is to provide the basis for favorable self-evaluation (Tajfel, 1981).

Although downward comparisons are clearly effective, this strategy can be risky if downward comparison is seen as gloating (on a personal level) or when done on an intergroup level as blatant prejudice—whether racism, sexism, or classism or other negative group-based comparison. How can social comparisons avoid this particular problem yet still produce the desired positive self-evaluative boost? One possibility is upward comparisons, which can promote positive evaluation to the extent that the other is seen as a role model, or the other's success is viewed as similar enough to one's own to directly provide a boost (Collins, 1996). However, this strategy is risky because it clearly highlights the gaps between the other's positive characteristics and one's own less positive characteristics and it risks suggesting that these differences are unbridgeable, which may result in dampened self-

evaluation (Mussweiler, Rüter, & Epstude, 2004; Taylor & Lobel, 1989).

Another possibility is to avoid social comparison altogether and to simply assimilate the target's positive attributes into one's own self-evaluation, to "bask" in the reflected glory (BIRG) of the other (Cialdini et al., 1976). Assimilating the target to the self feels good without risk of threatening social comparison. Moreover, because assimilating the other's success does not denigrate the other, basking in reflected glory (BIRGing) is likely to be both safer than upward social comparisons and a more socially acceptable way to enhance self-worth than downward social comparisons. To BIRG, it is necessary to create a sense of closeness and to reduce boundaries that would otherwise trigger self-other contrasts (Arnett, German, & Hunt, 2003; Pelham & Wachsmuth, 1995). BIRGing is especially likely to produce gains in positive self-regard when the target's positive attributes are in self-irrelevant domains (Chen et al., 2004; Hirt, Zillman, Erickson, & Kennedy, 1992). Because the domain itself is not central to self-definition, the other's success can simply be included in the self and does not provide an upward comparison standard. By creating a symbolic link between the self and the target, one can feel good when the target succeeds. Thus, nonathletes can BIRG athletes; nonartists can BIRG musicians, artists, and the stylistically cutting edge; and the non-ecologically minded can BIRG those who preserve the natural environment.

In the initial demonstration of this effect, Cialdini and his colleagues (1976) showed that students were more likely to wear school-themed clothing and refer to their university as "we" rather than "they" on weekends in which the college football team won the game. In this way, students symbolically took on the positive attributes of the winning team. Follow-up research has focused on the impact of BIRGing of successful or prestigious individuals, organizations, and groups (e.g., a successful sports team— Bernhardt, Dabbs, Fielden, & Lutter, 1998; Boen, Vanbeselaere, & Feys, 2002; a high-ranked university—Bhattacharya, Rao, & Glynn, 1995; a winner in political elections—Boen et al., 2002; or a successful marketer—Arnett et al., 2003).

However, successful targets are not always assimilated into self-views. Lockwood and Kunda (1997) provide a useful example. After reading materials about a "superstar" student, participants were asked to rate their own current and possible future success. When rating current success, students used the information about the superstar as a standard, relative to which their own current success looked more modest than without the standard. When rating possible future success, however, students incorporated the superstar as a possible self and rated their own future possibilities more highly after being exposed to the superstar. That is, in the former case, the superstar was a standard against which one's own performance was contrasted, while in the latter case the superstar informed one's judgment about what was possible and so became incorporated or assimilated into the target of judgment—one's future chances. A number of

follow-up studies have asked whether the propensity to assimilate versus contrast information about the other into one's judgments about oneself is influenced by factors other than the whether the judgment is focused on the present versus one's possible future. In particular, researchers have asked whether the tendency to incorporate or assimilate information about another into one's self-judgment is carried by a chronic or primed tendency toward interdependence.

Research from a number of studies suggests that the tendency to assimilate or incorporate social information into one's self-judgment as opposed to using this information as a yardstick to assess one's relative standing is indeed influenced by interdependence. Kemmelmeier and Oyserman (2001) showed that both Palestinian Israeli women and European American women are more likely to assimilate a downward target into their self-judgment than are men. They replicate this work with Palestinian Israeli, German, and Turkish students asked to generate an upward social comparisons, again showing that women are more likely to assimilate their self-judgment to that of a same gender comparison who is performing better than they are, whereas men are more likely to show contrast effects (Kemmelmeier, Oyserman, & Brosh, 2005). Unfortunately, this work does not provide a direct assessment of the prediction that assimilation is driven by tendency to interdependence, relying instead on research documenting that women are chronically higher in interdependence than men (Cross & Madson, 1997).

Fortunately, this issue has also been addressed directly in the experimental literature utilizing the pronoun-circling prime developed by Brewer and Gardner (1996; Gardner et al., 1999). In a series of studies with Dutch college students, Stapel and Koomen (2001) show that "I" priming makes salient contrast with other; "we" prime makes salient assimilation with other. The pattern of assimilation with "we" priming is also shown in studies with German participants using the pronoun-circling task (Kuhnen & Haberstroh, 2004) and by writing down independence (interdependence)-relevant words in scrambled sentences (Kuhnen & Hannover, 2000).

Stapel and Koomen (2001) note that there is a self-serving asymmetric pattern to these contrast effects: Contrast effects are larger when comparing self to low-performing standard or when the other's positive results are in an unimportant domain. However, when instead of using the "I" priming task, participants were primed by unscrambling sentences with the words *compare, distinguish, differ*, and *opposition*, the asymmetry disappeared and respondents contrasted themselves to standards even when this resulted in negative self-definitions (Stapel & Koomen, 2001).

Although not addressed by the authors, this latter finding is important because it suggests that when focused on the self as different from or in opposition to others—as may occur in either intergroup or interindividual contexts—individuals are likely to use other's performance not as a model for one's own possibilities but as a contrasting standard, against which one's own perfor-

mance looks relatively worse. This negative assessment of one's current state and future possibilities may trigger disengagement from the goal, either because one no longer sees the goal as possible or one no longer feels competent to engage in relevant goal pursuit activities (Bandura, 2001; Wrosch, Scheier, & Carver, 2003). Indeed, Gardner and colleagues (2002) find that when primed to think in terms of social category memberships using the Trafimow and colleagues (1991) Sumerian warrior prime (in which participant read about a warrior who chooses a general due to his family and tribal ingroup connections), participants rated their friends as likely to succeed on a self-relevant task, whereas participants primed to think about individuals as having separate traits and characteristics (after reading about a Sumerian warrior who chose a general due to his skills) are significantly less likely to do so.

Although preliminary, taken together these studies suggest first that assimilation of information about another is more likely for individuals chronically (e.g., women) or situationally (e.g., after priming tasks) interdependently oriented and less likely for individuals chronically (e.g., men) or situationally (e.g., after priming tasks) independently oriented. Conversely, these studies suggest that using information about another as a contrasting standard from which to evaluate the self is more likely for individuals chronically or situationally independently oriented and less likely for individuals chronically or situationally interdependently oriented. When cued, ingroup belonging should evoke both motivation to be like the ingroup and information about ingroup characteristics. Ingroup belonging can be cued chronically or by specific situational information. Cues can be subtle and the process should proceed automatically once cued.

As a more general frame, the inclusion–exclusion model (Schwarz & Bless, in press) proposes that social information is included in the self-judgment unless the information is judged incompatible with the self. Social information that cannot be included in the self is used as a standard of comparison. Social information is more likely to be judged incompatible with self-concept when it is extreme relative to current self-content and when the social information is explicitly or implicitly presented as separate from the self. The inclusion–exclusion model articulates the circumstances in which information about another will be included in the self, so that the other's successes and failures become part of oneself, and when this information will be excluded from the self, so that the other's successes and failures will become a standard of comparison.

Because social information that is irrelevant to the judgment task is unlikely to be used, not all social information will be included in or excluded from self-judgments. Some social information will be ignored. Relevance is subjective. Thus, for some, knowledge of American students' low ranking in international comparisons of math and science achievement creates a sense of urgency because international comparisons are relevant. Other countries are a standard against which "we" are doing badly. For others, the information is simply not relevant—other countries are not "us." Of course, what constitutes a relevant comparison is likely to be context dependent. A social cognition perspective makes clear that what social information is deemed relevant and how it is used is highly dependent on what makes sense in context. Meaning is made in the moment, it feels sensible, obvious, and natural in the moment, but slight shifts in context will shift meaning.

Early Formulation of the Self as a Motivational System

Once an image has been deemed relevant and either included in self-definition or formulated as a standard against which one should compare oneself, how does the self proceed? James (1890/1927) developed what can be considered a precursor of current self-motivation theories. He conceptualized the self as the metacognitive experience of being a self on the one hand and as containing cognitive and affective content (self-knowledge and self-feelings) on the other. He proposed that all things being equal, individuals would desire to be and become all possible selves simultaneously ("a Greek scholar, a bon vivant"), expanding to incorporate ever more self-goals to strive toward.

He argued that this tendency to incorporate ever more selves as possible future selves is limited or reigned in by a number of factors. First, some self-projects simply cannot be pursued simultaneously because the actions needed to pursue them are incompatible. The bon vivant wants to stay out late with friends; the scholar wants to return to his books—resulting in the need to choose which of two competing goals to focus energies on. Second, some self-projects turn out to be unattainable either because of failure of strategies to attain the future self or because of lack of ability. After years of lessons fail to create the desired child prodigy self, and yet more years fail to create even a gifted pianist self, at some point the self-goal will need either to be abandoned (e.g., "I played the piano when I was younger") or reshaped (e.g., "I play the piano just for fun").

When future imagined selves cannot be worked on, they are unlikely to engage much attention or affective response and so may wither away. Holding onto a blocked or failed self-goal or possible self has negative consequences for self-valuation. Continued engagement in blocked or failed self-projects is limited by one's ability to tolerate the negative feelings that failures to attain possible selves entail. Rather than continue lessons imagining that one will become a gifted pianist, one may over time revise the goal to instead imagine an "enjoying music" possible self or to abandon the goal altogether.

Within James's model there is an implied innate desire to self-regulate and to attain ever more self-goals. This desire is limited only by the need to succeed in some proportion of one's efforts. In James's model, self-regulation is associated with self-esteem, operationalized as proportionate success, the ratio of selves one is attempting to become to selves one is succeeding in attaining.

Thus, James's framework articulates a model of self-regulation that is focused on incorporating all the selves a person can imagine becoming. The system is assumed

to have finite energy, so that some self-regulation tasks are incompatible with each other. Self-regulation is also assumed to have emotional consequences; it feels good to succeed at self-regulation and it feels bad to fail. These components are present in current social cognition frameworks of self-regulation as well.

WHAT IS SELF-REGULATION?

While self-regulation is a universal capacity that develops along with other cognitive and socioemotional capacities, it is at the same time a deeply personal and self-defining capacity. Not only is motivation identity based, but success at pursuing a goal feels good because it reinforces the identity in which it is based. Self-regulation is the self-in-action—successful self-regulation feels good; failed self-regulation feels bad. Without the capacity for self-regulation, goal attainment would be impossible. Self-regulation entails the channeling of energy, effort, and motivation toward a goal, the strategies relevant to goal attainment, and the goal itself. Thus when racial identity is cued, one is primed to pursue relevant goals. If goal pursuit is successful, it feels good in part because successful goal pursuit affirms membership in the social identity group.

Self-regulation or self-control is the coordination of neural, cognitive, affective, and behavioral processes to moderate reactivity, excitability, and arousal (Rothbart & Rueda, 2005). Self-regulation requires both behavioral inhibition and behavioral activation (Avila, 2001). Self-regulation allows planned, sustained, and sequenced action in service of desired end states to occur (Mischel & Ayduk, 2004). It involves controlling, channeling, or mastering the self to produce sought after results whether these results are attaining a better mood, more satisfactory grades, being liked, fitting in, or gaining power (Brandstätter, Lengfelder, & Gollwitzer, 2001).

Self-regulatory capacity can be described as a motivational resource that can be turned on to pursue one's goals. It can also be described as inhibition of a dominant response—sleeping in, hanging out, saying whatever comes to mind, eating snacks, and replacing the dominant response with another response—getting up at the sound of the early alarm, doing homework, maintaining civility during an unpleasant social event, eating healthy. Thinking of self-regulation as inhibition implies that we self-regulate because we have to, not because we want to (Baumeister, 2002; Baumeister & Heatherton, 1996).

Yet competent self-control is rewarding (White, 1959, 1960). Because it is essential for goal striving, self-regulation is a necessary component of happiness; to self-actualize (Maslow, 1970), to attain a state of "flow" when one is positively focused on fulfilling life tasks (Csikszentmihalyi, 1996), one must be able to focus attention on one's goals. Because it is critical for goal attainment, self-regulation is basic to human happiness, self-worth, and social regard (Bandura, 2001). Efforts to self-regulate are not necessarily effective; one may or may not succeed in movement toward one's goals and self-regulatory efforts may backfire and make things worse

(Thayer, 2001). Individuals differ in their propensity for and success with self-regulation (Baumeister & Vohs, 2003; Bogg & Roberts, 2004).

Self-regulation may be in service of finding out what one can do, convincing others of one's worth, changing or improving one's self, obtaining resources for one's self, or fitting into one's social context. Self-regulation always involves focusing attention and resources on responses relevant to a focal goal to the relative neglect of other goals. At any particular moment in time, focusing attention on one self-relevant goal necessarily means reduced attention to other self-relevant goals. Focusing one's attention on one goal (e.g., the goal of completing homework) means not focusing on other self-relevant goals such as being athletic, popular, or a cooperative group member.

Self-Regulation Is a Socially Scaffolded Developmental Process

Whatever capacity for self-regulation one has will be brought to bear when identity is turned on. There is a normal developmental increase in self-regulatory capacity, a shift toward increased ability to control reactions to stress and to maintain focused attention and increased ability to interpret one's own and other's mental states in order to successfully predict the likely responses to one's self-regulatory efforts. Early effortful control involves ability to focus and shift attention while maintaining perceptual sensitivity, inhibitory control, and low-intensity pleasure (Rothbart & Rueda, 2005). Although infants differ (Bronson, 2000), there is a normative developmental process of improved control over reactivity, excitability, and arousal (Rothbart & Rueda, 2005). Ability to self-regulate is related to early response to novel stimuli, termed "reactivity," "excitability," or "arousability," but also develops through maturation and experience with the social world. Early caregiving involves attunement to individual differences in reactivity and setting up appropriate experiences that scaffold infants' efforts at self-regulation, providing infants with a sense that the context can be controlled (Brooks-Gunn & Markman, 2005; Serbin & Karp, 2004).

Such maternal scaffolding is predictive of successful self-regulation at age 16 months (Conner & Cross, 2003). Effortful control, as assessed by gaze, is observable at 9 months (Bronson, 2000) and predicts effortful control in toddlers at age 18 months (Bronson, 2000). Effortful control that is discernible in toddlers (18 months of age) (Rodriguez, Ayduk, & Aber, 2005; Rodriguez, Mischel, & Shoda, 1989), becomes stable across lab tasks by age 2.5 (Rothbart & Rueda, 2005). Early (preschool) ability to delay gratification predicts adolescent academic and social skill (Ayduk et al., 2000).

At later ages, scaffolding by parents and other adults entails focusing children's attention on effort (Dweck & London, 2004). The actions that allow for self-regulation—not eating that extra bowl of potato chips, not having that third brownie—may not sound hedonically satisfying yet developmental research suggests

that self-regulation is intrinsically pleasurable (Bronson, 2000). Feeling that one is controlling contingencies is likely to produce a positive affective response whether the feeling is that one is making positive things more likely to happen (self-will) or that one is making negative things less likely to happen (self-control).

As children learn about and experience the world, they begin to develop theories about contingencies. The capacity to self-regulate develops from this early base of "if I–then" relationships—that kicks and hand thrusts produce movement of a rattle or mobile, that crying engages soothing caregivers' attentions. Because self-regulation is so essential to humanness, caregiving is likely to universally foster this emerging self-regulatory capacity. Early self-regulation is scaffolded by caregivers who set up environments to facilitate it. Children experience "if I–then" contingencies within social contexts that set up which goals are worth pursuing and what strategies are worth using. These "if I–then" contingencies alone do not direct motivation but rather are cued a part of identity-based motivation. Thus, when identity as "girl" is cued, motivation to act like a girl is cued, if girls behave well in class, pay attention to the teacher, and take notes, these identity-based behavioral beliefs will be translated via a series of "if I–then" contingencies to behavioral sequences to become more like a "girl."

Self-Goals and Self-Regulation

Self-goals are temporally proximal or distal images of oneself in the future. They can be images of the selves one ideally wants to become or feels one ought to become (Higgins, 1996), the possible selves one expects to become, hopes to become, or is afraid one may become but wishes to avoid becoming (e.g., Markus & Nurius, 1986; Oyserman et al., 2004). The gap between one's current self and these future selves is assumed to motivate efforts to reduce the gap or discrepancy between current selves and positive future selves and increase or enlarge the gap between oneself and negative possible selves (Carver, Sutton, & Scheier, 2000).

Self-regulation in pursuit of a self-relevant goal may fail in spite of ongoing investment of effort due to utilization of inappropriate, ineffective, inefficient, or even iatrogenic strategies. What we do to try to attain our goals can produce much heat but little light or even make things worse (like dieting strategies that involve such rigid monitoring that they eventually cannot be kept up, resulting in eventual weight gain instead of loss). Self-regulation may fail not because the outcome is not valued but because the effort required to attain the goal is underestimated or because the strategies brought to bear are not effective.

Even when the outcome is valued and strategies are effective, self-regulation may fail if attainment is directed to another goal. Clearly, not all goals can be pursued with equal vigor. Individuals are likely to have multiple goals that might draw their attention and resources. Goals are likely to differ along a variety of dimensions—some are short term and concrete, others longer term and more abstract. Pursuing some more proximal goals may increase chances of attaining more distal goals—the goal of college is more likely when the goal of good high school grades is pursued, the goal of good high school grades is more likely when the goal of good middle school grades is pursued. Indeed, when the future feels far away, self-regulation may require linkage of distal goals to more proximal ones or goals will not be pursued at all.

But goals are not necessarily compatible with one another, so that focus on one goal may necessarily mean reducing likelihood of attaining another goal. For example, the goal of buying a first home may not be compatible with the goal of being home with one's children if buying a home requires saving money and saving money requires working longer hours. Assuming that individuals have multiple goals, some in the present and some in the future, some congruent and others incongruent, not all goals can be simultaneously pursued. Self-regulation to attain one goal must mean at least temporary abandonment of another goal. A key question then is which of competing goals will be chosen for self-regulatory attention.

As outlined in Figure 18.1, personal and social identities include all these future images. These selves carry motivational characteristics, providing reasons to act and to refrain from acting in any particular situation, specific behaviors to engage in as well as persistence and desistence scripts (how much and how long to keep trying and when to pull back effort). In this way, social identities scaffold one's goals. To the extent that goals trigger action, when these social identities are brought to mind, they should trigger goal-focused behavior. Because even skilled behaviors, once acquired, are grouped together as behavioral sequences or scripts that can be performed without conscious awareness (for reviews, see Kruglanski et al., 2002; Wegner & Bargh, 1998), identities do not necessarily need to be consciously triggered for relevant behaviors to occur. That is, an identity carries with it behavioral tendencies, scripts for action, that are cued when the identity is cued.

While all cybernetic-control or feedback models (e.g., Carver & Scheier, 1990) assume motivation to work toward becoming like positive goals and to avoid becoming like negative or antigoals, these models do not suggest particular linkages between goals and how they are worked toward or the strategies likely to be chosen. This further specification of process depending on self-goal is provided by self-regulatory models that distinguish between behavioral activation and behavioral inhibition or approach and avoid systems (Avila, 2001; Carver, Sutton, & Scheier, 2000; Carver & White, 1994; Elliot & Covington, 2001; Gray, 1990; Higgins, 1996, 1997). The behavioral activation system responds to signals of reward, nonpunishment, and escape from punishment, while the behavioral inhibition system responds to signals of punishment, nonreward, and novelty (Carver et al., 2000; Gray, 1982).

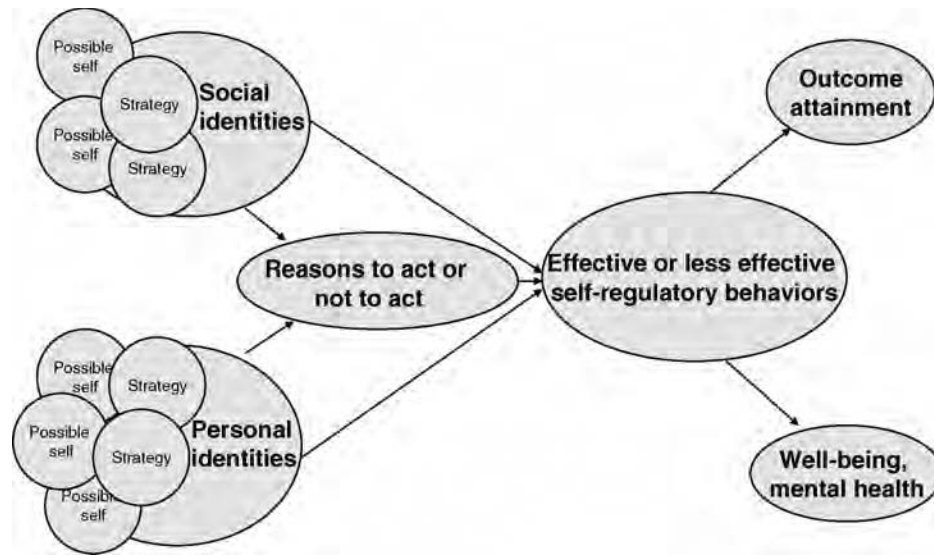
Higgins's (1997, 1998) self-regulatory focus model builds on these distinctions between behavioral activation and behavioral inhibition and further articulates two systems, one focused on attaining successes and avoiding


FIGURE 18.1. Identity-based motivation process model.

nonsuccesses (promotion focus) and the other focused on attaining nonfailure and avoiding failures (prevention focus). Different self-goals are likely to be regulated by differing self-regulatory systems; when seeking to attain or avoid failing to attain goals related to becoming like one's ideal selves, self-regulation focuses on promotion, a concern with attaining advancement, growth, and accomplishment. A parallel process occurs when one is seeking to attain or avoid failing to attain goals related to becoming like ought selves. In this case, self-regulation focuses on prevention, a concern with ensuring safety, being responsible, and meeting obligations (Higgins, 1997).

Primed or chronic promotion focus is associated with eagerness, risk taking, sensitivity to the presence or absence of gains, and motivation to ensure acceptance of relevant new behaviors and avoid incorrect rejection of relevant new behaviors. Conversely, primed or chronic prevention focus is associated with minimizing risk, sensitivity to the presence or absence of losses, and motivation to ensure correct rejections and avoid incorrectly accepting irrelevant new behaviors as relevant (Camacho, Higgins, & Luger, 2003; Crowe & Higgins, 1997; Higgins, 1997; Higgins, Idson, Freitas, Spiegel, & Molden, 2003; Liberman, Idson, Camacho, & Higgins, 1999; Liberman, Molden, Idson, & Higgins, 2001). This research suggests that individuals differ in their chronic styles and prefer using self-regulatory strategies that match their self-goals over mismatching ones (Higgins & Silberman, 1998). We prefer to work toward positive goals using eager approach strategies and to prevent negative goals using vigilant, caution-oriented strategies. Termed "value from fit," the underlying notion is that working toward a self-goal feels better when carried out with means that match the ends—eager pursuit of promotion goals feels better than vigilant pursuit of these goals; vigilant pursuit of prevention goals feels better than eager pursuit of these goals.

An identity-based motivation paradigm, a sociocultural identity model that includes self-regulation, is important because movement toward any of the basic self-goals—knowing, improving, bolstering, enhancing, or maintaining one's self all require self-regulation. While these self-goals are often assumed to be aspects of one's personal identity, following the logic of social identity and self-categorization theories (Foddy & Kashima, 2002; Onorato & Turner, 2002; Turner & Oakes, 1989) there is no reason why self-regulation cannot be part of social identity. Social identities include information about the self as a member of one or more social collectives (Abrams, 1994) as well as socially contextualized ways of being (Fiske, 1991; Fiske, Kitayama, Markus, & Nisbett, 1998; Oyserman, Coon, & Kemmelmeier, 2002). Therefore, self-goals and self-regulatory processes could equally be part of the one's social identity or interdependent self-concept. In this sense, motivation is identity based and personal goals are likely to be scaffolded by relevant social identities and the goals and strategies cued by these social identities.

Social and Personal Goals Require Self-Regulatory Focus

Which kinds of self-goals are the focus of self-regulation? To date, research on self-regulation has either omitted reference to whether something is or is or is not a self-goal or focused almost exclusively on personal goals (Gollwitzer, Fujita, & Oettingen, 2004; Gollwitzer, & Kirchhof, 1998). Thus, researchers have either asked about self-regulatory goals such as dieting and exercising (Bagozi & Kimmel, 1995; Herman & Polivy, 2004), or asked about pursuit of research tasks such as pressing buttons in response to the appearance of a letter or number (Brandstätter et al., 2001). These latter studies assume that the research task becomes a self-goal. Similarly, when children are studied, self-regulation often

focuses on children's ability (or willingness) to follow instructions of adults (typically the instructions of the child's mother or of the researcher). Children are asked to wait and not to eat a treat or to work on a boring task and not play with toys (Mischel, Shoda, & Rodriguez, 1989). Indeed, in children self-regulation is often called effortful control and delay of gratification to highlight the appetitive nature of the self-regulation being studied. Thus studies of "self-regulation" often omit actual self-goals. Yet motivation and thus "self-regulation" must be identity based to be meaningful.

When a self-goal is taken into account, goals are described in terms of personal identity. Yet social identity (Abrams, 1994; Abrams & Brown, 1989), self-categorization (Foddy & Kashima, 2002; Onorato & Turner, 2002), and cultural psychology (Markus & Kitayama, 1991; Oyserman, Kemmelmeier, & Coon, 2002) models all highlight the importance of examining the self as consisting of personal traits, abilities, and goals and the traits, abilities, and goals one takes on as part of inclusion in social units—such as the family—and social categories—such as gender, race–ethnicity, and other cultural groups. More generally, the goals that are the focus of self-regulation may be conceptualized as individual or group level. That is, the image one is controlling one's behavior in pursuit of can be a possible self embedded in a social identity. Thus, doing homework may be part of a "smart" or "successful" personal possible self, but it might also be part of self-regulation to attain "smart African American" social identity.

For example, doing homework may be seen as part of what "we" do. The "we" or social identity at the root of self-regulation may vary. In the case of doing homework, the social identity may be that of team member, family member, racial–ethnic, social class, or gender group. Doing homework may be part of meeting the minimal grade-point average (GPA) requirement to participate in sports, part of meeting the GPA requirements needed to be a "scholar athlete," part of being a good son or daughter, part of being a girl, or part of one's social class or racial–ethnic identity. To the extent that homework is linked with engagement in a social identity, desire to engage this identity will increase self-regulation. The same goal—high GPA—can thus be cued by a variety of social identities. In each case, pursuit of the goal will feel genuinely self-defining because motivation is identity based.

If the identity loses luster (e.g., becoming a good son feels less central to identity during adolescent identity development), then so too will the self-regulatory effort put into attaining goals relevant to the social identity. While self-regulation is central to our understanding of what it means to be a self, self-regulation is not commonly associated with social aspects of self-concept; social or collective identities and questions about differences in self-regulatory style or focus are only beginning to be examined in the fields of cultural and cross-cultural psychology.

In spite of its relative neglect in current research and theorizing, the notion that self-regulation is importantly directed by social identity has roots in Cooley's (1902) and Mead's (1934) frameworks. These early conceptualizations directed attention to the importance of social and interpersonal context in self-focused emotion and self-regulation. Indeed, it seems intuitively obvious that self-regulation is linked with the social aspects of identity and not simply with the personal aspects of identity. Much of self-regulation involves a combination of inhibition of socially inappropriate responses and centralization of socially appropriate responses or goals. Self-conscious emotions (i.e., shame and guilt) are likely to play an important part in motivating self-regulation to behave in socially appropriate ways (Baldwin & Baccus, 2004; Tracy & Robins, 2004).

What constitutes being socially appropriate, of course, depends on social identity—the person one is as characterized by fit with ingroup others. We imagine how others would respond, we feel pride or shame at ourselves as a result of these imagined responses, and these self-generated emotions focus self-regulatory effort to become the kind of person of whom relevant others are proud, not ashamed. In this sense, social identities provide ongoing context, clarifying both what would be prideful for people like me and what would be shameful for people like me. Because humans are wary of social approbation, we are mindful not to behave in ways that would cause shame. Because what would cause shame depends on what is valued, what is devalued, and what is irrelevant to the groups we belong to and have incorporated into our sense of self, social identities are important. Even the ways in which self-regulation is carried out are likely to be importantly shaped by social context and the social content of self-concept.

Possible Selves and Self-Regulation

Self-regulation is central to attaining one's self-relevant goals—one's possible selves (Markus & Nurius, 1986; Oyserman et al., 2003), one's wished for ideal selves, or obligated ought selves (Higgins, 1997). Possible selves have been shown to influence outcomes requiring self-regulation such as academic striving (Oyserman et al., 1995) and health-related behavior (Hooker & Kaus, 1994). Importantly, even when possible selves embedded in different social identities focus on the same issues, differences in social identities seem to inform content of strategies to attain these possible selves. For example, Oyserman and her colleagues (1995) found that whereas both African American and White first-generation college students had possible selves focused on academic attainment, the strategies these students described differed. African American students focused on what they could do to avoid becoming like their negative, feared academic failure possible selves, while White students described strategies to work toward positive academic possible selves.

Social identities that feel centrally defining and important are more likely to influence strategies. In the case of academic possible selves, compared with minority students, White students report that the social identity of "college student" is a more central and important identity and are more likely to believe that having this identity will facilitate attaining their important possible selves

(Cameron, 1999). However, relatively little attention has been paid to the ways that social identities influence self-regulation.

Even though self-regulation is typically described in terms of focus on attaining personal possible selves, because the goals one strives to achieve are likely to be the goals valued in one's social context, self-regulation is also central to social esteem and attainment of social possible selves (Bandura, 2001). Indeed, to the extent that all members of society are responsible for carrying out plans and fulfilling obligations, self-regulation is central to the social construction of humanness and social identity. While goals are typically described as part of the individualistically focused self, one's goals clearly are also embedded in social identities as well.

The efficacy of a possible self framework for improving self-regulation has been documented in research focused on school-focused possible selves and health-focused possible selves. Oyserman, Terry, and Bybee (2002) randomly assigned eighth graders to receive a seven-session after-school program of small-group activities that focused on possible selves. Youth in the intervention group attained better grades, had better in-class behavior, and skipped class less often. This initial test of a possible selves–based intervention was conceptually replicated as an in-school randomized clinical trial. Oyserman, Bybee, and Terry (2006) randomly assigned the cohort of eighth graders in three Detroit middle schools to receive the intervention as the first part of their elective sequence, during the first 11 weeks of school, with control youth receiving their regular elective. Follow-up data were collected at the end of the eighth-grade school year and again in the following year for a 2-year follow-up. The possible self-focused intervention improved both the self-control and the self-will aspects of self-regulation. In terms, of self-control, school records showed fewer unexcused absences (youth refrained from skipping class) and teacher report showed less engagement in disruptive behavior (hitting, threatening the teacher). Increase in self-will was reflected in teacher-reported increase in active engagement with learning (asking questions after class, coming to class prepared); youth also reported more time spent in homework preparation (based on a weekly diary method). Self-regulation had positive affective consequences—self-control (e.g., not skipping) predicted fewer depressive symptoms—and positive consequences for goal attainment—self-will (e.g., more time doing homework)—predicted better grades.

Effects were mediated by the impact of the intervention on possible selves. Youth in the intervention group had more balanced (positive and negative) school-oriented possible selves and were more concerned about avoiding off-track possible selves, such as becoming pregnant or involved with drugs, than youth in the control group. Self-regulation was also targeted; balanced school-oriented possible selves predicted more engagement with school and time spent in homework, not less skipping or less disruptive behavior. Feared off-track possible selves predicted less skipping school and less disruption but not more time spent in homework or engagement

with school. While these possible selves might be assumed to be part of these teen's personal identities, Oyserman and colleagues argued that they had become part of the teen's RES, showing that school-focused possible selves were positively associated with racial–ethnic identity in intervention youth but orthogonal to this social identity for control group youth (Oyserman, Bybee, & Terry, 2006).

Possible selves have also been used in a number of health and exercise-focused interventions. In one, possible selves of adults (averaging 68 years of age) were predictive of effective use of an exercise program (Whaley & Shrider, 2005). Another, briefer, possible selves–based intervention involved college students. Those asked to envision what they would be like in 10 or 20 years if they did not exercise regularly were more likely to report increased exercise a week later in a follow-up ostensibly unrelated phone interview (Ouellette, Hessling, & Gibbons, 2005). A third brief intervention had college students write for 20 minutes each day for 4 consecutive days about an important trauma, one's best (most positive) possible self, both, or neither (King, 2001). Five months later, those who wrote about a possible self, a trauma, or both a possible self and a trauma had better health outcomes; effects of writing about a possible self were as good or better than those for writing about a trauma. King (2001) suggests that either task evoked self-regulatory behavior. While these studies do not contextualize possible selves as part of either personal or social identities, our research on connection between racial–ethnic and social class-based social identities (Oyserman, Fryberg, & Yoder, 2006) suggests that these possible selves are likely to have been embedded in relevant social identities.

SELF-REGULATION OF SOCIAL IDENTITIES IS A CULTURALLY EMBEDDED PROCESS

Being able to control oneself is likely a universally developed skill. What is likely to be culturally determined are the goals toward which one self-controls and how one goes about controlling oneself as well as the circumstances that cue self-control. Clearly, pursuing traditional values requires self-regulation, so does pursuing postmodern values (see Inglehart & Baker, 2000). Whether living in a culture focused on individualism (vs. collectivism), secularism (vs. tradition), or self-expression (vs. survival) (Inglehart & Oyserman, 2004), the ability to control one's actions and will oneself into action is necessary. Self-regulation should be just as necessary whether focused on achieving idiosyncratic personal possible selves and goals or on consensually accepted social or relational possible selves and goals. Indeed, self-control is part of Schwartz's (Schwartz & Bilsky, 1987) restrictive-conformity value domain. Because self-regulation more generally is required to attain other universally valued goals, it is likely to be universally part of socialization. Childrearing values across countries do include socializing for self-regulation—variously termed "responsibility," "obedience," "determination," "perseverance," "thrift,"

and "good manners." Cultures differ in which of these particular aspects of self-regulation they most centrally endorse (e.g., Inglehart & Baker, 2000), but not on whether some form of self-regulation is a desired outcome of socialization. Like other core social values, universality of self-regulation does not mean uniformity in style (e.g., Schwartz & Bilsky, 1990); cultures are likely to vary systematically on the form that self-regulation takes—focusing on self-control and self-will in varying proportions and across different domains.

Developmentally, there is evidence of interplay between that which is culturally rewarded and self-regulation. Rodriguez and colleagues (2005) document cross-cultural difference in the relationship between effortful self-control and positive affectivity (extraversion/surgency) versus negative affectivity by 6 or 7 years of age. They compare U.S. and Chinese samples. Specifically, in Chinese (People's Republic of China) children of these ages, effortful control is negatively associated with extraversion/surgency—operationalized as activity, smiling and laughing, high-intensity pleasure, impulsivity, lack of shyness, and positive anticipation. Yet extraversion/surgency is orthogonal to effortful control among U.S. children of these ages. Conversely, in the United States, effortful control is negatively associated with negative affectivity—operationalized as being fearful, angry, sad, difficult to sooth, and high in discomfort—yet negative affectivity is orthogonal to effortful control among Chinese children. These findings suggest between-culture differences in the behaviors viewed as worthy of control (negative affect in the United States, outgoing behavior in China). These early differences in factors related to effortful control are congruent with differences in cultural values found among college students (e.g., Oyserman, Coon, & Kemmelmeier, 2002).

These results suggest that self-regulatory style and capacity are not only personal but also contextually and culturally shaped. Contexts make salient appropriate future horizons for self-regulation, varying from more proximal (e.g., getting through the afternoon without insulting Aunt Millie) to more distal (e.g., finishing high school) and even lifelong (e.g., being successful). Cultures endorse and therefore make salient some ways of self-regulating over others (e.g., Is it best to "shoot for the stars" and "say what you think" or does "haste make waste" and "fools rush in where angels fear treading"?). Within the context of universal socialization for self-regulation, the style with which goals are pursued may differ—does one take aim at attaining the goal, focusing on success with little concern for possible negative consequences of failure, or take care in attaining the goal, focusing on possible repercussions and negative implications along the way (Higgins, 1997, 2000; O'Brien & Oyserman, 2006)? Indeed, initial work in this area suggests that cross-culturally, prevention focus (typically studied as loss-framed focus) is more common in Eastern than in Western contexts (Aaker & Lee, 2001; Briley & Wyer 2002; Lee, Aaker, & Gardner, 2000).

Differences in focus of self-regulatory style do not imply differences in valuation of self-regulation. For example, within American culture, self-regulation is a valued trait; failures are assumed to be due to insufficient effort or insufficient exertion of will. Self-help manuals can be seen as the cultural artifact embodying this belief. They are produced in an ever updated abundance and bought in great numbers by individuals who believe that the potential for change is limited only by one's willingness to self-improve. Americans believe in the perfectible possible self—one could be one's thinner, better-toned, more patient, more ecologically friendly, better parent and more religiously observant self, if one just tried. At the same time, Americans also believe that talent is a fixed entity, not something that can be learned or attained through effort (Dweck, 2002). Things one cannot do well are assumed to be "not me" arenas, the proclivity to accept that which is as that which is inevitable melds with the belief that the willful yet untalented can only go so far. As reflected in the "for dummies" manuals, there are many things that the willful yet untalented can learn even if mastery is reserved for the talented.

American cultural frame embodies a Protestant focus on free will. The ability to control one's self is a basic assumption regulating not only personal goal setting but also one's relation to others and obligations within the social system. Yet belief in will power is not solely a Protestant cultural artifact—Catholicism also carries with it a focus on will via endurance of conditions that cannot be changed (Tropman, 2002). Moreover, self-regulation is clearly not simply an American or a Western cultural style. Non-Western cultures also centralize the ability to endure, to cheerfully do one's duty in the face of odds. This formulation of will is deeply part of other distinctly different cultural frames such as Hinduism (Weber, 1958) and Confucianism (Finegan, 1952).

Will in these non-Protestantism-infused contexts may focus less on the self as controlling the environment as on controlling oneself to fit the needs of the context or one's station within a larger context. Self-regulation thus can involve learning to control oneself to meet the demands of the context just as much as it can involve using one's resources to pursue personal goals. In this way, self-regulation can be just as central to humanness when the goal is shaping the self to the exigencies of the context as when the goal is pursuit of personally defined goals. Self-regulation can assume that effort; improves all goal pursuit or that effort only goes so far; in either case, the nature of motivation is identity based.

CONCLUDING COMMENTS

While the exact nature of what is universal and what is culture specific in the relationship between social identity and self-regulation has yet to be fully researched, it seems reasonable to assume that the process model described in this chapter is broadly applicable. Cultural and social factors are likely to influence the centrality of possible selves explicitly embedded in social identities as well as the appropriate style chosen to pursue these possible selves. While there is some reason to assume that self-regulatory style, and therefore the strategies one uses to avoid failure and attaining

success, is culturally linked, it is also clear that strategies are more concretely linked to specific social identities, what people like "us" do.

I have developed an identity-based motivation process model linking social identity with self-regulation by integrating a number of relevant lines of research. Within this model, culture matters for self-concept because it influences both content and process of self-concept. It influences what is of value, what matters, and therefore how one is likely to define the self but also which means toward goal attainment are endorsed, which are merely accepted, and which are denigrated. All cultures value self-regulation—controlling the self and molding the self to become more like valued possible self-goals. However, cultures differ in which self-regulation processes are likely to be primed and whether self-regulation is framed more in terms of fitting into a social role or creating a unique self.

When studied in terms of the individualism–collectivism axes, culture influences chronic salience of social identities as well as how one is likely to self-regulate—by eagerly pursuing goals in ways likely to maximize chances of success or cautiously moving forward in ways unlikely to produce errors and regret. Social identities contain traits and characteristic ways of being that are relevant to the social group defined by the identity. Therefore, they influence the possible self-goals and strategies to attain them of individuals who define themselves in terms of these social identities. Individuals are likely to incorporate social information as part of their identity unless the social information is framed as separate from the self. This is likely when social identities are primed and the information is tagged as relevant to an outgroup that cannot be assimilated into ingroup identity and when a bridge between the outgroup and ingroup identities has not previously been created.

Current social cognition theories focus on self-regulation as a contextually cued cognitive or "hot" cognitive process, infused with affect. The cognitive processes underlying self-regulation are likely to be universal, triggered by self-goals formulated as an "I" or "we" identity and carried out with strategies that are "I" or "we" identity congruent. Thus, self-regulation can involve controlling the self via inaction—not engaging in currently hedonically pleasurable activities (not sleeping in, refraining from smoking, not eating certain foods). This form of self-regulation or self-control makes sense when inaction is in pursuit of longer-term goals (being successful, being healthy, being a good member of one's religious group) that require not engaging in undermining actions along the way. Self-regulation can also involve willing the self into action or sustaining action—engaging in action that may or may not be pleasurable (preparing for class, studying, setting an alarm). This form of self-regulation or self-will makes sense when action is in pursuit of longer-term goals (e.g., learning, getting good grades, becoming successful, or fulfilling social role obligations) that require constant vigilance and action. Whether providing reasons for action or for inaction, social identities are central to the self-regulatory process, motivation is identity based.

CHAPTER 19

Value

E. TORY HIGGINS

To understand why people do what they do, why they feel what they feel, psychologists need to know what matters to them, what they want and don't want. A central concept concerned with "mattering" and "wanting" is *value*. Indeed, Allport (1961) suggested that value priorities were the "dominating force in life" (p. 543). Scholars have been studying what it means to value something and where value comes from for centuries. For example, an entire branch of classical and modern philosophy is concerned with understanding the nature and source of one kind of value—moral or ethical value. It is surprising, then, that social psychologists who care deeply about why people do what they do and feel what they feel have paid relatively little attention to the concept of value per se. If one checks the subject index of social psychology textbooks and handbooks, one discovers only a few references to "value." Those references that do appear mostly involve discussions of people's shared beliefs about general desirable ends (e.g., social values such as "freedom" or "security").

This is not to say that social psychologists are unconcerned with what makes something valuable to someone and how the value of something influences his or her behavior and feelings. Indeed, they are very concerned. However, these issues are addressed in terms of other concepts, such as "commitment," "goal," "norm," and, especially, "attitude." For example, a central component of attitudes is evaluation, which certainly relates to the concept of value. However, the attitude literature has been more concerned with the implications of there being an evaluative dimension of attitudes, such as what it

means for predicting behavior, than examining where the "goodness" and "badness" itself come from. Psychological work related to the concepts of "commitment," "goal," "norm," and "attitude" is also clearly relevant to understanding the nature and sources of value (e.g., work on attitude formation; see Zanna & Rempel, 1988), but, with some significant exceptions (e.g., Brickman, 1987), it is rarely concerned directly with what value is and where it comes from. A need remains to study value as a general principle in its own right, which is the purpose of this chapter.

I begin by briefly considering how "value" has been formally defined, which provides a preliminary answer to the question, "What *is* value?" Next, I review in more detail sociological and psychological answers to the question, "*Where does value come from?*" The major purpose of this chapter is to review the answers to this question that have been offered in the literature. Five major viewpoints on where value comes from are reviewed: *value from need satisfaction*, *value from shared beliefs about what is desirable*, *value from actual self-relation to end states*, *value from evaluative inference*, and *value from experience*. The section on value from experience is the most extensive because this viewpoint has played a dominant role within philosophy and psychology generally and within social psychology in particular. I also believe that value from experience is critical to understanding the psychological nature of value. Five different value experiences are distinguished: *hedonic experiences*, *moral or ethical experiences*, *regulatory fit experiences*, *understanding experiences*, and *agentic experiences*. At the end of the chapter, I return to the more

general question, "What is value?" I propose an answer that is inspired by the insights and perspectives provided by previous answers to where value comes from, especially those that have emphasized experience as a source of value.

WHAT *IS* VALUE?

What is meant by something having value to someone? According to the *Oxford English Dictionary* (1971, p. 3587), to value something is to estimate or appraise in respect of value. But what is the "value" being estimated or appraised in respect of? The same dictionary provides the following definitions of "value":

1. That amount of some commodity, medium of exchange, etc., which is considered to be an equivalent for something else; a fair or adequate equivalent or return.
2. The material or monetary worth of a thing; the amount at which it may be estimated in terms of some medium of exchange or other standard of a similar nature.
3. Possessed of (a specified) material or monetary worth.
4. The equivalent (in material worth) of a specified sum or amount.
5. Worth or worthiness (of persons) in respect of rank or personal qualities.
6. The relative status of a thing, or the estimate in which it is held, according to its real or supposed worth, usefulness, or importance.

Compare these definitions of "value" to those provided by Webster's dictionary, which is another standard dictionary (*Webster's Ninth New Collegiate Dictionary*, 1989, p. 1303):

1. A fair return or equivalent in goods, services, or money.
2. The monetary worth of something; marketable price.
3. Relative worth, usefulness, or importance; degree of excellence.
4. Something intrinsically desirable.

There is considerable agreement between these dictionaries in their definitions of value. It is noteworthy that in both cases the primary definitions of value refer to equivalence to something in exchange, such as some material, commodity, or service, but especially equivalence in money—*the value of something as its monetary worth or marketable price*. What this type of definition accomplishes is to provide an operational definition of "value." It is the kind of definition that would please behaviorists, or traditional economists for that matter. Indeed, it is useful as a measure that can be used across various contents and as a dependent measure in research on value. What it does not do is answer the question of what value is conceptually. What exactly is this "value" that people will exchange money for? Why are people willing to give up goods and services in exchange for this thing called "value"?

Another way of thinking about these primary definitions is that they concern the consequences of something having value—*what happens when something has value*? If

something has value, it can be exchanged for something else that is considered equivalent (i.e., a fair exchange). The other dictionary definitions, such as the usefulness, importance, rank, status, excellence, or intrinsic desirability of something, are not operational definitions of value like the exchange definitions, but they also define value in terms of consequences. If something has high value, it will be judged to be high in usefulness, or importance, or rank, or status, or excellence, or intrinsic desirability. The question remains, What is it about something that has value that makes it useful or important or desirable? Where does value come from? The next sections of this chapter review in some detail different answers to this question. For now it is sufficient to carry on with a working definition that is broad enough to capture the discussions of value in the literature—value as something about an object, action, activity, or event that makes it good or bad to some perceiver. With this working definition, let me turn now to the central issue in this chapter: *Where does value come from?*

VALUE FROM NEED SATISFACTION

At the turn of the 20th century, psychologists with theoretical perspectives ranging from behavioristic to Gestalt to psychodynamic proposed that value comes from need satisfaction. This viewpoint relates to dictionary definitions regarding the *usefulness* of something—its ability to satisfy physical needs or reduce drives or deficiencies, to increase an individual's survival in the world. This perspective on value as usefulness includes what an object or activity affords, such as a chair affording sitting (e.g., Gibson, 1979).

In the classic version of this value-from-need-satisfaction viewpoint, behavior is directed toward the removal of tissue deficits. Drives were manifest in behavior, had physiological correlates, and naturally gave rise to man's desires (see Woodworth, 1918). Value derives from homeostasis and physiological equilibrium (see Weiner, 1972). A striking illustration of this source of value is provided in Woodworth and Schlosberg's (1954) classic textbook. If one feeds an animal for a few days on a diet that is deficient in vitamin B, one creates a biological need for this vitamin. If one then offers the animal a choice between a meal that is rich in vitamin B versus one that lacks vitamin B, the animal will choose the vitamin B-rich meal.

The value-from-need-satisfaction viewpoint has had less influence within social psychology than the other viewpoints on where value comes from that are reviewed next. I discuss later why I would not include the influential consistency models (e.g., balance theory and cognitive dissonance theory) within this viewpoint, although one could arguably do so given the standard reference to "need for consistency." Clearly relevant to the need-satisfaction viewpoint is the research in the attitude literature that attempts to form attitudes through operant or classical conditioning (see Eagly & Chaiken, 1993). Unfortunately, the research on operant conditioning typically used a paradigm that confounded need satisfaction

with other sources of value. For example, the experimenter in most studies approved or disapproved of some class of response by the participant. This procedure not only satisfied a need, such as a need for approval or a need to be accepted, but also potentially created a shared belief about what is desirable or created a standard of excellence for self-regulation, which are alternative sources of value reviewed below. Still, after a careful review of the literature, Eagly and Chaiken (1993) concluded that the traditional conditioning account, which involves need satisfaction, is reasonable as an explanation for the findings in the attitude literature.

The value-from-need-satisfaction viewpoint in the attitude literature is not restricted to studies on conditioning. Evidence for attitudinal effects of mere exposure (i.e., that familiarity leads to liking or preferences) (Titchener, 1910; Zajonc, 1968) and the persuasive impact of fear appeals (Hovland, Janis, & Kelley, 1953; Rogers, 1975) can also be considered relating generally to value from need satisfaction in that anxiety reduction is likely to be involved. In addition, the literature on "message matching" (e.g., Clary, Snyder, Ridge, Miene, & Haugen, 1994) could be considered to reflect a need-satisfaction viewpoint. In their classic functional approach to attitudes, Smith, Bruner, and White (1956) and Katz (1960) proposed that attitudes have different motivational bases that serve different needs, such as the value-expressive function that satisfies the need to affirm desired identities and the social adjustment function that maintains (or disrupts) social relationships.

VALUE FROM SHARED BELIEFS
ABOUT WHAT IS DESIRABLE

An important feature of the value-from-need-satisfaction viewpoint is that value can occur at the biological system level without any need for reflection or beliefs. Moreover, value from this perspective is not restricted to humans. A very different answer to where value comes from has neither of these features—it is restricted to humans and involves beliefs. It relates to the common use of the term "value" that was mentioned earlier—value from people's shared beliefs about general desirable ends. This is typically the meaning of value when people talk about their personal values or the values of others. Although these values are personal in the sense of being internalized, they are acquired within a social context and thus are shared with others (see Williams, 1979). In a clear statement of this viewpoint, Rokeach (1980) describes values as "shared prescriptive or proscriptive beliefs about ideal modes of behavior and end states of existence" (p. 262). Similarly, Merton (1957) points out, "Every social group invariably couples its cultural objectives with regulations, rooted in the mores or institutions, of allowable procedures for moving toward these objectives" (p. 133). The cultural objectives are the "things worth striving for" (Merton, 1957, p. 133)— what has outcome value in the culture. The "allowable procedures" concern the acceptable ways to strive for the worthwhile

things—what has process value in the culture (see also Rokeach, 1979; Schwartz, 1992). This viewpoint, then, concerns *shared beliefs about both desired objectives or end states and desired procedures or means for attaining and maintaining them*. It includes norms about what goals are worth pursuing and what moral principles or standards of conduct one should live by. As captured in the concept of "procedural justice" (e.g., Thibaut & Walker, 1975; Tyler & Lind, 1992), for example, people in many societies value the fairness of decision procedures independent of decision outcomes.

Given the importance of cultural or socialized values in what makes humans a unique kind of animal, it is not surprising that these values have received special attention in the literature on the psychology of values (e.g., Seligman, Olson, & Zanna, 1996), including by such pioneers as Rokeach (e.g., 1973) and Schwartz (e.g., Schwartz & Bilsky, 1987). These shared beliefs about desired states of existence concern both the outcomes of goal pursuit, such as social justice, freedom, and social recognition, and the processes of goal pursuit, such as honesty, logic, and obedience. This viewpoint of value from shared beliefs about what is desirable relates to dictionary definitions regarding some *standard of excellence*. Lewin (1952) noted the special nature of such values. He said that such values influence behavior differently than do goals. For example, people do not attempt to "reach" the value of fairness even though it guides their behavior. He pointed out that such values function to define the valence of an action or activity in a given situation, to define which have positive valence and which have negative valence.

The viewpoint of values as shared beliefs about what is desirable provides a complement to the viewpoint on value from need satisfaction or affordance in its emphasis on social construction of values and potential variability across people as a function of socialization rather than nature. The "sharing" can be considered at more than one level of analysis—at both the broader community or societal level where the values apply to people in general or at the more interpersonal level where significant others apply values specifically to oneself. Values from shared beliefs at the broader societal level are usually treated as social values, whereas the interpersonal level with significant others is usually treated as personal values. The literature on personal values is somewhat different from the literature on social values and is considered in more detail in the next section.

VALUE FROM ACTUAL SELF-RELATION
TO END STATES

Classic cybernetic and control process models treat value in terms of the relation between a current state and some end state functioning as a standard or reference point. Approaching desired end states and avoiding undesired end states have positive value (e.g., Carver & Scheier, 1981, 1990; Miller, Galanter, & Pribram, 1960; Powers, 1973; Wiener, 1948). With respect to human motivation,

the desired and undesired end states that function as guides for self-regulation are typically acquired from interactions with significant others. A person's self-guides begin developmentally as representations of what that person's caretakers would like that person ideally to be (ideals) or believe that person should be (oughts). When that person develops his or her own standpoint, the ideals or oughts for that person from the significant others' standpoint can be shared by that person from his or her own standpoint. This creates a shared reality about desired end states—identified or internalized self-guides. With respect to the desired end states of ideals and oughts, there is considerable evidence that congruencies (or matches) have positive value and discrepancies (or mismatches) have negative value and (Higgins, 1987, 1991, 1998; James, 1890/1948; Moretti & Higgins, 1999; Rogers, 1961).

This viewpoint of value from actual self-relation to end states (desired and undesired) is also found in the literature on social comparison. Comparing yourself with another person who possesses less of a desirable (and self-relevant) attribute than you has positive value, whereas comparing yourself with another person who possesses more of a desirable attribute than you has negative value (e.g., Tesser, 1988). Value from comparing to others also occurs for end states represented by desired and undesired groups such as positive and negative reference groups (Hyman, 1942; Merton & Kitt, 1952). It has also been noted that positive value created by matching desired end states can be achieved through indirect means as well. For example, people who are made to feel insecure or uncertain about whether they have the kind of identity they want to possess, such as being a musician, will engage in activities or present themselves in ways that are traditionally associated with being that kind of person—"symbolic self-completion" (Wicklund & Gollwitzer, 1982). People will also form relationships with other people who possess an attribute they do not have but want to have, such as great beauty, in order to possess the attribute by association—"basking in reflected glory" (Cialdini et al., 1976; Tesser, 1988). People whose personal identity fails to meet their standards of excellence will act to enhance the value of the groups to which they belong in order to possess a social identity that does meet their standards (Tajfel & Turner, 1979).

It should be noted that the viewpoint of value from actual self-relation to end states treats value in two different ways. Like the previous viewpoint on value from shared beliefs about what is desirable, the person's ideal and ought standards of excellence that are shared with significant others are themselves desired end states that function as personal values. But in addition, the congruencies or discrepancies of the actual self from the ideal and ought self-guides themselves have positive or negative value. It is this second aspect of the proposal (i.e., value from actual self-relation to personal standards) that uniquely characterizes this viewpoint. It introduces the notion of value from monitoring one's success or failure in meeting standards or attaining goals—value from the answer to "how am I doing?" (Bandura, 1986; Boldero

& Francis, 2002; Carver & Scheier, 1990; Duval & Wicklund, 1972). When people speak of their life as having value (or not), it is typically in reference to this kind of value. Monitoring one's actual self-relation to end states is an important type of self-evaluative process. There are other processes of evaluating oneself that are also a source of value. They differ from the value created by actual self-relations to end states in their requiring an inference to identify the value. Such evaluative inferences as a source of value are considered next.

VALUE FROM EVALUATIVE INFERENCE

The value created from monitoring discrepancies or congruencies in relation to end states does not require an inference to create value. An actual-self congruency with ideals and oughts *is* good. An actual-self discrepancy with ideals and oughts *is* bad. But there are times when people do infer what the value of some activity or object is to them. Perhaps the most influential theory about such evaluative self-inferences in social psychology was proposed by Bem (1965, 1967) in his self-perception theory. A basic assumption of self-perception theory is that people function like behavioral scientists engaged in hypothesis testing (cf. Heider, 1958; Jones & Davis, 1965; Schachter & Singer, 1962). The critical proposal is that people make inferences about themselves in the same way that an uninterested outside observer would make inferences—based on observable evidence. They observe their own behavior and test hypotheses about its meaning or significance. When people engage in an activity, for example, one hypothesis is that they chose to do that activity because they value it. In Bem's terms, adapted from Skinner (1953, 1957), a person hypothesizes that the force to do the activity came from within and the behavior was emitted spontaneously (a tact). An alternative hypothesis is that the behavior was demanded from without and was elicited by outside forces or pressures (a mand). If there is strong support for the second hypothesis, such as a person was promised a large reward to do the behavior, then the person is less likely to infer that he or she values the activity. Classic studies on bolstering and undermining the value of an activity support the Bemian perspective on value from evaluative inference (see Kruglanski, 1975; Lepper, Greene, & Nisbett, 1973; Salancik & Conway, 1975).

The viewpoint of value from evaluative inference is broader than just the Bemian perspective. For Bem, the evidence must be publicly observable. But Andersen (1984) points out that the notion of evidence to test hypotheses and draw inferences about what one values need not be restricted to publicly observable evidence. Indeed, she reports that people are likely to use what they were thinking or feeling about some thing as evidence to infer its value to them more than their behaviors regarding it (cf. Schwarz & Clore, 1988). An especially broad form of evidence is whatever the current stimulus reminds one of from one's stored knowledge and past experiences. People use analogies, representa-

tiveness, and familiarity regarding their knowledge and experience of the world to assign meaning to a current object or event (e.g., Gilovich, 1981; Holyoak & Thagard, 1997; Tversky & Kahneman, 1974). Thus, for example, they could infer the value to them of some new activity from the value of a previously experienced activity to which the new activity is similar.

It is notable that the Bemian logic used to make an evaluative inference, like that originally proposed in Heider's (1958) theory of people's lay reasoning, is relatively simple—the likelihood of drawing an inference from your behavior about the value of something to you decreases as the evidence of external forces that could have produced the behavior increases. There are other more complex kinds of logical reasoning that can be used in the inferential process that creates value, such as Bayesian logic (e.g., Trope, 1986a) or the information gain logic that is proposed in Higgins and Trope's activity engagement theory (see Higgins, Trope, & Kwon, 1999). Of special interest historically is the reasoning postulated to underlie ethical value. One of the most influential models of inferential reasoning as a source of ethical value is that proposed by Kohlberg (1969, 1976) based on the earlier work of Piaget (1932/1965). According to this model, the moral value of an action depends on the reasons for doing or not doing it, and the reasons vary in their cognitive level of development. More generally, philosophers from Aristotle to Kant and Marx have proposed that determinations of what is morally good or bad should be based, and to some extent *are* based, on logical reflection using criteria of justice that are provided by religious and political authorities (cf. Haidt, 2001). Psychological research on the criteria people actually use to infer the ethical value of some action has found that people use multiple criteria and engage in trade-offs among them, such as trade-offs between equity and equality for distributive actions (Tyler & Smith, 1998).

Before closing this section on value from evaluative inferences, one other important factor in evaluative inferences must be mentioned—the role of context in providing factual frames of reference. People do not infer the value of something in a vacuum. They consider the value of something in relation to whatever factual standards are currently available (or accessible) to them, which can vary as a function of context (Higgins, Strauman, & Klein, 1986). The value of something can be assimilated toward or contrasted away from the context of current alternatives (Helson, 1964; Higgins & Stangor, 1988; Sherif & Hovland, 1961). It can also vary depending on which mental account the context suggests is appropriate for calculating its value (Thaler, 1999). It can increase or decrease in intensity depending on what the context suggests is normal (Kahneman & Miller, 1986) or could have happened instead (Kahneman & Tversky, 1982; Markus & Nurius, 1986; Roese, 1997). Standards of excellence that are desired end states have been discussed earlier. What is notable here is that some standards are factual states rather than desirable states, but they nonetheless influence value inferences. Moreover, whereas the standards of excellence that a person uses tend to be rela-

tively chronic, the factual standards a person uses often vary by context.

VALUE FROM EXPERIENCE

It is curious that value from experience is not explicitly mentioned in the dictionary definitions of value listed earlier. Nonetheless, the viewpoint of value from experience has a long history and has received considerable attention by psychologists. In philosophy, value from experience has a checkered history, especially with respect to ethical or moral value. Generally speaking, the dominant philosophical viewpoint has been more compatible with the value from evaluative inference viewpoint that was discussed in the previous section, but with the specific emphasis being more on using reason and reflection to create an objective basis for determining what is good or bad (Haidt, 2001; Williams, 1985). The tension between a reason versus an experiential account of ethical value is captured in Plato's (4th century B.C./1949) myth, described in *Timaeus*, of the gods beginning by creating human heads filled with reason. Because the heads alone could not move around in the world, the gods were forced to add bodies to the heads to permit movement. Emotions resided in the bodies. The moral of the story was that people were left with heads (i.e., reason), that must struggle with their passionate bodies to get them to behave ethically (and rationally). This moral was well accepted by most influential philosophers (e.g., Aristotle and Kant) and is embodied in Freud's (1923/1961) classic conflict between the reasonable ego and the passionate id. For centuries emotions have been connected with desires, desires with the potential for sin, and reason as the defense against sin (Haidt, 2001).

Plato's myth can be interpreted in another way, however. After all, the gods are not crazy and they understood that the heads alone could take no action. The problem of bridging the gap between knowing and doing has been well understood by mere mortal psychologists as well. There is the famous story of Edwin Guthrie, the "practical behaviorist," making a joke on this point at the expense of Edward Tolman, one of the founders of cognitive psychology. Tolman's influential theory of behavior emphasized hypotheses and expectations and Guthrie joked that Tolman's rats would never leave the start box to get to the goal because they would be "buried deep in thought." Reason alone does not produce movement. Something must provide the movement, must bridge the gap. The gods' solution of adding emotional bodies to the heads was an inspired solution. I propose, then, that Plato's myth has the useful moral that, without adding value from experience, value from reason cannot account for motivation and action. Value from experience is critical. I return to this point later after reviewing the different kinds of value from experience that have been proposed in the literature. At this point I should add that although somewhat in the minority, there have certainly been highly distinguished philosophers who have argued that experience is critical to ethical value

(e.g., Bentham, 1781/1988; Hume, 1777/1975; Smith, 1759/1997). Their arguments are considered next.

Hedonic Pleasure/Pain Experiences

The term "hedonic," which derives from the Greek term for "sweet," means relating to or characterized by pleasure (*Webster's Ninth New Collegiate Dictionary*, 1989, p. 561). When considering value experiences, hedonic experiences have received the most attention. From the time of the Greeks, hedonic experiences have been linked to the classic motivational principle that people approach pleasure and avoid pain. Our understanding of the subjective experience of pleasure and pain has become much more sophisticated (e.g., Kahneman & Tversky, 1979), and interest in hedonic experiences has never been greater (see Kahneman, Diener, & Schwarz, 1999). Perhaps the most influential early statement on the importance of hedonic experiences to value–both ethical and nonethical–was given by Jeremy Bentham (1781/1988) who stated: "Nature has placed mankind under the governance of two sovereign masters, *pain* and *pleasure*. It is for them alone to point out what we ought to do, as well as to determine what we shall do. On the one hand the standard of right and wrong, on the other the chain of causes and effects, are fastened to their throne" (p. 1). Bentham (1781/1988) defined the principle of *utility* as "that principle which approves or disapproves of every action whatsoever, according to the tendency which it appears to have to augment or diminish the happiness of the party whose interest is in question" (p. 2). Utility referred both to the property of producing pleasure and avoiding pain.

Kahneman (2000a) points out that the concept of utility has had two different meanings. One is like the primary dictionary definitions in its being an operational (behavioristic) definition–utility is inferred from observed choices. Kahneman refers to this concept of utility as decision utility. The second meaning reflects Bentham's perspective on utility as experiences of pleasure and pain and is called experienced utility by Kahneman. Kahneman argues that the best way to measure actual experienced utility is by moment-based methods where experienced utility of an episode is derived from real-time measures of the pleasure and pain that an individual experienced during that episode. But people also use their memory of pleasure and pain experiences to retrospectively evaluate past episodes, which Kahneman calls remembered utility. Redelmeier and Kahneman (1996) found, for the case of pain, that remembered utility was less influenced by the duration of the pain episode than by the "peak-end rule," which is the average of the most intense level of pain over the episode and the level of pain at the end of the episode. This indicates that remembered utility is not an accurate reflection of actual experienced utility, but people use what they remember to make choices. That is, decisions concerning the value of things (decision utility) can be determined more by retrospective value experiences based on memory (remembered utility) than by what pleasures or

pains were actually experienced at the time of the episode (experienced utility). Of course, remembered utility *is* the subjective hedonic experience at the time of the decision.

The role of peak experiences in hedonic value experiences may not be restricted to humans. Influential animal learning theorists argued that animals' emotional responses to stimuli played a critical role in their learning and performance (e.g., Miller, 1963; Mowrer, 1960; Spence, 1958). Spence (1958) suggested that animals differ characteristically in the magnitude of their emotional response to the same intensity of stressful stimulation and that the highly emotional animals would show a higher level of performance in aversive conditioning. In other words, higher emotionality would be related to a higher-level peak experience for the painful episode, which would produce a more negative remembered episode, which would enhance performance.

Hedonic experiences have received most attention in the voluminous literature on emotions and affect. Early on, Spinoza (1677/1986) proposed that all emotions can be reduced to some form of pleasure and pain. Since then it has been suggested that the primary function of emotional experiences is to signal or provide feedback about self-regulatory success or failure (e.g., Frijda, 1986; Mandler, 1984; Simon, 1967). Both appraisal and circumplex models propose a basic dimension that distinguishes between pleasant and painful emotions (e.g., Diener & Emmons, 1984; Feldman Barrett & Russell, 1998; Frijda, Kuipers, & ter Schure, 1989; Green, Goldman, & Salovey, 1993; Larsen & Diener, 1985; Ortony, Clore, & Collins, 1988; Roseman, 1984; Russell, 1980; Scherer, 1988; Smith & Ellsworth, 1985; see also Schlosberg, 1952; Wundt, 1896/1999).

As evident in the attitude and affect literatures (Eagly & Chaiken, 1993; Schwarz & Clore, 1996), the bulk of research in social psychology that is concerned with value experiences has emphasized basic hedonic experiences, such as basic distinctions between good and bad moods or between liking and disliking something. Influential theories and findings in decision science have also emphasized basic hedonic experiences, such as the pleasure of gains and the pain of losses (e.g., Kahneman & Tversky, 1979) or the pleasure of hope and the pain of fear (e.g., Lopes, 1987). This is not to say that there have been no theories and research in these literatures that have distinguished among types of pleasure and among types of pain. Self-discrepancy theory (Higgins, 1987), for example, distinguishes between the pleasures of ideal versus ought success or congruency (cheerfulness vs. quiescence, respectively) and between the pains of ideal versus ought failure or discrepancy (dejection vs. agitation, respectively). More generally, the emotion and affect literature distinguishes among many different types of pleasure and different types of pain based on the activation level of the experience, the target of the emotion (e.g., reaction to events versus agents), and other factors (e.g., Ortony et al., 1988; Roseman, 1984; Russell, 1980). But beyond identifying different types of hedonic experiences, it is important to identify types of value experi-

ences other than hedonic experiences. The remainder of this section reviews such types of experience.

Moral or Ethical Experiences

As mentioned earlier, for Bentham (1781/1988) the standard of right and wrong, what determined what one ought to do, the basis for approving or disapproving an action, was the pleasures and pains associated with the action. His influential system of ethics known as *utilitarianism* considered the amount of pain and pleasure an action produced for all interested parties in a community—the greatest happiness for the greatest number. Two things should be noted about Bentham's perspective. First, it can be used to distinguish ethical from nonethical experiences in that nonethical can concern only an agent's happiness whereas ethical must concern the happiness of all interested parties. Second, all the experiences being considered are hedonic experiences.

For other early moral philosophers moral experiences were broader than just hedonic experiences. Adam Smith (1759/1957), for example, described "the first perceptions of right and wrong" (p. 182). He stated that the first perceptions were *not* derived from reason but from immediate sense and feeling (see also Hume, 1777/1975). Although Smith did not agree with philosophers such as Francis Hutcheson that there was a specific "moral sense" that had its own peculiar nature, distinct from all other faculties or sentiments, he did believe that there was a specific process underlying moral sentiment—sympathy and empathy with what others were feeling. This included feelings of approval when our sentiment regarding the conduct of a third person coincides with the sentiment of another person toward the same conduct and feelings of disapproval when the sentiments are in opposition. Moral approval, according to Smith (1759/1957) does include a utilitarian component, but it also includes sympathizing with the motives of the agent and empathizing with the gratitude of those benefiting from what the agent did. He explicitly distinguished his perspective from the perspective that

> places virtue in utility, and accounts for the pleasure with which the spectator surveys the utility of any quality from sympathy with the happiness of those who are affected by it. This sympathy is different both from that by which we enter into the motives of the agent, and from that by which we go along with the gratitude of the persons who are benefited by his actions. It is the same principle with that by which we approve of a well contrived machine. But no machine can be the object of either of those last two mentioned sympathies. (pp. 192–193)

It is not clear how Smith's kind of moral feelings relates to what Haidt (2001) describes as moral intuition. According to Haidt (2001), a moral intuition involves the sudden appearance in consciousness of a moral judgment, including an affective valence. He does relate moral intuition to a process akin to aesthetic judgment that Hutcheson and Hume talked about—a moral sense in which one sees or hears about a social event and in-

stantly feels approval or disapproval. What is clear is that the moral experience from a moral intuition is *not* equivalent to a hedonic experience. It is more than feeling pleasure and pain. It is feeling approval or disapproval. As stated by a modern moral philosopher, Peacocke (2004): "What, additionally, is required for an emotion to be a moral emotion is that the positive or negative emotion, such as the delight or the indignation, be delight or indignation at a state of affairs that is (or is thought by the person having the emotion to be) morally good or morally bad respectively" (p. 254). That is, hedonic pleasure or pain is not sufficient. Moral experience includes a feeling of approval or disapproval. This position is also consistent with the dictionary defines "ethical" as "involving or expressing moral approval or disapproval" (*Webster's Ninth New Collegiate Dictionary*, 1989, p. 427).

Finally, it should be noted that popular culture for centuries has distinguished hedonic from ethical concerns in such maxims as "It is not enough to do good; one must do it in the right way," "What counts is not whether you win or lose, but how you play the game, "The ends don't justify the means," and "Never good through evil." It is notable that the ethical tends to be associated with the process of goal pursuit rather than the outcomes of goal pursuit. However, goal pursuit outcomes also vary in how ethical they are, and goal pursuit processes also vary in how hedonic they are. Thus, the critical distinction is between hedonic and ethical concerns, and these different concerns produce distinct value experiences.

Fit Experiences

When people "feel right" or "feel wrong" about something based on feelings of approval or disapproval, respectively, it can be properly considered a moral response. There is recent evidence, however, that there is another self-regulatory variable that can make people feel right or wrong about something—*regulatory fit*. People experience regulatory fit when their goal orientation is sustained (vs. disrupted) by the manner in which they pursue the goal (Higgins, 2000). For example, some students working to attain an "A" in a course are oriented toward the "A" as an accomplishment or aspiration (a promotion focus) whereas others are oriented toward the "A" as a responsibility or as security (a prevention focus). Some students read material beyond the assigned readings as a way to attain the "A" (an eager strategy) whereas others are careful to fulfill all course requirements (a vigilant strategy). An eager strategy fits a promotion focus better than a prevention focus, whereas the reverse is true for a vigilant strategy (see Higgins, 1997).

Regulatory fit experiences differ fundamentally from hedonic and ethical experiences because they arise from a different aspect of self-regulation. Fit experiences occur during the process of goal pursuit and are independent of the outcomes or consequences of the goal pursuit (both ethical and nonethical). This is not to say that hedonic and ethical experiences cannot arise as well during the process of goal pursuit, but they do so in relation to other goals that are or are not attained. For hedonic

experiences the other goals could be to have fun during the goal pursuit process ("Getting there is half the fun") or to expend as little effort as possible. For ethical experiences the other goals could be to pursue the goal in a way that would meet with others' approval or gratitude. In contrast to experiences from goal attainment, fit experiences arise from the relation between the manner of goal pursuit and the actor's current orientation toward the goal pursuit. Given one's current orientation to the goal pursuit, it is an experience of the suitability of one's manner of pursuing the goal. Unlike hedonic and ethical experiences, fit is not an experience of attaining some other goal. Perhaps this is why justifying one's choice of goal pursuit strategy by referring to hedonic or ethical experiences seems reasonable (e.g., "it was fun to do it that way" or "it was the socially proper way to do it") but attempting to justify it by referring to fit experiences does not seem reasonable ("it was the way to do it that happened to fit my motivational state at the time").

People experience regulatory fit when they pursue a goal in a manner that suits their current orientation toward the goal, and fit makes them "feel right" about what they are doing. Regulatory fit theory proposes that the "feel right" fit experience (Higgins, 2000; Higgins, Idson, Freitas, Spiegel, & Molden, 2003) is an experience that can influence subsequent evaluations of objects and actions. Regulatory fit increases the strength of people's engagement with what they are doing, thereby intensifying their reaction to what they are doing. When there is regulatory fit, people "feel right" about their positive reaction to something and "feel right" about their negative reaction to something (Cesario, Grant, & Higgins, 2004). Transfer of the regulatory fit experience can influence both utility and ethical evaluations.

In one set of studies, Higgins and colleagues (2003) examined the effect of regulatory fit on utility evaluations. Participants' chronic promotion and prevention orientations were measured prior to the experimental session. When the participants arrived for the experiment they were told that, over and above their usual payment for participating, they could choose between a coffee mug and a pen as a gift. (Pretesting indicated that the mug was clearly preferred.) The strategic manner of making the decision was manipulated through framing. Half of the participants were told to think about what they would gain by choosing the mug or the pen (an eager strategy), and the other half were told to think about what they would lose by not choosing the mug or the pen (a vigilant strategy). As expected, almost all participants chose the coffee mug. These participants were then asked either to assess the price of the chosen mug or to offer a price to buy it. Participants in the fit conditions (promotion/eager; prevention/vigilant) gave a much higher price for the mug than participants in the nonfit conditions (40–60% higher). Importantly, this fit effect on the money offered to buy the mug was independent of the participants' reports of their pleasure/pain feelings after making their decision. The fit effect was also independent of their perception of the efficiency (ease) and effectiveness (instrumentality) of the means they used to make their choice. Finally, another study demonstrated that regulatory fit created in one situation (from listing strategies that did or did not fit participants' personal goals) can influence later evaluations of a totally separate object (the "goodnaturedness" of pictured dogs).

Another set of studies by Camacho, Higgins, and Luger (2003) examined the effect of regulatory fit on ethical evaluations. One study, for example, had participants think back to a time in their lives when they had a conflict with an authority figure who resolved the conflict. The participants were asked to recall different kinds of resolution. For example, some participants recalled a resolution where the other person encouraged them to succeed (the pleasant/eager condition), whereas other participants remembered a resolution where the other person safeguarded them against anything that might go wrong (the pleasant/vigilant condition). Independent of whether the manner of resolution was itself pleasant or painful, and independent of their own pleasant or painful mood while making their judgments, participants judged the resolution to be more "right" if they were predominant promotion and the conflict was resolved in an eager manner or they were predominant prevention and the conflict was resolved in a vigilant manner. In another study by Camacho and colleagues (2003), a proposed policy for a new after-school program was judged to be more "morally right" when the manner of carrying out the program sounded eager than when it sounded vigilant for participants with a predominant promotion focus, but the opposite was true for participants with a predominant prevention focus.

As described earlier, there is evidence from studies by both Higgins and colleagues (2003) and Camacho and colleagues (2003) that "feeling right" from regulatory fit is more than just feeling pleasure or pain. Additional evidence of the independence of these value experiences was found by Cesario and colleagues (2004) in a study on persuasion. Similar to one of the Camacho and colleagues studies described earlier, Cesario and colleagues measured participants' chronic regulatory focus and manipulated whether a persuasive message advocating a new policy used either eager or vigilant means framing. The participants' hedonic mood after receiving the message was also measured. The study found that higher pleasant mood predicted greater message effectiveness in changing opinions in the advocated direction. At the same time, fit had an independent effect of increasing message effectiveness. Thus, regulatory fit and hedonic pleasure/pain mood each had independent effects on persuasion. In addition, the manipulation of regulatory fit did not affect participants' hedonic mood.

Because regulatory fit in this study by Cesario and colleagues (2004) involves the relation between participants' orientation and message framing, it is possible that some kind of "message matching" was involved. This could mean that value from need satisfaction might have contributed to the effects. Cesario and colleagues controlled for this possibility in another study, which also included a measure of hedonic mood. The study tested whether participants would be more persuaded by an

identical message if they had, versus had not, experienced regulatory fit prior to even receiving the message. Using an "unrelated studies" paradigm, participants in the first phase of the experimental session were asked to list either two promotion goals (i.e., listed two of their personal hopes or aspirations) or two prevention goals (i.e., listed two of their duties or obligations). Then they listed for each of their goals either eager means of pursuit (i.e., strategies they could use to make sure everything goes right) or vigilant means (strategies they could use to avoid anything that could go wrong). Promotion goals/eager means and prevention goals/vigilant means were the regulatory fit conditions. Following the goal/strategy listing, all participants received the identical persuasive message. Once again, the manipulation of regulatory fit did not affect participants' hedonic mood, and both pleasant mood and regulatory fit had independent effects on increasing the effectiveness of the message.

Together, these studies demonstrate that the regulatory fit, "feel right" experience is a distinct type of experience that can influence other types of value experience. It should be noted that the transfer is *not* a main effect of fit increasing the positive value of some action or object, unlike what one might expect from pleasant hedonic experiences for example. Rather, fit makes people *"feel right" about their response to an object or event*. This increases the strength of that response, whether it is positive or negative. Another study by Cesario and colleagues (2004) demonstrated this fact. They used a persuasive message of moderate persuasive strength such that participants varied in their positive or negative reactions to the message as measured by a standard thought-listing technique. They found that the fit effect on increasing attitude change occurred only for participants who had positive thoughts about the message. For participants who had negative thoughts about the message, fit had the opposite effect—it *decreased* attitude change. Thus, the "feel right" value experience from regulatory fit is a distinct experience of intensifying one's reaction to what one is doing, whatever that reaction happens to be.

As mentioned earlier, the regulatory fit experience differs from hedonic and ethical experiences in being an experience within the process of self-regulation that is independent of the ultimate, instrumental value of the goal pursuit. Regulatory fit is an experience produced by engaging in the goal pursuit activity itself that influences value. There are two other general types of value-related experience produced during activity engagement—understanding experiences and agency experiences. To understand the world and to act on it effectively can be thought of as two basic human motives (Pittman & Higgins, 2006; Stevens & Fiske, 1995; White, 1959), and the mechanisms by which people try to understand the world and act on it effectively have received considerable attention by psychologists generally and social psychologists especially (Anderson, Krull, & Weiner, 1996; Gollwitzer & Moskowitz, 1996; Heider, 1958; Snyder & Cantor, 1998). What is of interest in this chapter is the nature of understanding and agency as experiences that have value. These two general types of experience are considered next.

Understanding Experiences

People want to know how things work and they go about trying to figure things out and cope with the unknown (Kruglanski, 1989; Sorrentino & Roney, 2000). In social psychology, people's experiences from success or failure in making sense of the world have been examined most extensively by the various *consistency models* (Abelson et al., 1968), such as Heider's (1958) balance theory, McGuire's (1968) syllogistic model, Abelson and Rosenberg's (1995) psychologic model, Osgood and Tannenbaum's (1955) congruity principle, and, most influential of all, Festinger's (1957) cognitive dissonance theory.

Although multiple motives can play a role in consistency models, the central motive is to make sense of the world and one's relations to it (Fiske, 2004; Kruglanski, 1989). Consistencies and inconsistencies of various kinds produce different understanding experiences. Heider (1958), for example, describes an imbalanced state as leaving people with a feeling of disturbance, feeling that the factors in the situation "do not add up" (p. 180). The feeling of disturbance is only relieved when there is a change within the situation to achieve balance. Importantly, Heider (1958) also notes that the tension produced by imbalance can have a pleasing effect and balance can be unpleasantly boring. Thus, it is not the hedonic nature of balance or imbalance that is critical to the experience. Rather, it is the feeling that things do or do not add up—an understanding experience. Even when imbalance is hedonically pleasing, feeling that things "do not add up" is a value experience that motivates changing the situation, moving away from the current psychological situation to a new state.

According to Festinger (1957), " the human organism tries to establish internal harmony, consistency, or congruity among his opinions, attitudes, knowledge, and values" (p. 260). When people fail to do so, they experience dissonance, which gives rise to pressures to reduce that dissonance. Importantly, Festinger states: "In short, I am proposing that dissonance, that is, the existence of nonfitting relations among cognitions, is a motivating factor in its own right" (p. 3). What this suggests is that the motivational significance of dissonance does not derive from hedonic experiences alone but from it being a distinct type of value experience relating to nonfitting relations among cognitions. Indeed, part of the fascination with cognitive dissonance theory and other consistency models was their counterintuitive predictions that cognitive consistency as one kind of understanding experience had sufficient value that people would choose to engage in an unpleasant activity in order to achieve it, such as choosing to receive painful electric shocks (Comer & Laird, 1975) or agreeing to a request to install a large ugly sign in front of one's house (Freedman & Fraser, 1966).

The understanding experience of cognitive consistency is not the only kind of understanding experience that has value to people. There is also the value that derives from reducing uncertainty and drawing conclusions regarding some area of knowledge. Moreover, there is

evidence that these understanding experiences also differ from hedonic experiences. When it comes to the value of understanding, it is not the case that what matters is simply the pleasure or pain that results from the knowledge that is the product of the understanding. Sorrentino and Roney (2000) give the example of two mathematicians who solve a complex problem about the purpose of the universe and prove that it equals zero. The knowledge that is the product of their new understanding is itself hedonically painful but the understanding experience itself is the feeling of resolving uncertainty about the purpose of the universe. This feeling, like the feeling of discovery more generally, is independent of the hedonic consequences of the knowledge produced by the understanding. Similarly, some people value a feeling of certainty even when it concerns unpleasant knowledge about themselves (Sorrentino & Roney, 2000; Swann, Wenzlaff, Krull, & Pelham, 1992). Kruglanski's work on epistemic motivation (Kruglanski, 1989; Kruglanski & Webster, 1996) distinguishes between the need for specific closure that is concerned with whether the contents of the final knowledge are pleasant or unpleasant versus the need for nonspecific closure that is concerned only with arriving at a conclusion, having the experience of confidently knowing something, regardless of whether that something is pleasant or unpleasant.

As mentioned earlier, most emotion theorists, from Spinoza (1677/1986) to modern scholars, consider all emotions to be, in one form or another, hedonic experiences of pleasure and pain. It is interesting in this regard that Ortony and colleagues (1988) explicitly reject "surprise" as an emotion because it "can arise in the absence of a valenced reaction" (p. 32). They consider it to be, instead, a variable that can modulate the intensity of other emotions. The emphasis here is on surprise as a kind of understanding experience, where something happens that is different from what one thought one knew. Consistent with this position, surprise can be accompanied by either a pleasant or a painful experience. Its distinctive nature derives not from hedonic valence but from its relation to understanding. This is true of feelings like "wonder" and "interest" as well. Although these experiences are more often associated with pleasure, they are certainly not always pleasant. What distinguishes them is their relation to understanding—paying attention to something new to one's experience, to something that can increase one's knowledge. Even when understanding experiences are more clearly pleasant like "curiosity" or unpleasant like "doubt" or "uncertainty," their distinct character is their relation to understanding. Indeed, despite having a different valence, "curiosity" and "doubt" are both included in the definition of "wonder" (*Webster's Ninth New Collegiate Dictionary*, 1989, p. 1357).

Agentic Experiences

People not only want to understand how things work. They also want to make things work, to have a sense of control over what happens in the world (Bandura, 1977, 1982; Deci, 1975; Pittman & Higgins, 2006; Stevens &

Fiske, 1995; Weary, Gleicher, & Marsh, 1993). Two different kinds of agentic experiences have been described in the psychological literature: (1) experiencing oneself as being the agent of what happened versus something or someone else as the agent—feelings of personal control, autonomy or self-determination; and (2) experiencing the agency of bringing to bear one's resources to make something happen—feelings of effort, effectiveness or mastery. These two agentic experiences are related to the dictionary definitions (*Webster's Ninth New Collegiate Dictionary*, 1989) of "agent" as something that produces an effect, the efficient cause (p. 64) and "agency" as the capacity, condition, or state of acting or of exerting power (p. 63).

It has also been recognized in the literature that value from agentic experiences is *not* the same as value from either need satisfaction or hedonic value. Woodworth (1940) decades ago distinguished agentic value from need satisfaction:

> To some thinkers on these matters it appears self-evident that dealing with the environment occurs only in the service of the organic needs for food, etc. They say that the muscles and sense organs have evolved simply as tools for the better securing of food and other organic necessities, and for reproducing the race. Only the organic needs, on this view, are entitled to rank as primary drives; all activity dealing with the environment is secondary. The facts of evolution do not compel us to adopt this view, for motility and responsiveness to the environment are present way down to the bottom of the scale of animal life. There is no more reason for saying that the muscles exist for the purpose of obtaining food than for saying that food is needed to supply energy for the muscles. . . . (p. 374)

In an influential paper, White (1959) rejected the need satisfaction perspective on value experiences and emphasized instead the experience of dealing effectively in interactions with the environment, including evidence of humans and other animals being interested in exploring and manipulating their environment (see also Woodworth & Schlosberg, 1954). Recently, Kahneman (1999) distinguished agentic value from hedonic value when discussing the agentic "flow" experience described by Csikszentmihalyi (1990): "In particular, the measure of instant utility must allow for states of 'flow' in which one is so involved in an experience or activity that hedonic value fades into the background of experience" (p. 6).

Let me begin with the first kind of agentic experience from experiencing oneself, versus someone or something else, as being the causal agent. Perceiving an action in terms of actor as agent versus nonactor as agent is a major distinction in the person perception literature (Heider, 1958). Emotional experiences themselves have been distinguished in terms of whether the focus is on self as agent or other as agent (e.g., Ortony et al., 1988; Weiner, 1985). It is not surprising, then, that self versus other as agent underlies an important value experience. In an early statement of the value of experiencing personal agency, deCharmes (1968) stated: "Man strives to be a causal agent, to be the primary locus of causation

for, or the origin of, his behavior; he strives for personal causation" (p. 269). Deci (1975) also proposed that people engage in activities in order to feel a sense of self-determination. Deci and Ryan (1985) report that when people feel that they are in control of what they are doing, rather than being pressured by others or circumstances to do something, they enjoy more what they are doing, are more interested in doing it again, and generally experience a more positive emotional tone.

Value from the experience of personal agency is distinct from simple hedonic pleasure. This is illustrated by the fact that interest in an activity can be undermined by adding a pleasant reward for doing it if that reward changes the agentic experience of the activity from self-determined/endogenous to other-determined/exogenous (Deci, 1975; Krulganski, 1975). It should be noted as well that experiencing others as having influence on one's activity engagement will not always undermine the value of that activity. It will depend on whether the other's influence is experienced as "not me" versus "we." For example, undermining will not occur if young children or individuals in a collectivist or interdependent culture or communal relationship (Clark & Mills, 1979; Markus & Kitayama, 1991; Triandis, 1989) experience the influence of others (peers, parents, or trusted others more generally) as part of their own self-regulation. There is evidence consistent with this conclusion (Costanzo & Dix, 1983; Iyengar & Lepper, 1999). Thus, what is critical is not whether one experiences others as having an influence on one's activity engagement but whether that influence undermines one's own experience of personal agency.

Let me turn now to the second kind of agentic experience mentioned above in which people experience the agency of bringing to bear their resources to make something happen and to overcoming resistance through their efforts. The importance of this agentic experience has also been recognized for a long time, as evident in the following statement from James (1890/1948):

> Of course we measure ourselves by many standards. Our strength and our intelligence, our wealth and even our good luck, are things which warm our heart and make us feel ourselves a match for life. But deeper than all such things, and able to suffice unto itself without them, is the sense of the amount of effort which we can put forth . . . the effort seems to belong to an altogether different realm, as if it were the substantive thing which we *are* . . . (p. 458)

One important form of interacting with the environment occurs when people offer *resistance* or opposition to interfering forces, pressures, and circumstances with adverse significance for them. Woodworth (1940), for example, stated that people and other animals exert considerable resistance to environmental forces on them in order to maintain a degree of independence. They resist wind that is trying to blow them over and gravity that is trying to make them fall. They have an active give-and-take relation with the environment and value in the form of interests "springs from the individual's ability to deal effectively with some phase of the environment" (p. 396).

Value creation from resistance is central to social psychological research on reactance (Brehm, 1966; Brehm & Brehm, 1981; Wicklund, 1974). When people feel that their freedom to make their own choice on some matter is being taken away by outside pressure, they resist that pressure and attempt to restore their freedom. This resistance can create value (e.g., Brehm, Stires, Sensenig, & Shaban, 1966). Placing a barrier to attaining a desired object can also create resistance to losing freedom of access that increases the value of the object. Wright (1937), for example, reports an intriguing series of studies in which access to attaining food was made more difficult by adding a barrier. In one study, the experimenter arranged desserts on a serving table at various distances from where the waitresses stood to pick them up to serve. As long as the distance was not too great, the desserts further away were selected more than those that were closer. Another study found that kindergarten children chose a more distant candy with a wire sieve over it instead of one closer with no sieve.

In addition to value creation from the experience of resistance as opposition to external interfering forces, there is also value creation from the experience of overcoming personal resistance to doing something. When there are known adverse consequences of engaging in an activity, there is a natural resistance to doing the activity. When people overcome this internal resistance by freely choosing to engage in the activity, knowing its adverse consequences, they experience *commitment* to and value in the activity (Brickman, 1987). Great figures in psychology, including Sigmund Freud, Kurt Lewin, and Jean Piaget, have recognized that overcoming internal resisting forces is a special kind of agentic experience that relates to psychological commitment and "will" (Brickman, 1987; Deci, 1980).

There is evidence in the psychological literature that when people and other animals face adverse or difficult circumstances when engaging in some activity and continue the activity despite knowing those circumstances, this agentic experience of overcoming personal resistance increases the value of that activity. In a study by Lewis (1964), for example, rats had to displace either a heavy weight (high effort) or a minimal weight (low effort) in order to get to Rice Krispies as a food reward. Then all the rats were placed in a straight maze and allowed to run freely to the goal area (i.e., no weight to displace) where they were rewarded each time. The measure of the attractiveness of eating Rice Krispies was running speed to attain them, and the "high effort" rats ran faster (see also Lewis, 1965). Similarly, Carder and Berkowitz (1970) found that rats preferred pressing a lever to attain pellets than getting the same pellets freely available in a dish near the lever. Indeed, sometimes a rat would push the food-filled dish away from the food magazine to push the lever for a pellet (see also Jensen, 1963).

In the previous section I discussed how cognitive dissonance theory, like other cognitive consistency models, concerns value from an understanding experience. It should be noted, however, that this does not mean that cognitive dissonance only involves an understanding experience. Indeed, the cognitive dissonance literature has

clearly identified agentic experiences as being involved as well. Both the personal control kind of agentic experience (agent) and the overcoming personal resistance kind of agentic experience (agency) have been mentioned as being critical to creating the dissonant state. Some dissonance experts have emphasized the importance for dissonance induction that the actors' experience "free choice" or autonomy or personal responsibility for their decisions (e.g., Brehm & Cohen, 1962; Cooper & Fazio, 1984; Zimbardo, 1969). Others have emphasized the importance for dissonance induction that, in making their decisions, the actors experience personal resistance (which they overcome) from the negative features of the decision (e.g., Brickman, 1987; Wicklund & Brehm, 1976). Brickman (1987), for example, states that the effort involved in the dissonance studies creates value for the activity by increasing commitment to it. The effort occurs because the participants freely choose to do some activity that has negative consequences. The negative consequences produce resistance to do the activity. The effort involved when freely choosing to overcome this resistance increases commitment to the activity and increases its value.

As a final note, the case of cognitive dissonance illustrates how a phenomenon can involve both understanding and agency experiences. This is not surprising, perhaps, given that "thinking is for doing" (Fiske, 1992; James 1890/1948). The example of cognitive dissonance is complicated by the fact that for Festinger (1957) it was the understanding experience that was critical whereas for Brickman (1987) it was the agency experience that was critical. More directly in line with "thinking is for doing" is Pittman's theory of control deprivation (Pittman & D'Agostino, 1989; Pittman & Pittman, 1980). This theory proposes that experiencing an inability to control is disturbing because it calls into question one's understanding of how the world works, thereby undermining feelings of effectance or agency. Pittman and his colleagues find that following control deprivation, the value of accurate understanding increases so that people process subsequent information more thoroughly. The theory and research on control deprivation nicely illustrates how agency and understanding experiences can combine. Conflict between self-guides provides another example of how agency and understanding experiences combine. Van Hook and Higgins (1988) found that when individuals have discrepancies or conflict between their ideal and ought self-guides, they report feeling confused, unsure of themselves, and distractible. A discrepancy between two self-guides, such as what one ideally wants to be and what one's mother believes one ought to be, is both a problem of understanding who one is supposed to be and a problem of planning effective action.

Value from Experience versus Need Satisfaction

Several of the value experiences discussed in this section could be characterized as experiences associated with satisfying some need, such as pleasant experiences from fulfilling a need for consistency, a need for autonomy or agency, or a need for regulatory fit. Certainly there are experiences associated with need satisfaction, and the experiences I have described can relate to some kind of need satisfaction. However, the emphasis of the value from experience viewpoint is different from the value-from-need-satisfaction viewpoint. For the value-from-experience viewpoint, it is the experience itself that matters motivationally—it is the experience itself that has value implications. In contrast, for the value-from-need-satisfaction viewpoint the experience is just a consequence of satisfying the need—it is the need satisfaction itself that is critical for value. The difference between these positions is especially evident when the value experience has effects independent of whether any need is actually satisfied.

Consider the classic animal studies on value in relation to need satisfaction. Do animals value something solely as a function of whether it satisfies their biological needs or will they choose something simply because it provides hedonic pleasure experiences? There is clear evidence that animals will choose on the basis of value experiences independent of any biological need being satisfied (Eisenberger, 1972). There are early studies, for example, showing that sweet water with saccharine that has no physiological benefit is preferred to regular water, and that animals prefer sweet food to a physiologically better food, such as a food that is more beneficial for a vitamin deficiency they have (Woodsworth & Schlosberg, 1954). There are also studies showing that rats will work to press a bar that activates the pleasure area in the brain but does not satisfy any biological need (Olds & Milner, 1954). In the original and follow-up studies, metallic electrodes were implanted in certain regions of the lateral hypothalamus and some rats would push the lever up to 5,000 times an hour even to the point of collapsing. Some mother rats even abandoned their newborn pups in order to press the lever thousands of times per hour. In a T-maze, with both arms baited with mash, the rat would stop at a point halfway down the right arm to self-stimulate, never going to the food at all. Finally, there is evidence from classical conditioning studies of animals learning to value the conditioned cues themselves, even as objects of consumption. For example, autoshaped pigeons will make eating pecks at light cues that predict edible rewards and will make drinking pecks at the same light cues when they predict liquid reward even though the light cues themselves do not satisfy hunger or thirst (Berridge & Robinson, 2003).

WHAT IS VALUE?

The foregoing review of the psychological literature on proposed sources of value—where value comes from—sets the stage for answering the more general question of what is value psychologically. In brief, I agree with those who believe that value is best understood as a psychological experience. It is not simply a belief, inference, or judgment. I believe that inferences, judgments, and beliefs contribute to value, but they do so through their impact on experience. Consider the classic refrain that people often do not appreciate something (i.e., don't value

it) until they don't have it anymore—"Sometimes you don't know what you want until you've lost it." A related notion is that people take things for granted (i.e., don't value things that are objectively important to their well-being, if not critical to their survival). A classic example, especially for younger people, is being in good physical health. Young people know that being healthy is a good thing, but that knowledge alone is not enough to give health the value it objectively deserves—" Youth is wasted on the young." The general point of such refrains is that because the need is generally being satisfied, or the desired end state maintained, without the need to pay much attention to it or make it a priority, the *experience* of attraction to the value target is weak. When suddenly the need is not being satisfied or the desired end state is not being maintained, *then* people experience their attraction to it. Only *then* do they value it highly. This is true not only for health but also for resources such as electricity, water, and so on that are normally readily available (at least in wealthier nations). Something that satisfies a need, maintains a desired end state, and meets a standard is not valuable for that reason alone. It can still be taken for granted and not be appreciated. *Experiencing* the attraction to it is essential.

What exactly is the nature of this value experience? Inspired by Lewin's (1951) discussion of valence, I have proposed in a recent paper (Higgins, 2006) that value is a *motivational* experience. For Lewin, value related to *force*, which has direction and strength. For Lewin, the forces on a person's life space were analogous to natural physical forces on objects rather than something that a person experiences. Nonetheless, following Lewin's lead, I believe that value is a *force experience* that has direction and strength. Experiencing something as having positive value corresponds to experiencing attraction toward it (e.g., trying to move in the direction toward it), and experiencing something as having negative value corresponds to experiencing repulsion from it (e.g., trying to move in a direction away from it). Value experiences vary in strength. The experience of attraction toward something can be relatively weak or strong (low or high positive value), and the experience of repulsion from something can be relatively weak or strong (low or high negative value).

To understand the psychology of value, one must begin with the classic hedonic experiences of experiencing pleasure or pain from something (cf. Kahneman et al., 1999). This experience is critical to the resultant force experience because it provides *direction*. Many of the sources of value described earlier can be understood as contributing to hedonic experience. Pleasure can be experienced when a need is satisfied, a goal is attained, or a standard is met (although, as mentioned earlier, this is not always the case). One can distinguish between different contents of value experience, such as economic value (e.g., material resources), moral value (e.g., ethical character), political value (e.g., individual power), social value (e.g., social support networks), and so on, but they can all be understood as contributing to hedonic experience—making one's life more pleasurable. It is also notable that the "cognitive" sources of value described earlier can in-

fluence the experience of hedonic direction. For example, the shared beliefs about what is desirable and what is undesirable—both social values and personal ideals and oughts—directly concern what has positive value and what has negative value. The evidence used to make evaluative inferences also provides information about the positive or negative value of something.

In my recent paper (Higgins, 2006), I proposed that the value experience of the force of attraction or repulsion has two sources. One source is the hedonic pleasure/pain experience of the target. As discussed earlier, it has been recognized for centuries that pleasure has associated with it an approach motivation and that pain has associated with it an avoidance motivation—the classic hedonic principle. However, I propose that there is a second source of the value experience that does not involve the hedonic experience of pleasure or pain per se but rather involves the *experience of the motivational force* to make something happen (experienced as a force of attraction) or make something not happen (experienced as a force of repulsion). Although these two force experiences—hedonic experience and motivational force experience—often are experienced wholistically, they are distinct from one another. Some activity that provides little hedonic pleasure, for example, may have a strong motivational force associated with it because it is the proper thing to do or matches shared beliefs about appropriate procedures of goal pursuit—I don't "enjoy" doing this but I feel "compelled" to do it. What is critical here is the notion that value is not just an experience of pleasure or pain. Instead, value is essentially a directional force experience—the force of attraction toward or repulsion away from something. Because value is an experience of directional force and not just an experience of pleasure or pain, there can be contributions to value that are independent of hedonic experience.

What are the sources of the motivational force experience? Importantly, the pleasure/pain hedonic experience is itself a critical determinant of the motivational force experience, but it is *not* the only determinant. I have proposed (Higgins, 2006) that there is also a *nondirectional* source of motivational force experience—*strength of engagement*. The state of being engaged with some object or activity is to have sustained attention, to be involved, occupied, and interested in it. Strong engagement is to be absorbed or engrossed with something. Independent of their experience of a target's properties, for example, individuals can experience their opposition to interfering forces or experience overcoming their own personal resistance in relation to that target, and these experiences can increase the strength of engagement with that target. In contrast to experienced properties of the value target, strength of engagement has strength but not valence direction in itself. Strength of engagement concerns how much people are absorbed in what they are doing regardless of the strength of the pleasure/pain experience of what they are doing.

Historically, strength of engagement relates to the notion that people can be interested in something independent of its hedonic valence and that this has value implications. Perry (1926), for example, said that an object is

valuable when interest in taken in it. Ziff (1960) said that "good" means answering to certain interests. Mandler (1984) noted that what makes us attend to things also invests them with value, and events that are interesting may or may not be positively valued. Berlyne (1973) also distinguished "interesting" from pleasing or pleasant. Strength of engagement alone does not make something attractive or repulsive. Strength of engagement does not have direction. Instead, strength of engagement contributes to the experience of motivational force, to the strength of the experienced force of attraction or repulsion. Strength of engagement contributes to *how* positively or *how* negatively something is experienced.

There are various kinds of evidence that hedonic experience and motivational force from strength of engagement can independently contribute to value. Earlier I discussed how regulatory fit can produce a particular kind of experiential feeling–making people "feel right" or "feel wrong" about something. But this distinct feeling experience is not the only effect of regulatory fit. Regulatory fit also increases strength of engagement in what one is doing (Higgins, 2000), and this contributes to motivational force independently of hedonic experience, thereby influencing value. Some recent regulatory fit studies by Idson, Liberman, and Higgins (2004) provide evidence for these independent effects. Idson and colleagues proposed that imagining successfully making a more desirable choice has higher regulatory fit for people in a promotion focus (because success maintains the eagerness that sustains their concern with advancement) than for people in a prevention focus (because success reduces the vigilance that sustains their concern with safety). Therefore, people in a promotion focus, more than people in a prevention focus, should be more engaged and experience a stronger motivational force of attraction when they imagine successfully making a more desirable choice. In contrast, imagining failing to make a desirable choice has higher regulatory fit for people in a prevention focus (because failure maintains the vigilance that sustains their focus) than for people in a promotion focus (because failure reduces the eagerness that sustains their focus). Therefore, people in a prevention focus, more than people in a promotion focus, should be more engaged and experience a stronger motivational force of repulsion when they imagine failing to make a more desirable choice (i.e., imagine making a less desirable choice).

To test these predictions, Idson and colleagues (2004) modified a well-known example from Thaler (1980). All participants were instructed to imagine that they were in a bookstore buying a book for their classes. The orientation toward the buying decision was framed in two different ways–a promotion framing and a prevention framing. Participants in the promotion, "gain/nongain" framing condition were then told: "The book's price is $65. As you wait in line to pay for it, you realize that the store offers a $5 discount for paying in cash. Of course you would like to pay $60 for the book. You have both cash and a credit card and have to choose between them." After reading the scenario, half of the participants answered a "gain" question (i.e., "How would it feel

paying in cash and getting the $5 discount?"), and the other half answered a "nongain" question (i.e., "How would it feel using your credit card and giving up the $5 discount?"). Participants in the prevention,"nonloss/ loss" framing conditions were told instead: "The book's price is $60. As you wait in line to pay for it, you realize that the store charges a $5 penalty for paying in credit." Half of these participants answered a "nonloss" question (i.e., "How would it feel paying in cash and avoiding the $5 penalty?"), and half answered a "loss" question (i.e., "How would it feel using your credit card and paying the $5 penalty?"). All participants answered these questions about the value of the choice they imagined making on a scale that went from "feeling very bad" to "feeling very good."

As one would expect, the participants felt good when they imagined successfully making the more desirable cash choice and paying just $60 for the book, and they felt bad when they imagined failing to make the more desirable cash choice (i.e., using their credit card) and paying $65 for the book. This is the classic outcome valence effect. As predicted, however, there were also significant effects within the positive outcome condition and within the negative outcome condition. The positive response to the choice success/positive outcome was more positive in the promotion focus condition (fit) than in the prevention focus condition (nonfit). The negative response to the choice failure/negative outcome was more negative in the prevention focus condition (fit) than in the promotion focus condition (nonfit).

In a subsequent study, rather than inducing regulatory focus by framing the bookstore scenario in terms of gain/nongain from a discount (promotion) or nonloss/ loss from a penalty (prevention), regulatory focus was *experimentally primed* separately from the scenario itself. An unrelated-studies paradigm was used where participants began the session by writing about either their personal hopes and aspirations (promotion ideal priming) or their personal sense of duty and obligation (prevention ought priming). All the participants were given a scenario of planning to buy a book for a course and waiting a few days to go to the bookstore to buy it. Half of the participants in each priming condition were given either a positive outcome scenario (i.e., "Imagine that you go to the bookstore in a few days, and when you arrive, you find out that there are still copies of the book for sale. You won't have to go to other bookstores to look for it.") or a negative outcome scenario (i.e., "Imagine that you go there in a few days, but when you arrive, you find out that all the copies of the book are gone. You will have to go to other bookstores to look for it.").

The results for this study in which regulatory focus was manipulated through priming were the same as those for the previous study in which regulatory focus was manipulated through framing. Once again, these findings demonstrate that regulatory fit does not add positivity to outcomes. Rather, it intensifies whatever happens to be the reaction to something. Positive reactions to desirable events are more positive when there is fit than nonfit, and negative reactions to undesirable events are more negative when there is fit than nonfit. In addition to pro-

viding support for this part of the model, the Idson and colleagues (2004) studies also examined whether pleasure/pain hedonic experience and motivational force make independent contributions to the value of something. In addition to measuring how good or bad participants felt about the imagined decision outcome, separate measures of pleasure/pain intensity and strength of motivational force were taken. The framing study and the priming study used slightly different measures to provide convergent validity. The priming study, for example, measured *pleasure/pain intensity* by asking the participants how pleasant would it be for them to find the book at the local bookstore (in the positive outcome condition) or how painful would it be for them to not find it (in the negative outcome condition) and *strength of motivational force* by asking them how motivated would they be to make the positive outcome happen (in the positive outcome condition) or how motivated would they be to make the negative outcome not happen (in the negative outcome condition).

Both studies found that pleasure/pain intensity and strength of motivational force each made significant independent contributions to the perceived value of the decision outcome (i.e., its goodness/badness). The contribution of positive versus negative outcomes to the overall goodness/badness of the decision outcome was predicted by the pleasure/pain ratings but not by the motivational force ratings. The contribution of regulatory fit to the overall goodness/badness of the decision outcome (i.e., fit being more good for a positive outcome and more bad for a negative outcome) was predicted by the motivational force ratings but not by the pleasure/pain ratings. Both studies also found that the regulatory fit manipulation did not influence pleasure/pain ratings but did influence motivational force ratings, supporting the path from regulatory fit to strength of engagement to strength of motivational force to intensity of value experience. In sum, the results of these studies suggest that both pleasure/pain hedonic experience and motivational force contribute to the value of choice outcomes (i.e., their goodness or badness), and that regulatory fit is a source of motivational force through increasing strength of engagement.

In addition to regulatory fit, other sources of where value comes from that were reviewed earlier in the chapter can also be considered as contributors to the force experience of strength of engagement. For example, the agentic experiences of opposition to interfering forces and overcoming personal resistance increase strength of engagement and motivational force that can increase the value of what one is doing (see Higgins, 2006). The ethical experience of doing what one should or meeting shared beliefs about what is proper could also increase strength of engagement and motivational force. The pursuit of need satisfaction when a need is stronger would both increase strength of engagement and motivational force during the pursuit itself and increase the hedonic experience when the need was or was not satisfied.

What about value as actual self-relations to end states? Some self-monitoring or self-evaluation models treat the value experience as something separate from the actual self-congruency or discrepancy to a desired end state. Akin to Schachter and Singer's (1962) model of emotions, there would be a congruency or discrepancy and then some interpretation of it that would produce the value experience. From this perspective, the value experiences follow from inferential interpretations. An alternative perspective is that the value experiences are directly embodied in the congruencies or discrepancies themselves without there being any need for an additional inferential interpretation. For example, I have suggested in an earlier paper (Higgins, 1996) that an actual self-congruency to a personal ideal is a type of psychological situation, a type of presence of a positive, that *is* cheerfulness (happy, joyful), and an actual self-congruency to a personal ought is a type of psychological situation, a type of absence of a negative, that *is* quiescence (calm, relaxed). Similarly, an actual self-discrepancy to a personal ideal is a type of psychological situation, a type of absence of a positive, that *is* dejection (sad, disappointed), and an actual self discrepancy to a personal ought is a type of psychological situation, a type of presence of a negative, that *is* agitation (tense, nervous). From this perspective, people have direct value experiences when systems regulating the actual self to meet desired states succeed or fail. For example, when the promotion-ideal system fails people feel sad just like they feel thirsty when the water intake system fails. I believe that if the value experiences were not present, a self-regulatory success or failure would not feel like a success or failure and its critical feedback and incentive role would be lost.

The value-as-evaluative-inference viewpoint would seem to be quite different from the value-as-experience viewpoint. However, they might be more compatible than they seem. When people construct or form an attitude about some potential choice alternative, for example, it is their predictions about the potential, future value *experiences* from that choice (e.g., future pleasure or happiness experiences) that could be critical to the value they assign to that choice (Kahneman, 2000b; Wilson & Gilbert, 2003). Kahneman and Snell (1990) defined the predicted utility of an outcome as the individual's beliefs about its experienced utility at some future time, where the experienced utility of an outcome concerns the hedonic experience of that outcome.

What about evaluative inferences from past experiences such as those described in studies on self-perception theory and activity engagement theory? As reviewed earlier, these studies have been interpreted in purely cognitive inferential terms, but it is possible to add an experiential component. Indeed, the added experiential component could be critical. From the perspective of self-determination theory (Deci, 1971; Deci & Ryan, 1985), for example, the undermining of the value of the activity that occurs when individuals are promised an award for doing the activity happens because the external force of the promised award diminishes the agentic value experience (i.e., the experience of autonomy or self-determination; see also deCharmes, 1968). Similarly, one might argue that the diminished activity value that occurs when individuals switch back and forth between two liked activities that has been found in activ-

ity engagement research (Higgins et al., 1999) happens not only because of the inferences that are made but also because the actors experience themselves choosing to disengage from an activity they expected to like. In contrast to a Bemian perspective that emphasizes self-perception like an outside observer with no access to private experiences, this perspective emphasizes the experience itself. As mentioned earlier, for example, whether the value of an activity or choice to a person is undermined by another person influencing that person depends on whether the influence is experienced as external pressure or losing control, and this can vary by the developmental age of the actor and his or her cultural background (e.g., Iyengar & Lepper, 1999).

A key direction for future research is to consider how the different sources of where value comes from described in the literature might influence not only hedonic experiences but also motivational force experiences. In fact, the critical role of experience in value may have been underestimated in the previous literature because of the tendency to consider only the role of hedonic experiences in value creation rather than the more general role of motivational force experiences. Value creation that was not clearly attributable to hedonic experience has tended to be attributed to nonexperiential sources (e.g., inferential judgments) rather than considering nonhedonic, motivational experiences as underlying the value creation. More attention needs to be paid to the nonhedonic, motivational force experiences that create value. Another critical direction for future research is to consider how the different sources of hedonic and motivational force experiences interact with one another, and, especially, how one source of value can be confused with another. Indeed, the possibilities for value confusion, and what the benefits and costs of such confusion might be, are perhaps the most intriguing and significant issues that need to be explored.

Basic Human Needs

Thane S. Pittman
Kate R. Zeigler

It is vain to do with more what can be done with less.
—attributed to William of Occam (c. 1285–1349)

There is always an easy solution to every human problem—neat, plausible, and wrong.
—Mencken (1949, p. 443)

It has been a long time since a chapter devoted to the subject of basic human needs appeared in a major handbook in social psychology; indeed, there has never been one (Gilbert, Fiske, & Lindzey, 1998; Higgins & Kruglanski, 1996; Lindzey, 1954; Lindzey & Aronson, 1968, 1985; Murchison, 1935). A search of chapter titles in the *Annual Review of Psychology* also came up empty. The discovery of these facts gave us considerable reason to pause. But as interest in using a motivational perspective for the generation of hypotheses and the interpretation of findings has increased (cf. Higgins & Kruglanski, 2000; Pittman, 1998; Pittman & Heller, 1987), theorists have begun to return to the question, "What are the basic human needs?" It thus does seem to be an appropriate time to assess the ways in which ideas about basic human needs have been and are being used in social–psychological theories and research.

Rather than providing a thorough literature review of all research using constructs proposed to represent the operation of basic human needs, we instead review much more selectively the current state of theories about basic human needs, with a little historical context. We have chosen six theories for comparison. All these theories have been given extensive explication and review elsewhere, so we focus particularly on how these theories are structured and at what level of analysis they are designed to apply. We will find a little agreement but perhaps considerable food for thought.

HUMAN NATURE

What is human nature? Is there such a thing? Although it is not the way that social psychologists have approached this question, an informal consideration of other species in comparison suggests that there must be such a thing as human nature. We know that dogs are different from cats in many ways, and that neither is the same as a horse, a rat, a dolphin, or an orangutan. These mammals are very different in size and shape, but we also sense from their behavior that the differences among them go beyond those obvious physical characteristics. Humans share many basic similarities with all these animals but are also unlike any of them in many aspects of their physical construction and, we suspect, in their psychological processes. But what are those psychological differences, and to what extent are they simply differences in degree (e.g., in the extent of information-processing capability) versus qualitative differences (perhaps, for example, in ambition, or in the inclination and ability to construct symbolic meaning)? Such questions are not easy to answer, but it is also the case that most of our work in psychology has not been designed to address them.

To pursue this line of thinking a bit further, nevertheless, it is easy to distinguish a human from other animals based on physical appearance. Bipedal and relatively hairless would seem to do it. "Find the human" is not a common item on tests of intelligence. To make such dis-

tinctions based on behavior is also quite simple. A clue such as "makes automobiles" resolves all ambiguity as to which species we have in mind. Of course, not all humans make automobiles, but archaeologists do not need to expend a great deal of energy answering the question "made by which species?" upon discovery of clay tablets, tools, or pottery shards found in digs around the globe. Anyone reading this chapter indoors is surrounded by, sitting on, probably wearing, and using things fabricated by *homo sapiens*. Humans make things.

When we move into the realm of psychology, matters become more complex and considerably less clear. In considering what, psychologically, might constitute human nature, social psychologists have not taken up the method of cross-species comparisons illustrated in the aforementioned musings. In fact, in psychology more generally, instead of looking for what is unique about human nature, psychologists have tried repeatedly to come up with a few general principles that are meant to apply across all or virtually all species, essentially arguing that psychologically all species are governed by the same fundamental principles. This approach constitutes a scientifically sound strategy, in the spirit of Occam's Razor (i.e., given two equally good explanations, the more simple one is preferred), as an attempt to understand complexity by reducing it to a few simple laws that apply to many species. Familiar examples of this approach include the various serious attempts by behaviorists to explain everything in terms of basic principles of reinforcement (Hull, 1943; Pavlov, 1927; Skinner, 1938, 1981; Watson, 1930). These ideas were tested and refined extensively with experiments on rats and pigeons as well as humans, were extended into such realms as social learning (e.g., Miller & Dollard, 1941), attitude formation and change (e.g., Doob, 1947), and group behavior (Zajonc, 1965), and are still echoing in the traditional halls of economics. Here we have also found, repeatedly and particularly at social psychology's level of analysis, that as useful as such simple constructions have been, they are not adequate to the task of fully explaining, understanding, and predicting the behavior of humans (cf. Dweck, 1996; Festinger, 1957; Henchy & Glass, 1968; Kahneman & Tversky, 1979).

If social psychologists have not pursued a comparative or a multispecies approach, other than to show that simple cross-species analyses are not sufficient to understand human psychology, then how have they gone about the task of understanding human nature? Leaving aside the question of what makes humans distinctive or unique, and instead focusing on trying to understand human behavior in its own right, one approach (our subject) has been to specify the basic set of things that humans need. This is not the only way to proceed, and use of the need concept is not universally thought to be a good idea. But as part of a motivational approach to human behavior (also not embraced by all), trying to understand human nature means understanding the basic things that humans want and need. Of course, we learn to want all sorts of things—even to need them—but can we find a fundamental and universal set of basic needs that characterize human nature? What are the fundamental

dimensions of human desire, and how might understanding those basic human needs help us to understand human behavior?

WHAT ARE NEEDS, AND DO WE NEED THEM?

> Man is a wanting animal and rarely reaches a state of complete satisfaction except for a short time. As one desire is satisfied, another pops up to take its place. When this is satisfied, still another comes into the foreground, etc. It is a characteristic of the human being throughout his whole life that he is practically always desiring something.
> —MASLOW (1970, p. 24)

Motivational approaches focus on the generative aspect of human behavior, on the forward-moving, internally driven aspect of behavior that derives in part from internal impulses that include but also go beyond simple tissue deficits (see Higgins & Kruglanski, 2000; Pittman, 1998; Pittman & Heller, 1987, for reviews of motivational research in social psychology). Motivational analyses do not, however, necessarily include the use of any assumptions about fundamental needs, nor do they necessarily embrace the emphasis on motives as internal drivers. Instead of employing the concept of need, some have argued for a focus on *incentives* and *goals* as the way to understand motivation. For example, on the question of the nature of control motivation (Pittman, 1993; Pittman & D'Agostino, 1989; Weary, Gleicher, & Marsh, 1993), Bandura (1997) has argued against thinking of an inborn or acquired need for control as providing the *push* from internal motives and instead in favor of the *pull* from anticipated environmental incentives:

> Some theorists regard the striving for control as an expression of an inborn drive (Deci & Ryan, 1985; White, 1959). . . . In social cognitive theory, people exercise control for the benefits they gain by it. Some of these benefits may involve biological gratifications, but the striving for control is not a drive in its own right. (p. 16)

Similarly, this general expectancy × value incentive-based analysis, along with elaborations of the concept of negative feedback loops (Miller, Galanter, & Pribram, 1960), has been employed in Carver and Scheier's (1981, 1998, 2000) approach to self-regulation. Research using goals and self-regulation of goal pursuit also tends to be either purely or primarily cognitive in its theorizing and does not depend on assumptions about basic needs (cf. Gollwitzer & Moskowitz, 1996; Kruglanski, 1996).

The approach to motivation represented in the theories on which we will concentrate is one in which motives are seen as variable internal states that, when activated or aroused, energize and direct behavior. In these models, *deprivation* and *deviation* (from desired states) play a central role. In the early work on learning and conditioning, a common method for getting an animal prepared for a session would be to deprive the animal of food for some specified length of time. The practical effect of this prac-

tice was to create in the animal a real desire for food and a willingness to expend considerable energy to get it. Hungry rats will more reliably and persistently press a bar for food than will rats that are partially or completely satiated. It seemed clear, at least to many, that rats *need* food and are *motivated* to get it when deprived.

The recognition that there are physical nutrients such as food, water, and oxygen that are necessary for survival was used by theorists such as Hull (1943) to develop the concept of drive, a motivational force that provided the impetus toward behavior, an impetus that would wax and wane as a function of the extent of tissue deficits. As we have said, early attempts were made to explain all of animal (including human) behavior with a small set of learning and conditioning principles based on these tissue deficits. But the work of psychologists such as White (1959) on effectance, Hunt (1965) on optimal levels of stimulation, Berlyne (1960) and Harlow (1953) on curiosity, and Festinger and Carlsmith (1959) on the inverse relationship between incentives and attitude change began to make it clear that to understand the complexity of human behavior, it would be necessary to go beyond simple principles of learning and an exclusive reliance on building only on basic tissue deficit needs such as hunger and thirst.

How Should Needs Be Defined?

> It is characteristic of this deeper analysis that it will always lead ultimately to certain goals or needs behind which we cannot go; that is, to certain need-satisfactions that seem to be ends in themselves and seem not to need any further justification or demonstration. These needs have the particular quality in the average person of not being seen directly very often but of being more often a kind of conceptual derivation from the multiplicity of specific conscious desires. In other words then, the study of motivation must be in part the study of the ultimate human goals or desires or needs.
>
> —MASLOW (1970, p. 22)

A source of potential confusion lies in the varying meanings that are intended when theorists use the term "need." *Webster's Seventh New Collegiate Dictionary* (Gove, 1963) defines the noun "need" as a lack of something required, useful, or desired. Defining a need as something that is required leads to a set of implications that are quite different from those that would follow from defining a need as something that is useful or desired.

Some needs are clearly required, necessary in that without them the organism would, in a relatively short time, cease to be alive. Without food, a human would survive for a period of time conveniently counted in weeks; without water, days. In the frigid waters of the North Atlantic or the Artic Sea, mariners know that death from hypothermia following immersion would come in a matter of minutes. Without oxygen, human life only endures for seconds, perhaps a few minutes. These required forms of sustenance, the antidotes for otherwise fatal tissue deficits, provided the foundation for early studies of the phenomena of learning and conditioning (cf. Cofer & Appley, 1964).

Sexual relations, however, although needed in the sense of being required for the continued existence of a species and needed in the sense that they are at times strongly desired and clearly biologically based, are not necessary for individual survival in the same sense as are food, water, and air. Although sexual desire can be considered in terms of drive, and as something fundamentally desired, it is not needed by the individual in the same way as food and water are needed.

When social–psychological theorists talk about basic human needs, they are usually not talking about tissue deficits but such things as control, understanding, or self-esteem. It is worth thinking about what this use of the term "need" actually is intended to mean. One possibility is to consider that some basic needs are necessary for continued existence, but that the time scale for continued existence without satisfying those needs is more conveniently measured in years or decades rather than in minutes, hours, or days. We can take for an example the assumption that there is a need to belong (Baumeister & Leary, 1995). A need to belong is included in a number of the theories to be considered. At the beginning of life, survival without the assistance of others is not possible, because it is only with their help that an infant can obtain basic sustenance. At such young ages, social support is just as essential as food and water for survival. But beyond those early years, the data on survival rates as a function of the extent of social support (cf. Deeg, van Zonneveld, van der Maas, & Habbema, 1989) would still be consistent with this definition of basic need (i.e., something that is required for existence), but the time scale for damage due to deprivation would be considerably longer than it is at the beginning of life.

However, instead of using a definition of need as something required for existence, most current social–psychological theories of basic needs employ some version of the concept of *thriving*. For example, Deci and Ryan (2000) argue that truly basic needs are those that influence a person's well-being. Experiences that satisfy these basic needs are thought of as nutriments, and insufficient amounts of these nutriments result in a failure to thrive. Inadequate degrees of satisfaction of these basic needs may not lead to premature death but instead are revealed in the failure to achieve one's potential or to function as well as one might under more optimal conditions of need fulfillment. Need satisfaction should promote well-being and psychological thriving (Sheldon, Elliot, Kim, & Kasser, 2001). Those emphasizing survival-oriented considerations (e.g., Fiske, 2004; Pyszczynski, Greenberg, & Solomon, 1997) also seem to use the concepts of basic needs or motives as something that will leave the organism better off and probabilistically, if not necessarily individually, more likely to survive and thrive if satisfied.

Baumeister and Leary (1995), in their argument for considering belongingness to be a basic human need, suggested a set of criteria that could be used to evaluate whether a need is truly fundamental, distinguishable from needs that may be derived from other more fundamental ones. They argue that a *fundamental need* should:

1. Produce effects readily under all but adverse conditions.
2. Have affective qualities.
3. Direct cognitive processing.
4. Lead to ill effects when thwarted (e.g., poor health or adjustment).
5. Elicit goal-oriented behavior designed to satisfy it—subject to motivational patterns such as object substitutability and satiation.
6. Be universal in the sense of applying to all people.
7. Not be derivative of other motives.
8. Affect a broad variety of behaviors.
9. Have implications that go beyond immediate psychological functioning.

Although adoption of this or some similar set of criteria might seem sensible and broadly compatible with how the concepts of basic motives or needs are typically used in social–psychological theories, such tests are not typically employed by theorists to develop or evaluate a set of basic needs. Instead, the more common strategy is to pursue a hypotheticodeductive process of hypothesis generation and testing given the assumed basic need structure.

How Many Needs Do We Need?

In social and personality analyses, the notion of needs characteristic of the human organism had an early history, as did the recognition that specification of internal cognitive, emotional, and motivational processes would be required for an effective approach to understanding human psychology. But whether this approach also needed to include a specification of basic human needs was and continues to be a matter on which theorists disagree. Making lists of needs began to acquire a bad reputation with McDougall's (1926) concept of instincts, an approach that was soon rejected for using circular reasoning and leading to a plethora of assumed inborn tendencies. Murray's (1938) list of more than 20 needs was also seen by many as going down a path that would only lead to longer and longer lists, of dubious usefulness. It may be that the baby was thrown out with the bath, however, as the majority of experimentally inclined social and personality psychologists eschewed using the concept of basic needs altogether in favor of a focus on situational constraints and individual differences as the twin paths to understanding.

Most of those who made specific motivational assumptions (e.g., Festinger's, 1957, use of the consistency principle as a source of motivation) took no clear position on whether these motives were acquired or innate and also tended to focus on a single motivational dimension. This is still the dominant approach. Investigators can assume that something (e.g., self-esteem) is a strong motive or need and use their theoretical assumptions about how it works to generate hypotheses. They can do so without having to take a position on whether it is a fundamental need or an acquired motive, a derived motive based on some more fundamental need or on what other needs also might be fundamental. This approach leads to what

are sometimes described as minitheories as opposed to theories with a more comprehensive sweep.

Recently we have seen a reemergence of interest in specifying the set of basic needs, with an eye toward sticking to a short list that would avoid the criticisms that had been applied to the long and lengthening sets of needs of earlier theorists such as McDougall and Murray. Given the checkered past of long lists of needs, these theories confine their basic set to a number that can be counted on the fingers of one (human) hand. Before proceeding to our set of comparison theories, a brief review of Murray's approach provides a transition to the current theories of basic human needs that we will compare. Considering Murray's list may offer a useful perspective on the question of how many needs should be specified in the set of basic human needs.

Murray's List of Needs: A Nest of Boxes?

> . . . the list of drives one chooses to list depends entirely on the degree of specificity with which one chooses to analyze them. The true picture is not one of a great many sticks lying side by side, but rather of a nest of boxes in which one box contains three others, and in which each of these three contains ten others, and in which each of these ten contains fifty others, and so on.
>
> —MASLOW (1970, p. 25)

Murray's (1938) list was generated empirically and resulted in a large and well-known set of both manifest and latent needs. Several of these needs have been investigated intensively, particularly the needs for achievement (Atkinson, 1958; Atkinson & Raynor, 1978; McClelland, 1958; McClelland, Clark, Roby, & Atkinson, 1949), for power (McClelland & Watson, 1973; Winter, 1973; see also Fiske & Berdahl, Chapter 29, this volume), and for affiliation (Baumeister & Leary, 1995; Schachter, 1959), but many of the others have been less well studied, if not forgotten. What is remembered is that the list was too long. However, another look at Murray's (1938) analysis shows that the question of exactly how many needs he identified can be answered in more than one way. Although Murray did list 20 manifest needs, they were presented in nine groups. These nine groups were not named, but we have taken the liberty of doing so in Figure 20.1. Murray also noted that most of these manifest needs were represented by four basic reaction systems, also shown in Figure 20.1. In the spirit of Maslow's nesting boxes metaphor, the number of needs identified by Murray could be 20, 9, or 4 (see Figure 20.1). Or five: Costa and McCrae's (1988) analysis of the Jackson (1984) Personality Research Form (PRF) suggests that Murray's needs as measured by the PRF can largely be captured by the Big Five set of personality dimensions.

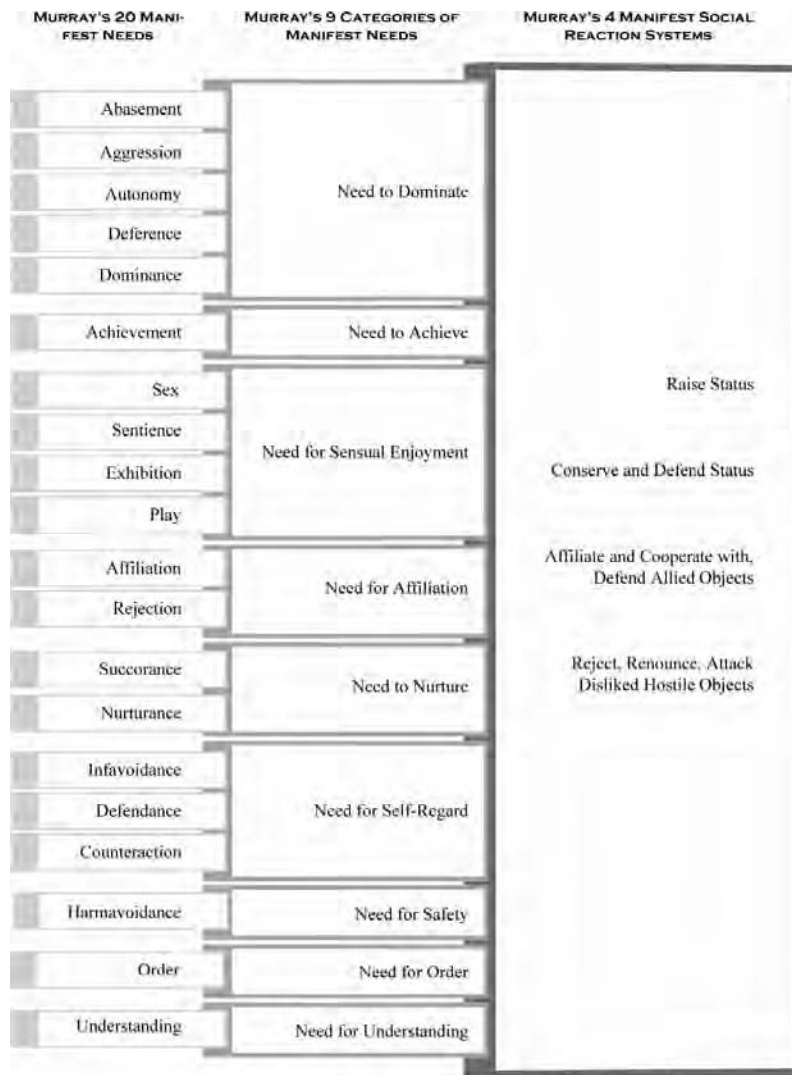
As we turn to the six theories chosen for comparison, it is worth remembering that the number of basic human needs is to a large extent dependent on the level of definitional generality or specificity being used by the theorist. All these theories present a set of basic motives ranging in number from three to five, but it is instructive to remember Maslow's nesting-boxes metaphor, as illustrated by the various ways of counting up the manifest


FIGURE 20.1. Murray's (1938) manifest needs represented as nesting boxes: 20, 9, or 4?

needs identified by Murray. In some cases, we can easily imagine reducing the set of basic needs that is proposed to fewer, or expanding it to more if we are willing to move to a more specified level of detail.

Theoretical Comparisons

Six need theories will be compared: Maslow's (1943) hierarchy of needs; core social motives theory (Fiske, 2004; Stevens & Fiske, 1995); terror management theory (Pyszczynski et al., 1997); attachment theory (Bowlby, 1969); cognitive-experiential self-theory (Epstein, 1992); and self-determination theory (Deci & Ryan, 1980, 2000). We focus on two general dimensions of these theories: how they structure the set of basic needs, and how those needs are distributed across levels of analysis. Although these are certainly not the only theories of basic needs we could have chosen to compare, they are representative and include among them several current theories that have led to a considerable amount of research.

STRUCTURAL ASSUMPTIONS IN THEORIES OF BASIC HUMAN NEEDS

One of the ways in which theories about basic human needs differ lies in the proposed structure of those needs. These structural assumptions vary considerably. We have included for comparison a *hierarchical model*; several theories that specify a *root primary need* to which other needs are related; a theory that proposes a *system of checks and balances* across a conscious/nonconscious divide; and a theory including a proposed *set of independent needs*. Figure 20.2 illustrates these structural variations.

Hierarchical Structure

Maslow's Hierarchy of Needs

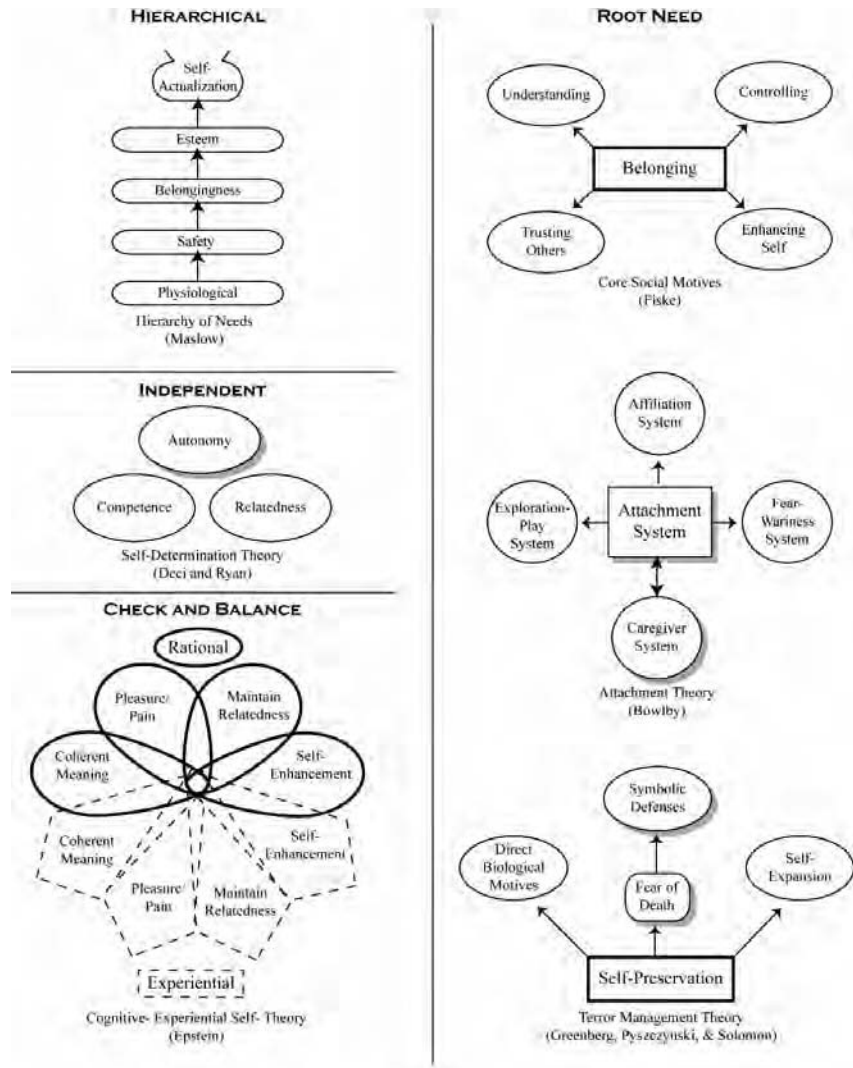
It could be said, with only a bit of exaggeration, that Maslow's hierarchy of needs is a theory that everyone knows, and no one uses. Typically portrayed in introduc-


FIGURE 20.2. Structural form of six theories of basic human needs. Shadowing indicates the needs that have generated the most empirical research.

tory textbooks in a familiar pyramidal figure, the basic structural assumption is that some needs take precedence over others, and that those more fundamental to existence must be satisfied before others will be addressed (Maslow, 1943). The theory is often portrayed, and we have done it again in Figure 20.2, as having five levels representing five types of needs. In fact, Maslow discussed a much more nuanced division of needs, so that one could argue about the actual number of needs that he thought were fundamental, as his "nesting boxes" quote at the beginning of the earlier section on Murray suggests. But regardless of the number of needs that are specified, the invariance of any such hierarchy is easy to call into question. We have ample examples of needs higher in the hierarchy taking precedence over those said to have priority (in the case of basic sustenance we find people starving themselves to death for the sake of appearance, to save a loved one, or in service to a cause). In actual operation, it becomes difficult to see how in

specific settings this hierarchy could either hold up or make testable predictions, particularly at the higher levels of the hierarchy. This may be why the theory has not generated a great deal of empirical research.

There are other current theories that use the notion of a hierarchy. Steele's (1988) self-affirmation theory is an example. When threatened with an inconsistency (Steele & Liu, 1981, 1983) or a failure (Liu & Steele, 1986), self-affirmation theory predicts that these concerns can be taken care of at the level at which discomfort was created (achieve consistency, regain control) or at the higher-level basic need to feel good about oneself (affirm self). Note that in this model, the most important need is the one highest in the hierarchy. This also illustrates an advantage of more targeted and bounded theories. In such theories predictions and explanations are limited to the particular conditions under which the processes specified in the model should operate. By not claiming to capture ev-

ery aspect of basic human needs these theories have the advantage of being more easily testable, even if the overall import of the analysis is on a scale less grand.

Maslow's theory has been most influential in organizational psychology and related fields as a model of motivation but has not itself motivated a great deal of empirical research. The concept of self-actualization, however, has been influential in the construction of other current theories, most notably self-determination theory. Our discussion of that theory comes later, but we note here that Vallerand (2000) has offered a hierarchical version of self-determination theory.

Root Need Structure

Another basic kind of theoretical structure is one in which a single need is identified as the most important one. This *root need* is either more important than the others, is the one to which the others are closely related, or the one from which the others are derived. Three different versions of root need models are discussed.

Core Social Motives Theory

Based on a comprehensive literature review of a wide variety of writings on basic needs and motives, Stevens and Fiske (1995) argued that there was overall agreement on five basic needs. Fiske (2002, 2004) continued to develop and elaborate this set of basic needs, or core social motives, using the BUC(K)ET acronym as a mnemonic device for the five motives: *belonging, understanding, controlling, enhancing self*, and *trusting* (leaving the "K" for students to play with if they would like to imagine a sixth motive). In this system, *belonging* is the root need, the essential core social motive. The others are all said to be in service to, facilitating, or making possible effective functioning in social groups. No structural relation among the five motives is specified, but we have visually arranged this theory in Figure 20.2 with belongingness at the center and the other four motives arranged around and connected to it.

As implied by its name, this theory is specifically designed to apply to needs that arise in social settings. "Core social motives describe fundamental, underlying psychological processes that impel people's thinking, feeling, and behaving in situations involving other people" (Fiske, 2004, p. 14). A basic assumption of this theory is that underlying all the basic needs is an evolutionary process that has led to these characteristics of human nature because they promote survival of the individual through belonging in groups. Although this kind of imagined evolutionary, survival-oriented thinking is not logically a required aspect of a theory of basic needs with a root need structure, in fact such thinking has been employed in the development of all three of the root need theories in Figure 20.2.

Core social motives theory has been used primarily as an organizing structure for understanding a wide variety of social–psychological research (Fiske, 2004). At this writing, it had not yet been used extensively to generate and test new research questions, and may need some further development to generate testable hypotheses.

Attachment Theory

We should begin by making it clear that attachment theory was not put forward as a theory of basic needs. Instead, attachment theory (Bowlby, 1969) was developed as a goal-corrected systems version of control theory (cf. Bandura, 1997; Carver & Scheier, 1981, 1990, 1998, 2000), without reference to needs. In fact, Bowlby explicitly objected to use of the need concept. His reasons included his apprehension about the difficulties inherent in using what we would call the strong form of the term (i.e., required for continued survival of the organism) given that humans can survive if not thrive even when several of the attachment systems remain unsatisfied. He was also concerned that the use of the need concept, in which action is designed to create some preordained future state, might invite in "the fallacy of teleology" (Bowlby, 1969, p. 137).

Even so, we have included attachment theory in our set of comparisons. Specifying an attachment system as the central organizing principle, this theory is based on deprivation and deviation, with self-correcting control systems that could easily be thought of as need based and motivational in character, even if Bowlby preferred not to do so. The attachment, caregiver, and affiliation systems could all be thought of under the heading of belongingness or relatedness. Viewed in this fashion, belongingness is seen to be a complex set of compatible but quite different processes (nesting boxes). Most of the work with adult attachment has focused on styles of attachment (secure, anxious, ambivalent) as they play out in adult close relationships (Ainsworth & Wittig, 1969; Hazan & Shaver, 1994; Reis & Patrick, 1996; Rholes & Simpson, 2004). Attachment theory also includes an exploration/play system that provides a dimension of comparison with self-determination theory and terror management theory. It includes as well a fear-wariness system that has been traditionally addressed with motivational analyses, and this provides a general point of contact with the pleasure/pain aspect of cognitive-experiential self-theory. The theoretical root need structure of this developmental theory also introduces a developmental change aspect to our discussion.

Bowlby did relate attachment and closeness to the survival needs of nurturance and security. This distinction forms the basis for the survival functions underlying promotion (nurturance) and prevention (security) focus in regulatory focus theory (Higgins, 1997, 1998, 1999) and in the previous self-discrepancy theory (Higgins, 1987, 1989). Regulatory focus theory is a kind of need distinction model, without strong claims about evolution but employing Bowlby's notion of survival through nurturance and security. The emphasis in this theory is on how the need-related orientations (promotion vs. prevention) are strategically carried out rather than on the orientations themselves. In this way, it is like terror management theory's emphasis on the defensive systems based on sur-

vival needs and the apprehension of mortality rather than the on needs themselves.

Terror Management Theory

Terror management theory (TMT; Pyszczynski et al., 1997, 2000) assumes that *self-preservation* is the root need or master motive for all other needs, including those based on tissue deficits and the derived *symbolic-defensive* and *self-expansive* desires. This root need, survival, is said to be the overriding desired end state. But given the fact of mortality, this creates an existential crisis for humans who are perhaps uniquely aware of their inevitable demise (Becker, 1973; Freud, 1933; Rank, 1936/1976). "According to TMT, the self-preservation instinct—the goal of staying alive—is the superordinate goal toward which all behavior is oriented. All other motives are, in one way or another, derived from and subservient to their "prime directive" (Pyszczynski et al., 1997, p. 5).

The assumption that there is a single underlying motive from which all others are derived is similar to other single motive approaches (e.g., the hedonic assumption of approach and avoidance of basic learning theories; the rational self-interest assumption in economic analyses; and the reproductive/species survival assumption of evolutionary analyses). However, at the social-psychological level of analysis it has the interesting character of motivating primarily defensive behavior designed to distract from or comfort in the presence of mortality salience. This also could be considered to be a hierarchical structure of a different kind. The root need, combined with the knowledge of the inevitability of death, creates a uniquely human need to deal with the knowledge of one's own inevitable mortality, leading to two fundamental defensive needs.

TMT specifies three sets of motives. *Direct motives* include the need for food, water, and temperature regulation as well as instinctive reactions such as flinching from noise and recoiling from pain. But the bulk of the empirical research inspired by TMT is focused on the *defensive motives*:

> Instinct for self-preservation → fear of death
> → defensive motives:
>   (a) pursuit of self-esteem
>   (b) faith in the cultural worldview

The empirical research literature on these defensive motives is extensive, enough so to have its own *Handbook of Experimental Existential Psychology* (Greenberg, Koole, & Pyszczynski, 2004).

More recently a growth component has been added to TMT, perhaps in an attempt to address the ground covered by self-determination theory (SDT). Unlike SDT, these *self-expansive motives* are also connected to the root need for survival. Although fear of death apparently motivates only the symbolic defensive system, self-preservation, underlies all three systems.

> A human being with a capacity to do nothing other than maintain an interior homeostasis and defend against physi-

cal and psychological threats would have little chance of long-term survival in a complex and changing environment. Such an animal must also be inclined to explore, assimilate new information, and integrate that information with its existing conception of the world, because survival depends on the development of an adequate understanding of the environment and a complex set of skills for interaction with that environment. Thus it seems clear that a motive for growth and expansion of one's capacities (e.g., Deci & Ryan, 1991; Maslow, 1943; Rank, 1932/1989; White, 1959) would make good evolutionary sense in that it would greatly increase the animals *sic*) chances of surviving long enough to reproduce. (Pyszczynski et al., 1997, p. 6)

The addition of self-expansive motives to TMT creates some interesting conflicts and contradictions. An organism motivated to explore, grow, and expand is a risk-taking organism. Existential terror would seem to be at odds with such an inclination. One possible solution to this problem would be to adopt the perspective of evolutionary theory (Buss, 1997), in which reproductive success rather than individual survival is considered to be the fundamental driver and crucial selector in evolutionary change. Or one might argue, with Woodworth (1958), that people wish to survive so that they can go about their business, rather than going about their business in order to survive—and in evolutionary terms their business is to reproduce for the sake of their species. However, this view tends to subordinate what is supposed to be the master motive, self-preservation. The potential for tension between the defensive and self-expansive systems provides fertile ground for future research in TMT.

Check and Balance Structure:
Cognitive–Experiential Self-Theory

Cognitive–experiential self-theory (CEST) is a global theory of personality, heavily influenced by psychodynamic thinking (Epstein, 1992, 1993, 1994; Epstein & Pacini, 1999). Epstein proposes that people process information via two fundamentally different (although related) systems. These two systems—*rational* and *experiential*—function in the formation of schemas, and in the more general information processing required for individuals to adapt to their surroundings. Although these two systems may be combined in the completion of a single act, they operate according to different rules. The experiential system is affected predominantly by emotions, relying on intuition and heuristic cues; it functions automatically (without the conscious deliberation characteristic of the rational system), organizing experiences and directing behaviors. By contrast, the rational system is assumed to be wholly conscious and affect-free, driven instead by analytical thought and socially mediated knowledge. From a psychodynamic perspective, the influence of the experiential system on the rational system is parallel to that of the unconscious on rational, waking thought. However, Epstein's specification of the "preconscious" modifies the psychodynamic unconscious with the cognitive unconscious based on contemporary experimental psychology.

CEST assumes that there are four fundamental human needs: (1) to maximize pleasure and minimize pain; (2) to maintain a stable, coherent conceptual system for organizing experience; (3) to maintain relatedness to others; and (4) to maintain a positive sense of self-esteem. Different from the other theories in our comparison set, CEST assumes these four needs function in a system of checks and balances at both the rational and experiential levels, helping to keep behavior within adaptive limits. For example, if one need is fulfilled at the expense of the others, these other needs become more insistent, serving to moderate the strength of the first need. Consequently, behavior is influenced simultaneously by all four needs and tends not to be dominated by any one need in particular. The specification of checks and balances among needs is in essence the opposite of the assumptions of hierarchical theories, in which some needs take precedence over and may have to be satisfied before others. It also differs from the root need theories in that balance among needs rather than the precedence of a root need is assumed.

Evidence for the utility of CEST comes from studies on the nature of inferences in the two systems (Kirkpatrick & Epstein, 1992); on inconsistencies in the literature on depressive realism (Pacini, Muir, & Epstein, 1998); on the use of the theory in justice research (Krauss, Lieberman, & Olson, 2004; Lieberman, 2002); and in understanding individual differences as revealed in thinking in the two systems (Epstein, Pacini, Denes-Raj, & Heier, 1996) and in temperament (Teglasi & Epstein, 1998).

The distinction between a conscious, deliberative, and rational system as opposed to a nonconscious, intuitive, and emotional system is seen in a number of other contemporary theories. For example, Metcalfe and Mischel (1999) have proposed a distinction between "hot–cool," *know* and *go* systems that determine self-control. Strack and Deutsch (2004 and Chapter 17, this volume) proposed a *reflective–impulsive* model that is very similar in overall conception to the rational–experiential distinction, although Strack and Deutsch's model relies much more on associative network assumptions to understand the operation of the impulsive system. McClelland, Koestner, and Weinberger (1989) argued for a distinction between *implicit motives* and *self-attributed motives.* At the level of emotion and preference, Zajonc (1980) demonstrated that *preferences need no inferences* in a seminal paper that argued for a distinction between affective and cognitive systems. However, none of these other theories are about the set of fundamental needs. In that regard, it is the articulation of four basic motives operating among each other and across the cognitive–experiential divide that sets CEST apart from these other approaches.

Independent List Structure: Self-Determination Theory

Deci and Ryan (1980, 1985, 1991, 2000) proposed three basic human needs: *autonomy*, *competence*, and *relatedness*. Deci and Ryan (2000) have also provided a very clear elaboration of how they use the concept "need":

human needs specify the necessary conditions for psychological health or well-being and their satisfaction is hypothesized to be associated with the most effective functioning" and that "we assert that there are not instances of optimal, healthy development in which a need for autonomy, relatedness, or competence was neglected, whether or not the individuals consciously valued those needs. In short, psychological health requires satisfaction of all three needs; one or two are not enough. (p. 229)

We have classified this theory as one with an independent need structure because although it is clearly stated that all three needs must be satisfied, the theory does not specify any structural organization among those needs. There is no hierarchical structure, no root need that is said to be more basic or more important than the others, no system of checks and balances. All three needs must be satisfied for optimal functioning according to the theory, but each need has its independent set of requirements.

Over the past 30 years SDT has generated an extensive empirical literature, more so than any of the other theories we have chosen for this review (for reviews, see Deci, Koestner, & Ryan, 1999; Sansone & Harackiewicz, 2000), including its own *Handbook of Self-Determination Research* (Deci & Ryan, 2002). We have shaded the need for autonomy in Figure 20.2 because that is the need that gave the theory its name, and it is the one that has received the earliest and most consistent research attention. The work of deCharmes (1968) on internal and external perceived loci of control was part of the original thinking about the need for autonomy. The concept of autonomy can also be related to Brehm's (1966, 1993) work on reactance theory with its concept of *behavioral freedoms*. When a perceived behavioral freedom is eliminated or threatened with elimination, reactance motivation increases the attractiveness of that freedom and motivates the person to reestablish that freedom. In this context, SDT suggests that the set of behavioral freedoms needs to be more than zero for the individual to thrive. From another perspective, in the current context of theories of self-regulation and self-control (cf. Wegner & Wenzlaff, 1996), the need for autonomy might be taken to mean that individuals need to engage in autonomous self-regulatory activities to a sufficient extent or well-being will suffer. From this viewpoint, self-regulation is not only something that humans can do, it is something they need to do.

The need for competence, in the tradition of White's (1959) analysis of effectance motivation, refers to a need for effective interaction with the environment, and in a different sense to Murray's (1938) need for achievement. In the early versions of SDT, the combination of autonomy and competence was found to underlie intrinsic motivation (Deci, 1975) and both generated a considerable amount of research on the nature of competence motivation (Boggiano & Pittman, 1992; Elliot & Dweck, 2005). Research combining the individual difference approach to achievement motivation (e.g., McClelland & Watson, 1973) with an experimental approach to research on intrinsic and extrinsic motivational orientations (e.g.,

Pittman, Boggiano, & Ruble, 1983) has proven to be a particularly fruitful avenue for empirical research on the effects of intrinsic, achievement, and competence motivation (Harackiewicz, Manderlink, & Sansone, 1992; Harackiewicz, Sansone, & Manderlink, 1985; Sansone & Harackiewicz, 2000).

The need for relatedness has not received as much empirical attention, perhaps because it is a more recent addition to SDT. In the research on intrinsic motivation, relatedness has been studied through its role as a source of support for autonomy and competence (e.g., Ryan & Grolnick, 1986; Ryan, Stiller, & Lynch, 1994). Here there is a clear connection with attachment theory, particularly with Ainsworth & Wittig's (1969) use of the "Strange Situation" in research on the exploration–play system (see Figure 20.2). In this work, the attachment system provides a secure base for exploration. The security provided by satisfaction of the need for relatedness is seen in SDT as an important influence on the ability of persons to engage in the pursuit of autonomy and competence (Ryan & LaGuardia, 2000). Relatedness has played a more direct role in the analysis of the process of internalization. The extent to which extrinsically imposed rules and regulations, cultural prescriptions, and shared habits of thought and action become integrated and part of a person's way of satisfying intrinsic motivation depends very much on the nature of the relationship between the individual and socializing agents. Internalization is most likely when relatedness needs are satisfied in a way that also promotes feelings of autonomy and competence (Deci & Ryan, 2000; Grolnick & Ryan, 1989).

SDT makes clear predictions about the overall effects of satisfying or failing to satisfy basic needs on individual functioning. Satisfaction of the three basic needs should promote optimal development, while failure to satisfy any one of the needs should interfere with that development. These predictions have been tested in studies of the relation between need satisfaction and well-being. In addition to positive affect, Deci and Ryan (2000, p. 243) define well-being as "an organismic function in which the person detects the presence or absence of vitality, psychological flexibility, and a deep inner sense of wellness (Ryan, Deci, & Grolnick, 1995; Ryan & Frederick, 1997)." These predictions have been tested with measures of well-being in studies relating daily experiences with autonomy and competence (Sheldon, Ryan, & Reis, 1996), and with autonomy, competence, and relatedness (Reis, Sheldon, Gable, Roscoe, & Ryan, 2000).

The theory can be and has been criticized for being too optimistic about human nature (e.g., Pyszczynski et al., 2000), and also for not allowing sufficiently for the possibility of joy in the pursuit of extrinsic goals (e.g., Sansone, 2000).

LEVELS OF ANALYSIS IN THEORIES OF BASIC HUMAN NEEDS

By limiting themselves to three to five basic needs, all of these theories are comparable in their level of generality, in the sense of Maslow's metaphor of the nesting boxes.

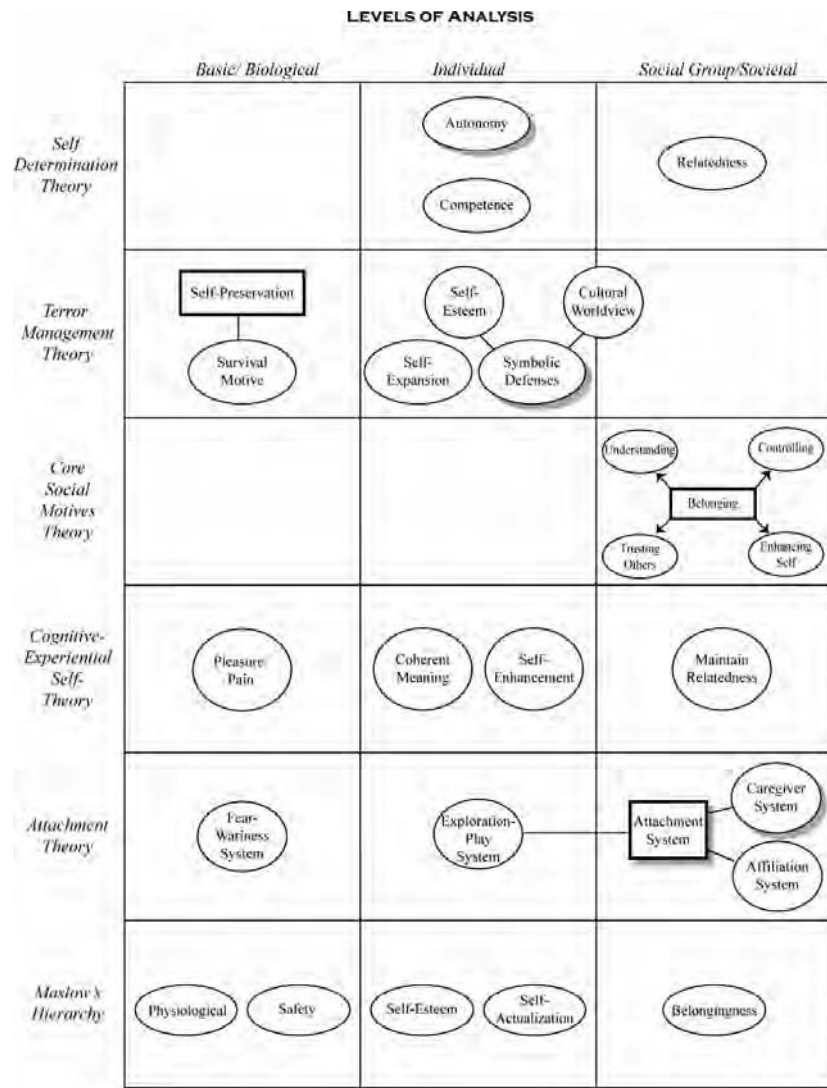
But in other important ways, their comparability is problematic. One important dimension of difference lies in the level of analysis at which each of the proposed basic needs is assumed to operate. Scientific disciplines are distinguished by their predominant level of analysis. While physicists typically work at the level of atomic and subatomic particles, biologists are more likely to work at the level of the cell or the organism. Psychologists take the perspective of the individual, while sociologists and economists tend to develop their analyses at the level of social groups. Although all six of our social–psychological theories of basic human needs do take the perspective of the individual, within that perspective they still can be understood to vary in the levels of analysis they employ. To illustrate these kinds of differences, we discuss three different levels of analysis as they are represented across these six theories: basic or biological-level needs, needs operating at the level of the individual, and needs operating at the level of the individual in social groups (see Figure 20.3). We recognize and want to state clearly that this rather crude classification scheme runs the risk, perhaps the certainty, of distortion through oversimplification. Our purpose in using these broad classifications is primarily to illustrate that social–psychological theories of needs are not always operating at comparable levels of analysis.

Theoretical Comparisons within Levels of Analysis

Basic/Biological-Level Processes

At the level of basic or biological processes are needs that are probably not so different in their fundamental action across a wide variety of species. In addition to the need for food, water, temperature regulation, and oxygen, this level of analysis includes needs involving basic processes such as fight-or-flight mechanisms of survival and fundamental psychological processes of learning and change based on classical and instrumental conditioning. This is a level of analysis that is typically assumed to be important but not commonly chosen for study by social psychologists. It is, however, represented in several of the theories under consideration.

Maslow's hierarchy starts at its base with needs at the physiological level. These most fundamental needs are assumed to take precedence over all others. In addition, the need for safety and security can be considered to fall into this level of analysis, at least partially if not entirely. One of the four basic needs in CEST, pleasure/pain, also can be classified as a basic biological level need. In attachment theory, we could think of the fear-wariness system as operating at this level. In TMT, the survival motive and its resulting need for self-preservation also operates at this level. We think that two of our six theories, SDT and core social motives, do not address needs at this level of analysis (see Figure 20.3).

Although four of the six theories do specify needs at this level, none of them has focused empirically on those needs. The three theories that have generated a substantial amount of research have not done so at this level. That is to be expected given that these are the theories of


LEVELS OF ANALYSIS

FIGURE 20.3. Levels of analysis of six theories of basic human needs. Shadowing indicates the needs that have generated the most empirical research.

social and personality psychologists. However, in two of the theories the needs at the basic/biological-level of analysis are given particular theoretical importance. In Maslow's hierarchy, it is the level of need that takes precedence over all others. In TMT, it is the home of the "master motive," survival. None of the other theories give such fundamental precedence to needs at the basic/biological level, instead locating their most important or root needs at the individual or the social group level of analysis.

Individual-Level Processes

More familiar in social–psychological theories in general are processes assumed to operate at the level of the individual. Many traditional motivational theories in social psychology such as cognitive dissonance theory (Festinger, 1957) and other consistency-based ap-

proaches (cf. Abelson et al., 1968) could be classified as individual-level analyses. The implied assumption here is that although these processes are embedded in each person's social world, and therefore affect and are affected by others, they are fundamental aspects of individual human functioning that would be present and important to understand even in the absence of social considerations. Indeed, the intensive study of such processes sometimes leads to questions and arguments about what it is that is social about such research (in other words, is it really social psychology).

Not surprisingly, five of the six theories specify basic needs at this level of analysis. In Maslow's hierarchy, self-esteem and self-actualization, the two needs at the top of the hierarchy, are individual-level needs. In attachment theory, the exploration–play system is where individuals express their curiosity about the environment. In CEST coherent meaning and self-enhancement are individual-

level needs. TMT includes the symbolic defenses for managing existential terror and the self-expansion system at this level of analysis. SDT has two of its three basic needs, autonomy and competence, at the individual level of analysis. Only core social motives theory makes no claims about individual-level needs (see Figure 20.3).

Also not surprisingly, this is the level at which most of the empirical research generated by three of these theories has been done. SDT has generated the most research on the needs for autonomy and competence. TMT has focused primarily on the operation of the symbolic defenses in the face of mortality salience as they are expressed in self-esteem and embracing the cultural worldview. We have placed the cultural worldview to straddle the individual and social group levels, but primarily the research focus has been on how and when individuals use their version of the cultural worldview to manage their personal terror. The empirical research guided by CEST has also been concentrated on the needs for coherent meaning and for self-enhancement. It is probably fair to characterize these three theories as primarily individual-level approaches, at least in terms of how they have been tested in the research literature.

One common thread worth noting is that in attachment theory, Maslow's hierarchy, and SDT, security of attachment, belongingness, or relatedness does or can provide the basis for effective satisfaction of needs at the individual level: exploration–play in attachment theory, self-esteem and self-actualization in Maslow's hierarchy, and at least as represented in some of the research on relatedness inspired by SDT, for satisfaction of autonomy and competence needs.

Social-Level Processes

At the social level of analysis are needs that depend on the individual being embedded in a social environment. They are still processes operating within an individual, but they depend on and are oriented toward social groups. Social comparison theory (Festinger, 1954) could be considered to be an early example of a theory oriented toward this level of analysis. Theories of social identity (e.g., Brewer, 1991; Brewer & Pickett, 1999; Tajfel & Turner, 1979; see Deaux, 1996, for a review) and the need for shared reality (Asch, 1951, 1956; Hardin & Higgins, 1996; Sherif, 1935, 1936) are also examples of theorizing at this level. The distinction between this level of analysis and that of the individual is that the social group is required for such processes to operate and make sense.

All six theories have at least one need or basic process at this level. Maslow's hierarchy specifies a need for belongingness in the middle of the hierarchy. CEST includes a need to maintain relatedness, and SDT also includes a need for relatedness. Attachment theory is primarily about the social level of analysis, including the attachment, affiliation, and caregiver systems. Core social motives theory is all about the social level of analysis, with all five needs related to functioning in social groups. Of all the theories, TMT is least oriented to this level of analysis. Maintaining a cultural worldview requires a community from which to learn and with which to share this source of comfort in the face of the knowledge of mortality, but we think that the generation of the shared culture from the combination of many individual personal existential problems and the waxing and waning of the use of defensive terror management mechanisms with the salience of mortality within the person still pulls the theoretical emphasis toward the individual level of analysis (see Figure 20.3).

Although there seems to be a great deal of agreement about what is important at this level of analysis, only attachment theory has generated much actual research on such needs; in addition to the extensive developmental work on attachment and its associated systems in infancy there is a burgeoning literature on adult attachment processes in close relationships (Reis & Patrick, 1996; Rholes & Simpson, 2004). Maslow's hierarchy and core social motives theory have not been used to generate empirical research; relatedness is the least intensively studied need in both SDT and CEST; and TMT is primarily oriented to the individual level, although there is a considerable amount of research on when individuals will embrace cultural values. The potential generative impact of assuming that there is a need for relatedness or belongingness (Baumeister & Leary, 1995) is not yet apparent in most of these theories.

Comparing theories with attention to differences in level of analysis helps to reveal, at least in part, why they are so different in the needs that they specify, and perhaps also why their theoretical structures are so different. Comparing an essentially social group/societal-level theory (e.g., core social motives) with an essentially individual-level theory (e.g., SDT or TMT) is more difficult than might otherwise be apparent in part because of these differences in levels of analysis.

Theoretical Comparisons across Levels of Analysis

Briefly comparing the theories across levels of analysis, Figure 20.3 reveals that the range of levels represented within individual theories varies considerably. Maslow's hierarchy and CEST both cover the range from basic/biological to social group/societal. In contrast, core social motives theory is completely contained at the level of the social group. Attachment theory, although not entirely at the social level of analysis, has its root motive and the systems that have been most heavily researched at that level. SDT and TMT, if judged by the research they have generated, are essentially individual-level theories.

As an example of what can be noticed by attending to levels of analysis, we note that in Maslow's theory as we go up the hierarchy, we don't go up the levels of analysis in a linear fashion. Instead, we move from the basic/biological level to the social group level, and only then to the individual level where self-esteem and self-actualization are at the top of the hierarchy. Seeing belongingness as the foundation for self-esteem and self-actualization is consistent with attachment theory and perhaps with SDT, but would seem to be at odds with TMT. Another concordance among attachment theory, SDT, and Maslow's hierarchy can be seen at the individual level of

analysis, where exploration and play, autonomy and competence, and self-actualization appear to be addressing comparable dimensions.

Positive and Negative Psychology?

SDT and TMT have generated a considerable amount of research. Both are essentially individual level of analysis models. But their assumptions about the nature of basic human needs and human nature are polar opposites. In the recently proposed language of positive psychology (e.g., Seligman & Csikszentmihalyi, 2000) and, by implication, negative psychology (e.g., Seligman, 1975), SDT is positive about human nature. On the other hand, if a Positive Psychology Hall of Fame were ever created, TMT would be unlikely to occupy a place of prominence.

> . . . it is part of the adaptive design of the human organism to engage interesting activities, to exercise capacities, to pursue connectedness in social groups, and to integrate intrapsychic and interpersonal experiences into a relative unity. (Deci & Ryan, 2000, p. 229)

> . . . many psychological needs are ultimately rooted in the existential dilemma into which our species was born." "Knowledge of the inevitability of death gives rise to the potential for paralyzing terror, which would make continued goal-directed behavior impossible." ". . . this terror is managed by a dual-component cultural anxiety buffer, consisting of . . . (a) an individual's personalized version of the cultural worldview, . . . and (b) self-esteem or a sense of personal value . . . (Pyszczynski et al., 1997, p. 2)

Perhaps a better to way to describe the difference between the two theories would be to say that SDT is a growth model while TMT is a defensive model. One is based on self-actualization, the other on managing anxiety. Both approaches have a long tradition in psychology, and both are probably capturing important aspects of human nature. Self-expansive motives have been added to TMT, but they are still justified as survival based, and do not have the optimistic self-actualizing quality of SDT's approach. The darker and brighter aspects of SDT and TMT have been discussed by the principles (Pyszczynski et al., 2000; Ryan & Deci, 2000), and further comparisons and contrasts, as well as empirical tests, are likely.

Basic Needs: Where Do We Stand?

Although it is tempting to try to come up with *the* basic set of human needs, we think that the theoretical differences we have revealed in structure and in levels of analysis make any simple attempt at synthesis of these theories premature. One might try thinking about, for example, the relations between autonomy and competence (SDT) and understanding and control (core social motives), but these theories are operating at two different levels of analysis. One could similarly wish to compare the need for self-esteem (TMT) and self-enhancement (CEST) and perhaps to think they might be the same thing. But in one theory, self-esteem is a derivative of the core motive, while in the other it is one of four equally balanced needs

maintained across a cognitive–experiential divide. Probably the differences in theoretical structure and in levels of analysis will need to be addressed before an overall integration or winnowing would be possible. Even so, some commonalities can be discerned. The most obvious of these is that five of the six theories share, at the level of the social group, an assumed need for relatedness, belonging, or affiliation.

Are theorists and researchers working on evaluating or integrating these disparate theories of basic human needs? Theoretical discussions and empirical comparisons among several of these theories have begun to emerge. At the empirical level, there have been comparisons or integrations of TMT and CEST (Simon et al., 1997), attachment theory and TMT (Mikulincer & Florian, 2000), and SDT, attachment theory, and TMT (Arndt, Routledge, Greenberg, & Sheldon, 2005). CEST has been used to examine self-verification theory and self-enhancement (Morling & Epstein, 1997; Swann, 1984, 1990; Swann, Stein-Seroussi, & Geisler, 1992), while an SDT-inspired approach to self-concordance uses a rational–experiential consistency model with features similar to CEST (Sheldon & Elliot, 1999; Sheldon et al., 2004). And at the theoretical level, discussions among SDT and TMT, as well as several other self-theories (Crocker & Park, 2004; Leary, 2004) have been published (Pyszczynski, Greenberg, Solomon, Arndt, & Schimel, 2004a, 2004b; Ryan & Deci, 2004). There have also been several investigations of cross-cultural evidence for the existence of a set of universal human needs (Grouzet et al., 2005; Sheldon et al., 2001; Sheldon et al., 2004).

In keeping with the beginning of this chapter, we should ask to what extent these theories tell us what it is that is distinctive about human nature. Have we learned how humans differ from other organisms? Many of the basic needs proposed by these various theories could easily be characteristic of other species as well. For example, basic attachment processes may not be uniquely human, nor perhaps are needs related to living in social groups, so in that sense we may not have made much progress in learning what is distinctive about human beings. TMT is based on what may be a unique, or if not unique at least unusual, ability to understand the concept of mortality and to deal with it through defensive symbolism. If self-reflexive consciousness is uniquely human (Higgins, 2005; Terrace & Metcalfe, 2005), then the rational–experiential distinction of CEST may also be uniquely human. If self-reflexive self-regulation is uniquely human, then the complex relations among autonomy, competence, and relatedness that play out in the extent to which reasons for task engagement are external, introjected, integrated, or internal (SDT) may be a uniquely human issue. It is an interesting and open question to ask more generally if self-actualization and the desire for autonomy and competence are uniquely human. The question of whether the best way, or even a good way, to understand what is uniquely human is through understanding basic human needs is still open.

Is the specification of basic human needs a useful psychological approach? On their own, several theories based on such specifications have led to extensive pro-

grams of empirical research, most notably SDT and
TMT. Although there is at this time considerable dis-
agreement among the various theories of basic human
needs, this disagreement also has had a generative im-
pact on theory and research. Much work remains to be
done. Differences in theoretical structure, levels of analy-
sis, and the set of basic human needs will need to be ad-
dressed. But it seems likely that this first handbook re-
view of *basic human needs* will not be the last.

The Goal Construct
in Social Psychology

AYELET FISHBACH
MELISSA J. FERGUSON

Goals constitute the focal points around which human behavior is organized. Much of what people think about, feel, and do revolves around the goals they are trying to meet, or those goals they have already met or dismissed. Goals can influence major life decisions such as choosing one's career path, as well as more mundane everyday choices, such as which book to read. Goals guide one's behavioral responses to the social environment, such as whether one responds to a provocation by being competitive, collaborative, or resigned, for instance. And goals, and the ways in which people pursue them, also determine people's evaluations, moods, and emotional experience both during a pursuit and after a pursuit has been completed or abandoned. The scholarship on goals in social psychology has reflected the centrality of goals in people's lives, and consequently the goal construct has been defined, examined, and challenged, iteratively, throughout almost the entire century of empirical psychology (e.g., Ach, 1935; Atkinson, 1964; Austin & Vancouver, 1996; Bandura, 1986; Bargh, 1990; Carver & Scheier, 1998; Deci & Ryan, 1985; Gollwitzer, 1990; Higgins, 1997; James, 1890; Kruglanski, 1996; Lewin, 1926; Locke & Latham, 1990; Mischel, Cantor, & Feldman, 1996).

In the current chapter, we propose a contemporary framework for understanding what goals are and how they influence human experience and behavior. In particular, we address how goals are activated, the characteristics of their operation, and the ways in which they interact with one another. We anchor the framework with a set of definitional assumptions about the structure and content of goals. In support of our framework, we draw primarily on research conducted over the last decade that is characterized by its social-cognitive approach. By adopting this approach to the study of goals we also emphasize the implicit nature of motivation, including the ways in which goals can become activated outside conscious intention and operate according to a variety of implicit mechanisms. This stands in contrast with much of the traditional research on goals, which has focused on the conscious processes involved in setting a goal and striving toward its completion (e.g., Carver & Scheier, 1981; Gollwitzer, 1999; Locke & Latham, 1990).

We organize the chapter into four major parts. We consider in the first part ("What Is a Goal?") a working definition of goals as well as a set of assumptions underlying goal research. We then move onto the second part ("On the Activation of a Goal"), which considers theory and findings on the determinants of goal activation. We discuss in the third part ("On the Operation of a Goal") the various characteristics of active goal operation that involve goal-related knowledge activation, evaluations, and affective experience. In the fourth and final part ("On the Interaction among Goals"), we turn to an arguably more realistic view of goals—one that assumes that people are constantly switching their attention and motivation from goal to goal, depending on a host of situational and personal variables (e.g., Atkinson & Birch, 1970). Any given goal pursuit potentially interferes with other possible pursuits, and thus we examine the special

challenges that simultaneous goal pursuits pose and the ways in which interaction and interdependence among goals occur. Our broadest objective in this chapter is to develop a goal framework that both grounds previous work as well as generates new questions and research directions.

WHAT IS A GOAL?

We define a goal as *a cognitive representation of a desired endpoint that impacts evaluations, emotions and behaviors.* Aspects of this definition have been echoed in goal literature throughout the past 50 years (e.g., see Carver & Scheier, 1981; Gollwitzer & Moskowitz, 1996; Higgins & Kruglanski, 2000; Locke & Latham, 1990; Sorrentino & Higgins, 1986). In what follows we explicitly consider a set of more detailed assumptions about goals that underlie this definition and much of the recent work on this topic. These assumptions can be organized into those that concern the *structure* of a goal in memory versus those that involve the *content* of goal representations.

The Structure of Goals

Researchers have long assumed that goals exist as cognitive representations in memory (Bargh, 1990; Hull, 1931; Kruglanski, 1996; Tolman, 1932), even if various theoretical treatments of goals over the last century have varied in terms of explicitly mentioning this point. We argue that although there is a general consensus that goals exist in memory, an explicit consideration of this point inevitably leads to certain implications, which have not been as widely discussed or tested. The fact that goals exist as knowledge structures suggests (at least) three characteristics. First, as a memory construct, a goal necessarily *fluctuates in accessibility* (i.e., its activation potential; Higgins, 1996). This means that the likelihood of the goal being activated will vary across time and situations according to its accessibility at the moment.

Another characteristic concerns the *multiple memories* underlying any given goal. In particular, rather than a goal consisting of a unitary, discrete construct, it consists of a wide array of interconnected memories that are related to that goal (e.g., means of attainment and opportunities) and become associated with one another through a variety of ways. For example, the interconnection among memories underlying the goal of riding a bike might develop through direct experience (e.g., when the bike tilts left, shift weight to the right) as well as semantic and episodic knowledge (e.g., bike riding is a form of exercise and recreation perfect for a sunny summer afternoon).

The fact that goals consist of many memories that are interconnected naturally leads to the third characteristic of goals. Namely, the memories of a goal become activated according to classical *knowledge activation* processes (Anderson, 1983; Anderson & Reder, 1999; Collins & Loftus, 1975; Neely, 1977, 1991; Posner & Snyder, 1975; Shiffrin & Schneider, 1977). In particular, it has long been postulated that the activation of a given memory will influence the activation of those memories with which it is connected. The nature of this influence can be either excitatory or inhibitory. With excitatory connections, as one memory of a goal construct becomes activated, and therefore, relatively more accessible, those memories interconnected with it should become activated and accessible as well. In this way, making one component of a goal construct more accessible can render much of the construct as a whole more accessible. For instance, the activation of a single memory concerning the goal of achievement could automatically lead to the activation (i.e., greater accessibility) of many other memories associated with achievement (see also research on stereotype activation; e.g., Bargh, Chen, & Burrows, 1996; Devine, 1989). But other connections among goal memories are inhibitory in nature, such that the activation of one goal automatically leads to the inhibition (i.e., lower accessibility) of another, competing goal. For instance, the activation of a central goal (e.g., academic achievement) might inhibit another tempting goal (e.g., partying—Fishbach, Friedman, & Kruglanski, 2003; Shah, Friedman, & Kruglanski, 2002).

Notably, the link between any two memories may not be bidirectional. Just because the activation of one goal memory can render accessible an associated memory, the same facilitative effect may not emerge in the reverse direction. For example, when considering the relationships among competing goals, whereas an immediately tempting goal can activate an overriding, more important goal, the reverse is not necessarily true. In fact, some recent research suggests that the same important goal might actually inhibit the tempting one (see Fishbach et al., 2003). In this sense, the connection among any two goal-related memories cannot be inferred merely on the basis of how one memory influences the activation of the other.

These three characteristics of goal structure (i.e., varying accessibility, multiple memories, and excitatory and inhibitory links) would be consistent with, and explained by, numerous types of cognitive models of memory, including simple associative networks as well as connectionist models, for example. A consideration of the types of cognitive architecture that might be able to explain and reproduce goal phenomena is beyond the scope of this chapter and we consider it to be one of the next challenges that social-cognitive psychologists will face in the near future, just as has been the case with research on attitudes and stereotypes (e.g., Bassili & Brown, 2005; Mitchell, Nosek, & Banaji, 2003; Smith, 1996).

The Content of Goals

Beyond these structural characteristics, what type of knowledge is reflected by goal memories? The answer to this question directly builds on our definition of goals as representations of desired endpoints that direct behavior, evaluation, and emotions. Below we consider in more detail what this view implies about the nature of goal memories.

Ends and Means

First and foremost, goals contain information about end states. End states are the reference points toward which behavior is directed. One notable feature of end states is that they can vary in their abstractness (Hommel, Muesseler, Aschersleben, & Prinz, 2001; Jeannerod, 1997; Kornblum, Hasbroucq, & Osman, 1990; Kruglanski et al., 2002; Miller, Galanter, & Pribram, 1960; Powers, 1973). For example, a goal may involve an end state that entails something tangible and perceptual in the world (e.g., having a cup of coffee) or one that is relatively more abstract and conceptual in nature (e.g., achievement).

Goals entail more than just end states, however. They also include the variety of behaviors, plans, and objects that enable one to reach that end state. For instance, the goal of getting a cup of coffee might entail temporally ordered, procedural information about first grinding coffee beans and then putting them into a filter in a coffee machine (see Norman, 1981), and the goal of achievement might include behaviors such as studying at the library and paying attention in class (Aarts & Dijksterhuis, 2000; Bandura, 1997; Bargh & Gollwitzer, 1994; Carver & Scheier, 1998; Custers & Aarts, 2005; Emmons, 1992; Schank & Abelson, 1977; Shah & Kruglanski, 2002, 2003; Vallacher & Wegner, 1985; Vallerand & Ratelle, 2002; Wilensky, 1983). The behaviors and objects associated with an end state can also vary in abstractness. For instance, the end state of achievement might include the specific behavior of neatly writing lecture notes as well as the relatively more general behavior of being punctual.

When considering ends versus means, it quickly becomes apparent that almost any end state can be understood as a means for a higher-order end state. For instance, the means of studying in order to attain academic success could itself constitute an end state with its own associated means (e.g., take notes and go to library). In such a hierarchical organization, the terms "end state" and "means" are clearly meaningful only in relation to one another. Despite the relative nature of the terms, they are nevertheless useful in that they identify the point toward which a person is striving, and the specific ways in which that person might succeed. In this way, the "end state" organizes one's behavior, whereas the variety of means can be somewhat interchangeable or substitutable, and an inability to utilize one means does not necessarily imply that the end state is abandoned (e.g., Kruglanski et al., 2002; Tesser, Martin, & Cornell, 1996).

Evaluative Information

We assume that a goal consists of an overall end state and the behaviors, objects, and plans needed for attaining it. But is that all a goal is? Just because someone possesses knowledge about how to put a tree house together, for instance, does not mean that that knowledge constitutes a goal. This leads to a second important aspect of the content of goal constructs—the end state (and its associated means) has to be *desirable* (Carver & Scheier, 1981; Custers & Aarts, 2005; Kruglanski et al., 2002; Peak,

1955; Pervin, 1989; Shah et al., 2002; Young, 1961). By definition, a goal that is desirable must be associated in some way with positive affect. We argue that, in line with the long-standing notion that people are motivated to approach pleasure and avoid pain (Arnold, 1960; Bogardus, 1931; Corwin, 1921; Doob, 1947; Frijda, 1986; Lang, 1984; Lazarus, 1991; Lewin, 1935; Mowrer, 1960; Osgood, 1953; Thurstone, 1931; Young, 1959), the positivity in a goal representation is what imbues the construct with its motivational force. In other words, the primary reason that goals influence and guide behavior is because the positivity associated with them is inherently motivating (see research on expectancy-value models, Atkinson, 1974; Tolman, 1932).

Although we define goals as desirable end states, and therefore assume that they must include positive evaluative information in their representation, it is not yet clear exactly how goals become positive. For instance, a goal might become positive and desirable in a conscious and intentional manner, such as when a person sees a friend playing a complicated, fun game and wants to learn it in order to join in. Or, a goal can become desirable in a more implicit, nonconscious fashion, such as through repeated pairings (i.e., conditioning) of a given activity and consequent reward experiences. Recent research has provided support for the latter claim. Custers and Aarts (2005) first implicitly conditioned a goal (e.g., playing a puzzle) with positive evaluations by creating a computer task in which they paired aspects of a task (e.g., the words "puzzle" and "number") with positive words (e.g., "happy"). They found that participants who had received positive (vs. neutral) conditioning of the puzzle words subsequently showed greater motivation to begin the puzzle task.

What Distinguishes a Goal Construct from Other Social Psychological Constructs?

We have noted so far that a goal construct varies in accessibility, consists of many interconnected memories, and operates according to classic knowledge activation principles. These memories refer to ends and means and also contain positive information. But, given these characteristics, how is a goal construct distinct from other types of knowledge structures?

Goals have been distinguished from other hypothetical constructs primarily by the nature of their effects on behavior (Aarts, Gollwitzer, & Hassin, 2004; Bargh, Gollwitzer, Lee-Chai, Barndollar, & Troetschel, 2001; Fitzsimons & Bargh, 2003; Kawada, Oettingen, Gollwitzer, & Bargh, 2004; Shah & Kruglanski, 2003; see review by Förster and Liberman, Chapter 9, this volume). In particular, the strength, or activation, of a goal only dissipates when the goal has been reached, whereas the activation of semantic constructs dissipates at a constant rate from the moment of activation (Atkinson & Birch, 1970; Gollwitzer & Moskowitz, 1996; Lewin, 1936; McClelland, Atkinson, Clark, & Lowell, 1953). Specifically, whereas Lewin (1936) suggested that a goal will stay active until the discrepancy between the actual and desired state is reduced, others have argued that the goal

strength will actually increase over time until it is met (Atkinson & Birch, 1970; McClelland et al., 1953), or when the pursuit becomes too difficult to sustain (Brehm & Self, 1989; Wright, 1996). This suggests, for example, that when the *goal* of achievement has been activated, the person will increase his or her efforts for a while until the goal has been met (or until he or she encounters an insurmountable obstacle). In contrast, when mere *semantic knowledge* about achievement has been activated, that activation should rapidly decay over time such that the person may quickly show less evidence of that activated knowledge in perception or judgment (see Bargh et al., 2001).

It follows that a cue for a goal (e.g., the word "achievement") does not always influence behavior in a goal-related fashion; rather, its influence depends on other variables such as the nature of the task and whether the goal is applicable to it. In addition, whereas all goals include semantic knowledge, not all semantic constructs are goals (i.e., have motivational force) or positivity associated with them. As we consider how a goal might become activated and then operate, we review the ways in which researchers have distinguished between goals versus other types of constructs.

ON THE ACTIVATION OF A GOAL

What determines whether a given goal is activated and then guides behavior? The main theme of classical goal research has been that goals are enacted when people deliberately and purposively decide to adopt them (Bandura, 1986; Carver & Scheier, 1998; Deci & Ryan, 1985; Gollwitzer, 1990; Locke & Latham, 1990; see also Mischel et al., 1996, for a review). This would suggest that a goal becomes activated via conscious, intentional thought. For instance, a person might consciously consider whether to intentionally pursue the goal of being funny while at a dinner party.

However, research over the last decade on how goals become activated suggests a different perspective. Many of the insights in this work follow from the definition of goals, and the assumptions regarding their structure in memory in particular. We noted earlier that goals consist of interconnected memories that become activated (i.e., more accessible) according to knowledge activation principles. This means that the perception of any stimulus that is strongly associated with the goal should be sufficient for the goal to become activated (Bargh, 1990; Bargh & Barndollar, 1996; Bargh et al., 2001; Gollwitzer, 1999; Jacoby & Kelley, 1987; Kruglanski, 1996; Shah & Kruglanski, 2003; see also McClelland, Koestner, & Weinberger, 1989). Importantly, the perception of a stimulus does not have to be conscious (e.g., Greenwald, 1992; Greenwald, Draine, & Abrams, 1996). And, even if people's perception of a stimulus *is* conscious, they may not be aware that it has activated a whole array of associated memories, including goal constructs (see Ferguson & Bargh, 2004a).

In general, by considering goals as constructs in memory, recent goal research acknowledges the possibility of

nonconscious goal activation. We review below the kinds of stimuli that are capable of triggering goal activation. This range of stimuli must, by necessity, be associated with that goal. In this way, not only does our review address the ways in which goals can become activated, it also further reveals the kinds of stimuli that are part of the goal construct.

It is also important to note that although we concentrate in this section on the ways in which goals are activated, the findings also necessarily speak to the operation of a goal. That is, we infer the activation of a goal from how the goal influences behavior, judgment, attitudes, and emotions. Although goal activation and goal operation are often empirically difficult to disentangle, we assume that goal activation precedes goal operation. Therefore, we emphasize in the next section the minimal requirements for a goal to be activated, and we then turn our attention to the types and kinds of downstream consequences of activation in subsequent sections.

Priming by End States and Means

In one of the first tests of how a goal can become activated and influential without the person's awareness or intention, Chartrand and Bargh (1996) subtly primed participants with either a person impression or memory goal. They administered to participants a scrambled sentence task in which participants had to create grammatically correct four-word sentences out of groups of five scrambled words (Srull & Wyer, 1979). Some sentences included words related to forming an impression (e.g., judge, impression, and personality), while others contained words related to memorization (e.g., remember, recall, and retain). Participants were then asked to read through a set of behaviors about a fictional target and were given a surprise recall test afterwards. The results showed that those who had merely read a few words related to forming an impression in fact processed and integrated the behavioral information about the target in a way similar to when someone is intentionally trying to form an impression. That is, they formed more clusters of the behaviors around personality traits and were also more likely to show deeper processing of those behaviors that were inconsistent with the overall personality theme (e.g., see Hamilton & Sherman, 1996; Stangor & MacMillan, 1992). This was one of the first demonstrations of how information-processing goals can become nonconsciously activated and influential.

But, what is the behavioral evidence that a goal is nonconsciously activated? Bargh and colleagues (2001) tested for goal activation by first asking participants to complete a word-search puzzle. Whereas for some participants some of the words were related to achievement (e.g., strive, achieve, and master), for others none of the words were related to this goal. After this subtle exposure to the notion of achievement, participants were asked to complete a series of other word-search puzzles. Those who were exposed to achievement words found significantly more words than those in the control condition. These findings demonstrate that by simply reading words related to a given end state, a person is likely to

perform goal-congruent actions unknowingly and unintentionally.

How might a nonconsciously activated goal compare with one that is consciously activated? To examine this question, participants in another study (Bargh et al., 2001) were explicitly told to cooperate, were subtly primed with cooperation words via a scrambled sentence task, or were not primed in any way. Each participant then played a resource management game with another participant in which they had to fish from a lake while ensuring that the lake did not become depleted. The results showed that those in the consciously activated goal condition, as well as those in the nonconsciously activated goal condition, showed more cooperation than those in the control condition. It appears that a nonconscious prime can have an effect similar to a conscious prime on goal-congruent behavior.

Another predominant issue concerns the evidence for the activation of a goal versus some other construct. That is, in these tests of nonconscious goal activation, how do we know that a goal was activated, versus perhaps simply semantic concepts related to the goal? For example, was participants' achievement behavior due to the influence of the *goal* of achievement or simply the *semantic concept* of achievement? Perhaps the priming task simply increased the concept of achievement, and then participants interpreted the situation as achievement related and acted accordingly. Recall that whereas the activation of semantic concepts decreases over time, the activation of goals increases over time until the goals are attained. Accordingly, Bargh and colleagues (2001) nonconsciously primed participants with achievement and then asked them to complete either a semantic task of evaluating an ambiguously achieving target (Higgins, 1996) or a goal task of solving a set of word-search puzzles. Participants also completed the measure either immediately after the priming or after a 5-minute delay. In the immediate condition, those in the priming condition who did the goal task performed better than those in the control condition, and those in the priming condition who completed the semantic judgment task rated the target as more achieving than those in the control condition. The critical question concerned the effects for those in the delay condition. If nothing but the semantic concept of achievement was activated, the effects for both the judgment task and the goal task should have decayed. However, if the goal of achievement was actually activated (in addition to semantic knowledge), the effect on the goal-relevant task should have increased over time. The pattern of results confirmed this, suggesting that the goal of achievement was indeed activated.

More recent research suggests that in addition to end states, goals can also be nonconsciously activated by relevant means and strategies. Shah and Kruglanski (2003) showed that people who were subliminally primed with a recently learned behavioral strategy showed evidence of pursuing the goal related to the strategy. In one study, before completing an anagram task, participants learned a strategy for solving anagrams. Those participants who were subliminally primed with the name of that strategy ("first–last," which refers to determining initially

whether the first and last letters of the letter string anchor any known words) showed a greater accessibility of words related to anagrams and also exhibited more persistence and better performance. These findings suggest that the perception of (even recently learned) means can activate the goal associated with that means.

Whereas the work described earlier showed that a goal can be nonconsciously activated by semantic cues (i.e., words) closely related to end state or means, what other ways might goals become triggered by the environment? We suggested that the perception of any stimulus that is associated with the goal should be sufficient for the goal to become activated. Because people live in a social environment, a large proportion of these stimuli are social stimuli. Indeed, a bevy of studies has now uncovered some of the main categories of social stimuli that lead to goal activation.

Priming by Relationship Partners

Goals can include the representation of individuals (e.g., a parent and a teacher) who expect the person to pursue the goal as well as the representation of individuals who pursue that goal themselves. For instance, a person's goal of making money might include representations of that person's father, who expects that person to make money, as well as representations of a best friend who is obsessed with making money. If goals include representations of others, the perception of a relationship partner can automatically activate those goals associated with that partner.

As a demonstration of this principle, Shah (2003) has shown that being subtly reminded of a significant other can activate the significant other's expectations, which can then influence the person's own expectations and performance. Shah demonstrated that participants who were subliminally primed with the name of a significant other who had high expectations for the person (e.g., a father) on an anagram task actually persisted longer and performed better than those not primed. In a similar line of research, Fitzsimons and Bargh (2003) claimed that people normatively have achievement goals for impressing their mothers. They accordingly found that those who were reminded of their mothers in a subtle way achieved more on a word-search puzzle than those not reminded.

Relationship partners can further activate the emotional experience that is included in the goal representation. For example, Higgins and colleagues have shown that people can adopt a style that emphasizes nurturance needs (a promotion focus) or one that emphasizes security needs (a prevention focus; see Higgins, 1997). Based on this theory, Shah (2003) showed that a significant other's regulatory focus can also influence one's own reactions to the task according to regulatory focus. For example, those whose fathers *hoped* that they would do well on academic tasks (a promotion goal), and who were primed with words related to father, experienced cheerfulness when given positive feedback on an anagram task and dejection when given negative feedback on the task, in line with the ways in which regulatory focus influences

emotion-specific reactions. Those whose fathers *expected* them to do well on academic tasks (a prevention goal), and who were primed with father-related words, experienced relaxation when given positive feedback on an anagram task and agitation when given negative feedback, again in line with research on how regulatory focus influences emotions (e.g., Higgins, Shah, & Friedman, 1997).

Priming by Group Members

In addition to relationship partners activating goals, the perception of (unfamiliar) group members can also activate the goals that the perceiver tends to pursue when in the presence of those group members (Cesario, Plaks, & Higgins, 2006). When one encounters another person, an automatic preparation to interact with that person, either in an approach or an avoidance manner, is activated, depending on that person's implicit attitudes toward that group. The result is that the perception of a group member activates one's goals toward that group (in addition to stereotypes) and these goals influence behavior. As a demonstration of this principle, Cesario and colleagues (2006) primed participants with gay or straight men and then introduced a mild provocation when the computer failed and participants' data were supposedly lost (a paradigm developed by Bargh, Chaiken, Raymond, & Hymes, 1996). The degree to which participants then interacted with the experimenter in a hostile manner constituted the main dependent measure. If the contents of the gay stereotype are most influential, then those who were primed with gay should behave in a more passive manner after the provocation (given that gay men are stereotyped as passive; e.g., Herek, 2000, 2002) compared with those not primed. However, if one's goal to interact with the group member is activated and assuming that most people have negative implicit attitudes toward gay men, those primed with gay men should be more hostile toward the experimenter than those not primed. The results favored the latter hypothesis—priming gay men activated the goal to act with hostility.

Priming by a Stranger's Goal Pursuit

In addition to relationship partners and group members, the perception of another person engaging with goal-related actions might be sufficient to trigger the goal related to these actions, even if the actor is unfamiliar. This is because people infer other people's goals from their actions, and these inferred goals have implications for one's own behavior (Aarts et al., 2004; Aarts, Hassin, & Ferguson, 2005). As a demonstration, Aarts and colleagues (2004) gave participants a vignette about a target person's behavior (which implied a goal), and then participants were placed in a setting where they could behave in line with that goal or not. For instance, in one study, male participants either read about a target person who was trying to pick up women in a bar (implying the goal of seeking casual sex) or read a control vignette that did not imply the goal. Participants were then asked to provide feedback on one of the experimental tasks to the experimenter, who was described to half of the partici-

pants as female and to the other half of participants as male. Because men who are sexually interested in women tend to show more helping behavior toward them (e.g., Baumeister & Tice, 2001; Buss, 1988), those who had read the vignette implying the goal of casual sex gave more feedback (i.e., showed more helping behavior) toward the female experimenter but not the male. These findings show that merely observing someone else's behavior can activate the goal associated with the behavior.

Notably, these "goal contagion" effects reflected the influence of a goal rather than the influence of simple behavior priming (e.g., Bargh et al., 1996; Dijksterhuis & van Knippenberg, 1998). Namely, because the dependent measure (giving feedback to a female experimenter) was sufficiently semantically distinct from the primed behavior (picking up women in a bar), the effect was probably due to an overarching goal that contained both behaviors as means.

Summary

The research we have described in this section shows how a goal can become activated (and influential) on the basis of the mere (conscious or nonconscious) perception of a goal-related stimulus. There is precedent for this notion in classic goal research, which assumes that the degree to which a person is consciously thinking about a goal determines the likelihood that the person will pursue it (e.g., Bandura, 1986; Deci & Ryan, 1985; Gollwitzer, 1990; James, 1890; Lewin, 1935; Locke & Latham, 1990; Mischel et al., 1996). The present analysis expands on classical research, by showing that if accessibility is in fact the underlying mechanism, goals should be able to be activated by even the nonconscious perception of goal-related stimuli.

Importantly, the claim that a goal's influence will depend on its accessibility in memory does not imply that people will behave in line with whatever memories have recently been activated. Once a goal is activated, its effect on behavior still conforms to the principle of applicability (Higgins, 1996). Increased accessibility of a construct via priming simply means that it will be more likely to be applied to a stimulus that is *relevant to that construct*. In the research reviewed earlier, participants were primed with cues for a certain goal and were then placed in a situation that "afforded" the relevant goal pursuit to some degree. The degree to which a particular task is goal related determines the extent to which an accessible goal guides behavior.

In our discussion of goal activation, we inferred activation based on the downstream behavioral effects of goals (e.g., puzzle performance, helping behavior, and hostile behavior). In this way, this research joins a litany of other classic findings showing how goals influence behavior. However, in thinking about the downstream consequences of goals on behavior, we now move away from merely documenting overt, behavioral effects to identifying more subtle effects that perhaps might mediate between a goal and overt behavior. Specifically, we are interested in examining the ways in which an activated

goal, and in particular a nonconsciously activated goal, influences knowledge accessibility, evaluations, and emotions, and we review these influences in the next section.

ON THE OPERATION OF A GOAL

In this section we identify the characteristics of goal pursuit, including goal-relevant knowledge accessibility, goal-relevant evaluations, goal-relevant moods and emotions, and, of course, goal-relevant choices and behaviors. Just as we did in the section on the activation of a goal, we develop the current section on the operation of a goal based on the definition of the goal construct that we outlined in the beginning of the chapter. In particular, throughout the following section we note how some of the characteristics of goal operation derive directly from our assumptions about the content and structure of the goal concept. For instance, because goals contain information on evaluations and behaviors, the operation of goals can be characterized by changes in the evaluation of goal-related stimuli and the enactment of goal-congruent behaviors.

Goal-Relevant Knowledge Accessibility

We proposed earlier that increased accessibility of goal-related knowledge is what it means for a goal to be activated. In addition, the accessibility of goal-related knowledge can also be understood as a *consequence* of goals. This suggests that goal-relevant knowledge should be more accessible during the pursuit of that goal, compared with when the pursuit is over or has not been initiated. For example, the activation of the hunger goal should increase the accessibility of knowledge that is related to that goal, such as restaurants. In this way, the increased accessibility of restaurants simultaneously represents what it means for a hunger goal to be activated and one type of downstream consequences of goal activation.

There is a long history of the theoretical notion that the (conscious) activation of a goal influences the types of knowledge that become accessible (Ach, 1935; Bargh, 1997; Bruner, 1957; Gollwitzer, 1996; Jones & Thibaut, 1958; Klinger, 1996; Kruglanski, 1996; Kuhl, 1987; McClelland & Atkinson, 1948). Some of the precedent for this started with the New Look research movement. In contrast with the classic view of perception in the first half of the 20th century that perception was entirely driven by the stimulus (Stevens, 1951), New Look research showed that people's perceptions are influenced by the value of the stimulus being perceived (Bruner, 1957; Bruner & Postman, 1948; Jones & Thibaut, 1958; McClelland & Atkinson, 1948; for a review, see Greenwald, 1992). For example, in the classic experiment by Bruner and Postman (1948), poor children overestimated the size of coins to a greater degree than rich children, for whom the money was presumably less intensely desired. In a review of the New Look research, Bruner (1957) argued that what people want, need, and desire can influence the accessibility of knowledge, and thus how they see the world around them. Each nonconscious

act of perception is an act of categorization, with multiple categories being available for a given stimulus. People's needs and motives can influence the accessibility of those categories and thus make them "perceptually ready" to categorize, or perceive, stimuli in certain ways. For instance, when people are looking at an ambiguous object in the distance that looks like a storefront but could be a restaurant façade, they should be more likely to "see" a restaurant when they are hungry than when they are not (see Bruner, 1957; see also Glenberg, 1997).

Recent evidence provides more methodologically rigorous support for the theoretical claim of the New Look that an active goal increases the accessibility of related knowledge (Aarts et al., 2001; Balcetis & Dunning, 2006; Förster, Liberman, & Higgins, 2005; Moskowitz, 2002). For instance, Moskowitz (2002) tested whether knowledge that is related to an active goal automatically captures attention. Based on self-completion theory, people who receive negative feedback about an important self-relevant domain should be especially motivated to reestablish competence in that domain. Accordingly, Moskowitz (2002) reasoned that athletes who think about one of their recent athletic failures (e.g., missing a crucial foul shot) should be highly motivated to reclaim or prove their competence as athletes, and if so, those who have recently thought about failure should demonstrate the strongest accessibility of knowledge related to their goal of athleticism. Participants thought about either a recent failure or success in athletics or nothing at all, and then they completed a computer task in which there were distractors either related or unrelated to athleticism (e.g., athletic, fast, and agile). Those participants who had been thinking about failure, and thus who presumably had particularly accessible goal-related knowledge, responded more slowly to the focal task when the distractors were athletic-related versus unrelated. Apparently, when a goal is activated, stimuli related to the fulfillment of that goal become highly accessible and automatically attract attention.

But, part of our argument (also consistent with the New Look research) is that the accessibility of goal knowledge should influence the stimuli in the environment to which people pay attention. Does this happen? Aarts, Dijksterhuis, and De Vries (2001) manipulated participants' thirst by asking some of them to consume salty snacks. Participants then completed a lexical decision task in which some of the words were beverages or items used to drink beverages (e.g., juice, soda, and bottle). The results showed that those who had been manipulated to be thirsty showed significantly greater accessibility of drinking-related words, compared with control words, and compared with nonthirsty participants. Aarts and colleagues then showed in a second study that thirsty participants were more likely than nonthirsty participants to recall drinking-related objects. These studies demonstrate that the goal of quenching thirst can render accessible knowledge concerning stimuli, actions, and concepts related to sating that goal, just as Bruner (1957) and others argued, and, importantly, that greater accessibility then determines the objects to which people attend in their environment.

Although an active goal increases the accessibility of knowledge related to that goal, which then influences the stimuli that are noticed, does it influence what people actually see in the world, as New Look researchers claimed? Recent research by Balcetis and Dunning (2006) has provided support for this notion. In one study, participants were told that they were going to be randomly assigned by the computer to one of two conditions. In one (desirable) condition, they would be asked to taste a glass of fresh orange juice, and in the other (undesirable) condition, they would have to sip an unappealing, green vegetable drink. They were told that the computer would randomly present either a number or letter to them, and that either a number or letter (depending on counterbalancing) would mean that they were assigned to the OJ condition. The computer then flashed the well-known, ambiguous "B/13" figure, and then there was a message indicating computer failure. The experimenter, who had not seen what was flashed, asked the participant what he or she saw on the screen. Whereas those for whom the *number* meant the desirable condition were more likely to see the 13, those for whom the *letter* meant the desirable condition were more likely to see the B. A series of additional experiments demonstrated (using a variety of implicit measures) that the effect was not due to response bias but, rather, reflected what participants actually perceived. On the basis of this work, we conclude that what someone wants does influence how they disambiguate stimuli in the world; critically, this seems to happen because what someone wants influences the types of knowledge that are accessible in memory, which then serve to capture any ambiguous stimuli relevant to that knowledge (see Bruner, 1957; Higgins, 1996).

Interestingly, goal pursuit is not simply characterized by accessible knowledge during the pursuit; the completion of a pursuit leads to the inhibition of related knowledge. Recently, Förster and colleagues (2005; see also Liberman, Förster, & Higgins, in press) have demonstrated this point. They asked participants to search for a picture of a pair of glasses on a computer screen and found that during the search, but before participants found the target, the accessibility of words related to glasses was greater compared with the accessibility for those who were not searching for the target. This is in line with the findings we just described. However, once participants found the target, the accessibility declined below the level for control participants. This work is consistent with work in cognitive science showing that knowledge related to fulfilled intentions becomes inhibited (Goschke & Kuhl, 1993; Liberman & Förster, 2000; Marsh, Hicks, & Bryan, 1999).

Goal-Relevant Evaluations

We argued in the previous section that the accessibility of goal-related knowledge can be understood as evidence of goal activation as well as a consequence of goal activation. In a similar way, the effects of goals on *evaluations* of stimuli in the environment can be conceptualized both as evidence that those stimuli are relevant to an active goal and as effects of that active goal. Indeed, we argue in this framework that the evaluations that follow from goal pursuit reveal the nature of the associations in memory between the goal construct, means and objects, and evaluative information. We therefore suggest that the "effects of a goal" on evaluation and emotion also speak to the content of the respective goal construct.

How then does active goal pursuit influence the way in which people evaluate stimuli related to that goal? In one way, the answer to this question is obvious and straightforward, and seems self-evidently true. When people are actively pursuing a goal, by definition they want (desire) those things that can help them achieve the goal, and similarly should not want those things that prevent them from reaching the goal. For example, being thirsty makes water more desirable and positive because it can alleviate one's thirst, and salty things more undesirable because they can exacerbate one's thirst (see also Loewenstein, 1996). Thus one consequence of goal operation is more positive evaluations of those stimuli that can facilitate the goal, and perhaps more negative evaluations of those stimuli that can thwart the goal (Brendl & Higgins, 1996; Cabanac, 1971; James, 1890; Lazarus, 1991; Lewin, 1926, 1935; Markman & Brendl, 2000; Rosenberg, 1956; Shah & Higgins, 2001).

In what follows, we explore how goals influence evaluations but focus in particular on studies that used implicit rather than explicit measures of evaluation. There are two reasons for this focus. First, implicit measures capture changes in evaluations that are not contaminated by people's response biases, self-presentation pressures, or demand effects. In this way, any changes in implicit evaluation as a function of goal pursuit can be regarded as spontaneous and likely to occur in "real-world," nonlaboratory settings. Second, research has shown that explicit and implicit evaluations are not identical; not only might they rely on different memories and underlying processes (e.g., Gawronski & Strack, 2004; Hofman, Gawronski, Gshwendner, Le, & Schmidt, 2005), they also seem to guide different types of behaviors (e.g., Asendorpf, Banse, & Mücke, 2002; Devine, 1989; Dovidio, Kawakami, Johnson, Johnson, & Howard, 1997; Egloff & Schmukle, 2002; Fazio, 1990; Wilson, Lindsey, & Schooler, 2000). Whereas explicit evaluations seem to guide behaviors of which the person is aware, and that are easy to guide and monitor, implicit evaluations seem to direct behaviors that are less intentional and relatively more difficult to control and monitor. Given that implicit evaluations influence people's subtle and unintentional behaviors, any effect of goals on implicit evaluations would explain and demonstrate one way in which goals can guide people's behavior in a subtle and nonconscious manner.

Evaluations of Stimuli Consistent with the Goal

Stimuli are evaluated implicitly in line with one's active goals (Ferguson & Bargh, 2004b; Moors & De Houwer, 2001; Moors, De Houwer, & Eelen, 2004; Sherman, Rose, Koch, Presson, & Chassin, 2003). In support of this proposition, Sherman and colleagues (2003) found, for example, that chronic cigarette smokers automatically

evaluate cigarette paraphernalia more positively when they are in need of a fix, versus when they just recently satisfied the urge. In one study, heavy smokers who had been instructed to refrain from smoking automatically evaluated smoking-related stimuli in a more positive fashion than those heavy smokers who had just recently smoked. This suggests that when a goal is activated, those stimuli that can help the person to reach the goal are automatically evaluated as positive.

But how long does this implicit positivity last? Ferguson and Bargh (2004b) showed that stimuli that are relevant to a currently active, but not recently completed, goal are implicitly evaluated as more positive than control stimuli. This suggests that the effect of a goal on implicit evaluations lasts only as long as the goal is active. In one study, participants who were still involved in a competitive word game automatically evaluated game-related words (e.g., win and achieve) as more positive than those who had never played the game, as well as those who had played the game but were already finished. This demonstrates that the automatic evaluation of stimuli is contingent upon what the perceiver is currently doing at the moment, rather than what the perceiver has just done. In another demonstration of goal-based evaluation, Ferguson and Bargh asked thirsty participants to either drink multiple beverages, thereby sating their thirst, or sample salty, dry pretzels, thereby exacerbating their thirst. The participants then automatically evaluated a series of words that varied in their relevance to thirst. The results showed that those who were still thirsty automatically evaluated words that were strongly related to the thirst goal (e.g., water and juice), but not unrelated to the thirst goal (e.g., chair), as more positive than those who had just sated their thirst.

In general, then, there is some evidence for our claim that objects and means related to a goal become more implicitly positive when that goal is active compared with when it is not. However, what about the end state itself? When someone is pursing an achievement goal, for instance, are words such as *success* and *achievement* evaluated in a more positive manner? We claim that people who are actively pursuing a goal automatically evaluate relevant end states as more positive compared with when the goal is not being pursued. In a study that tested for this possibility, Ferguson and Bargh (2004b) assumed that participants who were asked to think about recent failure in an important, relevant domain would be the most motivated to pursue that end state (reestablish their competence in the domain) compared with those who thought about success in the domain, or who thought about an unrelated topic (see research on self-completion theory; e.g., Wicklund & Gollwitzer, 1982). Participants who were athletes were thus asked to think about recent failure or success in athletics, or an unrelated topic. Their automatic evaluations of words related to the goal of improving their athleticism (e.g., athletic and agile) were then measured. As predicted, those participants who had thought about a recent failure in athletics generated the most positive automatic evaluations of the end states (and not other types of words) compared to those who had thought about success or an unrelated topic. Consistent with previous research on self-

completion theory, this effect emerged most strongly for those for whom the athletic domain was the most important—varsity athletes. The activation of a goal thus renders as positive those end states that are directly related to the goal.

Even though the evaluation of stimuli seems to depend on whether those stimuli are related in some way to people's current goals, this does not mean that stimuli that are unrelated to a current, primary goal will have no valence. People's average evaluations of stimuli should indicate the average relevance of those stimuli for the person's goals. Obviously, those stimuli that are consistently useful for a person's important goals might be evaluated as positive most of the time, whereas those that are only occasionally useful might be less consistently positive. If so, it should be the case that people's implicit evaluations of stimuli in default (non-goal-related) settings should predict the likely influence of that goal in a goal-relevant setting. Ferguson (in press) tested this by measuring participants' chronic, implicit evaluations of end states in one setting, and then testing whether those evaluations predicted participants' goal pursuit in another setting. In one study, participants' implicit evaluation of the goal to be thin was measured. A week later, participants were asked to report how much over the previous week they had avoided eating tempting foods, as well as how often they planned to do so in the upcoming week. Participants' implicit evaluations measured a week earlier significantly predicted their goal-relevant behavior, and even did so significantly above and beyond their explicit evaluation of the goal. Such findings suggest that people's chronic goals influence their evaluation of stimuli related to the respective end states.

Evaluation of Stimuli Inconsistent with the Goal

The activation of a goal representation might also lead to more negative evaluations of stimuli that undermine that goal (e.g., Ferguson, 2006; Fishbach, Zhang, & Trope, 2006). For example, participants who were consciously or nonconsciously primed with a goal construct (e.g., academic pursuits) implicitly generated negative evaluations of words that were related to another low priority goal (e.g., social life) that might undermine the primed goal (Ferguson, 2006). But importantly, whereas an active high-priority goal undermines the positive value of stimuli related to a competing low-priority goal (as in the previous case), an active low-priority goal may actually increase the positive value of stimuli related to a competing higher-priority goal, because of the motivational priorities of the person pursuing these goals. For example, reminding participants of their social goals led to a more positive evaluation of academic pursuits among students who strived toward academic excellence and considered it more important than social activities (Fishbach, Zhang, & Trope, 2006; Trope & Fishbach, 2000). In the section "On the Interaction among Goals," we discuss these patterns of influence between conflicting goals in more details.

Are there any variables that might determine when negative evaluation of goal-undermining stimuli is most

likely to occur? One possibility is that the extent to which it occurs depends on whether the person can effectively self-regulate in the focal goal domain. The findings from Ferguson (2006) and Fishbach, Zhang, and Trope (2006) together suggest that negative goal-related evaluations emerge most strongly for those who are skilled in the focal domain. For example, when participants were nonconsciously primed with academic concerns (e.g., grades), they automatically evaluated social temptations as more negative—especially so if they had relatively high grade point average (GPA) scores. This suggests that the degree to which goals might shift automatic evaluations of pertinent stimuli in some cases depends on the person's skill level and experience in the relevant goal domain.

We further argue that the activation of a goal can have repercussions for the evaluation of stimuli that are irrelevant to the goal. Recent work by Brendl and colleagues (Brendl, Markman, & Messner, 2003; Markman & Brendl, 2000) has suggested that such "devaluation effects" occur when the activation of a given goal (e.g., hunger) renders as negative those objects (e.g., movie tickets) that might draw resources away from the focal goal. From this perspective, even though movie tickets do not directly undermine the goal of getting food, they indirectly do so by drawing limited resources away from the focal pursuit (see also Shah et al., 2002). To test this idea, they asked smokers who had or had not recently smoked to purchase raffle tickets for a prize of either cash or cigarettes. A devaluation effect occurred such that deprived smokers bought fewer tickets for the cash prize than those smokers who were not deprived. In this way, the active goal to smoke led to a lower evaluation of cash. We conclude that the activation of a goal may make stimuli that are not directly relevant to the overall goal less positive.

Goal-Relevant Moods and Emotions

Beyond evaluations of specific stimuli, how might the operation of a goal influence one's affective state more generally? There are at least two ways to approach this question. It is possible to consider the ways in which goal pursuit might influence people's moods and emotion both *during* the pursuit as well as *after* the pursuit has been completed. We first consider the former, and then move to the latter.

Considering our earlier argument that during goal pursuit the related end state and associated means should be evaluated as more explicitly and implicitly positive, it seems possible that the positivity associated with a specific stimulus (e.g., a means) might extend to a more general affective state, such as a mood or emotion. This possibility was supported in research by Fishbach, Shah, and Kruglanski (2004). These researchers documented a transfer of emotions from goal to related means in proportion to the degree of association between the means and expected goal attainment. In particular, while pursuing a given means, people experience some of the emotions that characterized goal attainment. For example, in one of their studies, participants self-generated a goal

(e.g., making friends), and one versus two activities that serve this goal attainment (e.g., joining a fraternity and being helpful to people). Listing a second activity was expected to dilute the association between the goal and the first activity, thereby decreasing the magnitude of the emotional transfer. Accordingly, participants perceived the first activity listed as more enjoyable when it was the only activity listed compared with it being the first of two activities listed. In another study, it was shown that the quality of feelings (promotion- or prevention-type affect) experienced toward social figures who also serve the attainment of means (e.g., a hair designer and a tax consultant) varied as function of the type of goals they were helpful in mediating.

People also experience general affective states during goal pursuit as a result of feedback processes, a possibility posed by cybernetic models of behavioral control. For example, Carver and Scheier (1990, 1998) have argued that people monitor the discrepancy between the desired end state and their current status, and that their mood can be an important part of the feedback for such monitoring. Specifically, when people are progressing faster than they expected, a positive mood will be generated. A negative mood, on the other hand, should result when one's progress is slower than expected. Theoretically, this means that as long as mood is associated with goal performance, a negative mood should prompt people to increase their efforts and pursuit, while a positive mood should signal that people should relax their efforts given that they are moving more quickly than they planned (see Carver, 2003).

What about moods and emotions that emerge *after* the termination of a goal pursuit? In one way, an answer to this question is straightforward. Psychologists have long recognized that there are general affective consequences for attaining desirable things and failing to do so. Those who attain things that they view as desirable feel good; indeed, things are desirable precisely because they promise to deliver pleasure or an escape from pain. And, by extension, those who fail to reach something desirable will undoubtedly feel bad. Although people may not be able to accurately calibrate the actual extent to which they will feel good or bad once they reach or fail to reach a goal (Gilbert, Pinel, Wilson, Blumberg, & Wheatley, 1998; Wilson, Wheatley, Meyers, Gilbert, & Axsom, 2000), it is well established that such affective experience transpires in this way (e.g., Bandura, 1989, 1991; Carver & Scheier, 1990, 1999; Clore, 1994; Frijda, 1996; Higgins, 1999).

Moreover, the nature of a given goal pursuit influences moods and emotions (e.g., Higgins et al., 1997). Specifically, different goals will lead to different emotional responses to completing the pursuit. A focus on reducing the discrepancy between one's actual and ideal self (a promotion focus) leads to feelings of cheerfulness in the case of success and dejection in the case of failure. In contrast, a focus on reducing the discrepancy between one's actual and "ought" self (a prevention focus) leads to feelings of calmness in the case of success and anxiety in the case of failure.

We therefore suggest that goal pursuit can influence more generalized affective states in addition to evalua-

tions of specific stimuli. Furthermore, the termination of a goal pursuit induces certain affective states. One important question, however, is whether these "effects on affect" can also be considered part of the goal construct; that is, whether they should be considered both part of what it means for the goal construct to be activated in memory as well as the consequences of goal operation. We argued earlier that implicit effects on knowledge activation and evaluations can reveal the content of the goal construct, and we extend this logic to more generalized affective states. Goal constructs include the positive emotions that characterize goal attainment as well as the negative emotions that characterize goal failure. These emotions may be associated with the end state as well as with the related means of attainment and be part of the goal structure (Fishbach et al, 2004; Higgins, 1997). In addition, emotions are downstream consequences of goal activation and goal pursuit, as we reviewed here.

Goal-Relevant Behavior

Goals influence how people choose to react and behave toward the world (e.g., Bandura, 1986; Carver & Sheier, 1998; Deci & Ryan, 1985; Fiske, 1989; Gollwitzer, 1990; Locke & Latham, 1990; Miller et al., 1960; Mischel et al., 1996; Norman & Shallice, 1986; Shallice, 1972). The research that we have reviewed in this chapter so far shows that even nonconsciously activated goals influence overt behavior, including achievement, cooperation, helping, expressing anger, seeking casual sex, and much more.

In addition to such overt behavioral effects, goals also influence more subtle types of action. Thus, Fishbach and Shah (2006) demonstrated that people possess implicit behavioral dispositions (approach, avoid) toward stimuli that are consistently desirable (high-priority goal stimuli) or undesirable (low-priority temptations). They first asked participants to generate words related to important goals and words related to associated, undermining temptations (e.g., studying, exercising, vs. movies, alcohol). They then measured participants' implicit behavioral tendencies toward those stimuli by asking participants to push or pull a standard joystick in response to each of those stimuli. Given that previous research has shown that pulling movements are faster in response to desirable stimuli, and pushing movements are faster in response to undesirable stimuli (e.g., Solarz, 1960), Fishbach and Shah hypothesized that participants would show implicit behavioral responses in accord with the desirability of the goal-related stimuli. The results showed that participants were in fact faster to pull (vs. push) a joystick toward them in response to a goal-related word; they were also faster to push (vs. pull) the joystick away from them in response to a temptation-related word. These implicit behavioral dispositions predict explicit behavior and successful self-regulation.

It should be noted that although plenty of the research we have reviewed examined the effects of goals on knowledge activation, evaluations, and emotions, it is ultimately concerned with predicting behavior. This research is grounded on the assumption that such phenomena mediate between the goal and more overt behavior. For instance, the accessibility of knowledge should eventually translate into how the person behaves (Higgins, 1996). Similarly, a large and extensive literature details how evaluative and affective experiences lead to behavioral effects (e.g., Albarracín, Johnson, & Zanna, 2005; Carver & Scheier, 1990). In this way recent work has emphasized the (often implicit) mediators at work in goal pursuit.

Summary

In this section we discussed the characteristics of goal operation, including those that involve knowledge activation, evaluations, moods and emotions, and behavior. We now turn to a new direction in the study of goals. This next section addresses how multiple goals interact, and it includes topics such as goal competition and self-control. Just as most of the characteristics we considered in the previous two sections depend on the definitional assumptions about the structure and content of goals, so too does the theory and research in the next section. In particular, this theory relies on the assumption that goals are often interconnected with one another and may contain facilitative as well as inhibitory links.

ON THE INTERACTION AMONG GOALS

Soren Kierkegaard, the Danish existentialist philosopher, instructed his readers to will only one thing (Kierkegaard, 1938). However, according to modern goal research, it is unclear whether people wish or can ever follow his recommendation (e.g., Kruglanski et al., 2002). Indeed, in previous sections we discussed how a variety of stimuli that people might naturally encounter in everyday situations, including various semantic stimuli (words), objects, relationship partners, and strangers, can activate goals. This suggests that in a typical and richly complex social environment, in which there undoubtedly exist multiple cues for different goals, the coactivation of simultaneous goals seems inevitable. In addition, people also at times consciously choose to pursue several goals simultaneously (e.g., career and family). In the face of such numerous competing pursuits, a person necessarily has to prioritize the pursuits and resolve goal conflict in order to best ensure the successful attainment of as many goals as possible (Cantor & Langston, 1989; Emmons & King, 1988; Higgins, 1997; Markus & Ruvolo, 1989; Shah, 2005). Which of multiple goals deserves priority? And when does a person decide to emphasize the pursuit of a single goal versus balance between the pursuits of several goals?

As is evident, an integral part of understanding how goals operate is an understanding of how *multiple* goals interact with each other and together influence behavior, evaluation, and emotion. Virtually all of our earlier discussion dealt with the requirements for the activation of a single goal and the characteristics of the operation of that goal. In this section, we discuss the challenge presented by multiple goals and how the interaction among goals poses a special problem for decision making and

choice. We specifically distinguish between three configurations of multiple goals. First, we consider the implications of pursuing multiple goals that are of similar centrality to the individual. We then move on to theorizing about situations in which a person is confronted with multiple goals of different centrality, which, therefore, pose a potential self-control conflict between a central goal with delayed benefits and a less central goal with immediate benefits. Finally, we look beyond the impact of several goals on a *single* action to the effects of multiple goals on a *sequence* of actions that unfold over time.

Just as in previous sections, much of the principles we consider in these areas of research derive from the definitional assumptions concerning the structure and content of goal representations that we described at the outset of the chapter. In particular, it is assumed that many goals have been activated simultaneously in the past, or are related with each other in semantic or emotional meaning. We therefore argue that many goals themselves are interconnected in memory, just as are the memories associated with a single end state. This implies then that the activation of a given goal can automatically facilitate other compatible goals or perhaps inhibit competing goals. This assumption lies at the heart of much of the research on multiple goals.

Multiple Goals of Similar Centrality

How does a person manage multiple goals of approximately equal centrality that conflict with one another? We identify two assumptions that govern research on the effect of multiple goals of similar centrality: *goal competition* and *multiple goal attainment.* In what follows, we discuss their implications for behavior, evaluation, and emotional experience.

Goal Competition

One underlying assumption of goal research is that simultaneously activated goals compete for limited motivational resources. And, because resources are limited, the pursuit of a given goal will inevitably pull resources away from another goal. In particular, goals compete for attention, commitment, and effort (Anderson et al., 2004; Baumeister, Bratslavsky, Muraven, & Tice, 1998; Förster et al., 2005; Shah et al., 2002; Shah & Kruglanski, 2002).

In one demonstration of goal competition, Shah and Kruglanski (2002) found that priming participants with a background goal (vs. a control word) undermined their commitment to the focal goal, which then hindered the development of effective means for goal pursuit and dampened participants' emotional responses to positive and negative feedback about their goal progress. In one study, participants expected to perform two consecutive tasks corresponding to two goals. While working toward the first task (i.e., the focal goal), they were subliminally primed with the name of the second task they expected to perform later (i.e., the background goal) or with a control prime. The activation of the background goal led to a decline in persistence on the first task, lower performance success, and lower emotional reactivity to success

and failure feedback. In other words, the activation of an alternative goal pulled away motivational resources from the focal goal.

Because goals compete for attentional resources, the activation of one, focal goal can sometimes lead to the inhibition of another, alternative goal in memory; in this way, the focal goal "shields" itself from alternative ones by directly reducing the accessibility of alternative goals in memory (Shah et al., 2002). Empirically, this inhibition is often reflected in the slowing down of lexical decision times to concepts that represent alternative goals. For example, Shah and colleagues (2002) demonstrated that when a goal-related concept (e.g., "study" vs. control word) was subliminally primed, it slowed down the lexical decision time to concepts related to alternative goals (e.g., "jogging"). The degree of inhibition of alternative goals was moderated by participants' commitment to the focal goal they were currently pursuing, such that only highly committed individuals (i.e., those who indicated that the goal is important) inhibited completing goals. In addition, because goals compete with each other, there is a self-regulatory advantage for inhibiting focal goals once they are accomplished, because by inhibiting completed goals, a person frees up resources to be used for new goal pursuits (Förster et al., 2005; Liberman & Förster, 2000).

An underlying assumption in research on goal competition is that goals acquire their motivational force from a limited pool of motivational resources. In other words, any act of self-regulation is by definition resource depleting (Baumeister, Heatherton, & Tice, 1994; Muraven & Baumeister, 2000; Vohs & Heatherton, 2000). Research on *ego depletion* has provided ample demonstrations for the depleting nature of self-regulatory acts across many self-regulatory domains (see Baumeister, Schmeichel, & Vohs, Chapter 22, this volume). For example, participants who were asked to control their emotional responses to an upsetting movie (vs. watching that movie with no goal in mind) were subsequently less able to persist on holding a handgrip. Or, in another study, participants who suppressed forbidden thoughts (vs. no suppression condition) were subsequently less likely to persist on trying to solve unsolvable anagrams (Muraven, Tice, & Baumeister, 1998).

But because goal pursuits are resource depleting, people withdraw from a current, effortful goal in order to save their resources for another upcoming, goal-related task. For example, dieting students might stop trying to control their food intake just before they undergo an important academic test. In general, over a lifetime's worth of experience with regulating limited motivational resources, people may develop strategies of resource conservation and resource management, which are designed to save self-regulatory recourses for future goal pursuits (Shah, 2005). These resource management processes may further operate outside conscious awareness. Shah and his colleagues found that participants who were subliminally primed with the name of an upcoming difficult task (vs. nonword control) were less likely to put effort into the present task, took longer breaks, and consumed more juice, which they were told was helpful for the subsequent task (Shah, Brazy, & Jungbluth, 2005). This work

suggests that resource management is often strategic (while still nonconscious) and can follow different patterns of self-regulation, such that lower efforts follow or precede actual physiological depletion. Because resource management is strategic, the extent of decline in goal performance also depends on one's lay belief that another act of self-regulation is or will be depleting (Mukhopadhyay & Johar, 2005).

Taken together, there is converging evidence for the phenomenon of goal competition. How does goal competition influence a person's evaluations, emotions, and behavior? First, beyond the effects of the activation and operation of a single goal on evaluations, goal competition presents some consequences for patterns of evaluations more generally. One such consequence is instability of evaluations over time. Because various goals wax and wane in accessibility, the evaluations of objects related to those goals (means and hindrances) will also fluctuate. This means that a decision that is made according to the goal relevance of options at one point in time may not be as optimal at a later time when the goal relevance of those same options has changed. This can be particularly troublesome if the accessibility of the goals and the corresponding fluctuation of evaluations all take place nonconsciously, without the person's awareness. For example, a person who selected flight tickets based on low price may find this selection incompatible with another, competing goal of saving time, which becomes salient later on. Because the person may be unaware of this goal conflict, he or she may experience little satisfaction with the choice and may regret it if the accessible goal has changed from saving money to saving time. In this way, the fluctuating nature of goal activation might sometimes introduce negative emotional consequences and mean that people are often somewhat dissatisfied with their choices.

Second, what implications does goal competition have for behavior? With respect to behavioral effects, a normative choice theory (e.g., the multiattribute utility theory, or MAUT) entails that when people want to make a single choice in a way that will meet several goals (e.g., ordering food that is healthy, tasty, and not too expensive), they should integrate these various goals by weighing their relative importance (e.g., Baron, 2000; Keeney & Raiffa, 1976). However, our analysis attests that the relative weight of a goal in the decision process is not fixed, and therefore integration is rarely optimal. That is, because multiple goals that are brought into a decision process can directly interfere with the attainment of each other, people may tend to overemphasize a focal goal in their decision while discarding other background goals that are temporarily inhibited by the focal goal. For example, when primed with "ease," students may choose to work on a project that is easy while completely overlooking other goals, such as their level of interest in any particular project.

Multiple Goal Attainment

We assume that the pursuit of multiple goals is characterized by a desire for *multiple goal attainment*. According to this assumption, given the presence of several salient goals and limited motivational resources, self-regulators search for attainment means that are *multifinal*, that is, means that are linked to the attainment of several goals simultaneously (Kruglanski et al., 2002). For example, a person may prefer to dine out (vs. dine in) in order to satisfy both hunger and various social motives (to see and be seen, etc.), or commuters may choose to commute by bike (vs. car) in order to save money and keep in shape.

What are the implications of the assumption that people try to find means that can meet as many active goals as possible? Multifinal means are by definition scarce because they constitute a subset of the original set of means to a goal and are therefore more difficult to find. Thus, when individuals wish to achieve multiple goals, any increase in the number of accessible goals negatively affects the number of satisfactory means, thus elevating the difficulty of the search (Kruglanski et al., 2002; Tversky, 1972). For example, while many restaurants will satisfy one's hunger, somewhat fewer of them will provide an interesting scene, and fewer still are also not too expensive. In general, when holding multiple goals people end up searching longer for satisfying means and they also end up choosing "compromise" options that are less effective at satisfying each goal separately (Simonson, 1989). Moreover, because compromise options imply that none of the goals is met very strongly, people may at times choose to abandon the search for multifinal means altogether and focus on only one goal.

The search for multifinal means also has consequences for evaluation, emotions, and behavior. The preference for multifinal means may have an adverse effect on the evaluation of the selected choice options if these options are only partially associated with the attainment of any salient goal (e.g., when people order food that is moderately tasty and moderately healthy). We argued earlier that goal-facilitating stimuli acquire positive value and goal-thwarting stimuli acquire negative value (Brendl et al., 2003; Ferguson & Bargh, 2004; Fishbach et al., 2004). However, in the course of pursuing multiple goals, an attainment means to one goal can potentially interfere with satisfying another goal, and hence, although this means may be positively evaluated because its facilitation of one goal, it might also tend to be negatively evaluated because it hinders another goal. Thus, even though a given means to an active, focal goal should be particularly positive because it facilitates that goal, the simultaneous activation of another goal, one that the given means cannot facilitate, can end up dampening the positivity of that means. One consequence of this is that the quest for multifinal means may undermine the evaluation of a given available means and lead to choice deferral and decision aversion because none of the means seems satisfying (Dhar, 1996, 1997; Iyengar & Lepper, 2000; Tversky & Shafir, 1992). As one example of this notion, Iyengar and Lepper (2000) found that students are more likely to choose a class assignment when offered a limited array of a few options that activate fewer goals, compared with when more options are presented. It also follows that holding a single goal (or fewer goals) should lead to the positive evaluation of means and decision-seeking behav-

iors related to this goal. For example, a student who wishes to select an interesting project to work on would be less likely to defer her choice and be more satisfied with the selected project than her classmate, who might share equal interest in selecting an interesting and easy project.

In terms of the emotional experience of goal pursuit more generally, the quest for multiple goal attainment can lead to mixed emotions and ambivalence when people strive toward incongruent ends (e.g., academics and leisure) and a means to one end (e.g., a textbook) acts as a hindrance to another. Under these circumstances, the same object or activity may be experienced both positively and negatively at the same time and end up seeming ambivalent (e.g., Cacioppo, Gardner, & Berntson, 1999). For example, a student who works on an easy but uninteresting project would be both satisfied and unsatisfied with her choice.

It was shown that the preference for multifinal means has further behavioral implications, and, in general, people prefer choice alternatives that partially meet, or strike a compromise between, several goals at once rather than ones that fully meet or highlight a single goal (e.g., Simonson, 1989). As a demonstration, Simonson asked participants to evaluate several consumption products (e.g., apartment, calculator, and television). Participants exhibited a greater preference for options that struck a compromise between several goals (e.g., large/small size and low price) than those that accomplished a single goal (e.g., provided low price).

Because in a multifinal choice the number of activated goals is inversely related to the number of acceptable means, it follows that there should be a negative relationship between the number of goals and the number of acceptable means that a person would choose to pursue. This pattern was demonstrated in a study conducted around lunchtime by Köpetz, Fishbach, and Kruglanski (2006), in which participants listed three goals that they had for that day (vs. goals already accomplished on that day), other than getting lunch, before indicating the number of different lunch options that they would consider. Compared to participants in the control (accomplished goals) condition, those for whom actual goal alternatives were activated listed significantly fewer food options in which they were interested.

Though highly desirable to have, multifinal means may suffer a disadvantage as well in that they may be perceived as less effective and instrumental to goal attainment. This may be so because multifinal means can be objectively less effective. But this may also be because perceived effectiveness of a given means to goal attainment is determined in part by the strength of the association between that means and the goal, with stronger associations leading to higher perceived effectiveness. When the number of goals attached to a given means increases, each association becomes weaker, as demonstrated by a lower retrieval rate of the associated goal when the means is activated (Anderson, 1983; Anderson & Reder, 1999). The result is a dilution of the means–goal association, which may reduce the perceived effectiveness of the means with respect to the goal. In a demonstration of such a *dilution effect*, Zhang, Fishbach, and Kruglanski (in press) found that when participants considered the different goals (e.g., building muscles and losing weight) that a single means (e.g., working out) could satisfy, an increase in the number of goals resulted in a reduction in the perception of the instrumentality of the means with respect to each goal.

As a result of a dilution effect, means that are connected with multiple goals are also less likely to be chosen and pursued when a single (vs. multiple) goal needs to be fulfilled. For example, participants were less likely to use the writing function of a pen that had also been used as a laser pointer (vs. was not used as a laser pointer) when they only needed to write (Zhang et al., in press). It appears that multifinal means are desirable when the individual foresees the pursuit of multiple goals, but those same means are judged as less effective and they are less likely to be selected when the individual focuses on a single goal.

Self-Control Conflicts

We have identified two underlying mechanisms for managing multiple goals that are of similar centrality: goal competition and multiple goal attainment. But people often hold multiple goals that differ in their importance or centrality, and these goals can impose a self-control dilemma. In what follows, we address such a situation.

People face a self-control problem when the attainment of their central, higher-order goals comes at the expense of foregoing low-order desires or temptations (Ariely & Wertenbroch, 2002; Baumeister, Heatherton, et al., 1994; Dhar & Wertenbroch, 2000; Gollwitzer & Moskowitz, 1996; Kivetz & Simonson, 2002; Kuhl & Beckmann, 1985; Loewenstein, 1996; Metcalfe & Mischel, 1999; Rachlin, 1997). For example, the pursuit of academic excellence, professional success, or fitness and general health comes with the expense of foregoing low-order although salient goals (e.g., partying, taking long vacations, or consumption of fatty foods, respectively). As these examples demonstrate, temptations are defined within a given situation and with respect to the higher-order goals at hand. For example, while going on vacations interferes with pursuing professional success, thoughts about one's career can undermine one's ability to relax and enjoy a vacation. This context-specific definition of temptations suggests that when individuals strive toward multiple goals, any goal can potentially constitute an interfering temptation with respect to another, currently more central, goal. In response to self-control dilemmas, people exercise self-control (Dhar & Wertenbroch, 2000; Gollwitzer, 1999; Kivetz & Simonson, 2002; Kuhl, 1986; Muraven & Baumeister, 2000), and these self-control operations influence behavior, evaluation, and emotion.

The Operation of Self-Control through Construal

What do self-control operations entail? One category of such operations involves the construal of the self-control conflict in abstract (vs. concrete) terms. For example, in

one of the first systematic studies of self-control operations, Walter Mischel and his colleagues found that an abstract representation of the immediate reward (e.g., a small candy) helped children wait for the delayed, preferred reward (e.g., a large candy) (Mischel, 1964; Mischel & Mischel, 1983; Mischel, Shoda, & Rodriguez, 1989). According to Mischel and colleagues, abstract representations facilitate success at self-control because they activate a "cool" (cognitive and evaluative) system, while suppressing a "hot" (emotional and operating) system (Metcalfe & Mischel, 1999; Mischel & Ayduk, 2004). When a person is in an evaluative mode, rather than an action mode, the person is more likely to follow a higher-order goal. As a recent demonstration of this idea, Kross, Ayduk, and Mischel (2005) manipulated abstractness by asking participants to elaborate on the "why" versus "how" aspects of their experience (Freitas, Gollwitzer, & Trope, 2004; Vallacher & Wegner, 1987). They found that participants displayed improved self-control in coping with anger-provoking experiences when they had elaborated on why they had the experience (an abstract construal) as opposed to how they exactly felt (a concrete construal).

In addition, abstract processing increases success at self-control by directing people's attention to their central, high-order (vs. low-order) goals (e.g., Fujita, Trope, Liberman, & Levin-Sagi, 2006; Rachlin, 2000). According to a construal-level analysis (e.g., Trope & Liberman, 2003), abstract processing is associated with high-level construal and it can facilitate success at self-control by directing people's attention to high-order goals. In support of this analysis, Fujita and colleagues (2006) found that asking participants to generate superordinate category labels (abstract processing) versus subordinate exemplars (concrete processing) for a variety of common objects, increased participants' subsequent motivation to undergo a difficult yet important test. Presumably, abstract processing allows one to successfully ignore the immediate aversiveness of adhering to high-order goals.

The Operation of Self-Control through Evaluation and Emotion

Another category of self-control operations includes *counteractive control* processes, which offset the influence of temptations on adherence to a central goal. Of particular interest, counteractive control processes influence the evaluation of and the affective experience of choice alternatives related to a central goal and less central temptations when these are in conflict (Fishbach & Trope, 2005; Trope & Fishbach, 2000, 2005).

Research on counteractive control attests that when people anticipate a self-control problem, they proactively increase the desirability of adhering to a goal relative to yielding to temptation. The presence of tempting alternative may thus influence goal-directed behavior in two opposite directions: directly, the perception of tempting alternatives decreases the likelihood of adhering to a more central goal; but, indirectly, the perception of tempting alternatives triggers the operation of counteractive control, which then acts to increase the likelihood

of adhering to the goal. For example, an invitation to go out on the night before an important exam directly decreases the likelihood of studying, but it may further set into action counteractive bolstering of the value of studying, which increases the likelihood of engaging with this activity. As a result of counteractive control such invitation has no effect on studying for the exam overall.

Some of the counteractive control operations that people employ involve changes in the actual choice situation. For example, people may impose penalties on themselves for failing to adhere to an important goal (e.g., failing to abstain from smoking), or they may eliminate certain choice alternatives such as cigarettes or fatty foods from their environment, thus making their decision irreversible (Ainslie, 1975; Green & Rachlin, 1996; Rachlin & Green, 1972; Schelling, 1978, 1984; Strotz, 1956; Thaler, 1991; Thaler & Shefrin, 1981). In addition, people counteract temptations by changing the positive evaluation of adhering to their goals and pursuing temptations (see also Kuhl, 1986; Mischel, 1984), and they further change the perceived emotional significance of goals and temptations.

To demonstrate changes in evaluation in response to temptation, Trope and Fishbach (2000) offered participants an opportunity to take a diagnostic test that was described as requiring abstinence from food containing glucose for either a long or a short period (3 days vs. 6 hours). Participants evaluated the test more positively when it required a long (vs. short) period of glucose abstinence (i.e., when the temptation to forego the test was stronger). They also found that whereas the length of the abstinence directly decreased interest in the test, indirectly it increased interest in undergoing the test, by increasing its positive evaluation. Other studies demonstrated similar effects on the emotional reactivity to succeeding on goal-related activities. When facing strong versus weak temptations, participants reported that goal pursuits were associated with more intense pride while failing on goal pursuits was associated with more intense guilt.

Bolstering the value and emotional reactivity of a goal in response to a temptation can be deliberate and may require some level of conscious awareness, intentionality, and processing resources (Baumeister et al., 1998; Mischel, 1996; Muraven & Baumeister, 2000; Trope & Neter, 1994; Vohs & Heatherton, 2000). However, our analysis suggests that goals and the process of self-regulation may not require consciousness and intentionality, and it follows that processes of self-control and overcoming temptations can also proceed nonconsciously (Ferguson, 2006, in press; Fishbach et al., 2003; Gollwitzer, Bayer, & McCulloch, 2005; Moskowitz, Gollwitzer, Wasel, & Schaal, 1999). One such implicit strategy involves the activation of goal representations in response to cues for temptations (Fishbach et al., 2003). For example, Fishbach et al. assessed the lexical decision time to respond to words representing a potential goal following the subliminal presentation of words representing potential temptations. They found that subliminal temptation primes (e.g., "drugs" vs. control words) facilitated the lexical times for goal-related targets (e.g.,

"bible"). In addition, goal-related primes (vs. control words) inhibited the lexical time for temptation-related targets, and these implicit and asymmetrical activation patterns were shown to increase success at self-control.

Other implicit self-control operations involve changes in the implicit positivity of goals and temptations. For example, Fishbach, Zhang, and Trope (2006) documented an implicit negative evaluation of temptations and an implicit positive evaluation of goals when these two were in a conflict. In one study, dieters (vs. non dieters) responded faster to positive concepts after being subliminally primed with words related to dieting (e.g., diet), and they responded faster to negative concepts after being subliminally primed with words related to food (e.g., cake). We claimed that such changes in implicit positivity directly influence behavior (e.g., Ferguson & Bargh, 2004). Indeed, as indicated earlier, Fishbach and Shah (2006) documented a similar tendency to automatically approach stimuli related to a goal (through faster pulling responses) and automatically avoid stimuli related to temptation (through faster pulling responses). These implicit approach and avoidance responses predicted the attainment of high-order interests. For instance, the rate of responding by pulling a joystick in response to academic targets (e.g., "library") and by pushing a joystick in response to nonacademic, tempting targets (e.g., "party") predicted student participants' GPA scores.

The Bidirectional Relationship between Emotions and Self-Control

We have thus far claimed that self-control operations involve changes in evaluation and emotions. Here we consider more generally the relationship between emotions and success at self-control. We suggest that the resolution of a self-control conflict has implications for one's emotional experience, and in addition, people's emotional experience and mood influence how they resolve a self-control conflict. In what follows we address these influences.

First, with regard to the effect of self-control on people's emotions, whereas the successful resolution of a self-control conflict is characterized by the experience of feelings such as pride, a failure at self-control is characterized by feelings such as shame and guilt. These emotions (e.g., pride vs. guilt) are high-level, self-conscious emotions that people experience when they engage in a self-control behavior directed toward higher-order goals, and they are qualitatively different from more basic emotions such as happiness and fear that are low level and signal immediate rewards or punishments (e.g., "hot" feelings; Metcalfe & Mischel, 1999). Presumably, part of the reason that people adhere to high-order goals is because they wish to experience positive self-conscious feelings and avoid negative self-conscious feelings (Beer & Keltner, 2004; Giner-Sorolla, 2001; Tangney, Miller, Flicker, & Barlow, 1996; Tracy & Robins, 2004). In support of this notion, guilt is associated with failing to maintain social relationships and with overeating, and therefore, considering one's possible guilty feelings leads to improving social relationships (Baumeister, Stillwell, & Heatherton, 1994) and reducing the amount of fatty food eaten by dieting individuals (Giner-Sorolla, 2001).

But how do existing affective states influence the subsequent motivation to exercise self-control? This second question refers to the effect of emotions on self-control, and previous research poses an apparent contradiction in addressing it. Some research has claimed that positive mood undermines self-control (e.g., Wegener & Petty, 1994, 2001), while others have claimed that positive mood improves self-control (e.g., Aspinwall, 1998; Raghunathan & Trope, 2002). Specifically, researchers have claimed that positive mood impairs self-control because happy (vs. unhappy) people prefer activities that prolong the quest for positive mood. For example, Isen and Simmonds (1978) reported that participants in a happy mood were less helpful than those in a neutral mood when the helping behavior involved reading unpleasant information. Similarly, Wegener and Patty (1994) found that happy (vs. neutral or unhappy) participants chose to see more happy films but not more interesting films. Conversely, other mood researchers found that positive mood is often "used" for accomplishing tasks that have immediate costs and require self-control (Aspinwall & Taylor, 1997; Raghunathan & Trope, 2002; Trope & Pomerantz, 1998). For example, research on the delay of gratification attests that happy (vs. unhappy) children are better able to wait for a delayed, preferred reward than for an immediate, less preferred reward (Moore, Clyburn, & Underwood, 1976; Schwarz & Pollack, 1977). In addition, research on negative feedback seeking (i.e., feedback about a person's shortcomings) reveals that people take an increased interest in this potentially useful information when positive mood is induced. For example, caffeine drinkers who were induced to feel good were more attentive to negative information about the health effects of caffeine (Raghunathan & Trope, 2002, see also Trope & Neter, 1994). Also consistent with this latter possibility, there is research showing impaired self-control ability during negative mood states (Leith & Baumeister, 1996; Tice, Bratslavsky, & Baumeister, 2001).

How can these areas of work be reconciled? Our view assumes that people can use their mood as information about the task at hand (e.g., Schwarz & Clore, 2003) and, in particular, we suggest that moods are seen as signals to either adopt or reject any accessible goal. That is, while the experience of positive mood signals to people that they should approach a stimulus, the experience of negative mood signals to them that they should avoid a stimulus (e.g., Cacioppo et al., 1999; Higgins, 1997; Larsen, McGraw, & Cacioppo, 2001; Lazarus, 1991). Accessible goals are one set of stimuli that people need to decide whether to approach or avoid. Thus, it follows that a positive mood should increase people's tendency to adopt any accessible goal, whether the goal is high order (e.g., self-improvement) or low order (e.g., mood management). In this way, happy people should perform better on self-control tasks when they hold an accessible high-order goal but perform poorly when they hold an accessible low-order goal.

In support of this analysis, Fishbach and Labroo (in press) found that when self-improvement goals were accessible, happy (vs. unhappy) participants invested more effort in a task that furthered the goal, even if the task was unpleasant or demanding. Conversely, when mood management goals were made more accessible, happy people invested less effort than unhappy people. In one study that tested for charity donations, happy (vs. unhappy) participants were asked to describe what they generally do to "be better" (high-level, self-improvement) versus "feel better" (low-level, mood enhancement). They were then asked to participate in a local charity campaign that promoted protecting young children from injury or death by improving children's product safety. Happy (vs. unhappy) participants donated more money when they had considered the self-improvement goal but not when they considered the mood management goal. Other studies replicated the effect of mood on self-control by nonconsiously priming self-improvement or mood management goals, which further demonstrates that the direction of the relationship between mood and success at self-control depends on a person's accessible goal.

The Pursuit of Multiple Goals in a Choice Sequence

The previous sections refer to situations that involve the consideration of multiple goals of either similar or different centrality, which influence the selection of an action that secures their attainment. Notably however, few goals can be completed by the execution of a single action; rather, goals frequently require taking several actions that maintain goal pursuit over time. The challenge that individuals face over repeated choice situations is to decide between emphasizing, or highlighting, the pursuit of a single goal and balancing between several goals. In this section, we address this challenge and consider how the specific strategy of goal pursuit (highlighting a single goal vs. balancing among several goals) that an individual employs for actions that unfold over time may influence their immediate behavior, evaluations, and emotional experience.

As stated previously, when individuals simultaneously hold multiple goals that they wish to pursue over time, self-regulation may follow one of two possible dynamics: highlighting the pursuit of a single goal in several consecutive actions versus balancing among several potentially incongruent goals across several actions (e.g., Fishbach & Dhar, 2005, in press; Fishbach, Dhar, & Zhang, 2006). For example, consider a person who chooses to dine out and wishes to both save money and seek pleasure. In the absence of compromise options, that person can balance between these conflicting goals by choosing an expensive appetizer and a less expensive entrée, or, the person can highlight one of these goals (e.g., by choosing an expensive appetizer and an expensive entrée). *Choice highlighting* refers to a dynamic of self-regulation where pursuing one goal enhances the commitment to this particular goal relative to competing ones and motivates complementary actions over time. *Choice balancing* refers to a dynamic of self-regulation where pursuing one goal liber-

ates the individual to pursue other, conflicting goals at the next opportunity (Dhar & Simonson, 1999; Fishbach & Dhar, 2005; Fishbach, Dhar, & Zhang, 2006).

What then determines a person's interest in choice highlighting versus choice balancing? One factor is how the person interprets the meaning of an initial action that is congruent with one of the goals. It is possible that a person could interpret such an action as indicating a strong commitment to the respective goal. If so, such an interpretation would then increase the motivation to make similar, complementary actions and to inhibit any competing goals (Aronson, 1997; Atkinson & Raynor, 1978; Bem, 1972; Feather, 1990; Festinger, 1957; Locke & Latham, 1990). The following choices then would be considered *choice highlighting* because the person would be prioritizing one goal over the others. On the other hand, it is also possible that a person might interpret that initial choice as indicating progress toward that goal. If so, that person might consequently relax his or her efforts toward the goal and begin to attend to the other competing goals. In this way, the interpretation of a goal-congruent action as progress signals the reduction of a discrepancy between the present state and goal attainment (Carver & Scheier, 1998; Miller et al., 1960; Powers, 1973). The person's choices would thereafter be considered *choice balancing* because he or she would be attempting to pursue multiple goals as much as possible, rather than focusing on a particular goal.

Research by Fishbach and Dhar (2005) demonstrated that people do indeed make inferences concerning goal commitment or goal progress, and these inferences activate different dynamics of self-regulation when there are multiple goals at stake. As an illustration, these researchers found that when initial academic success was interpreted as indicating greater commitment to academic goals, students were subsequently more interested in pursuing additional academic tasks and they were less interested in pursuing incongruent leisure activities. Yet, this same level of initial academic performance decreased interest in additional academic tasks and increased interest in balancing between initial success and subsequent choice of leisure activities when students inferred that progress had been made on the academic goals.

In addition to an initial goal-congruent action being able to be interpreted in multiple ways, an initial failure to pursue a goal is also open to multiple interpretations. Such a failure can signal either a lack of sufficient commitment to a goal or a lack of progress toward the attainment of that goal (Fishbach, Dhar, & Zhang, 2006). If people infer low goal commitment based on an initial failure, they tend to subsequently highlight this failure by disengaging from the goal (Cochran & Tessser, 1996; Soman & Cheema, 2004). If, however, following failure people infer a lack of progress toward the goal to which commitment remains intact, they tend to balance between the initial failure and their subsequent greater motivation to work harder by choosing additional actions that pursue this goal (e.g., see research on self-completion theory—Brunstein & Gollwitzer, 1996;

Wicklund & Gollwitzer, 1982). Thus, for example, failure on an exam decreases the subsequent motivation to study if it signals low commitment to doing well academically but increases the subsequent motivation to study if it signals the absence of progress toward the goal of academic excellence.

Previous goal research has often focused on one of these dynamics only. Thus, as an example of choice balancing, Shah and Kruglanski (2002) examined goal substitution. In one study, these researchers framed two anagram tasks as relating either to the same goal or to different goals. In one condition, one task was linked to promotion goal and the other task was linked to prevention goal (see Higgins, 1997); in the other condition the tasks were linked to the same prevention or promotion goal. They found that success at the first task decreased performance on the second when it served the same (vs. different) regulatory goal, because participants experienced goal attainment. But failure at the first task increased performance on the second task if both served the same (vs. different) goals, because participants did not experience attainment. Such substitution was shown to lead to ironic results when people substitute intention for action (e.g., Prelec & Bodner, 2003; Tesser et al., 1996). For example, Monin and Miller (2001) gave participants an opportunity to disagree with blatantly sexist statements, and those who received the opportunity (vs. not) were later more willing to favor a man for a stereotypically male job, presumably because the first task was sufficient to establish their moral credentials.

In yet another demonstration of ironic substitution, Fishbach and Dhar (2005) found that an initial sense of successful weight loss increased dieters' tendency to indulge. In their study, dieting participants were asked to draw a line that represented the distance between their current and ideal weight on a scale that either had –5 lbs. or –25 lbs. as its maximum discrepancy. Providing a scale with a wide range (–25 lbs.) created an illusion of smaller discrepancy (e.g., 4% vs. 20%, for a person who would like to lose 1 lb.), which led to greater perceived goal attainment. As a result, those who completed a wide (vs. narrow) scale were more likely to choose a chocolate bar over a low-calorie snack on a subsequent, supposedly unrelated choice task.

But how does substitution influence everyday behavior? People's intuitive belief in balancing between multiple goals leads them to seek variety and switch among goals when choosing items such as foods or leisure activities (Drolet, 2002; Ratner, Kahn, & Kahneman, 1999; Simonson, 1990). As a result, people sometimes end up choosing the less preferred item that is associated with the less valuable goal and that undermines choice satisfaction. According to the current framework, a variety-seeking behavior is driven by individuals' beliefs about satiation and maximizing the attainment from multiple goals. Therefore, for example, people incorporate more variety when simultaneously choosing several items than when choosing one item at a time (Simonson, 1990), because of their overestimation of the rate at which they will experience attainment (Read & Loewenstein, 1995).

However, people also demonstrate choice highlighting when they infer commitment and end up performing congruent behaviors. For example, research by Fishbach, Ratner, and Zhang (2006) demonstrated that variety-seeking behavior is attenuated and even reversed (as indicated by a greater preference for a previously selected item in a sequence) if participants consider their stable preferences based on their initial choice rather than the extent of satiation on that goal. In general, consistency theories in social psychology documented a desire to express congruency in a behavioral sequence; thus once a person engages in an initial action, the person feels that she should pursue similar actions (e.g., Aronson, 1997; Bem, 1972; Cialdini, Trost, & Newsom, 1995; Heider, 1958). For example, once participants agreed to display a small sign to advocate driving safety, they were more likely to display a larger sign to advocate the same goal compared with those who did not display the small sign (Freedman & Fraser, 1966). Other researchers have further indicated that behavioral consistency is associated with emotional benefits (Aronson, 1997; Festinger, 1957).

Future Plans Influence Present Actions

We described the effect of past actions on the present preference for actions that pursue the same or different goals, but what about the effect of future, planned actions? Do these actions also influence which goals a person decides to pursue in the present? There is some evidence that planned actions do influence present ones (Bandura, 1997; Oettingen & Mayer, 2002; Taylor & Brown, 1988). Thus, research on self-efficacy (Bandura, 1997) and positive illusions (Taylor & Brown, 1988) attest that exaggerated beliefs in actions that will be taken in the future lead to higher motivation to work harder on that goal in the present (see also Atkinson, 1964; Weiner, 1979). But others suggested that future plans can also undermine the motivation to work on a goal in the present. For instance, Oettingen and Mayer (2002) found that positive *expectations* of future goal pursuit lead to greater effort and successful performance on a focal goal in the present. But the reverse was true for positive *fantasies*, which are images depicting future goal attainment. Fantasies predicted lower effort on a focal goal in the present. As a demonstration, in one study college students who expected to start a relationship with a person were more likely to start an intimate relationship compared with those who experienced positive fantasies about future romantic success.

But regardless of the direction of the influence on present actions (more vs. less goal pursuit), what is the relative impact of future plans compared with past actions? Building on the observation that people are unrealistically optimistic (Buehler, Griffin, & Ross, 1994; Weinstein, 1989; Zauberman & Lynch, 2005) and therefore believe more goal-congruent activities will be accomplished in the future than in the past, it is possible that future plans have a greater impact on immediate goal pursuits than retrospection on past pursuits (Zhang,

Fishbach, & Dhar, 2006). The direction of the impact should then depend on the framing of the goal pursuit as indicating commitment versus progress. When people consider their level of goal-commitment, thinking about plans for future (vs. past pursuits) leads to greater persistence on the goal in the present. Conversely, when people consider their level of goal progress, thinking about future plans (vs. past pursuits) justifies disengagement from the focal goal in the present. As a demonstration, Zhang and colleagues (in press) asked gym members to estimate either the frequency of their exercise in the coming year or the frequency of their actual exercise regimen last year. Those who considered future (vs. past) exercise were more likely to consume healthy food in the present, if the exercise was framed as increasing commitment to the health goal. But envisioning future (vs. recalling past) exercise decreased the relative preference for healthy food in the present when the exercise was framed as increasing progress toward the health goal.

When Do People Highlight versus Balance Multiple Goals?

We described evidence in support of people's preference for making congruent choices that highlight a single goal when they consider their goal commitment, and people's preference for making incongruent choices that balance between different goals when they consider their goal progress. Several variables determine the relative focus on commitment versus progress. First, these inferences may be determined by situational cues, such as framing questions that direct one's attention to different aspects of goal-related actions. For example, Zhang and colleagues (in press) manipulated the degree of optimism that gym members experienced (following Taylor, Pham, Rivkin, & Armor, 1998) before asking them whether by exercising they are "getting closer" to their workout objectives (progress frame), or whether they are "feeling more committed" to their workout objectives (commitment frame). High levels of optimism had opposite consequences for the subsequent interest in healthy eating: dampening the interest among those who focused on the progress from their actions and increasing the interest among those who focused on the commitment from their actions.

Second, the degree to which individuals infer progress or commitment from their actions depends on their relative attention to the concrete aspects of the action in comparison with the corresponding abstract goal that initiated this action. When people consider the attainment of the action itself, they may experience some of the benefits associated with goal fulfillment, which motivates them to move temporarily away from the goal. On the other hand, when the focus is on an overall, more abstract goal, the same level of successful attainment provides evidence for a person's higher commitment to, and identification with, the goal more than it indicates progress. Fishbach, Dhar, and Zhang (2006) tested this idea by giving participants an opportunity to work on two independent verbal ability tests that represented actions to an academic achievement goal. The first test had correct solutions,

whereas the second test was unsolvable. They found that those who received high (vs. low) success feedback on the first test exhibited lower motivation to persist on a second similar but unsolvable test. This pattern replicated Shah and Kruglanski's (2002) findings on substitution. However, when in another condition an overall achievement goal was nonconsciously primed, high (vs. low) success feedback elicited greater motivation to persist on the second test, because success signaled greater commitment.

In another study, Fishbach, Dhar, and Zhang (2006) tested temporal distance (e.g., Trope & Liberman, 2003) as another variable that determines the relative focus on the action itself (for proximal actions) versus the abstract goal that initiated it (for distant actions). They found that actions that were scheduled in the near future signaled their own attainment, whereas actions that were scheduled in the distant future signaled commitment to an overall goal. For example, studying for an exam in the present signaled the accomplishment of an academic task whereas studying in the future signaled the commitment to an academic goal. These inferences in turn increased the amount of time that participants intended to invest on additional actions to an overall goal that were scheduled in the distant versus proximal future (e.g., study for a second exam).

Third, with regard to goals with an obvious end state, the relative focus on commitment versus progress may depend on whether a person attends to the amount of goal pursuit that was accomplished, as opposed to the remaining amount of goal pursuit that is required to meet the goal. Whereas completed actions establish a sense of commitment by signaling to the person that the goal is important, actions that are yet to be taken highlight the amount of progress that is still needed for goal accomplishment. For example, in the decision to participate in a charity campaign, learning about the amount of seed money that was collected thus far provides information regarding the importance of the campaign, which establishes commitment, whereas learning about the amount of money that is needed to complete the campaign goal provides information that establishes a sense of goal progress. It follows that uncommitted individuals, who wish to assess whether the goal is important, would be more influenced by learning about accomplished actions, whereas committed self-regulators, who wish to assess the required efforts in order to accomplish the goal, would be more influenced by considering the remaining distance for goal completion. These predictions were recently tested by Koo and Fishbach (2006) who conducted a field study as part of an HIV/AIDS initiative. Participants in their study were potential donors who were either committed individuals who donated money before or uncommitted individuals who did not donate money before. Uncommitted participants were more likely to donate and donated higher amounts when they read about the amount of money raised thus far as opposed to the amount of money that is still required, whereas committed participants were more likely to donate and donated higher amounts when they read about the amount of money still required than the amount of money that was raised.

Effects on Evaluations and Emotions

These aforementioned dynamics of multiple goal pursuit have further implications for evaluation and emotion. We proposed that in self-control situations, people secure the attainment of an important goal by increasing the positive evaluation of the high-order goal relative to temptations (e.g., Fishbach & Trope, 2005; Trope & Fishbach, 2000). But what if people perceive an opportunity to balance between the goal and temptations and, hence, view these options as complementary rather than competing? For example, a dieter may choose to balance between low- and high-calorie foods, or choose to highlight a choice of low-calorie foods. We next explore how each of these dynamics influences the evaluation of choice options.

When people plan to highlight the pursuit of a single goal across several actions, they should generate a positive evaluation of objects or means related to this goal, and a negative evaluation of objects or means related to competing alternatives (i.e., temptations). Conversely, when people wish to balance between goals and temptations that they see as complementary rather than competing, they should express a more positive evaluation of objects or means related to the tempting option relative to those that are related to the goal option. The reason for this latter evaluative pattern is that goals (relative to temptation) offer delayed benefits (Ainslie, 1975; Rachlin, 1997; Thaler & Shefrin, 1981), and therefore when people expect to balance, they prefer to pursue the temptation in the present and postpone goal pursuits for the future and, thus, maximize the attainment from both. For example, people may choose to indulge today and start a diet tomorrow and therefore express a positive evaluation of fatty food in the present.

In studies that demonstrated these evaluative patterns, Fishbach and Zhang (2006) manipulated the perception of items related to goals and temptations as complementing each other versus as competing with each other. Complementary items were presented in one choice set and competing items were presented in two different choice sets. They found, for example, that when healthy and unhealthy foods are included on one menu, participants saw them as complementing and planned to balance between them. As a result, the value of unhealthy foods was higher relative to the value of healthy foods. However, when these foods were presented apart in two different menus, participants saw them as competing with each other and planned to highlight the consumption of healthy food. As a result, the value of healthy foods was higher. Importantly, when these items were evaluated in isolation (i.e., in the absence of cues for alternative goals), they had similar value.

The evaluation of items related to multiple goals has further influence on the emotional experience that characterizes the self-regulatory process and goal attainment. That is, when people wish to highlight the pursuit of a single goal in a sequence, actions related to this goal are associated with positive emotions and actions that interfere with it are associated with negative emotions. However, when people wish to balance between several goals,

actions directed toward one goal can interfere with the attainment of another goal and, hence, might be less associated with positive emotions. Similarly, actions that interfere with the initial goal can advance the pursuit of another goal and be less emotionally negative. For example, socializing before an important exam is less guilt provoking if a student plans to balance between academic and social pursuits. The result is that when people consider the pursuit of multiple goals across several actions and over time, the emotional experience from goal-related actions is less intense.

Summary

Research reviewed in this section addresses the phenomena surrounding those situations in which multiple goals are at stake. We considered the effects of goals that are of similar centrality as opposed to goals that vary in their relative centrality and impose a self-control dilemma. We also described research on how multiple goals interact when a person only considers a single act of self-regulation, as opposed to when a person considers the pursuit of multiple goals over time and across several decisions. Based on research reviewed here, we suggest that multiple goals (vs. a single goal) present unique implications for people's behaviors, evaluations, and emotions. We further propose that these effects follow from our definition of the goal construct that we outlined in the first section.

CONCLUDING REMARKS

Multiple researchers across various domains of psychology have documented the wide-ranging effects of goals on behavior, attitudes and evaluations, and emotions and moods. In this chapter, we sought to identify the main principles from this literature by focusing on how goals become activated in the first place, the mechanisms that underlie and enable their operation, and the ways in which they interact with one another. Our analysis was grounded in basic definitional assumptions about goals concerning their structure in memory and the nature of memories assumed to be relevant to goals. We attempted to showcase throughout the chapter how many of the recent findings we reviewed derive from these definitional assumptions.

One central distinction between past research and the current framework concerns the degree to which people are aware of goal activation and pursuit. Throughout most of the last century of empirical and theoretical psychology, goals have been commonly understood as objects, states, or experiences that people consciously want or do not want (e.g., Gollwitzer & Moskowitz, 1996; Locke & Latham, 1990). Such conscious desires naturally dictate people's (conscious) thoughts, emotions, and behaviors. This past research also largely focused on the various determinants and effects of specific types of goals (e.g., accuracy vs. impression formation), and different ways of approaching the same goal (attaining achievement via academic or social means). In contrast with this

work, our framework involves the consideration of goals that can become activated and operate without the person's awareness or intention, either in isolation or among other goal pursuits, a move that reflects much research in social cognition over the last two decades (e.g., Bargh & Chartrand, 1999; Kruglanski et al., 2002). With the assumption that goals essentially consist of constructs in memory that operate according to basic principles of knowledge activation (e.g., Higgins, 1996) comes the potential for such constructs to be activated in memory without the person's awareness. And, just as a given thought, emotion, and action can be prompted by processing that remains implicit, so too can goal pursuit. In this way, people's choices of actions, emotions, and evaluations can be driven by goals of which they are unaware.

It is noteworthy that even though this recent framework differs in arguably substantive ways from much traditional research on goals, it nevertheless follows directly from classical research in social psychology more broadly. In particular, the view that goals can become activated and influential merely on perception of features of the environment follows from the tradition in social psychology to understand and document the power of situational forces to influence human behavior (since Asch, 1952; Cartwright, 1959; Lewin, 1935; Milgram, 1963). In this way, some of the recent work on goals provides a fuller picture of how goals might be selected merely as a function of the prompts and triggers in people's everyday surroundings.

CHAPTER 22

Self-Regulation
and the Executive Function

The Self as Controlling Agent

Roy F. Baumeister
Brandon J. Schmeichel
Kathleen D. Vohs

A man squanders his money on gambling. A woman beats her child. A drunk driver causes a crash that destroys three cars and injures several people. A student postpones studying until the night before the test and gets a bad grade. A young couple engages in unprotected sex and creates an unwanted pregnancy. A delinquent shoots an acquaintance during an argument. A dieter eats seven donuts and a pint of ice cream at one sitting. An athlete trains off and on for a year without any improvement in performance. A girl breaks a promise and betrays a friend's confidence. An old man again neglects to take his daily dose of insulin and goes into diabetic shock.

What these disparate events have in common is failure of self-regulation. When self-regulation works well, it enables people to alter their behavior to conform to rules, plans, promises, ideals, and other standards. When it fails, any one of a broad range of human problems and misfortunes can arise. Self-regulation is thus a key to success in human life and, when it falls short, a contributing cause that helps explain many forms of human suffering.

In this chapter, we provide an overview of the psychology of self-regulation. We review what it is, its importance, how it functions, how it fits into the broader context of human psychological functioning, and what some of its principal applications are.

THE IMPORTANCE OF SELF-REGULATION

To appreciate the importance of self-regulation, it is necessary to consider both practical and theoretical implica-

tions. The practical ones were anticipated in the opening paragraph of this chapter, but they can be stated more systematically as follows: Most of the social and personal problems that afflict people in modern Western society have some element of self-regulatory failure at their root. This is not to say that better self-regulation would alone solve all society's problems—but it would probably go a long way toward that end.

Perhaps the problems that most obviously revolve around self-control failure are those of impulse control. Drug and alcohol addiction has multiple determinants, but to the extent that people can regulate their consumption of these problematic substances, they will be less vulnerable to addiction. Many of the problems associated with sexual behavior are fully preventable, if only people would control themselves sufficiently to minimize risks. These include the paradoxical epidemic of unwanted and out-of-wedlock pregnancy (paradoxical because those problems have proliferated in recent decades despite the concomitant, historically unprecedented availability of highly effective contraceptive methods), as well as epidemics of sexually transmitted diseases. Eating disorders likewise have remained problematic for young women, and obesity has been officially declared a national and even international health problem (the so-called globesity epidemic), as people find themselves unable to regulate the most basic human function of eating.

Self-regulation failure is less obvious but perhaps no less central to many other problems. A landmark work of criminology concluded that deficient self-control is the single most important key to understanding criminality (Gottfredson & Hirschi, 1990). Subsequent work testing

this hypothesis has confirmed the central importance of low self-control, even if it is not the only key predictor. Apparently, people become criminal because they are poor at regulating their antisocial impulses and hence violate many of society's formal (and informal) rules. This pattern helps explain many hitherto baffling aspects of criminality, including the so-called versatility of criminals (i.e., most criminals are arrested repeatedly but for different crimes).

Money problems are also often linked to self-regulatory problems. Americans often fail to save money, and the low rate of savings is a problem both for individuals, who find themselves unable to cope with unexpected financial needs, and for the society and economy as a whole, for which the low reservoir of savings creates a lack of available capital. Many people earn good incomes but suffer from heavy debt loads, often attributable to unregulated use of credit cards.

Underachievement in school and work likewise has a dimension of poor self-control. Procrastination is now generally regarded as both a cause of poor performance and a reflection of poor self-regulation, and so it is one dimension of underachievement. Poor self-regulation can contribute in other ways to underachievement, such as by making people less willing to persist in the face of failure, less able to choose effective performance settings, less able to set and reach goals, and less able to sustain effort over a period of time.

Another way of appreciating the benefits of self-regulation is to compare the lives of people with good versus bad self-control. Although such comparisons are inherently correlational, and as a result it is in principle possible that self-control is the result rather than the cause of such differences, most theorists assume that personality traits precede behaviors and are therefore more likely the cause than the consequence. A recent set of studies by Tangney, Baumeister, and Boone (2004) included a trait measure of self-control and then examined multiple indices of effective functioning. People with high scores on self-control were better off than those with low self-control on virtually all of them. They had better grades in school. They had better relationships with family and friends: less conflict and more cohesion. They were better able to understand others and scored higher on empathy. They showed better psychological adjustment, including fewer psychological problems, fewer signs of serious psychopathology, and higher self-esteem. Not surprisingly, they reported fewer impulse control problems, such as overeating and problem drinking. They had healthier emotional lives, such as being better at managing their anger and being more prone to guilt than shame. They had less juvenile delinquency.

Other work using the same scale has confirmed the benefits. Supervisors who score higher in self-control are rated more favorably (e.g., as fairer) by their subordinates (Cox, 2000). People with high self-control make better relationship partners, especially because they are better able to adapt to partners (Finkel & Campbell, 2001; Tangney et al., 2004; Vohs & Baumeister, 2004).

Probably the most dramatic and conclusive evidence of the long-term benefits of self-regulation comes from the research by Walter Mischel and his colleagues. Mischel was a pioneer of self-regulation research because of his studies on delay of gratification, beginning in the 1960s. Self-regulation is required to override the impulse to seek immediate gratification in order to obtain greater but delayed rewards. His research group then followed up the early studies, which were typically done with young children, to see how they fared on into adulthood. Four- and 5-year-olds who were able to resist the temptation of one cookie in order to eat two cookies a short while later grew up to earn better marks on the SAT, to be rated by others as rational and socially competent, and to cope with frustration and stress better than those kids who were relatively unable to resist the tempting cookie at a young age. Thus, effective self-regulation can be recognized as an important key to success in life (see Mischel & Ayduk, 2004).

If practical benefits are not enough, however, self-regulation can also be recognized as important based on its theoretical implications. It is an important key for understanding what the human self is and how it operates. An analysis of psychological and behavioral processes is inadequate without it. Perhaps the emergence of self-regulation is one of the central steps in human evolution and a crucial aspect of human nature—one of the traits that most distinguishes the human psyche from the majority of other life forms on this planet. These implications cannot be easily summarized, however, and certainly not until the theoretical context and inner processes of self-regulation have been more thoroughly elucidated. In the coming sections, we shall attempt to do that. First, however, some definitions are required.

DEFINITIONS

Self-regulation refers to the self altering its own responses or inner states. Typically this takes the form of overriding one response or behavior and replacing it with a less common but more desired response. For example, when a dedicated smoker has an urge to smoke but does not then light up a cigarette, he self-regulates his own impulses. Self-regulation also includes the ability to delay gratification, such as when a child overrides the desire to eat the cookie on her plate and waits instead for the two in the oven.

Self-regulation is one of the self's major executive functions. The executive function of the self refers to its active, intentional aspects (see Baumeister, 1998; Gazzaniga, Ivry, & Mangun, 1998) and may be thought of as that part of the self that is ultimately responsible for the actions of the individual. The other major executive function of the self is choice. Not only may a self initiate behavior or control it, but a self also is responsible for deliberating and making choices from among the universe of possible options. As we shall see, choice and self-regulation are intertwined, and they often work in concert to achieve novelty and diversity in human behavior.

Technically speaking, a self does not regulate itself directly, but it may control the behaviors, feelings, and thoughts that comprise it. In this sense, self-regulation re-

fers to the regulation of processes *by* the self. Regulation *of* the self also falls under the rubric of self-regulation, but note that this may mean the regulating is done by something (or someone) else. For example, when otherwise quite different people go to the movie theater, they tend to behave in similar ways. They sit quietly, they occasionally whisper, and they pay attention to the action on the screen. Most of this behavior occurs without much in the way of active self-regulation, although to a naive observer it may appear that the moviegoers are inhibiting their normal behavior. Instead, it is likely that the context—the movie theater, the presence of other moviegoers, the start of the movie—triggers behavior directed toward watching the movie (e.g., Schank & Abelson, 1977). Thus, the environment surrounding the self is also a powerful shaper of behavior, one that occasionally reduces the necessity of active regulation *by* the self. Thus, although self-regulation has typically implied regulation of behavior by the self in pursuit of a conscious intention or purpose, some forms of self-regulation occur without conscious awareness or active intervention by the self.

Finally, our view of self-regulation is consonant with the notion of secondary control derived from a dual-process view of control (see Rothbaum, Weisz, & Snyder, 1982). According to this view, people strive to achieve a better "fit" with their environment using either primary or secondary control strategies. Primary control involves attempts to change the world to accommodate the self, such as by donating to political candidates in order to influence policy decisions in one's favor. Secondary control strategies refer to attempts to change the self in order to fit the world, such as by regulating one's own actions not to violate current policy or law. Given the difficulties inherent in changing the world to fit one's self, secondary control probably represents the more common and more consistently successful strategy of achieving harmony between self and world.

THE BROADER CONTEXT

We said earlier that the theoretical importance of self-regulation can only be appreciated within a broader perspective of relevant contexts and concepts. In this section, we seek to describe the place and importance of self-regulation amid human psychological functioning.

The Self

Self-regulation is one important function of the human self and perhaps a significant dimension of its *raison d'etre*. In this, it is not simply one of many functions, but one of a select few that help define the self. Higgins (1996) spoke of the "sovereignty of self-regulation," referring to its preeminent importance as compared with many of the other everyday activities of the self. Self theory is incomplete without an account of self-regulation.

The activities and functions of the self, as well as the accumulated knowledge and understanding arising from research on the self, can be broadly grouped according to three main dimensions (Baumeister, 1998). These are presumably based on three basic phenomena that give rise to selfhood. The first is reflexive awareness: Consciousness can be directed toward its source, so that just as people become aware of and learn about the world, they can also become aware of and learn about themselves. The eventual upshot is a body of knowledge and belief about the self, often called the self-concept. Without this, a self would be inconceivable.

Second, the self is used to relate to others. People do not in fact develop elaborate self-concepts simply by contemplating themselves or reflecting on what they have done. Instead, they come to know themselves by interacting with others. Moreover, interpersonal relatedness is not just a root of self-knowledge but an important goal of most human functioning. Human beings essentially survive and reproduce by means of their interpersonal connections. The "need to belong" is one of the most powerful and pervasive human motivations (Baumeister & Leary, 1995), probably because evolution has designed us to achieve our biological successes through membership in groups and relationships. Throughout human evolutionary history, lone wolves have been few and far between, and they generally were less likely to pass along their genes than their more gregarious peers. Thus, the self is also a dynamic tool for connecting with others.

The third aspect of the self may be called its executive function, though it is also sometimes called the agent or agentic aspect. The first aspect of self was a knower and a known, the second a belonger or member, but this third aspect is a doer. By means of its executive function, the self exerts control over its environment (including the social environment of other people), makes decisions and choices, and also regulates itself.

Self-regulation should thus be understood in connection with the self's executive function, though it also has some relevance to self-knowledge and to interpersonal belonging. The executive function essentially does two things: It controls the self and controls the environment. Self-regulation is loosely related to decision making and choosing. We shall review research showing that self-control is directly affected by making decisions, even if the decision making is on something that has no apparent relation to the focus of self-control. Conversely, exercises in self-regulation have effects on decision making. To foreshadow, we find that making choices and exerting self-control draw on a common, limited resource, and so doing either one of them temporarily reduces one's effectiveness at the other. The connection between the two may shed light on one of the most enduring questions about human nature, namely, free will. We now turn to that.

Free Will

The magazine *The Economist* is fond of quoting Ronald Reagan's surprisingly apt characterization of an economist as someone who sees something that works in practice and wonders whether it will work in theory. In our view, this captures the approach toward choice and free will in psychology. All around us, every day, we see peo-

ple facing choices in which multiple options are really viable and possible, and they exercise some sort of strength or power to make themselves select among them. Yet, in order to be good scientists, many psychologists think they must believe that every event is caused and that the apparent exercise of choice cannot be real. And so psychologists reject the evidence of our senses and our personal experience in order to insist that people are not really choosing. The outcome of each decision must have been the only outcome that was ever really possible.

Setting metaphysics aside, let us approach the question from an evolutionary perspective (Baumeister, 2005; Dennett, 2003). If free will exists in any sense, it is almost certainly the result of evolution, and it may therefore be more advanced in human beings than in other species. What sense of free will would produce gains in terms of survival and reproduction? We (along with Baumeister, 2005, Searle, 2001 and, in some respects, Dennett, 2003) can suggest two.

The first of these is rational choice. The evolution of cognition is intricately linked to the evolution of choosing, in that organisms became more capable of selecting among behavioral options and modifying their behavior based on appraisal of their environment (Tomasello & Call, 1997). An animal that could alter its behavior to find more food or avoid newly arising dangers would survive and reproduce better than an animal that could not.

Most social sciences currently have a significant contingent of researchers whose research is based on a rational choice model. That is, they assume that people appraise their options and choose on the basis of what will further their self-interest in the long or short term. Rational analysis, which requires logical assessment (such as cost-benefit analyses) of possible outcomes, is assumed to underlie most of the decisions people make about whom to vote for (in political science) or how they invest their money (in economics). Rational analysis is a distinctively human process: As far as research has shown, no other animals engage in rational analysis, though they can make somewhat sophisticated assessments of immediate situational choices (Tomasello & Call, 1997).

Rationality, however, presupposes free will, at least in some sense. As Searle (2001) has pointed out, rational analysis is useless without free will. That is, there is no point in being able to use logic to figure out the best thing to do—if you cannot then actually do it. At best, the human capacity for logical thought would enable people to think about why what they are doing is foolish or self-defeating. If evolution created free will, it was most likely for the sake of being able to do what logic chose as the most profitable course of action.

Self-regulation is the second form of free will, if rationality is the first (and we concede that the two may be intertwined). The capacity to alter one's behavior to maximize situational payoffs, achieve long-term gains, and conform to meaningful (even abstract) standards is also highly adaptive. From an evolutionary or biological standpoint, the capacity to override an initial response and substitute another response is an immense step forward and can be powerfully adaptive. This brings up perhaps the broadest context of all.

Cultural Animals

One of us has recently argued that an adequate explanation of human psychological functioning requires a rethinking of the nature–nurture debate that has defined social sciences' ultimate explanations of human nature for decades. The two opponents in the perennial debate are nature and culture. Nature, as represented by evolutionary psychology, emphasizes similarities, specifically similarities between humans and other animals. Culture, as represented by cultural psychology, focuses on differences, especially differences among cultures.

In contrast, Baumeister (2005) proposes that we also attend to evolutionary differences and cultural similarities. That is, in what sense are humans different from other animals, and in what respects are all or most cultures similar? Crucially, Baumeister proposes that these are linked—that what all cultures have in common is also what differentiates humans from other animals. By this reasoning, the key to human nature is that evolution created us to sustain culture, in the sense of an organized network of relationships that makes the totality of its members more than the sum of its parts. Culture is the central biological strategy of human beings and the basic source of the success of the human species.

For human beings to become cultural animals, humans had to evolve to have multiple capabilities. These include language, theory of mind, reasoning—and, in some sense, free will.

Self-regulation, we think, is the evolutionary root of free will. Rational choice is the main rival for that claim. As we shall show, however, self-regulation and rational decision making draw on a common resource, which suggests these did not evolve as separate mechanisms. Rather, the common resource suggests that evolution created that resource for one of them, and human beings enjoy the second as a by-product (in biological terms, a spandrel). The question is therefore whether self-regulation or rational choice was the first to appear and was therefore the driving force.

We think self-regulation was more likely the first to appear and therefore deserves priority in the evolutionary analysis. We freely admit that this is mere educated guesswork, and we are willing to revise our assessment if contrary evidence (i.e., that rational choice preceded self-regulation) emerges. Let us, however, present the basis for our assumption.

Baumeister (2005) distinguishes social animals from cultural animals. It has become something of a truism in social psychology that human beings are social animals (Aronson, 1995). They are. But in no sense are they the only social animals—wolves, zebras, even ants are social animals. Humans may not even be the most social animals. We are, however, the most, and arguably the only, cultural animals. The evidence of culture in other species is limited, and in no sense is any other species as fundamentally cultural as we are. Frans de Waal (2001a, 2001b), one of the most passionate and persuasive advocates of culture in other species, readily concedes that no nonhuman culture remotely approaches the extent of human culture. Although other animals do qualify as cul-

tural in multiple respects, these reflect isolated adaptations that capitalize in a very limited manner on the powerful biological benefits that culture can offer. In contrast, humans are thoroughly cultural, to the extent that human life is almost unimaginable without culture. Put another way, other animals occasionally dabble in culture, whereas human beings rely indispensably on culture for all our survival and reproduction. Among the 6 billion humans alive today on the planet, hardly any survive and reproduce independently of their culture.

The distinction between social and cultural animals is therefore crucial. Being social involves coordinated action between conspecifics. Being cultural depends on use of meanings to organize collective action. Social hunters may swarm, working together to achieve what none could do alone, but cultural hunters employ division of labor to benefit from expertise and generate systemic benefits. Social animals copy each other, thereby benefiting from one another's adaptive actions, but cultural animals can transmit knowledge from one generation to another. Thus, a pack of wolves today, though undeniably social, lives largely the same as a pack of wolves did 10,000 years ago, with no accumulation of knowledge or progressive improvement of techniques and technology, let alone redefinition of gender roles or organizational structures. In contrast, human life has changed drastically and dramatically even just in the past century, and less than 1% of the human population lives like its ancestors of 10,000 years ago.

To our (admittedly speculative) view, self-regulation was already important for social animals, whereas rational choice is limited to cultural animals. Therefore, if one of those deserves priority in evolutionary analysis, it should be self-regulation. Self-regulation is beneficial for social life. The ability to override one response, to substitute a more adaptive alternative, would be helpful to merely social (i.e., not cultural) animals. As one example, if the alpha male dictates that certain mates or certain foods should be reserved for him alone, then other males would benefit by being able to inhibit their impulses to pursue those gratifications for themselves. Pursuing them would lead to severe physical punishment and possibly expulsion from the group (if not death). Rational analysis here is irrelevant. The rules that operate in social groups of the biological relatives of humankind require self-regulation but not rationality, because they depend on the immediate stimulus environment. If the alpha male is absent, his rules can be flouted: One can eat his favored food or perhaps even copulate with his favored mates. We think that nonhuman primates only follow rules when there is the prospect of immediate punishment. In contrast, human beings follow rules even in the absence of any visible enforcers. Such behavior would be unknown and incomprehensible to merely social animals, who mainly follow rules enforced by powerful others who are present and ready to enforce them immediately.

In contrast, rationality is reserved to cultural animals, who can use meaning and language and abstract reasoning to dictate the optimal course of action. Social animals without language cannot exploit the power of reasoning,

for the most part, because logical reasoning operates within the rules of meaning, which require language to understand and process. To be sure, logical reasoning may in some respects be even more powerfully adaptive than self-regulation, because choices can in principle be made on the most optimal and hence adaptive basis. Still, insofar as self-regulation arose earlier and is more basic than rationality, rational choice may have been a side effect (spandrel). The resource needed for both self-regulation and rationality was selected by evolution first to serve the need for self-regulation, and then it was applied to enable full rational choice.

If we abandon the absurd requirement proposed by some opponents of free will that free will should be for the sake of purely random action, and if we assume instead that free will evolved to promote adaptive actions and choices, then we can discern the themes that are in common between self-regulation and adaptation. Self-regulation is vital for social animals because it enables them to match their behavior to externally dictated standards, such as rules imposed by the alpha male. Rational choice entails that individuals can work out for themselves (by logical analysis) standards and rules, and so rational behavior enables people to alter their behavior to conform to standards that they themselves have constructed. It is thus a more advanced stage of free will, in the sense that conforming to one's own standards entails greater autonomy than conforming to someone else's rules. Psychologically, the same mechanism may be involved in self-regulation and rational choice, even if rational choice represents a philosophically more advanced purpose. But both are highly adaptive.

BASIC THEORETICAL ISSUES

Having explicated the theoretical context of self-regulation, we turn now to consider how it operates. We shall first survey several central or controversial theoretical issues and assumptions surrounding self-regulation. Then we turn to consider the three essential components of self-regulation, namely, commitment to standards, monitoring of relevant behavior, and the capacity for overriding responses and altering behavior.

Irresistible Impulses or Acquiescence?

In everyday life, people seem to have a ready explanation for failures at self-control: "I couldn't resist." The implication is that certain impulses are irresistible, and so they overwhelm the powers of the self. This view depicts self-control as a struggle between the strength of the impulse and the strength of the self, and whether the person resists temptation depends on the strength of the impulse. Somehow, apparently, neither nature nor nurture has provided people with strong enough powers to resist many of the temptations they encounter, or so they say.

While reviewing the research literature on self-regulation, Baumeister, Heatherton, and Tice (1994) became increasingly skeptical of the doctrine of irresistible impulses. To be sure, there are some truly irresistible im-

pulses. For example, the urge to go to sleep, stop standing up, or urinate can eventually become so overwhelming that no amount of self-regulatory power can restrain it. But these may be exceptions. When a shopper returns home and explains to a disgruntled mate that the lovely but overpriced sweater had to be purchased, wreaking havoc on the family budget, because "I just couldn't resist," the mate may justifiably think this irresistibility is not on a par with those unstoppable biological urges. Likewise, when jurors hear a defendant claim that he or she committed the crime because his or her anger created an irresistible urge to kill the victim, they are probably justified in thinking that the defendant ought to have been able to resist that violent impulse.

There are empirical signs that so-called irresistible impulses may be resistible after all. Peele (1989) noted that addiction, which is commonly understood to cause irresistible cravings, is much less compelling than often surmised. For example, many American soldiers became addicted to heroin during the Vietnam War but then seemingly easily gave up heroin when they returned home. Even more surprising, others were able to use heroin occasionally after returning to the United States without resuming their addiction, contradicting the common view that a recovered addict is in constant danger of resuming full addiction if he or she gets any small amount of the addictive substance. Many heroin addicts may experience their cravings as irresistible, but this is perhaps attributable to their own chronic weakness of will rather than anything in the nature of heroin itself.

Converging evidence comes from studies of people who suffer from obsessive–compulsive disorder (OCD). The public may assume that obsessive thoughts are somehow unstoppable, but interviews with these individuals tend to yield the pattern that they attribute their problems to weakness of self and will rather than to any overwhelming power of the thoughts (Reed, 1985). Indeed, successful treatment of OCD is barely conceivable without acknowledging the person's capacity to alter his or her thoughts.

A similar observation comes from a very different source, namely, violent criminals. Douglas (1996) rejected the view that serial killers and other brutal criminals are driven by unstoppable impulses to commit their crimes. He observed that he and his colleagues had investigated hundreds of such crimes by many different individuals, yet no such crime was ever committed in the presence of a police officer. Police officers are found in many places, perhaps especially in the sorts of locations criminals pass by, and so the odds are good that sometimes police officers would be present when a violent killer gets an irresistible impulse to commit violence. The fact that no crimes take place under such circumstances suggests that these impulses are somewhat resistible after all.

Cultures can certainly help individuals perceive some impulses as irresistible, but this may be more a matter of convention than of recognizing reality. One famous example of culturally sanctioned loss of control was the pattern of "running amok," observed in the Malay of the Indian Archipelago. According to the local customs, young men who felt they had been treated unfairly or offended might lose control and go on a violent rampage, doing damage to property and even to other people. These rampages were strongly rooted in the belief that under those circumstances people could not possibly restrain themselves. One consequence was that such rampages were not punished or only lightly punished, which seems reasonable given the assumption that the individual could not have stopped himself from the violent and destructive acts. However, when the British colonized that area, they took a dim view of running amok and began punishing men who did it. The practice diminished with surprising rapidity, indicating that it had been more controllable than people thought all along.

The "gun to the head" test was proposed by Baumeister and colleagues (1994; Baumeister & Heatherton, 1996) as a way of distinguishing the truly irresistible impulses from the more resistible ones. If an impulse is truly irresistible, then one will act on it even if someone with a gun were threatening to shoot one if one acts that way. The examples we listed earlier, such as sleep, sitting or lying down, and urinating, all pass this test: Eventually the person will perform those acts even if threatened with imminent death. But buying the expensive sweater or committing the crime would probably turn out to be resistible (see Pervin, 1996).

The implication is that most undesirable thoughts and actions are probably far more resistible than people are likely to admit. To understand failures at self-regulation, therefore, we cannot simply invoke the commonsense model of powerful urges overwhelming the self. Rather, the person may acquiesce in yielding to temptation. The shopper could resist the sweater but somehow opts not to do so.

What Is Controllable?

The previous section suggests that many impulses are more controllable than some people may admit. The human capacity for controlled processing is impressive, but it is certainly limited. Hence it becomes necessary to distinguish what is controllable from what is not.

In the 1970s and 1980s, psychology was heavily influenced by the distinction between automatic and controlled processes. This simple dichotomy has, however, evaporated with the accumulation of data (e.g., Bargh, 1994). Most relevant to the present analysis is the necessity to invoke a series of processes that might normally be automatic but that could potentially be controlled. These are thus ripe for self-regulation, whereas the hard-core uncontrollable processes are not.

Self-knowledge thus becomes an important resource for effective self-regulation (Higgins, 1996). It is helpful for people to know what they can versus cannot change about themselves. The more extensive and accurate that self-knowledge is, the more people can profitably alter the controllable responses and avoid wasting their time trying to change unchangeable things. Seligman (1994), for example, has written a book attempting to dispel myths about the controllability of some responses and the uncontrollability of others.

Much of self-regulation is often subsumed under the term "impulse control," but impulse control may be a misnomer. Most impulses are automatic responses and cannot be prevented from arising. Strictly speaking, a person with so-called good impulse control does not really control the impulse itself but rather the behavior that would follow from it. Priests who live up to the Catholic Christian ideal of celibacy, for example, do not genuinely prevent themselves from having sexual desire. Rather, they experience desire, but they refrain from acting on it and seeking sexual activity (see Sipe, 1995).

Emotion is an important category of largely uncontrollable responses. That is, people cannot generally create or terminate an emotional state by act of will. Effective affect regulation is possible, but mostly by means of indirect strategies. For example, an angry person may not able to exert control over the emotion directly, but by distracting oneself, or by reframing the issue to interpret the situation in less upsetting terms, or by exercising to the point that one grows tired and the arousal dissipates, the person can possibly help the anger to dissipate. Someone with a false belief in the controllability of the emotion itself would thus be less effective at escaping the anger than someone who correctly appreciated the need to focus on controllable things (such as how one thinks, or whether to undertake vigorous exercise) and hence used those to exert indirect influence over the emotion.

Lapse-Activated Patterns

Lapse-activated responses refer to a class of behaviors that come into play after an initial (possibly quite minor) failure of self-control. Marlatt (e.g., Marlatt & Gordon, 1985) is one of the most influential researchers into lapse-activated responses. He documented an abstinence violation effect among problem drinkers. Once such drinkers believe they have had any alcohol, they may become consumed with a sense of futility and lose their confidence that they can resist temptation. (Zero-tolerance doctrines support such a response by claiming that any alcohol will cause a problem drinker to lose control utterly.) Marlatt showed, moreover, that the abstinence violation effect is psychological rather than physiological, in the sense that it depends more on the beliefs, perceptions, and assumptions of the drinker than on any irresistible, physiological consequence of consuming alcohol. In some studies, drinkers who falsely believed they had consumed alcohol were prone to go on a binge, whereas drinkers who falsely believed they had not had alcohol maintained restraint.

Similar findings have been documented in the eating realm, under the rubric of counterregulation or, more colloquially, the "what the hell" effect (Cochran & Tesser, 1996; Herman & Mack, 1975). Dieters who believe their diet is blown for the day eat more than dieters whose diets are presumably intact. Moreover, these responses depend on the perception rather than the actual caloric consumption. In one classic set of studies, dieters who ate salads maintained control over their eating subsequently, whereas those who ate ice cream abandoned restraint and overate—even if the salad contained twice as many calories as the ice cream (Knight & Boland, 1989).

Thus, again, beliefs about the self and about the controllability of responses contribute to effective (or ineffective) self-regulation. Researchers who proposed that some recovering alcoholics can learn to use alcohol in controlled amounts have been vilified, because their recommendations go against the prevailing zero-tolerance doctrines (Sobell & Sobell, 1984). But it can be counterproductive for people to believe that any lapse will inevitably lead to a full-blown binge. In reality, preventing the first sip or first bite is probably easier than stopping after a couple, but people can also learn to stop after a limited indulgence.

Beliefs are of course not the only factor relevant to lapse-activated patterns. Alcohol abuse has been implicated in nearly every form or sphere of self-control failure (see Baumeister et al., 1994, for review), from sex and violence to overeating to just drinking all the more alcohol. Apparently alcohol has special powers to undermine self-regulation. In our view, this is most likely connected with the fact that alcohol undermines self-awareness, thereby making it difficult for the person to continue keeping track of behaviors. We return to this issue below, as we explore exactly how self-regulation operates. For now, it is sufficient to observe that alcoholic indulgence facilitates loss of control over a broad range of behaviors, enabling initial lapses to snowball into serious breakdowns.

Transcendence, and Delay or Gratification

The ability to regulate or inhibit behavior is not uniquely human. Most dog owners have been able to observe that dogs can follow simple rules, at least when the owner is present to enforce them. (Our experience is that when a dog owner tries to teach a dog not to get up on the couch, it mainly learns not to get up on the couch when the owner is present; when he or she comes home from the office, there are still dog hairs on the couch.) If the dog has learned the "stay" command, it will sit still and stare fixedly at the bacon biscuit until the owner says the word that permits the dog to come forward and eat it. If the treat is tempting enough, the dog's owner can even observe the inner struggle, as the dog's legs shake with incipient motions and the dog has to struggle to remain in place.

No doubt this capacity for restraint was something that natural selection favored during human evolution, producing perhaps increased willpower among humans. However, there appears to be one crucial aspect of self-regulation in which people differ seriously, perhaps categorically, from other species. Humans can respond to circumstances beyond the immediate stimulus environment. This is crucial for our success as cultural animals.

We favor the term "transcendence" to refer to the human capacity to process and respond to things or events that lie beyond the immediate stimulus environment. Transcendence thus does not imply any kind of spiritual or metaphysical experience (e.g., transcendentalism) but simply a psychological capacity to respond to something

that is not physically present. There is little evidence that any nonhuman animal can do this.

Much of self-regulation depends on transcendence. Indeed, perhaps the most common dilemma concerns a conflict between being tempted to enjoy something in the immediate stimulus environment versus being restrained according to some abstract rule or standard, which may be linked to something in the distant past or future. The Jewish practice of keeping kosher, for example, involves refusing to eat what most animals would regard as perfectly good food, on the basis of religious principles that were laid down centuries ago.

Such self-regulation is qualitatively different from the earlier example of the dog's regulatory efforts. The dog resists the tempting food but mainly because the master is in view and presents an imminent threat of physical punishment if the dog's self-control fails. In contrast, a Jew may refuse to eat a ham sandwich even if no one else is present and no one would ever know he ate it.

In the same way, self-regulation can be guided by distal future goals. A college student who passes up a tempting beer party in order to study at the library may be guided by concerns that have little force in the present, and indeed the immediate stimuli (such as beer-guzzling roommates) may all favor joining the party. The conscientious, good student may, however, transcend the party-favoring stimulus environment in favor of doing something that will contribute to goals that may lie weeks (the final exam) or even years (graduating with honors and going on to a better career) in the future.

Transcendence is thus instrumental for delay of gratification, and the capacity for delay has contributed both collectively and individually to human success. Farming is just one of the many activities that depend on the capacity to delay gratification and that also have provided immense benefits to human beings as a species. (We also noted that the capacity for delay produces immense benefits for individuals, including in modern society.) Getting an education is a fine illustration of the importance of pursuing delayed gratifications. Attending class, going to the library, reading, studying, taking examinations, and similar activities are not intrinsically enjoyable for either human or nonhuman animals, but humans are willing to perform them over and over, in part because they confer immense advantages in the very long run. Americans with college degrees earn tens, even hundreds of thousands of dollars more than those without such degrees, but these benefits are over a lifetime, and in the short run most people could earn more money and live more comfortably by dropping out of college and taking a job.

Research by Mischel and his colleagues (Mischel, Ebbesen, & Zeiss, 1972; Mischel, Shoda, & Peake, 1988; Mischel, Shoda, & Rodriguez, 1989; for a review, see Mischel & Ayduk, 2004) has underscored the importance of transcendence for effective self-regulation in delaying gratification. In his studies, children must resist the highly salient temptation to enjoy a cookie or marshmallow in order to garner greater pleasures and rewards in the (admittedly not-so-distant) future. Observations of children in these studies show them attempting to blot out the immediate stimulus environment, such as by shutting their eyes, turning away from the sight of the tempting stimulus, or distracting themselves via singing. To the initial surprise of the research team, seeing representations of the rewards (e.g., pictures of cookies) facilitated self-regulation, in the sense that children who looked at pictures (and not the actual cookies) were better able to delay gratification. The implication is that such representations can enable transcendence by helping the child to think of the large future reward and to disregard the most appealing properties of the immediate temptation, thereby bolstering the child's ability to delay gratification.

BASIC ELEMENTS OF SELF-REGULATION

Self-regulation depends on three main components, and in this section we discuss each in turn. The first is commitment to standards. The second is monitoring of the self and its behaviors. The third is what is needed to change the self's responses. All are necessary for effective self-regulation. Hence, a breakdown or problem with any one of them can produce failure at self-regulation.

Commitment to Standards

Goal-directed behavior is impossible without a goal. In the same way, self-regulation cannot proceed without a standard, insofar as self-regulation is the effortful attempt to alter one's behavior to meet a standard. Standards are concepts of possible, often desirable states. They include ideals, expectations, goals, values, and comparison targets (such as the status quo, or what other people have done). Self-regulation is essentially a matter of changing the self, but such change would be random or pointless without some conception of how the self ideally ought to be.

There is some evidence that problems with standards can contribute to self-regulation failure. In particular, vague, ambiguous, or conflicting standards can undermine self-regulation. For example, if the two parents disagree as to how the child should behave, or even if they disagree as to the desirability of some particular kind of behavior, children are far less likely to learn to behave properly. Conflicting standards is one important source of self-regulatory breakdown (Baumeister et al., 1994)

Probably the most important work on standards comes from Higgins (1987) and his colleagues (e.g., Higgins, Roney, Crowe, & Hymes, 1994; Shah, Higgins, & Friedman, 1998). They distinguish between "ideal" and "ought" standards. Ideals form the basis of positive strivings toward the way one would like to be. Oughts are also rooted in concepts of how one would like to be, but the focus is on what to avoid rather than what to pursue. Ideals and oughts can come from within the self (e.g., if a person embraces a particular goal or value system) or from other people (e.g., parents can communicate expectations about their offspring's behavior). Higgins (1987)

further proposed that different sets of emotions are associated with the different types of regulatory standards, though of course both types of regulatory failure produce bad (negative) emotions. That is, failures to self-regulate toward ideals produces dejected, low-arousal emotions, such as sadness and disappointment. In contrast, failures to self-regulate according to oughts lead to agitated, high-arousal emotions, such as anxiety and worry.

One possible way of accounting for these differential emotional responses is that violating ought standards is more troubling than violating ideal standards, and so failures in the "ought" domain produce arousal. Arousal, as generally understood, prepares the body for action and mobilizes physical responding. It is more important or at least more pressingly urgent not to break important rules, such as by performing immoral behavior, than it is to move toward one's ideals. This may reflect the broader principle that bad is stronger than good (Baumeister, Bratslavsky, Finkenauer, & Vohs, 2001; Rozin & Royzman, 2001). A single violation of moral rules, for example, can directly cause ejection from social groups or create other problems for a long period of time, whereas a failure to move toward one's ideals does not necessarily have such ramifications and might simply mean that the person will have to seek another opportunity. Put another way, failing to advance toward ideals does not generally do as much harm to one's social position as does violating one's "ought" requirements.

Thus far we have emphasized having and knowing standards, but there is a motivational aspect as well. Specifically, the person must have some inner wish or proclivity to conform to the standards. If people do not care about being good, they will not be so good! Variation in self-regulatory motivation is an important but understudied aspect of self-regulation. A dieter, for example, may mostly want to keep to the diet, but under some circumstances that motivation may wane, and the person may knowingly violate the diet simply because at that moment he or she ceases to care much about losing weight.

Perhaps the most active area of research on self-regulatory motivation is Higgins and colleagues' work on regulatory focus (see Higgins & Spiegel, 2004, for a review). Building on Higgins's work on ideal and ought standards, regulatory focus refers to a person's characteristic motivational orientation. Some people are typically promotion focused, meaning that they are mainly motivated to achieve desirable outcomes using eager, approach-oriented strategies (i.e., to pursue ideals and obtain nurturance). Other people are prevention focused, meaning that they are mainly motivated to achieve desirable outcomes using vigilant, avoidance-oriented strategies (i.e., to satisfy oughts and to obtain security). A burgeoning literature attests to both the subjective and objective consequences of these two regulatory foci. For example, people who are characteristically promotion focused experience greater success when a task is framed as a pursuit of ideals. Conversely, people who are prevention focused experience greater success when a task is framed as an opportunity to do what one ought to do (Shah et al., 1998). Thus, when people experience regulatory fit—when their preferred regulatory motivation is matched by characteristics of the task at hand (Higgins, 2000)—self-regulatory outcomes are improved. To return to the dieting example, the regulatory focus view would suggest that promotion-focused individuals would best adhere to a diet if they considered it as a way to obtain an ideal body image, whereas prevention-focused individuals would best maintain motivation if their diet was framed as a way to eat in a responsible manner.

Monitoring

One hotbed of research activity in the 1970s was the study of self-awareness (from Duval & Wicklund, 1972). A landmark event in the evolution of that line of work was Carver and Scheier's (1981) book, which was received as a book on self-awareness but presented itself (starting with its title) as a book on self-regulation. At the time, the term "self-regulation" was quaint and obscure, whereas self-awareness was a familiar term. But Carver and Scheier were proposing that the main purpose of self-awareness was to facilitate self-regulation.

Linking self-awareness to self-regulation was a key, relevant point: It is very hard to change or otherwise a behavior if one is not aware of it. Monitoring one's behavior is an indispensable component to regulating it.

The writings of Carver and Scheier (1981) persuaded most social psychologists that the feedback-loop theory, originally developed by cybernetics theorists to enable missiles to hit and destroy their targets more effectively, could be profitably adapted to the psychology of self-regulation of human behavior. The core concept of the feedback loop (see Powers, 1973) involved a sequence of steps, under the acronym TOTE (for test, operate, test, exit). The test phases consist of comparing the self's current status against the relevant standards. This fact alone represents a key insight from the self-awareness research of the 1970s, which is that attending to self is not a mere act of noticing the self but, rather, almost invariably involves comparing the perceived aspect of self against some standard.

The operate phase consists of attempts to alter discrepancies between the perceived aspect of self and the relevant standards. Thus, if the test phase determines that the self is not trying hard enough, the operate phase will most likely consist of efforts to reduce that discrepancy by trying harder. During or after these operations, the self may perform additional tests to see whether the discrepancy has been resolved.

The exit phase terminates the process (as the name implies). When the self has met the relevant standards, there is no need for further operations, and the self's attention can turn to other issues.

The feedback loop is a rather cognitive theory, but of course emotion is a powerful feedback system in the human psyche, and emotion does influence self-regulatory processes. One mechanism is that emotions serve to highlight discrepancies that arise in test phases. Thus, being below the standard is likely to yield aversive emotions, whereas positive emotions may arise when the test reveals the self to have surpassed the relevant standard.

A more nuanced theory was proposed by Higgins (1987), who distinguished different types of standards. As noted earlier, he proposed that different categories of emotion are linked to different kinds of discrepancies. Failing to live up to "ought" goals produces high-arousal, agitated emotions such as anxiety, whereas failing to live up to "ideal" standards causes low-arousal, dejected emotions such as sadness.

Another useful advance was contributed by Carver and Scheier (1990), who concluded that emotions do not simply react to whether a discrepancy exists or not. Emotions are better designed to register change, and so Carver and Scheier proposed that emotions react to the rate of progress toward the goal or standard. If the person is moving toward the goal on or ahead of schedule, positive emotions will be felt, whereas if progress is overly slow, negative emotions will be felt. The novel contribution is that emotion can be positive long before one reaches one's goal, simply because the person feels he or she is making satisfactory progress.

We noted previously that alcohol is implicated in a broad range of self-regulatory failures, probably because alcohol reduces self-awareness (Hull, 1981). Alcohol use thus leads to more alcohol consumption, partly because drinkers soon lose track of how much they have consumed. Based on the notion of external monitoring, we can suggest one policy that might work to reduce problem drinking: Prohibit bartenders and other liquor servers from removing the empty glasses until the patron leaves the establishment. That way, someone who has had six drinks cannot fool him- or herself into thinking it has been just a couple. The empty glasses will furnish a clear tally of the number of drinks consumed.

Improving monitoring is one good way to improve self-regulation. Success is more likely when people observe their own behavior, such as by noticing the types of situations that induce anxiety to anticipate them or even avoid them in the future. People may also rely on external monitoring, such as keeping a journal of when they exercise or how they spend money, or when they ask the bartender not to remove the empty beer bottles.

The Strength Model

The third component of self-regulation is the capacity to make changes. This corresponds to the "operate" phase in the TOTE model, and cybernetic and other theorists were often rather vague about just how self-regulatory "operations" operated. It was plausible that a wide assortment of behaviors could be invoked to resolve discrepancies and bring the self into line with standards. Few obvious generalizations about such operations were apparent.

Recently, however, some evidence has accumulated to suggest that self-regulatory operations tend to consume a limited resource that seems to operate like an energy or strength. The idea that self-regulation depends on such a resource has long been anticipated in various places, including folk wisdom, which has treated "willpower" as an important ingredient in self-control. The term "willpower" implies a strength or energy that the self uses to bring about the changes it seeks. In a more scientific source, the research literature on self-regulation reviewed by Baumeister and colleagues (1994; Baumeister & Heatherton, 1996) also led those authors to conclude that self-regulation seemed to operate as if it depended on a limited resource resembling strength or energy. This would provide a useful explanation for an assortment of empirical findings and informal or anecdotal observations pointing to the apparent pattern that after people exert self-control to regulate some behavior, they seem vulnerable to self-regulatory breakdowns in other and seemingly unrelated spheres. For example, most university personnel have observed that students seem around examination time to exhibit a multitude of signs of poor self-control (e.g., they may eat badly or irregularly, become irritable or rude, resume smoking or other bad habits, or neglect personal grooming). Saying that "stress" causes these consequences is too vague: Stress produces no one of those effects reliably. Instead, the common mechanism may be that when examinations loom, students need to use all their limited self-regulatory resources (i.e., their willpower) to manage their studying, including completing assignments that may be late or have been neglected, and trying to master a complex amount of material in a short period of time. Because the demands of studying and preparing for the examinations consumes a large share of their self-regulatory resources, they have less left over for other, more everyday concerns of self-regulation, such as eating properly, being polite, managing their feelings, and keeping their bad habits under control.

These observations led to the formation of a strength model of self-regulation. Its main ideas are as follows. First, acts of self-regulation consume the limited resource, so that after performing such an act, the person's stock of this resource is at least temporarily reduced. Second, when the resource has been somewhat depleted, the person will be less effective at other self-regulatory tasks. Third, the same resource is used for a wide assortment of self-regulatory activities. Fourth, as with strength, the resource can be restored via rest and possibly other mechanisms. Fifth, also as with strength, regular exercise can increase strength over the long term. Thus, although the immediate result of exercising self-control is to reduce the person's capacity for more self-control, the long-term effect is the opposite, namely, to increase the capacity. Sixth, the self may begin to alter its responses long before the resource is fully depleted. Like athletes conserving their muscle strength when the first part of the athletic contest has begun to produce some degree of fatigue, everyday self-regulators may seek to conserve what is left of their strength when some of it has been depleted.

A series of laboratory investigations sought to test the strength model against other plausible models, including the idea that self-regulatory processes are essentially knowledge modules and hence would operate along the lines of information-processing systems, and the view that self-regulation is a skill that is gradually acquired during development and socialization. Those theories make competing predictions as to what would happen if a person engages in one act of self-regulation and then,

soon thereafter, engages in another act of self-regulation, possibly in a very different sphere. The strength model is based on the notion that the same resource is used for a wide range of different self-regulatory efforts, and so once some of that resource has been expended, subsequent self-regulation will likely be impaired, even in seemingly unrelated areas.

In one study by Muraven, Tice, and Baumeister (1998), participants watched an emotionally distressing film clip under instructions to try to suppress their emotional reactions, to amplify and maximize these reactions, or to let their emotions go without trying to alter or manage them. The first two of those conditions consumed self-regulatory resources as people tried to alter their emotional state, but the third condition would not consume them. Then all participants were given a test of physical stamina in the form of a handgrip exerciser, which they were to squeeze as long as possible. The people who had tried to alter their emotional reactions subsequently performed poorer on the handgrip stamina task, as compared to participants who had not tried to regulate their emotions. Thus, apparently, the effort to regulate emotional responses consumed some of the resource, leaving the people with less to use in performing well on the handgrip task.

In other studies, people who first tried to control their thoughts by suppressing any thoughts about white bears (adapted from Wegner, Schneider, Carter, & White, 1987) subsequently gave up faster on unsolvable anagrams. Trying to suppress the thought of a white bear seems to have consumed some strength, leaving less available for making oneself keep trying and working on the anagram test (Muraven et al., 1998). Likewise, people who had to resist the temptation to eat chocolates and cookies to instead make themselves eat radishes subsequently gave up faster on difficult puzzles (Baumeister, Bratslavsky, Muraven, & Tice, 1998).

These and similar studies (e.g., with solvable puzzles and other dependent measures) yielded generally consistent support for the first crucial aspect of the strength model, namely, that self-regulation depends on a limited resource that becomes depleted when the person exerts self-regulation. Thus it became appropriate to speak of "regulatory depletion" (Muraven et al., 1998).

Other Executive Functions: Making Choices

Not only self-regulation but also acts of effortful choice and volition use the same resource. The stimulus for these studies was Baumeister's (1998) review of research on the self. Baumeister grouped self-regulation under the broader category of the self's executive function, which involves exerting control or choice in relation to the external world alongside efforts to exert control over the self. Baumeister wondered whether the self-regulatory resource would prove to be relevant to choice as well. A first study (Baumeister et al., 1998) borrowed the choice procedure from cognitive dissonance research: Participants were either assigned to make a counterattitudinal speech with no attempt to enlist their

concurrence or make them decide or else requested and subtly pressured into making it, despite the experimenter's insistence that "the decision is entirely up to you" (e.g., Linder, Cooper, & Jones, 1967). Afterward, all participants were given the task of solving unsolvable geometric puzzles, and their perseverance was measured as an index of self-regulatory powers. Apparently, making the choice depleted the resource, insofar as participants in the high-choice conditions quit significantly faster than participants in the various control conditions. This provided a first indication that making an effortful choice depleted the same resources that were needed for self-regulation. The concept of regulatory depletion therefore seemed too narrow. In homage to Freud, whose theory of the ego was one of the last and only energy models of the self, we adopted the term "ego depletion." In the new formulation, this limited resource was needed not only for self-regulation but also for all acts of volition, including choice and active responding (as opposed to passivity).

The link between ego depletion and choice has been made in a further series of studies by Vohs and colleagues (2005). Using a variety of procedures and measures, these authors repeatedly showed that making an effortful choice (or, more commonly, a series of choices) depletes some resource relevant to self-regulation, as reflected in poorer self-regulation afterward. Thus, in one study, participants who made a series of choices about which commercial products they would prefer to own (and one of which they were slated to receive) subsequently showed impaired self-regulation as compared to people who merely rated the same products on a variety of dimension without having to make choices among them. The self-regulation measure consisted of making oneself drink an ostensibly healthful but quite bad-tasting beverage. Ego-depleted participants drank less than one-third as much as those in the control conditions. In another study, participants who had made more choices while shopping gave up faster on a mathematical computation task.

Increasing Strength

Another aspect of the strength model is that self-regulation should improve with regular exercise. If self-control does resemble a muscle, then exercise should strengthen the muscle. Several studies have yielded findings consistent with this view, though each has found considerable noise in the data. A variety of self-control exercises have been used, such as using one's non-dominant hand for routine tasks such as opening doors and brushing teeth, modifying one's speech such as by using complete sentences and avoiding abbreviations or profanity, and cultivating good posture. Participants who perform these exercises regularly for some weeks have been found to perform better afterward in laboratory tests of self-regulation (Muraven, Baumeister, & Tice, 1999; Oaten & Cheng, 2004; Oaten, Cheng, & Baumeister, 2004; for review, see Baumeister, DeWall, Gailliot, & Oaten, in press).

Replenishing the Depleted Self

Perhaps the least well understood aspect of the strength model is how the resource is replenished. Rest appears to be the most common route to replenishment; for example, when people get a good sleep their self-control (even if previously depleted) is better. One sign of this is that self-control appears best after a good night's sleep, whereas it gets weaker as the day wears on, as indicated by the diurnal distribution of self-regulatory failures: Diets are broken in evenings more than mornings, drug or alcohol binges are rare in the morning, most impulsive crimes are committed after midnight, and so forth. These patterns suggest that a person gets up (at least after a good night's sleep) with a full complement of resources, which are then gradually expended as the day wears on. There are also some indications that sleep deprivation weakens self-regulation, though more systematic data would be desirable.

The hypothesis that rest replenishes the self also received some support in a dissertation by Smith (2002). After an initial exercise designed to deplete the self, participants performed a variety of tasks, after which their self-regulatory effectiveness was measured. Participants who had been guided through a brief meditation period prior to the final regulatory task performed much better on it than those who performed other tasks such as reading magazines. Even resting quietly did not work as well as meditation for restoring the self's powers.

Several studies have suggested that positive emotion may help restore the self's resources. In a series of laboratory studies, affect inductions have been interpolated between two self-regulatory tasks. Neutral and bad moods do little to reverse ego depletion, but positive moods (such as induced by watching a humorous video clip) seem to improve the individual's performance on subsequent self-regulation tasks (Tice, Muraven, Slessareva, & Baumeister, 2004). Similarly, asking people to think and write about what is truly important to them (a method of self-affirmation; see Steele, 1988) appears to offer some protection from ego depletion. Three experiments have found that self-affirmation prior to or immediately after initial self-regulatory acts prevents impaired performance on subsequent, target self-regulatory tasks (Schmeichel, Vohs, & Baumeister, 2005). In the main, however, finding strategies to prevent or counteract ego depletion remains an important avenue for further research.

Possible Mechanisms

Thus, self-regulation operates like a strength or energy. It becomes depleted when used, regular exercise appears to increase the resource, and rest may be crucial for replenishing it. What exactly this resource is remains a formidable challenge for future research. At present, there are some early signs that have begun to illuminate the inner processes that attend ego depletion.

The resource does not appear to be closely linked to emotion. Many ego depletion studies have administered emotion measures, and these typically show no effects or changes as a result of depletion manipulations (e.g., Baumeister et al., 1998; Muraven et al., 1998; Vohs & Schmeichel, 2003). The only exception is that sometimes depleted people rate themselves as more tired than other participants, but this effect has only been found in some studies and with some measures. It is possible that depletion is felt as tiredness only when it reaches a certain threshold, even though its effects on behavior appear well before that.

Recent studies addressing the interrelation between the restraint component of self-regulation and the impulse component suggest that depletion may affect how strongly an urge is felt. Vohs and Baumeister (2004) depleted participants by asking them to control their thoughts about a white bear, whereas other participants were given free rein to think about a white bear and thus were not taxed of self-regulatory resources. Subsequent to the mental control task, participants were shown an emotionally provocative video and then immediately afterwards described their feelings in response to the video. Participants who had earlier suppressed thoughts about a white bear reported stronger emotional reactions to the video. This study and others like it (see Vohs & Faber, 2005, who showed that people report more intense urges to buy impulsively when they are depleted) indicate that one consequence of initial self-regulation attempts is an amplification in the experience of impulses and urges, suggesting another route by which self-control fails under depletion.

Most of the work on the ego depletion model has tested new spheres in which self-control processes may be operating (e.g., interpersonal processes, intelligent thought, and addictions), boundary conditions, and specifications of the tenets of the model. A recent paper by Vohs and Schmeichel (2003) attempted to pin down a mechanism to account for the negative effects of resource depletion on subsequent self-control capacity. They identified time perception as one potential signal that people are in a state that precedes a lack of self-control. The experience of time as moving very slowly (i.e., that tasks seem to take more time than they do in actuality) as a mechanism was suggested by findings from the animal literature and from the time perception literature. Animals appear not to have a sense of the far future (Roberts, 2002). Rather, they experience reality as an "extended now" period in which impulses take precedence over anything resembling long- or midterm goals, such as accruing resources (e.g., acorns) to consume later (e.g., in the winter). From the time perception literature, it is known that being highly aware of time (e.g., asking oneself "how long has it been?") leads to perceptions of longer duration (Block & Zakay, 1997). Vohs and Schmeichel (2003) tested the idea that depletion leads to altered time perception and this reduces later self-regulatory ability. More precisely, the researchers found that ego depletion made people more likely to think that they had been continuing their activity longer than people who had not been regulating. Thus, in a sense, depleted people become like animals who are stuck in the

present and unable to orient their behaviors toward future outcomes.

Nonconscious Self-Regulation

The self-control strength model, and indeed the majority of research we have reviewed so far, has considered self-regulation to be a conscious, active process. However, evidence continues to mount for the existence of highly efficient, automatic self-regulatory mechanisms as well.

First, the automotive model of Bargh and colleagues (Bargh, 1990; Bargh, Gollwitzer, Lee-Chai, Barndollar, & Troschel, 2001) explains that goal pursuit, from goal setting to goal completion, may proceed completely outside conscious awareness. Hence some goal-directed activity may occur in the absence of conscious intent and even without the person being aware that they are engaging in goal-directed behavior.

For example, one recent set of laboratory experiments demonstrated that social and behavioral goals could be activated outside conscious awareness and then pursued as if they were consciously intended (Bargh et al., 2001). Research participants who had been primed with the concepts "achievement" or "cooperation" went on to achieve better performance or to cooperate with a partner more readily on a task, respectively, compared to participants who had not been primed with those concepts.

Similarly, simply thinking about a significant other (such as a family member) can prime goals that one associates with that significant other (Fitzsimons & Bargh, 2003) and also prime goals that the other has for the self (Shah, 2003). Once those goals are activated, even though they may not occupy conscious awareness, behavior may conform to the activated goal. For example, among students who believed that their mothers would be pleased by their academic achievement, priming by stimuli related to their mothers led to improved performance on a verbal achievement task compared to participants who did not associate their mothers with academic achievement (Fitzsimons & Bargh, 2003).

Not just goal-directed behavior but also emotional states may also be regulated outside conscious awareness and without intentional intervention. For example, recent research found that shortly after an emotional experience, people spontaneously generated mood-incongruent thoughts presumably as a way to alter their mood state (Forgas & Ciarocchi, 2002). Similarly, Gilbert, Pinel, Wilson, Blumberg, and Wheatley (1998) have posited the existence of a "psychological immune system," which works to ameliorate negative feelings and protect the self from psychological threat. This system is thought to operate automatically, without purposeful self-direction. Again, then, it appears that some emotional states may be regulated nonconsciously.

What is the relationship between conscious and nonconscious self-regulation? Research by Gollwitzer and colleagues (Gollwitzer, 1999; Gollwitzer & Brandstätter, 1997) provides some insight into this relationship. In their study of *implementation intentions*, they have found that forming explicit behavioral plans (e.g., by designating a specific time and place in which goal-directed activity will be pursued) triggers subsequent goal-directed behavior efficiently and automatically, without continued self-intervention. For example, participants who formed explicit implementation intentions enacted goal-directed behavior immediately upon discerning the appropriate conditions to do so (Gollwitzer & Brandstätter, 1997). Similarly, establishing an implementation intention to ignore a target person's gender led to less gender-stereotypical responding after exposure to the target than having no such intention (Gollwitzer, Achtziger, Schaal, & Hammelbeck, 2002). Thus, it appears that conscious intentions can facilitate nonconscious or automatic self-regulation.

According to the self-regulatory strength model outlined earlier in this chapter (see also Baumeister, Muraven, & Tice, 2000; Schmeichel & Baumeister, 2004), conscious and active self-regulation leads to ego depletion, which results in poorer subsequent self-regulation. It is likely that nonconscious self-regulation, because it does not entail purposeful intervention by the self, would not deplete self-regulatory resources. Furthermore, ego depletion should not interfere with efficient nonconscious self-regulation because this type of regulation does not require active involvement by the self.

One recent pair of studies touched on the links between conscious and nonconscious self-regulation by combining implementation intentions and ego depletion (Webb & Sheeran, 2002). These researchers had participants perform the Stroop color–word interference task, a classic cognitive task that depletes self-regulatory strength. The Stroop task requires the performer to inhibit the natural tendency to read a word and to replace the reading tendency with the naming of the ink color in which the word is printed. Webb and Sheeran found that participants who performed the Stroop task gave up more quickly on an ensuing test of self-regulation, consistent with the self-regulatory strength model. However, if participants had formed explicit implementation intentions about Stroop task performance (i.e., to ignore the meaning of the words and to name the colors), they did not show the ego depletion effect. Apparently, forming an implementation intention made Stroop task performance less dependent on conscious self-regulation, and so it became less taxing of self-regulatory strength.

Similar findings come from recent research showing that nonconscious priming can overcome the damaging effects of ego depletion. Weiland, Lassiter, Daniels, and Fisher (2004) depleted some participants using a task involving complex rules about when to cross out "e's" in a page of printed text, whereas other participants were given simple rules to follow. Prior to the editing task, some participants encountered supraliminal but nonconscious achievement-related primes in a scrambled sentence task whereas others encountered neutral primes. On a subsequent task involving unsolvable puzzles, depleted participants who received the neutral prime quit significantly sooner than depleted participants who received the achievement prime. These findings suggest that at least some self-regulatory resource depletion effects involve motivation more than ability, in-

sofar as goals activated outside awareness can overcome deficits in self-control ability due to depletion.

Thus, there is some evidence that depleting self-regulatory tasks may be made less depleting by an act of conscious will. Forming an implementation intention can make later self-regulation more automatic, and therefore less reliant on regulatory strength. Moreover, one study found that nonconscious achievement-goal primes can protect self-regulated behavior from weakened regulatory strength. These encouraging notions deserve further research attention, as does the broader issue of the relationship between conscious and nonconscious forms of self-regulation.

APPLICATIONS

In this section, we focus on applications of the self-regulatory strength model. These show some of the phenomena that are involved in self-regulation.

Cognitive Processing

Intelligent thought, especially logical reasoning, is a supreme achievement of the human intellect that sets humans substantially apart from what other animals are capable of doing. Logical reasoning is hardly natural, in that sense, and thus it may well require guidance by the self's executive function. Simply put, self-regulation of thought may be necessary for successful thinking. Ego depletion may therefore impair the self's ability to think effectively.

A series of studies by Schmeichel, Vohs, and Baumeister (2003) confirmed that some (but not all) forms of intelligent thought are impaired by ego depletion. Specifically, the relatively simple forms of thinking that may proceed automatically were largely unimpaired, whereas thought that required active work to transform one set of ideas into another often showed substantial impairments. To use the terms favored by (some) intelligence researchers, depletion should affect *fluid intelligence* (the capacity to reason, manipulate abstractions, and discern logical relationships), but it should have relatively little effect on crystallized intelligence (involving the retrieval of knowledge acquired via learning and experience; Cattell, 1987; Garlick, 2002). Sure enough, depletion impaired people's performance on fluid intelligence tasks, such as extrapolating from a known to an unknown quantity, or logical reasoning, or being able to take newly acquired information and apply it to novel problems or questions. In contrast, depletion had no substantial effect on such crystallized intelligence tasks as rote memory for nonsense syllables and responding to a test of general knowledge. Thus, apparently, some forms of thought involve self-regulation and depend on the self's precious resource, whereas other (simpler and more automatic) processes do not use this resource. Put another way, ego depletion makes people stupid in complex ways but leaves them intelligent in simple ways (see also Schmeichel, Demaree, Robinson, & Pu, 2006).

Recent work has begun to explore the links between self-regulation and memory. Schmeichel, Gailliot, and Baumeister (2005) set out to show that active self-involvement in memory processes can improve memory, and that resource depletion may undermine this benefit. Previous work had suggested a *self-choice effect* on memory, which is to say that people remember stimuli they have chosen better than stimuli chosen by others or not chosen (e.g., Kuhl & Kazén, 1994). Schmeichel et al. found signs that ego depletion destroys the self-choice effect. The most likely explanation is that when the self has been depleted, people choose in a less effortful and possibly more arbitrary manner, with the result that such choices leave a weaker memory trace. Thus, in one study subjects were instructed by the experimenter to remember some items and forget others; depleted subjects performed just as well as nondepleted ones on this task. However, when subjects were permitted to choose which items to remember and which to forget, depleted subjects performed more poorly (as measured by total recall of both "remember" and "forget" items) than nondepleted subjects. In another study, subjects were given a list of possible tasks. They chose some for themselves to perform, and others were chosen for them by the experimenter (and others were unchosen). Nondepleted subjects remembered the ones they chose best, followed by the ones the experimenter chose, and followed by the unchosen ones—which would seemingly be an adaptive pattern of memory. Depleted subjects, however, recalled the unchosen ones just as well as the self-chosen ones, with the experimenter-chosen ones recalled even worse. The memory for self-chosen items was significantly worse among depleted than among nondepleted subjects.

The idea that the self regulates thought processes is not new, and indeed many of Freud's theories can be read as support for this view. For example, defense mechanisms involve the attempt to think certain thoughts and especially to avoid other thoughts. To be sure, Freudian defense mechanisms did not typically invoke conscious, deliberate control, but presumably some forms of self-regulation can become automated, resulting in nonconscious self-regulation (e.g., Bargh, 1990; Higgins et al., 1994; see the section "Nonconscious Self-Regulation").

A systematic treatment of (often motivated) self-regulation of cognitive processes was provided by Baumeister and Newman (1994). Insofar as self-regulation involves seeking to bring inner responses and processes into line with standards, it was necessary to distinguish two main types of standards that guide thought. One is the truth, in which case self-regulation may seek to guide processing toward the most accurate conclusions, whatever they may be. The other is an a priori preferred view, in which case self-regulation tries to guide thought toward the preordained conclusion. Baumeister and Newman used the metaphors of intuitive scientist for the first (insofar as scientists ideally seek the truth, whatever it may be) and intuitive lawyer for the second (because lawyers try to make the best case for their client, such as to establish his innocence even if he is guilty).

The two self-regulatory goals then yield different prescriptions for regulating thought across four stages of

cognitive processing. The first stage involves gathering evidence. The intuitive scientist seeks to get the most thorough and reliable evidence available, whereas the intuitive lawyer seeks evidence that fits the desired conclusion, such as by means of selective attention and confirmation bias. The second step involves recognition of the implications of various pieces of evidence. This step is mostly automatic, and as such it offers relatively little opportunity for self-regulation.

The third step is reassessment of implications. The automatic conclusions arising from the second step can be scrutinized. The intuitive lawyer may search for sources of bias or distortion that might render some evidence less conclusive than they first seemed. If so, the person might adjust or recompute the tentative conclusions. Meanwhile, the intuitive lawyer may reject some tentative conclusions or implications insofar as they conflict with the preferred conclusion. Selective criticism of unwelcome evidence is one strategy that can be used, such as when people subject hostile evidence to critical scrutiny while accepting congenial evidence uncritically (Lord, Ross, & Lepper, 1979).

The fourth step is to combine and integrate the various implications to formulate a general conclusion. The intuitive scientist can try extra hard to make sure that all viewpoints are considered and that the decision criteria are maximally fair. In contrast, the intuitive lawyer can channel the decision process toward the desired conclusion by selecting decision rules or criteria that favor it.

Probably most people are capable at both intuitive lawyer and intuitive scientist modes of regulating cognitive processes. The intuitive lawyer is useful for self-deception, for supporting a party line or boss's dictates, and generally for helping people sustain the comfortable views they prefer. The intuitive scientist is useful for careful decision making and, more generally, for making decisions in which the person does not have a vested interest in a particular outcome.

Another influential line of research on the self-regulation of thought processes has considered some of the unintended consequences of intentional thought control. Wegner and colleagues (Wegner, 1989, 1994; Wegner et al., 1987) have created an elegant model of the ironic processes of mental control. According to their model, attempts to suppress or inhibit particular thoughts often have as a consequence an increase in those very thoughts. For example, when people try not to think about a white bear, they may succeed temporarily only to experience an abundance of white-bear thoughts a short while later (Wegner et al., 1987). This rebound in the unwanted thought is a result of two related mental processes—a monitoring system, which operates automatically to scan the mental landscape for the occurrence of the forbidden thought, and the conscious operator system, which attempts to occupy the mind with anything but the unwanted thought. The operator requires mental resources to function, and thus successful thought suppression depends on the workings of the conscious operator system. When mental resources are diverted, however, the conscious operator fails to fulfill its function while the automatic monitor continues to operate normally. This combination of events leads to increases in awareness of the unwanted thought.

Earlier we considered the relationship between conscious and nonconscious self-regulation, and Wegner's work on thought control is also relevant in this connection. The automatic monitor in Wegner's model, responsible for detecting occurrences of an unwanted thought, is a nonconscious aspect of self-regulation initiated by the person's conscious attempt at thought control. However, the nonconscious monitor may actually work against the conscious goal of thought suppression by making the forbidden thought more available to conscious awareness. When the conscious operating system is distracted or depleted (which is apparently all too often), the automatic monitor continues to report occurrences of the forbidden thought to conscious awareness, and thus the nonconscious monitor may work against the conscious attempt at mental control.

Interpersonal Processes

We have suggested that self-control abilities probably played a vital role in the social and cultural lives of our forebears, such that those who could suppress or hide their selfish desires acquired advantages that their more uninhibited counterparts did not. For example, keeping one's unpopular views to oneself may have made it easier to get along with others in the group, and it would also have reduced the likelihood of being socially sanctioned or even cast out of the tribe. Recent research has begun to support these speculations by indicating the role of self-regulatory strength in interpersonal functioning.

Self-Presentation

Projecting to others just the right impression of oneself is a tricky task, but one that is crucially important for meeting social goals. Meeting prospective in-laws, negotiating a higher salary, and trying to talk one's way out of extra housework are only a few instances in which self-presentation demands are high. Research by Vohs, Baumeister, and Ciarocco (2005) demonstrated that self-presentation and self-regulation are linked, with each process affecting the other. In a series of studies, Vohs and colleagues found that self-presentation demands influenced self-regulatory ability.

In one study, presenting oneself very positively to a friend or modestly to a stranger—patterns that run counter to typical self-presentational patterns of being modest with friends and enhancing with strangers (see Tice, Butler, Muraven, & Stillwell, 1995)—led to decreased persistence on a series of math problems as compared to acting in ways that are consonant with typical self-presentational patterns. In four additional studies, Vohs and colleagues (2005) found that diminished self-regulatory resources led to less successful self-presentation. In one study participants were asked to ignore (by carefully controlling attention) a series of irrelevant words scrolling across the bottom of the screen of a videotaped interview, whereas other participants saw the same tape (with the same extraneous words) but were not

instructed to ignore the words. The former group would presumably use more regulatory resources than the latter, and therefore be poorer at effortful self-presentation afterward. The self-presentation task in that experiment was self-descriptions of oneself on a narcissism scale. Sure enough, the depleted group was more egotistic, as evidenced by higher scores on the narcissism scale.

The ability to control one's expressive behaviors to make a very specific impression on other people is crucial to interpersonal success. It is, however, costly in the sense that such effortful self-presentation depletes the self of resources that could otherwise be used for a broad variety of goal-related and self-regulatory endeavors. These findings may perhaps explain why people are sometimes unable (or unwilling) to manage their self-presentations optimally to be seen in a socially acceptable light: They are using those limited resources to achieve other regulatory goals.

Close Relationship Maintenance

Interpersonal interactions presumably require some degree of self-regulation, but interacting with people who are demanding or difficult likely requires even more self-regulation. This hypothesis was tested by Finkel, Campbell, Brunell, and Burke (2004), who parsed interactions into two kinds: high and low maintenance. High-maintenance (HM) relationships take effort and are relatively inefficient at accomplishing complex tasks, whereas low-maintenance (LM) relationships are relatively effortless and efficient. Finkel and colleagues found that participants assigned to interact with a HM (vs. LM) confederate later exhibited passivity by choosing to work on easy anagrams as opposed to more challenging anagrams. Indeed, 85% of HM-condition participants chose to work on easy rather than challenging anagrams, whereas only 38% of LM participants preferred the easy task.

In order for romantic relationships to survive, persons in such relationships must be able to cope constructively with negativity on the part of one's partner. Finkel and Cambell (2001) found that the ability to be accommodative and constructive in the presence of a partner's bad behavior relies on self-regulatory resources. In one study, participants in the depletion condition were assigned to control their emotional responses during an emotionally evocative film, whereas participants in the no-depletion condition watched the same film but did not have to control their emotions. Later, all participants were asked how they would respond to a series of potentially destructive partner behaviors (e.g., being 2 hours late for a date), a measure that tapped participants' accommodative tendencies. Finkel and Campbell found that tendencies to be accommodative were lower among participants who had earlier controlled their emotions than among those who had been allowed freely to express their emotional reactions. Hence, people whose regulatory resources had been drained by previous instances of self-control were at risk for responding destructively to others' bad behaviors.

The tendency for people to credit successes to their own internal, stable abilities but to blame others or the situation for failures is called the self-serving bias and it is one of the most reliable attribution effects in psychology (see Campbell & Sedikides, 1999). In the context of a romantic relationship, shared credit for success and taking responsibility for one's role in failure would seem to be beneficial to the health of the relationship. Two persons in a couple who both behaved that way would have a very nice relationship indeed ("Without your help we never would have made it this far" or "I am sorry that I made a mistake"). Initial findings suggest that having more self-regulatory strength allows one to think and speak in these unselfish ways (Vohs & Baumeister, 2004).

Remaining committed to a romantic partner not only means turning a blind eye to the partner's potentially destructive behavior (see Finkel & Campbell, 2001) but also to the positive, attractive aspects of alternative potential partners. Miller (1997) demonstrated that eye-gaze length is an indication of attraction toward another: Short gazes reflect superficial consideration and long gazes reflect deeper processing of the person's attributes. Moreover, Miller's research showed that length of time spent looking at pictures of attractive persons predicted relationship dissolution 2 months later.

Vohs and Baumeister (2004) hypothesized that ego depletion would cause people to look longer at such tempting alternative partners. Just as dieters must turn their attentions away from tempting but forbidden snacks in order to remain faithful to their diet, would-be faithful relationship partners must turn their attentions away from the temptations of new partners. To deplete participants of their regulatory strength, participants were asked to read aloud dull historical biographies under instructions to exaggerate their emotional and facial expressions. In the no-depletion condition, participants read aloud the same biographies but were not given explicit instructions on how to do so. The former was presumed to require more behavioral control and thus tax self-regulatory resources more than the latter. Subsequently participants were told to page through a booklet of scantily clad male and female models, a task they performed while being secretly videotaped. Time spent paging through the booklet was the dependent measure. Consistent with predictions, depleted participants spent more time looking through the book of attractive, near-naked models than did nondepleted participants. Moreover, their slowness did not reflect mere passivity, because the effect was stronger for pictures of opposite-sex models than for same-sex models, as would be consistent with an attraction to alternates hypothesis. When people are low in regulatory strength, they may not have the willpower to turn their eyes away from attractive alternate partners.

Resisting Persuasion

Getting people to do what one wants often entails having to wear down their resistance, which suggests that depleting people's regulatory strength is one route to increasing persuasion. A series of studies by Knowles and colleagues tested this hypothesis by predicting that initial persuasion attempts will be rebuffed more easily than

later persuasion attempts because strength will have been drained combating the earlier attempts, leaving people unable to resist later on. In one study, Knowles, Brennan, and Linn (2004) gauged people's reactions to political advertisements. The results showed participants were indeed most skeptical (i.e., most resistant) when rating the first ad as compared to the last ad, indicating that regulatory resources and thus resistance were worn away with each need to be critical.

Moreover, before rating the last ad, participants were given the task of either listing all the potential problems of going on a Fiji vacation or listing which activities they would like to do on a Fiji vacation. (Participants had earlier watched a video of Fiji vacations so they had the information necessary to complete this task.) The hypothesis was that by having a break from being skeptical and describing the Fijian activities they thought they would enjoy, participants' regulatory strength would be able to rebuild and therefore ratings of the final ad would be more skeptical than if they had to spend the extra time continuing to be skeptical (this time of tropical vacations). The results confirmed this hypothesis in showing that when participants got a pleasant rest from having to be critical, they were then able to be more skeptical when evaluating the last political ad relative to participants who had listed problems with Fiji. However, the finding emerged only for participants who reported being fairly accepting of political ads, suggesting perhaps a practice effect or an individual difference that moderates these effects. In sum, people who battled repeated persuasive attempts became less able to defend against those attempts and consequently became accepting of advertising messages. After a pleasant break, though, the strength rebounded and enabled people to be resistant again. These results also converge with other findings that positive feelings help restore depleted regulatory strength (see Tice et al., 2004).

Controlling Prejudice

Interacting with people of an ethnicity other than one's own may also represent a self-regulatory challenge. Stereotypes and expectations about outgroup members appear to spring automatically to mind in interracial interactions (e.g., Devine, 1989), and so attempting to keep these thoughts at bay may deplete self-regulatory strength. Richeson and Shelton (2003) found support for this view in their study of interracial interactions. When prejudiced White participants interacted with a Black person, they went on to perform more poorly on the Stroop task (a classic measure of cognitive control) compared to when they had just interacted with a White person.

Apparently, face-to-face interaction with an outgroup member is not the only context in which stereotype suppression may deplete self-regulatory strength. Research by Gordijn, Hindriks, Koomen, Dijksterhuis, and Van Knippenberg (2004) found that suppressing stereotypes while writing a short narrative about an outgroup member also led to ego depletion effects. Reduced self-control strength after stereotype suppression was most pronounced among people low in internal motivation to suppress stereotypes (see Plant & Devine, 1998). Moreover, when people with low internal suppression motivation had to suppress stereotypical thoughts, they subsequently showed an increased reliance on stereotypes in general, even stereotypes unrelated to the ones that had initially been suppressed. Presumably, suppressing stereotypes depleted self-control strength so that all manner of stereotypical thoughts increased in salience subsequently.

If suppressing stereotypes is depleting, can exercises aimed at increasing self-regulatory strength enable people to resist stereotypes more easily (i.e., without the detrimental effects)? A series of studies by Gailliot, Plant, Butz, and Baumeister (2004) suggested a positive answer.

The emergence of perceptions and attendant stereotypical associations of stigmatized individuals are affected by people's current self-control strength, according to the results of recent research. Participants who performed a strength-reducing version of the Stroop color-naming task were more likely to mistakenly identify a gun (when it was a tool) after the presentation of a Black (vs. White) face (Govorun & Payne, 2004). This effect occurred only among participants who possessed a strong automatic race bias. Thus, prejudicial tendencies to associate Black faces with dangerous weapons were more likely to emerge and affect behavior when people's regulatory strength was weakened.

Having a stigmatized social identity will likely affect self-regulatory resources in contexts that contain threats related to the social identity. Research by Inzlicht, McKay, and Aronson (2003) supports this contention. The Stroop color-naming task was used to threaten participants, who in the threat condition were told that the task was an intellectual test, which acts as a threat to Black more so than White participants. Time spent completing the Stroop task was used as the dependent measure of self-control, and this measure showed that Blacks who thought the task was diagnostic of intellectual ability performed the task more slowly than Blacks who were not told of the task's purported diagnosticity and more slowly than Whites in the threat condition. A second study with men and women showed effects on a second self-control task, such that women who thought an initial math task was related to gender differences performed worse on a handgrip task than women who did not believe the task was related to gender. They also performed worse than men in the gender differences condition. Thus, self-identification as a stigmatized person can render one vulnerable to ego depletion when faced with a task that accentuates perceived deficits of that identity.

Rejection and Ostracism

Given the supreme importance other people play in our lives and the fundamental nature of the human need to belong, working actively against belongingness needs by ostracizing another person probably requires self-control. Thus, purposefully ostracizing another person may cause ego depletion. In one set of studies, participants who actively ignored another person subsequently

showed poorer self-regulatory performance in terms of physical stamina and persistence in the face of failure (Ciarocco, Sommer, & Baumeister, 2001). Actively ostracizing another person also led to worse mood in the ostracizer, but poorer mood did not account for the poorer self-control. These studies suggest that although self-regulatory abilities probably exist to increase belongingness and interpersonal bonds, they may also be used to ostracize others and prevent bonds from being formed (see Vohs & Ciarocco, 2004).

Rejection can also be bad for self-regulation among the people who are rejected. A series of studies by Baumeister, DeWall, Ciarocco, and Twenge (2005) showed that people who had been rejected by a group or told that their future lives would be lonely performed worse on a variety of self-regulation tasks, including making themselves drink a bad-tasting beverage, restraining their consumption of snack foods, persisting on a frustrating task, and attention control (dichotic listening). Further studies indicated that rejected people were able to self-regulate if there was a compelling, self-interested reason, such as a cash incentive. Thus, apparently, rejection does not render people unable to self-regulate but merely unwilling.

The impact of rejection brings us back to the importance of self-regulation for social connection. Self-regulation enables people to get along with each other, but some of this occurs at a cost to the self, insofar as self-regulation functions to stifle selfish and self-interested impulses in order to do what is best for others (or for the relationship). Humans are social and cultural animals, and so in general the rewards of belongingness are sufficient to justify the sacrifices required for self-regulation. However, when people are socially excluded, they act as if they no longer find it worthwhile to regulate themselves. In that sense, self-regulation is part of an implicit bargain between the individual and society, such that the individual makes the effortful sacrifices in exchange for the benefits of belonging to the group. The bargain can break down on either side. Individuals who fail to self-regulate sufficiently are often rejected by others, such as in divorce, peer ostracism, and even imprisonment. Conversely, when society withholds belongingness (e.g., by rejecting the person), the individual responds with a significantly decreased willingness to self-regulate—except for explicitly selfish rewards.

Individual Differences

Undoubtedly some people are better at self-regulation than others. As noted earlier, a trait measure of self-control was recently published by Tangney and colleagues (2004). It appears to be an effective manner of differentiating people who are good self-regulators from those who are not, although undoubtedly some people may claim better self-control than they actually have. Tangney and colleagues went to great lengths to include many different spheres of self-control in their measure to be able to advance self-regulation theory by establishing a clear factor structure (which would be reflected in the subscales of their measure). However, the factor structure did not replicate well, and all the subscales essen-

tially performed as weaker measures of the full scale. The implication is that self-control is a fairly unidimensional construct, and people who are good at some aspects of self-regulation tend to be good at most of them. This too fits the view of self-regulation as depending on a single, common resource or strength.

Another question that individual difference measures can illuminate is whether there is such a thing as too much self-control. Popular wisdom and anecdotal evidence suggests that people with too much self-control might alienate friends (e.g., by lacking spontaneity) or perform less well in work (e.g., by obsessing about details and failing to make progress). Tangney and colleagues (2004) included a broad set of outcome measures including adjustment, school performance, mental health, and relationship quality, and they aggressively conducted statistical tests for nonlinearity in order to find any downturn in outcomes at the high end of self-control scores. None of these tests yielded any results supporting the notion that a person may have too much self-control ability. Thus, at least to the extent that self-report measures are valid, there is no sign that high levels of self-control produce bad outcomes. The better the self-control, the better the person's other outcomes.

The investigation of individual differences in self-control has also yielded an interesting twist. Self-control trait scores were significantly correlated (at around .5) with scores on a social desirability questionnaire (Crowne & Marlowe, 1960). Social desirability scales are often used as "lie scales" in research, on the assumption that they assess people's willingness to distort the truth to make themselves look good. By this reasoning, it might be assumed that self-control scores are tainted by deceptive self-presentations. On the other hand, we have proposed that self-regulation functions primarily to enable people to overcome selfish impulses so they can behave in ways that are better for interpersonal relations, which means that having self-control should actually and honestly make people perform more socially desirable acts. Tangney and colleagues (2004) found that the effects of self-regulation remained significant and nearly unchanged when they controlled for social desirability, whereas the effects of social desirability on the dependent measures dropped below significance when they controlled for self-control. Thus, it appears that self-control (rather than social desirability) is the more fundamental predictor of positive outcomes, and indeed self-control is probably responsible for many socially desirable acts.

Apart from individual differences in self-control, other individual differences may affect self-regulatory performance. Any given challenge may require self-regulation for one person but not another. Consider alcohol consumption. Restraining alcohol intake probably requires only very little self-control for a person who does not normally drink or who does not particularly care for alcohol. However, some people drink alcohol regularly and may even be addicted to it. Thus, only frequent drinkers should become depleted by restricting alcohol intake. Furthermore, ego depletion should only interfere with alcohol restraint among those who must actively self-regulate their drinking impulses. This view was sup-

ported in experiments reported by Muraven, Collins, and Nienhaus (2002). They found that people who reported a high level of preoccupation with alcohol drank more beer after a depleting thought-control task than similarly preoccupied people who had not done the thought-control task. Beer consumption among people only modestly interested in alcohol was not substantially affected by prior ego depletion.

People may also differ with regard to their social orientation, such that some people are more sensitive to society's demands (i.e., are "other-oriented") than others. As we suggested earlier, self-control abilities probably developed in order to facilitate social interaction and the development of culture. Therefore, people who are preoccupied with smooth social interaction and who prioritize the needs of the group over the needs of the individual should be well practiced at self-control. In support of this view, Seeley and Gardner (2003) found that people high in other orientation were more resistant to ego depletion than people low in other orientation, consistent with the view that other orientation is linked with frequent self-control and therefore greater self-control strength.

Framing a given task in a manner that is concordant or discordant with one's preferred regulatory style is also likely to affect how depleting the task will be. Work by Grant and Park (2003) and Johnson and Shah (2004) indicated that situational demands interact with people's chronic regulatory focus (Higgins, 1997) to affect depletion levels.

In Grant and Park's (2003) studies, students from America and Korea completed two consecutive tasks in which each task was framed as either a promotion task or a prevention task. The researchers took advantage of the finding that Americans are typically promotion focused and Asians are typically prevention focused and hypothesized that it would be less depleting to perform consecutive tasks with a shared regulatory focus (i.e., either two promotion tasks or two prevention tasks), especially when the tasks matched the chronic style of the performer. Their findings were generally supportive of this expectation, such that American students persisted longest on an anagram task (a measure of self-control capacity) when the task and a typing task that preceded it were framed as promotion tasks. Thus, for American students who are mainly promotion focused, two promotion tasks in a row were less depleting than two prevention tasks or either set of mixed-focus tasks. Korean students, conversely, showed the most depletion in the promotion–promotion condition. For Korean students, performing a task that contained at least one prevention-focused aspect buffered against depletion.

Johnson and Shah (2004) took a more evolutionary approach to the study of regulatory focus and self-regulatory strength. They surmised that accomplishing promotion-related tasks would be dependent on the availability of self-regulatory strength, whereas accomplishment of promotion-related tasks would be independent of regulatory strength. In one study they found evidence for this pattern in showing that participants who were depleted by having to use a rule that became more complex between a practice task and the test task were

more likely to solve difficult anagrams under a prevention frame than a promotion frame. In a second study, Johnson and Shah tested for positive emotional states that would suggest a fit between regulatory focus and the situation (e.g., Higgins, Idson, Freitas, Spiegel, & Molden, 2003) and found that depleted participants felt less dejected and more satisfied if they had performed a task under prevention, compared to promotion, instructions, suggesting that prevention was a better fit under depletion than promotion.

These two sets of studies give a hint of what is to come for self-regulatory strength research: the integration of different theories of self-regulation to see where and how they converge. Research by Grant and Park (2003) and Johnson and Shah (2003) illustrates the important role that chronic regulatory focus plays in determining how taxing a given self-control task will be.

The specificity of ego depletion effects among individuals preoccupied with alcohol and people with different social and regulatory orientations highlights the role that chronic differences play in the fluctuation of self-regulatory strength. Surely other individual differences play a role in making some self-regulation particularly depleting for some people but hardly depleting for others. For example, some people are more emotionally expressive than others, and so suppressing emotional reactions should be more depleting for the highly expressive people. Continued study of individual differences and how those differences relate to self-regulatory strength promises to increase understanding of when, and why, some self-regulatory behaviors are particularly taxing.

Affect Regulation

The control of emotional states is a self-regulatory problem that probably touches the lives of every person. Only some people must regulate their alcohol intake or gambling behavior, whereas all people feel emotions and must occasionally strive to manage them. We mentioned earlier some findings suggesting that emotional states may be regulated outside conscious awareness, but much more work has considered the purposeful and active regulation of emotion.

The process model of emotion regulation (see Gross, 1998, 2001) distinguishes between emotion regulation that occurs before the onset of an emotional experience (antecedent-focused emotion regulation) and regulatory effort initiated during or after an emotional experience (response-focused regulation). The best understood antecedent-focused strategy is reappraisal, which entails anticipating an emotional event and resolving not to react to the event by reinterpreting its meaning. For example, a person might remind oneself prior to viewing a scary movie that the events to be depicted are fictional, and that the people in the movie are not actually being tormented by a knife-wielding psychopath. Contrast this reappraisal strategy to the one that requires the active stifling of fear and disgust while watching the movie. By the time the fear hits, one may be too involved in the movie to think rationally about its fictional nature.

Richards and Gross (1999, 2000) studied the cognitive consequences of these two forms of emotion regulation. They found that when people suppressed their emotional reactions while watching a gory slide show, they later had poorer memory for the information presented with the slides than participants who had reappraised what they were seeing. Apparently, stifling emotional reactions interfered with the cognitive processing of the nonemotional information. Reappraisers, by contrast, successfully limited their emotional responses and also showed good memory for the presented information.

The pattern of findings reported by Richards and Gross (1999) suggests that response-focused emotion regulation taxes self-regulatory strength, whereas antecedent-focused regulation may not. Research by Vohs and Schmeichel (2003) confirmed this view. They had research participants suppress, exaggerate, or reappraise their reactions while watching an emotional film clip. Only the response-focused regulators (i.e., the suppressors and the exaggerators) showed reduced self-regulatory strength, while the reappraisers showed no evidence of reduced strength. Thus, consistent with the work of Gross and colleagues, only response-focused emotion regulation reduced self-control strength.

Finally, some evidence suggests that low self-control strength impairs emotion regulation ability. In one study, one group of participants purposefully suppressed a forbidden thought while the other group was free to think whatever they wanted. Later, all participants watched a funny film clip and were instructed to limit their laughter. Those who had suppressed thoughts were relatively unable to prevent themselves from laughing subsequently (Muraven et al., 1998). Thus, ego depletion due to mental control disrupted later response-focused emotion regulation. Whether depletion influences emotion reappraisal or other antecedent-focused regulation strategies is still an open question.

Dieting and Addiction

In everyday life, people most often decide for themselves whether an object is "off limits" or should be denied. That is, individuals frequently create their own regulatory guides (Higgins, 1996). Individual differences in chronic inhibitions are examples of rules or guides individuals undertake to reach their goals. Chronic inhibitions have been studied in terms of their influence on self-regulation under tempting conditions. Externality theory (Schachter, 1968) proposed that obese individuals—who presumably are trying to inhibit food intake—are guided more by external cues than by their internal states. Research by Schachter and his colleagues demonstrated that one consequence of external responsiveness is diminished ability to resist temptation. For instance, Herman, Olmsted, and Polivy (1983) found that obese diners were more likely to order dessert after being given a luscious description of it, relative to when they were simply told that dessert was available. In addition, chronic dieters consumed significantly more snack foods in the presence of salient food cues relative to neutral cues, but this effect did not pertain among

nondieters (Collins, 1978). Thus, dieters appear especially vulnerable to food cues, perhaps because the presence of such cues is more tempting for them than it is for nondieters.

Studies of addictive and compulsive behaviors provide additional evidence for the idea that chronically resisting temptation can lead to deleterious effects, especially with respect to self-regulatory processes (Polivy, 1998). For instance, research on consumer buying habits demonstrates that when consumers resist the temptation to purchase a product, they experience a dramatic increase in desire for the product, which apparently is due to feelings of deprivation (Hoch & Loewenstein, 1991). This effect is exacerbated by the presence of environmental cues that encourage buying, such as free trial periods or free samples. Many people who are dependent on an addictive substance actively try to minimize use of that substance, and research has shown that addicts are especially vulnerable to cues relevant to their particular addiction. For example, smokers exposed to smoking-related cues have been found to exhibit shorter latencies to begin smoking, smoke more cigarettes, report stronger urges to smoke, and show changes in heart rate and blood pressure (Herman, 1974; Rickard-Figueroa & Zeichner, 1985). Likewise, alcoholics who have been exposed to salient alcohol cues report stronger urges to drink (for a review, see Niaura et al., 1988). These studies suggest that individuals set themselves up for failure when they engage in chronic inhibition.

Research on chronic dieting directly tested this suggestion within the framework of the self-regulatory strength model. Vohs and Heatherton (2000) exposed chronic dieters and nondieters to tempting foods that were said to be either available for eating or that were not allowed to be touched (as they were there, supposedly, for a future experiment). The researchers reasoned that dieters but not nondieters would have to actively exert control over their desire to eat the available candies by virtue of their ongoing restriction of off-limit foods. (Indeed, although several of the nondieters dipped in and ate the candies, only one of the dieters did so.) Later, dieters and nondieters were asked to sample three flavors of ice cream ostensibly for the purposes of completing a perceptual ratings task. Dieters who had been tempted by the freely available snack food ate considerably more ice cream than did their counterparts who were told "please, don't touch" the snacks. Nondieters' eating (tested only among those did not partake in the snacks earlier) was unaffected by these manipulations, presumably because they did not have to expend self-regulatory strength in order to not eat the snacks in the earlier phase. Two additional studies confirmed the globality of this effect in showing that a food temptation led dieters to give up sooner on a task involving persistence, and also that an emotional regulation task caused dieters to consume significantly more ice cream consequently.

More recently, work by dieting researchers showed that interpersonal demands in the form of conforming to the group can have significant effects on consumption among people who chronically inhibit their eating. Kahan, Polivy, and Herman (2003) used an Asch-type

conformity task in which dieters and nondieters responded to a visual task either while in a room alone or in a room with confederates who uniformly gave the wrong answers to certain target stimuli. Under the pressure of having to conform, the researchers reasoned, dieters would use up regulatory strength that would otherwise help them not to overconsume food, a prediction that was supported by the increased eating among dieters who were in the conformity condition. Nondieters' eating was unaffected by conformity pressures, not because conformity did not deplete their resources but, rather, because they normally do not put their resources toward curbing caloric intake.

Hence, work on chronic dieters shows how habitual goals interact with situational demands to affect regulated behavior. Whether through emotion control, resisting temptation, or a need to conform, even chronic self-regulation goals can be undermined when momentary pressures deplete precious self-regulatory strength.

CONCLUDING REMARKS

Social scientists have been fascinated by questions of self and identity for many years, but only the past two decades has there been widespread recognition that self-regulation is a centrally important process. Not only does it hold important keys to self theory, but it also has extensive pragmatic applications. Indeed, the majority of personal and social problems faced by modern Western citizens—addiction, violence and crime, debt, sexually transmitted diseases, underachievement, unwanted pregnancy, obesity, failure to exercise, gambling, failure to save money, and others—are rooted in failures of self-regulation.

Self-regulation is one of the key adaptations of the human psyche to enable it to live in cultural groups. It allows people to change their behavior to conform to the expectations of others and, as culture develops, to the abstract rules of the group such as morals and laws. It is an important root of free will in the sense that it enables people to override their first impulses and it furnishes people more complex and flexible ways of deciding and behaving.

This chapter has emphasized a strength model of self-regulation. Altering the self's responses consumes a limited resource that can be conserved, replenished, and even strengthened via exercise. This model is compatible with other contributions to self-regulation theory, such as Higgins's (1987, 1996) self-guide model and Carver and Scheier's (1981) feedback-loop model.

Decades ago, Freud (1930/1961) proposed that most animals could not easily live together in a cultural civilization, and he suggested that some of the psyche's energy had to be rechanneled into the superego in order to make the human being capable of such collective life. Although the march of progress in psychology has moved beyond many of Freud's ideas, in retrospect there does seem to have been something correct about the view that an energy-based capacity for self-regulation is vital for the success of human culture, at both the individual and the collective level. Further research on self-regulation promises to shed light on one of the key aspects to human nature.

Self-Interest and Beyond

Basic Principles of Social Interaction

PAUL A. M. VAN LANGE
DAVID DE CREMER
ERIC VAN DIJK
MARK VAN VUGT

What interpersonal orientations drive social interactions? Does selfishness underlie most of our behavior? Are we also inclined to benefit others? Are we naturally committed to sharing and pursuing equality? Do we tend to compete with others, even if we suffer from it by doing so? When and why do we aggress? Such questions are among the most fundamental to understanding interpersonal relations and group processes, which may explain why these topics have attracted the attention of so many scientists from so many fields and disciplines for so long. A complementary reason may be that the questions raised above touch on the long-standing scientific debate about "human nature": Are people by nature good or bad? Thomas Hobbes is often acknowledged as being one of the first to explicitly address this basic question. In *Leviathan* (1651/1996) he raised the interesting problem of why societies and collectivities are able to function at all, if—so he believed—humankind is basically self-interested. The puzzle, which later was termed "the Hobbesian paradox," is central to much theory developed in the social and behavioral sciences. It deals with relationships between the individual and the society at large, but also to smaller scale issues, such as the relationships between individuals in dyads or small groups, and to relationships between groups. How have the social and behavioral sciences sought to solve the Hobbesian paradox?

THE ASSUMPTION OF THE BENEFICENT INVISIBLE HAND

Over a century after Hobbes' writings, Adam Smith (1776) sought to solve the Hobbesian problem by his famous notion of the beneficent *invisible hand*, assuming that private and collective interests tend to correspond rather than conflict. Indeed, in his *Wealth of Nations*, Adam Smith assumed that, for the most part, groups and societies are well-functioning *because* individuals pursue their self-interest. The underlying assumption is that the pursuit of self-interest often has the unintended consequence of enhancing collective interest.

It is now widely acknowledged that Adam Smith's notion of the beneficent "invisible hand" is too limited—and perhaps too simple to be true. In fact, not long after his writings, many scientists came to subscribe to the Hobbesian paradox, assuming that self-interest is often, and in important ways, incompatible with collective interests. As such, the paradox gave rise to two interrelated questions. First, is human behavior primarily or exclusively guided by self-interest? And second, if the costs of selfishness outweigh its benefits, how then can we control selfishness? In the latter question, the costs often refer to collective costs (shared by all involved), whereas the benefits often refer to the gains for the individual.

It took a long time before these questions were studied empirically. In fact, it is only five to six decades ago that some influential books were written that systematically addressed such issues from a formal, mathematical perspective (Luce & Raiffa, 1957; Von Neumann & Morgenstern, 1944) and from a psychological perspective (Thibaut & Kelley, 1959). These books, and especially the empirical research that they inspired, have exerted an enormous influence on the science of interpersonal orientations. First, by systematically analyzing situations, scientists informed each other about the various situations that may (or may not) exist in everyday life. For example, some scientists were able to logically deduce around 96 situations from 2×2 matrices (which represented two persons each having two behavioral options). This work has led to an understanding that there are many kinds conflicts in everyday life—conflicts between self-interest and collective interest, conflicts between self-interest and equality, conflicts between equality and collective interest, and so on.

Second, by actively examining a wide variety of situations, in the laboratory or the field, it became increasingly clear that many situations represent a conflict between self-interest and collective interest. Such situations are omnipresent in our close relationships (e.g., whether to preemptively do the dishes), in relationships with colleagues (e.g., whether or not to prepare very well for a meeting, when it takes costly time to do so), and in our links with organizations or the society at large (e.g., whether or not to engage in citizenship or volunteering activities to help others). Clearly, a relationship is unlikely to be healthy or even to persist if people would not engage in costly acts that benefit the partner. A collaboration between colleagues is unlikely to be fruitful if either or both partners are often ill prepared for a meeting. And a society is unlikely to function well if most people, for example, pollute the environment, never intervene in emergency situations, or volunteer for the greater good of all.

In fact, conflicts between self-interest and collective interests are so pervasive in everyday life that one can go so far as to claim that the most challenging task that governments, groups and organizations, as well as friends and close partners, face is to successfully manage conflicts between self-interest and collective interest. This may explain why many various scientific disciplines have such a long-standing interest in themes that are directly relevant to understanding conflicts between self-interest and collective interest, or *social dilemmas* (e.g., Dawes, 1980; Komorita & Parks, 1995). Beyond the scope of empirical research on social dilemmas, there has been a strong interest in social psychology for cooperation and competition, prosocial behavior, altruism, aggression, trust, reciprocity, and many more. These topics are primarily studied from an interpersonal or small-group perspective, but it should be clear that they have also been studied from an intergroup perspective or from a large societal perspective. Thus, the broad scientific and societal relevance of social dilemmas is beyond dispute.

We are discussing conflicts between self-interest and collective interest in so much detail because it is precisely this domain of situation that is relevant to all the topics discussed previously. If the social world was not social (e.g., the world of Robinson Crusoe before Friday came), or if the world was much like Adam Smith initially imagined (i.e., almost no conflict of interest), many of the specific themes just described would be irrelevant. Cooperation and competition would not be called for, and one cannot communicate or develop trust if there are no conflicts between self-interest and collective interest. This would be a world in which "good and bad" do not seem to matter. But, of course, Robinson Crusoe started to face many opportunities and constraints after Friday's arrival. He and Friday could share food in an equal manner, overbenefit themselves a little every now and then, reciprocate favors over time, cooperate on building shared goods, or compete for scarce resources. Because they became interdependent in terms of fulfilling their basic needs, each of them developed orientations toward each other, which are essential to adapting to they various situations that they face. For example, they could develop orientations toward cooperation, equality, altruism, individualism, competition, or aggression.

In this chapter, interpersonal orientation is broadly defined as the set of cognitions, affect, and motivation that underlie interpersonal behavior and social interaction. We deliberately use a broad definition to reveal its relevance to many interpersonal topics, from affiliation to attachment, and from altruism to aggression. The conceptual basis for interpersonal orientation is derived from Kelley and Thibaut's (1978) interdependence theory assuming that people may *transform* interpersonal situations into new situations that guide their behavior and interactions. Also, we should note that in illustrating principles and mechanisms, we focus on research on social value orientation, which is formally defined as preferences for distributions of outcomes for self and other. The concept of social value orientation deals with prosocial, individualistic, and competitive orientations and often has been examined and conceptualized as an individual difference variable. In this chapter, we use the concept of interpersonal orientations to explicitly acknowledge the assumption that such orientations can be influenced by the person, the situation, or the interaction partner, as we discuss later.

SOCIAL INTERACTION IS A FUNCTION OF PERSONS A AND B AND THE SITUATION

The illustration about Robinsoe Crusoe already illustrates the power of the situation—after Friday's arrival, Robinson's life changed dramatically. Indeed, the essence of a social psychological "way of thinking" is often described in terms of the power of the situation. A classic case in point is, of course, the Lewinian equation $B = f(P, E)$, which assumes that that behavior (B) is shaped not only by properties of the person (P) but also by features of the situation, or social environment (E) (Lewin, 1935). The essence of a social psychological analysis can be even more fully expressed by construing our goals in terms of the relationships *between* two (or more) persons. To develop a truly *social* psychology, we may wish to expand

our formulation, noting that an interaction (I) between persons A and B can be conceptualized in terms of the persons' needs, thoughts, and motives in relation to one another (A and B) in the context of the specific social situation (S) in which their interaction transpires (Holmes, 2002; Kelley et al., 2003; Van Lange, Otten, De Bruin, & Joireman, 1997). Expressed in an equation, $I = f(S, A, B)$.

To illustrate the utility of an interaction-based analysis, imagine two scenarios for John and Mary, who are deciding where to spend their summer vacation. In one scenario their interests conflict in that John wants to go to a beach resort whereas Mary wants to go to Paris. In this type of situation, each person will seek to communicate the basis for his or her preference ("I need the excitement of Paris"), and each will engage in cognitive activity oriented toward understanding the other's needs ("Does John want to relax because he had a stressful year?"). The situation makes it possible for each person to display his or her goals and motives (e.g., selfish vs. prosocial). Communication and information seeking will center on each person's needs, goals, and motives in relation to those of the partner ("Whose needs are more pressing?"; "Will Mary be responsive to my needs?"). The two may rely on fairness norms to resolve their problem ("It's my turn"; "You deserve a break"). Thus, situations involving conflicting interests are interpersonally rich, affording psychological processes such as self-presentation and attributional activity, and activating morality- and benevolence-relevant motives and norms.

In a second scenario John's and Mary's interests correspond, in that both want to vacation in Paris. Neither person is likely to be particularly concerned with information seeking, self-presentation, or attribution in that there is no problem and "nothing to think about." It is not possible for either person to display benevolent motives in that the course of action that would benefit John simultaneously benefits Mary. Interaction is a coordination problem—the two must agree on a date for their vacation, and one person must arrange for travel and lodging. Thus, in comparison to situations with conflicting interests, situations with corresponding interests are relatively simple in that they are less likely to inspire activities such as information seeking or self-presentation and are unlikely to give rise to moral dilemmas or questions of benevolence.

These scenarios very simply illustrate an important point: To understand social interaction we must consider the person (*the Self*), the interaction partner (*the Partner*), and *the Situation*. Likewise, social interaction experiences can be shaped by any of these three components, independently or in combination. For example, a person may be likely to yield noncooperative, selfish interactions because of person influences (e.g., the person does not tend to trust others' cooperativeness), partner influences (e.g., the partner holds in fact a competitive orientation), or situation influences (e.g., the two people often are faced with zero-sum-like situations, with very little opportunity for fruitful exchange through cooperation).

Several theories tend to assume such influences, although often focusing on one of these influences. Models or theories that focus on self-fulfilling prophecies tend to focus more strongly on influences of the Self. For example, individuals with competitive orientations are likely to elicit noncooperative behavior from others, because they expect noncooperation from others, they behave noncooperatively toward others, through which they elicit noncooperative behavior from others—thereby supporting their initial belief that "everybody is selfish" (cf. Kelley & Stahelski, 1970). There are many models that suggest strong partner influences. For example, traditional formulations of attachment theory suggest that early social interaction experiences tend to underlie the development (or not) of secure attachment, and that "partner influences" are strong (Bowlby, 1969). In particular, when the primary caregiver (usually the mother) acts in a cold, unloving, and untrusting manner, the child is unlikely to develop secure attachment—which is more likely to be developed when the primary caregiver is highly responsive to the primary needs of the child, communicating trust and love. Finally, there are some classic theories or models that emphasize the important role of situation. Perhaps the most illustrative example is the Robber's Cave experiment, revealing that the presence of conflicting goals among groups of children undermined friendly behavior and turned it into hostility, distrust, and overt aggression between the two groups (Sherif, Harvey, White, Hood, & Sherif, 1961/ 1988).

Social interactions are important in their own right (i.e., as a topic of study), but we suggest that an interaction-based analysis has strong theoretical benefits. First, it is true, almost by definition, that interaction is a function of the situation and the persons involved. This analysis forces us to analyze situations in terms of what orientations they afford (what orientations they call for, or may activate). Interdependency theory has advanced a taxonomy of situations. The degree to which individuals' interests correspond versus conflict (i.e., covariation in interests), discussed and illustrated earlier, is only one of the six dimensions that contemporary formulations of interdependence theory incorporate (Kelley et al., 2003). The other dimensions capture (1) degree of dependence (how strongly are outcomes determined by the partner's actions or the partner's actions in combination with one's own actions); (2) mutuality of dependence; (3) basis of dependence (whether dependence derives solely from the partner's behavior [partner control], or from partner's behavior in combination with one's own behavior [behavior control]); (4) information availability (e.g., the degree to which we have information about the partner's preferences); and (5) extended situations (e.g., the degree to which interaction situation extend over time and/or the degree to which diverse behavioral options are available). It is beyond the scope of this chapter to fully discuss and illustrate these dimensions (for a detailed overview, see Kelley et al., 2003; Rusbult & Van Lange, 2003). We do wish to note, however, that the dimension of corresponding versus conflicting interest is among the most essential to understanding interpersonal orientations.

Second, the concept of interaction is essential to observation. We never directly see people's motivations or in-

tentions displayed, but we do see two (or more) people reacting to each other, thereby usually producing good or not so good outcomes for each other. Thus we can speak of cooperative interactions (when two people behave cooperatively toward each others), noncooperative interactions (when two people ignore one another's interests), or aggressive interactions (when to people seek to produce bad outcomes for each other). Because observation is essential to social learning and modeling, it is likely that the observation of social interaction, along with the (causal) analysis of it, is an important determinant of our beliefs regarding the orientations that other people may have as well as our beliefs regarding the norms for appropriate conduct. For example, when watching a fighting couple, people may strengthen their belief that most people are not to be trusted and perhaps come to believe that even small forms of verbal abuse are violating norms of decency and respect.

Third, perhaps even more essential than observation, the most direct experiences we have with our social environment are derived from own social interactions. Given that social interactions can be chronically influenced by some situational factors (e.g., the degree to which we needed to share important resources with our siblings), or by an essential interaction partner (e.g., "the primary caregiver"), people may acquire different social interaction experiences. These social interaction experiences are likely to shape the relatively stable interpersonal orientations that people may rely on and use with particular partners (e.g., a prosocial orientation toward one's caring father) or across multiple interaction partners (e.g., a prosocial orientation across most [nonclose] interaction partners). Of course, any interpersonal orientation is subject to continuity *and* change.

Fourth, and finally, psychological processes such as cognition and affect are often both determinants of social interaction and consequences of social interaction. Cognition, motivation, and affect in many ways guide our behavior, reactions, and ultimately interactions. Indeed, much of our thinking and affect is oriented toward making sense of interaction situations and the partner(s) that is so essential to interaction. Automatic or more controlled forms of impression formation are obvious examples—and it is certainly true that much of our thinking and feeling are "for doing" (Fiske, 1992; cf. Jones & Thibaut, 1958). At the same time, during and after social interactions, people are likely to evaluate and summarize their interaction outcomes—for example, cognitions may help us understand the partner's actions, motivation may provide the frame for interpretation while emotions may signal satisfaction or dissatisfaction with the outcomes (along with potential emotions such as anger, disappointment, happiness, etc.). The important point is that, in many ways the concept of social interaction is key to understanding the functions of cognition, motivation, and affect.

To conclude, an analysis that focuses on social interaction has the theoretical benefits of understanding "the Situation," understanding social learning through observation, understanding social development (continuity and change) of interpersonal orientations, as well as cog-

nition, motivation, and affect as determinants and consequences of social interaction.

BASIC PRINCIPLES OF INTERPERSONAL ORIENTATIONS

Which interpersonal orientations help us understand interpersonal behavior and social interaction phenomena? What types of interpersonal orientations, other than selfishness or individualism, should be meaningfully distinguished? Briefly, we suggest the importance of three prosocial orientations (cooperation, equality, and altruism), two proself orientations (individualism and competition), and one antisocial orientation (aggression). The theoretical basis for these orientations is largely derived from interdependence theory (Kelley & Thibaut, 1978) and early research and theory of social value orientation (MacCrimmon & Messick, 1976; McClintock, 1972; Messick & McClintock, 1968). It is interesting to note that this early research and theory by Messick, McClintock, and their colleagues has inspired the transition of a model of social exchange, which largely departed from the assumption of rational self-interest (Thibaut & Kelley, 1959), to the theory of interdependence, which assumes that individuals may "transform" a given situation according to broader orientations, such as cooperation, equality, or competition (Kelley & Thibaut, 1978).

Interdependence theory describes these four non-individualistic orientations in terms of outcome transformations, delineating enhancement of joint outcomes (MaxJoint), minimizing differences between own and other's outcomes (MinDiff), enhancing outcomes for other (MaxOther), enhancing relative advantage over others (MaxRel), and reducing other's outcomes (MinOther). Specifically, the theory argues that given settings of interdependence (i.e., the given matrix) may be transformed according to these orientations to yield a reconceptualized scheme (i.e., the effective matrix), which is more strongly predictive of behavior and social interaction. The given matrix is typically a function of basic, but nonsocial, preferences, such as whether a person prefers to watch movie X or movie Y. When two partners differ in their preferences but want to go to the theater together, they may take into account broader preferences. Such broader preferences are inherently social, because the individual takes into account the partner's preferences, which then yields a reconceptualization of the given matrix. That is, through transforming the given matrix by orientations such as cooperation, equality, altruism, or competition, the individual constructs an effective matrix, which may account for how the individual seeks to solve this interdependence problem (e.g., whether to give in, whether to persist in his or her initial preferences) as well as how the two partners eventually reach a solution (which movie they attend).

The broader considerations, or transformations, may be the product of systematic information processing, shallow or heuristic processing, or even virtually no processing at all (automaticity; Bargh, 1996). In fact, because

TABLE 23.1. An Overview of Basic Propositions of Interpersonal Orientations

Proposition 1
   Most people pursue good outcomes for self, either in the short term, the long term, or both (individualism), but this is often not the sole orientation that people adopt to interaction situations.

Proposition 2
   Interpersonal orientations reflect not only individualism (enhancement of own outcomes) but also cooperation (enhancement of joint outcomes), equality (enhancement of equality in outcomes), altruism (enhancement of other's outcomes), competition (enhancement of relative advantage over others), and aggression (minimization of other's outcomes).

Proposition 3
   The prosocial orientations of cooperation and equality frequently operate in a concerted or interactive manner. That is, these orientations tend to go hand in hand, and it is the interplay of both "prosocial" orientations that best accounts for behavior and interaction in settings of interdependence.

Proposition 4
   Interpersonal orientations are partially shaped by social interactions—therefore, shaped by the self, the interaction partner, and/or the situation.

Proposition 5
   Interpersonal orientations represent different probabilities with which one or more decision rules (e.g., outcome transformations such as MaxJoint, MinDiff) are activated and used.

we encounter several types of interdependence situations quite regularly, often with the same or similar partners, it is plausible that such transformations frequently take place in a habituated, automatic manner. For example, parents may fairly automatically respond to the basic needs and preferences of their children, friends may fairly automatically help each other without a lot of thought, and the desire "to compete" with others may sometimes come into being without any deliberation.

We advance five basic propositions relevant to interpersonal orientations. The term "proposition" is a deliberate choice, as we believe that alternative concepts are either too broad and too remote from the empirical world (e.g., assumptions) or too specific and too closely linked to direct empirical tests (e.g., hypotheses). The empirical literature relevant to these propositions focuses on basic work in social psychology and related fields. Table 23.1 presents an overview of the propositions advanced in this chapter.[1]

INTERPERSONAL ORIENTATIONS AS DECISION RULES

Proposition 1 states that "most people pursue good outcomes for self, either in the short term, the long term, or both, but this is often not the sole orientation that people adopt to interaction situations."

As noted earlier, Thomas Hobbes, and many of his contemporaries, assumed that humankind is basically self-interested, suggesting that humankind involves little (if any) motivation to enhance the well-being of others, to enhance the well-being of the collective, or to enhance equality in outcomes. While many philosophers since Hobbes (and before) held similar views (though less explicitly so), it is perhaps more surprising that this view continued to be influential for a long time. More recently, the notion of self-interest, later extended and termed the "assumption of *rational self-interest*," has dominated much of the traditional theories relevant to interpersonal and intergroup behavior, including early formulations of game theory (Luce & Raiffa, 1957; Von Neuman & Morgenstern, 1944) and of social exchange theory (Blau, 1964; Homans, 1961; Thibaut & Kelley, 1959). This seems especially true for economic theory. As Gordon Tullock (1976), an influential economist and theorist on public goods, once said: "the average human being is about 95 percent selfish in the narrow sense of the term" (cited in Mansbridge, 1990, p. 12).

But within psychology too, the assumption of rational self-interest is embedded in several key constructs, such as reinforcement, the pursuit of pleasure, and utility maximization, as developed in the context of behavioristic theory (including social learning theory), psychoanalytic theory, and theories of social decision making. Moreover, many of the "self-enhancement" phenomena documented in social psychology tend to assume that people seek out material or esteem-related outcomes for the self, often neglecting the power of considerations aimed at benefiting others. Although there is little doubt that people seek to construct realities in ways that serve to maintain or enhance a positive self-imagine (i.e., self-enhancement), it is also likely that similar tendencies are at work in describing close partners, friends, and members considered to belong to the own group (e.g., Murray & Holmes, 1993).

In the current article we do not wish to discard self-interest as a powerful motivation. We do, however, maintain that self-interest tells only part of the story, not all of it. Also, we suggest that Tullock's 95% should be regarded as an overestimation. But why are we so confident that self-interest tells only part of the story? First, several researchers have addressed the fundamental issue of whether people may be willing to make a cooperative choice, in the absence of several (although not all) self-serving goals such as reputational, self-presentational, or reciprocal concerns. Specifically, researchers have designed prisoner's dilemma situations in which participants are strangers who made a single and anonymous choice for relatively large amounts of money and interaction among participants was prevented before and after the experiment. These studies have revealed that under such conditions, a substantial number of people make a cooperative choice (for a review, see Caporeal, Dawes, Orbell, & Van de Kragt, 1989).

Second, in a different program of research, it has been demonstrated that feelings of empathy provide a power-

ful motivation to make a cooperative choice in single-trial prisoner's dilemmas, even if the other had just made a noncooperative choice (Batson & Ahmad, 2001). That is, people who are informed about the misfortune of another person (e.g., partner has ended a relationship) and instructed to put themselves in their position (empathy instruction) tend to act in ways that cannot be understood in terms of self-interest (for an overview of earlier evidence, see Batson, 1998).

Third, the long-standing research on justice and fairness reveals that (at least some) people are often inclined to favor fair outcomes over self-enriching outcomes that represent unequality. A more recent phenomenon is the notion of altruistic punishment, the well-supported tendency for people to punish others (at a cost to themselves) who fail to cooperate and thereby undermine the "cooperative atmosphere" in a small group (Fehr & Gächter, 2002). This phenomenon too clearly shows that people are strongly motivated to pursue equality and to "do justice" to those who tend to exploit others.

Fourth, what is impressive about the lines of research just described is that considerations other than selfishness can be observed with relative strangers, with whom they interact in a fairly abstract social dilemma task, often under completely anonymous conditions. Clearly, in the context of ongoing relationships, people should be quite prepared to engage in self-sacrificial acts, to "nurture," or to accommodate in an attempt to promote the well-being of family members, close partners, and friends (see Rusbult & Van Lange, 2003). Although such tendencies are not easy to isolate from long-term selfish interest in ongoing relationships (because there is a history and future to the relationship), research on communal relationships suggests that prosocial behavior often may occur in the absence of "recordkeeping" or reciprocity in favors. That is, people tend to respond to variation in the other's needs, and less so (or not at all) to whether the partner has engaged in similar acts in the past (Clark & Mills, 1993). And the fact that people harbor exceedingly favorable views of close others is certainly consistent with the notion that the partner's ego is quite important to themselves as well (Murray & Holmes, 1993).

Last but not least, the long-standing program of research on social value orientation, to be discussed later, is strongly at odds with the view of self-interest. In fact, this program of research was initiated in part because early research on the prisoner's dilemma and the like revealed pronounced intraindividual consistency in tendencies toward cooperation or selfishness.

Thus, various lines of research provide support for the notion that selfishness is not the only orientation that people adopt in interaction situations with others—close others, or even complete strangers. In this respect, we agree with recent insights that suggest that the importance of self-interest may be overstated. Miller and Ratner (1998; see also Ratner & Miller, 2001), for example, demonstrated that participants overestimate the impact of financial rewards on their peers' willingness to donate blood, as well as the power of social rewards (as assessed by group membership) on their peers' attitudes. Also, research has revealed that people tend to assume that most others adopt an individualistic orientation to a prisoner's dilemma, believing that most others are simply seeking to enhance their own outcomes with no or very little regard for other's outcomes (Iedema & Poppe, 1994; Maki & McClintock, 1983).

There may be several mechanisms that support the "myth of self-interest." For example, people are more likely to reciprocate noncooperation than to reciprocate cooperation. The implication is that a belief in the selfishness of others is more easily confirmed than a belief in the cooperative nature of others (Kelley & Stahelski, 1970). There are several specific mechanisms as well that support selfishness rather than cooperativeness. One example is the strong tendency for people to assign greater weight and attention to negative behaviors than to positive behaviors (e.g., Fiske, 1980; Skowronski & Carlston, 1989). Another mechanism derives from the availability of information. Often in the context of groups, what we can observe (noncooperative interaction) may actually be due to a few or even only one person, in that the cooperative intentions are (often) not visible. In other words, observable noncooperative behavior in groups may be due to noncooperative intentions of only a few group members. Finally, at the societal level, the myth of self-interest tends to be supported in the media, which tends to focus more on the bad parts of human nature than the good parts.

To conclude, we suggest that self-interest is a powerful motivation, but one that is often overestimated in strength. Such overestimation often is accompanied by a neglect of other important interpersonal orientations, to which we direction our attention next.

Proposition 2 states that "interpersonal orientations reflect not only individualism (enhancement of own outcomes) but also cooperation (enhancement of joint outcomes), equality (enhancement of equality in outcomes), altruism (enhancement of other's outcomes), competition (enhancement of relative advantage over others), and aggression (minimization of other's outcomes)."

Cooperation

There is a fair amount of research showing that the enhancement of joint outcomes, or cooperation, is an important consideration. People have a pronounced tendency to consider not only outcomes for themselves but also outcomes for others. The enhancement of joint outcomes may sometimes take the form of self-interest and assigning positive weight to other's outcomes (or doing no harm to others). But perhaps just as often, or more often, the enhancement of joint outcomes takes the form of enhancing outcomes for the group as a whole (a tendency sometimes referred to as collectivism, see Batson, 1994). In terms of decision rules, in both cases, individuals tend to enhance joint outcomes (even though they may assign greater weight to outcomes for self than to outcomes for other).

Psychologically, the two types of cooperation are substantially different. The tendency to assign some positive weight to other's outcomes may be accompanied by a va-

riety of mechanisms, such as want to act in line with the "no harm" principle (Batson, 1994), adopting a norm of social responsibility, which dictates helping. The tendency to enhance group outcomes may readily be activated (e.g., at the very beginning of group formation), and it is powerfully activated by identification with the group (e.g., Brewer & Kramer, 1986; Kramer & Brewer, 1984). To the extent that a person feels more strongly part of the group and valued by the group, or the extent to which a person derives self-definition and esteem from the group, individuals are more likely to behave cooperatively. A classic case in point is research by Brewer and Kramer (1986), in which participants were categorized as psychology students (i.e., the actual participants, hence strong group identity) or economics students (i.e., weak group identity). Using a specific resource dilemma, Brewer and Kramer showed that under conditions of strong identity, individuals were more likely to behave cooperatively when it was essential to the group (i.e., when the resources were near depletion). Such cooperative efforts were not observed when group identity was low. It has been suggested that under conditions of strong identity, there may be a blurring of the distinction between personal outcomes and collective outcomes— that is, me and mine becomes we and ours, just as we and ours becomes me and mine (e.g., De Cremer & Van Vugt, 1999).

Egalitarianism

The existence of egalitarianism or equality may be derived from various lines of research. To begin with, several experiments have been conducted within the realm of resource-sharing tasks to examine the factors that may determine different "rules of fairness." In these tasks, a group of people shares a resource and the problem that these decision makers are confronted with is how to optimally using the resource without overusing it. Research by Allison and Messick (1990) provided a powerful demonstration of what happens in such situations. That is, their results showed that when participants (in a group of six people) are asked to harvest first from the common resource, people almost without exception use the equal division rule. Individuals tend to favor equality in outcomes (rather than more complicated rules of fairness; for related evidence, see Van Dijk & Wilke, 2000). Allison and Messick (1990) suggested that equality represents a decision heuristic that has the advantages of being simple, efficient, and fair. Equality has great potential to promote the quality and effectiveness of interpersonal relationships, and therefore it can be considered a "decision rule" that is deeply rooted in people's orientations toward others (see also Deutsch, 1975, Grzelak, 1982; Knight & Dubro, 1984).

Another powerful illustration of equality in interdependence situations is when people have to negotiate allocations (e.g., how to allocate monetary outcomes). This problem is often addressed in research on ultimatum games, an exceedingly popular paradigm in experimental economics (see Güth, Schmittberger, & Schwarze,

1982). In this negotiation setting, two players have to decide on how to distribute a certain amount of money. One of the players, the allocator, offers a proportion of the money to the other player, the recipient. If the recipient accepts, the money will be distributed in agreement with the allocator's offer. If the recipient rejects the offer, both players get nothing. Some of the first studies using this research paradigm demonstrated that allocators generally proposed an equal distribution (i.e., a 50–50 split) of the money (for an overview, see Camerer & Thaler, 1995). Subsequent studies, however, wondered whether this was true fairness and that allocators may have acted out of fear that recipients would reject their offer. Recent evidence suggests that at least some people do persist in employing the equality rule in ultimatum games, even when recipients can be cheated on or when recipients hardly have any power over the decision to reject the offer or not (see Van Dijk, De Cremer, & Handgraaf, 2004). Again, equality seems to be an orientation that people carry with them when engaging in social interactions.

Although equality is in the eye of many the prime example of fairness, we already noted that fairness might also take different forms, independent of outcomes. More precisely, allocating outcomes is always accompanied by procedures guiding allocation decisions (Thibaut & Walker, 1975). People also wonder about how fair these procedures are and these perceptions in turn also have strong effects on people's behaviors and experiences in social relationships (De Cremer & Tyler, 2005). The focus on procedural fairness was further inspired by research showing that when people are asked to talk about their personal experiences of injustice they usually talk primarily about procedural issues, in particular about being treated with a lack of dignity and politeness when dealing with others (e.g., Messick, Bloom, Boldizar, & Samuelson, 1985; Mikula, Petri, & Tanzer, 1990).

Moreover, there is research revealing that the opportunity for "voice" (e.g., being asked your opinion) may convey strong surplus value in that people feel more strongly valued and respected. Voice also means that people are given an opportunity to express their values (i.e., "value-expressive" worth). For example, some research shows that people still rated a procedure to be fairer if they had voice than if they lacked voice, even if they estimated that what they said had little or no influence on the decisions made and on the outcomes that one would receive (Tyler, Rasinski, & Spodick, 1985).

An important field study by Tyler and Degoey (1995) examined people's perceptions of the fairness of the legal authorities in California and their sense of identification with their state. At the time of their study, California was plagued by a severe drought and people had to try to maintain water resources—a situation that resembles a social dilemma. Results revealed that perceptions of procedural fairness (i.e., how accurate, ethical, neutral, consistent, and participative they perceived the procedures enacted by the authority) significantly influenced people's willingness to save and maintain water resources. Especially when they exhibited a strong sense of identification with the community. High identifiers particularly

cared about the fairness of the procedures because this indicated to them that they were valued society members and thus should be treated with respect (Tyler & Lind, 1992). More recently, De Cremer and Van Vugt (2002) experimentally demonstrated the powerful effects of procedural fairness on cooperation behavior in a public good dilemma by showing that a procedurally fair leader (i.e., a leader allowing voice to group members in the decision on how to allocate the public good) promoted prosocial behavior, but particularly among those who identified strongly with the group toward the group (i.e., high group identifiers). These results thus indicate that procedural fairness, independent of outcomes, guides people's actions in social relationships, and especially when the focus is on the common group. More recent research supports the notion that procedural fairness (examining by the availability of voice or not) often is used as a cue or heuristic as to whether "the authority" is to be trusted. In fact, Lind (2001) notes that "people use overall impressions of fair treatment as a surrogate for interpersonal trust" (p. 65) (for empirical evidence, see Van den Bos, Wilke, & Lind, 1998).

To conclude, egalitarianism has received attention in distinct literatures, often supporting the notion that equality in outcomes and treatment is deeply rooted in our system and often serves as the norm as well as a heuristic for own actions and expectations regarding other's actions.

Altruism

The claim that altruism should be considered an interpersonal orientation is rather controversial. Indeed, as most readers know, there has been a fair amount of debate about the existence of altruism both within and beyond psychology. Much of the controversy, however, deals with definitions of altruism, ranging from behavioral definitions (i.e., acts of costly helping are considered altruistic) to definitions that seek to exclude any possible mechanism that may be activated in some way by self-interest. If we limit our discussion, for parsimony's sake, to research on cooperation and competition, and to allocation measures, then we see that altruism is not very prominent. For example, in assessments of interpersonal orientations in a specific resource allocation task, the percentage of people who should be classified as altruistic (i.e., assigning no weight to their own outcomes while assigning substantial weight to other's outcomes) is close to zero (Liebrand & Van Run, 1985). Similarly, when people playing a single-choice prisoner observe that the other makes a noncooperative choice, the percentage of cooperation drops to 5% or less (Van Lange, 1999).

But this evidence should not be interpreted as if altruism does not exist. In fact, what is more likely is that it does not exist under the (interpersonal) circumstances that are common in this tradition of research. People usually face a decision-making task, be it a social dilemma task, a resource allocation task, or a negotiation task, in which they are interdependent with a "relative stranger" in that there is no history of social interaction or other

form of relationship. Accordingly, there is no basis for feelings of interpersonal attachment, sympathy, or relational commitment. We suggest that when such feelings are activated, altruism may very well exist.

As alluded to earlier, recent research by Batson and Ahmad (2001) provides convincing evidence. Specifically, they had participants play a single-trial prisoner's dilemma in which the other made the first choice. Before the social dilemma task, the other shared some personal information that her partner had ended the relationship with her, and that she finds a it hard to think about anything else. Batson and Ahmad compared three conditions, one of which was a high-empathy condition in which participants were asked to imagine and adopt the other person's perspective. The other conditions were either a low-empathy condition, in which participants were instructed to take an objective perspective on the information shared by the other, or a condition in which no personal information was shared.

After these instructions, participants were informed that the other made a noncooperative choice. Batson and Ahmad found that nearly half of the participants (45%) in the high-empathy condition made a cooperative choice, while the percentages in the other low-empathy and control conditions were very low, as shown in earlier research (less than 5%, as in Van Lange, 1999). Hence, this study provides a powerful demonstration of the power of empathy in activating choices that can be understood in terms of altruism, in that high-empathy participants presumably assigned substantial weight to the outcomes for the other at the expense of their own outcomes.

Also, the existence of altruism was also supported by earlier research that was designed to test the hypothesis that feelings of empathy could promote choices that benefit one particular individual in a group rather than cooperation that benefits the entire group (Batson et al., 1995). Specifically, participants could choose to benefit themselves, the group, or other group members as individuals, which extends the dichotomy of self versus collective-as-a-group that is so common in social dilemma research. Using experimental manipulations of empathy (study 1) and naturally occurring variation in empathy (study 2), Batson et al. found that feelings of empathy created or enhanced the desire to benefit one particular other person in the group (i.e., the one for whom strong empathy was felt), thereby reducing tendencies toward benefiting the collective. This study indicates that just as tendencies toward individualism may form a threat to collective well-being, so may tendencies toward benefiting specific others, or altruism, form a threat to collective well-being. That is, feelings of empathy may lead one to provide tremendous support to one particular person, thereby neglecting the well-being of the collective. For example, as noted by Batson and colleagues (1995), an executive may retain an ineffective employee for whom he or she feels compassion to the detriment of the organization. We suggest that such tendencies toward altruism are likely to be observed when individuals deal with others with whom they have developed attachment, closeness, or sympathy.

Competition

There is also strong evidence in support of competition as an orientation quite distinct from self-interest. As noted earlier, the work by Messick and McClintock (1968) has inspired considerable research that reveals that not only cooperative orientations but also competitive orientations may underlie social interactions. For example, Kuhlman and Marshello (1975) have demonstrated that individuals with cooperative orientations do not tend to exploit others who exhibit cooperation at every interaction situation, irrespective of the individual's own behavior. They also showed that individuals with competitive orientations do not exhibit cooperation, even if cooperative behavior, rather than noncooperative behavior, best serves their own personal outcomes. For example, when interacting with a partner who pursues Tit-for-Tat (Axelrod, 1984), which begins with a cooperative choice and subsequently makes the same the choice as the other did in the previous interaction situation, it make sense to cooperate if one is selfishly oriented. The reason is that cooperative choices yield mutual cooperation (good outcomes), whereas noncooperative choices yield mutual noncooperation (less good outcomes). Interestingly, unlike individualists who do respond cooperatively, competitors do not tend to behave cooperatively in response to a Tit-for-Tat strategy. The plausible reason is that competitors do not seek to enhance their own outcomes in an absolute sense—they seek to maximize the gain (or minimize the losses) *relative* to the other person.

The importance of competition is even more directly shown in research on a decision-making task that represents a conflict between on the one hand cooperation and individualism (option A) and on the other hand competition (option B). Hence, the only consideration to choose option B is to receive better outcomes (or less worse outcomes) than the other, even though one could do better for oneself by choosing option A. Research using this so-called maximizing difference game has revealed that quite a few people choose the competitive alternative; it is also of some interest to note that among some (young) age groups competitive tendencies tend to be even more pronounced (McClintock & Moskowitz, 1976). Specifically, among very young children (3 years old) individualistic orientation dominates, after which competition becomes more pronounced (4–5 years), which is then followed by cooperative orientation (6–7 years).

Finally, one might wonder whether it is the aversion of "getting behind" or the temptation of "getting ahead" that underlies such competition. In a very nice study by Messick and Thorngate (1967), it was shown that the former tendency (aversive competition) is much more pronounced than the latter tendency (appetitive competition)—in other words, not losing seems a strong motivation than winning. This early research was later extended, and generalized, by Kahneman and Tversky's (1979) gain and loss frames in their prospect theory, and by Higgins's (1998) distinction between prevention and promotion focus as two distinct self-regulatory systems. Recent research has also revealed that under condi-

tions of uncertainty, competition may be especially pronounced, presumably because people really want to make sure that they do not get less than the other (Poppe & Valkenberg, 2003). Thus, there is little doubt that competition is an important orientation that needs to be carefully distinguished from self-interest.

Aggression

The orientation of aggression has received very little attention in research on social dilemmas. It is interesting to note that, especially in comparison to the orientation of altruism, much research on aggression focuses on genetic and biological factors. Examples are not only twin studies but also studies focusing on associations of aggression with hormonal activity, such as variations in levels of testosterone. Generally, this body of research supports the view that aggressiveness, examined by self-report methodology, is substantially "influenced" by genetic factors and biological makeup. For example, research shows that manipulations of levels of testosterone, varied as part of a treatment for sexual transformations, influence the proclivity to anger. There is an increase in the tendencies toward anger among individuals who transform from woman to man, and a decrease in such tendencies among individuals who transform from man to woman (Van Goozen, Frijda, & Van de Poll, 1995).

Importantly, the correlation between aggressiveness and testosterone is especially pronounced for scale items assessing aggressiveness-in-response-to-provocation (Olweus, 1979), suggesting that aggression needs to be considered in terms of anger that is interpersonally activated. Indeed, the methods typically used to study aggression consist of examining aggressiveness in response to provocation by another person. Hence, anger and aggressiveness should be easily aroused by others who fail to exhibit cooperative behavior. Indeed, the fact that there is not much systematic research on aggression in social dilemmas is not to imply that aggression is not an important orientation or motivation in the context of social dilemmas. We suspect that many or most of the readers who have conducted social dilemma experiments will immediately recognize not only the involvement but also the hostility described by Dawes, McTavish, and Shaklee (1977):

> One of the most significant aspects of this study, however, did not show up in the data analysis. It is the extreme seriousness with which subjects take the problems. Comments such as, "If you defect on the rest of us, you're going to live with it the rest of your life," were not at all uncommon. Nor was it unusual for people to wish to leave the experimental building by the back door, to claim that they did not wish to see the "son of bitches" who double-crossed them, to become extremely angry at other subjects, or to become tearful. (p. 7)

Because it is unlikely that aggression is a self-activated phenomenon in social dilemmas, people are unlikely to approach one another aggressively, with the primary goal in mind to reduce the outcomes for other(s). As noted earlier, aggression may be activated when others

fail to cooperate. This interpersonal basis of aggression is important, and suggests several interesting phenomena. For example, it may well be that tendencies toward aggression are most pronounced among those who do not expect others to behave selfishly. As a point in case, Kelley and Stahelski (1970) provide some evidence for what they referred to as *overassimilation*, the tendency for cooperative individuals (at least, some cooperative individuals) to behave eventually even more noncooperatively than the fairly noncooperative partner with whom one interacts (see also Liebrand, Jansen, Rijken, & Suhre, 1986).

But why might people respond so aggressively to noncooperative behavior by others? Is it only because the other's noncooperative behavior provides one with much less good outcomes than the other's cooperative behavior? We think not. In fact, it may well be strongly linked to a violation in equality of outcomes that often is created (and often perceived as intentionally created) by the other's noncooperative behavior. But then the question becomes, "Why would people respond so aggressively to a violation of equality in outcomes?" Speculatively, three reasons seem especially noteworthy.

First, a violation of equality is generally easily observed. When comparing two outcome situations, it seems easier to compare both situations in terms of equality in outcomes than it is to compare them in terms of quality of joint outcomes (cf. Allison & Messick, 1990). Second, people often use social standards for evaluating the quality of their own outcomes (cf. comparison level; Kelley & Thibaut, 1978). In the context of a social dilemma, the social standard (or social comparison) is also salient (1) because typically people can "explain" any given outcome directly in terms of the other's behavior, and to some degree, the other's intentions, and (2) because individuals' own behavior, at least in part, may be guided by expectations regarding other's behavior (e.g., Kelley & Stahelski, 1970). Third, people are generally aversive to receiving fewer good outcomes than others. One is reminded here of classic research by Messick and Thorngate (1967), revealing that aversive tendencies toward ensuring that the other does not attain greater outcomes than oneself are stronger than "appetitive" tendencies toward attaining greater outcomes for oneself. In most situations, a violation of equality, caused by others' noncooperative behavior, may not only hinder or frustrate one's interaction goals, but also negatively influence a person's pride, honor, or self-esteem (i.e., two consequences that are likely to instigate anger, see Averill, 1982).

It is interesting that responses to aggressive acts (specifically, offenses) have recently received greater attention in studies on interpersonal forgiveness. In support of the notion that (aggressive) offenses often are violations of justice, it has been shown that forgiving is effectively promoted by a compensatory act or an apology by the offender (McCullough, Worthington, & Rachel, 1997). If such restorations are not made, forgiving is less likely to happen, especially when justice concerns remain prominent. Such may lead to an inability to forgive, which in turn may challenge quality of relationships and

undermine psychological well-being (e.g., Karremans, Van Lange, Ouwerker, & Kluwer, 2003). Aggression is, of course, by no means confined to dyads or small groups. Also, in large-scale social dilemmas, aggression, or at least subtle forms of aggression, may account for patterns of reactance, resistance, protest, and so on. Such aggression is often evoked by the behavior of specific group members, managers, or local and global authorities. Much research on large-scale social dilemmas has focused on individuals' willingness to contribute or cooperate, which may be regarded as a line of research that would benefit from greater attention for the opposite side of the coin (i.e., examining the psychological aspects of individuals' readiness to aggress in subtle or more explicit ways). Also, the topic of forgiveness is, of course, of great relevance to resolving conflict between large groups. To conclude, it is surprising that aggression has received so little attention in social dilemmas, because—unless research suggest otherwise—aggression seems an important orientation in social dilemmas, albeit one that seems activated primarily by the behavior of others.

Proposition 3 states that "the prosocial orientations of cooperation and equality frequently operate in a concerted or interactive manner. That is, these orientations tend to go hand in hand, and it is the interplay of both "prosocial" orientations that best accounts for behavior and interaction in settings of interdependence."

Thus far, we distinguished among six orientations, which, in decreasing order of benevolence, are (1) altruism, (2) cooperation, (3) egalitarianism, (4) individualism, (5) competition, and (6) aggression. As noted earlier, it is unlikely that each of these orientations operates in a completely independent manner. We argue that two or more orientations may well activate each other in some way, and thus may over time become "psychologically interrelated" orientations. As illustrated in Table 23.2, we suggest a model of interpersonal orientations that focuses on five relatively distinct interpersonal orientations, whereby "prosocial orientation" is the broader term representing both cooperation and egalitarianism as two interrelated orientations.

There is good theoretical and empirical reason to believe that at least two "prosocial orientations" (i.e., coop-

---

TABLE 23.2 An Overview of Five Orientations

1. *Altruism*
   Enhancement of outcomes for other

2. *Prosocial orientation*
   Enhancement of joint outcomes (cooperation)
   Enhancement of equality in outcomes (egalitarianism)

3. *Individualism*
   Enhancement of outcomes for self

4. *Competition*
   Enhancement of relative outcomes in favor of self

5. *Aggression*
   Reduction of outcomes for other

eration, and egalitarianism) tend to go hand in hand, at least in social dilemmas. How so? To begin with, one very robust phenomenon observed in the two-person prisoner's dilemma is the phenomenon of *behavioral assimilation* (Kelley & Stahelski, 1970). This phenomenon, which may also be referred to as reciprocity, holds that individuals with a prosocial orientation cooperate with others who also cooperate but turn to noncooperation when others do not cooperate (i.e., they become behaviorally similar to noncooperative others). The phenomenon of behavioral assimilation has been observed and supported in the most intensely studied prisoner's dilemma. Importantly, one could theoretically infer that if an individual is merely concerned with enhancing joint outcomes, one should behave cooperatively *irrespective* of the other's behavior. Thus, individuals with prosocial orientations should do more than simply enhancing joint outcomes. In fact, a model in which prosocial orientation is understood in terms of (1) egalitarianism alone or (2) cooperation and egalitarianism together (an "integrative model") is able to account for behavioral assimilation.

In past research, the phenomenon of behavioral assimilation has been supported only in research on iterated social dilemmas. In such repeated choice situations, reciprocity could be guided by a multitude of specific considerations, following from an interplay of other's past choices (or past interactions) and individuals' long-term interaction goals (e.g., the perceived feasibility of attaining particular interaction goals). For example, a partner's past actions may to some degree influence considerations relevant to long-term interaction goals, because the partner's past actions (e.g., noncooperative choices) might bring about beliefs regarding the feasibility of attaining particular long-term interaction goals (e.g., diminished confidence in the feasibility of establishing patterns of mutual cooperation). Thus, because considerations regarding the past, present, and future are inextricably linked to patterns of choice in iterated prisoner's dilemmas, it is difficult to understand the specific considerations and motivations that underlie patterns of reciprocity (but Gallucci & Perugini, 2003; Parks & Rumble, 2001; Sheldon, 1999).

Such accounts are irrelevant to a single-trial social dilemma, in which participants make only one choice. In such contexts, the only basis for choice follows from the present (the immediate present), and not from the past or the future. In one such study, participants made a choice after the other had made a choice (Van Lange, 1999). As noted earlier, this study manipulated information about the other's choice, having participants believe that the other gave away one chip, two chips, or three chips from a total of four chips, which were more valuable to the self than to the other. The participant him- or herself also possessed four chips, which were more valuable to the other than to the self. This situation represents a prisoner's dilemma because giving away chips is costly, but both would be better off to the degree that they exchanged a greater number of chips. Prior to the social dilemma, we assessed participants' social value orientations using a nine-item decomposed game technique (i.e., the triple-dominance measure of social value orien-

tation), to examine whether tendencies toward reciprocity would be more pronounced among prosocials than among individualists and competitors.

The analysis focused on reciprocity choices, giving away exactly the same number of chips as the other had given away. Across the three conditions, prosocials exhibited greater reciprocity (64%) than did individualists (33%) or competitors (17%). In another study, we examined reciprocity in the context of a single-trial social dilemma in which the participant and the other made their choices simultaneously (Van Lange, 1999). Reciprocity choices were operationalized as giving away exactly the same number of chips as they expected the other to give away. In this study, too, prosocials (79.6%) exhibited greater reciprocity than did individualists (58.4%) and competitors (45.4%).

The covariation between cooperation and egalitarianism is also supported in some other research. For example, relative to individualists and competitors, prosocials use and recall decision-making heuristics that focus on enhancement of joint outcomes (e.g., "take a problem-solving approach") and enhancement of equality of outcomes (e.g., "play fair" or "share and share alike"; De Dreu & Boles, 1998). Such findings are also interesting because they indicate that individuals may fairly automatically (i.e., without a lot of thought) attach different meanings to the same situation (cf. Liebrand et al., 1986; Sattler & Kerr, 1991; Van Lange & Kuhlman, 1994).

That prosocials are concerned with enhancing both collective outcomes and equality in outcomes is also demonstrated by recent research on ultimatum bargaining. As noted earlier, it has been argued that in ultimatum bargaining offers tend to be "strategic" in that allocators may offer an equal split of the money to the recipient simply to avoid the recipient's rejection of an unequal offer. Van Dijk and Vermunt (2000), for example, designed an ultimatum game in which bargainers had to divide 100 chips that were worth twice as much to the allocator than to the recipient. In the symmetric information condition the allocators were led to believe the recipient too was informed about this differential value, whereas in the asymmetric information condition allocators were led to believe that the recipient was not informed about differential value. Allocators in the symmetric information condition tended to give the recipient more than half of the chips in order to compensate for the differential value. But allocators in the asymmetric information condition made substantially lower offers, suggesting that allocators exhibit a tendency of self-servingly using informational advantage. That is, because the recipient does not know about the differential value, the allocator can offer to split the number of chips equally—a seemingly fair offer to the recipient—without much fear that the recipient is going to reject the offer. Such tendencies have been interpreted in terms of the strategic use of fairness (e.g., Kagel, Kim, & Moser, 1996; Pillutla & Murnighan, 1995).

Interestingly, a recent study by Van Dijk and colleagues (2004) revealed that only individuals with proself orientations (individualists and competitors) used fairness in a strategic, self-serving manner. In contrast, indi-

viduals with prosocial orientation revealed a "true" preference for an equal distribution of the outcomes. That is, in agreement with the notion that prosocials assign great weight to minimizing differences in outcomes, their findings indicated that even when prosocial allocators thought that the recipient was not aware that chips were worth twice as much to the allocator, they did compensate for the differential value of the chips by offering twice as many chips to the recipient as to themselves. Such findings are not only in line with the integrative model of interpersonal orientations but also suggest that prosocials are genuinely concerned with equality in outcomes.

The integrative model of interpersonal orientation is also supported in research on coalition formation, an area of research that has not been conceptualized in terms of egalitarianism. Specifically, Van Beest, Wilke, and Van Dijk (2003) compared bargaining behavior of prosocials and proselfs in a three-person negotiation setting. In this setting, group members could form two-person coalitions by excluding a third party from the coalition—the excluded party would then yield substantially lower outcomes because it does not benefit from the coalition. Alternatively, group members could form a grand coalition of all three parties, yielding a somewhat lower outcome for each party than in a two-party coalition but yielding equality in outcomes. The results indicated that prosocials were more than proselfs reluctant to excluding another party from a coalition. This tendency to not exclude, and to include all members in distributing the bargaining payoff, once again suggests that prosocials are strongly motivated to obtain equality in outcomes.

Similar conclusions can be reached on the basis of research on social dilemmas. For example, Samuelson (1993) investigated in a resource dilemma how prosocials and proselfs reacted to collective inefficiency and inequality. He investigated people's preferences for structural change when they observed that the common resource became depleted (as compared to efficient use of the resource), and when they observed that some members harvested more than others (as compared to a more equal distribution of harvests). Both dimensions—collective inefficiency and inequality—appeared to be more important to prosocials than to proselfs.

A recent study by Stouten, de Cremer, and Van Dijk (2005) provided further evidence for Samuelson's findings by examining emotional reactions to violations of equality. In this study, participants learned that they were a member of a four-person group, and that their group could obtain a monetary bonus if the combined contributions of the group members would surpass a certain threshold. After participants had decided on their contribution they received (bogus) feedback: They were informed that their group had not been successful, and that the total contribution fell below the threshold needed for provision because one member had violated the equality rule by contributing less than an equal share. After this feedback, however, Stouten and colleagues introduced a manipulation of outcome feedback by informing half of the participants that even though the

contributions fell short, the public good would be provided after all. Thus, for these participants what seemed like failure turned out to be a success after all. For the other half of the participants the negative outcome was not altered.

Interestingly, Stouten and colleagues (2005) found that the emotional reactions of proselfs were less negative and more positive if they learned that the public good was provided after all than if they learned that the outcome remained unchanged. In contrast, information that the public good would be provided after all was not enough for enhancing mood in prosocials. That is, even if the public good was provided after all, prosocials remained angry and unhappy. These findings suggest that prosocials' emotional reactions are deeply affected by violations in equality—the anger and frustration caused by one of the members who did not contribute (and received much greater outcomes than the others) was not resolved by yielding a good result for all four.

Taken together, there is good support for the link between cooperation and egalitarianism. Enhancement of joint outcomes and enhancement of equality tend to go together and are characteristic of how prosocials tend to approach social dilemmas and related situations of interdependence. One might further speculate about the *relative* importance of cooperation and equality. There is some initial evidence suggesting that enhancement of equality is "stronger" than enhancement of joint outcomes (e.g., Eek & Gärling, 2000; Gärling, 1999). For example, Gärling (1999) found that relative to individualists and competitors, prosocials exhibited greater levels of universalism, an attitude closely related to equality and fairness, but no greater levels of benevolence, an attitude closely related to altruism in the model discussed earlier. As noted earlier, it is plausible that in the context of prisoner's dilemmas and related structures, the violation of equality is so strong that mutual noncooperation is preferred to even weak forms of unilateral cooperation (or weak forms of altruism) whereby one behaves—or expects to behave—somewhat more cooperatively than the other. That is, prosocials may behave cooperatively up to the point that it violates equality in outcomes too strongly. Future research could examine how, more precisely, these two orientations work in concert, and whether some of the other orientations may in some ways activate each other.

DETERMINANTS OF INTERPERSONAL ORIENTATIONS

Proposition 4 states that "interpersonal orientations are partially shaped by social interactions—therefore, shaped by the self, the interaction partner, and/or situation."

To most social psychologists this proposition should not come as a surprise in that it adds very little (if anything at all) to what most of us already assume. So, why is the proposition stated at all? The reason is that we want to illustrate "the power of the situation" (the situational view) as well as seek to clarify some issues relevant to "influences" of personal dispositions (the dispositional

view) and the partner's observable tendencies ("the partner view"). These goals are all the more important because, empirically, interpersonal orientations are primarily addressed from the dispositional standpoint (i.e., known as social value orientations). We begin our discussion with the situational view.

In their review of interdependence processes, Rusbult and Van Lange (1996) advance three sources of interpersonal orientation, arguing that interpersonal orientations are manifested in at least three general forms: (1) *interpersonal dispositions*, or person-specific inclinations to respond to particular patterns of interdependence in a specific manner across numerous interaction partners; (2) *relationship-specific motives*, or partner-specific inclinations to respond to particular patterns in a specific manner within the context of a given relationship; and (3) *social norms*, or rule-based inclinations to respond to particular patterns of interdependence in a specific manner, either across numerous interaction partners (e.g., never be the first to "defect") or within the context of a given relationship (e.g., never betray your best friend). Clearly, relationship-specific motives and social norms form an important situational basis of interpersonal orientations. For example, a relationship-specific motive may be derived from commitment to a partner, embodying feelings of attachment, intent to persist, and long-term orientation (Rusbult, Verette, Whitney, Slovik, & Lipkus, 1991; see also Agnew, Van Lange, Rusbult, & Langston, 1998). Commitment is ultimately a product of previous social interaction experiences, and broadly shaped by satisfaction with a relationships, alternatives to a relationship, and investments to a relationship. Importantly, relative to partners to whom we feel not very committed, partners to whom we feel strongly committed are more likely to elicit or activate prosocial orientations (Rusbult et al., 1991; Van Lange, Rusbult, et al., 1997). Similarly, the degree to which social norms activate prosocial versus proself orientations is powerfully linked to differences in situations. In some situations, such norms are very strong and often habituated, whereas in other situations such norms may be less salient or more ambiguous (i.e., when two or more social norms tend to conflict). For example, the "equality norm" is a powerful norm in informal, communal situations, whereas other norms, such as equity (Adams, 1965), might be more important in formal, business-like situations. In yet other situations, it may be a norm to compete, often meaning doing the best one can, as in many games or sports where only one can win.

There is even good reason to believe that prosocial orientations (or proself orientations) are fairly easily activated by relatively subtle situational differences. Slight variations in the degree to which another person is perceived as likable or unlikable, close or not so close, similar or dissimilar might exert considerable influence on the activation of prosocial versus proself orientations (e.g., De Bruin & Van Lange, 2000). Similarly, slight variations in the degree to which some norms are made salient in a given situation might exert considerable influences on the activation of prosocial versus proself orientations. For example, Hertel and Fiedler (1994) found higher levels of

cooperation after a morality prime than after a power prime. Several studies have replicated these findings, while at the same time showing that the effects of priming morality may be especially pronounced for individuals who do not tend to have a stable social value orientation (e.g., Hertel & Fiedler, 1998; Smeesters, Warlop, Van Avermaet, Corneille, & Yzerbyt, 2003). And finally, there is evidence indicating that priming people with "intelligence" may strengthen prosocials' tendencies to cooperate, and—more significantly—strengthen competitors' tendency to take advantage of a partner's cooperation (Utz, Ouwerkerk, & Van Lange, 2004). Thus, there is little doubt that the situation (even subtle situational differences, we believe) may exert powerful influences on the activation of prosocial versus proself orientations.

At the same time, decades of early research on the prisoner's dilemma and related situations revealed a remarkable consistency in individuals' orientations. That is, across various situational manipulations, some individuals tended to behave in a prosocial manner, whereas other individuals tended to behave in a proself manner. These observations inspired several researchers to examine individual differences in interpersonal orientations. Indeed, the important line of research on social value orientation (e.g., Messick & McClintock, 1968) provided the methodological tools for assessing prosocial versus proself orientations. Subsequent research has demonstrated that even brief measures involving allocational choices (such as the nine-item decomposed-game instrument, see Appendix 23.1) are predictive of cooperative and noncooperative behavior in various settings, including two-person prisoners' dilemmas, social dilemmas, resource dilemmas, and actual forms of helping behavior. An example of the latter is that individuals with prosocial orientations are more likely to donate time to the university than do individualists and competitors (McClintock & Allison, 1989). There is also evidence that these differences are linked to motivations for willingness to sacrifice in ongoing relationships (Van Lange, Agnew, Harinck, & Steemers, 1997), and to various forms of prosocial behavior in the context of large communities (e.g., donation to noble causes; Van Lange, Van Vugt, Bekkers, Schuyt, & Schippers, 2005).

Some researchers and theorists might believe that the situational view is inconsistent with the dispositional view, thinking that it is an "either–or" matter. We regard both views as perfectly consistent as well as perfectly complementary, and we believe that theoretical analyses would benefit from taking into account *both* views rather than focusing on either point of view. How so? First, it is the situation that *affords* interpersonal orientations. That is, it is the situation that dictates the relevance of a particular interpersonal orientation and determines which orientations are in conflict with one another. For example, the prisoner's dilemma, especially the single-trial prisoner's dilemma, affords cooperative orientations versus self-interested orientations. A coordination situation, on the other hand, affords none of the orientations outlined in this chapter. Thus, first and foremost, it is important to analyze and define situations in terms of "affordances": What is it that the situation calls for?

Second, within a domain of situations that afford cooperative versus noncooperative orientations (e.g., the so-called mixed-motive situations), the distinction between "strong" and "weak" situations, advanced by Snyder and Ickes (1985; see also Mischel, 1977), becomes important. Strong situations are ones that "provide salient cues to guide behavior and have a fairly high degree of structure and definition, whereas weak situations do not tend to have salient cues to guide behavior and are relatively unstructured and ambiguous" (Snyder & Ickes, 1985, p. 904). Strong situations are the ones in which situational influences should be large, whereas weak situations are the ones in which dispositional influences should be large. Applying these concepts to the domain of mixed-motive situations, it is important to note that by its very structure, mixed-motive situations are almost by definition ambiguous. Indeed, they often represent "dilemmas." Thus, the structure itself, by its affordances, is weak and therefore suggests the importance of dispositional influences. This may explain why the "remarkable consistency in individuals' orientations" in mixed-motive situations should in fact not be all that remarkable. However, even mixed-motive situations have the capacity to become strong. In particular, they may become strong because of relationship-specific motives (e.g., commitment) or because of social norms (which, as suggested earlier, may even be activated through some subtle priming procedures). Under such circumstances, the dispositional influences should be substantially weaker.

The implication for research is that when one compares strong with weak situations, one should obtain statistical interactions of disposition and situation (Magnusson & Endler, 1977), because the influences of dispositions should be greater in weak rather than strong situations. For example, preexisting differences in social value orientation do predict willingness to sacrifice in close relationships when one's commitment to the relationship is relatively weak but fail to predict willingness to sacrifice in close relationships when one's commitment to the relationship is strong (Van Lange, Agnew, et al., 1997). Research by Kramer, McClintock, and Messick (1986) provides another illustration revealing that the effects of social value orientation are especially pronounced when the dilemma reaches the point at which the resources are close to being depleted (or circumstances of scarcity and urgency), and much weaker when the resources seem abundant.

Third, the dispositional view does not hold that there is always a perfect correspondence between orientation and behavior. This applies even to very "weak" situations that by their structures afford cooperative behavior versus noncooperative behavior (i.e., when there is in fact a perfect match between orientations and the situational features). For example, the correspondence between prosocial (vs. proself) orientation and cooperative (vs. noncooperative) behavior need not be perfect, even in a single-trial prisoner's dilemma. Why not? First, it is unlikely that one particular orientation is completely independent of some other orientation. Indeed, Proposition 3 suggests that there is a correspondence between enhancement of joint outcomes and enhancement of equality in outcomes. Second, and perhaps more important, the more accurate characterization of the dispositional view is that people differ in the *probability* with which one or more of the interpersonal orientations will be activated—which we discuss as the next proposition.

Proposition 5 states that interpersonal orientations represent different probabilities with which one or more decision rules (e.g., outcome transformations such as MaxJoint and MinDiff) are activated and used.

It is not uncommon for scientists and laypeople alike to assume (often implicitly, we believe) that a disposition or orientation must translate directly into behavior. Perhaps due to the human need for predictability and control, we parsimoniously tend to believe that "prosocial people behave (almost) always prosocially" just as "competitive people behave (almost) always competitively." Rather than taking a deterministic perspective, a more accurate characterization of the dispositional view is probabilistic, based on the assumption that people differ in the *probability* with which one or more of the interpersonal orientations will be activated. As a metaphor, we prefer to frame this in terms of the *slot-machine model of interpersonal orientations*. But what does it mean—more precisely? We suggest that for relatively stable orientations (as dispositions or as partner-specific orientations) people differ in terms of the percentages of slots that represent prosocial, individualistic, and competitive preferences—just as slot machines represent different frequencies of bananas, lemons, and oranges (so we assume). For example, a prosocial person is a person with a relatively high percentage of prosocial slots (let's say, 70%), and relatively low percentages of individualistic and competitive slots (let's say, 20% and 10%). Similarly, a person with strong attachment for his sibling may have the same distribution of slots when facing dilemmas with his or her sibling. The reverse pattern is likely to be for a competitive person, while an individualistic person may take an intermediate position (with 60% individualistic slots, 20% prosocial slots, and 20% competitive slots).

The slot-machine metaphor of interpersonal orientation is reasonable because people behave in a variety of different interaction situations, even with the same partner. Experience accumulates across interaction situations, which is likely to shape a "probability distribution of interpersonal orientations." Indeed, it would appear to be dysfunctional or maladaptive if people relied on only a single orientation in their interactions with others, even if the situational features are the same. The slot-machine model of interpersonal orientation is also plausible (1) because there is variation in the external (and impersonal) circumstances to which individuals may respond in some way (e.g., the weather, noise), and (2) because there is a fair amount of variation within an individual even on a day-to-day basis, which may also exert influences on the activation of a particular orientation (e.g., differences in mood states, or differences in energy levels on a particular day).

The slot-machine metaphor has important implications. One implication is that the metaphor assumes flexibility and adaptation. If a person were to repeatedly

(and rigidly) adopt the same orientation (irrespective of whether it is prosocial, individualistic, or competitive orientation) across multiple partners, or even to one and the same important partner, the person would be unlikely to adapt to small but important changes in the situation or to small but important changes in the partner's behavior. Indeed, rigidity would probably imply that one does not even notice certain changes in the situations (e.g., new possibilities for effective communication) or changes in the partner's behavior (e.g., increased tendency toward cooperation, increased tendency toward "cheating"). Hence, interpersonal orientations require flexibility to be adaptive—and indeed, if we were to be the slave of a particular orientation, our adaptive quality, and hence survival opportunities, would be very slim.

A second implication of the slot-machine metaphor is that people will have experience with prosocial, individualistic, and competitive "states." This is important because it suggests that people should be able to change perspectives when called for. For example, it has been shown that prosocials are more likely than individualists and competitors to evaluate other's cooperative and noncooperative actions in terms of "good versus bad" associating cooperation with goodness and noncooperation with badness—they adopt readily a morality perspective. Conversely, individualists and competitors are more likely than prosocials to evaluate other's actions in terms of strength and weakness, associating cooperation with weakness and noncooperation with strength—they adopt readily a "might" perspective (Liebrand et al., 1986; Van Lange & Kuhlman, 1994). According to the slot-machine metaphor, people should not find it hard to change perspectives: Prosocials should not find it difficult to adopt a perspective whereby competing is construed as a sign of strength, while competitors should not find it difficult to see that cooperation is often the right (or good) thing to do. People should also adapt by changing perspectives when dealing with their close partner from the perspective they have when dealing with a secondhand car salesman (or at least the stereotype thereof). While it may be seen as immoral to misinform your close partner, it may be seen as fairly "smart" to do so when buying (or selling) a secondhand car.

But is there empirical evidence for the slot-machine model of interpersonal orientation? Although the evidence is very indirect, we think of three complementary sources of empirical support. First, as discussed earlier, relatively subtle cues or associations seem to be able to activate one orientation rather than another. Priming morality, fairness, competence, power, and competition have all been shown to affect behavior in prisoner's dilemmas. Moreover, merely describing a situation as a business transaction may be enough to evoke more self-interested behavior (Batson & Moran, 1999; see also Elliott, Hayward, & Canon, 1998). Interestingly, recent research on social dilemmas has suggested that whether a situation is perceived as a business transaction depends not only on the actual words used to describe the situation but perhaps even on other situational characteristics. For example, Tenbrunsel and Messick (1999) demonstrated that perceptions of social dilemma situations

are strongly affected by the introduction of sanctions on selfish behavior. After introduction of sanctions on selfish behavior, the perception of a social dilemma may shift so that people are more likely to regard their decision as a business-like decision rather than an ethical decision. Hence, sanctions of selfishness may activate individualistic or competitive orientations (see also Gneezy & Rustichini, 2000; Mulder, Van Dijk, De Cremer, & Wilke, 2006). Perhaps, the use of explicit interventions may undermine a more natural tendency ("intrinsic motivation"; Deci & Ryan, 2000) to exhibit cooperation among prosocials—those likely to do so under other circumstances.

A second source of indirect support is that the temporal stability of social value orientation is good but far from excellent. As noted earlier, there are often high levels of intrapersonal stability (and interpersonal variability) within various types of social dilemmas that are partially accounted for by measures of social value orientation. At the same time, while the test–retest reliability of social value orientation (i.e., the nine-item, triple-dominance measure) is generally good, it is not excellent. In a study involving a small sample size, it appeared that 18 of 24 classifiable participants (75%) at time 1 expressed the same interpersonal orientation at time 2 (*Kappa* = .60; Van Lange & Semin-Goossens, 1998). In another study (Van Lange, 1999, study 1), the sample was large, fairly representative of the Dutch adult population, and the time lag between measurement sessions was 19 months. Despite some differences in instructions and procedures between the two measurements, it appeared that 342 of 581 participants (58.8%) expressed the same interpersonal orientation at time 1 and time 2 (*Kappa* = .19). Clearly, the stability of interpersonal orientation is somewhat lower than one would expect from a "stable dispositional" point of view, yet comparable to those found for other individual-difference variables (e.g., adult attachment styles; Shaver & Brennan, 1992). We suggest that temporal states that may be accounted for by variability in day-to-day mood, prior experiences with situations resembling social dilemmas, or other "subtle influences" (e.g., media influences) may determine whether prosocial, individualistic, or competitive orientations are more easily activated.

Third, within the context of specific partners, we tend to see considerable variation in the interpersonal orientations we adopt. Clearly, some key relational constructs, such as commitment and trust, are able to predict various propartner behaviors that align with altruism, cooperation, and fairness (cf. Holmes, 2002; Rusbult & Van Lange, 2003). Yet even when the relational circumstances are ideal, we witness behavior that resembles individualism or even competition. Conversely, even when the relational circumstances are bad, we may witness inherent forms of propartner behavior. And despite decades of research on social dilemmas and the like, no empirical overview can point at one variable that is most certainly going to direct all (or even most) people into making cooperative or noncooperative choices. The only exception may be, as noted earlier, when the partner repeatedly engages in noncooperative behavior (cf. Kelley & Stahelski, 1970).

From a more conceptual perspective, it may be instructive to relate the slot-machine metaphor to two complementary theoretical constructs. First, the metaphor is congruent with the notion of "accessibility." For example, in forming impressions of others, for some people some trait concepts tend to be chronically accessible (e.g., appearance) whereas for other people different trait concepts tend to be chronically accessible (e.g., politeness; Higgins, King, & Maven, 1982). Such accessibility differences may influence impressions of others without people being aware of it. Such effects have also been demonstrated for attitudes, for attributes relevant to people self-definitions, and the like. Similarly, a person with a prosocial orientation is more likely to use and rely on decision rules that dictate "equality in outcomes" or "collective outcomes," and so the person may—often without being aware of it—attend to information regarding equality in outcomes and collective outcomes.

The other concept that is related to the slot-machine metaphor is the notion of *goal activation* and habits. As an interesting case in point, Aarts and Dijksterhuis (2000) have shown that habitual bicycle riders rapidly responded to the word "bicycle" when they had been primed with the goal of traveling to nearby locations (e.g., the university); in contrast, nonhabitual bicycle riders did not. Similarly, competitors' tendencies to compete may be activated by relatively small "cues" in social dilemmas and the like whereas such tendencies may not at all present among prosocials. As this literature of automatic goal activation suggests, such tendencies may be automatic—and beyond any awareness. Hence, some interaction goals ("slots") may be activated in an automatic manner (as well as in a more controlled manner).

Taken together, although the evidence is indirect, they do seem to converge on the point that consistent differences in interpersonal orientations represent consistent differences in the probability with which a particular interpersonal orientation may be activated. The same seems to be true for situational effects, which tend to take strong probabilistic (rather than deterministic) forms. The best oxymoron to capture such effects is perhaps "consistent contingency" whereby probability is influenced by numerous other variables that determine contingency, including randomness.

SUMMARY AND CONCLUDING REMARKS

This chapter discusses five propositions that are relevant to understanding the interaction goals with which people adapt to various situations in which self-interest and collective interest are conflicting. Interpersonal orientations are broadly defined as the set of cognitions, affect, and motivation that underlie interpersonal behavior and social interaction. They reflect *interaction goals* by which people seek to enhance the outcomes for themselves (individualism) as well as enhance the outcomes for other (altruism), enhance joint outcomes (cooperation), enhance equality in outcomes (egalitarianism), enhance relative advantage over others (competition), or minimize outcomes of another person (aggression). We suggest that interpersonal orientations are of broad relevance to diverse social psychological phenomena in that the construct is relevant to the internal processes (cognition and affect) that prepares one for interaction as well as to the internal processes that in many ways summarize the interaction—and that prepares one for the next interaction, either with the same partner or with a third, unrelated person. In the following paragraphs we discuss some further theoretical and evaluative issues relevant to these propositions that we have advanced in this chapter.

We begin by noting that the psychology of interpersonal orientations, while inherently social psychological, cuts across several shifts in the dominant theoretical paradigms in the past as well as integrates several fields of psychology—which is arguably important for any scientific topic to grow, bloom, and progress to yield cumulative knowledge (e.g., Kruglanski, 2006; Mischel, 2004). It is closely connected with almost any interpersonal process that is relevant social interaction. The list is endlessly long and is illustrated by (but by no means limited to) concepts such as altruism, generosity, fairness, equality, cooperation, forgiveness, sacrifice, trust, conflict, aggression, hostility, reactance, competition, suspicion, retaliation, and so on. Most of these topics are essential to understanding relationship processes underlying interactions among kin, friends, close partners, or colleagues, as well as group processes underlying interactions among members of teams, work units, interest groups, and even nations. Also, most of these topics have been studied not only by social psychologists but also by personality psychologists, developmental psychologists, health psychologists, cognitive psychologists, and so on. For example, the topic of forgiveness was originally studied by clinical and health psychologists and recently has become an exceptionally productive area of research within social psychology—and for good reasons, in that forgiveness is a response to an interpersonal offense, with strong implications for future interactions between two persons or two groups. Within social psychology, interpersonal orientations are at the heart of interpersonal and group processes, even though each of the phenomena described above applies (perhaps often with even greater societal relevance) to processes that operate within and between large groups (e.g., within and between nations; e.g., Bornstein, 1992). Many processes that receive considerable attention in contemporary social psychology, such as affect regulation, promotion and prevention foci, and stereotyping, are intimately—and importantly—linked to interpersonal orientations and the situations in which they are relevant. For example, those who cooperate, while discovering that the others did not, need to regulate their anger and frustration in some form; social dilemmas can easily evoke a prevention focus of seeking to reduce loss or a promotion focus of reaching mutual cooperation; and even subtle cues regarding another person's (stereotyped) characteristics can affect cooperation (e.g., De Bruin & Van Lange, 2000; De Dreu, Yzerbyt, & Leyens, 1995).

More generally, by being so closely related to social interaction, the literature of interpersonal orientations may serve as a bridge between (1) micro (or molecular)

approaches, with a strong focus on principles and mechanisms that may account for why individuals function as they do, and (2) macro (or molair) approaches, with a strong focus on principles and mechanisms that may account for why large groups and societies function as they do (for a related argument, see Kelley, 2000; see also Penner, Dovidio, Piliavin, & Schroeder, 2005; Van Lange, 2006). We discuss each in turn.

In support of the *micro* side of interpersonal orientations, we suggest that most if not all of the propositions can be supported by neuropsychological and related psychophysiological research. For example, there is research on the neurological basis of empathy, revealing for humans and monkeys that observing someone else's actions automatically activates neural systems underlying the production of our own actions (for a review, see Blakemore & Decety, 2001). Recently, this line of research has been extended to consider our ability to understand the feelings and sensations of others (i.e., our ability to *empathize*). Such research may well illuminate a neural basis for altruism (Singer & Frith, 2006).

Moreover, recent functional magnetic resonance imaging research reveals that attaining patterns of reciprocal cooperation in social dilemmas activates areas of the brain that are associated with the processing or rewards (Rilling et al., 2002). One may argue that the activation of this neural network helps individuals to resist the temptation to take advantage of the partner's cooperation—but instead to develop patterns of cooperation. Such research is consistent with Propositions 1 and 2, but also with Proposition 3, arguing that enhancing collective outcomes and equality in outcomes tends to go together. It would be interesting to examine whether the activation of cooperative goals tends to enhance the goal of equality and vice versa. On the basis of Proposition 3, and the empirical evidence in support of it, it seems likely that these goals are closely associated, and this association may well be demonstrated in a variety of automatic and controlled cognitive mechanisms (e.g., in implication associations), neuropsychological methods, and the like.

In support of the *macro* side of the interpersonal processes, interpersonal orientations are of great relevance to large groups, even nations. In fact, there is good reason to believe that the distribution of social value orientation is the way it is because of "functionality" at the societal level. Specifically, across a variety of different countries (although mostly "Western" countries), the distribution of prosocials, individualists, and competitors is around a 4:2:1 ratio (see Van Lange, Otten, et al., 1997). According to *frequency dependent selection* explanations, often used in evolutionary theory, such a ratio is unlikely to be random. Rather, the success of one strategy depends on the relative frequency of other strategies in the same population (Maynard Smith, 1982). For example, it is plausible that a stable, high-frequency group of prosocials invites individualists and competitors to develop and grow. In particular, a small percentage of competitors may always be there (and never become extinct) because of the presence of prosocials, who allow a little bit of "exploitation" (e.g., in single interactions), when there is no opportunity for behavioral assimilation (cf.

Kelley & Stahelski, 1970). It is of interest to note that the distribution of 4:2:1 has also been observed in computer simulations (e.g., Lomborg, 1996), which provides further evidence in support of the claim that distributions of social value orientation are as they are because of the functioning at the societal level (see also Ketelaar, 2004).

We also suggest that interpersonal orientations, more broadly, reflect how people interact not only with other individuals in the context of dyads but also with individuals as part of medium-size and large groups. There is a fair amount of evidence that social value orientation is also predictive of cooperative behavior in groups and to large-scale social dilemmas, such as environmental dilemmas (e.g., Parks, 1994; Van Vugt, Van Lange, & Meertens, 1996). Also, relative to individualists and competitors, prosocials are more likely to exhibit anonymous forms of prosocial behavior, for the good of their own society or even other societies (e.g., donations to the third world; Van Lange et al., 2005). Furthermore, although dispositions, such as social value orientation, have received little attention in the context of intergroup relations, there is strong evidence that intergroup interactions tend to be more strongly guided by individualistic and competitive goals than interindividual interactions (Insko & Schopler, 1998).

As alluded to earlier, the psychology of interpersonal orientations is closely connected to evolutionary theorizing. Why are people willing to cooperate at all? Why are they willing to engage in costly acts to benefit others or the group? Why do we do so even with complete strangers with whom there is no future of interdependence? Such issues are relevant to the evolution of cooperation. Interestingly, reciprocity is considered to be the key mechanism through which social interactions evolve, both as a direct mechanism (Axelrod, 1984) and as an indirect mechanism, accounting for cooperative behavior among strangers (Nowak & Sigmund, 1998). Reciprocity in social dilemmas seems to be accounted for by enhancement of *both* joint outcomes and equality (see Proposition 3), and thus it is important to examine the evolution of both mechanisms. Similarly, there is good reason to believe that some forms of altruism and generosity ultimately account for the evolution of cooperation. For example, when there is some uncertainty regarding other's actions (e.g., when there is "noise" so that social signals cannot always be detected), it is arguably adaptive to give the other the benefit of the doubt (and not immediately reciprocate) and behave more cooperatively than the other was believed to do (Van Lange, Ouwerkerk, & Tazelaar, 2002).

We also suggest that Propositions 4 and 5 can make important contributions to the evolutionary theory. First, Proposition 4 is relevant to a taxonomy of interaction situations, and it is clear that the scientific discussion about the evolution of cooperation would benefit from an analysis of situations—after all, social life is not limited to social dilemmas, or even to exchange situations. And even within such situational domains, there are differences in the size of groups, in the availability of information regarding the intentions underlying another's actions, and

the degree to which the situation extends in time. A *taxonomic* approach, such as the one advanced by Kelley and colleagues (2003), is essential to understanding the interpersonal circumstances under which various prosocial orientations versus selfish orientations are adaptive. Proposition 5 emphasizes probability in the ways in which interpersonal orientations are activated—by the self, the partner, or the situation. We suggest that the debate about the evolution of cooperation benefits from the notion that decision rules (or transformations) are activated in a probabilistic manner. After all, such a probabilistic approach provides people with the *flexibility* that is needed to adapt to changes in the partner's actions and needed to adapt to changes in situations.

We wish to close by noting that interpersonal orientations are strongly guided by cognitions and affect—a topic that has not yet received much empirical attention. The theorizing regarding interpersonal orientations is most directly rooted in Kelley and Thibaut's (1978) *transformational analysis*—which assumes that individuals may, depending on their orientations, transform a given situation into "an effective situation" that guides behavior and interactions. Part of such transformation processes are the cognitions and emotions that may help individuals "to make sense" of situations—often in a goal-oriented (yet not necessarily conscious) manner. Social dilemmas, in particular, afford multiple and conflicting cognitions (for many, it is a dilemma), and emotions that may guide behavior, and that summarize interaction outcomes (the reader is reminded of the spontaneous comments by participants, reported by Dawes, 1980). For example, people may interpret social dilemmas in terms of classic dimensions of judgment and impression formation, perceiving it in terms of moral evaluation, strength and weakness, intelligence, and the like (Osgood, Suci, & Tannenbaum, 1957; Rosenberg & Sedlak, 1972). Also, the anticipation of experiencing guilt may prompt prosocials to behave cooperatively, to avoid taking advantage of the other's cooperation, or to avoid being accused of such tendencies (Frank, 1988). It goes without saying that feelings of anger, disappointment, and regret may be experienced when the individual discovers that he or she is the only one who cooperated. Conversely, feelings of interpersonal liking, enjoyment, and gratification, may be experienced when individuals have developed stable patterns of mutual cooperation. And some pleasure (e.g., *schadenfreude*) may be derived from punishing free riders, as well as from observing others engaging in such punitive activities (e.g., Price, Tooby, & Cosmides, 2001; cf. Fehr & Gächter, 2002). Frequently, cognitions, and certainly emotions, are guided by strong norms, which often serve to counteract tempting tendencies toward cheating, deception, and otherwise hurtful forms of "rational" self-interest (Ketelaar, 2004; Mealey, 1995). After having criticized Adam Smith (1757/2000) for his (narrow) view regarding situations, we should give him considerable credit for bringing to our attention the important role of hot cognitions and emotions, in particular "moral sentiments" that help us overcome or resolve social dilemmas that threaten interpersonal, intergroup, and international relations.

APPENDIX 23.1. AN INSTRUMENT TO MEASURE INTERPERSONAL ORIENTATION

In this task we ask you to imagine that you have been randomly paired with another person, whom we will refer to simply as the "other." This other person is someone you do not know and that you will not knowingly meet in the future. Both you and the "other" person will be making choices by circling the letter A, B, or C. Your own choices will produce points for both yourself and the "other" person. Likewise, the other's choice will produce points for him or her and for you. Every point has value: The more points you receive, the better for you, and the more points the "other" receives, the better for him or her.

Here's an example of how this task works:

	A	B	C
You get	500	500	550
Other gets	100	500	300

In this example, if you choose A you would receive 500 points and the other would receive 100 points; if you chose B, you would receive 500 points and the other 500; and if you chose C, you would receive 550 points and the other 300. So, you see that your choice influences both the number of points you receive and the number of points the other receives. Before you begin making choices, please keep in mind that there are no right or wrong answers—choose the option that you, for whatever reason, prefer most. Also, remember that the points have value: The more of them you accumulate the better for you. Likewise, from the "other's" point of view, the more points he or she accumulates, the better for him or her.

For each of the nine choice situations, circle A, B, or C, depending on which column you prefer most:

	A	B	C			A	B	C
(1) You get	480	540	480		(6) You get	500	500	570
Other gets	80	280	480		Other gets	500	500	300
(2) You get	560	500	500		(7) You get	510	560	510
Other gets	300	500	100		Other gets	510	300	110
(3) You get	520	520	580		(8) You get	550	500	500
Other gets	520	120	320		Other gets	300	100	500
(4) You get	500	560	490		(9) You get	480	490	540
Other gets	100	300	490		Other gets	100	490	300
(5) You get	560	500	490					
Other gets	300	500	90					

Note: Participants are classified when they make six or more consistent choices. Prosocial choices are: 1c 2b 3a 4c 5b 6a 7a 8c 9b; individualistic choices are: 1b 2a 3c 4b 5a 6c 7b 8a 9c; and competitive choices are: 1a 2c 3b 4a 5c 6b 7c 8b 9a.

ACKNOWLEDGMENT

NOTE

1. There are several theoretically important issues that are important to the five propositions. For example, one key issue concerns whether we should include orientations other than outcome-distribution orientations in the analysis of interpersonal orientations (e.g., dominance vs. submission). Another key issue concerns the "explanations" for prosocial orientation and prosocial behavior: (1) whether prosocial orientation and behavior may to some degree be mediated by concrete self-rewards (e.g., enhancement of mood and the desire to uphold a moral principle), and (2) whether prosocial orientation and behavior to some degree may reflect the goal of enhancing long-term personal outcomes (i.e., the issue of "time"). Generally, we believe that interpersonal behavior and social interactions are guided by other broad orientations (such as dominance vs. submission), the automatic or controlled pursuit of specific self-benefits, and the broader considerations of long-term self-interest. These are very important theoretical issues but considered beyond the scope of this chapter.

PART IV

INTERPERSONAL SYSTEM

CHAPTER 24

Attitude Change

GREGORY R. MAIO
GEOFFREY HADDOCK

Attitudes are important because they involve large parts of our mental life. When we really like something or someone, our relevant feelings, beliefs, and behaviors are all swayed in a positive direction, and it is difficult for people to be "objective" and ignore these tendencies. This potent effect of attitudes is the reason why people often think of attitudes as the principal cause and the principal consequence of important social problems. For instance, if people wish to explain bitter fighting between two ethnic groups (e.g., Shia and Sunni Muslims or Serbs and Croats), the first explanation usually considered is "ethnic hatred," which is simply a negative attitude toward the other ethnic group. Consequently, if people seek a means to reduce the conflict, they will suggest ways to try and ameliorate the bitter intergroup attitudes.

The success of such interventions to change attitudes may vitally depend on developing a thorough understanding of the persuasion process. Attempts at persuading people to like another group may work well on some occasions but many terribly backfire on other occasions. To facilitate successful interventions, persuasion researchers have long searched for the factors that influence attitude change and for models that can explain how these factors are influential. This search has led to a large corpus of data spanning a variety of domains of application, including social groups (e.g., Blacks), policies (e.g., tuition fees), social values (e.g., equality), health-relevant behaviors (e.g., smoking), religious behavior (e.g., attending church or synagogue), environmental behaviors (e.g., recycling), food items (e.g., jams), household utensils (e.g., razors), simple tasks (e.g., choices be-

tween objects), and even humorous stimuli (e.g., cartoons). This chapter attempts to summarize some basic principles of persuasion that operate across these domains, drawing heavily on well-researched models of persuasion.

To begin, the chapter describes the content, structure, and function of attitudes, which helps to lay the foundation for understanding principles of attitude change. We then begin to foreshadow specific principles by reviewing models of attitude change and noting their points of agreement. Next, the chapter considers four basic principles in detail and briefly highlights other potential principles. Finally, we note relevant issues for future research.

ATTITUDE CONTENT, STRUCTURE, AND FUNCTION

The first step to understanding attitude change involves comprehending the content, structure, and function of attitudes. These terms have had varied uses in the past. For example, the phrase "attitude structure" has been used to reflect both the capacity of attitudes to reflect different beliefs and emotions and the capacity to reflect different combinations of positivity and negativity (Eagly & Chaiken, 1993). Similarly, the term "attitude function" is used to denote specifically the needs served by expressing or possessing attitudes, which are often related to the function served by the object of the attitude, but not always (Kruglanski & Stroebe, 2005; Shavitt, 1990). In this chapter, the phrase "attitude content" refers to the ways

in which attitudes may express different psychological constructs, such as beliefs and emotions. The phrase "attitude structure" refers to the ways in which attitudes summarize positivity and negativity toward the attitude object. The phrase "attitude function" refers to the ways in which the attitudes themselves may serve different psychological motivations, such as needs to be correct or to be liked by others. By understanding the content, structure, and function of attitudes, it becomes clearer what attitude change attempts must achieve in order to claim success at eliciting attitude change. So, what contents, structure, and functions must be addressed?

Attitude Content

Research on the content of attitudes has been dominated by two perspectives: the three-component model and the expectancy-value model. According to the three-component model, attitudes express people's feelings, beliefs, and past behaviors regarding the attitude object (Zanna & Rempel, 1988). For example, both authors of this chapter disliked the first two Oscar-winning films in the "Lord of the Rings" series because they thought the films were boring and abhorrent (affective component) and believed that the films were not particularly innovative and overly violent for children (cognitive component). Nonetheless, one of the authors sat through the third film in this series (behavioral component), despite his negative affective and cognitive reactions. The three-component model predicts that his behavior is also an important part of his attitude toward these films because, to some extent, it is difficult to believe that a person completely dislikes something that he or she has endured three times. Through the process of self-perception (Bem, 1972; Olson, 1990, 1992) and cognitive dissonance (Festinger, 1957), people tend to decide that they like something when they can recall doing it often.

This example points out an interesting feature of attitudes. Specifically, it is not necessary that all the attitude components express the same sentiment toward the object of an attitude. People's feelings, beliefs, and behaviors may imply conflicting evaluations of the attitude object, and this situation is often labeled "intercomponent ambivalence" (MacDonald & Zanna, 1998; Maio, Esses, & Bell, 2000). There may also be intracomponent ambivalence such that people possess both positive and negative feelings, beliefs, and behaviors. The amount of evaluative conflict within and between components can vary as a function of the attitude object (Bell, Esses, & Maio, 1996), the attitude holder (Thompson & Zanna, 1995), and the situation (Bell & Esses, 2002). Moreover, the net attitude itself may match or mismatch the evaluations in the components on which it is based (Chaiken, Pomerantz, & Giner-Sorolla, 1995).

Nevertheless, there is also a press toward "synergy" among the attitude components (Eagly & Chaiken, 1993; Zanna & Rempel, 1988). That is, despite the frequent existence of ambivalence, people also tend to have positive attitudes toward an object when their feelings, beliefs, and behaviors all express favorability toward an object. In contrast, people tend to have negative attitudes toward an object when their feelings, beliefs, and behaviors express unfavorability toward the object. This consistency may occur because, in general, internal psychological conflict is aversive to us (Festinger, 1957). Consequently, we seek information that confirms our preexisting beliefs, feelings, and behaviors (Frey, 1986; Frey & Stahlberg, 1987), while also processing new information in a manner that might help to reduce ambivalence (Jonas, Diehl, & Bromer, 1997; Maio, Bell, & Esses, 1996; Maio, Greenland, Bernard, & Esses, 2001).

If a result of these information-processing biases is consistency between the components, it could be argued that we should adopt a model of attitude content that focuses simply on one of the components. Some researchers also argue that a model focusing on one component alone has the advantage of simplicity, because there is a danger in making attitudes too much of an all-encompassing entity. These factors buttress the argument for models of attitudes that focus on the belief component. According to models with this focus, attitudes are based on beliefs that are evaluative in nature, and the most interesting issue is how people combine the beliefs to form an attitude (McGuire, 1960b; Wyer, 1970). This issue is central to the expectancy-value models of attitudes, such as the theory of reasoned action (Ajzen & Fishbein, 1980). This perspective proposes that an attitude is the *sum* of all the evaluative beliefs regarding the attitude object. For instance, if people believe that a new snack product is healthy and good tasting, they should hold a positive attitude toward it. Nevertheless, beliefs are rarely held with perfect certainty. For example, a person may be only 70% certain that the snack is healthy but 100% certain that it is good tasting. According to the expectancy-value model, the effect of each belief is a function of the certainty with which it is held. This notion is expressed using a well-known formula: $A = \Sigma b_i e_i$, where A is the total attitude toward the attitude object, b_i is the subjective belief that the object possesses attribute i (e.g., the probability that the snack is healthy) and e_i is the evaluation of attribute i (e.g., the positive value attached to health promotion).

Research has examined the utility of the three-component and expectancy-value models in different ways but has obtained support for both approaches. With regard to the expectancy-value approach, evidence indicates that people's reports of their own attitudes are at least moderately correlated with the summed products of the attitude-relevant expectancies and values (Bagozzi, 1981; Budd, 1986; van der Pligt & de Vries, 1998), although there have been statistical and methodological criticisms of these findings (Sparks, Hedderley, & Shepherd, 1991). In addition, it is clear that persuasive messages influence evaluative beliefs and that these beliefs influence attitudes when people are motivated and able to process persuasive messages in a systematic manner (Chaiken, Liberman, & Eagly, 1989; Petty & Cacioppo, 1986). With regard to the three-component model, evidence indicates that people's beliefs, feelings, and behaviors toward an attitude object are correlated but distinct (Breckler, 1984; Crites, Fabrigar, & Petty, 1994; Haddock & Zanna, 1998). There is also evidence that attitude-

relevant feelings and beliefs are clustered separately in memory (Trafimow & Sheeran, 1998) and that the affective and cognitive components each account for unique variance in attitudes (Breckler & Wiggins, 1989; Brinol, Petty, & Tormala, 2004; Crites et al., 1994; Trafimow & Sheeran, 1998).

The findings in support of the three-component model could be rebutted by the argument that affective reactions and past behaviors are simply different types of beliefs about the attitude objects. For example, people may form a positive attitude toward a snack that tastes good (an affective response) because, as the expectancy-value model proposes, people *believe* that the bar makes them happy and value their own happiness. Nevertheless, this "affective belief" is made salient only by considering the three-component model. Thus, the three-component model at least spurs the expectancy-value approach to consider different types of beliefs, which must be altered during the persuasion process.

Furthermore, as we shall see, there is evidence that appeals that are based on affective or cognitive information may be differentially effective at changing attitudes that are based primarily on affective information or cognitive information. Specifically, appeals can elicit more attitude change when they contain content that matches the content of the message recipient's attitude than when they contain content that mismatches the content of the attitude. For example, affective interventions influence affectively based attitudes more than cognitively based attitudes (Edwards & von Hippel, 1995; Fabrigar & Petty, 1999; Huskinson & Haddock, 2004). These effects form the basis for the third principle of persuasion that we describe below, while also providing further support for two components of the three-component model.

Attitude Structure

An important issue is how positive and negative evaluations are organized within and between components. The intuitive and most frequently assumed possibility is that the existence of positive feelings, beliefs, and behaviors inhibits the occurrence of negative feelings, beliefs, and behaviors. In other words, the positive and negative elements are stored in memory at opposite ends of a single dimension, and people tend to experience either end of the dimension or a location in between.

This one-dimensional view is opposed by a two-dimensional view, which suggests that positive and negative elements are stored along two separate dimensions (Cacioppo, Gardner, & Berntson, 1997; Thompson, Zanna, & Griffin, 1995). One dimension reflects whether people have few or many positive elements, and the other dimension reflects whether people have few or many negative elements. This view proposes that people can possess any combination of positivity or negativity in their attitudes. Consistent with the one-dimensional view, attitudes may subsume little positivity and high negativity, little negativity and high positivity, or no positivity or negativity (i.e., a neutral position). Inconsistent with the one-dimensional view, attitudes might occasionally subsume high amounts of positivity

and negativity, leading to attitudinal ambivalence. The bidimensional perspective explicitly allows for this ambivalence to occur, whereas the one-dimensional perspective does not. As a result, the bidimensional perspective challenges the meaning of the neutral point in one-dimensional scales for assessing attitudes (Kaplan, 1972). In these scales, a neutral response (e.g., neither like nor dislike) is halfway between the most extreme positive response option (e.g., "extremely likable") and the most extreme negative response option (e.g., "extremely dislikable"). People could choose this option because it is a compromise between many positive and negative elements of their attitude or because they have no positive or negative elements whatsoever.

This failure to distinguish between these two reasons for the neutral selection is consequential, because measures that directly assess ambivalence predict a variety of outcomes. The best known outcome is response polarization (Bell & Esses, 2002; Katz & Hass, 1988; MacDonald & Zanna, 1998): People who are highly ambivalent toward an object are more strongly influenced by features of their environment that make salient its positive or negative attributes, causing them to behave more favorably toward it when the positive elements are salient than when the negative elements are salient; nonambivalent people are less strongly influenced by the acute salience of the positive or negative attributes. More relevant to this chapter, ambivalence predicts attitude change, because ambivalent attitudes tend to elicit more message scrutiny (Jonas et al., 1997; Maio et al., 1996). Hence, ambivalent people exhibit more favorable attitudes in response to strongly argued messages than in response to weakly argued messages, whereas nonambivalent participants show little sensitivity to argument strength. Thus, ambivalence may enhance the motivation and ability to carefully consider the merits of persuasive information, causing more relevant information to be relied on more than less relevant information.

Ambivalence is therefore one of many variables that is relevant to another basic principle of persuasion that we describe next. This principle describes a tendency for the motivation to be correct to elicit greater use of relevant information in the persuasion context. Indeed, there is evidence that people who tend to experience ambivalence are more likely to fear invalidity in their judgments (Thompson & Zanna, 1995). Moreover, it is possible that ambivalence is relevant to the matching principle mentioned previously. That is, ambivalent individuals may be more persuaded by messages that recognize their ambivalence by presenting both sides of the arguments than by one-sided messages, whereas nonambivalent individuals may be more persuaded by one-sided messages than by two-sided messages. At present, however, we know of no evidence directly examining this hypothesis.

Attitude Function

Theorists have proposed that attitudes fulfill a variety of psychological needs or functions (Katz, 1960; Smith, Bruner, & White, 1956). Smith and colleagues' (1956) object-appraisal function is often considered the most ba-

sic motive served by attitudes: All attitudes serve to simplify reasoning and behavior by providing guides for how to interact with (e.g., approach or avoid) an attitude object. This function is served by any attitude that is easy to retrieve from memory. Consider a person whose attitude toward eating chocolate is strong and easy to retrieve. This person should have an easier time deciding whether to purchase a bar of chocolate than a person who has only a weak attitude toward chocolate (Fazio, 2000). Indeed, people spontaneously devote greater attention to objects of their more accessible attitudes (Fazio, Blascovich, & Driscoll, 1992), and they exhibit lower physiological arousal when making decisions about the objects of these attitudes (Blascovich et al., 1993). This spontaneous devotion of attention and low physiological arousal may help to make it easier to make decisions regarding the attitude object.

A second basic function of attitudes may be that they help people to experience emotions (Maio & Esses, 2001). Emotions themselves serve basic psychological needs (Damasio, 1994; Zajonc, 1980), and, as a result, people *seek* emotional experiences, even when the experiences are unpleasant (e.g., scary or sad films). One way of experiencing these emotions is through the possession and expression of strong positive or negative attitudes. For example, people might fulfill their need for affect by developing a strong hatred or affection for members of another ethnic group. Supporting this hypothesis, people who score high on an individual difference measure of the need for affect indicate more extreme attitudes across a variety of topics than people who are low in the need (Maio & Esses, 2001). Also, as we describe later, there is evidence linking this motive to individual differences in attitude structure and attitude change.

Both the object appraisal and the need for affect motivations are purported to influence the tendency to form attitudes in the first place, regardless of whether the attitudes are positive or negative. Other functions are used to predict when attitudes will be positive or negative. For instance, the utilitarian function of attitudes causes people to dislike things that are harmful to them and like things that are beneficial (Herek, 1986; Katz, 1960; Shavitt, 1989); the social-adjustive function causes people to like attitude objects (e.g., fashionable clothes) that are popular among people whom they admire and dislike attitude objects that are unpopular (DeBono, 2000; Smith et al., 1956); the value-expressive function causes people to favor objects that promote their personal values (e.g., the Socialist party), while disliking objects that threaten their values (Katz, 1960; Maio & Olson, 1995a, 1995b, 2000a, 2000b); the ego-defensive function causes people to like objects that promote their self-esteem and reject objects that threaten the self (Katz, 1960).

These functions do not constitute the full list of potential needs served by attitudes or the needs served by attitude objects themselves (Kruglanski & Stroebe, 2005). Additional attitude functions could be derived from findings within and outside social psychological research. Within this research domain, it has been found that people attempt to form attitudes that are consistent with their attitude-relevant beliefs and behaviors, because inconsistencies elicit an aversive arousal or "dissonance" (Festinger, 1957; Harmon-Jones & Mills, 1999). Perhaps, then, the maximization of consistency is a basic function of attitudes (Cialdini, Trost, & Newsom, 1995). A similar case can be made for the idea that attitudes can be used to protect oneself from feelings of mortality (Greenberg, Solomon, & Pyszczynski, 1997). Outside of social psychological research, many basic human motivations have been postulated, including some that are similar to the aforementioned attitude functions (Murray, 1938). For example, Murray suggested that there is a motivation to attain recognition, which is similar to the social-adjustment function. He also proposed other motivations that are not apparent in theories of attitude function, such as the motivation to dominate others. His account is particularly important because the motivations postulated by Murray map on to the so-called five basic dimensions of personality: neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness (McCrae & John, 1992; Paunonen & Jackson, 1996; Piedmont, McCrae, & Costa, 1992). One could therefore argue that Murray's motivations should be used to further develop the list of potential and distinct attitude functions.

As with attitude content and structure, there are strong ramifications of attitude function for understanding the process of persuasion. As we describe later, a classic theory of persuasion proposed that messages are successful only insofar as they yield reinforcements for the individual (Hovland, Janis, & Kelley, 1953). Theories of attitude function complemented this view by suggesting that messages would be most effective when they addressed needs that are most important to the message recipients' attitudes—messages that address irrelevant needs would not really be reinforcing to the individual (Katz, 1960; Smith et al., 1956). Thus, similar to attitude content and structure, attitude function may serve as a basis for predicting the effects of messages that vary in their content, again supporting the matching principle.

Integrating the Role of Attitude Content, Structure, and Function

The similar potential roles of attitude content, structure, and function as determinants of the effects of message content illustrate how it would be a mistake to regard them as isolated entities. In a discussion of attitude theory, we have argued that attitude content, structure, and function are like three witches who make a better brew together than alone (Maio & Haddock, 2004). In areas of scientific exploration outside psychology (e.g., chemistry and physics), it is a virtual fact of life that the nature, structure, and function of physical entities are inextricably intertwined and mutually influential. In the attitudes literature, attitude content, structure, and function are intertwined. For example, the affective, cognitive, and behavioral components of attitudes may each express varying levels of positivity or negativity. Each feeling, belief, or behavior could subsume one-dimensional evaluations (i.e., negative to positive), but the resultant attitude

that integrates these may be one- or two-dimensional. Alternatively, it is conceivable that each feeling, belief, and behavior can subsume some degree of positivity *and* negativity (i.e., possess two-dimensionality), as is proposed in some research on emotion (Watson, Wiese, Vaidya, & Tellegen, 1999) and motivated behavior (Elliot & Harackiewicz, 1996). The net attitude might retain this two-dimensionality or not. Indeed, it has been proposed that attitudes may be two-dimensional at deep nonconscious levels of cognitive responding to objects, while being one-dimensional at higher levels that demand integration of the positive and negative elements (Cacioppo et al., 1997).

In addition, although it is possible to partly disentangle the effects of content and function (Maio & Olson, 2000a; Marsh & Julka, 2000; Murray, Haddock, & Zanna, 1996), it is apparent that they are often related. For example, if attitudes toward a brand of automobile are based on a need to conserve fuel, then these attitudes should be based on beliefs about the extent to which the car obtains good fuel economy. Similarly, if attitudes toward a style of clothing fulfill a psychological need to enhance social relations, then these attitudes should be based on beliefs about the extent to which the style is preferred among one's friends. These examples illustrate how attitudes that serve different functions should often differ in the content of the beliefs that support them. An additional consideration is that attitude content, structure, and function may interact (Carstensen, Isaacowitz, & Charles, 1999; Kempf, 1999; Maio & Haddock, 2004). For example, affective reactions may be stronger predictors of attitude when the attitude object has a hedonic purpose than when the object has a utilitarian purpose (Kempf, 1999). Full empirical description of these interactions remains an important topic for future research.

MODELS OF ATTITUDE CHANGE

Now that we have discussed what attitudes are and what they do, the foundation is in place to consider the manner in which attitudes change. Most of the research on this issue has examined attitude change in a somewhat indirect way, by examining the effects of diverse variables on the attitudes that people form about novel issues (e.g., comprehensive exams) or objects (telephone answering machines). This focus on novel attitude objects leaves a lot of research on "attitude change" open to the criticism that it is actually examining "attitude formation" or, at best, "attitude change" for weakly held attitudes. Notwithstanding this concern, the extant research is well summarized by six models that retain an emphasis on understanding attitude change: The Yale model of persuasion (Hovland et al., 1953), the information-processing paradigm (McGuire, 1968), the social judgment model (Sherif, 1980; Sherif & Sherif, 1967), the elaboration likelihood model (Petty & Cacioppo, 1986), the heuristic–systematic model (Chaiken et al., 1989), the unimodel (Kruglanski, Fishbach, Erb, Pierro, & Mannetti, 2004), and the cognition-in-persuasion model (Albarracin, 2002). This section briefly describes each model and

foreshadows the principles of attitude formation and change revealed within them.

Yale Model of Persuasion

After conducting seminal research on the effects of war propaganda in World War II (Hovland, Lumsdaine, & Sheffield, 1949) , Carl Hovland and his colleagues established the Yale Communication Research Program. This program initiated a systematic and empirical dissection of the factors that influence the success of persuasive messages. The program's researchers focused on three factors identified by Lasswell's (1948) famous statement that, to understand the effect of a communication, one must know "*Who* says *what* in which channel to *whom* with *what effect*" (emphasis added; p. 37); in other words, one must know the source of the message, the audience of the message, and the message itself. Their classic monograph, "Communication and Persuasion" (Hovland et al., 1953), was organized around various source, message, and audience variables. Their analysis included effects of source credibility, message threat, and audience personality on the attitudes targeted in the messages and relevant behaviors, while examining different dependent variables across studies (addressing the "what effect" issue in Lasswell's statement).

In addition, the group proposed that successful persuasion requires a sequence of events. Processing begins with attention to the message, leading to comprehension of the message and subsequent acceptance or rejection of it (Hovland et al., 1953). In theory, each persuasion variable could affect each of these processing stages. For example, people who are in a negative mood might be less likely to pay attention to a message, while being too distracted to comprehend it fully and too grumpy to agree with it. Thus, a complete understanding of the effects of a persuasive variable entails analysis of its effects on each processing stage.

Despite the importance of all these stages, the process of message acceptance has garnered the most empirical research from the Yale researchers and investigators of subsequent models. The Yale researchers proposed that message acceptance would be more likely when the audience silently rehearses the message arguments together with their initial attitude and the recommended attitudinal response. In this manner, the message content becomes associated in memory with the new and old attitude. After this double association is in place, the critical issue of interest is whether people choose to accept the new attitude over the old attitude.

To adopt the new attitude, an individual must anticipate receiving some reinforcement or incentive for attitude change. The incentive could be the presentation of a positive reinforcement (i.e., reward) or a negative reinforcement (i.e., the removal of something unpleasant). Either way, the incentive would address an important motive or function that is served by the individual's attitude. For example, a message that induces fear (e.g., about the effects of drunk driving) might motivate people to agree with the message in order to avoid suffering the cited negative consequences (a utilitarian function).

In addition, a persuasive message may heighten people's motivation to agree with others in order to smooth their social relations with them (social adjustment function). Also, agreement with an expert source may be a good means to satisfy the need to form correct and accurate knowledge (knowledge function).

The group conducted many studies that provided some support for their predictions. For example, they found that the inclusion of fear-eliciting stimuli in a message increases acceptance of the message, as long as the stimuli are not so fear inducing that they divert people's attention from the recommendations in the message (Janis & Feshbach, 1953). In addition, participants who scored high on a personality measure of social inadequacy showed more evidence of agreement with persuasive messages (Janis, 1954). Also, Hovland and Weiss (1951) found that participants evaluated articles from high-credibility sources (e.g., a reputable journal) more favorably than articles from low-credibility sources (e.g., a politically biased columnist) across several topics (e.g., atomic submarines and steel shortage). In these studies, the evidence was consistent with the notion that message acceptance is a function of the reinforcements that are elicited by message sources, message content, and the message recipients. It is also plausible that these reinforcements helped to satisfy motivations that were important functions of participants' prior attitudes rather than to address unimportant functions. Insofar as this assumption is correct, the Yale evidence can be construed as partial support for the matching principle mentioned earlier.

Subsequent investigations have greatly expanded the examination of source, message, and audience variables. One prominent area of expansion has focused on the link between the message source and important social groups, such as whether the source is a member of a minority or majority opinion groups. Despite initial classic observations of strong persuasion from members of majority groups (Asch, 1956), there is also evidence that minorities can have a significant impact on attitudes (Moscovici, 1980), and it is now clear that either source can elicit stronger persuasion and that majorities and minorities can trigger the same or different methods of message processing (Baker & Petty, 1994; Kruglanski & Mackie, 1991; Martin, 1998). This evidence fits data indicating that the effects of many persuasion variables (e.g., communicator credibility and communicator attractiveness) and message acceptance can be null or even reversed in different circumstances (Petty & Cacioppo, 1981). Such patterns call into question the Yale group's assumptions about the reinforcement-based learning mechanisms that elicit persuasion and, as described later, led to the creation of models that scrutinized the role of cognitions during message processing.

The Information-Processing Paradigm

One key element of the Yale group's model was the idea that there is a sequence of events from message attention to message comprehension and, finally, message acceptance. Yet, the implications of this sequence were not fully laid out and tested until McGuire's (1968) information-processing model. He suggested six core message processing states, which occur in the following order: presentation of the message, attention to the message, comprehension of the message, yielding to the argument, retention of the changed attitude in memory, and behavior relevant to the attitude. He later proposed that this model could include additional steps, such as two steps between retention of an attitude and behavior: the retrieval of an attitude from memory and the integration of this attitude with other relevant information (e.g., situational demands).

The important point of this sequential analysis is not how many specific stages exist; it is the idea that there are many steps at which the whole process can come to a halt. A behavior change can occur only through the completion of all the prior stages. This task looks challenging when expressed in terms of probabilities. If one assumes that there is a .70 chance of each stage occurring, the odds of passing through all the stages to the decision whether to perform a relevant behavior are $.70^5 = .17$. If you add to this process just two of the other stages indicated by McGuire (e.g., retrieval and integration), then attitude change becomes an even more daunting exercise, $.70^7 = .08$.

The second important feature of McGuire's (1968) model is that variables may have different effects on different stages during message processing. (Later, we will see how more recent models have further incorporated this notion that a single variable can act in different ways during the persuasion process.) This differential influence is most easily viewed by considering McGuire's simplified presentation of his model, which focuses on two stages. The first broad stage is reception, which occurs when people have attended to the message and understood it. The second stage, yielding, involves agreeing with the message content. According to McGuire, the impact of a message should be greatest when the separate probabilities of message reception and yielding are high:

$$p(I) = p(R) \times p(Y)$$

where $p(I)$ is the probability that the message exerts the desired influence, $p(R)$ is the probability of message reception, and $p(Y)$ is the probability of yielding to the message after it reception. An important caveat to this equation is that variables may have different influences on the processing stages, causing one probability to be high while the other is low. For example, intelligent audiences should be more likely to complete message reception than less intelligent audiences, but intelligent audiences might also be less likely to yield to the message after it is understood. Thus, intelligence might increase $p(R)$, but lower $p(Y)$. These opposite effects would lead to a curvilinear effect of audience intelligence. Intelligence would increase the impact of a message as intelligence changes from low to moderate levels, but intelligence would decrease the impact of a message as intelligence changes from moderate to high levels. McGuire also predicted that the precise shape of the curve would vary across contexts. For example, complex

messages increase the importance of reception, because many people will find it difficult to understand the message. For such messages, the positive impact of intelligence on reception may be more important than its negative impact on yielding.

These insights provided a valuable extension of the Yale model's simpler predictions about the effects of persuasion variables on different processing stages. McGuire's (1968) model drew more attention to this idea and provided a method for predicting the outcome of the distinct effects on the various processing stages. Nonetheless, applications of this model have received mixed support. Most tests have examined his specific predictions regarding the effects of audience intelligence and self-esteem on receptiveness to persuasive messages, and a recent meta-analysis of these studies (Rhodes & Wood, 1992) found evidence consistent with the hypothesis that high self-esteem increases reception (by enhancing comprehension) but decreases yielding (by enhancing skepticism). (Insufficient evidence existed to yield strong conclusions about intelligence.) There is also evidence that people can skip processing stages or use them in different order. For example, message recipients sometimes appear to pay little attention to message content and simply yield or not based on some salient aspect of the communicator, such as his or her expertise (Chaiken, 1980; Petty, Cacioppo, & Goldman, 1981). On other occasions, people are aware of and initially reject the conclusion of a message and then give the message greater scrutiny to defend their position (Edwards & Smith, 1996).

Of particular relevance is evidence of an automatic link between the comprehension phase and yielding. Some studies indicate that the mere comprehension of a false statement can be sufficient to elicit instantaneous belief in its validity, and this belief is later corrected only after further deliberate thinking (Gilbert, Tafarodi, & Malone, 1993). The idea is that the initial statements serve as anchors for our judgments, and we adjust belief in them up or down depending on the results of further processing (Tversky & Kahneman, 1974). Abundant social cognition research has made clear that people frequently take shortcuts to conclusions rather than exhaustively considering evidence beforehand (Fiske & Taylor, 1991). In addition, as we describe later, there is evidence that attitudes can be shaped outside conscious awareness, which raises questions about the necessity of many of the processing phases (e.g., attention and comprehension) and the levels of consciousness at which they occur. Thus, other models of persuasion have focused on describing shortcuts that appear to bypass some of the processing stages and on discovering when people use shortcuts instead of the more elaborate, sequential routes.

Social Judgment Model

The social judgment model was among the first to focus on a shortcut to persuasion (Sherif, 1980; Sherif & Sherif, 1967; Sherif, Sherif, & Nebergall, 1965). This model proposed that a quick and automatic perceptual mechanism of assimilation versus contrast affects the manner in which people react to message arguments. In this mechanism, message arguments are automatically compared with recipients' prior attitude, and their prior attitude can encompass a range of positions. This range of positions is tapped by three "latitudes." The latitude of acceptance encompasses the range of positions that a person accepts; the latitude of rejection encompasses the range of positions that a person rejects; the latitude of noncomittment encompasses the range of positions that a person neither accepts nor rejects. These latitudes are important because the social judgment model posits that message positions within the latitude of acceptance are perceived differently from message positions within the latitude of rejection. A message position that falls within the latitude of acceptance seems closer to the message recipient's attitudes than it actually is (assimilation), whereas a message position that falls within the latitude of rejection seems more distant from the recipients' attitude than it actually is (contrast). As a result, the model proposes that message recipients' attitudes move toward the message position when the position is within or close to the audience's latitude of acceptance. In contrast, little attitude change, or even reverse attitude change, can occur when the message position is in the latitude of rejection. In both instances, it is conceivable that the process of attitude change itself is very deliberate and thoughtful, but its direction is determined by the automatic perceptual shift in judgment of the message.

The model also proposes that wide latitudes of rejection and narrow latitudes of acceptance are likely to arise when people perceive the issue to be highly relevant to their self-concept or ego, which includes the cherished aspects of the self (Sherif et al., 1965). This self- or ego involvement (Sherif et al., 1965) has been labeled "value-relevant involvement" by other researchers (Johnson & Eagly, 1989; Maio & Olson, 1995a) because the social judgment model focuses on cherished aspects of the self that closely resemble social values, which are abstract ideals that serve as important guiding principles (Maio & Olson, 1998; Rokeach, 1973; Schwartz, 1992). Many empirical examinations of the model have tested whether higher levels of such ego or value involvement are associated with more message rejection (Hovland, Harvey, & Sherif, 1957; Johnson, Lin, Symons, Campbell, & Ekstein, 1995; Maio & Olson, 1995a; Ostrom & Brock, 1968), and reviews of this research have concluded that message recipients with high involvement exhibit greater resistance to message-based attitude change than those with low involvement (Johnson & Eagly, 1989; Sherif et al., 1965).

It is nonetheless unclear whether these effects occur because of assimilation and contrast mechanisms. Direct tests of the assimilation and contrast mechanisms have failed to support the model (Eagly & Telaak, 1972). It is possible that the effects of involvement occur because ego/value involvement causes message recipients to be more confident and certain about their attitude position (Eagly & Telaak, 1972; Hovland et al., 1957). Alternatively, ego/value involvement may reflect the presence of stronger ties between the recipients' attitudes and

other attitudes or beliefs (Krosnick, Boninger, Chuang, Berent, & Carnot, 1993).

Although these alternate mechanisms may explain the effects of ego/value involvement, it would be a mistake to consider these alternate explanations as evidence that assimilation and contrast play no role in the persuasion context. Assimilation and contrast processes in evaluative processes have been repeatedly demonstrated, particularly in examinations of the processes by which people form judgments of others (Abele & Petzold, 1998; Judd, Kenny, & Krosnick, 1983; Mussweiler, 2003; Schwarz & Bless, 1992; Stapel & Winkielman, 1998). What remains to be seen is how and when these processes occur in a persuasion context. For a message position to be assimilated or contrasted to attitudes, people have to be aware of the position, and this awareness often occurs only after people have at least partly considered the source, content, and context of the message. As a result, people might be influenced by these features (e.g., source attractiveness and logical coherence) prior to having completely inferred the message position. Thus, it is possible that the operation of assimilation and contrast is dependent on other factors in the persuasion context.

In fact, every subsequent model of persuasion has focused on one potentially important feature of the persuasion context: people's cognitive responses to the message content. This trend began with the insight that people might react differently to the same message content and that people's idiosyncratic cognitive responses could predict agreement with the message more strongly than qualities of the message itself (Greenwald, 1968). Many subsequent studies tested this prediction by including measures that asked people to indicate their thoughts about the presented message, after having read it, and the results frequently revealed that people who listed more favorable cognitive responses expressed more agreement with the message (Brock, 1967; Osterhouse & Brock, 1970; Petty, Wells, & Brock, 1976). Other studies have found that a direct manipulation of message-relevant thoughts predicts postmessage attitudes, supporting the notion that these thoughts play a causal role in the persuasion process (Killeya & Johnson, 1998). Thus, although the social judgment model introduced important ideas about the potential operation of quick perceptual processes of assimilation and contrast, later evidence indicated that cognitive responses to persuasive messages may be at least as important.

Elaboration Likelihood Model

The elaboration likelihood (ELM) model built on the previous research by proposing that there are times when attitude change occurs through shortcut, quick routes and times when attitude change occurs through more elaborate, cognitive processing (Petty & Cacioppo, 1986; Petty & Wegener, 1999). The former, *peripheral* route includes a number of potential antecedents of persuasion (Petty & Cacioppo, 1986; Petty & Wegener, 1999). For example, people might agree with a message because the communicator appears trustworthy (Petty et al., 1981). They might also be influenced by simple affec-

tive cues that are present in the message, such as physically attractive models (Chaiken, 1979). In addition, the length of the message and the number of its arguments can determine message acceptance, such that people agree with the longer messages that contain more arguments (Petty & Cacioppo, 1984). The common feature of all the peripheral processes is that people do not need to process the message carefully in order to reach their postmessage attitude. They can base their attitude on an easy-to-recognize aspect of the source, message, or context, without further reflection.

In the more elaborate, *central* route, persuasion occurs through its impact on cognitive responses to the message content (Petty & Cacioppo, 1986; Petty & Wegener, 1999). Strong arguments in the message should elicit favorable cognitive responses, whereas weak arguments in the message should elicit unfavorable cognitive responses. These cognitive responses, in turn, should shape subsequent attitudes, such that the attitudes are more favorable when the cognitive responses are more positive. Moreover, the bases of the postmessage attitude in elaborate cognitive responses should make them stronger than if the attitudes would have been formed through the peripheral route, because associations with cognitive support helps attitudes withstand persuasive attack and predict behavior.

According to this model, people are likely to use the peripheral route when their motivation and ability to process are low, while using the central route when their motivation and ability are high. Many factors can influence motivation and ability. For example, motivation can be high when the message appears highly relevant to personal goals (Petty & Cacioppo, 1984) or the message recipient has a dispositional inclination to engage in and enjoy effortful thinking (Cacioppo, Petty, Feinstein, & Jarvis, 1996). Ability can be high when people possess sufficient knowledge to understand the message (Wood, Kallgren, & Preisler, 1985) and are not suffering from distractions (Petty et al., 1976). Using such factors to manipulate motivation and ability, research has found that manipulations of argument strength have more impact on attitudes when the motivation and ability to process the message are high than when they are low, whereas manipulations of peripheral cues (e.g., source attractiveness) have more impact on attitudes when motivation and ability are low (Chen & Chaiken, 1999; Eagly & Chaiken, 1993; Perloff, 2003; Petty & Wegener, 1998a). These results foreshadow the second principle that we describe later, which refers to people's ability to more greatly weigh highly relevant persuasive information (e.g., cogent arguments) over less relevant persuasive information (e.g., source attractiveness) when motivation and ability to form correct judgments is high. In addition, as the model predicts, postmessage attitudes are more stable and predictive of behavior when they are formed through the central route than when they are formed through the peripheral route (Petty, Haugtvedt, & Smith, 1995).

Although the central route appears to involve more detailed message processing and create stronger attitudes, an interesting issue is whether these attitudes are equally

responsive to weaknesses and strengths in the message. The ELM proposes that people are generally responsive to both the strengths and weaknesses of a message, but people can also weight the strengths or weaknesses more strongly when any of several "biasing" factors are present. For instance, individuals may possess prior knowledge that causes them to endorse either the strengths or weaknesses more strongly (Wood et al., 1985). Thus, although message processing is generally directed at objectively attaining a valid attitude, the ELM acknowledges that processing can be biased by other factors in the persuasion context.

Without doubt the strongest aspect of the ELM is its use of motivation and ability as determinants of the way in which people process persuasive messages. This approach is strong partly because it overlaps with abundant evidence of differences between shallow, quick processing and deeper, elaborate processing in the literature on basic cognitive processes (Craik & Lockhart, 1972; Moscowitz, Skurnik, & Galinsky, 1999). Moreover, like McGuire's information-processing paradigm, the ELM permits multiple roles for variables in the persuasion context. For example, source expertise usually acts as a peripheral cue but can also act as an argument for the validity of a message (Heesacker, Petty, & Cacioppo, 1983). However, it is worth considering that the model itself does not specify which role each persuasion variable should assume, which is an interesting and important issue for attitude change practitioners.

Heuristic–Systematic Model

The heuristic–systematic model (Chaiken et al., 1989; Chen & Chaiken, 1999) shares the ELM's emphasis on motivation and ability as determinants of the depth of message processing. Like the ELM, the heuristic–systematic model proposes that people expend more effort to assess the quality of message arguments when the motivation and ability to process the message are high than when they are low, and this type of processing is labeled "systematic." In addition, the heuristic–systemic model predicts that people will be more likely to utilize simple persuasive cues, or *heuristics*, when the motivation and ability to process a message are low (Chaiken, 1987). Thus, both models share an emphasis on two distinctly different routes to persuasion and are consistent with the notion that people will be more greatly affected by less relevant persuasive information when their motivation and ability to be correct is low rather than high.

Key differences begin in their lower processing routes. The heuristic route does not encompass the range of influences described in the ELM, such as affective mechanisms of association. Instead, the heuristic route includes only simple "if–then" decision guides as determinants of persuasion. For instance, "if a communicator is an expert, then he or she is likely to be correct" is a decision heuristic (or shortcut) that message recipients could use to accept or reject a message without further processing. It is possible that at least some of the processes covered in the ELM could be conceived of as heuristics. For example, some affective mechanisms of influence could be explained by a straightforward heuristic: "if I feel good while listening to a message, then it must be correct." The limits of the heuristic mechanisms in the lower processing route have yet to be fully delineated.

The models also differ in their assumptions about the compatibility between the lower and higher processing routes. The heuristic–systematic model proposes that the systematic route can co-occur with heuristic processing when the systematic route is insufficient to reach a confidently held attitude. In contrast, stronger activity through the ELM's central route is supposed to suppress activity in the peripheral route, although both routes can be used simultaneously at moderate levels of motivation and ability and cues within the peripheral route (e.g., mood) can often act as arguments within the central route (Petty & Wegener, 1998a, 1999). Consistent with the heuristic–systematic model, there is evidence that enhancements of the motivation to process a message also lead to increased use of source credibility information when the message arguments conflict and are incapable of supporting a strong conclusion (Maheswaran & Chaiken, 1994), suggesting that use of cues is not excluded by higher levels of message processing. (Recall, however, that source credibility information could be regarded as a persuasive argument within the central processing route of the ELM, although source credibility is usually treated as a peripheral cue.)

Finally, the models differ in their assumptions about people's goals during message processing. The ELM and the heuristic–systematic model both propose that people focus on attaining a valid and correct attitude, but the heuristic–systematic model proposes that people are also motivated by the desire to project a desirable impression to others and by the desire to protect their values and self-concept. The model proposes that the latter two motives should elicit somewhat more biased processing than the accuracy motive, and this hypothesis has been supported by a meta-analysis of past studies and by several experiments (Johnson & Eagly, 1989; Johnson et al., 1995; Maio & Olson, 1995a). In addition, this multiple motive approach better fits abundant theory and research suggesting that social behavior and judgment in general tend to serve multiple motives (Chaiken, Duckworth, & Darke, 1999; Katz, 1960; Maio & Olson, 2000a; Smith et al., 1956). Awareness of these multiple motives is important because the more specific motive to be correct may elicit the most differential use of relevant and irrelevant persuasive information.

Unimodel

Despite the differences between the ELM and the heuristic–systematic model, they share an emphasis on the notion that message processing is affected by motivation and ability to consider the information that is relevant to the judgment at hand. The unimodel of persuasion (Thompson, Kruglanski, & Spiegel, 2000) shares many of the dual-process models' assumptions about the roles of motivation and ability. As in the dual-process models, the unimodel proposes that increases in motiva-

tion and ability to reach a correct judgment enhance the scrutiny of presented information. With a few possible exceptions (Kruglanski & Thompson, 1999), the factors that affect motivation and ability are similar to those examined in the dual-process models of persuasion (e.g., personal relevance and distraction).

The model's unique attributes stem from its use of lay epistemic theory (Kruglanski, 1989) to add three important stipulations about the processing of information in persuasion contexts. The first stipulation is that *any* information that is relevant to the persuasive conclusion can be considered persuasive evidence (Kruglanski & Thompson, 1999). This relevant evidence can go beyond the message content to include information about the source and context. The unimodel proposes that such information might receive high or low processing and does not distinguish between extramessage information (e.g., source expertise) and message arguments. It indicates that prior evidence of differences in the effects of extramessage cues and message arguments have been confounded by differences in levels of processing difficulty. Specifically, the typical research presents the extramessage information briefly and early in the messages, whereas the message arguments were longer, more complex, and later in the message. As a result, the extramessage cues did not require higher levels of processing motivation and cognitive capacity to affect attitudes, whereas the message arguments did require higher levels of motivation and ability. When extramessage information is allowed to be higher in processing complexity (e.g., by presenting source expertise through a lengthy vita at the end of a message), it can act in the same way as message arguments. In contrast, research on the ELM and the heuristic–systematic model has largely confined source and context information to their lower processing routes, although each model notes exceptions in principle to this confinement (Chaiken et al., 1999; Petty, Wheeler, & Bizer, 1999b).

These exceptions often involve instances wherein the extramessage information is considered to be relevant to the conclusion by the message recipient. For example, the attractiveness of a spokesmodel's hair is relevant to her claims about the shampoo she promotes. This *subjective* judgment of relevance is the unimodel's second unique stipulation and its cornerstone (Kruglanski et al., 2004; Kruglanski & Thompson, 1999). The unimodel proposes that persuasion involves a single process of hypothesis testing and inference, during which people attempt to weight the relevant information more strongly than the less relevant information. Any information that has subjective relevance to the conclusion is considered more deeply when the motivation and ability to process this information is high, which applies also to broader classes of situations wherein people form subjective judgments (e.g., impressions of others and self-assessment). This emphasis on the differential use of relevant and irrelevant information is again supportive of the second principle of persuasion, which we describe next.

The third stipulation is that this deeper consideration of relevant information also depends on the structuring of the message. According to the model, earlier information affects the processing and construal of later information. By virtue of occurring earlier, information that is presented first should be easier to process than information that is late in a message. As a result, manipulations of motivation (e.g., personal relevance and accountability) and ability (e.g., distraction) should have an impact on the use of relevant information more strongly when it is presented later in a message sequence. Several experiments have supported this prediction (Pierro, Mannetti, Kruglanski, & Sleeth-Keppler, 2004).

Cognition-in-Persuasion Model

Similar to the unimodel, the cognition-in-persuasion model (Albarracin, 2002) builds on the assumption that motivation and ability affect message processing, while reintroducing the notion of processing sequence. In this model, message recipients' reaction to a message begins with their interpretation of the message and any other information (e.g., source characteristics and own affect) that is available at the time. Recipients retrieve prior knowledge from memory to help evaluate the message, and then they identify and select information to serve as the basis for their final attitude and subsequent behavior. Any of these processing stages can be disrupted by reductions in the motivation and ability to process the information available. Moreover, unlike earlier stage models (McGuire, 1968), message processing can occasionally bypass early stages, perhaps creating more stable attitude change (Albarracin, 2002).

The separate analysis of information identification, retrieval, and selection has interesting implications for the use of relevant information (e.g., message arguments) and irrelevant information (e.g., mood) in the model (Albarracin & Kumkale, 2003). According to the model, decreases in motivation and ability should gradually decrease the use of message arguments, because people attempt to use them but simply fail to process them fully. In contrast, the impact of irrelevant information depends on it being identified (or noticed) and then selected (or utilized). As a result, there should be a curvilinear impact of irrelevant information on attitude change: Irrelevant information should be used when people are sufficiently motivated and able to identify it but insufficiently motivated and able to go a step further and recognize its irrelevance. There should be no impact of the irrelevant information when motivation and ability are lower (thereby permitting its identification) or higher (thereby permitting recognition of irrelevance) than this moderate level. Of interest, the potential null role of less relevant information at low levels of motivation and ability acts as an important caveat to the notion that this information is used at lower levels of motivation and ability than at higher levels of motivation and ability (our second principle).

In addition, the model emphasizes a potential for effects of conflict within a message, similar to the heuristic–systematic model (Chaiken et al., 1989; Maheswaran & Chaiken, 1994). The cognition-in-persuasion model asserts that the detection of conflict triggers attempts at further analysis (during message

processing) and integration (postmessage processing). This proposal fits some evidence about the effects of conflicting information within a persuasion context (Baker & Petty, 1994; Jonas et al., 1997; Maheswaran & Chaiken, 1994) and is also relevant to the earlier discussion of attitude structure, because conflict within premessage attitudes can increase message scrutiny (Maio et al., 1996).

FOUR PRINCIPLES IN PERSUASION

Having considered the psychological nature of attitudes and models of how they change, we now turn to the challenge of articulating basic principles that are shared across the research and theory that we have identified. In this section, we present more detail about each of the four basic principles that we have highlighted throughout our review. We summarize arguments and evidence regarding these principles, and then, consistent with admonitions that every hypothesis is true in only a restricted set of conditions (McGuire, 1983), we outline potential caveats to each principle.

Extraneous Information Can Influence Persuasion

Although attitudes research has rightly focused on the fine-grained determination of the mechanisms through which variables influence attitudes, this mechanistic approach has often led to a focus on the trees at the expense of the wood. With at least one exception (Cialdini, 1993, 2001), persuasion researchers have underemphasized one of the most interesting and consistent findings in persuasion research: People are often persuaded by factors that they would not see as being logically relevant. The significance of this finding can be appreciated merely by attempting to explain persuasion research to a lay audience. Whenever we describe classic experiments to practitioners and our students, they are continually surprised by the range of *extraneous* variables that influence attitudes and often appear to disbelieve that these variables would actually influence *them*.

Nonetheless, one of the earliest empirical demonstrations of this principle tends to be the easiest for people to accept. Specifically, people can be more amenable to an argument when they are in a good mood than when they are in a bad mood (Razran, 1938, 1940). This effect of mood can be reversed (Wegener, Petty, & Klein, 1994), but this variance does not alter the fact that mood does indeed affect persuadability. Yet, if you were to ask someone whether it is a good thing that her judgment of someone's message is affected by her current mood, she would likely respond with concern. If, for example, a person agreed to buy a product partly because he or she was in a good mood, the person would be giving insufficient weight to factors that are actually far more relevant and important, such as the cost and utility of the product. Thus, even though this result probably confirms human intuition about persuasion, it is disturbing and robust enough to ask whether this finding is part of a larger phenomenon.

The extant literature reveals that mood is, indeed, only one of many extraneous variables that affect persuasion. Another important variable is prior commitment to a relevant attitude or behavior. For example, people may become favorable toward buying a product after being told that the product will feature certain desirable attributes (e.g., a high discount) and then remain favorable even after subsequently learning that the desirable attributes will not occur (Burger & Petty, 1981; Cialdini, 1993). People become somewhat obligated to the source of the message and bound to their initial attitude, even though it is not the attitude they would have formed with the correct information.

Whereas both mood and prior commitment are attributes of the message recipient, other extraneous variables are attributes of the source of a message or the message itself. For example, messages paired with likable (Chaiken, 1980), attractive (Chaiken, 1979), powerful (French & Raven, 1959), famous (Petty, Cacioppo, & Schumann, 1983), and ingroup sources (Whittler & Spira, 2002) tend to elicit more favorable attitudes, although these characteristics can also occasionally cause more negative attitudes (Petty, Fleming, & White, 1999; Roskos-Ewoldsen, Bichsel, & Hoffman, 2002). In addition, somewhat extraneous message variables include rate of speech (Smith & Shaffer, 1995; Woodall & Burgoon, 1984), humor (Conway & Dube, 2002), number of arguments (Petty & Cacioppo, 1984), citations of consensus (Darke et al., 1998), and framing of the attributes (Blanton, Stuart, & VandenEijnden, 2001).

Of course, these audience, source, and message variables can vary in the extent to which they are (1) irrelevant and extraneous to the veracity of the message and (2) cause attitude change. With regard to the degree of relevance to the message's validity, there are occasions when it is reasonable for someone to be more persuaded by an attractive source than by an unattractive source. For example, an advertisement for a brand of shampoo should be very unpersuasive from someone who has dull, lifeless hair, because, if the shampoo were really effective, the person advocating its use should have tried it and found it to be useful (Kahle & Homer, 1985). Similarly, rate of speech might be relevant if it is a useful cue to the spokesperson's credibility and expertise (Smith & Shaffer, 1995) and the framing of messages might be relevant to acute or chronic goals (Rothman & Salovey, 1997; Tykocinski, Higgins, & Chaiken, 1994). There may also be individual differences and cultural differences in what is regarded as relevant or diagnostic information (Cialdini, Wosinska, Barrett, Butner, & Gornik-Durose, 1999; Livingston, 2001).

When the information is believed to be irrelevant, however, its effects may diminish when it is followed by highly relevant information that people are motivated and able to process (Albarracin, 2002; Pierro et al., 2004). One potential reason for this effect is that people tend to accept arguments automatically, even when their validity is weak or obviously false (Gilbert et al., 1993). People who are motivated and able might then attempt to correct for the potential impact of the extraneous information on their attitudes and beliefs, but these at-

tempts at correction should depend on having awareness of the existence of a potential extraneous effect and a theory about its impact (Wegener & Petty, 1997, 2001). To this point, however, research has revealed comparatively little about when, where, and how we manifest awareness of extraneous influences and attempt to correct them. This neglect has occurred partly because we tend to assume that people possess little awareness of the influence of extraneous variables. Yet, people do have lay theories of persuasion that occasionally recognize the extraneous variables, such as mood (Friestad & Wright, 1999; Wilson & Brekke, 1994; Wilson, Houston, & Meyers, 1998). Now that the day-to-day impact of extraneous variables is clear, the next important question for research is what people can do to resist their influence and how lay theories play their part (Sagarin, Cialdini, Rice, & Serna, 2002).

Motivation and Ability to Form a Correct Attitude Increase the Impact of Relevant Information

One of the mechanisms for resisting the impact of extraneous variables involves increasing people's motivation and ability to consider deeply a persuasive message and its implications for their attitudes, as is suggested by most of the models of persuasion that we review. This deeper consideration of a message may cause the relevant information to override the impact of the irrelevant information, particularly when the relevant information is difficult to process (Pierro et al., 2004). In addition, this override effect should arise without any awareness or theories about the impact of the extraneous information, because the effect simply relies on a much greater weighting being accorded to the relevant information. More important, our foregoing review describes how numerous manipulations of motivation and ability increase the impact of relevant information on attitudes and notes that all the contemporary models agree about this potential effect of motivation and ability. Therefore, the tendency for motivation and ability to increase the use of relevant information is a viable candidate for our second principle of persuasion.

To make this principle most defensible, we explicitly focus on the motivation and ability to form a *correct* attitude. This focus on the pursuit of the correct attitude is important because manipulations of motivation can confound this goal with other goals, such as the goal to protect values or self-esteem. For example, it is often assumed that manipulations of the personal relevance of a topic increase the motivation to form a correct attitude, but they may also occasionally prime motives to protect existing values or attitudes (Johnson & Eagly, 1989; Maio & Olson, 1995a). An example is the frequently used topic of comprehensive examinations. Students who believe that the exams will take place during their degree should be more concerned about the issue than students who believe that the exams will not occur during their studies, so the timing of exam implementation is used to manipulate the personal relevance of messages favoring these exams in numerous studies. Nonetheless, a person who is used to thinking in terms of the costs and benefits of such

policies may be more interested in an accurate assessment of the impact of the exams than a person who is used to linking policies with personally cherished values (e.g., freedom and equality). As a result, the high "personal relevance" of taking the exams might motivate the former student to accurately assess messages on the topic, while motivating the latter student to reject the message with little thought because of a perceived threat to values (Maio & Olson, 1995a).

Given the widespread use of personal relevance to manipulate motivation in the persuasion context, it is important to note its ability to activate quite diverse motives. Any need that is strong and salient for the individual could be activated by personal relevance, and research on personality and social processes has identified a plethora of such needs (Murray, 1938). Personal relevance may have a particularly strong effect on some basic self-motives, including needs to protect self-esteem, assess the self accurately, verify self-conceptions, and improve the self (Sedikides & Strube, 1997). These self-motives help to illustrate the potentially diverse effects of personal relevance. In theory, needs for self-assessment and self-improvement should promote more objective processing, while self-verification might promote less effortful scans for confirming information. In contrast, the need to protect self-esteem might facilitate closer scrutiny of a personally relevant message but in a biased fashion. This can happen when, for example, people receive messages about personally relevant healthy behaviors (Liberman & Chaiken, 1992; Sherman, Nelson, & Steele, 2000). Thus, when using personal relevance to manipulate the motivation to form a correct attitude, researchers should ensure that the motives concerned with correctness and improvement are dominant. This goal can be achieved by verifying that effects of the manipulations are mediated by their effects on motives to be accurate, and there are extant measures that might be used as prototypes for the development of such tests (Kruglanski et al., 2000; Kruglanski & Webster, 1996; Neuberg, Judice, & West, 1994). In addition, researchers should be mindful that each motive may be pursued in different ways. For instance, people may attempt to fulfill a need for achievement by seeking to prevent failure or to approach success (Elliot & Harackiewicz, 1996; Higgins, 1997). Matching the method of pursuit of the individual's preferred orientation tends to elicit better success (Higgins & Spiegel, 2004).

A final caveat is that the motivation to be correct can, by itself, cause the use of irrelevant information on occasion. The heuristic–systematic model predicts that people use less relevant persuasive information (e.g., source credibility) when people are highly motivated to form a correct attitude and the only available relevant information is ambiguous or contradictory (Chaiken et al., 1989; Maheswaran & Chaiken, 1994). This effect may occur because the less irrelevant information becomes somewhat relevant in the presence of contradictory information. Indeed, past research showing this effect has focused on a source characteristic—credibility or trustworthiness—that has potential relevance (Maheswaran & Chaiken, 1994). Another possibility is that people in this predica-

ment simply need to base their views on some piece of information—whether it be a random toss of a coin or something with dubious validity. Also, people in this situation may expand their theories of the attitude object to include the information as a plausible guide. The result can be an overinterpretation of irrelevant evidence, at least when people are faced with difficulties identifying and correcting for this evidence (Pelham & Neter, 1995; Tetlock & Boettger, 1989; Tetlock, Lerner, & Boettger, 1996). Thus, increased motivation to be veridical can occasionally increase the use of irrelevant information, in addition to increasing the use of relevant information, and this effect on the use of irrelevant information may be particularly evident when the relevant information is conflicting and difficult to disentangle from the irrelevant information.

Persuasion Is Enabled by Congruence between Message Content and Recipients' Accessible Knowledge and Goals

A long-standing topic in research on persuasion concerns whether the effectiveness of a persuasive appeal is enhanced by matching its arguments to properties of the recipient's attitude. Over 50 years ago, it was suggested that an appeal is more likely to elicit persuasion when it highlights an incentive for attitude change (Hovland et al., 1953). Such an incentive may come from a recipient perceiving a match between the content of an appeal and the content and function of their attitude. If this hypothesis is correct, it may provide a useful third principle of persuasion.

Extant research has focused on matches to salient knowledge (elicited by preexisting attitude content) and salient goals (elicited by preexisting attitude function) separately. Using the multicomponent model of attitude, a number of investigators have considered how single attitudes based on affective or cognitive information might be differentially susceptible to affective and cognitive persuasive appeals. On the whole, this line of research has provided relatively strong evidence for structural matching. One design involved the creation of novel attitudes toward a fictitious beverage named "Power-Plus" (Edwards, 1990). These attitudes were deemed to be affective or cognitive dependent on the order in which participants were exposed to positive affective and cognitive information about Power-Plus. After forming an initial attitude about the product, participants entered the persuasion stage of the experiment, in which they were provided with negative affective and cognitive information. As in the attitude formation stage, the basis of the persuasive appeal was manipulated by varying the order of presentation of the affective or cognitive information, the assumption again being that the type of information presented first would represent the basis of the appeal. Edwards (1990) found strong evidence of a structural matching effect: The affect-based appeal was significantly more effective in changing attitudes that were affect based, while the cognition-based appeal was somewhat (but not significantly) more effective in changing cognition-based attitudes. With few exceptions (Millar &

Millar, 1990), similar patterns have since been obtained using a variety of experimental materials, procedures, and attitude objects (Edwards & von Hippel, 1995; Fabrigar & Petty, 1999).

In addition, recent research has considered whether individual differences in attitude structure elicit matching effects. One line of work has demonstrated that individuals differ in the degree to which their attitudes are guided by affective and cognitive information (Huskinson & Haddock, 2004). That is, some individuals rely primarily on affective information when forming attitudes, whereas others rely primarily on cognitive information. More relevant to structural matching, an affective appeal is more effective in eliciting attitude change among individuals whose attitudes were affect based, whereas a cognitive appeal is slightly more effective in eliciting attitude change among individuals whose attitudes were cognition based (Huskinson & Haddock, 2004). In a similar vein, research has found that individual differences in the need for affect (Maio & Esses, 2001) and need for cognition (Cacioppo et al., 1996) moderate the effectiveness of affect- and cognition-based appeals. Consistent with a structural matching perspective, an affective message was more persuasive among individuals who were high in the need for affect and low in the need for cognition (Maio, Esses, Arnold, & Olson, 2004).

There is also abundant evidence for the importance of matching persuasive content to the goals of the message perceiver. Using an individual difference perspective, research has tested whether individuals high versus low in self-monitoring (Snyder, 1974, 1986) are differentially influenced by appeals that highlight either social-adjustive or value-expressive concerns. A number of experiments demonstrated that high self-monitors (whose attitudes are posited to primarily fulfill a social-adjustive function) are more persuaded by appeals targeting social-adjustive concerns, whereas low self-monitors (whose attitudes are posited to primarily fulfill a value-expressive function) are more persuaded by appeals targeting value-expressive concerns (DeBono, 2000; Prentice, 1987).

Additional evidence supporting the functional matching effect comes from research that has employed paradigms in which an attitude's function is manipulated at either the level of the object or via an experimental induction technique. In one experimental induction, participants were led to believe that their attitudes typically fulfilled either a social-adjustive or value-expressive function (Murray et al., 1996). Subsequently, these participants were more persuaded by an appeal that matched their perceived attitude function. At the level of the attitude object, research carried out by Shavitt and colleagues (Shavitt, 1990; Shavitt & Nelson, 2000) demonstrated that attitude objects that primarily fulfill an instrumental function (e.g., coffee) were more likely to change in response to an instrumental-based appeal (e.g., emphasizing the product's flavor and freshness) than to a social-identity-based appeal (e.g., emphasizing the message recipient's personality and discernment), whereas the attitude objects that primarily fulfill a social-identity function (e.g., greeting cards) were less likely to change

in response to an instrumental-based appeal than to a social-identity-based appeal.

While the existing research provides convergent evidence that persuasion is enhanced by matching an appeal to an attitude's functional or structural basis, it is clear that matching does not always enhance persuasion (Petty, Wheeler, & Bizer, 2000). One reason stems from the ELM, which suggests that the functional matching effect might be attributable to the enhanced scrutiny of matched appeals (Petty & Wegener, 1998b). Interestingly, an explanation based on enhanced scrutiny implies that a matched appeal could produce more or less persuasion, dependent on the strength of the arguments contained within the message. To the extent that the arguments are strong, enhanced scrutiny should produce greater attitude change. However, if the arguments in an appeal are weak, enhanced scrutiny should produce less attitude change. To test this proposed mechanism, Petty and Wegener created strong and weak appeals that matched (or not) the functional basis of an individual's attitude. The results revealed that postmessage attitudes were more strongly affected by argument quality when the message matched the functional basis of the recipient's attitude.

The notion that enhanced scrutiny might account for matching effects is consistent with the previous research, because that research has tended to use arguments that the researchers expected to be cogent. In these instances, scrutiny of the messages causes positive message-relevant thoughts, which should increase agreement with the message (Lavine & Snyder, 1996). Exceptions to this pattern have occurred primarily in instances in which the appeals may have been counterargued with relative ease (Millar & Millar, 1990).

This pattern indicates that matching operates as an *enabler* of persuasion but not as an elicitor of persuasion. Through functional matching, people may be more likely to consider the message content, thereby detecting informational matches and mismatches. Functional matching may elicit this effect by affecting both the motivation and the ability to process message information. Motivation may be augmented by the perception of matching knowledge and goals, which may increase the sense of personal relevance (Petty & Wegener, 1998b; Petty et al., 2000). Ability may be increased by greater comprehension of the message content, which is facilitated because the message is framed in a way that is compatible with the individual's accessible knowledge and goals. As a result of this greater comprehension of message content, people may be better able to detect matches between the message content and their own prior knowledge and beliefs (e.g., when arguments seem "strong") and mismatches between the message content and their prior knowledge and beliefs (e.g., when arguments seem "weak") (Lavine & Snyder, 1996). In other words, matching is akin to pitching a message in the recipient's own language, rather than a foreign language—the common language makes the message more interesting, easy to understand, and compelling.

If matching works in this way, it may also be the case that matching is effective *within* categories of attitude content, structure, and function. DeSteno, Petty, Rucker, Wegener, and Braverman (2004) have obtained interesting evidence consistent with this view. In their research, participants who were induced to feel sad were subsequently more persuaded by arguments that induce sadness than participants who were previously made to feel anger. In contrast, participants who were induced to feel anger were subsequently more persuaded by arguments that induce anger than participants who had been made to experience sadness. These effects are driven by increases in the perceived validity of the arguments when the affect-matching occurs. Nonetheless, this specific within-component matching does not always arise (Fabrigar & Petty, 1999), and the effect uncovered by DeSteno and colleagues is partly dependent on a high motivation to process the messages. Additional research is needed to ascertain whether within- and between-component matching effects are sufficiently similar to conclude that they arise from the same common mechanism, such as a common "language" or frame-of-reference for processing.

Persuasion Can Occur without Awareness

Although the vast majority of persuasion research has considered the degree to which conscious thought processes influence how individuals respond to persuasive appeals, a number of experiments have tested whether attitudes might change in the absence of conscious awareness (Dijksterhuis, Aarts, & Smith, 2005). For instance, experiments using classical conditioning paradigms have revealed small but significant effects of subliminal affective primes on diverse stimuli such as Chinese ideographs (Murphy & Zajonc, 1993), neutral words (De Houwer, Hendrickx, & Baeyens, 1997), and unfamiliar people (Krosnick, Betz, Jussim, & Lynn, 1992). In addition, such effects can be found using both implicit and explicit postconditioning measures of attitude, despite participants' unawareness of the covariation between the conditioned stimulus and the unconditioned stimulus during the conditioning procedure (Olson & Fazio, 2001, 2002). Taken together, this research suggests that attitudes toward novel stimuli can be formed and changed in the absence of participants being aware of the link between an attitude object and evaluative information.

Betsch and colleagues (Betsch, Plessner, & Schallies, 2004; Betsch, Plessner, Schwieren, & Gütig, 2001) have suggested that such associative conditioning effects may occur through a different mechanism than the traditional mechanism of attitude formation and change. Their dual-process *value-account model* postulates that attitudes can be produced by implicit processing (which occurs unintentionally and without awareness) and explicit processing (which occurs intentionally and with awareness). With respect to the implicit formation of attitudes, evaluative information about an attitude is implicitly *added* into a hypothetical memory structure they refer to as a value account. With respect to explicit attitude formation, summary evaluations are deliberately normalized, or *averaged* with, the amount of sampled evaluative information.

To date, a number of studies by Betsch and colleagues (2004) have supported the model. For instance, one experiment used a dual-task procedure in which participants processed television advertisements while at the same time reading aloud share price information scrolled at the bottom of the screen (Betsch et al., 2001). The results indicated that spontaneous attitude judgments toward individual shares reflected the objective sum of their return values, with a perfect rank-order correlation between intuitive attitude judgments and the actual total yield of shares. These differences were found despite participants being unable to recall evaluative information about individual shares. Another experiment found direct evidence supporting the use of a summation mechanism for implicit attitude formation and an averaging mechanism for explicit attitude formation (Betsch et al., 2001).

Recent work has also demonstrated that subliminal priming can, under certain conditions, enhance effects of subsequent persuasive messages. Some research has indicated that subliminal primes can be used to activate goal-relevant cognitions (Fitzsimons & Bargh, 2003), which, when combined with a motivation to pursue the goal, enhances the effectiveness of a relevant persuasive appeal (Dijksterhuis et al., 2005; Strahan, Spencer, & Zanna, 2002). According to this perspective, both the activation of goal-relevant cognitions and the motivation to pursue the goal are necessary to make an appeal especially persuasive. In one study testing this hypothesis, participants who were either thirsty or satiated were subliminally primed with either thirst-related or neutral words. When subsequently offered the opportunity to sample different beverages, thirsty participants who had been primed with thirst-related words drank significantly more than all other participants (Strahan et al., 2002). A subsequent study demonstrated that thirsty participants who had been primed with thirst-related words were significantly more persuaded by an advertisement for a thirst-quenching beverage than by an advertisement for an electrolyte-restoring beverage. Furthermore, participants who received the thirst-related primes were also more likely to select coupons for the thirst-quenching beverage (Strahan et al., 2002). In essence, this research provides further support for the function-matching principle that we described earlier, but using a subliminal activator of attitude function.

An important distinction in this context is between awareness of the variables that instigate attitude formation and change and awareness of the attitude itself. Participants in the studies described earlier exhibited no knowledge of the subliminal primes or conditioning that affected their attitudes but revealed clear awareness of their attitude in explicit measures of the attitudes. These studies thus provide elegant instantiations of a more general limitation of people's introspective abilities: People can often report attitudes without accurately ascertaining why they feel the way that they do (Nisbett & Wilson, 1977). People may even hold incorrect theories about the factors impinging upon their attitude and overcorrect or undercorrect for these factors as a result (Wegener & Petty, 1997; Wilson & Brekke, 1994). Thus, an important question is whether people will on occasion exhibit more veridical knowledge of the bases of their attitudes and also be more able to resist the influence of factors beyond their awareness.

There is evidence that this veridical knowledge and resistance may occur for strongly held attitudes that are based on a large amount of knowledge. Such attitudes tend to be more predictive of behavior and resistant to change (Kallgren & Wood, 1986), and they are less vulnerable to interventions that elicit introspection about the bases of attitudes (Wilson, Dunn, Kraft, & Lisle, 1989; Wilson, Kraft, & Dunn, 1989). Introspection about attitudes typically causes people to access an assortment of inaccurate theories of the bases of the attitudes, which causes them to change (Wilson, Dunn, et al., 1989). This effect disappears when the attitudes are based on extensive knowledge (Maio & Olson, 1998; Wilson, Kraft, et al., 1989), suggesting that some veridical access of the true bases of the attitude may be occurring. Thus, an interesting issue is whether, for such attitudes, subliminal interventions fail to elicit attitude change, because people are fully able to access a set of representations to support their attitude. We anticipate that this moderating effect of attitude strength may be an important caveat to the nonconscious operation of persuasion.

Summary of Principles and Future Directions

All the models of persuasion that we have encountered appear to assume that, regardless of differences in how the effects of extraneous information on attitudes are modeled, such information does exert an important impact. Put simply, all models agree that there are times when a person is influenced by information that has, at best, equivocal relevance to the object of judgment (principle 1). Fortunately, increasing people's motivation and ability to form a correct attitude often attenuates the impact of this information, except perhaps when the relevant information is difficult to interpret and the irrelevant information is difficult to identify (principle 2). Nonetheless, people appear more motivated and able to make such distinctions when there is congruence between their attitude-activated knowledge and goals and the contents of a message (principle 3), and the fact that persuasion can occur without conscious awareness of the persuasive factors (principle 4) provides an interesting potential limitation to this process of relevance detection and correction. Together, these four principles help to summarize significant patterns across the literature.

The need to be concise prevents us from elaborating on other potential principles, but a couple of possibilities merit some mention. First, there is consistent evidence that attitudes are more resistant to change when they are highly accessibility from memory or based in knowledge that is extensive and evaluatively consistent (Bassili, 1996; Chaiken et al., 1995; Wood, Rhodes, & Biek, 1995). These characteristics can be viewed as indicators of attitude strength, which is another variable property of attitudes (Krosnick & Petty, 1995). This convergence tempts the conclusion that "strong attitudes are more resistant to change," but this statement is too circular for inclusion

as a principle of attitude change. In addition, all the traditional indicators of attitude strength are dependent on attitude content, structure, and function, as we outlined earlier. For example, attitudes with more supporting behavioral experiences and structurally consistent content are stronger (Chaiken et al., 1995; Wood et al., 1995), and attitudes that strongly serve a utilitarian function are easier to retrieve from memory (Fazio, 2000). Consistent with other researchers (Krosnick et al., 1993), we expect that there is more to be gained by examining the unique roles and interactions among these facets than by treating them solely as common indicators of a single underlying principle.

We are particularly intrigued by the possibility of delineating a sequential operation in the persuasion process. Ever since the seminal models of persuasion outlined a sequence of processing stages, experiments have attempted to understand attitude change as a sequence of information-presentation and -processing stages, including classic demonstrations and many recent experiments and models (Albarracin, 2002; Pierro et al., 2004). The extant evidence leaves us with little doubt that the sequence of information presentation is important. We would go so far as to suggest a tentative fifth principle: Information presented early in a persuasion sequence affects the construal of later information. This principle emerged with classic research on impression formation (Asch, 1946; Asch & Zukier, 1984; Hamilton & Zanna, 1974) and may be consistent with basic principles in the nature of verbal persuasive dialogue (Rips, Brem, & Bailenson, 1999). Nonetheless, we have not yet seen this potential principle integrated in a consistent manner in research on persuasion, despite some promising beginnings (Kruglanski et al., 2004). A vital issue for such integrations is the role of people's initial attitudes as biasing "information" early in the processing sequence—a possibility that is emphasized in the social judgment, elaboration likelihood, and cognition-in-persuasion models—because it appears that initial attitudes can bias information processing, at least when the attitudes are accompanied by a strong sense of conviction (Edwards & Smith, 1996; Siero & Doosje, 1993) or because of easy retrieval from memory (Houston & Fazio, 1989; Schuette & Fazio, 1995). Thus, this potential principle merits further analysis and evaluation.

In any attempt to extrapolate basic principles from the literature on persuasion, it is inevitable that attention is also drawn to basic issues that have not yet been fully addressed. One important issue is the need for an integrated perspective on how persuasive interventions affect nontargeted attitudes. Fishbein and Ajzen (1981; Ajzen & Fishbein, 1980) described how persuasive arguments might occasionally influence beliefs that were not directly part of the message content. For example, people who learn that a detergent is inexpensive might also come to believe that it is also ineffective, because of a belief that inexpensive items tend to be of less use. Thus, ironically, an argument that seems positive on the surface may have negative implications for the attitude, and it is important to consider the indirect effects of a message through such associations (McGuire, 1960a). The overwhelming majority of past research on persuasion has focused heavily on numerous, diverse *antecedents* (e.g., source characteristics) of changes in the valence of the target attitude. Consideration of the impact of these variables on nontargeted attitudes is an important step toward broadening our examination of the potential consequences of persuasive processes.

An additional approach to broadening the consequences of persuasive processes involves looking at changes in other properties of the targeted and nontargeted attitudes. The ELM partly helps to address this issue because it predicts that deliberate consideration of a persuasive message causes the targeted attitude to become stronger (Petty & Cacioppo, 1986). In other words, the attitudes formed after systematic processing should be more predictive of behavior, stable, and resistant to change. These effects could occur because the post-message attitude is held with more certainty, seen as more important, more accessible from memory, less ambivalent, and so on. Understanding the effects on these attributes is important because it may help to predict the likelihood that effects of a message persist over time. With some notable exceptions (Gruder et al., 1978; Pratkanis, Greenwald, Leippe, & Baumgardner, 1988; Zanna, Fazio, & Ross, 1994), most recent studies have examined attitude change immediately after message presentation, and it is important to develop principles for describing when and why change might persist over a longer period.

It would also be useful to examine the effects of message processing on the functions of attitudes. For example, do messages that mismatch the attitude's pre-existing function diminish the extent to which the attitude subsequently serves that function? Also, in the specific circumstances wherein a mismatching message *is* relatively effective (e.g., when people are motivated to process arguments that are weak) (Petty et al., 2000), does this lead to an attitude that serves multiple functions? If multiple functions do arise, the attitude might potentially become stronger and more predictive of behavior because of its new relevance to motives that may arise across different situations. Such possibilities make clear the importance of moving beyond paradigms that treat attitude valence as the sole (or principal) dependent variable following exposure to a persuasive message.

It is also important to consider a more diverse set of attitude topics in persuasion research. Most highly cited persuasion research focuses on educational policies (e.g., tuition fees and comprehensive exams) or commercial products (telephone answering machines, mobile phones) and is ominously silent about the predictors of attitude change on noncommercial topics. Yet, noncommercial messages are highly visible from many sources: political interest groups continually promote particular political candidates (especially at election time), healthy behaviors (e.g., safe driving and use of contraception), environmentally friendly behaviors (e.g., recycling and nonlittering), religious beliefs (e.g., Church of Latter Day Saints), legislative agendas (e.g., National Rifle Association promotions), and volunteer behaviors (e.g., blood

donation). Marketers have an entire subfield of research examining such campaigns, which they label "social marketing," and one of the guiding clichés in this area is that selling social ideas and behaviors is more difficult than selling commodities (Rothschild, 1979; Wiebe, 1951), perhaps because people are resistant to being persuaded about such self-relevant issues (Cohen, Aronson, & Steele, 2000; Correll, Spencer, & Zanna, 2004). As a result, social marketing may often be ineffective. For example, several studies of antiracism advertising in the United Kingdom have found that the messages may even backfire among those who are ambivalent toward ethnic minorities (Maio, Haddock, Watt, & Hewstone, in press). Similarly, other research has found that common approaches to advocating environmentally friendly behavior in advertising actually encourage less of the behavior, by making the environmentally unfriendly behaviors appear to be common and something that everyone does (Cialdini, 2003). The challenge is for persuasion researchers to collect more data on applications to social issues and to understand factors that predict resistance to persuasion more generally.

CONCLUSION

We have reviewed the literature on persuasion, described six models that attempt to integrate this literature, and extracted four principles that appear evident thus far: (1) attitude change can be elicited by extraneous features of a message or persuasion context; (2) motivation and ability to form a correct attitude increase the impact of relevant information; (3) persuasion is enabled by congruence between the message and accessible knowledge and goals; and (4) persuasion can occur without awareness. These four principles are not the only principles that may be extracted from the research that we have considered, and others may emerge after research addresses the basic and applied issues that we identified (e.g., antecedents of argument strength and effects on nontargeted attitudes).

We are always mindful of the argument that the opposite of every principle might also be true (McGuire, 1983). Nevertheless, the four principles that we have described provide good testimony to the remarkable achievements of persuasion research in the past 50 years. These principles have endured many rigorous tests through this period, and, despite McGuire's sage warning, they may be evident in research for years to come. We hope that our articulation helps to make the principles more salient and leads to research that fully delineates their scope.

CHAPTER 25

Foundations of Interpersonal Trust

JEFFRY A. SIMPSON

Trust: "confidence that [one] will find what is desired [from another] rather than what is feared."
—DEUTSCH (1973, p. 148)

According to Morton Deutsch, who many consider the founder of modern theory and research on trust, trust involves the delicate juxtaposition of peoples' loftiest hopes and aspirations in relation to their deepest worries and darkest fears. For this reason, situations in which trust is relevant often generate strong approach–avoidance gradients, particularly when individuals feel vulnerable and must count on the benevolence of their partners to receive important outcomes. Although not a complete definition of the construct, Deutsch's crisp observation captures the quintessential features of interpersonal trust, which is the topic of this chapter.

Trust is one of the most important components—and perhaps the most essential ingredient—for the development and maintenance of happy, well-functioning relationships (Fehr, 1988; Regan, Kocan, & Whitlock, 1998). Several lifespan theories, ranging from Bowlby's (1969, 1973) attachment theory to Erikson's (1963) theory of psychosocial development, contend that early exposure to relationships defined by strong trust lays the foundation on which most future relationships are constructed. Without some basic level of trust, individuals are reluctant to initiate, invest in, or sustain most voluntary relationships (e.g., with friends, recreation partners, and romantic partners). Indeed, trust appears to be crucial for the emergence of healthy and secure relationships (Holmes & Rempel, 1989; Larzelere & Huston, 1980), and the betrayal of trust is one of the most commonly mentioned reasons for the demise of relationships (Miller & Rempel, 2004). Outside the realm of relation-

ships, trust acts as a social lubricant that promotes cooperation between group members, sustains social order, and permits beneficial long-term exchanges that otherwise might never occur (Cook & Cooper, 2003; Ostrom & Walker, 2003).

Given the central importance of trust in interpersonal affairs, one might suspect that it has received widespread theoretical and empirical attention. Though there have been significant pockets of theory (e.g., Holmes & Rempel, 1989; Kelley & Thibaut, 1978) and research (e.g., Mikulincer, 1998; Rempel, Holmes, & Zanna, 1985) on trust, surprisingly little is known about how trust develops, how it is maintained, how it shapes and interacts with major interpersonal processes (e.g., the development of intimacy and closeness) and outcomes (e.g., relationship satisfaction and stability), and how it unravels when betrayed.

Why has trust received such limited attention? There are a variety of viable reasons. To begin with, trust is a complex, multidimensional construct, rendering it amenable to diverse interpretations in different social situations (Kramer & Carnevale, 2001). Second, trust might be construed differently and take on varying importance at different stages of relationship development (Fletcher, Simpson, & Thomas, 2000; Larzelere & Huston, 1980). Views about what constitutes sufficient trust in a partner/relationship during the initial stages of relationship development (such as a partner's general reliability and predictability) may be quite different from those used to gauge trust in long-term relationships (such as a partner's

dependability and one's confidence that he or she will remain loyal and supportive over time). Third, trust develops and changes in situations that are notoriously difficult to observe and study, such as in "strain test" situations (Holmes, 1981; Kelley, 1983). Creating or simulating these situations in the lab is challenging, especially when one wants to study partners in established relationships. Fourth, relationship satisfaction has often been treated as a proxy for many conceptually related yet distinct relationship constructs, including trust (Huston, 2000). The failure of researchers to clearly define, measure, and conceptually tease apart relationship constructs that are correlated with yet theoretically distinct from interpersonal trust—constructs such as satisfaction, love, commitment, passion, and intimacy—has hampered our understanding of trust.

This chapter addresses a series of fundamental questions central to understanding interpersonal aspects of trust. What is interpersonal trust? When, how, and why does it develop? What are the dispositional, relational, structural, and situational factors that instigate, facilitate, inhibit, or destroy it? Why do some people repeatedly experience greater trust in their close relationships than others? Why are certain relationships characterized by greater or more mutual levels of trust? What happens when trust is seriously questioned or betrayed? Provisional answers to these and other questions are offered.

The first section of the chapter reviews basic definitions, conceptualizations, and operationalizations of interpersonal trust. After reviewing some of the linguistic origins of trust, both individualistic (dispositional) and interpersonal (dyadic) definitions and conceptualizations of trust are presented. The second section highlights some of the major theoretical foundations and bases of trust at different levels of conceptual analysis. At the ultimate level of analysis, traditional genetic evolutionary models relevant to trust as well as multilevel selection/cultural coevolutionary models are showcased. At the ontogenetic level, some prominent lifespan models of social and personality development that are most pertinent to interpersonal trust are highlighted. At the proximate level, a few of the most significant social and psychological processes bearing on trust are outlined. Following this, major models specifying the normative (i.e., typical or modal) and individual-difference processes believed to govern the development, maintenance, and deterioration of trust in close relationships are discussed. The third section provides a selective yet representative overview of research on trust, with most attention focusing on interpersonal (rather than intergroup) trust. This overview begins with the seminal contributions of Deutsch and the early Prisoner's Dilemma Game (PDG) studies conducted prior to the mid-1960s, progresses to the dispositional movement that was popular from the late 1960s through the mid 1970s, and concludes with more recent dyadic formulations of trust. In the final section, six core principles of trust are identified. Following this, important constructs from different interpersonal models are merged to form an integrative process model, which suggests how trust might develop and be maintained in relationships.

DEFINITIONS AND CONCEPTUALIZATIONS OF TRUST

As alluded to previously, the study of interpersonal trust has been constrained by several interrelated factors. Two of the greatest hindrances have been the complex, multifaceted nature of the construct and the tendency of investigators to define and operationalize trust differently in different studies. Another part of the problem, however, stems from how trust is defined and expressed in different languages. In French, for example, the word for trust indicates that one merely has "confidence" in someone or something. Several other languages either do not have specific words for trust or have created new words only recently. For instance, there is no noun in Norwegian that corresponds to the English definition of trust, and the Japanese invented a new word to capture the construct merely a century ago (Hardin, 2003). Even in English, which contains more words than any other language and has a fairly nuanced definition of trust, the origins of the word come from the root "tryst," which refers to "an agreement . . . to meet" or "an appointed meeting or meeting place." Thus, even languages that have a clear word or phrase connoting trust might have derived the term from slightly different roots.

Most of the confusion surrounding trust, however, emanates from disparities in, or the lack of precision with which, trust has been defined and operationalized in different studies by different investigators. Some of the earliest research-based definitions of trust adopted a dispositional view of human nature (e.g., Rotter, 1971; Sato, 1988; Wrightsman, 1991). According to this perspective, trust entails generalized beliefs and attitudes about the degree to which other people are likely to be reliable, cooperative, or helpful, independent of the specific context or situation in which an interaction with them might take place. This global, context-free conceptualization of trust, which is assessed by measures such as the Machiavellianism Scale (Christie & Geis, 1970) and Wrightsman's (1974) Philosophies of Human Nature Scales, conceptualizes trust as a stable dispositional orientation toward the world and the people in it. As a rule, individuals who score higher on dispositional trust have warmer, more communal, and more benevolent perceptions of others, whereas less dispositionally trusting individuals harbor colder, more individualistic, and more cynical views of others (Wrightsman, 1991).

In the early 1980s, conceptualizations and measures of trust started to become more partner and relationship specific (Kelley & Thibaut, 1978; Lewis & Weigert, 1985; Rempel et al., 1985). According to this more dyadic (interpersonal) perspective, trust is a psychological state or orientation of an actor (the truster) toward a specific person (the trustee) with whom the actor is in some way interdependent (i.e., the truster needs the trustee's cooperation to attain valued outcomes or resources). What makes trust a particularly complex construct is that it has three components (e.g., "*I* trust *you* to do *X*"; Hardin, 2003). Accordingly, trust is a function of properties and characteristics of the self (I), the specific partner with whom one is interacting (you), and the unique features,

requirements, or constraints of the current situation (to do X). When any one of these components changes, an individual's thoughts, perceptions, feelings, and actions with regard to trusting a particular other may also change.

To complicate matters, individuals also vary in how broadly they define what "X" is or could be. For some people involved in certain relationships, "X" might constitute almost anything (e.g., to do the shopping, to be helpful and considerate, or to offer emotional support in times of need). Individuals who define "X" broadly should think, feel, and behave in a more stable manner across different trust-relevant situations, at least with reference to the same partner. For other individuals, however, "X" may be limited to a small set of circumscribed behaviors or activities (e.g., to do the shopping, *or* to be helpful and considerate, *or* to provide emotional support, but not all three). Individuals who subscribe to a more activity-specific view should adjust their trust-relevant thoughts, perceptions, feelings, and actions as situations and events change. Elements of Hardin's (2003) tripartite definition of trust can be found in many definitions and conceptualizations of the construct that have been proposed by various interpersonal and intergroup scholars.

Several scholars have also advanced more content-specific definitions of trust. Intergroup researchers, for example, have defined trust as a specific set of socially learned *expectations* that people hold about various social systems, ranging from other people to social organizations to the larger moral social order (Barber, 1983). Trust has also been defined as a constellation of *beliefs* regarding the extent to which others are or will be concerned about one's personal welfare and best interests (Pruitt & Rubin, 1986), and as a set of *attributions* that individuals routinely make when inferring motives beneath the actions of their partners (Tyler, 2001). According to this attributional perspective, trust is evident when individuals repeatedly presume that specific others are concerned about their welfare, will take their views and personal interests into account when making decisions, and will work toward fair and equitable outcomes.

Trust has also been defined in relation to specific situational contexts. Bacharach and Gambetta (2001), for instance, conceptualize trust as involving situations in which an individual expects his or her partner to pursue a particular course action (i.e., to do X) and two conditions hold: (1) if the partner does *not* perform the expected action, the individual would have benefited more by doing something else; and (2) the individual encourages the partner to complete the expected action. This viewpoint suggests that trust should be highest when both partners' "raw" payoffs (i.e., the outcomes that are best for each of them personally) coincide with their "all-in" payoffs (i.e., the outcomes that are best, on average, for themselves, their partner, *and* the relationship). Trust should also be higher when both individuals believe that their *partner* will base his or her decisions and actions on what is best for the relationship (i.e., on joint-interest payoffs) in a given situation, even if the partner's "raw" and "all-in" payoffs do not completely coincide. Over time,

self-expansion processes (Aron, Aron, & Norman, 2001) might help relationship partners transform their raw (i.e., selfish and self-centered) payoffs so they overlap more closely with their all-in (i.e., more partner- and relationship-centered) payoffs. Doing so could, in turn, generate better or more stable prorelationship outcomes (Kelley & Thibaut, 1978). Kelley and colleagues (2003) have recently proposed that trust can also be conceptualized as a particular type of interpersonal situation. In particular, trust situations involve the unique configuration of high interdependence between partners, a mixture of coordination *and* exchange as the basis for interdependence, and moderately corresponding interests. This new model is discussed in greater detail later.

Blending features of various definitions, Kramer and Carnevale (2001) claim that trust involves a suite of specific beliefs, expectations, *and* attributions that the actions of partners with whom one is interdependent will be beneficial (or at least not detrimental) to one's self-interest, especially in situations in which one must count on partners to provide unique benefits or valuable outcomes. They argue that trust-relevant situations elicit two interlocking cognitive processes: (1) feelings of vulnerability, which arise from uncertainty about the partner's true motives, intentions, or actions with regard to the self, and (2) perceptions and expectations about how the partner will behave across time, particularly in "strain test" situations in which an individual is highly outcome dependent and specific actions or decisions that would promote his or her own best interests are at odds with those that would maximally benefit the partner (Holmes, 1981; Kelley, 1983). When the partner promotes the individual's best interests over his or her own interests, *both* parties may experience heightened trust.

Scholars have also offered dyadic definitions of trust. Working within interdependence theory (Thibaut & Kelley, 1959), Wieselquist, Rusbult, Foster, and Agnew (1999) suggest that trust is evident when individuals believe that their partners are highly committed, harbor benevolent intentions, and are willing to undergo prorelationship transformations of motivation that result in self-sacrificial or accommodative behaviors (e.g., "voice" reactions during relationship conflict). Adopting a slightly different theoretical angle, Holmes and his colleagues (Holmes & Rempel, 1989; Rempel et al., 1985) propose that trust has three components, namely, the degree to which (1) partners are perceived as reliable (predictable); (2) partners are perceived to be concerned about one's welfare and are willing to support one's best interests, especially in times of need (high dependability); and (3) individuals are confident about the continued strength and permanence of the partner and relationship (faith). In recent years, these investigators have shifted their conceptualization of dyadic trust away from predictability and more toward dependability and faith (see Rempel, Ross, & Holmes, 2001).

Interpersonal trust can also be conceptualized in terms of the core motives that may drive and sustain it. According to McClintock (1972, 1976), five core social motives can shape the level or quality of trust that exists in a particular relationship. Specifically, an individual's inclina-

tion to trust another person can be motivated to advance (1) his or her own gain maximization (reflecting an individualistic or egoistic orientation), (2) his or her relative gain maximization (reflecting a competitive orientation), (3) his or her joint gain maximization (reflecting a cooperative orientation), (4) others' gain maximization (reflecting an altruistic orientation), and/or (5) others' gain minimization (reflecting an aggressive, spiteful orientation). Greater dyadic trust should be witnessed when individuals and their partners *both* display—or believe that they display—either joint gain maximization or others' gain maximization social motives, depending on the specific social and situational circumstances.

Deutsch (1973) also has speculated that individuals trust others for assorted motivational reasons. Individuals may, for instance, trust others out of despair (when the possible consequences of *not* trusting someone could be worse than trusting them), social conformity (trusting to avoid ostracism or violations of social norms), innocence (trusting others due to lack of knowledge, information, or experience), or impulsiveness (failing to give proper weight to the future consequences of an act). In addition, individuals might trust others out of virtue (to affirm their core values), masochism (in the hope of eventually being betrayed), faith (hoping that dreaded consequences never unfold), confidence (when individuals believe they will get what they desire rather than what they fear), or a desire for risk taking (trusting as a way of taking greater risks).

Trust might also have further motivational foundations. For example, interpersonal trust that is based on important *personal* goals and motives (e.g., I trust you because I know that you love me and will always consider my best interests) should be different from trust that is based on either *moral* goals/motives (e.g., I trust you because you are morally committed to fulfilling your promises to me) or *structural* goals/motives (e.g., I trust you because you have other relationships or valued possessions that would be damaged if you did not fulfill your obligations to me). Trust that is anchored in personal goals and motives should remain stable as long as personal goals and motives remain constant, even if moral or structural factors change. Trust that is grounded in moral or structural factors, on the other hand, should remain stable unless major moral or structural variables shift across time. Insufficient attention has been devoted to determining whether and how different motivational sources influence the nature, quality, and strength of trust in close relationships.

In summary, the multidimensional nature of trust makes the construct challenging to define, operationalize, and measure. The different definitions and operationalizations of trust that have been proposed do not constitute rival alternatives; rather, they highlight different facets and components of trust. Hardin's (2003) tripartite definition of the construct—"*I* trust *you* to do *X*"—accentuates the complex, multidimensional, and very interpersonal nature of trust. This complexity is simply compounded by the fact that assorted social motives and personal needs can serve as the basis of trust with different partners and in different relationships.

THEORETICAL FOUNDATIONS AND BASES OF TRUST

Virtually all constructs are situated within, and require explanation at, three levels of conceptual analysis (Sherman, 1988; Tinbergen, 1963): ultimate causation, ontogeny, and proximate causation. Questions of ultimate causation focus on the possible phylogenetic, evolutionary, or cultural/coevolutionary origins of a specific trait or behavior. Why, for instance, do many people trust total strangers, at least until they demonstrate that they are untrustworthy? Why do people continually enter complicated, long-term exchange relationships with so many different individuals? What genetic/evolutionary and cultural/coevolutionary forces might have instigated and sustained these proclivities?

Questions of ontogeny address the experiential factors that shape how a given trait or behavior develops and changes across the lifespan. Ontogenetic questions fall into two categories (Tooby & Cosmides, 1990). Some address how or why certain early environmental experiences shunt individuals down different developmental pathways, culminating in the enactment of different behavioral strategies in adulthood. What early life events or experiences, for example, are associated with the tendency to develop more versus less trusting relationships in adulthood? Other ontogenetic questions focus on how and why specific developmental experiences produce different activation thresholds. What sorts of early social experiences, for instance, motivate certain people to value trust highly, to think about it often, or to respond more intensely when it is violated?

Questions of proximate causation deal with how and why specific stimuli or events in the current environment activate, maintain, or regulate a given trait or behavior. Which classes of situations or events, for example, activate working models (relationship schemas) relevant to trust? Which specific experiences or events make people more versus less likely to trust others at particular points during a relationship? Constructs cannot be fully understood unless cornerstone questions relevant to each level of analysis are asked and sufficiently answered.

Ultimate Causation Explanations

To comprehend the distal causal factors that might be responsible for the development of the capacity to trust others witnessed in humans, one must first look back to the most stable features of the environments in which humans most likely evolved. During more than 98% of human evolutionary history, our ancestors lived as hunters and gatherers (Hill, 2002; Kelly, 1995), most likely in small, cooperative tribes or bands (Richerson & Boyd, 2005). Many people in a tribe or band were biologically related (Foley, 1987), and complete strangers were probably encountered infrequently, most often during intertribal trading or war (Wright, 1994). Although some people migrated in and out of their original tribes/bands, most individuals probably lived in the same tribe/band their entire life. Children probably were raised with considerable help from extended family members and the

entire tribe/band, and older children—especially older siblings—most likely assumed important roles in socializing younger children (Eibl-Eibesfeldt, 1989). Both genders participated in securing food, with men doing most of the hunting and women doing most of the gathering (Konner, 1982; Richerson & Boyd, 2005). Thus, extensive cooperation with other tribe/band members—both kin as well as biologically unrelated individuals—was mandatory, particularly in light of the changing and precarious nature of the climate, competing tribes, and the food supply. These conditions happen to be ideal for reciprocal altruism to evolve (see Cosmides & Tooby, 1992). Brewer and Caporeal (1990) suggest that active participation in cooperative groups might have been the primary "survival strategy" of early humans. Willingness to enter and maintain mutually cooperative, long-term alliances with others, therefore, may have been essential for survival, successful reproduction, and adequate parenting.

Various gene-centered evolutionary models can explain how and why humans developed the capacity to trust others and become so disturbed when trust is betrayed. According to inclusive fitness theory (Hamilton, 1964), genes are replicated not only through one's own reproduction but also via the reproduction of biological relatives who carry the same genes. Selection, therefore, should have favored individuals who invested in and made sacrifices for their relatives, provided that the average cost of giving benefits (C) was less than the value of the benefits to relatives (B) multiplied by their degree of genetic relatedness (r) (i.e., Hamilton's rule, where C < rB). Although inclusive fitness theory can explain how and why altruism, cooperation, and the capacity for trust could have evolved with respect to biological relatives, it fails to explain the evolution of these traits with regard to interactions and social exchanges involving biologically unrelated individuals.

To solve this conundrum, Trivers (1971) developed reciprocal altruism theory. According to Trivers (1971), altruism is a "behavior that benefits another organism, not closely related, while being apparently detrimental to the organism performing the behavior, benefit and detrimental being defined in terms of contribution to inclusive fitness" (p. 35). According to this view, if two biologically unrelated individuals provide mutual benefits to each other that are greater than the costs each individual incurs by providing the benefits, both individuals should benefit through the economic principle of gains in trade. Consequently, genes that led our ancestors to recognize and selectively enter certain mutually beneficial transactions with nonkin (e.g., long-term tit-for-tat exchanges with highly resourceful and trustworthy partners) could have been preferentially selected.

Simulation research has confirmed that tit-for-tat strategies (whereby positive partner overtures are immediately rewarded and negative ones are immediately punished) tend to develop quickly and remain stable as long as interaction partners continue to make cooperative choices, at least in two-person experimental games (Axelrod, 1984). Moreover, all the conditions necessary for the evolution of reciprocal altruism in humans—important benefits can be conferred, individuals have re-

peated interactions with the same people, individuals can remember whom they have given benefits to and received benefits from, and exchange decisions are based on the outcomes of earlier interactions with certain people—were probably present during much of evolutionary history.

Among others, Kurzban (2003) suggests that the need for cooperative hunting could have been one of the major selection pressures that jump-started reciprocal altruism in humans. Moreover, delayed exchanges of goods and resources may have been more common in evolutionary environments than simultaneous exchanges, requiring that trust in others be carefully and judiciously placed. Interestingly, tit-for-tat strategies require a willingness to trust partners and to be cooperative on the first "move" (trial), after which decisions are governed by whether partners behave cooperatively or noncooperatively on subsequent trials. Extending these ideas, Clutton-Brock and Parker (1995) propose that spite (i.e., the inclination to punish or ostracize defecting or uncooperative individuals, even when such actions are costly to the self) could have evolved to "back up" trust if partners reneged on important promises. Tooby and Cosmides (1990, 1992) conjecture that certain specialized cognitive abilities in humans (e.g., cheater detection and superior memory for faces) may have evolved to help individuals identify and envision new ways in which valuable resources could be exchanged, further fueling the evolution of reciprocal altruism. Certain cognitive adaptations, therefore, might have accelerated the evolution of trust, including humans' specialized abilities to discern when trust is warranted and well-placed and when it might be violated (see Kurzban, 2003).

Other ultimate-level accounts of trust have been formulated in response to the fact that gene-centered evolutionary models do not fully explain the pervasiveness and depth of human altruism. These accounts, which are collectively known as multilevel selection or gene-cultural coevolutionary models, claim that humans are unique among species in their tendency to display "strong reciprocity" (Fehr & Fischbacher, 2003). Strong reciprocity is evident when individuals assume the costs of rewarding or punishing others in situations in which cooperation is required to secure vital resources or good outcomes, even if "enforcers" receive no personal benefits or incur major costs. Unlike reciprocal altruism, which presumes that individuals should reward or punish others only if tangible benefits are likely to be received (Axelrod & Hamilton, 1981), strong reciprocity indicates that individuals are willing to enforce important social rules or norms to ensure that cheaters and noncooperators do not destroy cooperation and goodwill within groups. Laboratory studies using the Ultimatum Game have confirmed that most individuals closely monitor and quickly punish people who behave unfairly (e.g., who cheat or fail to reciprocate cooperation) or who offer others unfair outcomes, even if providing sanctions harms their own rational self-interest (Fehr & Fischbacher, 2003). Research using intergenerational Ultimatum Games has also revealed that receiving advice from previous players increases altruistic punishments and rewards enacted by

current players, and that players who receive advice achieve greater cooperation from others over time.

What might explain this strong willingness to make personal sacrifices in the service of maintaining cooperative norms and behavior? The answer probably lies in how easily cooperation can disintegrate. Because a very small percentage of free riders or chronic cheaters can destroy cooperation in most groups, cooperative systems usually fail unless a clear majority of group members vigilantly monitor and sanction norm violaters, even if they have no personal stake or investment in a given interaction (Fehr & Schmidt, 1999). Individuals who regularly police and enforce important rules and norms, however, may also gain personal benefits through being seen as highly altruistic, which either could enhance their reputation within groups (Alexander, 1987; Nowak & Sigmund, 1998) or signal that they are sufficiently viable to withstand the costs of engaging in altruistic acts (Gintis, Smith, & Bowles, 2001; Zahavi, 1995)

Advocates of gene–cultural coevolutionary models have also questioned whether tit-for-tat strategies could have been responsible for the evolution of reciprocal altruism in humans. Although the results of repeated two-person interactions suggest that tit-for-tat strategies develop readily and remain fairly stable (Axelrod, 1984), these strategies are less stable in *n*-person PDGs unless nearly *all* group members cooperate on every trial (see Boyd & Richerson, 1988). Moreover, tit-for-tat strategies typically stipulate that individuals cannot "leave the game" (exit) and that third parties cannot intervene unless they can personally benefit from rewarding fair players or punishing unfair ones. These conditions rarely exist in most real-world settings.

In summary, gene–culture coevolutionary models posit that traditional genetic selection models (e.g., inclusive fitness theory and reciprocal altruism theory) cannot fully explain the evolution and existence of strong reciprocity, whereas theories of cultural group selection (Henrich & Boyd, 2001) and gene–culture coevolution (Gintis, 2003) can. These latter models propose that certain norms and institutions (e.g., food sharing, hunting, and serial monogamy) could have been maintained only if nearly all group members monitored and sanctioned important norm violations. This propensity may have spawned altruism in humans, which might have launched both the capacity for trust and the need to gauge the trustworthiness of others.

Ontogenetic Causation Explanations

Ontogenetic explanations address when, how, and why a particular trait or behavior develops and changes across the lifespan. The earliest ontogenetic theoretical accounts highlighted the critical role that experiencing trust with a primary caregiver assumes in social and personality development. In his psychosocial theory of development, for example, Erikson (1963) posits that all individuals encounter a series of basic conflicts at different stages of social development. The first major conflict, which takes place in infancy and early childhood, involves issues of basic trust versus mistrust. During this stage, highly dependent children first learn whether their basic needs will be met, ignored, or overindulged by their primary caregivers. Children who experience sufficient levels of satisfaction relative to frustration typically develop a sense of hope and confidence that their needs will be met in the future, which then influences how they perceive and behave when later psychosocial conflicts are encountered. Children who are ignored or overindulged tend to experience mistrust, which sets the stage for maladaptive responses to later life conflicts. Trust, therefore, serves as the foundation of personality and social development.

In developing attachment theory, Bowlby (1969, 1973, 1980) argued that children who receive warm, supportive, and situationally contingent care when distressed develop positive working models (relationship schemas) of themselves, significant others, and the world in general. One cardinal component of positive working models of others is having confidence in their availability and responsiveness, particularly during times of acute need. This core feature of attachment security is also a defining feature of trust. According to attachment theory, having trusting and supportive relationships early in life instills a sense of felt security (Sroufe & Waters, 1977), which provides an "inner resource" that allows individuals to take leaps of faith and place greater trust in significant others. Children who are subjected to rejection, unpredictable care, neglect, or abuse normally develop negative working models of others, which should retard or hinder the development of trust in later adult relationships (cf. Simpson, Ickes, & Grich, 1999).

Family systems theory (Bowen, 1976, 1978) has also been invoked to explain the development of interpersonal trust. According to this perspective, individuals who develop more differentiated self-concepts based on interactions with family members in the past should be able to establish and maintain emotional ties with future significant others more readily. Highly differentiated individuals tend to feel both connected to yet independent from significant others (Allison & Sabatelli, 1988; Shapiro, 1988). Because their self-concepts are more diversified, well balanced, and fully integrated, highly differentiated people can achieve closeness and intimacy without overidentifying with partners or becoming enmeshed with them (Bartle & Sabatelli, 1995). These characteristics should facilitate interaction patterns that result in greater trust, partly because highly differentiated people may feel more comfortable taking the risks necessary to forge deeper levels of trust.

Recent life-history models might also explain some of the developmental antecedents of dispositional trust. Adopting an evolutionary-based lifespan perspective, Belsky, Steinberg, and Draper (1991) contend that certain early experiences provide children with diagnostic information about the kinds of environments that they will most likely encounter in adulthood. As they develop, children implicitly use this information to adopt an appropriate reproductive strategy—one that is most likely to increase their inclusive fitness—in future environments (see also Hinde, 1986). According to this model, contextual factors in the family of origin (e.g., the amount of

stress, spousal harmony, and financial resources) systematically affect early childrearing experiences (e.g., the degree of sensitive, supportive, and responsive care). These experiences then influence children's psychological and behavioral development (e.g., their attachment patterns/styles and the nature of their working models), which in turn influence the rate of somatic development (how quickly individuals reach sexual maturity) and the mating orientation that they adopt in adulthood (short term vs. long term). Belsky and colleagues (1991) surmise that high levels of early stress and family dissention are associated with less sensitive parenting, which leads children to develop more negative working models of themselves and/or others and, therefore, more insecure attachment patterns. This information ostensibly signals that future pair-bonds may be short term and unstable, which prompts insecure individuals to mature more quickly and adopt a short-term, opportunistic orientation toward mating in which sexual intercourse with multiple partners occurs earlier in life and parental investment in children is lower. One central feature of short-term mating orientations is lower dyadic trust. The Belsky and colleagues model, therefore, suggests that the seeds of distrust may be planted early in life when individuals first learn about the world, primarily in their families of origin. Chisholm (1993, 1996) has proposed a similar lifespan model but argues that mortality rates in local environments are the focal cues that shunt individuals toward different adult mating orientations (see Simpson, 1999).

Proximate Causation Explanations

Various theories and models have outlined the proximal factors and processes that might facilitate or impede the development of trust in relationships.

Kelley and Colleagues (2003)

Informed by interdependence theory (Kelley & Thibaut, 1978), Kelley and colleagues (2003) have proposed that the development and deterioration of trust in relationships can be understood via the properties of the social situations in which relationships are embedded. They argue that "trust situations" reflect the unique combination of high interdependence between partners, coordination (the need to synchronize interactions), and exchange (the need to receive good outcomes from the partner) as the basis for interdependence, and corresponding (similar or joint) interests. Prototypical trust situations, therefore, entail both mutual partner control (e.g., quid pro quo situations) and corresponding mutual joint control (e.g., situations that require synchrony of choices).

Figure 25.1 depicts the unique 2 × 2 pattern of payoffs (benefits and costs) associated with choices that partners can make in prototypical trust situations. If both partners choose option 1 (they work on a difficult but important task together, reflected in the a1/b1 cell), each partner receives 20 units of benefit because the task gets accomplished while partners share the pleasure of each other's

FIGURE 25.1. The payoffs (outcomes) associated with Kelley et al.'s (2003) trust situation. Payoffs above the diagonal in each cell are for Partner A; those below the diagonal in each cell are for Partner B.

company. If both partners select option 2 (neither works on the task, represented by the a2/b2 cell), neither partner receives benefits because nothing gets accomplished. If partner A chooses option 2 (not to work on the task: a2) whereas partner B chooses option 1 (works solo on the task: b1), partner A benefits by 10 units because some progress is made on the task, but partner B experiences a net loss of 10 units because he or she is saddled with all the work. The reverse pattern exists when partner A chooses a1 (to work on the task) and partner B chooses b2 (to not work on the task).

Trust situations have several special properties. First, they involve collective rationality in that cooperative behavior by both partners (a1/b1) *always* yields superior outcomes compared to when partners fail to cooperate (a1/b2 or a2/b1). Second, the best outcome *always* occurs when both partners make the cooperative choice (a1/b1). Third, cooperative choices are risky because if one's partner decides to make a noncooperative choice, a cooperative choice generates the worst possible outcomes given that one has been exploited. Kelley and colleagues (2003) suggest that cooperation is undermined primarily by fear in trust situations and that, when individuals fail to make cooperative choices, they frequently do so for competitive or self-protective reasons. Partners who repeatedly enter or find themselves in trust situations and make joint cooperative choices should not only receive superior outcomes over time but also should develop greater trust. The "added value" that comes with joint cooperative decisions (i.e., the 10 additional units of benefit that accrue when both partners complete a valued activity *together*) is crucial to understanding what makes joint cooperative decisions so powerful and transforming. Though not much is known about what "added value" represents, most individuals find it intrinsically rewarding when, rather than taking advantage of their vulnerabilities, their partners repeatedly make choices that are beneficial to themselves or the relationship (Holmes, 1981).

Tit-for-tat tactics may generate trust more rapidly in newly formed relationships because they encourage rela-

tionship partners to gravitate toward a1/b1 decisions. When using tit-for-tat tactics, individuals remain cooperative until their partners make the first noncooperative overture, after which they respond noncooperatively until their partners revert back to cooperative choices. Because individuals never make the first noncooperative move, they are not perceived as aggressive or exploitative by their partners. Because noncooperative behavior is always responded to with noncooperation, partners also quickly learn the importance of cooperative norms. And because individuals immediately switch to cooperative choices when their partners do, they convey a willingness to forgive, which is likely to strengthen the inference that the individual yearns to establish and maintain cooperation. The strongest trust, however, may be forged in somewhat asymmetrical relationships in which one individual has power over the partner but consistently makes decisions that benefit the low-power partner at the expense of his or her own self-interest. In these situations, both the low-power partner and the high-power partner should perceive the benevolent and caring motives harbored by the high-power partner. These perceptions might contribute to the "added value" of a1/b1 decisions discerned by *both* partners.

Holmes and Rempel (1989)

Holmes and Rempel (1989) have proposed a dyadic model of trust that contains both normative (i.e., typical or modal) and individual difference components. According to their model, trust should be enhanced when relationship partners successfully resolve basic concerns regarding dependency issues, such as what happens when partners encounter noncorrespondent or conflicting payoff structures. The normative component of the model specifies the progression of events and psychological processes that should promote or diminish trust in relationships *in general*. The individual-difference component clarifies how these normative features may be qualified by the level of trust (high, medium, or low) that characterizes a current relationship.

From a normative standpoint, Holmes and Rempel (1989) suggest that the development of trust involves a process of uncertainty reduction as individuals gradually migrate from having confidence in their partner's general predictability to having confidence in their benevolent relationship values, motives, goals, and intentions. During the initial stages of relationship development, individuals typically project their hopes and ideals onto their partners. These projections tend to be vague and rarely challenged, usually because partners are not highly interdependent, their interactions are positive and limited in scope, they are well mannered, they want to view one another in the best possible light, and they have not yet experienced major conflicts. At this stage, trust is based chiefly on individuals' hopes that their partners will, over time, live up to these idealized images.

As individuals become increasingly dependent on their partners, concerns about being vulnerable to loss, exploitation, and rejection begin to surface. To assuage the anxiety associated with this predicament, individuals

try to quell relationship uncertainties by searching for evidence that their partners truly care for and are genuinely concerned about them, a process that Holmes and Rempel (1989) term "reciprocal reassurance." Reassurance should be strongest when partners make costly personal sacrifices for the individual, take bold risks such as providing costly "no strings attached" outcomes to the individual, or adopt more vulnerable positions than the individual has previously taken (Pruitt, 1965). Trust is not likely to grow, however, unless exchanges between relationship partners are reasonably reciprocal and balanced, and partners view one another as being neither overly anxious nor overly reluctant to venture interpersonal risks. Indeed, Holmes and Rempel contend that equal and gradually increasing mutual involvement by *both* partners should facilitate greater trust by further dampening relationship uncertainties. Equal involvement ensures that both partners are similarly dependent and, therefore, equally vulnerable. For this reason, equal involvement may function as a temporary substitute for trust until genuine trust can develop.

As relationships move into the accommodation stage, resolved relationship uncertainties allow individuals to take greater leaps of faith and to place increasing confidence in their partners. Gradually, most individuals begin to amass an "economy of surplus," which enables them to ignore, discount, or excuse minor partner transgressions that, if committed during earlier stages, could have shaken the emerging foundation of trust. During the accommodation stage, however, individuals start to view their partners more realistically, which can reignite relationship uncertainties as partners become increasingly interdependent and their self-interests occasionally diverge. To resolve this dilemma, individuals begin to view the relationship prospectively, whereby the costs of remaining in the relationship are weighed against the prospect of future rewards (Huesmann & Levinger, 1976; Kelley & Thibaut, 1978). Individuals also contemplate whether they are in the best possible relationship and can count on their partners to fulfill their fundamental needs. As a result, decisions to invest further in the relationship become more contingent upon subjective forecasts about what the future may hold. At this point, trust becomes less highly correlated with other markers of relationship quality such as love (Larzelere & Huston, 1980).

When relationship uncertainties resurface at the accommodation stage, individuals may enter or create "strain test" situations (Holmes, 1981; Kelley, 1983) to gauge their partner's true degree of commitment and devotion. If the partner (1) demonstrates care, concern, and responsiveness when the individual is highly vulnerable or dependent and (2) takes actions that run counter to his or her own best interests, trust should increase. Trust should also be enhanced if partners repeatedly acknowledge an individual's core needs and reaffirm his or her self-worth, if partners' actions are perceived as being unconditional, if partners are willing to relinquish control to individuals in important situations, if they have behaved fairly and benevolently in difficult (e.g., noncorrespondent) situations in the past, and if they engage in acts that lead individuals to make positive, intrinsi-

cally motivated attributions for the partner's behavior (Holmes & Rempel, 1989; see also Kruglanski, 1971).

Holmes and Rempel (1989) also elucidate how individual differences in trust may alter or qualify these normative stages and psychological processes. Individuals involved in relationships characterized by greater trust should have more benevolent, long-term views of their partner's motives and actions. They also should harbor more positive, well-integrated, and well-balanced working models that instill more benevolent expectations and, therefore, more constructive, problem-focused styles of resolving relationship difficulties.

Individuals involved in relationships containing moderate levels of trust should have more suspicious and guarded views of their partner's motives and behavior. Because they possess chronically accessible relationship uncertainties, "medium trust" individuals should closely monitor and frequently test their partner's care and responsiveness, even if such tests might confirm their darkest fears. Given their hypervigilant, emotion-focused style of coping with relationship problems, these individuals may unwittingly amplify or create the very outcomes they wish to avert by constantly questioning and testing their partner's trust and commitment, effectively driving the partner away.

Individuals involved in relationships defined by low trust have minimal confidence in their partner's ability or willingness to ever be caring or responsive. As a consequence, they hold highly cynical and negative views and expectations about relationships. This tendency may generate distress-maintaining attributions, whereby the implications of possible negative partner behaviors are ac-

centuated and positive partner actions are disregarded or dismissed. These cognitive tendencies should lead "low trust" individuals to display heightened anger or to withdraw when major relationship problems arise. Because a fair amount of research has addressed some of these speculations, we revisit the individual-difference component of Holmes and Rempel's model in the next section.

Wieselquist, Rusbult, Foster, and Agnew (1999)

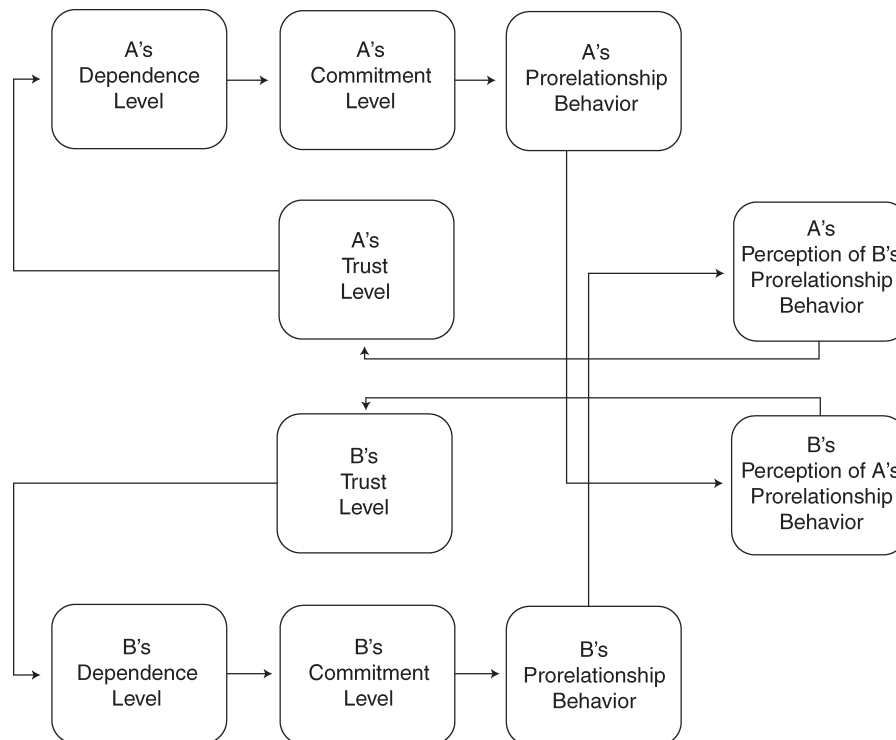
Guided by the investment model (Rusbult, 1983), Wieselquist and colleagues (1999) claim that trust is most evident when partners display large prorelationship transformations of motivation, which are indexed by the discrepancy between a partner's initial self-interests (captured in the given matrix) versus his or her final, transformed outcomes and observable actions (represented in the effective matrix). Individuals who make larger transformations from purely self-interested outcomes (e.g., MaxOwn) to either partner (e.g., MaxOther) or relationship (e.g., MaxJoint) outcomes should and do have relationships characterized by greater trust (Yovetich & Rusbult, 1994). Given that commitment generates so many crucial relationship-maintenance acts (e.g., disparagement of alternative partners, willingness to sacrifice, accommodative behaviors, positive partner and relationship illusions, and a sense of cognitive interconnectedness), Wieselquist and colleagues believe that commitment should play a central role in both the generation of and changes in dyadic trust. According to their mutual cyclical growth model, shown in Figure 25.2, greater dependence by one partner in a relationship should in-


FIGURE 25.2. Wieselquist et al.'s (1999) mutual cyclical growth model.

still greater commitment, which should then launch prorelationship actions that yield MaxJoint outcomes. These behaviors should then be witnessed by the other partner who should experience greater trust. This, in turn, should promote greater dependence, greater commitment, and more prorelationship acts, which are witnessed by the first partner, who subsequently experiences greater trust. According to the model, the process then begins again, at least to some asymptotic level. As we shall see, although cross-sectional data support certain paths in the model, most of the antecedent variables do not predict temporal *changes* in the downstream variables.

Deutsch (1973)

Deutsch (1973) has proposed one of the most detailed proximate-level accounts of trust. He suggests that trust is evident when individuals select an "ambiguous path" in which the strength of their positive motivations to pursue a course of action is *less* than the strength of their negative motivations. In addition, individuals' subjective estimates of positive outcomes occurring must be greater than their subjective estimates of negative outcomes occurring, and they must have sufficiently high "security" to take the action. Subjective estimates ought to be based on past experiences in similar situations, past experiences with or beliefs about specific partners, more global working models of self and others, and one's confidence in being able to achieve positive outcomes or avoid negative ones.

A series of specific hypotheses can be derived from these central premises. Deutsch claims, for instance, that the longer the time frame in which events that would have negative motivational significance might take place, the more individuals should make trusting choices and decisions in their relationships. After an individual has made a trusting choice, he or she should then seek reasons that justify and support the wisdom of the choice, especially if the choice was originally difficult to make. Furthermore, an individual's perception of his or her *partner's* intention to perform a future action or behavior should depend on the partner's presumed strength of motivation to engage in the action or behavior, the partner's commitment to engaging in it, the source of the partner's motivation (e.g., internal vs. external or altruistic vs. exchange focused), and the individual's own attentional focus.

In terms of perceiving altruistic or trust-promoting intentions in others, Deutsch speculates that positive intentions should be more likely to be inferred when individuals believe that others (e.g., their partners) like them. Liking, in turn, should depend on the amount, frequency, and diversity of benefits that an individual has received from a partner in the past. It should also be greater if individuals are aware that their partners were *not* forced to provide benefits and if individuals believe that partners knew a priori that their actions would have positive consequences. Liking should also be heightened if the partner is perceived as having little to gain by providing benefits to the individual, if the partner's actions

provide greater gains to the individual than to the partner, and if the partner knows that his or her benevolent actions would be costly from the start.

In terms of perceptions of power, Deutsch claims that individuals who perceive that their partners have relatively greater power should be either more trusting *or* more suspicious (i.e., an amplification effect). More powerful individuals should be less inclined to infer altruistic motives and intentions in their partners and, hence, less likely to trust them. These perceptions should be easier to change, however, if individuals enter interactions or relationships with the belief or goal that mutual trust is possible. Deutsch argues that communicating a desire for cooperation (which can be conveyed by expectations, intentions, or reactions to norm agreements and norm violations) should increase dyadic trust and render the communicator more trustworthy.

In sum, more theoretical attention has been paid to the proximal processes that might facilitate or impede interpersonal trust than to ontogenetic processes. Models of proximate causation have viewed the antecedents of trust as anchored in how relationship partners routinely make choices in certain types of critical situations (e.g., prototypical trust situations; Kelley et al., 2003) and the typical manner in which trust usually unfolds as relationships develop, enter new stages and partners grow more interdependent (Holmes & Rempel, 1989). Proximate models have also highlighted the important role that commitment and the responses of relationship partners may assume in the development of trust in relationships (Wieselquist et al., 1999) and some of the more detailed psychological processes and mechanisms that might guide specific decisions to enter situations or make decisions that could promote or stall the development of trust (Deutsch, 1973).

A REPRESENTATIVE REVIEW OF RESEARCH ON INTERPERSONAL TRUST

Though there was a smattering of theory and research on trust prior to the late 1950s, Morton Deutsch was largely responsible for launching interest in the topic. In his early work, Deutsch (1960) marshaled evidence that the development of mutual trust between interaction partners was essential for cooperation to emerge and be maintained. He argued that mutual trust should develop when interaction partners adopt a positive and benevolent orientation toward one another's welfare. Using the PDG as the primary investigative paradigm, Deutsch confirmed that people who enter single-trial PDGs with a cooperative orientation tend to make more cooperative choices that yield greater gains for both interaction partners. On the other hand, those who have a competitive orientation frequently make noncooperative choices that culminate in losses for both partners. Deutsch also found that cooperative individuals do not necessarily communicate to enact cooperative choices, whereas competitive individuals often convey motives or behaviors that block or subvert trustworthy communication. Later studies

(e.g., Ellison & Firestone, 1974; MacDonald, Kessel, & Fuller, 1972; McAllister & Bergman, 1986) revealed that more intimate self-disclosure, which frequently includes expressions of vulnerability and willingness to trust others, generates greater liking for and trust in partners who also disclose personal information.

Unfortunately, there were problems with this early line of experimental work (see Cook & Cooper, 2003). First, Deutsch did not operationalize and measure trust directly in these initial studies. Cooperative behavior was treated as an indirect proxy of trust. Second, this initial wave of research confounded trust and cooperation, which are distinct constructs. Third, the early studies were grounded in a social exchange perspective, which left little room to explain cases in which trust develops in the absence of direct exchanges. Fourth, the majority of the early PDG studies examined single-trial interactions between strangers. By not permitting multiple interactions over time between people who shared a past or a future, it proved difficult to generalize the results of early PDG experiments to everyday interactions and relationships. Consequently, these early single-trial PDG studies produced outcomes that tend to be different than those found when iterative, higher-stakes games are used (e.g., Fehr & Fischbacher, 2003).

The rise of dispositional views of trust in the late 1960s and early 1970s was a reaction to these shortcomings. Rotter (1967), in fact, developed self-report scales of generalized (dispositional) trust directly in response to Deutsch's initial program of trust research. Rotter believed that single-trial PDG studies generated situation-specific results that were confined to a small set of competitive situations not representative of everyday interactions. Once dispositional measures of generalized trust were developed, trust research in the 1970s identified systematic differences between people who reported being more versus less trusting of people in general. This body of work revealed that individuals who score higher in dispositional trust are more trustworthy partners in different types of social interactions, find it more difficult to lie, are more well liked by others, contribute more to philanthropic projects, are better at judging whom to trust and whom *not* to trust, and are more willing to trust strangers (Rotter, 1971). Although greater dispositional distrust was initially tied to poorer psychological adjustment and greater antisocial behavior (Rotter, 1980), later research indicated that links between dispositional trust, maladjustment, and distress are modest (Comrey & Schiebel, 1983; Folkman, Lazarus, Gruen, & DeLongis, 1986; Wrightsman, 1974). When highly distrusting individuals have problems, they usually report greater interpersonal difficulties, especially with excessive competitiveness, envy, resentfulness, vindictiveness, and lack of feelings or concern for others (Gurtman, 1992). Highly trusting persons, in contrast, adopt more kind and benevolent orientations toward others. However, they are not more gullible or exploitable than less trusting persons (Rotter, 1980), perhaps because more trusting individuals respond to partner transgressions by immediately withdrawing cooperation when partners behave badly in a tit-for-tat, situation-contingent manner.

In the early 1980s, research shifted toward dyadic conceptions of trust. Kelley (1980), for example, speculated that certain interpersonal traits (dispositions) might be systematically correlated with dyadic measures of trust. He surmised that people who score lower on dominance and nurturance might be particularly inclined to distrust relationship partners (for the theoretical reasons, see Carson, 1979). Testing relations between various interpersonal traits and dyadic trust, Gaines and colleagues (1997) documented that affiliative–dominance (e.g., extraversion) is the best predictor of high-faith scores on Rempel and colleagues' (1985) dyadic trust scale. Aloofness–introversion, on the other hand, is the strongest predictor of low-faith scores.

Holmes (1991) also examined ties between dyadic measures of trust and global interpersonal orientations. He found that individuals who either yearn for extreme emotional intimacy *or* fear being too close tend to trust their current romantic partners less. Moreover, dyadic trust tends to be higher among people who value moderate amounts of autonomy in relationships and lower in those who place greater emphasis on being independent and self-sufficient. These effects might reflect the fact that the core motives underlying autonomy and affiliation are associated with different styles of coping with relationship uncertainty (Holmes & Rempel, 1989). They may also reflect the fact that these higher-level interpersonal orientations contain some of the cardinal features that define attachment security and insecurity (Bowlby, 1973; Mikulincer, 1998). Correlations between interpersonal traits (dispositions) and dyadic measures of trust, however, tend to be modest (Holmes & Rempel, 1989).

The principal drawback of the dispositional approach was that it did not address the inherently dyadic, partner-specific, and context-dependent nature of trust that characterizes many close relationships. For this reason, dyad-centered measures of trust (e.g., Johnson-George & Swap, 1982; Rempel et al., 1985) and dyad-centered programs of research (e.g., Rempel et al., 1985) rose in the mid-1980s, partially in response to theoretical advances spearheaded by Deutsch (1973), Kelley and Thibault (1978), and Holmes and Rempel (1989), and partially in response to landmark empirical studies that cast trust within a dyadic framework (e.g., Kelley & Stahelski, 1970; Larzelere & Huston, 1980). Several key findings have emerged from the dyad-centered approach, only some of which can be highlighted. Some of the most influential research has been guided by two of the most dominant theoretical perspectives in interpersonal relationships: interdependence theory (Kelley & Thibaut, 1978; Thibaut & Kelley, 1959) and attachment theory (Bowlby, 1969, 1973, 1980).

Interdependence Theory-Based Approaches

Working from an interdependence theory perspective, Holmes, Rempel, and their colleagues have engaged in one of the most systematic and sustained programs of empirical work on dyadic trust. While interested in both normative and individual difference components of trust, the bulk of their research has focused on how indi-

vidual differences in trust are related to the way in which individuals appraise, construe, feel, and behave in situations when partners must grapple with dependency issues and their self-interests are discrepant. Their research has highlighted several crucial differences in how persons involved in high-, medium-, or low-trust relationships process information and respond when dependency issues are salient.

Individuals involved in relationships defined by high levels of trust (whom Holmes & Rempel, 1989, term "high-trust" people) harbor more optimistic and benevolent expectations about their partner's motives, make more positive and global attributions about their partner's behaviors, and have more integrated and well-balanced working models that remain open to assimilating new information (Rempel et al., 2001). High-trust individuals also disregard or downplay their partner's negative relationship-relevant actions, which isolates and minimizes the potential negative impact of partner indiscretions. When resolving relationship conflicts, high-trust individuals display more positive affect and less negative affect (Holmes & Rempel, 1986), and their evaluations of their partners and relationships are less strongly tied to the emotions they experience during these intense discussions. High-trust individuals also evaluate their partners more positively, not only when they are asked to recall positive or neutral relationship experiences but particularly when they recount *negative* relationship experiences (Holmes & Rempel, 1989). That is, when high-trust individuals encounter relationship threats, they step back and contemplate their partner's probable benevolent goals and motives within a broader, long-term perspective (Holmes, 1981).

On the basis of these and other findings, Holmes and Rempel (1989) suggest that the working models of high-trust individuals (e.g., their trust-related hopes and fears vis-à-vis the current partner and relationship) should be more unified and better integrated than those of medium- or low-trust persons. This greater integration might result from several cognitive mechanisms, including limiting or dispelling the implications of negative relationship actions or events when they occur (Rempel, 1987), altering the meaning of negative actions/events so positive perceptions of the partner and relationship can be maintained (e.g., using "yes, but . . . " refutations; Murray & Holmes, 1993), or framing negative actions/events within the broader constellation of past positive relationship experiences (Murray & Holmes, 1993). Holmes and Rempel (1989) also surmise that greater trust should enhance felt security, which might liberate high-trust individuals from having to monitor their partners and relationships and could motivate them to err on the side of benevolence when interpreting ambiguous partner behaviors. In addition, high-trust individuals may have higher thresholds for perceiving relationship threats, they might experience or construe negative events as less aversive, or they may recover from adverse relationship experiences more quickly (see Holmes & Rempel, 1989).

Individuals involved in relationships that contain moderate levels of trust (termed "medium-trust" individuals)

have less coherent and more fragmented working models in which trust-relevant hopes and fears are intermingled in strange and sometimes contradictory ways (Holmes & Rempel, 1989). These individuals are often trapped in strong approach–avoidance situations in which positive partner behaviors are viewed as hopeful signs of possible relationship improvement but any negative behavior is taken as clear evidence that relationship dissolution could be imminent. For this reason, medium-trust individuals continually monitor and test for signs of their partner's care, concern, and responsiveness. Ironically, this hypervigilance may lead medium-trust individuals to perceive or unwittingly create the negative relationship outcomes they wish to avoid, given their likely overreliance on the diagnostic value of negative relationship information (see Reeder & Brewer, 1979). Moreover, when medium-trust individuals recall positive relationship events from the past, they judge their partner's behavior positively yet make cynical attributions about the motives behind their partner's actions (Holmes & Rempel, 1986; Rempel et al., 2001). In other words, medium-trust individuals superficially acknowledge their partner's positive actions but fail to infer that their partner's motives might be constructive and benevolent. As a result, positive partner actions may trigger latent worries about what could eventually "go wrong" in the minds of medium-trust people, a process that might impede or derail the development of what they crave— deeper intimacy and greater security.

Thus, contrary to high-trust individuals, who probably adopt a promotion focus toward relationships (Gable & Reis, 2001), medium-trust people adopt a risk-averse, prevention-focused strategy, one that is revealed by their chronic feelings of vulnerability, their incessant worries about mistakenly making positive attributions for their partner's actions, and their lingering concerns about eventually being hurt by their partners. These defensive, self-protective tendencies should reduce the likelihood that constructive partner behaviors will be accepted as evidence of the partner's genuine care and concern. To compound matters, medium-trust individuals also have more poorly integrated views of their partners and relationships (Holmes & Rempel, 1989). Memories of hurts and fears in the minds of medium-trust individuals, therefore, could be more sharply segregated from memories of positive relationship experiences. In addition, medium-trust individuals are likely to possess negative relationship models and memories that are more easily activated, and they may experience more volatile emotional swings in their relationships across time, perhaps owing to the greater compartmentalization or the haphazard connections that define their working models (see Mikulincer, 1998).

Individuals involved in relationships characterized by low trust (termed "low-trust" persons) have minimal confidence in their partner's care and responsiveness. These individuals are convinced that their partners will not take their needs or concerns into account when important decisions are made, and they are least likely to attribute their partner's positive actions to either benevolent or altruistic motives (Holmes & Rempel, 1989). Instead, low-

trust people exhibit distress-maintaining attributions (Holtzworth-Munroe & Jacobson, 1985), accentuating the ramifications of negative partner behaviors and ignoring or downplaying positive partner behaviors. When trying to resolve relationship problems, low-trust individuals consciously report having more specific (i.e., less global) neutral or slightly negative attributions regarding their partner's actions. However, more indirect measures suggest that they actually harbor strong negative attributions about their partner's real underlying motives (Rempel et al., 2001). These destructive attributional patterns may sustain the cynical and suspicious working models of low-trust persons. Because they believe that their partners cannot be trusted and will never be responsive to their basic needs, low-trust individuals rarely take the interpersonal risks necessary to build greater trust and felt security. In fact, they typically disengage or withdraw from interactions in which greater trust could be forged (such as in initially noncorrespondent situations with their partners; Rempel et al., 2001), possibly to protect themselves from the anguish of further rejection.

Testing the dependency regulation model (Murray, Holmes, & Griffin, 2000), Murray and colleagues (2005) have confirmed that, before they can fully trust their partners, low-self-esteem people may first need to either view themselves more positively *or* view their partners less positively to believe that their partner's love and benevolent actions are genuine, justified, and valid. Specifically, when low-self-esteem individuals are given feedback that they are more desirable as romantic partners than most people *or* that their current partners have treated them badly, they report greater felt security and more positive views of themselves *and* their romantic partners. Furthermore, the connection between the low-self-esteem/negative feedback experimental condition and improved self-perceptions is mediated by enhanced felt security. These psychological processes may play a critical role in nurturing trust.

Extending Rusbult's (1983) investment model, Wieselquist and colleagues (1999) have found that the degree of dyadic trust in relationships is likely to be contingent on aspects of the self, the partner, *and* the relationship (see Figure 25.2). In two longitudinal studies, they have shown that greater trust is concurrently associated with greater dependence on the partner, which in turn forecasts greater concurrent commitment. Heightened commitment concurrently predicts the enactment of more prorelationship behaviors (e.g., accommodation and personal sacrifice), which is perceived by the partner. These partner perceptions are then linked to a string of positive relations between the partner's level of trust, dependence, commitment, and prorelationship actions, which subsequently predict the *partner's* perceptions of these actions.

Wieselquist and colleagues (1999) propose that perceiving greater prorelationship accommodation and sacrifice by one's partner might be responsible for promoting trust. Indeed, when individuals perceive that their partners have experienced a major transformation away from purely self-interested outcomes (MaxOwn) toward partner-centered outcomes (MaxOther) or relationship-centered outcomes (MaxJoint), they do report greater trust (see also Yovetich & Rusbult, 1994). If, however, one partner has an anxious–ambivalent attachment style (i.e., chronically worries about whether partners love or will stay with him or her), lower levels of trust tend to be reported by *both* relationship partners. Wieselquist and colleagues also suggest that partners may occasionally use "diagnostic" or "strain test" situations to test the strength of their partner's prorelationship motives or demonstrate their *own* prorelationship motives. Trust is less likely to develop or grow if partners never experience these situations, if one or both partners fail these critical tests by not showing expected transformation tendencies, or if one or both partners do not perceive or fail to infer the other's genuinely positive, prorelationship motives. Wieselquist and colleagues also conjecture that trust may be more likely to develop and grow if mutual (similar) levels of vulnerability, mutual changes in commitment, and reciprocal positive behaviors are exchanged between partners. Sometimes, however, trust may grow stronger if partners do *not* reciprocate evenly, at least over short time periods (see Drigotas, Whitney, & Rusbult, 1995).

Miller and Rempel (2004) have extended this line of work by testing whether charitable attributions might be responsible for increasing dyadic trust. Noting that Wieselquist and colleagues (1999) found little evidence for which variables predict actual *changes* in trust over time in relationships, Miller and Rempel conjecture that partner-enhancing attributions regarding the motives behind a partner's relationship-relevant actions and behaviors might predict actual increases in dyadic trust. Studying married couples, they found that partner-enhancing attributions (e.g., the belief that one's spouse has good intentions when discussing a conflict) predicted significant gains in trust 2 years later. Increases in trust also predicted increases in the tendency to make partner-enhancing attributions, suggesting that both processes may operate in a mutually reinforcing fashion. Changes in trust, therefore, do not appear to be driven by attributions about a partner's specific interaction behaviors; rather, they arise from the more global attributions that individuals make regarding the *motives* that guide a partner's habitual relationship-relevant actions.

Attachment Theory–Based Approaches

Additional research on trust has been informed by attachment theory. The earliest work linking adult attachment styles to dyadic trust (e.g., Simpson, 1990) indicated that more securely attached people (who have positive models of themselves and relationship partners) report greater dyadic trust than either more avoidantly attached people (who have variable self-views and predominately negative views of partners) or anxiously attached people (who have negative self-views and hopeful yet guarded views of partners). More secure people also sustain higher levels of trust in their relationships across time than do their insecure counterparts (Keelan, Dion, & Dion, 1994). The working models of more securely attached individuals may partially explain their stronger in-

clination to trust others. Baldwin, Fehr, Keedian, Seidel, and Thompson (1993), for example, have found that more secure people expect hypothetical partners to behave more benevolently in situations that call for trust. They also respond more rapidly to words connoting positive relationship outcomes (e.g., care), whereas more insecure individuals react more quickly to words suggesting negative relationship outcomes (e.g., hurt). Highly secure individuals also possess more available and accessible positive relationships exemplars, whereas highly avoidant and highly anxious individuals have more available and accessible negative relationship exemplars (Baldwin, Keelan, Fehr, Enns, & Koh-Rangarajoo, 1996). When individuals feel more secure in a given relationship, they report heightened trust, above and beyond any effects associated with their chronic (dispositional) attachment style. Pistole (1994) suggests that the lower trust displayed by more insecurely attached people might also be attributable to how these individuals regulate important social interactions. Highly anxious individuals, who crave emotional closeness and intimacy, may smother their partners, unwittingly pushing them away. Highly avoidant individuals, who desire self-reliance and emotional independence, may erect barriers that create and maintain emotional distance, a tendency that could launch or exacerbate destructive "distance/pursuer" interaction cycles.

The most detailed research linking adult attachment styles and dyadic trust has been conducted by Mikulincer. Mikulincer (1998) claims that confidence in and positive expectations of a partner's availability and responsiveness are core elements not only of dyadic trust but of secure working models as well. He argues that in response to the quality of previous care and support they have received (or *perceive* they have received), individuals with different attachment styles should have different trust-related goals. More securely attached persons ought to organize their interpersonal behavior around creating and maintaining greater closeness and intimacy in their relationships, partly because they do not have to worry about attaining felt security. Achieving greater intimacy may, in fact, be essential for developing greater trust. According to Mikulincer, the tendency of securely attached individuals to be more trusting should facilitate their quest for greater intimacy because heightened trust should serve as an "internalized secure base" that permits more secure people to take the interpersonal risks and leaps of faith necessary to build deeper trust. Many of these risks are likely to include the disclosure of personal goals, hopes, feelings, and fears.

The central interaction goals of insecurely attached individuals, by comparison, should mirror the defenses that insecure people use to combat attachment-related distress (Bowlby, 1988). Given their unrelenting concerns about receiving deficient care, attention, and support (Bowlby, 1973), highly anxious people should adopt interaction goals that are geared toward attaining what they desire the most—greater felt security. In light of their prolonged history of rejection and subsequent desire to avoid emotional entanglements (Crittenden & Ainsworth, 1989), highly avoidant people should adopt

goals to attain what they ultimately desire—gaining and maintaining control and autonomy in relationships.

Mikulincer (1998) has provided compelling evidence for the existence and operation of these goals in people who have different attachment styles. More securely attached people do have more accessible memories of trust-validating experiences, they feel more positive affect when remembering these experiences, and they report more trust-validating experiences. They also place greater importance on trust-validating experiences and view them as being attributable to the benevolent traits and motives of their partners. More secure individuals also talk more openly with their partners about trust-violation events, they have less accessible negative trust-related memories, they react less negatively to negative memories, and they do *not* attribute trust violations to their partner's stable dispositions or enduring motives (i.e., they make situation-specific and transient attributions for negative partner behaviors). Although more secure individuals tend to be involved in more satisfying relationships with perhaps better adjusted romantic partners than many insecure individuals (Simpson, 1990), the cognitive and emotional tendencies documented by Mikulincer ought to accentuate positive views of partners and relationships and curtail negative ones, possibly fueling greater trust.

More insecure individuals, in contrast, report less trust and have more accessible negative trust-related memories (Mikulincer, 1998). In addition, they view trust as a means to achieve security-based goals (in the case of highly anxious people) or control/autonomy-based goals (in the case of highly avoidant people). More insecure individuals also exhibit more maladaptive coping strategies when distressed. Highly anxious persons, for instance, use more emotion-focused coping strategies, whereas highly avoidant persons use more avoidance/distancing coping strategies. Finally, highly anxious individuals respond to negative trust-related experiences with greater negative affect and place more weight on these negative experiences.

Other Theoretical and Empirical Approaches

There have been other notable studies of dyadic trust. Several, for example, have documented that trust tends to be high during the initial stages of relationship development (Fletcher et al., 2000), after which it gradually declines once the honeymoon phase is over (Larzelere & Huston, 1980). What is not known, however, is whether relationship partners define and weigh trust similarly at different stages of relationship development. Other research has indicated that individuals who engage in more self-disclosure and communicate greater trust often have partners who are more trusting (Butler, 1986; Haas, 1981; Larzelere & Huston, 1980). Trust may be especially facilitated by the combination of intimate self-disclosures and reciprocated trust from partners (Deutsch, 1960; Ellison & Firestone, 1974; McAllister & Bergman, 1986), though some research has questioned the importance of reciprocity (Bartle, 1996). Other lines of work have discovered small but stable gender differences in dyadic

trust. Women typically score slightly higher than men on trust measures (Butler, 1986; Canary & Cupach, 1988), perhaps because certain family-of-origin experiences might affect women and men differently (see Cooper & Grotevant, 1987). These gender differences might also stem from how men and women are socialized in Western cultures. Given that most men are taught to value independence and autonomy (Block, 1983; Gilligan, 1982), many men may eschew the greater dependence on others that higher levels of trust entail. Given that most women are socialized to be interdependent and relationship oriented, many women may feel more comfortable entering and maintaining more dependent relationships that involve greater trust.

Work conceptualizing trust from family systems theory (Bowen, 1976, 1978) suggests that women who are less empathetic, who are poorer at solving relationship problems, who are less likely to take responsibility for their actions, and whose families-of-origin did not express thoughts and emotions accurately tend to be less trusting (Reeves & Johnson, 1992). In addition, Bartle (1996) has found that greater emotional and behavioral reactivity to emotion-evoking events involving one's *parents* predicts less dyadic trust of one's current romantic partners. Men's trust, however, correlates most highly with their level of emotional/behavioral reactivity (such that less reactive men report the most trust), whereas women's trust is most strongly tied to their comfort with making intimate self-disclosures to significant others. Borrowing principles of family systems theory, some research insinuates that the *lack* of sufficient self-differentiation from significant others (e.g., parents, romantic partners, and close friends) may foreclose the kinds of social interactions needed to develop stronger trust (Ryder & Bartle, 1991). According to this view, if an individual's self-concept is more diversified, he or she should be more willing to risk placing deeper confidence and faith in others. If relationships fail, the self-concepts of these "well-diversified" individuals should be buoyed by the other sources that define and contribute to their sense of self-worth (see Crocker & Wolfe, 2001).

The most recent wave of research on dyadic trust is starting to identify the specific brain structures and processes implicated in the psychological experience of trust. The amygdala, one of the primary centers for processing emotions, becomes more active when people view faces that they later rate as untrustworthy relative to faces they rate as more trustworthy (Winston, Strange, O'Doherty, & Dolan, 2002). Although little is known about the facial cues that signal untrustworthiness, some evidence suggests that expressions of anger and sadness or the absence of happiness might be systematically tied to perceptions of untrustworthiness, at least from photographs (Adolphs, 2002). In addition, bilateral damage to the amygdala tends to impair judgments of untrustworthy faces (Adolphs, Tranel, & Damasio, 1998). Adolphs (2002) suggests that seeing untrustworthy people may trigger automatic, largely unconscious processing in the amygdala, which launches more conscious processing in the orbitofrontal area of the brain. This secondary processing may then generate the cognitive and somatic changes that individuals sense as negative emotional responses.

Other recent research has revealed that people are more likely to trust others who resemble them in physical appearance (DeBruine, 2002), and they systematically reward partners who trust them and punish those who do not (Fehr & Rockenbach, 2003). Though preliminary, some research suggests that levels of the hormone oxytocin rise when individuals who are playing monetary games against others receive information that their interaction partners trust them (Zak, 2003). Individuals who have higher baseline levels of oxytocin are also more likely to reciprocate signs of trust, and women who are ovulating are *less* inclined to trust others compared to when they are not ovulating (Zak, 2003). When oxytocin is administered experimentally to people, they are more willing to trust strangers (but not machines) in trust games that involve real monetary stakes (Kosfeld, Heinrichs, Zak, Fischbacher, & Fehr, 2005).

In conclusion, a reasonable amount of research, much of which has been informed by interdependence theory or attachment theory, has investigated various aspects of trust in close relationships. The first wave of seminal work was structured around single-trial PDG experimental paradigms involving strangers (e.g., Deutsch, 1960). Largely in response to problems with this research, the second wave of research conceptualized trust as a fairly stable disposition relevant to others in general. The most recent wave of work, which was launched in the 1980s, has conceptualized trust in more dyadic (interpersonal) and process-oriented terms (e.g., Holmes & Rempel, 1989; Mikulincer, 1998; Wieselquist et al., 1999). Most of the extant research, however, has focused on individual differences in trust (e.g., the way in which individuals who differ in the degree of trust within a relationship differentially think, feel, and behave in trust-relevant situations) rather than the more basic normative processes that, over time, might promote or inhibit the development of trust in relationships. Future research needs to test and delve more deeply into the normative components of models that attempt to explain the growth and decline of trust in established relationships across time.

MAJOR PRINCIPLES AND A DYADIC MODEL OF TRUST IN RELATIONSHIPS

One of the goals of the current volume is to identify overarching principles that capture the core essence of a given psychological construct or set of processes. Based on the preceding review, at least six fundamental principles of trust are apparent.

- *Principle 1*: The desire to view partners positively and to want to trust them (i.e., enhancement motives) plays a larger role in guiding relationship and social interaction processes during the early phases of relationship development.
- *Principle 2*: The desire to view partners more accurately and objectively (i.e., accuracy motives) becomes more important in guiding relationship and social inter-

action processes in latter stages of relationship development.

- *Principle 3*: Individuals assess the degree to which they can trust their partners by observing whether partners display proper transformation of motivation in *trust diagnostic* situations (e.g., in potentially noncorrespondent "trust" or strain test situations in which partners make decisions that work against their own self-interest and support the best interests of the individual and/or the relationship).

- *Principle 4*: Individuals may at times intentionally enter or create trust diagnostic situations to test whether their current level of trust in a partner is warranted.

- *Principle 5*: Individual differences associated with attachment processes, self-differentiation, and/or self-esteem are likely to influence the growth or decline of trust at different normative stages over time in relationships (see the model presented below).

- *Principle 6*: Neither the level nor the trajectory of trust in relationships can be fully understood without considering the dispositions and actions of *both* relationship partners, especially in trust diagnostic situations.

These principles are by no means exhaustive. However, they capture six of the most central themes that anchor the major theoretical and empirical work that has focused on interpersonal trust.

Several theories and models of trust have been reviewed. How might their major features be integrated to highlight the most important situational and psychological processes through which trust is likely to develop and be maintained in close relationships? Figure 25.3 depicts one way of conceptualizing how some of the core constructs reviewed earlier in the chapter might be interconnected in trust-relevant social interactions. The dyadic model of trust in relationships contains both normative and individual difference components. The normative part of the model is shown in the five boxes (constructs) that form the middle of the figure. The individual difference portion of the model is displayed in the dispositions of *each* relationship partner and her or his respective links to each normative construct. To keep the figure simple, feedback loops from the terminal normative construct (*each partner's* perception of felt security) to the construct that should launch future trust-relevant interactions (*each partner's* decision about whether to enter the next trust-relevant situation) are not depicted, but they are presumed to exist. The model holds that, during interactions, each individual's perceptions of both his or her own *and* the partner's standing on each construct is necessary to explain what transpires for each partner in the downstream constructs of the model.

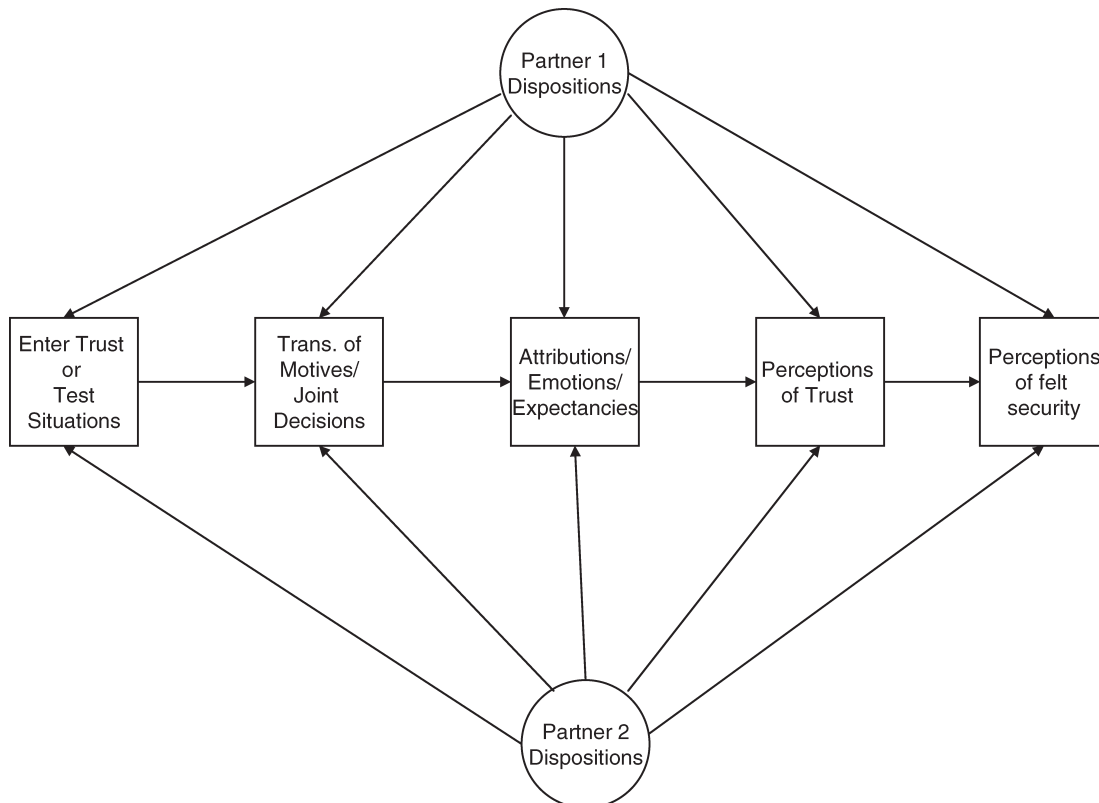
The model assumes that information about the dispositions of *both* partners (e.g., their attachment styles and working models, their typical relationship decision-making tendencies, and their attribution styles) is necessary to explain the growth of trust—or the lack thereof—in a given relationship across several interactions. Each


FIGURE 25.3. The dyadic model of trust in relationships.

partner enters the relationship with myriad personal and interpersonal experiences, some of which have shaped his or her attachment style and working models, his or her self-esteem, or the degree to which he or she has a differentiated self-concept. These dispositional attributes are important because they might affect what occurs in downstream components of the model, given each individual's own attributes (e.g., his or her own attachment style) and his or her *partner's* attributes (e.g., the partner's attachment style).

Dispositional tendencies such as greater attachment security, a more differentiated self-concept, and/or higher self-esteem may motivate and enable individuals to enter, elicit, or transform social interactions into ones that foster greater trust across time. Two types of situations should give individuals a particularly good opportunity to assess the degree of trust that is warranted in the partner/relationship at a specific point in time: (1) "trust situations" (Kelley et al., 2003) in which partners can repeatedly make or fail to make a1/b1 decisions, and (2) "strain test" situations (Holmes, 1981; Kelley, 1983) in which partners can demonstrate or fail to demonstrate their willingness to make personal sacrifices for the good of the partner or the relationship. For these *trust diagnostic* situations to be entered or created, however, one or sometimes both partners must have sufficient confidence to take the interpersonal risks required to confirm or reaffirm that the partner truly *can* be trusted. Individuals and partners who have more secure, more self-differentiated, and/or more positive self-views should be in a better position to take these risks and leaps of faith on a regular basis.

Once individuals find themselves in trust diagnostic situations, those who routinely display the transformation of motivation needed to carry out MaxOther or MaxJoint decisions in everyday trust situations or occasional strain test situations should be on the path toward experiencing greater trust and felt security. Moreover, individuals and partners who have more secure, more self-differentiated, and/or more positive self-views may engage in these transformations more often and more extensively. Given their stronger sense of security and greater promotion focus, these individuals should be more motivated to—and perhaps more capable of— steering trust-relevant social interactions toward a1/b1 decisions. Once such decisions have been made, each individual's working models may then influence how he or she interprets the extent of transformation that both the self *and* the partner have undergone. As a consequence, highly secure, differentiated, and/or self-confident individuals may grant themselves and their partners "fuller credit" for each partner's willingness to maximize partner or relationship outcomes instead of each partner's more egocentric self-interests.

This process, in turn, may trigger more benevolent attributions regarding one's own as well as the partner's core relationship motives (Miller & Rempel, 2004). These positive attributions may then facilitate more constructive problem solving, more adaptive emotion regulation, and more optimistic expectations about what is likely to happen in future trust diagnostic interactions.

These outcomes might also be affected by each partner's degree of attachment security, self-differentiation, and/or self-esteem. Patterns of attribution, emotion regulation, and situation-specific expectancies are displayed in a single box in the model because the temporal order of these processes is likely to differ depending on idiosyncratic features of the interaction (e.g., the specific topic being discussed), the dispositions of each partner, or unique emergent properties of the relationship itself. These positive outcomes should then increase perceptions of trust, which ought to make individuals feel more secure, at least temporarily (Holmes & Rempel, 1989). Once again, greater security, more self-differentiation, and/or higher self-esteem might facilitate perceptions of greater trust and felt security. Perceptions of felt security may then "set up" the next trust-relevant interaction, determining whether or when the next trust situation or strain test is entered.

Across time, individuals who repeatedly experience a1/b1 outcomes with their partners should begin to perceive greater "added value" following these outcomes, especially when they occur in trust diagnostic situations. These mutually beneficial outcomes may also encourage individuals and their partners to perform additional relationship-maintenance acts (e.g., disparagement of alternatives, accentuation of partner or relationship attributes, or heightened cognitive interdependence) that might facilitate or reinforce a1/b1 decisions in the future. These effects should diminish, of course, if one or both partners have dispositional vulnerabilities (e.g., an anxious attachment style; Wieselquist et al., 1999), fail to display proper transformation, repeatedly decide *not* to enter a1/b1 agreements, or make chronically negative attributions regarding their partner's basic relationship motives.

It is important to emphasize that this model does *not* presume that dispositions are chiefly responsible for generating, sustaining, or short-circuiting trust in relationships. Certain dispositions most likely amplify or qualify the basic normative processes outlined in the middle section of the model. Individuals who are insecurely attached, have weak self-differentiation, or have low self-esteem can and do form trusting relationships. To achieve higher levels of trust, however, such persons may need to either (1) be involved with partners who help them suppress or change their destructive perceptual, emotional, and behavioral tendencies or (2) have unusually committed or mutually rewarding relationships that enable these "vulnerable" individuals and their partners to overcome their liabilities.

There is an interesting paradox surrounding the transformation of motivation and trust as relationships grow and develop. Early in relationship development, large amounts of transformation by both partners should be a good barometer of the amount of trust that is warranted in a partner/relationship, particularly when partners are equally dependent on one another for unique or important outcomes (Holmes & Rempel, 1989) or have similar levels of vulnerability and commitment (Wieselquist et al., 1999). As relationships progress, however, most individuals incorporate their partners and relationships

more centrally into their self-concepts (Aron et al., 2001). This means that *less* transformation of motivation is likely to occur in well-established relationships. For this reason, partners in long-term relationships occasionally may need to identify *new* trust diagnostic issues or situations in which each partner's self-interests start out being slightly discrepant from what might be best for his or her partner or the relationship. If partners can jointly demonstrate that they are still willing to undergo large transformations in new trust diagnostic situations, this might reaffirm and sustain trust in well-established pairs.

As discussed at the beginning of the chapter, our knowledge of how trust is generated, sustained, and compromised in close relationships remains surprisingly limited. Future theory and research on dyadic trust might profit from addressing the following issues. First, we need to gain a better understanding of how the dispositions and behaviors of relationship *partners* affect how individuals (actors) think, feel, and behave in trust-relevant situations. Very few if any studies have investigated whether or how "partner effects" might affect these processes. Second, research should explore how and why certain within-dyad combinations of partner attributes (e.g., very different levels of power, dependence, or commitment in a relationship) promote or impede the development and maintenance of trust. Of particular importance will be learning whether, how, and why certain highly asymmetrical relationships (e.g., those in which partners have vastly different levels of power) occasionally generate very high levels of trust (see Drigotas et al., 1995). Third, research should examine whether the normative component of the model shown in Figure 25.3 holds with equal effect at different stages of relationship development (see Holmes & Rempel, 1989). Fourth, more needs to be understood about how normative processes and individual differences reciprocally influence one another across time in trust-relevant situations. For simplicity, the model depicted in Figure 25.3 does not show that normative processes may, over time, shape and revise dispositions within individuals, yet such reciprocal feedback is bound to take place. Fifth, greater attention should be devoted to understanding the events depicted in the middle box of the model (attributions/emotions/expectancies). Features critical to the development of intimacy in relationships, such as feeling understood, valued, and cared for by one's partner, may also promote trust and felt security (Deutsch, 1973; Mikulincer, 1998; Reis & Shaver, 1988), especially when these perceptions repeatedly occur in trust-relevant interactions. Sixth, more needs to be known about what "added value" entails and how it is generated. Though the prospect of receiving future rewards from one's partner may make joint a1/b1 decisions feel unusually good (Huesmann & Levinger, 1976), more than the prospect of rewards is likely to be involved in generating high "added value" perceptions.

In conclusion, there are few constructs in the field of interpersonal relationships that are more central or important to relationship functioning and outcomes than trust. Without trust, voluntary relationships are not likely to develop, let alone grow or be maintained. Experiencing trust in close relationships may be more important today than ever before when one considers that most Americans have fewer and less meaningful ties to friends, organizations, and community activities than was true 30 years ago (Putnam, 2000). This pattern of declining social capital may be exerting further pressure on people to establish stronger emotional connections, greater dependency, and deeper levels of trust with their intimate partners. Trust may, in fact, be a "cardinal construct" (cf. Asch, 1946) in relationships to the extent that it transforms the meaning of other accompanying attributes and descriptors of a relationship. The fact that so little is known about such a pivotal construct attests to the difficulty of operationalizing, measuring, and studying trust in close relationships. For the science of relationships to advance, however, we must develop a deeper and more sophisticated understanding of how trust emerges, operates, changes, and declines within close relationships.

The Psychology of Negotiation
Principles and Basic Processes

CARSTEN K. W. DE DREU
BIANCA BEERSMA
WOLFGANG STEINEL
GERBEN A. VAN KLEEF

The myriad agreements underlying close relationships, group decision making, or other forms of collective action often result from some type of negotiation—the communication between parties with perceived divergent interests to reach agreement on the distribution of scarce resources, work procedures, the interpretation of facts, or some commonly held opinion or belief (Pruitt, 1998). Negotiation occurs at all levels of society—between diplomats talking about arms reduction, between business leaders settling the conditions of a merger, between the owner of a house and a potential buyer, and even between travelers on an airplane deciding on who gets what part of the armrest. When individuals create high-quality agreements that meet both parties' needs and integrate both parties' aspirations, they create order and stability, foster social harmony, increase feelings of self-efficacy, reduce the probability of future conflict, and stimulate economic prosperity (Rubin, Pruitt, & Kim, 1994). When individuals create poor agreements, or fail to agree, they leave dissatisfied, create frustration and annoyance, and face continued conflict and disharmony.

This chapter is about negotiation and has three goals. First, we review recent developments in the social psychological study of negotiation. Such a review is needed because other reviews are 5–10 years old (e.g., Bazerman, Curhan, Moore, & Valley, 2000; Carnevale & Pruitt, 1992; Pruitt, 1998; Thompson, 1990) and do not cover recent work on, for example, motivated information processing and the social functions of emotion in negotiation. Second, we develop a set of basic principles that covers current insights into the negotiation process and

captures cognitive, motivational, and affective influences on the quality of agreements people reach. Third, we develop the idea that to make strategic decisions, individuals in negotiation need to make sense of their situation and their counterpart. That is, to understand negotiation we need to understand how people search and process information and use the emerging insights to make strategic decisions that, ultimately, affect their own as well as their counterpart's outcomes.

We begin this chapter with a brief discussion of the *structure* of negotiation and argue that individuals in negotiation face fuzzy situations that are full of uncertainties and ambiguities and require sense making on the part of the negotiators. We then discuss the *strategies and interaction patterns* that characterize negotiation and develop principles about strategic repertoires negotiators have, and about action–reaction patterns across different phases of negotiation. In the third section we discuss the *negotiator as motivated information processor*, concentrating on the (often detrimental) impact of cognitive heuristics, naive realism, and ego defensiveness. In this section we also discuss work showing that the influence of these information-processing barriers may be countered by the epistemic motivation to process information systematically and deliberately. In the fourth section we view the *negotiator as social animal*, and focus on impression management motives, and the wealth of research on proself versus prosocial motivation, questioning the rather popular assumption that individuals in conflict and negotiation are self-interested and ignorant of their counterpart's needs and desires. In the fifth section we consider

the *emotional negotiator* and discuss the intra- and interpersonal functions of affect and emotion in negotiation. In each of these five sections we identify one or more *basic principles of negotiation*. To examine the generality of these basic principles and processes, we review in the sixth section recent research on *cross-cultural differences* in negotiation. We conclude with a summary and integration of the 10 principles identified in this review and provide some general direction for future inquiry.

STRUCTURAL FEATURES OF NEGOTIATION

To understand negotiation we need to understand the structure of the interdependencies between negotiators. This structure provides the basis for strategizing, defines the boundaries on negotiator goals, and gives insight into the range of agreement options that exist. In this section we begin with a description of the interdependence structure that characterizes most, if not all, negotiation situations. We briefly discuss such notions as mixed-motive interdependence, power, and integrative agreements. We end this section with an analysis of the way negotiators themselves may perceive their situation, noting that most negotiations are not so clear-cut and simple but, instead, rather *fuzzy situations*. We conclude that an important task for individuals in negotiation is to make sense of their situation. The sense-making process, and its consequences for strategic choice and the quality of agreement, is further analyzed in the sections that follow.

Critical in what follows is that negotiation is about distributing and creating value. Value can be, first of all, positive or negative and negotiation can be about gains and rewards, about costs and losses, or about both (Larrick & Blount, 1997). Second, value can be realized immediately or delayed (e.g., Okhuysen, Galinsky, & Uptigrove, 2003) and, third, it can be certain or probable at best (e.g., Lax & Sebenius, 1986). These latter two aspects—delay and uncertainty—are important aspects of the fuzziness of negotiation situations, something we return to at the end of this section. Finally, it should be emphasized that value often is material and tangible, but this need not to be. Examples of nonmaterial value are relationship quality (e.g., in marriage), job satisfaction, and positive affective tone (in a work group). A good understanding of negotiation takes material as well as nonmaterial results into consideration (De Dreu & Beersma, 2005).

Interdependency, Power, and Control

In negotiation, parties depend on each other to acquire positive outcomes, to avoid negative outcomes, or both. This interdependence is usually mixed motive (Schelling, 1960): People start negotiations because they believe an agreement is potentially more beneficial than no agreement. They therefore have a *cooperative incentive* to work together with the other party. At the same time, they also have a *competitive incentive* to increase personal gain. Of course, the cooperative and competitive incentives are not always in balance. In some negotiations the cooperative incentive is relatively weak, for example, because negotiators have good alternatives to a negotiated agreement (Pinkley, 1995) or can walk away from the negotiation table and start new negotiations with someone else (Giebels, De Dreu, & Van de Vliert, 2000). In other negotiations the cooperative incentive is relatively strong, for example, because time in negotiation is costly or because one wishes to secure a valued relationship with the other.

The interdependence structure in negotiation provides the basis for influence and thus determines the participant's power (Bacharach & Lawler, 1981; Kelley & Thibaut, 1978). Power as the possibility to control and influence is different from any specific use of power, such as launching an attack, providing a reward, uttering a threat, or making a promise. Although power may derive from a variety of power bases such as someone's position within a group or one's expertise, it is the mutual dependence of individuals that allows power to occur. In negotiations between two persons A and B, B's dependence on A increases with the value of the benefits A can give B, and it decreases with B's access to alternative sources for those benefits (Emerson, 1972). Power and power asymmetries influence negotiation processes and outcomes primarily through their effects on the setting of aspirations and goals (Zetik & Stuhlmacher, 2002), and on the depth and deliberateness of information search and processing (Fiske, 1993). We return to these processes in the section on motivated information processing.

Negotiation research has been concerned primarily with the extent to which one can provide a negotiation partner with rewards and punishments (for reviews, see Bacharach & Lawler, 1981; Rubin & Brown, 1975). Some researchers have also considered the second aspect of dependence—the availability of alternatives (e.g., Giebels et al., 2000; Pinkley, 1995). In recent work, power has even been operationalized as the extent to which someone is central or peripheral in the group where negotiation takes place (Kim, 1997), or how easily coalitions with others can be formed (Beersma & De Dreu, 2002). Network positions and attractiveness as a coalition partner are relevant bases for power and influence in multiparty negotiations and less important (or even nonexistent) in dyadic negotiations (e.g., Polzer, Mannix, & Neale, 1998; Van Beest, Wilke, & Van Dijk, 2003).

When negotiation parties are groups rather than individuals, individuals experience mixed-motive interdependence within their ingroup, as well as with the outgroup. Bornstein (2003) provides examples of situations in which hostility toward the outgroup is perceived as cooperative, loyal behavior by members of one's ingroup. Vice versa, cooperative and conciliatory behavior toward an outgroup may be perceived, by one's fellow ingroup members, as disloyal and cowardly behavior that jeopardizes the ingroup's fate. As a result of this, groups tend to be more competitive and less cooperative with each other than individuals are in a interpersonal negotiation (Mikolic, Parker, & Pruitt, 1997; Robert & Carnevale, 1997; Wildschut, Pinter, Vevea, Insko, & Schopler, 2003).

Constituencies and Accountability

In intergroup conflict, it is typically neither feasible nor desirable for all those concerned to be present at the bargaining table, and usually representatives conduct the negotiation (Walton & McKersie, 1965). Representatives are often accountable to their constituents, either for the outcomes they achieve or for the process of making decisions (Tetlock, 1992). The former type is called *outcome accountability* and generally biases representatives' thinking and decision making toward the outcome (assumed to be) desired by the constituency. For instance, accountable representatives are motivated to impress constituents (Wall, 1991), and this often translates into a competitive stance toward their counterpart (e.g., Carnevale, Pruitt, & Seilheimer, 1981; O'Connor, 1997; but see Gelfand & Realo, 1999; Peterson & Thompson, 1997). The latter type is called *process accountability* and means that representatives have to account for the strategic decisions they made during negotiation. It generally increases the epistemic motivation to think deeply and systematically about one's reasons for (not) making certain decisions (Tetlock, 1992). We return to this when we discuss motivated information processing.

Single and Multiple Dimensions of Value

Negotiations can be about one single dimension of value or they can be multi-issue. In the case of the shared armrest in an airplane, a negotiation is about one single issue. However, when negotiating the division of household chores, partners talk not only about making dinner but also about the laundry, paperwork, gardening, and so on. When buying a car, we discuss the price as well as delivery and financing issues. These are multi-issue negotiations.

In the case of a single dimension of value the negotiation is about how to divide and distribute value. Such single-issue situations have been commonly studied in research using *prisoner's dilemmas* (PD; Dawes, 1980) or *ultimatum bargaining games* (UBG; Guth, Schmittberger, & Schwarze, 1982). In the UBG, for example, one participant divides a certain amount of value (e.g., $10) between him- or herself and a recipient. The recipient then decides whether to accept the proposed division or to reject it. When rejected, neither participant gets anything.

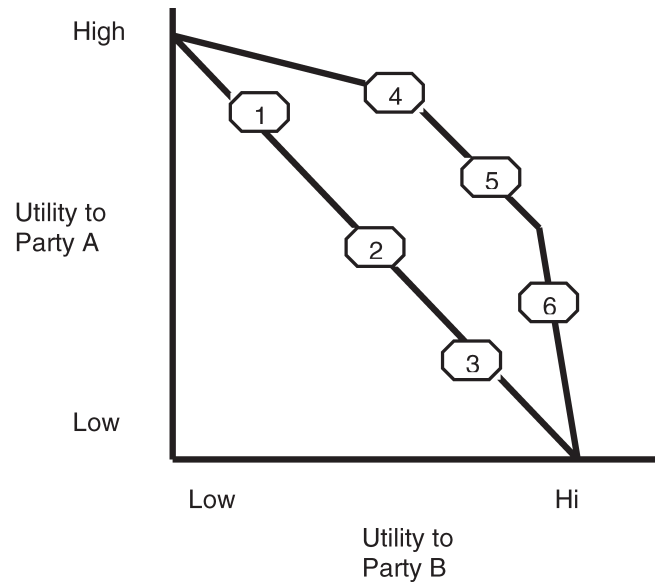
Negotiation often involves multiple issues. When the number of issues in a negotiation increases, it becomes less and less likely that parties (1) disagree on each and every issue, (2) see all issues as equally important, and (3) have the same rank order of issue importance (Raiffa, 1982). For example, a potential car buyer may be very concerned about the price of the car but indifferent about the delivery time. To the salesperson, however, the delivery time may be very important and getting the advertised price on the car may be a lesser concern. If preferences across issues are not diametrically opposed, the negotiation has *integrative potential* (Pruitt, 1981) and agreements exist that provide higher joint outcome than 50–50 compromises, or victory-for-one solutions. This is illustrated in Figure 26.1, which depicts the joint utility


FIGURE 26.1. Integrative potential in a joint utility space.

space for a two-person negotiation. Agreements above the distributive border (numbers 4, 5, and 6) provide higher joint outcome than agreements at that that border (numbers 1, 2, and 3). Note also that agreements 1 and 4 provide Party A with a relative advantage, that agreements 3 and 6 provide Party B with a relative advantage, and that agreements 2 and 5 provide an equal distribution of outcomes between both negotiators. This illustrates that the level of joint outcome achieved by the negotiators does not necessarily mean there is an equal, or fair, distribution of outcomes between the two. Finally, it can be seen that Party A(B) does not get more outcomes in agreement 4(6) than in agreement 1(3), but that the former does provide the counterpart, and thus the collective, with higher outcomes than the latter. Agreements 4–6 are integrative agreements (note that agreement 5 also provides an equal distribution of outcomes between the two parties).

Many analysts have argued that integrative agreements are superior because they optimally exploit resources available to the negotiators, and because they provide high levels of relationship stability—both parties are happy with the agreement, feel self-efficacious, and are motivated to accurately implement the negotiated agreement (O'Connor & Arnold, 2001; Rubin et al., 1994). A key issue in much of the negotiation research and theory that we discuss in this chapter has been to understand when and why individuals (fail to) create and discover integrative potential and (fail to) reach integrative agreements. Accordingly, much of the negotiation research we review and discuss below has relied on (some variation of) a task developed by Siegel and Fouraker (1960), Kelley (1966), and Pruitt and Lewis (1975).

An example of this typical negotiation task is given in Table 26.1. The participants play the roles of management and union negotiators faced with the task of reach-

TABLE 26.1. Issue Charts for Management (Top) and Union (Bottom) Negotiators

Salary	Vacation days	Annual raise	Medical coverage
	Management issue chart		
E70.000 (00)	3 weeks (00)	15% (00)	100% (00)
E65.000 (15)	2.5 weeks (30)	12% (60)	80% (100)
E60.000 (30)	2 weeks (60)	9% (120)	60% (200)
E55.000 (45)	1.5 weeks (90)	6% (180)	40% (300)
E50.000 (60)	1 week (120)	3% (240)	20% (400)
	Union issue chart		
E70.000 (400)	3 weeks (120)	15% (240)	100% (60)
E65.000 (300)	2.5 weeks (90)	12% (180)	80% (45)
E60.000 (200)	2 weeks (60)	9% (120)	60% (30)
E55.000 (100)	1.5 weeks (30)	6% (60)	40% (15)
E50.000 (00)	1 week (00)	3% (00)	20% (00)

Note. In most studies individuals only see their own issue chart and are instructed not to show it to their counterpart.

ing agreement, here on four issues. The management negotiator is given the issue chart shown at the top of Table 26.1, and the union negotiator is given the issue chart shown on the bottom. These charts list five possible settlement points on each issue. Each side sees only its own chart, and typically both sides get the instruction that they can say anything to one another about it. As can be seen, the issue on the left has greater value to one side than to the other, and the opposite is true for the issue to the far right. This means that there are many possible agreements, and they vary in their value to the negotiators, both individually and collectively. The two issues in the center of the task have equal value for both parties and, in the parlance of negotiation research, are "distributive" issues; the other two issues that can be traded for one another are called "integrative." An integrative agreement in this task (a settlement of Euro 70 on "salary" and 20% on "medical") provides an outcome of greater value to each individual and to the pair together than a 50–50 agreement that split these two issues down the middle (joint gain of 800 vs. 460 on these two issues; see Table 26.1).

Fuzzy Situations and Sense Making in Negotiation

In many analyses of negotiation and strategic decision making, including those in behavioral economics and game theory, it is assumed that negotiators are fully informed players who perceive the structure as it is. We reject this assumption because it is unrealistic. Negotiators face and manage fuzzy, ambiguous, and messy situations. Parties to a negotiation do not have a full and accurate insight into the structure of the negotiation. They lack information about their partner's utility functions in that they do not know what is and what is not important to their partner, they do not know the amount of gain or loss their partner faces on specific issues, and they do not

know what goals their partner strives for. In terms of the integrative negotiation task in Table 26.1, each party only sees his or her own payoff chart and not the counterpart's (most studies using this task even explicitly forbid participants to show each other their charts).

Through communication, both verbal and nonverbal, negotiators may receive information about their counterpart's preferences and priorities. But even if they do, negotiators still have many good reasons to doubt the accuracy and trustworthiness of information about their partner's utility functions. One reason is that "organisms could employ functionally irrelevant external stimuli as seed values from which unpredictable responses could be generated by some internal and nonrandom process. . . . Animals must be able to produce behavior that is irreducibly uncertain from the point of view of their opponents" (Glimcher, 2003, pp. 293–294). In other words, the (human) brain has a fundamental capacity to confuse and mislead interaction partners. Another reason is the so-called information dilemma in which negotiators often find themselves. (Kelley & Thibaut, 1978; see also Murnighan, Babcock, Thompson, & Pillutla, 1999; Steinel & De Dreu, 2004). The exchange of honest and accurate information fosters the achievement of high joint gain and, at the same time, makes one vulnerable to exploitation by a (relatively more knowledgeable) partner. To prevent exploitation and foster personal gain, negotiators can use misrepresentation and deception. Individuals in negotiation thus constantly face the question of whether they should provide accurate information to achieve high collective outcomes, or rather strategically misrepresent their preferences to foster the achievement of good personal outcomes. Because of the information dilemma, negotiators have a fundamental reason to doubt any information from their partner. (This sometimes leads to quite ironic processes. For example, Moore [2004a, 2004b] showed that although revealing the deadline one faces speeds up concession making by one's counterpart, people believe such revelations are strategically unwise and thus forego personal and collective gain.)

The conclusion that negotiation situations are, in the eyes of the negotiators themselves, rather fuzzy situations directs us away from the use of simple, clear-cut games in which individuals have full information about both their own and their partner's outcomes and evaluations thereof, and in which individuals and their partners face a limited set of decision alternatives. We are not saying that using such situations to study negotiation is not useful and that insights gleaned from research into these situations are not interesting—we have, in fact, used this type of analysis quite often in our own research (e.g., De Dreu & McCusker, 1997; Steinel & De Dreu, 2004). What we are saying, however, is that to understand how individuals or groups interact and manage conflict-prone situations, we need to study how individuals *make sense* of their social environment: What types of information are negotiators looking for? How much information do individuals need before making a strategic decision? How thoroughly is new information that becomes available during negotiation processed and integrated into exist-

ing knowledge structures? And does all this influence the nature of the strategic interaction and the quality of the agreements people reach? It is these and similar questions about strategic decision making in fuzzy situations that drives the social psychological study of negotiation, setting it apart from analyses in game theory and behavioral economics that often are mathematically sophisticated and logically comprehensive but weak in truly accounting for human judgment and strategic choice.

NEGOTIATION STRATEGIES AND INTERACTION PATTERNS

The fuzziness of most negotiation situations, and the need to make sense of the situation, makes the communication processes and interaction patterns extremely important. Communication—verbal or nonverbal—contains information that allows negotiators to develop a more or less accurate understanding of their situation. As mentioned previously, however, the information dilemma in which negotiators find themselves may lower the extent to which communication is truthful and thus the degree to which negotiators develop an accurate understanding of their fuzzy situation. Furthermore, and because of the mixed-motive nature of negotiation, communication and interaction directly or indirectly serves the goal of safeguarding and promoting (1) personal interests and needs, (2) collective interests and needs including those of the counterpart(s), or (3) both. For example, making demands and refusing to concede serves personal interests, whereas giving up a position and making concessions fosters agreement and serves the counterpart's needs and interests. And as we see below, exchanging information about preferences and priorities often serves both personal and the partner's needs and interests.

In this section we review and categorize negotiation tactics and strategies, and we consider interaction patterns and processes. We develop our first three principles—the *strategic repertoire principle*, the *mindless matching–mindful mismatching principle*, and the *differentiation-before-integration principle*. We end with a brief discussion of the effectiveness of (combinations of) tactics and strategies in producing integrative agreements.

Strategic Repertoire Principle

Although an infinite number of strategies and tactical moves in negotiation may be conceived of, research and theory tend to converge on a five-way taxonomy that distinguishes between contending, compromising, conceding, problem solving, and inaction (Pruitt, 1998; Van de Vliert, 1997). Contending, compromising, and conceding are distributive strategies because they all focus on a particular distribution of outcomes that are predominantly in one's own advantage (contending), or in the counterpart's advantage (conceding). *Contending*, sometimes referred to as claiming value, focuses on imposing one's will on the other side. It involves the use of threats

and bluffs, of persuasive arguments, and of positional commitments. The flip side of contending is *conceding*, sometimes referred to as yielding. It is oriented toward accepting and incorporating the counterpart's will and involves unilateral concessions, unconditional promises, and offering help. *Compromising*, finally, involves the matching of other's concessions, making conditional promises and threats, and actively searching for a middle ground.

Problem solving, sometimes referred to as integration, involves a full and open exchange of information about priorities and preferences, the showing of and verification of insights, and logrolling—making trade-offs between important and unimportant issues (Pruitt & Rubin, 1986). Sometimes problem solving is implicit and indirect. Consider, for example, a "heuristic trial-and-error" strategy (Pruitt & Lewis, 1975; Siegel & Fouraker, 1960). Heuristic trial-and-error can be used in multi-issue negotiations and means that negotiators make, over time, a series of offers each having the same overall value to oneself but, perhaps, different value to one's partner. In Table 26.1, for example, some offers (e.g., E60,000, 2 weeks, 12%, and 40%) provide the same overall value of 450 to management as some other offers (e.g., E70,000, 1.5 weeks, 12%, and 40%) but more value to union (i.e., 455 and 625, respectively). By systematically varying offers in this way negotiators explore integrative potential without directly communicating about their preferences and priorities. Heuristic trial-and-error thus is a strategy that can be used when there is low trust and high fear of being exploited by one's counterpart.

In addition to these distributive (claiming) and integrative (creating) strategies, negotiators often engage in withdrawal behaviors, remain inactive, and avoid their counterpart. *Avoiding* is sometimes part of an overarching contending strategy and used strategically to get further concessions. For example, by (threatening to) withdraw from negotiation the counterpart may realize that making a concession is better than having no agreement whatsoever.

Often avoiding is genuine and the result of a decision dilemma. Contending is dangerous (it may escalate the conflict), conceding is contrary one's own interests, and problem solving is difficult, is time-consuming, and involves the risk of being exploited. To escape this difficult choice, individuals may opt for avoiding. Avoiding does not necessarily need to be inactive and passive. For instance, an interesting instance of avoiding that future research could further explore what we call *complexification*—making issues at the negotiation table more difficult, complex, fuzzy, and uncertain—to confuse the counterpart and to convince him or her that it is not (yet) the right time to make decisions.

There is quite some evidence for the above five-way taxonomy. Many studies have coded behavior from videotaped interactions into a number of categories that represent one of the aforementioned negotiation strategies, most often using an adapted version of a coding scheme developed by Pruitt and Lewis (1975; see, e.g., Carnevale & Lawler, 1986; De Dreu, Giebels, & Van de

Vliet, 1998; Weingart, Hyder, & Prietula, 1996). For example, contending is represented by "making positional commitments" (a strong statement that the speaker is unwilling to change his or her proposal) and by "persuasive arguments" (statements that bolster the importance of the speaker's case, or downplay the importance of the counterpart's case). Problem solving is often represented by "information exchange" (searching or providing information about preferences and priorities) and "cooperative statements" (expressing willingness to collaborate with the counterpart). Other work has used questionnaires in both field and laboratory settings and examined self-reports and peer reports of more global conflict management strategies. Psychometric analyses of these questionnaire data again reveal good support for the above five-way taxonomy (e.g., De Dreu, Evers, Beersma, Kluwer, & Nauta, 2001; Rahim & Magner, 1995).

Taken together, several decades of work on the types of negotiation tactics and strategies, in both the laboratory and the field, point to a *strategic repertoire principle*: Negotiator behavior takes one of five distinct forms—contending, conceding, inaction, compromising, and problem solving. Underlying these five behavioral strategies are a distributive (claiming value) and an integrative (creating value) dimension.

The Mindless-Matching–Mindful-Mismatching Principle

The strategic repertoire principle is mute about behavioral processes and interaction sequences. Some work, primarily using single-issue negotiation tasks, tracked over time the exchange of demands and concessions. In general, individuals have a strong and seemingly automatic tendency to mimic and reciprocate their counterpart's behavior (Axelrod, 1984; Gouldner, 1960). Pruitt and Carnevale (1993) refer to this as the matching of concession size and/or frequency.

Matching is a powerful tendency because it is simple (just do what the other did), because it prevents exploitation and at the same time rewards cooperation. Recent work provides further support. It has analyzed reciprocity and sequences of distributive and integrative behavior in multi-issue negotiations. Using Markov chain analyses, which describes the probability of an event occurring as dependent on the occurrence of a preceding event, Weingart, Prietula, Hyder, and Genovese (1999) found that negotiators tended to respond in kind to both distributive and integrative behaviors of their opponents. Interestingly however, the model could predict behaviors only when the previous two behaviors were known—rather than being a mere reaction to the behavior of the counterpart, a negotiator's behavior seems to depend on both parties' prior behaviors. Future cooperation, therefore, cannot be predicted from one prior cooperative move of the other party but only from prior reciprocated cooperation (see also Brett, Shapiro, & Lytle, 1998; Olekalns, Smith, & Walsh, 1996).

Matching and reciprocity are not limited to negotiation. They are very basic properties of social interaction.

In reviewing several relevant literatures, Ostrom (1998) noted: "while individuals vary in their propensity to use reciprocity, . . . a substantial proportion of the population . . . has sufficient trust that others are reciprocators to cooperate with them even in one-shot, no-communication experiments. Furthermore, a substantial proportion of the population is also willing to punish non-cooperators (or individuals who do not make fair offers) at a cost to themselves. . . . " (p. 12). Likewise, Komorita, Parks, and Hulbert (1992) note "the reciprocity norm is relevant and important in a social dilemma situation . . . [it] prescribes that we should help those who have helped us in the past, and retaliate against those who have injured us . . . the reciprocity norm is the underlying basis of stable relationships, and theorists have postulated that reciprocity is a basic norm of social interaction . . . " (p. 608).

In negotiation people may have incentives to not reciprocate their counterpart's behavior. For example, reciprocating other's competitive and tough strategy may lead to an impasse, providing neither party with positive outcomes. Vice versa, reciprocating other's cooperative behavior may be unwise when one's goal is to maximize personal gain, or when other's cooperative behavior was a strategic ploy and reciprocating other's cooperativeness leads to being exploited. That reciprocity is indeed not always the best option is reflected in the fact that negotiators often engage in *mismatching*—they place high demands when their counterpart appears soft and low demands when their counterpart appears tough (e.g., Liebert, Smith, Hill, & Keiffer, 1968). Mismatching occurs especially when there is time pressure and deadlines are looming (Smith, Pruitt, & Carnevale, 1982). Interestingly, mismatching also occurs when negotiators lack information about the partner's outcomes (Liebert et al., 1968) and limits (Pruitt & Syna, 1985). This suggests that from the counterpart's concessions negotiators derive insights into other's limit (Pruitt, 1981).

Pruitt and Carnevale (1993) propose that mismatching is more likely in the early and in the late phases of the negotiation, whereas matching is more likely in the middle. Early mismatching takes place because parties try to develop an understanding of their counterpart's bargaining strength and limit. Late mismatching occurs because a deadline is looming and agreement is better than impasse. In both cases, there is quite some strategic thinking underlying the tendency to mismatch, something that not necessarily precedes matching and reciprocity. This then allows us to advance the *mindless matching–mindful mismatching principle*: Whereas negotiators who do not engage in deep, deliberate, and strategic thinking match their counterpart's behavioral tendency, those who engage in such deep and strategic thinking will choose mismatching in early and late phases of the negotiation and matching in the middle phase.

The Differentiation-before-Integration Principle

Some work on interaction processes and behavioral sequences has looked at the different phases through

which negotiations cycle. For example, following an in-depth analysis of labor-management negotiations, Walton and McKersie (1965) suggested that negotiations often begin in quite a harsh and competitive way. After a series of competitive exchanges parties come to realize that this leads nowhere but to a costly impasse, that a change in behavior is needed, and that mutual problem solving is a viable alternative for safeguarding and promoting self-interest. This so-called differentiation-before-integration pattern is not limited to the ritual dance of labor-management negotiations. A laboratory study by Brett and colleagues (1998) showed that procedural remarks—statements that refer to the process of the negotiation itself—changed the focus from contentious, distributive communication to more constructive, integrative communication. Harinck and De Dreu (2004) coded temporary impasses—points in the negotiation where parties deadlocked on some issues and remained stuck for a while. Higher levels of contending early in the negotiation were related to temporary impasses, and temporary impasses were, in turn, related to problem solving late in the negotiation. Stepping back from and reflecting on the negotiation during a temporary impasse appears to facilitate a switch from competitive contending to more cooperative problem solving (see also Olekalns, Brett, & Weingart, 2003).

The work on interaction patterns and phases in negotiation points to the *differentiation-before-integration principle*: Negotiators engage in distributive contending early in the negotiation and in later phases switch to integrative problem solving.

Effectiveness of Strategies and Interaction Sequences

The research reviewed above often included some measure of dyadic or group performance, such as the extent to which agreements were integrative. As one might expect, problem-solving behavior, and especially the exchange of information about preferences and priorities, is an important positive predictor of integrative agreements (Pruitt, 1998). Studies that track contending and problem solving over time reveal that problem solving early in the process seems to have little impact, while problem solving late in the negotiation strongly fosters integrative agreements (Harinck & De Dreu, 2004). From the work on differentiation-before-integration it even follows that contending early in the negotiation facilitates, through temporary deadlocks, late problem solving and thus the discovery of integrative agreements.

Related to this is work on the effectiveness of the *good-cop/bad-cop strategy* showing that problem solving is more effective in creating integrative agreements when it is preceded by contending behavior (Hilty & Carnevale, 1992). Perhaps negotiators fear their counterpart returns to contending when the attempt at problem solving fails and thus cooperate without restraint (Brodt & Tuchinsky, 2000). Alternatively, the attempt at problem solving may loom particularly cooperative and constructive when it is embedded in, and contrasted with, a tough and contending strategy that preceded it.

THE NEGOTIATOR AS MOTIVATED INFORMATION PROCESSOR

The social psychological analysis of negotiation has traditionally considered the reasons for people's failure to uncover and exploit integrative potential. Although some answers derive from an analysis of the (sequences) of tactics and strategies that people employ, this type of work does not answer the question why it is that people do not engage in problem solving, and why it is that people more often than never try to exploit their counterpart. To understand this, we need to realize that even the simplest negotiations are both cognitively and emotionally taxing. Earlier we noted that most negotiation situations are fuzzy, and that sense making is a crucial aspect of negotiation. In this section, we review two decades of research that dealt with information processing in negotiation and revealed a number of information-processing barriers to constructive negotiation that prohibit people from reaching mutually beneficial, integrative agreements. These information-processing barriers can be placed under the rubric of cognitive heuristics, naive realism, and ego defensiveness (De Dreu & Carnevale, 2003; Ross & Ward, 1995). We discuss exemplars of each of these consecutively. Thereafter, we critically assess the assumptions underlying this work and propose that much of the influence of cognitive heuristics, naive realism, and ego defensiveness is reduced or even alleviated when individuals have high levels of epistemic motivation to process information deep and deliberately.

The Cognitive Heuristics Principle

Kahneman and Tversky (1973) identified three types of heuristics that people use to make sense of their complex environment and that sometimes lead to suboptimal, even downright incorrect, conclusions: (1) *anchoring*—the tendency to overly rely on an arbitrarily chosen reference point; (2) *availability*—the tendency to overly rely on information that is salient in memory; and (3) *representativeness*—the tendency to make judgments based on the most obvious features of the stimulus. Instances of these heuristics have been shown to be a barrier to constructive negotiation and dispute resolution.

Negotiation is all about relative values, and comparison standards have an important influence when it comes to setting one's aspiration or determining one's limit (Pruitt, 1981; Raiffa, 1982). Goals promote performance when they are difficult but feasible (Locke & Latham, 1990), and high aspirations should thus be useful when based on thorough and carefully calibrated information processing. Higher aspirations indeed produce higher demands and smaller concessions but also closer scrutiny of the issues and negotiation problems, and thus sometimes they promote both personal and joint gain (Huber & Neale, 1986; Zetik & Stuhlmacher, 2002). Unfortunately, however, humans have a tendency to base estimates on irrelevant anchor information and to adjust their estimates inappropriately (Kahneman & Tversky, 1973). Indeed, real estate agents insufficiently adjust for irrelevant anchor information when providing estimates

of real estate value (Northcraft & Neale, 1987). Negotiators also anchor on their counterpart's opening offer and inadequately adjust for this when making a counterproposal (Galinsky & Mussweiler, 2001; Kristensen & Gärling, 1997; Moran & Ritov, 2002). Put differently, anchoring leads to inadequately high or low aspirations, and thus negotiators unnecessarily deadlock or forego personal and joint gain. Interestingly, these anchoring effects hold for individuals as well as groups of negotiators and generalize across novices (e.g., students) and professionals (Whyte & Sebenius, 1997).

A related phenomenon is that people simplify the negotiation by coding prospective outcomes above a salient anchor or reference point as gains and outcomes below that anchor as losses (Kahneman & Tversky, 1979). When everything below one's aspiration is coded as a loss, the majority of the outcomes represent losses and concessions imply one is increasing the amount of loss one is willing to incur. When, in contrast, everything above the no-settlement outcome is coded as a gain, the majority of the outcomes represent gains and concessions imply that one is reducing the amount of gain one is striving for. Put differently, one and the same concession can be seen as an increase in one's losses or a decrease in one's gains. Because the negative utility of losses exceeds the positive utility of gains (Kahneman & Tversky, 1979), loss framing increases resistance to concession making (Pruitt, 1998), produces smaller concessions (De Dreu, Carnevale, Emans, & Van de Vliert, 1994), and increases the likelihood of an impasse (Bottom, 1998; Kristensen & Gärling, 1997). In multi-issue negotiation, loss framing tends to decrease integrative agreements (Bazerman, Magliozzi, & Neale, 1985), although this appears to be true especially when individuals are focused on personal rather than collective welfare (De Dreu & McCusker, 1997; Trötschel & Gollwitzer, in press).

The representativeness heuristic manifests itself in the use of stereotypes to interpret and predict the counterpart's behavior (Macrae, Bodenhausen, & Milne, 1994). Negotiators rely on stereotypic information when predicting their partner's tendency to compete, and concomitant expectations predict one's own behavior. De Dreu, Yzerbyt, and Leyens (1995) showed, for instance, that the decision to cooperate or not was influenced by information about one's partner's group membership. When the partner was a business major—a group seen as opportunistic and competitive by Dutch psychology students—participants made less cooperative choices than when the partner was a religion major—a group seen as moral and cooperative. Morris and colleagues likewise showed that individuals tend to interpret their partner's bargaining behavior in terms of his or her personality (e.g., low vs. high agreeableness) whereas the behavior was in fact due to situational constraints (i.e., high vs. low aspirations given by the experimenter). Importantly, this person attribution then formed the basis for subsequent action, leading negotiators into a self-fulfilling prophecy (Morris, Larrick, & Su, 1999).

Related to the above is recent work on *reputation*. Negotiation dyads involving individuals notorious for their competitiveness achieve lower joint outcomes than dyads without such an individual (Tinsley, O'Connor, & Sullivan, 2002). In iterated social dilemmas, competitive individuals get involved in fewer transactions and tend to end up with lower personal outcomes than do cooperative individuals (e.g., Axelrod, 1984). Like group membership, reputation serves as a heuristic cue that people use to make decisions about whether to start negotiations with this person and, if so decided, how to approach the counterpart.

A final example of representativeness is *fairness* as a heuristic device to settle disputes. An agreement that is deemed fair by both parties often serves as a focal point on which people coordinate their activities, and therefore it often is prominently reflected in the final settlement (Messick, 1993; Ohtsubo & Kameda, 1998). The prominence of the fairness heuristic can be seen in ultimatum bargaining where, from a utility-maximizing point of view, it is rational to propose the other an outcome slightly above zero (e.g., $9 – $1), and to accept any proposal that provides one with an outcome above zero. It is most common, however, that people propose a 50–50 split of the available value and reject proposals that deviate too much from such a fair division (e.g., Van Dijk, De Cremer, & Handgraaf, 2004). Pruitt (1981; see also Schelling, 1960) refers to these types of settlement as *prominent solutions* and discusses a variety of fairness heuristics including "equality" (both parties get the same amount), "equity" (each party receives a share proportional to their input), and "need" (the party that needs it the most gets the greatest share). Less well known, but highly relevant in some negotiation settings, are fairness heuristics like "opportunities," which state that the party who can make most use of a reward should therefore get the largest share of the reward, and the "historical precedent," which defines the parties' entitlements. Prominent solutions of this kind often develop into norms that have some aura of moral superiority and correctness and therefore strongly guide behavior (Thibaut & Kelley, 1959; see also Tyler, Huo, & Lind, 1999).

Using fairness heuristics can be efficient in single-issue negotiations. In multi-issue negotiations, however, they often lead parties away from integrative agreements because fairness principles focus people on (equally) distributing rather than creating value. Also, some fairness heuristics serve the personal interests of one party more than those of the counterpart. For example, in a divorce negotiation, the husband may prefer an equality rule for dividing the savings account when he contributed less salary to the household but an equity rule when he contributed more salary. What fairness rule to use may thus constitute a source of conflict in itself (Thompson & Loewenstein, 1992).

The above are only a few examples of the many cognitive heuristics negotiators may use to make sense of their situation and to reach judgments and decisions. This work on cognitive heuristics can be summarized in our *Cognitive Heuristics Principle*: Sense making in fuzzy negotiation situations leads individuals to rely on cognitive heuristics that provide simplified views of the negotiation. Reliance on these heuristics often speeds up effi-

cient decision making but also undermines the quality of negotiated agreement.

The Naive Realism Principle

Some bias in the individual's attention, encoding, and retrieval processes are due to naive realism—the individual's tendency to assume that he or she sees the world as it is, and that other rational perceivers will therefore share these perceptions. When others fail to see the world as it is, this reflects that others had different information, are lazy, or are biased by ideology or self-interest (Robinson, Keltner, Ward, & Ross, 1995; Ross & Ward, 1995).

Naive realism manifests itself in the *fixed-pie assumption* (Thompson & Hastie, 1990). When negotiators lack information about other's preferences and priorities they tend to assume that the other wants the same and values the same things in the same way as they do. The size of the pie thus is perceived to be fixed, and one's own and the other's preferences are perceived as diametrically opposed (Schelling, 1960). Making a fixed-pie assumption leads negotiators to engage in distributive bargaining and to forego possibilities for integrative agreement (Gelfand & Christakopoulou, 1999; Harinck, De Dreu, & Van Vianen, 2000; Pinkley, Griffith, & Northcraft, 1995; Thompson & Hrebec, 1996).

Naive realism is also reflected in *optimistic overconfidence*, which can lead disputants to forego attempts at settlement, "believing that time is on their side, and that complete, unilateral victory is just around the corner" (Ross & Ward, 1995, p. 266; see also Neale & Bazerman, 1985; Pronin, Gilovich, & Ross, 2004). Optimistic overconfidence may lead both parties to assume that an arbitrator will side with their case and therefore to prefer costly arbitration to constructive negotiation.

Finally, naive realism is reflected in the strong tendency for negotiators to engage in confirmatory information search. Disputants often seek confirmation rather than disconfirmation of their initial beliefs, plans, and strategies: "By framing questions in ways that could only confirm their hypotheses, both sides would be likely to discover only what they wanted to find" (Rubin et al., 1994, p. 105). Confirmatory search exacerbates the problems associated with building a strategy on inadequate and incorrect assumptions, beliefs, and cognitive structures (Neale & Bazerman, 1991). Diekmann, Tenbrunsel, and Galinsky (2003) found that negotiators who expect their counterpart to be very competitive set lower limits and began with less competitive claims than negotiators who expect their counterpart to be not so competitive. This tendency reflects the mismatching pattern we discussed in the section on strategies and interaction patterns. Obviously, a negotiator who sets low limits and makes modest claims invites his or her counterpart to set high limits and to respond with competitive claims. Indeed, Diekman et al. found strong evidence for such a self-fulfilling prophecy—the more competitive one expected the other to be, the lower one's demands, and the higher (i.e., more competitive) one's counterpart's demands became (for related work, see De Dreu & Van Kleef, 2004; Morris et al., 1999).

The aforementioned work can be summarized under the header of the *naive realism principle*: Negotiators make sense of their fuzzy situations by assuming others, including their counterpart, views and thinks like them. This tendency leads to inadequate assumptions and inaccurate conclusions about the true state of the negotiation situation; it drives toward distributive strategies including contending, compromising, and yielding and away from problem-solving behavior.

The Self-Threat Principle

Not all problems in negotiation can be traced to naive realism or the use of inadequate heuristics. Many problems stem from the fact that humans are motivated to develop, maintain, and protect a positive self-concept and that evaluations of the self are positively biased (e.g., Campbell & Sedikides, 1999). Ego defensiveness and the tendency to view oneself as better and more cooperative than average, including one's counterpart, hampers conflict resolution (e.g., Paese & Yonker, 2001). Consider, for example, reactive devaluation—the tendency to reduce the value of a concession or proposal received just because the concession was made or the proposal was offered. Mo'az, Ward, Katz, and Ross (2002) showed that Israeli Jews evaluate an actual Israeli-authored peace plan far less positively when it is attributed to the Palestinians than when it is attributed to their own government: What comes from the participant's ingroup is good and valuable, and what comes from the counterpart is bad, useless, and suspicious.

Self-serving bias extends to objects associated with the self in that people have greater liking for objects they possess compared to objects they do not own. Individuals indeed ask more money to give up something they own (e.g., a coffee mug) compared to what they are willing to pay to acquire that same object (Kahneman, Knetch, & Thaler, 1990). Although this may reflect loss aversion—giving up an object induces greater pain than receiving that same object induces pleasure—*mere ownership effects* occur without the possibility of loss (e.g., Nesselroade, Beggan, & Allison, 1999) and are stronger for people in high need of self-enhancement (Beggan, 1992).

Mere ownership has important implications for conflict management and dispute resolution. Kahneman and colleagues (1990) aptly noted that when opposing individuals overvalue what they own and undervalue what they do not own, trade becomes exceedingly difficult. Carnevale and Ledgerwood (2004) reported that endowment effects are moderated by social identity, with the effect being larger for group-oriented objects that reflect a person's group identity. De Dreu and Van Knippenberg (2005) showed that because people identify with arguments associated with their self-concept so easily, any attack of, or opposition to, that argument constitutes a self-threat. This in turn elicits ego-defensive responses, including competitive behavior, negative views of the interaction partner, and attitude polarization (see also Baumeister, Smart, & Boden, 1996).

The work on self-enhancement tendencies and ego defensiveness points to the *self-threat principle*: Because indi-

viduals desire a positive self-view, and opposition and conflict inherently form a threat to the self, negotiators develop ego defensive (i.e., hostile and competitive) reactions vis-à-vis their counterpart. Self-threat drives toward contending (and perhaps avoiding) behaviors and away from problem-solving and yielding. Self-threat thus is a basis for conflict escalation.

Epistemic Motivation and the Deep Thinking Principle

A fundamental assumption underlying much of the work reviewed thus far is that people have limited cognitive capacity and are bound to use cognitive heuristics, to engage in erroneous reasoning, and to perceive the world exclusively from their own perspective. Although social psychologists have embraced this "cognitive miser" perspective for quite some time (see, e.g., Fiske & Taylor, 1991), work on individual judgment and decision making and on social influence and persuasion uncovered that individuals can, within their limited cognitive capacity, choose from two alternative strategies for processing information. The first strategy is to solve logical problems, to evaluate persuasive arguments, or to form impressions of others through a quick, effortless, and heuristic processing of information that rests on well-learned prior associations. Alternatively, individuals may engage in more effortful, deliberate and systematic processing that involves rule-based inferences (Chaiken & Trope, 1999).

The extent to which individuals in negotiation search, encode, and retrieve information depends on their *epistemic motivation*—the desire to develop and hold accurate and well-informed conclusions about the world (De Dreu & Carnevale, 2003; Kruglanski & Webster, 1996; Webster & Kruglanski, 1994). Epistemic motivation can be dispositional. For example, individuals differ in their chronic need for cognitive closure. Individuals with high need for closure are characterized by cognitive impatience, a tendency to leap to judgments on the basis of inconclusive evidence, and rigidity of thought. Individuals with low need for closure, in contrast, may prefer to suspend judgment, engaging in extensive information search and generating multiple interpretations for known facts. However, situational cues may influence epistemic motivation as well. Epistemic motivation increases, for example, when there is *process accountability* and individuals expect to be observed and evaluated by others with unknown views about the process of judgment and decision making (Lerner & Tetlock, 1999). Epistemic motivation also depends on *power differences*. Fiske (1993) has argued, for example, that low-power individuals try to (re)gain control over their situation by paying close and careful attention to their powerful other, to accurately predict other's needs, desires, and possible actions. Finally, *time pressure and noise* reduce epistemic motivation and increase the motivation to reach (cognitive) closure (e.g., Webster, Richter, & Kruglanski, 1996).

Features of the negotiation process may also raise or undermine epistemic motivation. The negotiation process may be tiring, and fatigue has been shown to lower epistemic motivation (Kruglanski & Webster, 1996). Unexpected events, such as having one's first offer being accepted, provoke surprise and counterfactual thought (Galinsky, Seiden, Kim, & Medvec, 2002) and may raise epistemic motivation. Finally, there is growing evidence that critical events in the negotiation, such as temporary impasses (Harinck & De Dreu, 2004) and so-called turning points (Druckman, 1986), raise epistemic motivation and lead to thorough and open-minded information processing.

Epistemic motivation reduces the extent to which cognitive heuristics impact negotiation processes and outcomes. When negotiators have low need for cognitive closure, are placed under low time pressure, or are stimulated to think about counterfactuals, they are less influenced by irrelevant anchors, or by stereotypical information about their counterpart (e.g., Bar-Joseph, & Kruglanski, 2003; De Dreu, 2003; De Dreu, Koole, & Oldersma, 1999; Galinsky & Mussweiler, 2001; Golec & Federico, 2004). Epistemic motivation also reduces the impact of naive realism. When negotiators have less power than their opponent, they engage in more diagnostic and less confirmatory information search (De Dreu & Van Kleef, 2004), and when they are placed under low time pressure or under process accountability, they are more likely to revise their erroneous fixed-pie assumption (De Dreu, 2004; De Dreu, Koole, & Steinel, 2000). Also, when individuals adopt a third-party instead of partisan perspective, they consider the conflict from multiple instead of one perspective and come to more balanced judgments (Kemmelmeier & Winter, 2000). Finally, as we see in the section on affect and emotion, epistemic motivation influences the extent to which negotiators take their opponent's emotional state into consideration during the negotiation (Van Kleef, De Dreu, & Manstead, 2004b). In other words, raising epistemic motivation leads negotiators to engage in more systematic and thorough information processing, and this undermines the (often detrimental) impact of cognitive heuristics, of naive realism, and of self-enhancement and ego-defensive tendencies (De Dreu & Carnevale, 2003; De Dreu & Van Knippenberg, 2005).

The foregoing work points to the *deep thinking principle*: Negotiators may be more or less motivated to develop a rich and accurate understanding of their situation and therefore engage in more or less deep, systematic, and deliberate search for, and processing of, information. Higher levels of epistemic motivation are associated with less reliance on cognitive heuristics, faster and more rigorous correction of inadequate assumptions and perceptions, and less ego defensiveness following self-threat.

Summary

Constructive negotiation is often impeded by the use of cognitive heuristics, naive realism, and ego defensiveness. Part of the problem is related to the complexity and uncertainty that are inherent to negotiation and forces individuals to use suboptimal cognitive shortcuts. Part of the problem is, however, due to fundamental psychologi-

cal principles that operate inside as well as outside negotiation. Because of naive realism, negotiators make a fixed-pie assumption and forego possibilities of joint gain, or engage in confirmatory information search and get trapped into a self-fulfilling prophecy. Because of ego defensiveness, negotiators underestimate the value of their partner's proposal and respond overly hostile when their partner opposes their arguments or disputes their needs and desires. However, consistent with dual-process models (Chaiken & Trope, 1999) and lay epistemic theory (Kruglanski & Webster, 1996), growing evidence suggests that negotiators can switch from shallow and heuristic to deep and deliberate information processing. Systematic information processing, which is likely under high epistemic motivation, reduces the detrimental influence of using cognitive heuristics, naive realism, and ego defensiveness.

THE NEGOTIATOR AS SOCIAL ANIMAL

For quite some time, the study of the individual negotiator as a motivated information processor ignored the social context in which negotiation takes place (Kramer & Messick, 1995), and thus that much of what negotiators do is driven by their need to impress an audience or constituency, or by their need to build a particular reputation. In addition, the work reviewed above implicitly or explicitly proceeds on the assumption that negotiators are motivated by self-interest and are ignorant of, or indifferent about, their counterpart's concerns, needs, and interests.

In this section we review research and theory that view the negotiator as a social animal, one concerned with his or her social reputation, with the impressions he or she makes on others, including the counterpart, and with the needs and interests of his or her counterpart. We begin with work on impression management and reputation concerns and then discuss research and theory on social motives—the negotiator's preference for a particular distribution of outcomes between oneself and the counterpart (McClintock, 1977).

Impression Management and Reputation Concerns

Impression motivation is usually defined as the desire to make a good impression on the other and to get along (Snyder, 1992; Tetlock & Manstead, 1985). Individuals in negotiation may, however, also be highly motivated to convey the impression of a tough negotiator not to be trifled with (Chaiken, Gruenfeld, & Judd, 2001; Wall, 1991). For example, a manager may be motivated to convey the image of a tough negotiator, only to avoid his or her employees trying to negotiate about every single task assignment or allocation decision.

Impression management motives are particularly prominent in intergroup negotiations where individuals need to convey a certain impression not only toward their counterpart but also toward their fellow ingroup members. Brown (1977) showed, for instance, that negotiators are willing "to cut their nose to save their face"

(i.e., to incur substantial cost to impress an audience). Sometimes impressing an audience and a counterpart needs to be done at more or less the same time, for example, when constituents are surveying the negotiation (Carnevale et al., 1981). In some instances, this needs to be done sequentially, when a deal needs to be sold to one's constituents, when negotiation progress is discussed during caucuses, or when negotiation results are part of someone's annual performance appraisal. How the timing of impression management concerns influences its nature and effects is yet unknown, however, and could be addressed in future research.

Early work suggests that constituent surveillance increases competitiveness because negotiators believe being competitive would impress their constituents (Carnevale, Pruitt, & Britton, 1979). More recent studies suggest that surveillance reduces the negotiator's tendency to strategically misrepresent information (Steinel & De Dreu, 2004), and in collectivist cultures it leads to greater cooperation (Gelfand & Realo, 1999). Apparently, the expectations of the audience drive the kind of impressions negotiators wish to convey, and this steers them toward a cooperative or competitive stance (Enzle, Harvey, & Wright, 1992).

The issue of impression management motivation can also be approached from intergroup relations perspectives such as social identity theory (Turner, 1987). An example is a study by Van Kleef, Steinel, Van Knippenberg, Hogg, and Svensson (in press), who investigated how a representative's behavior in an intergroup negotiation is influenced by his or her standing within the group. They reasoned that peripheral group representatives, who occupy a marginal position within the group, should be motivated to gain the approval of their fellow group members, especially if group membership is seen as attractive. One way to do this would be to adopt a tough negotiation stance vis-à-vis the outgroup. Their study indeed showed that peripheral group representatives were tougher than prototypical representatives (who are at the core of the group), but only when the other group members could monitor their negotiation behavior and group membership was perceived as attractive.

Some studies on impression management in negotiation have considered cognitive processes. For example, Jordan and Roloff (1997) classified negotiators as being high or low in self-monitoring and showed that high self-monitors engaged more in planning of impression management (e.g., "be friendly so he'll think I'm giving him a good deal"). They also designed a greater variety of tactics and strategies than low self-monitors. The latter result may reflect greater flexibility of thought among high self-monitors. Ohbuchi and Fukushima (1997) indeed found self-monitoring to be associated with more integrative negotiation, albeit only when there was mild (rather than acute) time pressure.

Taken together, impression management and reputation concerns clearly are important in negotiation. Some promising findings have been reported, but clearly more and more systematic research is needed to uncover the forms impression management motivation can take, and to further substantiate the idea that impression manage-

ment motivation relates to flexibility of thought and strategic choice.

Social Motivation

In the section on motivated information processing we noted that individuals are predisposed to develop, maintain, and defend a positive view of themselves. This should, however, not be taken as an indication that individuals are only motivated to pursue their self-interests. In fact, a variety of social motives can be distinguished, including altruistic, competitive, individualistic, and cooperative (McClintock, 1977). Many studies on social dilemmas, conflict, and negotiation have relied on the more global distinction between proself and prosocial motivation (e.g., Beersma & De Dreu, 2002; Carnevale & Lawler, 1986; De Dreu & Van Lange, 1995; Weingart, Bennett, & Brett, 1993). Proself motivation comprises both competitive and purely individualistic goals, and prosocial motivation comprises both cooperative and purely altruistic goals. Individuals with a proself motivation desire to maximize their own outcomes, and they have no (or negative) regard for their partner's outcomes. They tend to see the negotiation as a competitive game in which power and personal success is important. Individuals with a prosocial motive desire a fair distribution that maximizes both own and other's outcomes, and they have a positive regard for their partner's outcomes. They tend to see the negotiation as a cooperative game in which fairness, morality, and harmonious social relations are key.

Although prosocial motivation sometimes reflects "enlightened self-interest," growing evidence indicates that it often is genuine and detached from immediate self-interest (Batson, 1998; Caporael, Dawes, Orbell, & Van de Kragt, 1989). Evidence also suggests that social motives have a strong dispositional component. Kelley and Thibaut (1978) have argued that individuals learn to adopt a specific social motive through direct experience, observation, and modeling (e.g., when one witnesses the behavior of important social models like parents, siblings, and teachers). Examples of dispositions that drive toward a prosocial motivation include dispositional trust (Parks, Henager, & Scamahorn, 1996), agreeableness (Barry & Friedman, 1998; Graziano, Jensen-Campbell, & Hair, 1996), need for affiliation (Langner & Winter, 2001), and prosocial value orientation (De Dreu & Van Lange, 1995).

Apart from individual dispositions, the tendency to adopt a prosocial versus proself motivation can also be triggered by features of the situation. For example, interaction partners can be instructed to see the other as a "partner" instead of as "opponent" (Burnham, McGabe, & Smith, 2000), or they can be rewarded for joint instead of personal success (e.g., Weingart et al., 1993). Finally, positive affect (Carnevale & Isen, 1986; Forgas, 1998) and the expectation of cooperative future interaction (Ben-Yoav & Pruitt, 1984) make a prosocial motivation more likely than a proself one.

Consistent with the notion that people encode and retrieve goal-consistent information easier and better

(Fiske & Taylor, 1991), proself negotiators selectively search and process information that corroborates their idea that the negotiation is a competitive game and that their counterpart cannot be trusted. Pro-socially motivated negotiators, in contrast, selectively search and process information that corroborates their idea that the negotiation is a collaborative game, that their counterpart can be trusted, and that cooperation is morally superior (e.g., Camac, 1992; De Dreu & Boles, 1998; Van Kleef & De Dreu, 2002). Finally, there is some evidence that prosocial individuals see the world in broader categories, and that proself individuals see the world in more discrete, narrow categories (Carnevale & Probst, 1998).

Most work on social motives has focused on strategic choice and negotiation outcomes. This work centers around two interrelated theories—the theory of cooperation and competition developed by Deutsch (1973), and dual-concern theory (Pruitt & Rubin, 1986). The *theory of cooperation and competition* argues, in brief, that proself negotiators develop distrust, hostile attitudes, and negative interpersonal perceptions. They use persuasive arguments, positional commitments, threats, bluffs, and coercive power to get their way. Prosocial negotiators, in contrast, develop trust, positive attitudes, and perceptions; engage in constructive exchange of information; listen; and seek to understand one another's perspective. Pro-socially motivated negotiators thus are more likely to reach integrative agreement.

Pruitt and Rubin's *dual-concern theory* postulates two kinds of concern, other concern and self-concern, each ranging in strength from weak to strong. Other concern is related to the concept of social motive, with proself negotiators having weak other concern and prosocial negotiators having strong other concern. Self-concern is related to *resistance to yielding*—the negotiator's intransigence about concession making. Negotiators have higher resistance when there is low rather than high time pressure, when they have been given a high rather than low limit or aspiration level, when outcomes are framed as losses rather than gains, or when parties have good rather than bad alternatives to an agreement (Druckman, 1994; Pruitt, 1998). The theory further postulates that social motives and resistance are independent—the former refers to outcome utility and desirable end states, and the latter refers to concession making as a means of achieving that end state. Thus, a prosocial negotiator with high resistance may truly value his partner's outcomes but may be unable to make any more concessions. Likewise, a proself negotiator with low resistance may not care at all about her partner's outcomes but may make yet another concession to avoid an impasse yielding no outcomes whatsoever.

A meta-analysis of 28 studies by De Dreu, Weingart and Kwon (2000) examined support for the theory of cooperation and competition and the dual-concern theory. Effects of social motive and resistance to yielding (high vs. low vs. unknown) on contending, problem solving, and joint outcomes were examined. Consistent with dual-concern theory, results showed that negotiators were less contentious, engaged in more problem solving, and achieved higher joint outcomes when they had a

prosocial rather than proself motive, but especially when resistance to yielding was high (or unknown). Although more complex than the theory of competition and cooperation, dual-concern theory thus better fits the data. In addition, the meta-analysis revealed no moderating role of the way social motivation was measured or manipulated. Dispositions and situational cues thus appear to have similar effects on negotiation processes and outcomes.

It is important to note that most of the research discussed above provided all participants with the same social motive—all members of the dyad or group had a prosocial, or a proself motivation (for an exception, see Rhoades & Carnevale, 1999). When in motivationally heterogeneous settings prosocial individuals discover that their counterpart has a proself motivation, they tend to switch from cooperative, problem-solving behavior to more competitive strategies. In fact, there is some evidence for an overassimilation effect—prosocial individuals behave even more competitively with a proself partner than proself people do (Kelley & Stahelski, 1970; Steinel & De Dreu, 2004; Van Lange, 1992). An explanation for this overassimilation effect is that prosocial individuals have a moralistic desire to teach the other a lesson (Van Lange, 1992). In general this work suggests a "pull" toward proselfness in dyads and groups where at least one member has a proself motivation.

In the section on motivated information processing we reviewed work showing that epistemic motivation increases systematic, effortful information search and processing. Combining this insight with work on social motives led to the formulation of a *motivated information-processing model* of negotiation (Carnevale & De Dreu, 2006; De Dreu, 2005; De Dreu & Carnevale, 2003; De Dreu, Weingart, et al., 2000; De Dreu et al., 1999; De Dreu, Koole, & Steinel, 2000; De Dreu & Van Kleef, 2004; Van Kleef et al., 2004b). The basic idea is that because negotiators often lack information about the task and about their counterpart, a motivated search for and provision of information provides new pieces of information on an almost continuous basis. Based on the research evidence discussed previously, the model further assumes that social motivation drives the kind of information (i.e., either cooperative or competitive) that negotiators seek, provide, and consider. Epistemic motivation, in contrast, primarily determines the extent to which this "cooperative" or "competitive" information is being processed, and thus the extent to which this information impacts strategic choice and the quality of agreement.

According to the motivated information-processing model, prosocial negotiators are more likely to develop trust, to engage in problem solving, and to reach high-quality agreements than are proself negotiators, but especially when epistemic motivation is high. Evidence for this central hypothesis was obtained in three experiments that showed that prosocial compared to proself negotiators had better recall of cooperative information, developed more trust, engaged in more problem solving, and reached more integrative

agreements when they had high but not when they had low levels of epistemic motivation (De Dreu, Beersma, Stroebe, & Euwema, 2006). The motivated information-processing model thus accounts for and integrates past research and makes new and valid predictions about the interplay between basic classes of motives in conflict and negotiation.

Summary: The Social Motive Principle

Although research has demonstrated the importance of impression management concerns, especially in the context of intergroup negotiations, more systematic work is needed to uncover its consequences for information processing and strategic choice. Much more developed is our insight into the determinants and consequences of having a proself versus prosocial motive, and this lends itself for proposing the *social motives principle*: (1) Negotiators have or adopt a prosocial or a proself motivation; that (2) drives for confirmatory sense-making processes so that prosocials are more likely to see the negotiation as a collaborative game, and their counterpart as a trustworthy person, whereas proselves are more likely to the negotiation as a competitive game, and their counterpart as untrustworthy; and (3) leads prosocials to engage in more problem solving when there is high resistance to concession making and more yielding when there is low resistance.

One important area for theory and research is to further our understanding of the interplay between impression management concerns and social motives. At first blush it may seem that prosocial negotiators desire and develop a softer and friendlier image than proself negotiators, who more easily develop a reputation of being cunning, shrewd, and tough. However, we believe that negotiators often use the impression they wish to convey in service of the prosocial or proself end goals they try to achieve. Prosocial negotiators may well believe that conveying a tough image serves their desire to get collectively beneficial outcomes better than conveying a soft image. Vice versa, proself negotiators may convey the impression of a weak, soft, and lenient negotiator to "trick" their counterparts in making more concessions. It is these possibilities that require further study, and such work will allow us to further integrate currently isolated lines of inquiry.

THE EMOTIONAL NEGOTIATOR

Perhaps because negotiation and conflict research has strong roots in game theory and models of rational decision making, social psychology has for a long time ignored emotions as part and parcel of the negotiation process. In the past decade this unfortunate situation has changed, with more and more articles incorporating emotions into the study of conflict and negotiation (Barry, Fulmer, & Van Kleef, 2004). In this section we review this work and demonstrate that much of the effects of emotions can be understood in terms of the motivated

information-processing principles outlined in the previous sections.

There are myriad definitions of *emotion*, most of which point to three distinct features of emotion: physiological reactions, action tendencies, and subjective experience (Lazarus, 1991). Emotions differ from *moods* in that they are discrete, of relatively high intensity and short duration, and intentional, that is, directed at an object, person or event (Frijda, 1993). We use the term "emotion" in the sense intended above, whereas *affect* is used as an umbrella concept encompassing both moods and emotions (cf. Barry et al., 2004).

Much of what happens in negotiation provokes emotions. Impasse in negotiations elicits frustration (O'Connor & Arnold, 2001), and perceptions of unfairness trigger anger and spite (Pillutla & Murnighan, 1996). Procedural justice in negotiations enhances positive feelings about the negotiation and attenuates negative feelings over outcomes, while distributive justice produces satisfaction and lowers disappointment and resentment (Hegtvedt & Killian, 1999). Other work shows that having your first offer accepted elicits not only counterfactual thoughts but also worry and disappointment (Galinsky, Mussweiler, & Medvec, 2002; Galinsky, Seiden, et al., 2002; see also Kwon & Weingart, 2004; Naquin, 2003). Likewise, receiving outcomes superior to the counterpart's may induce happiness, whereas receiving outcomes inferior to the counterpart's produces a variety of negative feelings (Thompson, Kramer, & Valley, 1995), although this seems to be particularly true among individuals with a proself rather than prosocial motivation (Gillespie, Brett, & Weingart, 2000).

The Moody Negotiator Principle and the Emotion-as-Strategic-Information Principle

Emotions not only follow from but also drive negotiation processes and outcomes. An early study was conducted by Carnevale and Isen (1986). They manipulated mood by means of humorous cartoons and a small gift and found that participants with a positive mood used fewer contentious tactics and obtained higher joint outcomes than did negotiators in a neutral mood (see also Baron, 1990; Forgas, 1998). In contrast, negative moods tend to produce less constructive behavior. Sadness stimulates evasiveness especially when conflict is intense (Forgas & Cromer, 2004), and anger increases the use of competitive strategies (Forgas, 1998) and reduces joint outcomes (Allred, Mallozzi, Matsui, & Raia, 1997). Together these works point to the *moody negotiator principle*: Angry negotiators are more likely to play tough and to make small concessions, than are sad negotiators who are more evasive and happy negotiators who easily make concessions.

Recognizing that negotiation is a social phenomenon, several scholars have emphasized the importance of the interpersonal or social effects of emotions in negotiations, arguing that emotions have important social functions and consequences (Barry et al., 2004; Morris & Keltner, 2000). Most notably, emotions convey information about how one feels about things, about one's social intentions, and about one's orientation toward other people. In this way, emotions can serve as incentives or deterrents for other people's behavior: Negative emotions serve as a call for mental or behavioral adjustment, whereas positive emotions serve as a cue to stay the course (Keltner & Haidt, 1999). Thus, emotions can influence our own behavior and the behavior of others.

To study the interpersonal effects of emotions in negotiation, Van Kleef and colleagues (Van Kleef, De Dreu, & Manstead, 2004a; Van Kleef et al., 2004b) used a computer-mediated negotiation task introducing a simulated opponent who appeared angry, nonemotional, or happy. Participants with an angry opponent made larger concessions than did participants with a nonemotional opponent, whereas those with a happy opponent made smaller concessions. Results further showed that these effects result from *tracking* (see Pruitt, 1981): Negotiators with an angry opponent estimated others' limit to be high, and to avoid costly impasse they made large concessions. Conversely, negotiators with a happy opponent judged the opponent's limit to be low, assumed agreement was not endangered, and accordingly made small concessions. These findings suggest that the epistemic motivation to consider and process other's emotion information should moderate the foregoing effects of anger and happiness. Van Kleef and colleagues (2004b) indeed showed that negotiators with high epistemic motivation (i.e., individuals with a low need for cognitive closure, placed under low time pressure, or being relatively independent of the counterpart) were strongly influenced by their counterpart's emotions, whereas those with low epistemic motivation (high need for closure, high time pressure, high dependence) were unaffected.

Whereas the work by Van Kleef and colleagues (2004a, 2004b) shows that angry negotiators elicit more concessions from their opponent than happy negotiators, recent work by Friedman, Anderson, Brett, Olekalns, and Lisco (2004) suggests that alternative patterns may be possible as well. In their study, Friedman et al. used data from online mediations in disputes arising over eBay transactions. They coded, from email messages parties send to each other and their mediator, anger words and correlated this with dispute settlement rate. Their results showed that expressing anger lowers settlement rate, in part because expressing anger elicits an angry response from one's counterpart. When respondents were particularly vulnerable, however, expressing anger did not lower settlement rates, suggesting that powerless negotiators are more likely to yield to an angry opponent than are powerful negotiators (see also Van Kleef, De Dreu, Pietroni, & Manstead, 2006).

As is clear from the foregoing, research on the interpersonal effects of emotions in negotiations so far has paid a disproportionate amount of attention to the effects of anger and happiness. At present, we are aware of only one study that addressed demands and concession making in negotiation as a function of other emotions expressed by the counterpart (Van Kleef, De Dreu, & Manstead, 2006). Extending previous work on supplica-

tion and appeasement (e.g., Clark, Pataki, & Carver, 1996), this study revealed that participants whose opponents expressed emotions of appeasement (guilt or regret) developed a positive impression of their opponents but were nonconciliatory in their demands. By contrast, participants whose opponents showed supplication emotions (disappointment or worry) rated their opponents less positively but made larger concessions and placed lower demands.

The study of the social functions of emotion in negotiation is still in its infancy. Nevertheless, there is evidence to the support the *emotions-as-strategic-information principle*, which holds that one's counterpart's emotions (e.g., anger, happiness, disappointment, and guilt) provide information that has strategic implications, and which is used as such provided that there is sufficient motivation.

A logical next step in the exploration of the role of emotions in negotiation would be to investigate the interplay between the intrapersonal and interpersonal effects of emotions. Do the positive effects of happiness at the intrapersonal level of analysis (e.g., more creative problem solving) outweigh the negative effects at the interpersonal level (e.g., risk of exploitation)? Does the strategic advantage of expressing anger outweigh the negative impact of anger on the negotiation climate? Aside from the interplay between the intra- and interpersonal effects of emotions, future research could investigate the effects of other emotions than anger and happiness. For instance, what are the effects of fear, sadness, disappointment, and worry? And how do people respond to others' expressions of guilt or regret? We believe that such questions constitute a fruitful starting point for future research on the role of emotion in negotiation.

NEGOTIATING WITHIN AND ACROSS CULTURES

The research we have reviewed so far has predominantly been conducted in Europe and the United States. More and more interactions take place, however, between people from different parts of the world, with different cultural backgrounds. Not surprisingly, therefore, scholars from around the world have questioned the validity of "Western" knowledge and insights and commenced to study the possible cultural influences on negotiation processes and outcomes (Gelfand & Brett, 2004; Tyler, Lind, & Huo, 2000). In this section we review this work, partly because it represents an exciting area for further inquiry, and partly because it allows us to see whether the principles and processes reviewed in the previous sections generalize across cultures.

Much of the work on culture and negotiation relies on Hofstede's (1991) distinction between individualism and collectivism. According to Hofstede, "individualism pertains to societies in which the ties between individuals are loose. . . . Collectivism as its opposite pertains to societies in which people from birth onwards are integrated into strong, cohesive ingroups, which throughout people's lifetime continue to protect in exchange for unquestion-

ing loyalty" (p. 5). The United States and the Western European countries are high on individualism. Collectivistic countries can be found in Southern Europe, Asia, Africa, and South America.

Culture and Information Processing

Culture influences information processing in a number of ways. It shapes and determines the norms people have for managing disputes and resolving conflicts (Tinsley & Brett, 2001), including whether or not lying and deception are morally appropriate (Triandis et al., 2001). Culture also drives the cognitive representations of conflict people have. Individuals with a collectivist background, for example, view conflict more as compromise focused whereas individuals with an individualist background view these very same conflicts more as win–lose focused (Gelfand et al., 2001). This finding maps onto our earlier suggestion that individuals scoring high on collectivism may have stronger prosocial motivation than individuals scoring high on individualism (see also Chen, Chen, & Meindl, 1998; Chen, Mannix, & Okumura, 2003; Hulbert, Correa da Silva, & Adegboyega, 2001; Probst, Carnevale, & Triandis, 1999). It also suggests that some heuristics—like the equality rule—may be more prominent in some culture than in others (e.g., Leung, 1987).

Culture also affects the *level* at which information processing bias emerges. For example, Carnevale (1995) found *mere ownership effects* in U.S. subjects, who held individualistic values, but not in Hong Kong subjects, who held collectivistic values. Among participants with collectivistic values, a group ownership effect occurred: Whereas it was relatively easy for these subjects to part with objects that were their own, it was difficult for them to give up an object that was owned by themselves and an ingroup member. Carnevale referred to this as a *group endowment effect*. This work points to the intriguing possibility that in negotiation, egocentric bias and self-enhancement tendencies emerge at the group rather than individual level among individuals with a collectivist background. Instead of ego defensiveness, individuals with a collectivist background may thus show ingroup defensiveness—as long as their negotiation counterpart is an ingroup member, they will be relatively cooperative, but their behavior is likely to become more competitive when their counterpart is an outgroup member. Future research needs to address this general question of cultural influences on information processing in conflict and negotiation.

Culture, Social Motives, and Strategic Choice

Given that individualism—collectivism has much in common with the proself–prosocial motive distinction discussed earlier, it comes as no surprise that this culture dimension strongly influences strategic choice in negotiation and conflict. Tjosvold, Hui, Ding, and Hu (2003) have shown that Chinese participants often approached conflicts in a problem-solving way, leading to enhanced team effectiveness. Other work also shows that collectiv-

ist individuals are more inclined to make concessions, to engage in problem solving, or to accept a 50–50 compromise. This tendency holds especially when the counterpart is not seen as outgroup—when this is the case, individuals from collectivist backgrounds tend to become more hostile and competitive than those with an individualist background (Carnevale & Leung, 2001; Gelfand & Brett, 2004).

Related to individualism–collectivism is the distinction between low- versus high-context cultures (Triandis, 1989). In high-context cultures, such as Japan and China, meaning is communicated not only by a person's words or acts but also by the context in which those words or acts are communicated. Many Western cultures (e.g., United States and Germany) are low-context cultures, in which meaning is carried by words or acts and communication is typically direct. Negotiators from the United States indeed rely on logic and reasoning to make their point, whereas negotiators from Taiwan (a high-context culture) relied more on normative statements, referrals to social roles, and relationships (Drake, 1995). Negotiators from low-context cultures engage in more direct communication (e.g., saying "no") than negotiators from high-context cultures (e.g., Adair, Okumura, & Brett, 2001). All in all, these studies thus show that culture influences social motives—the tendency to focus on own, or on own and other's outcomes—and impression management and reputation concerns.

Culture and Emotion

Culture, finally, may shape the intra- and interpersonal effects of emotion in negotiation. Thus far the interpersonal effects of emotions in negotiations have been investigated in individualistic cultures like the Netherlands (Van Kleef et al., 2004a, 2004b), the United States (Friedman et al., 2004), and Italy (Van Kleef, De Dreu, Pietroni, et al., 2006). Although a considerable body of research has investigated cultural variations in antecedents, appraisal, regulation, expression, and perception of emotion (e.g., Mesquita & Frijda, 1992), little is known about cultural differences in the ways people respond *behaviorally* to others' emotions. An exception is a study by Rodriguez Mosquera, Manstead, and Fischer (2000), who showed that expressions of shame may be more appropriate in collectivistic cultures, whereas expressions of pride may be more positively received in individualistic cultures. It would be interesting to see how cultural differences influence the ways in which negotiators respond to their opponent's emotions. Do people in collectivistic cultures respond more empathically to another's worry or disappointment, or do they find these emotions inappropriate because they communicate a preoccupation with the self rather than the collective? Will collectivists exploit others' expressions of guilt or regret to the same extent as individualists, or will they be more lenient because guilt and regret signal interpersonal concern? Future research could address these and other questions regarding possible cultural influences on reactions to other people's emotional experiences and expressions.

PRINCIPLES OF NEGOTIATION: SUMMARY AND CONCLUDING THOUGHTS

We began this review by noting that much of what individuals in negotiation do is making sense of their situation. This sense-making process is closely intertwined with strategic considerations, and these in turn depend heavily on motivational goals. We organized the relevant literatures under the headers of three interrelated rubrics—the negotiator as *motivated information processor*, the negotiator as *social animal*, and the *emotional negotiator*. We examined cognitive, motivational, and affective influences on behavioral strategy and interaction processes that were captured in three basic principles:

1. *Strategic repertoire principle*: At any given point in time negotiator behavior takes one of five distinct forms—contending, conceding, inaction, compromising, and problem solving. Underlying these five behavioral strategies are two dimensions—distributive (claiming value) and integrative (creating value) strategies.
2. *Mindless matching–mindful mismatching principle*: Whereas negotiators who do not engage in deep, deliberate and strategic thinking match their counterpart's behavioral tendency, those who engage in such deep and strategic thinking choose mismatching in early and late phases of the negotiation, and matching in the middle phase.
3. *Differentiation-before-integration principle*: Negotiators engage in distributive contending early in the negotiation and in later phases switch to integrative problem solving.

The motivated information-processing perspective has resulted in a variety of cognitive and motivational barriers to constructive negotiation, including the use of inadequate cognitive heuristics, naive realism, and ego defensiveness. The detrimental effects of these processes can be reduced when negotiators have epistemic motivation and engage in deep and deliberate information processing. This happens when time pressure is mild rather than strong, when there is a power balance rather than power asymmetry, when negotiators are process accountable, or when they have low chronic need for cognitive closure. In short, this section gave rise to four basic principles:

4. *Cognitive heuristics principle*: Sense making in fuzzy negotiation situations leads individuals to rely on cognitive heuristics that provide simplified views of the negotiation. Reliance on these heuristics often speeds up efficient decision making but also undermines the quality of negotiated agreement.
5. *Naive realism principle*: Negotiators make sense of their fuzzy situations by assuming others, including their counterpart, view and think like them. This tendency leads to inadequate assumptions and inaccurate conclusions about the true state of the negotiation situation, it drives negotiators toward distributive strategies, including contending, compro-

mising, and yielding, and away from problem-solving behavior.

6. *Self-threat principle*: Because individuals desire a positive self-view, and opposition and conflict inherently form threat to the self, negotiators develop ego-defensive (i.e., hostile and competitive) reactions vis-à-vis their counterpart. Self-threat drives toward contending (and perhaps avoiding) behaviors and away from problem solving and yielding. Self-threat thus is a basis for conflict escalation.

7. *Deep thinking principle*: Negotiators may be more or less motivated to develop a rich and accurate understanding of their situation and therefore engage in more or less deep, systematic, and deliberate search for, and processing of, information. Higher levels of epistemic motivation are associated with less reliance on cognitive heuristics, faster and more rigorous correction of inadequate assumptions and perceptions, and less ego defensiveness following self-threat.

Whereas the motivated information-processor perspective focused on the individual negotiator, the social animal perspective emphasizes the social context within which negotiations take place. In our review we distinguished between impression management concerns and proself versus prosocial motives. We advanced the (8) *social motives principle*: (a) Negotiators have or adopt a prosocial or a proself motivation; that (b) drives for confirmatory sense-making processes so that prosocials are more likely to see the negotiation as a collaborative game and their counterpart as a trustworthy person, whereas proselves are more likely to view the negotiation as a competitive game and their counterpart as untrustworthy; and (c) leads prosocials to engage in more problem solving when there is high resistance to concession making and more yielding when there is low resistance.

In the section on the emotional negotiator we returned to this individual–social divide when we showed that the individuals' emotions have an effect on their own cognitive and motivational processes, as well as on their counterpart's cognition, motivation, and behavioral moves. The work on interpersonal effects of emotions in negotiations suggests the intriguing possibility that information about one's counterpart's emotions is often used strategically, and that these strategic considerations are more important than, and perhaps even overrule, implicit and immediate contagion-like processes. Specifically, we formulated two basic principles, namely, the (9) *moody negotiator principle*, which holds that angry negotiators are more likely to play tough and to make small concessions than are sad negotiators, who are more evasive, and happy negotiators, who easily make concessions and are likely to collaborate; and (10) the *emotions-as-strategic-information principle*, which holds that a counterpart's emotions provide information that may serve as input in the negotiator's strategic decision-making process, but only when the negotiator is sufficiently motivated to consider the strategic implications of the other's emotion.

Stepping back from these 10 basic principles reveals that our decision to organize the literature around moti-vated information processing, social motives, and affect and emotion should not be taken as suggesting that these three components are unrelated to each other and can be understood in isolation from each other. In fact, the 3 perspectives and 10 principles are mutually related in a variety of ways: Affect and emotion influence information processing, and epistemic motivation determines to some extent whether affect and emotion can exert effects on negotiator demand and concession making. Social motives may explain why negotiators experience certain emotions, and much of the information processing in negotiation is social in nature. Given that we have developed a quite thorough understanding of the cognitive, motivational, and affective underpinnings of negotiation, future work needs to continue recent work on the interplay among these three core components (cf. De Dreu & Carnevale, 2003; Kramer & Messick, 1995; Morris & Gelfand, 2004; O'Connor, 1997).

Before concluding we wish to highlight two main questions that have thus far been ignored in negotiation research:

1. What makes people believe negotiation would work for them and solve their problem—why do people engage in negotiation?
2. What happens once the negotiation is over, and life retakes its course?

The first question basically points to *initiation motives*, which we define as those motives that people have to (not) begin negotiations with someone else (Carnevale & De Dreu, 2006). *Initiation motivation* guides the start of negotiation and has three basic forms that reflect the notion that the situation is *ripe for negotiation* (Zartman, 1991): The first is a mutually hurting stalemate, where the parties are not winning and costs are mounting. The second is an impending or narrowly avoided catastrophe, and the third is a mutually enticing opportunity, where the divergent interests stand in the way of accomplishing important aims on both sides. All three forms reflect the notion of negotiation as an adaptation to problems of interdependence, an adaptation that reflects sense making prior to rather than during negotiation.

The second main question basically points to the aftermath of negotiation and dispute resolution. Surprisingly little is known about what happens once agreement is reached, and surprisingly strong assumptions are made about the aftermath of conflict and negotiation. For example, integrative agreements are often assumed to be the best that could happen to negotiators and are recommended because they stimulate parties' self-efficacy, increase their self-esteem, renders them satisfied, and fosters economic prosperity and political stability (Rubin et al., 1994). That this thinking is wrong is suggested by a recent study showing that groups with proself-motivated negotiators showed greater dedication, functioned more effectively, and performed better than groups with prosocially motivated members in a creativity task, whereas prosocial groups outperformed proself groups on all these dimensions when the task involved planning (Beersma & De Dreu, 2005). This work thus shows that

affective, cognitive, and motivational processes during negotiation may have surprising effects on interpersonal and group processes that take shape once the negotiation is over and life retakes is normal course.

We began this chapter with the notion that negotiation is omnipresent and shapes much of our day-to-day interactions along with the more encompassing social events that affect the lives of many. The analysis of negotiation in terms of its motivational, cognitive, and affective underpinnings has generated a thorough understanding of when and why individuals (fail to) achieve mutually beneficial agreement. These insights into the psychology of negotiation may provide a fruitful basis for continued integration with work on negotiation and dispute resolution being conducted in adjacent disciplines, including economics and political science. Doing so will provide calibrated advice on negotiation and dispute resolution, move us toward more comprehensive theory, and stimulate new research in this important and exciting area.

Grounding Communication

Synchrony

GÜN R. SEMIN

FOCUS

Any close inspection of how face-to-face human communication is possible reveals that it is not short of a miracle unique to the species. It is a species-specific endowment that in its diverse instantiations can be the source of diversity, conflict, and strife or merriment, harmony, and creativity. Communication and its potential pitfalls occupy considerable space in popular books, gossip columns, and recommendations about relationship maintenance or political advancement. In social psychology, analyses of diverse socially relevant phenomena such as intergroup communication, discrimination, and gender differences constitute but a few of the compelling and inviting themes that have attracted considerable empirical investigation. While these types of investigations have uncovered interesting phenomena a scientific journey that takes us from the roots of communication to its remarkable manifestations reveals the extraordinary biological, neural, and social composition of what makes human communication possible. Although communication plays second fiddle to a great number of issues that are central to current social psychological research, it is undoubtedly the case that communication constitutes the most fundamental question that social psychology can address because human communication constitutes the core to social life as we know it.

Communication is not a biologically unique phenomenon. It is an endowment that a great number of species have and in each case it has its unique specialization (cf. Seyfarth & Cheney, 2003). This can be seen in the distinc-

tive types of dedicated media (e.g., gestural, acoustic, chemical, optical, mechanical, or even electrical as in the case of electrical fish) serving communication and that are reportedly idiosyncratic for different species. For example, vervet monkeys have three types of alarm cries (Seyfarth, Cheney, & Marler, 1980) that are specialized for three different kinds of predators (snakes, leopards, and eagles), which they call out when they see one of the predators. The respective cries engage the vervets to look down for snakes, run into trees (leopard alarms), or look up (eagle alarms). Bees use chemicals and movement for communication purposes. Honeybees (*Apis Melifera*) communicate via a number of different movements, grouped into dances (von Frisch, 1947, 1967).[1] Termites appear to use a sophisticated chemical (pheromone) communication system regulating social relations in the nest (e.g., Pasteels & Bordereau, 1998) and nest-building behavior (Beckers, Holland, & Deneubourg, 1994), while male stickleback fish use visual displays to initiate reproduction (Tinbergen, 1952). The particular specialization by means of which communication is achieved takes the form of a specific *shared medium* in each species, may this be acoustic, chemical, mechanical, optical, or some combination thereof. A large number of communication systems exist that are unique to the respective species, recruit unique resources, and remain largely incomprehensible between different species.

Explaining communication requires answers to two questions. The first is: "What makes communication possible?" The answer to this involves explaining how two (or more) organisms—adapted to group living—are con-

nected because successful group living requires that a member has to be "coupled" with another one in a two-way interaction (Semin, 2000). This means two (or more) members are linked together by some *common* or *symmetrical base*, namely, a base that puts them on comparable footing, that gives partial mutual access to internal states between them, thereby making it possible for the organisms to "communicate." Whatever specialization is deployed to achieve communication, and whatever the unique signal patterns that a species utilizes, *the chief function of these signals is to establish equivalence or parity* between *a sender and receiver*. The common denominator to any communication is the recruitment of processes and a medium shared by producer and perceiver (production and perception) by means of which producer and receiver is put on the same footing (cf. Liberman & Mattingly, 1985; Liberman & Whalen, 2000). This is a general requirement for any successful communication.

The second question is: "What are the biological, neural, psychological, and social foundations of *human* communication?" While the answer to the first question is about a necessary requirement for communication in general—irrespective of species—the second is about the specific processes that ground human communication. Research attempting to answer these questions in the social psychology of communication has been driven by a predominant focus on language. The issues driving such research have been how parity is established by means of language or how parity efforts are manifested in language. A significant proportion of this work has relied on the transmission of "representations" in interpersonal communication (see Krauss & Chiu, 1998; Krauss & Fussell, 1996, for reviews). A recurrent theme is what can be referred to as coordination in communication and has to do with the different ways in which representational correspondence can be established, for instance, in joint action. This theme has been approached from a variety of angles. Thus, audience design (see Krauss & Chiu, 1998; Krauss & Fussell, 1996), referential communication (Clark & Brennan, 1991; Fussell & Krauss, 1989a, 1989b), and grounding (Clark, 1996a, 1996b; Clark & Brennan, 1991; Clark & Wilkes-Gibbs, 1986; Keysar, 1997) are some of the converging approaches about how representational correspondence between the members to a dialogue is achieved. The actions and processes servicing coordination address the explicit or manifest face of how equivalence is obtained in interpersonal communication. The medium by which these actions and processes are realized is language and is therefore also a central feature of research on interpersonal communication. However, language and representational correspondence are not all there is to human communication.

A somewhat neglected aspect of communication is the embodied grounding of this process. Communication is a process drawing on experiences that originate from bodily interactions (e.g., emotional expressions, articulatory gestures, and bodily movements) and is grounded by the socially tuned architectures of our body and brain. It is a *multimodal* process involving a diversity of *neural and motor* processes (perceptible, coordinated bodily *productions* such as articulatory gestures, facial expressions,

and emotional displays, as well as "imperceptible" neural states) aside from language. These processes are involved in both the production and *perception* sides of communication. If we are to understand this miracle then we need to examine the biological, neural, psychological and social foundations of communication and this is the central theme of this chapter. Thus, this chapter provides a framework of the embodied grounding (Smith & Semin, 2004) of communication rather than reviewing the diverse classic thematic foci in the social psychology of communication, which constitute deep research pockets in their own right (see Krauss & Fussell, 1996, for a review).

FROM PARITY TO SYNCHRONIZATION

As I argued previously, the parity requirement to communication necessitates the presence of processes that are recruited symmetrically by both the sender and receiver of a communicative act. In this chapter, I argue that the psychological and neural mechanisms that constitute an embodied grounding (Smith & Semin, 2004) of communication rely on a unique knowledge system. The unique features of this knowledge system are that it is specialized for social cognition and is grounded on processes that give privileged and immediate mutual access by *coupling* two agents. It is only through *jointly* recruited processes that it is possible for two agents to be coupled and put on the same footing. In other words, such mechanisms must facilitate obtaining a state of equivalence between two parties: What counts for one member must also count for the other. I refer to this process as *synchronization*. Synchronization gives simultaneous partial mutual access to internal states, thereby establishing a type of knowledge that is different from knowledge about manipulable objects, spatial orientation, or numerosities. I regard *a jointly and simultaneously recruited process* by means of which correspondence is established at neural, perceptual, affective, and behavioral levels between producer and perceiver as synchronization (cf. Semin & Cacioppo, 2005). Moreover, I posit that synchronization precedes communication by means of language both evolutionarily and ontogenetically. It is a process that occurs without the presence of explicit communicative intent.

What evidence is there for synchronization? There is an unusually rich literature and substantial empirical research across diverse areas that have a direct bearing to synchronization processes at neural, emotional, and behavioral levels. This research literature has not been conceptualized as integral processes in the production of synchronization. A surprising facet of the research I review below is that its foundational significance for communication has not been realized. This is largely due to the fact that the terminological framework within which these diverse areas were developed has a perspective that is committed to the individual as the analytic unit and consequently focuses on individual driven processes rather than social, namely, jointly recruited, processes. This applies to broad research fields driven with con-

structs such as mirroring, simulating, and resonance upon perceiving another's action (e.g., Rizzolatti & Craighero, 2004; Rizzolatti, Fadiga, Gallese, & Fogassi, 1996); the extensive social psychological work on mimicking, matching another's behavior (e.g., Bavelas, Black, Chovil, Lemery, & Mullett, 1988; Bernieri, 1988; Bernieri, Reznick, & Rosenthal, 1988; Chartrand & Bargh, 1999); and the voluminous work on imitation, empathy, sympathy (e.g., Heyes, 2001; Iacobini, 2005; Meltzoff & Moore, 1997; Preston & de Waal, 2002; Tomasello, 1998), or emotion contagion (Hatfield, Cacioppo, & Rapson, 1994). As the central constructs in these converging fields all indicate, the analytic anchor is located at the level of the *individual*, who is imitating somebody else, or being emotionally taken over by the feelings of the other, simulating, mimicking, or putting him- or herself in the shoes of the other, emphatically or otherwise. Undoubtedly, the processes that are observed are located in the individual; however, the phenomena are all examined in *co-presence* situations. Looking at the same research from a *communication perspective*, namely, as *jointly recruited processes*, gives these processes a different functionality, as compared to looking at these processes from an *individual-centered perspective*. The former perspective suggests that jointly recruited processes serve the function of establishing parity between producer and perceiver. An individual-focused analysis suggests that the perceiver is "emulating" the producer, but it is not necessarily clear what such emulation serves.[2]

In the following section I review research on synchronization, focusing first on neurophysiological evidence obtained with nonhuman primates and humans. Next, I turn to some developmental evidence obtained in infant studies and related comparative evidence with nonhuman primates. Finally, I provide an overview of the voluminous behavioral evidence, which has a long history in social psychology. In closing the next section I circumscribe what synchronization as a core knowledge system entails.

NEURAL FOUNDATIONS OF SYNCHRONIZATION

The origins of an intraspecies "synchronization" process were discovered in single neuron studies with macaque monkeys. These studies revealed that a particular class of visuomotor neurons (mirror neurons) discharge when the monkey *engages* in a particular *action* and when it *observes* another monkey engaging in the *same action* (e.g., Di Pellegrino, Fadiga, Fogassi, Gallese, & Rizzolatti, 1992; Gallese, Fadiga, Fogassi, & Rizzolatti, 1996; Rizzolatti et al., 1996). These studies have given rise to a burgeoning field that can be seen as a major contribution toward uncovering the neural foundations of communication.[3] There are at least three distinctive reasons that this research is important to understand the neural foundations of communication. The first is that the logic of the design underlying this research field is typically a *social* (copresence) paradigm. It involves recording *and* comparing neural activities that are recruited jointly in

two agents, of whom one is engaged in executing an action and the other in observing the very same action. Despite its apparent simplicity, the design relies on the logic of communication by recording the type of neural activities recruited in the execution (producer) and observation (perceiver) of action. Second, "mirror neurons" constitute a *direct link* between an executor and perceiver in the absence of (1) any mediating symbols or—in fact—(2) apparent motive, drive, or intention to communicate. It is an automatic phenomenon that escapes conscious access. Finally, such jointly recruited and shared neural processes represent a means of achieving synchronization between or among individuals and thus providing an embodied grounding (Smith & Semin, 2004) for the essential parity requirement for communication, namely, the joint recruitment of neural processes by executor and perceiver (production and perception) by means of which producer and receiver are put on the same footing.

Evidence from Monkeys

A substantial body of neurophysiological evidence with human and nonhuman primates has shed light on the neural mechanisms underlying the representation of intentional action (e.g., Rizzollati & Craighero, 2004, for a recent review). This evidence suggests intentional action, and its perception has a shared neural notation. That is, intentional action is represented or "embodied" in the form of (nonsymbolic) cognition and is distributed across actor and observer. Gallese, Keysers, and Rizzolatti (2004) suggest that the function of this neural notation is to permit direct experiential access to the "mind" of the other (direct matching hypothesis). Observing the action can trigger the same neurophysiological mechanisms as executing the action, with the consequence being that the observer has implicit access to the mental contents and feelings of the actor.

The early studies showed that a particular class of visuomotor neurons (in the F5 area of the macaque monkey premotor cortex) discharge when the monkey engages in a particular action (e.g., grasping a peanut) *and* when it observes another monkey engaging in the same action (Rizzolatti et al., 1996). These mirror neurons do not respond to seeing a hand merely mimicking an action or for that matter observing the object alone (Gallese et al., 1996; Rizzolatti et al., 1996). Note that mirror neurons are not limited to the F5 area in the monkey brain but several interconnected areas (inferior parietal lobule area PF and STS) that are responsive to biological movement (Rizzolatti, Fogassi, & Gallese, 2001, p. 662).

Recent studies have shown that mirror neurons in the F5 area also become active even when the final part of the action (e.g., gasping the peanut) is hidden (Umilta et al., 2001). Critically, in the hidden condition, the monkey must "know" that an object (e.g., a peanut) is behind the occluder and must observe the experimenter's hand going behind the occluder without seeing the completion of the action. More recently, Keysers and his colleagues (2003) have reported that specific populations of neurons ("audiovisual mirror neurons") in the ventral pre-

motor cortex of the monkey discharge not only when a monkey performs a specific action but also when it sees or *hears* another monkey perform the same action. These neurons therefore represent actions independently of whether these actions are performed, heard, or seen. The adaptive nature of the mirror neuron system is illustrated in a recent study (Kohler et al., 2002) where monkeys were trained to rip paper. It was shown that once trained the mirror neurons involved in the execution of this action were recruited in response to the action sound only. These studies suggest not only that single neurons in the premotor cortex synchronize to the actions the other is executing but also that the action "goal" is represented and inferred across different modalities. The correlation between mirror neuron activation in partially observed or merely heard conditions corresponds largely to the pattern of neurons recruited in the full performance of the actions, which result in a sound (peanut cracking) or complete action (grasping food). It is argued that mirror neurons in the F5 area can *retain* abstract representations such as action goals and intentions. However, it is equally plausible to suggest that what is retained is the production of an event (e.g., with sound) as both seen and heard, rather than an abstract representation.

The important point is that single neurons are recruited for some actions irrespective of the modality (sound, vision) by means of which they are inferred. Moreover, it is not merely the action but the consequence of the action that is represented. Rizzolatti and his colleagues (e.g., Rizzolatti & Craighero, 2004) suggest that mirror neuron activity mediates meaning. It is argued that the brain capacity to link first- and third-hand experience is a "simulation" mechanism by the third party that is central to the understanding of action. The proposed mechanism is based on the *direct matching hypothesis*, which suggests that understanding an action results from mapping an observed action onto motor representations of that action. The mirror system translates visual information (action) into knowledge (e.g., Rizzolatti et al., 2001).

It is not entirely clear what knowledge means within the direct matching hypothesis, because an observer recruits only about 20% of the neurons that are recruited in the performance of an action (e.g., Adolphs & Spezio, in press; Gallese et al., 1996). Furthermore, a number of issues require closer inspection before we obtain a clearer picture of synchronization processes. One is that all the evidence on mirror neurons with adult monkeys must be the result of learned associations. Some support for the generalization of synchronization comes from studies involving learned auditory associations, where specific acquired sounds associated with the action goal were sufficient to activate action-related motor neurons (e.g., Kohler et al., 2002). The important question is the ontogeny of synchronization, and to my knowledge there is no evidence on this. However, some behavioral evidence with nonhuman primates and neonates, reviewed below, is suggestive of innateness.

The evidence to date suggests that actions involving biological movement that are goal directed (transitive), as well as the observation of the entire action or some aspect of it (e.g., goal attainment alone), activate a corresponding neural representation (i.e., namely executor and perceiver synchronize). The process takes place without any explicit communicative intent. The evidence also suggests that synchronization is a jointly recruited process that is highly adaptive to novel actions (e.g., ripping a paper) as well as novel features of actions or their consequences (e.g., sound of ripping paper or cracking peanut). What evidence is there for humans?

Evidence from Humans

Action–Bodily Movement

The findings regarding neural synchronization in the case of humans converge with those described in the earlier section, except that with humans synchronization processes have been revealed for a broader range of actions, significantly when observing and executing *intransitive* (e.g., biological movement with no apparent goal) and mimed actions as well as transitive actions (e.g., Fadiga, Fogassi, Pavesi, & Rizzolatti, 1995). Recent work (e.g., Cochin, Barthélémy, Roux, & Martineau, 1999) provides further support. For instance, Cochin and colleagues (1998) showed their participants video film consisting of 20-second sequences with still shots and moving shots that were either human movements or object movements. Their findings show the participation of the sensorimotor cortex during visual observation of human motion.

Research with functional magnetic resonance imaging (fMRI) suggests that the human premotor cortex (involved in voluntary movements) is active during the observation of actions made by another individual (Buccino et al., 2001). It seems that similar to monkeys, humans automatically generate a neural replica of the action they observe in their premotor cortex—that is, the regions activated correspond to those that are active during the execution of the action. Grèzes, Tucker, Armony, Ellis, and Passingham (2003), using event-related fMRI, also show neural synchronization when subjects execute movements or observe these movements (intraparietal and ventral limbs of the precentral sulcus). Convergent evidence using magnetoencephalography (MEG) indicates that the primary motor cortex is activated during both the execution of different manipulatory actions (e.g., using chopsticks) and their observation (e.g., Hari et al., 1998; Jarvelainen, Schürmann, & Hari, 2004; Nishitani & Hari, 2000).

The time course of synchronization is an important issue and there is some recent work on addressing this. Flanagan and Johansson (2003) used a block-stacking task and recorded the eye gaze and action–execution (hand coordination) for the executor and eye-gaze action–observation for the observer. Their results reveal that for observers eye gaze is predictive rather than reproductive or reactive of the executor's movements. An important contribution to this question is to be found in a study by Gangitano, Mottaghy, and Pascual-Leone (2001). They recorded the motor-evoked potentials of individuals at different moments while they were observ-

ing another person perform grasping movements and showed that motor cortical excitability followed the phases of the observed action.[4] As a more recent review by Fadiga, Craighero, and Olivier (2005) suggests, the "motor system simulates underthreshold the observed action in a strictly congruent fashion. The involved muscles are the same as those in the observed action and their activation is temporally strictly coupled with the dynamics of the observed action" (p. 213). What is important is that it is not merely observing an action but also listening to words that have to do with actions (verbs such as lick, kick, pick) that is revealed to be accompanied by motor facilitation (e.g., Tettamanti et al., 2005; Wilson, Saygun, Sereno, & Iacobini, 2004).

An interesting question in this context is, Why does observation of action and neural synchronization not lead to action in the observer? There are two answers. A preliminary one is provided by Baldissera, Cavallari, Craighero, and Fadiga (2001), who examined whether the observation of action involves not only cortical motor areas but also low-level motor structures that resonate the observed actions as if they were performed by the observer. They had participants observe hand opening and closure and measured H-reflex size (to examine spinal cord excitability) evoked in the flexor and extensor muscles. The findings reveal that observing participants' H-reflex for flexors increased for hand opening and decreased for hand closing. The reverse was noted for extensors. These results suggest that there is an inhibitory mechanism *in the spinal cord* that stops the execution of the observed hand action. While this may apply in their experimental setting when the execution of a simple movement is observed by explicit instruction, social psychological research on so-called mimicry reviewed below suggests that complete inhibition of behavioral synchronization in complex social interaction may not be the case. Thus, the conditions for inhibition and lack thereof present an interesting conceptual and empirical issue. The second answer to why action observation does not lead to action in the observer is perhaps obvious. What I have termed "synchronization" does not suggest complete equivalence or identity between producer and receiver but correspondence or "parity." For instance, in the research on mirror neurons with monkeys observing and performing an action, approximately 20% of the neurons in the F5 are overlapping (Gallese et al., 1996). Thus, it is important to qualify that synchronization does not produce *identity* between producer and perceiver but parity or correspondence. Obviously, if synchronization were to lead to equivalence between a producer's and perceiver's actions and emotions rather than an overlap, then there would be confusion between producer and perceiver (Adolphs & Spezio, in press).

Emotion

Emotions play a central regulatory role in social interaction, and there is substantial behavioral evidence on the synchronization of emotions, which is generally referred to as emotional contagion (Hatfield et al.,

1994). These authors suggest that unintentional mimicry of nonverbal and verbal behavior is responsible for the transfer of emotion in social interaction. There is also growing evidence with humans suggesting that the observation of perceptually opaque movements such as the facial expression of emotions induce the recruitment of the same neural activities that are involved in the execution of such expressions. A number of brain imaging studies examined experimentally induced disgust (e.g., Phillips et al., 1997, 1998) showing that the amplitude of the insular response was a function of the degree of expressed disgust. Indeed, impairment to the insula has been shown to impair the recognition of disgust (and other emotional expressions; Adolphs, Tranel, & Damasio, 2003). Wicker and colleagues (2003) address the question of whether the same sector of the insula is activated when experiencing disgust. In this fMRI study, participants were shown brief video clips of faces expressing disgust induced by inhaling odorants. The same participants were used for both the expression and the observation of disgust. Both conditions led to the activation of the same sites in the anterior insula (see also review by Singer & Frith, 2005).

Although single neuron recording experiments with humans show that the observation of pain and the experience of pain activate the same neurons (Hutchison, Davis, Lozano, Tasker, & Dostrovsky, 1999), generally speaking the regions of the brain important for imitation are not the regions important in emotion, but instead there is substantial overlap in the brain regions important in imitation and observation. By mimicking the observed action, however, individuals are in a better position to know by feeling themselves what another person is feeling. This reasoning implies a mechanism through which imitation produces *emotional* contagion. Evidence for this reasoning is provided by Carr, Iacobini, Dubeau, Mazziotta, and Lenzi (2003). Using fMRI, Carr and colleagues found that the brain regions important for action representation and imitation, such as the superior temporal sulcus, are connected to the insula and amygdala—regions in the limbic lobe that are involved in emotions.

Synchronization of perceptually opaque facial expressions (i.e., emotions) comes from a number of studies that investigate *electromyographic* (*EMG*) activity, when individuals were exposed to pictures of emotional expressions. For instance, Dimberg, Thunberg, and Elmehed (2000) presented happy, angry and neutral faces subliminally (30 msec, with backward masking) and revealed that participants reacted with distinct facial muscle reactions corresponding to the happy and angry stimulus faces and that this muscular synchronization occurs within a window of 500 msecs, automatically and without conscious access to the emotion expressed. Similar findings are reported by Sonnby-Borgstrom, Jonsson, and Svensson (2003), both at the subliminal level as well as supraliminally, moderated by differences in the degree of emotional empathy (see also Sonnby-Borgstrom, 2002). Walbott (1991) asked participants to classify photographs of people's expressions. While participants were

engaged in doing this task, they were surreptitiously videotaped. The results showed that participants synchronized to the expressions of the faces they were classifying—thus, while classifying a happy face they were more likely to smile. Indeed, accuracy of classification was positively correlated with the extent of synchronization between expression on the photograph and participants' expression.

BEHAVIORAL EVIDENCE FOR SYNCHRONIZATION

Evidence from Neonates

If synchronization is a jointly recruited process that provides an embodied grounding to communication, then the question arises as to whether or not this is an innate capacity. The neurophysiological evidence is obtained with adult subjects and it is difficult to disentangle whether synchronization is an innate process or an acquired one. It is self-evident that the diverse actions (e.g., cracking peanuts, ripping paper, and using chopsticks) used in human and nonhuman primate studies are acquired skills. If, however, synchronization is an innate social process then such jointly recruited processes should be evidenced early on in development. The question is therefore whether the evidence reviewed previously has an innate base or whether it is a capability that requires substantial environmental input before there is a manifest phenotypical performance. There is in fact behavioral evidence with humans and nonhuman primates that speaks to this issue and runs under the terminology of "imitation." The conceptual framework is thus defined in terms of a model performing some bodily movement and an observer copying it, whereby the copying is an instance of imitation if there is a clear causal relationship between movement observation and copying.[5] The issue is a so-called correspondence problem. That is, it is possible for observed actions to be matched with imitated actions and not entail the transfer of a novel skill by observation.

The research reported in this section uses the imitation terminology and therefore anchors the analytic focus at the individual level. Furthermore, it relies on the minimal co-presence social paradigm similar to those in the neurophysiological studies reported earlier. In this case, the dependent variables are behavioral and are concerned with whether an observer synchronizes (or reproduces) a feature of the body movement that is executed by a "model."

Research with primates suggests that chimpanzees can imitate (Preston & de Waal, 2002), whereas other studies suggest that extensive training (e.g., Custance et al., 1995) or experience and contact with humans (e.g., Whiten, 1998; Whiten, Custance, Gomez, Teixidor, & Bard, 1996) is necessary for imitation. For instance, Myowa (2004) examined a nursery-reared infant chimpanzee (Pan troglodytes) between 5 and 15 weeks of age demonstrating that the infant imitated tongue protrusion (during 5–10 weeks) and mouth opening (5–11

weeks). Both types of imitation ceased after 12 weeks. In another study with two chimpanzees reared from birth by their biological mothers, Myowa-Yamakoshi, Tomonaga, Tanaka, and Matsuzawaz (2004) observed discrimination between and imitation of tongue protrusion and mouth opening at less then 7 days of age. This differential neonatal imitative behavior ceased after 2 months of age and was replaced by indiscriminate mouth opening responses. What these results suggest is that the disappearance of neonatal imitation also marks the onset of social communicative behavior such as a decrease in neonatal spontaneous smiling and an increase in social smiling (e.g., Tomonaga et al., 2004). They also reveal evidence for a very early but limited and short-lived repertoire (tongue protrusion and mouth opening) of synchronization processes with primates.

Whether human infants have an innate ability to imitate specific facial gestures were stimulated by two experiments reported by Meltzoff and Moore (1977) suggesting that 2- to 3-week-old infants can imitate the specific facial gestures (e.g., tongue protrusion and mouth opening). The research was followed up by Meltzoff and colleagues (e.g., Meltzoff & Moore, 1983, 1992; see Meltzoff & Moore, 1997, for a review) as well as by other research groups (e.g., Heimann, Nelson, & Schaller, 1989; Legerstee, 1991). Although there are claims for neonate imitation across a range of gestures in the literature, a careful analysis of the data by Anisfield (1991, 1996) shows that there is only conclusive and reliable evidence for *tongue protrusion*—the most widely studied gesture (see also Heyes, 2001). The likelihood of neonates performing a tongue protrusion gesture increases significantly if they have observed the gesture being performed. Although there are parallels drawn between the research on mirror neurons and the research with neonates (e.g., Meltzoff & Decety, 2003), it is not clear to which extent the evidence with neonates warrants such sweeping interpretation. As Heyes (2001) points out:

> If tongue protrusion is the only body movement that newborns can imitate, it is plausible that the mediating process is an innate releasing mechanism; an inborn stimulus response link, wherein the response coincidentally resembles the stimulus from a third party perspective. (p. 253)

A less negative way of looking at the nature of the supportive and nonsupportive evidence is possible if one takes the current perspective that synchronization is constitutive for communication. Indeed, the finer analysis afforded by Anisfield can be seen as providing support for the contention that synchronization has an innate basis. The fact that the supportive evidence is only reliable in the case of movements of the mouth and face regions may not be surprising given that this part of the human body has the highest overall communicative significance. Thus, ironically, the critical assessment of the reliability of human neonate imitation may not be due to a coincidental resemblance, as Heyes (2001) has suggested, but may be regarded as constituting evidence for the innate

bases of synchronization processes that ground communication.

Evidence from Adults

The research literature on behavioral synchronization is extremely rich and varied in terms of both its history and the facets of behavior for which synchronization has been demonstrated. The types of behaviors that have been investigated range from paralinguistic features of speech like pauses or hesitations (see, e.g., Capella, 1981; Giles & Coupland, 1991, for different reviews) to arbitrary movements such as nose rubbing or foot shaking (Chartrand & Bargh, 1999) to experimental demonstrations of a particular syntactic structure that has been used by one person to be used again by the other dialogical partner (e.g., Bock, 1986, 1989; Bock & Loebell, 1990) to emotion contagion (Hatfield et al., 1994).

An early research pocket on synchronization examines a "thread of the communication tapestry" and has focused on specific measurable features of speech such as pauses, vocalization, and latency (see Capella, 1981, for a review). For instance, Jaffe and Feldstein (1970) assessed speech and silence at every 300-msec interval, thus recording vocalization and pauses across different dialogical settings (interviews, resolution of attitudinal differences, open-ended discussions over eight sessions). They reported substantial and consistent interclass correlations of average pauses between speakers across dialogical settings. In a set of conceptually convergent but methodologically different studies Matarazzo and Wiens (1967, 1972) experimentally manipulated interviewers' switch pauses. Their results showed that across the different switch pause conditions interviewees' pauses increased when the interviewers' pause increased and decreased when the interviewers' pause decreased. Capella and Planalp (1981) have reported convergent results for pauses and switch pause durations in informal 20-minute conversations by means of time series analyses.

A pattern similar to pauses-and-switch pause duration has been found for speech rate (Street, 1984; Webb, 1969, 1972; however, see Koomen, 1976) and vocal intensity. For instance, Natale (1975) found across 20 interviews that interviewees adapted their voice intensity to that of interviewers. In a second study, two-person dialogs lasting for 1 hour each and repeated over three occasions showed that the discrepancy in intensity between the speakers decreased linearly over time. These findings regarding voice intensity "convergence" appear to be stable across different studies (see Cappella, 1981). There are also numerous studies that have examined utterance length, number of words spoken, and other measures of verbal productivity across a number of dialogical settings and as Capella (1981) has summarized, there is no consistent pattern comparable to the ones obtained for pauses and vocal intensity, certainly not in informal settings. More recently, McGarva and Warner (2003) report coordination of vocal activity rhythms showing

speech accommodation. There is also a substantial amount of converging evidence from research on speech accommodation theory (see Giles & Coupland, 1991, for a review).

A substantial amount of psycholinguistic evidence on syntactical priming provides converging evidence on synchronization processes in dialogue or experimentally induced dialogical settings. The general gist of the findings is that if a particular syntactic structure has been used, the likelihood that the same grammatical structure will be used again increases significantly. The classic examples are a series of studies by Bock (1986, 1989; Bock & Loebell, 1990). Under the pretext of a memory test, Bock (1986) gave participants a prime sentence and subsequently a picture that they had to describe. Participants' task was to repeat the sentences (primes) they saw and then construct a sentence describing the picture they were presented next. The prime sentences varied in terms of their syntactic construction and the pictures were chosen such that they could be described by using one of two possible forms. For instance, in one condition participants were given an active sentence (e.g., "One of the fans punched the referee") and in the other a passive sentence (e.g., "The referee was punched by one of the fans"). Alternatively, a prime sentence was constructed with a propositional object form of an alternating dative verb in one condition (e.g., "A rock star sold some cocaine to an undercover agent") and in another condition the prime sentence used the double object form (e.g., "The rock star sold an undercover agent some cocaine"). Participants were much more likely to use the syntactic form of the prime when describing the picture they saw next, thus active or passive form, and so on, depending on the prime.

Furthermore, Bock was able to show that *prepositional object* sentences were much more likely to prime prepositional object sentences, although the prepositions differed, Thus, "The secretary took a cake to her boss" or "The secretary baked a cake for her boss" both elicited "The girl handed a paintbrush to the man." Similarly, sentences with prepositional phrases specifying locations (e.g., "The wealthy widow drove her Mercedes to the church") primed prepositional object descriptions even when the preposition did not specify location (e.g., "A rock star sold some cocaine to an undercover agent"). Bock and her colleagues argue that the production of a sentence activates *procedures* that are peculiar to the specific syntactic form. Thus, a passive sentence may be based on a specific procedure that is different from the production of a passive sentence. The procedure that is entailed in the production of a particular syntactic form thus persists and facilitates its subsequent use. Moreover, they argued against a view that suggests a phonetic or episodic trace of a sentence, as the diverse syntactic priming experiments show that syntactic priming occurs even when the prime and target sentences are very different (however, see Pickering & Brannigan, 1999).

Bernieri (1988) investigated *perceived movement synchrony* by having participant judges code the postures of 38 high school juniors and seniors in 19 interactive teach-

ing dyads presented on video recordings and compared them with pseudo-interaction control clips. Ratings of perceived movement synchrony were higher for real interactions (see also Bernieri et al., 1988; Bernieri, Davis, Rosenthal, & Knee, 1994, for synchrony measurement method and similar results). Moreover, there was a strong relationship between participants' rapport and the degree of perceived synchrony by raters—providing evidence for the interpersonal coordination hypothesis advanced by Tickle-Degnen and Rosenthal (1987). A recent study by Shockley, Santana, and Fowler (2003) showed interpersonal coordination of postural sway in the context of a cooperative verbal task.

Bavelas and her colleagues (e.g., Bavelas et al., 1988; Bavelas, Black, Lemery, & Mullett, 1986a, 1986b) report a number of studies on what they refer to as motor mimicry, defined as behavior by an observer appropriate to the situation of another (e.g., wincing at the other's injury or ducking when the other does). They argue that the function of such motor mimicking is primarily communicative (Bavelas et al., 1988b). They created a situation with a victim of an apparently painful injury and controlled the amount of eye contact that the victim had with a participant observing the victim. They were able to reveal that motor mimicry displayed by the observing participant was significantly shaped by the visual availability of the victim, thus suggesting that mimicry serves a communicative function.

Chartrand and Bargh's (1999) influential contribution initiated the currently active field on behavioral synchronization. They had a trained experimenter rub her nose or shake her foot while interacting with a participant. Their findings showed that when the experimenter rubbed her nose, participants were more likely to do so as well rather than shake their foot, and in the experimental condition when the experimenter shook her foot, the likelihood of participants shaking their foot was higher than rubbing their nose. This particular synchronization termed the "chameleon effect" (Chartrand & Bargh, 1999) refers to the tendency to adopt the postures, gestures, and mannerisms of interaction partners. The research evidence to date suggests that his type of mimicry occurs outside conscious awareness and without any intent to mimic or imitate. There are (in the interim) a number of studies that illustrate the diverse moderating conditions and consequences of the so-called action–perception link, namely, the assumed direct link between perceiving a behavior and performing that same behavior (Dijksterhuis & Bargh, 2001). Nonconscious synchronization has been shown to be moderated by self-monitoring (Snyder, 1974, 1987), with high self-monitors being more likely to mimic in situations involving affiliative cues than low self-monitors (Cheng & Chartrand, 2003). Similarly, inducing a self-construal that is more interdependent (or collective) either by experimentally priming or by recruiting participants differing on their chronic self-construal has been shown to give rise to stronger mimicry effects compared to persons who were chronically more individualistic or independent (van Baaren, Maddux, Chartrand, de Bouter, & van

Knippenberg, 2003; see van Baaren, Horgan, Chartrand, & Dijkmans, 2004, for a similar set of studies).

There is a substantial literature on emotion contagion (see Hatfield et al., 1994). Neumann and Strack (2000) report nonintentional mood contagion for participants who, under the pretext of a text comprehension study, listened to an affectively neutral speech spoken in a slightly sad or happy voice. They showed that the emotional tone induced a congruent mood state, leading the authors to conclude an emotion contagion (Hatfield et al., 1994) account of their results. This led them to interpret their findings in terms of a perception–behavior link (Chartrand & Bargh, 1999).

As can be seen from the foregoing compilation of studies from social psychology, the history of social behavioral research on what is termed here "synchronization processes" is extremely rich. Some of the earlier work is acknowledged *in passim* in the current social psychological literature on mimicry but is not fully recognized in terms of the conceptual foundations that these early researchers were trying to construct and establish. Indeed, the classic volume by Martha Davies (1982) was an important theoretical and methodological landmark, which somehow got buried by fashionable currency winning over cumulative knowledge. Indeed, one of the concerns central to this research was treating communicative behavior in terms of social interaction as the unit of analysis rather than the individual (e.g., Scheflen, 1982). The early research did deploy terminology referring to the jointly manifested and attuned feature of behaviors. Thus, one comes across a variety of terminological anchors such as "imitation," "mimicry," "empathy," "sympathy," "matching" (e.g., Capella, 1981), "entrainment" (Condon & Ogston, 1966), "interpersonal synchrony" (Bernieri et al., 1999; Condon & Ogston, 1966; Kendon, 1970), "periodicity" (Davies, 1982), and "contagion" (Hatfield et al., 1994).

CONCLUSIONS ON SYNCHRONIZATION AND ITS CONSEQUENCES

The research I have reviewed so far shows considerable consistency across disciplinary and thematic foci, ranging from neurophysiological to neuroscientific to developmental and social psychological traditions. First, there is an overall paradigmatic consistency. The experimental setups entail typically *co-presence* paradigms—this is a defining characteristic of the entire literature that has been reviewed so far. Obviously, the disciplinary visions and questions involve different but complementary definitions and manipulations of variables. In the neuroscientific tradition, behavior constitutes the tightly controlled independent variable and neural activity of the dependent variable. Oftentimes, the behavior is a very simple well-defined bodily movement (e.g., picking up a peanut) with the exception of perceptually opaque movements (e.g., facial expression of emotions). In the developmental work both independent and dependent variables are very limited and specific ranges of behaviors

with reliable evidence only for tongue protrusion. In the social psychological work, behavior is the dependent variable with changing controlled co-presence conditions. The general behavior in such settings is complex within which a specific experimentally controlled component (e.g., nose rubbing and foot shaking) is embedded. It is possible that in such experimental conditions other types of behaviors synchronize (e.g., speech rate, pauses, accent, bodily sway, and facial expressions) as revealed by a number of earlier studies that have investigated synchronization of motor behavior in natural interaction settings (Capella, 1981).

The second and more important consistency for the foundations of communication is simply that across all the reported research there is evidence of jointly and simultaneously recruited processes by means of which parity is established between producer and perceiver at neural, perceptual, affective, and behavioral levels. These processes are shown to be automatic, to escape conscious access, and to occur without the presence of explicit communicative intent. It is noteworthy that in the social psychological work the conceptual focus has been on phenotypical features of synchronization (e.g., affiliation and prosocial behavior) rather than the underlying communicative function of synchronization (discussed in the next section).

Obviously, the difference in research foci (e.g., neural vs. behavioral processes) brings with itself systematic differences in the wealth of observed and recorded data that are informative and can lead to cross-fertilization between the disciplinary fields, particularly as they throw a new light on communication and its embodied foundations. In the following section I proceed through these diverse implications and consequences that emerge from the work so far.

The Sameness Principle: "Genotypical" Basis of Communication

The social dimension of our lives plays a crucial role in the way we are shaped; the way we form images of our world; how we interact with and within it. Obviously, this is not only peculiar to primates or cetaceans but also to a number of species as different as graylag geese, termites, and bees. The nature and functions of social behavior across species differ, as do the mechanisms that drive them. However, what does not differ as a general principle for any social species is the necessity of mutual *recognition* and *intelligibility*. It is important for any social species to have evolved mechanisms that permit them to be coupled by being put on the same footing. Such mechanisms must facilitate obtaining a state of equivalence—what counts for one member must count for the other and such mechanisms, by giving privileged access to each other, ground mutual recognition and intelligibility.

Mutual recognition is by definition a collaborative process and it takes two to collaborate. In other words, "sameness recognition" cannot come about without interacting, or without exchanging information while navigating in a joint environment. While the particular ways in which mutual recognition and intelligibility are achieved vary between species, the general characteristics of the mechanism or process by which two parties communicate and by which mutual recognition and intelligibility are achieved remain the same.

For members of any social species to be able to communicate they must have mechanisms in place that permit them to be coupled by being put on the same footing. In other words, such mechanisms must facilitate obtaining a state of equivalence between two parties: What counts for one member also must count for the other and thereby also must ground mutual recognition and intelligibility. Imagine how short-lived the existence of vervet monkeys would be if vervets started to look down for snakes or look up for an eagle when they heard a leopard alarm. Communication can only succeed when two parties have a common understanding. This parity assumption (Liberman & Whalen, 2000) also constitutes the basis of mutual recognition and intelligibility. Thus, species sameness and its recognition is a biological necessity for any social species. *If there was no within-species parity, one would not be able to classify "same" and discriminate it from the "other." It is therefore significant for adaptive purposes not only to be able to recognize another as "same" or different but also to recognize that what another "same" does is intelligible.* I refer to this as the *sameness principle.* An important implication of this principle is that recognition of sameness goes hand in hand with the recognition of difference—an issue that will be further addressed at the conclusion of this chapter.

We have reviewed research that has to do with the neural and behavioral synchronization processes. This research reveals evidence supporting the notion of jointly recruited processes by two parties allowing for an embodied grounding of a coupling process. Notably, synchronization is not a process leading to equivalence between a producer and perceiver's neural activity, actions, and emotions. Such a state would lead to complete confusion between producer and perceiver. Rather, it is a *multimodal* process that provides a partial overlap.

One question that can be raised is whether the particular neural coupling process is species specific? Obviously, neural synchronization as a process is not specific to humans but has been observed in nonhuman primates. However, is it possible that observing the movements of the member of another species recruits corresponding neural structures? Indeed, if synchronization would be noted between species then it would be impossible to perceive sameness and difference. The research evidence available to date suggests that neural synchronization is not a process that is recruited across species and is not observed in the case of bodily movements of other species. In a fMRI study, Buccino and colleagues (2004) had participants observe mouth actions performed by humans and by individuals belonging to other species (monkey and dog). They were able to show that actions that belong to the motor repertoire of a human observer (e.g., biting and speech reading) were mapped on the observer's motor system. However, actions that do not belong to this repertoire (e.g., barking) are recognized on

the basis of their visual properties. Similarly, Martineau and Cochin (2004) have examined the relation between visual perception of motion and cortical activity by presenting children ranging from 29 months to 5 years with a still image (a lake) and animated images with human, animal, and virtual movement. Their study revealed that stimuli representing human, animal, and virtual movement activate different cortical areas suggesting that real human movement is processed neurally in a distinctive manner. It would therefore seem to be reasonable to assume that the architecture of the human perceptual and neural system is specifically designed for the recognition of species-specific movements in a privileged way, thereby *establishing a type of knowledge that has an entirely different ontological status than knowledge about the world in general*. This is the genotypical foundation of communication and the *embodied building block* of social cognition. Synchronization is therefore very much like a species-specific password that gives simultaneous privileged multimodal access to "each other," thereby establishing the basis for mutual recognition and the intelligibility.

"Phenotypical" Consequences of Synchronization and the Embodied Foundation of Communication

The social psychological research has long since converged on the positive consequences of behavioral synchronization along with the observation that these consequences are mediated automatically and unconsciously. The positive interpersonal consequences of unconscious behavioral synchronization postulated (e.g., Tickle-Degnen & Rosenthal, 1987) and reported early on along with supportive data (e.g., Bernieri, 1988) have revealed a strong relationship between participants' rapport and the degree of perceived synchrony. There is substantial evidence showing that the phenotypical manifestation of behavioral synchronization finds expression in experiences of greater liking for the other and reports of a more cohesive relationship, perceptions of shared identity, and smooth interaction *inter alia* (e.g., Bernieri, 1988; Hatfield et al., 1994; LaFrance, 1985; LaFrance & Broadbent, 1976; LaFrance & Ickes, 1981; Neuman & Strack, 2000). More recent work has examined the consequences of synchronization in terms of affiliation and prosocial behavior (Gump & Kulik, 1997; Lakin & Chartrand, 2003; Lakin, Jefferis, Cheng, & Chartrand, 2003; van Baaren, Holland, Kawakami, & van Knippenberg, 2004; van Baaren, Holland, Steenaert, & van Knippenberg, 2003). These consequences may also be what some refer to as the fundamental need to belong (e.g., Baumeister & Leary, 1995; Caporael, Dawes, Orbell, & van der Kragt, 1989; Leary & Baumeister, 2000).

It should be noted at this point that as much as synchronization is an automatic and nonconscious process the investigations of behavioral synchronization have focused predominantly on contexts that are not adversarial. Research within a speech accommodation theory (SAT; Giles & Coupland, 1991) framework has long ago demonstrated synchronization and desynchroni-

zation processes as a function of cooperative and competitive relationships. The behavioral focus in these studies was accent and changes in the interlocutor's accent or language (e.g., Giles, Bourhis, & Taylor, 1977; Giles & Smith, 1979; Giles, Taylor, & Bourhis, 1973). This research suggests that in multilingual contexts, a cooperative or competitive relationship between interlocutors influences accent and language use, originally taken as indicators of attitudes. Desynchronization (i.e., divergence in SAT) is found to be pronounced in intergroup contexts when the speaker expects competitive interactions with outgroup members (e.g., Doise, Sinclair, & Bourhis, 1976; Taylor & Royer, 1980) or when outgroup members are known to hold negative attitudes toward the transmitter's group (Bourhis, Giles, Leyens, & Tajfel, 1979). Bourhis and Giles (1977) provide a classic demonstration in which an adversarial conversational context is shown to induce participants to introduce a variety of strategies, such as accentuating differences in speech as well as nonverbal behavior to emphasize the difference between themselves and the adversarial "other" signaling divergence from the "other." In contrast to desynchronization (i.e., divergence), a number of communicative acts and styles are used to reduce differences, such as speech rate, pausal phenomena, utterance length, but also smiling, gaze, and so on. These are strategies by which individuals adapt to each other's communicative behaviors. Levin and Lin (1988) provide an interesting example of convergence. They showed that during the Watergate trials John Dean converged in terms of his median word frequency (an index of formality) to his different Senate interrogators. Similarly, Coupland (1984) conducted a phonological analysis of a travel agent and showed that she converged to her clients as a function of her clients' socioeconomic status and education. In short, situated goals influence whether synchronization or desynchronization is likely to be manifested.

There are two sets of implications of the foregoing findings:

1. The goals that are pursued shape whether *behavioral* synchrony or desynchrony will emerge. The point is that desynchronization is decoupling. Decoupling leads to the recognition of the other as different, and the phenotypically manifested form of it will be expressions of social distance. Thus, while synchronization leads to parity and the classification of the other as the same, desynchronization leads to disparity and discrimination of the other as different. It is therefore significant for adaptive purposes not only to be able to recognize another as "same" or different but also to recognize that what another "same" does is intelligible. Notably, this process is bidirectional. Thus, the process of behavioral synchronization or desynchronization can lead to positive or negative phenomenal expressions and experiences respectively as well as the reverse.

2. Phenomenal expressions and experiences rely on underlying synchronization processes and grounded by them. Thus, any experienced sense of "belongingness" or "motivation to engage in prosocial behavior" would

have to be based on and result from an exchange of information occurring at a modality different from speech—the behavioral evidence reviewed earlier repeatedly reveals the automatic and unconscious nature of the process. Moreover, there is certainly no access to neural synchronization. The evidence strongly suggests that synchronization is a process that serves a communicative function and is embodied. Thus, jointly recruited multimodal processes precede the phenotypically experienced social consequences of synchronization. Communication must have taken place for any other implication to be processed in the first place. This takes the form of jointly experienced bodily states—synchronization—and can be manifested in different phenotypical expressions—but the distinctive feature of the diverse phenotypical manifestations is a positive "oneness" of two individuals.

Synchronization: The Building Block of Communication

As the evidence reviewed so far shows, synchronization is a process fundamental for the embodied grounding of communication. It entails a specific architecture involving psychological and neural mechanisms that are designed for the joint processing of information about conspecifics and is a central *scaffold* to human communication, as we know it. The distinctive feature of this scaffolding architecture is that it is designed for the neural representation of knowledge that is jointly recruited in *coaction*, thus establishing correspondence between multimodal production and perception processes by automatically aligning processes of production and perception. Compared to other communication modalities, such as modern language, which are, in evolutionary terms, recent modes of communication and are specifically human, synchronization is prelinguistic and ancient, thus displaying some continuity with primates. Furthermore, synchronization is a heritable foundation albeit with considerable plasticity.[6] Moreover, as an architecture, it is specific to and constitutional for communication and by implication a uniquely defining feature of the domain of social cognition.

I would like to argue that synchronization is a specialized building block of communication very much akin to what Spelke (e.g., 2000, 2003; Hauser & Spelke, 2004) refers to as core knowledge systems. These knowledge systems rely on

> specialized perceptual systems for detecting particular kinds of sensory information and specialized motor systems guiding particular types of actions, infant animals have specialized, task-specific cognitive systems; systems for representing material objects, navigating through the spatial layout. . . . (Spelke, 2003, p. 278)

The type of knowledge systems she refers to are primarily nonsocial, such as numerosity and spatial orientation, and are grounded on a relational ontology in that features of these realities exist as a function of the interaction between the physical capabilities and properties of the observer and the physical properties of the environment (Gibson, 1977, 1979). Synchronization is, however, different, because it refers to a process underlying a knowledge system that is jointly recruited by a producer and perceiver.

The particular characteristics of core knowledge systems are that they are domain specific, task specific, and encapsulated and constitute an isolated system (Spelke, 2003). Synchronization shares these very same features, which are summarized by Hauser and Spelke (in press) as follows:

> a system of core knowledge is characterized by four properties. . . . First, it is domain specific: each system functions to represent particular kinds of entities such as conspecific agents, manipulable objects, places in the environmental layout, and numerosities. Second it is task-specific: each system uses its representation to address specific questions about the world, such as "who is this?" (face recognition), "what does this do?" (categorization of artifacts), "where am I" (spatial orientation), and "how many are there?" (numeration). Third, it is relatively encapsulated: each uses only a subset of the information delivered by the animal's input systems and send information only to a subset of the animal's output systems. Finally, the system is relatively automatic and impervious to explicitly held beliefs and goals.

Synchronization can therefore be regarded as constituting a separate core knowledge system because it shares the four general features but is distinctive from the types of knowledge systems investigated by Spelke and her colleagues. It has a uniquely designed architecture that joins two conspecifics and furnishes the possibility of socially shared representations by means of establishing neural parity between perceptual and production processes.

Much like core knowledge systems for navigating the nonsocial environment (or the physical features of the social environment), synchronization is a process that has undergone major transformations in human evolution—in particular with the acquisition of language as the powerful communication tool. The emergence of language as a tool to implement action gives rise to substantially sophisticated forms of communication—aside from dramatically extending our cognitive powers by introducing the uniquely human combinatorial capacity and thereby contributing to the creation of new systems of knowledge. While synchronization constitutes the fundamental building block for communication in general (and may also be responsible for the grounding of the uniquely human skill, namely, language[7]) the shape of communication and its uses underwent a dramatic transformation with the introduction of language. While *synchronization is a distinctly situation-specific process* regulating communication in terms of jointly recruited processes that establish parity between producer and perceiver, language is a means by which it becomes possible to detach from the immediacy of the situation both temporally and spatially. This facility enhances the attainment of increasingly complex individual and collective goals that are removed from the here and now by means of language- and convention-driven processes of coordination to which we turn in the next and final part of this chapter.

FROM SYNCHRONIZATION
TO COORDINATION

Communication as purposeful social interaction takes place in a social context and is regulated by social rules and conventions that are deployed to establish a shared reality and to attain individual or group goals (e.g., Austin, 1962; Grice, 1975; Higgins, 1981, 1992; Krauss & Fussell, 1996; Searle, 1969). When we move on to complex and purposeful communicative events such as a mundane dialogue or other joint activities, as in the case of recurrent social or task situations such as executing a heart operation, then the successful achievement of any of these activities relies on skillful *coordination* between two or more people. For instance, a heart surgery team consists of diverse experts (the surgeon, the anesthetist, etc.) who have expertise and have to coordinate unshared knowledge bases relevant to the performance of the operation. While each member of such a composite team of experts has a unique knowledge base they also have to have shared knowledge about how to coordinate their knowledge bases in order to be able to organize and execute the sequential joint activities properly. The coordinated communication between the different members of the team is intended to structure collective action such that a continuously monitored and publicly shared cognitive state is achieved (Hutchins, 1995). The socially distributed knowledge between team members in its public coordination, as well as physical tools such as heart–lung machine and electrocardiograph in which knowledge is literally embodied, become scaffolds for the successful performance of the operation. Instances ranging from dialogue to the performance of tasks that include external entities (e.g., other people or physical objects) to perform a task such as heart surgery require coordination and rely on communication by language to achieve such coordination.

Coordination in conversation or dialogue involves establishing parity at multiple levels of sequential processes. First of all, speakers and addressees rely on a number of conventions that have evolved to regulate the speaker–addressee relationship in conversation. Conversationalists concurrently access a set of "tacit" conventions or maxims. These maxims are derived from the unspoken *principle of cooperation*, which is important in conveying intended meaning in communication, and involve giving the right amount of information, making an informative, true, relevant and unambiguous contribution that is orderly and brief (Grice, 1975, 1978). The roles of speaker and addressee reverse in a turn-taking process regulated by conversational conventions signaling turns (Sacks, Schegloff, & Jefferson, 1974), opening and closing conversation, *inter alia* (Mehan & Wood, 1975).

For conversation to be successful interlocutors have to share information (i.e., mutual knowledge, beliefs, and assumptions). This shared information is referred to as common ground, and conversational partners continuously coordinate with each other to ground the content of their conversation (Clark & Brennan, 1991). Common ground refers to the set of knowledge and beliefs that are shared and assumed to be shared between the interlocutors. The process of grounding entails seeking and providing evidence of understanding in conversation. Accomplishing common ground is achieved by keeping track of the knowledge state of the interlocutor (e.g., Clark, 1996a; Clark, Schreuder, & Buttrick, 1983; Clark & Schober, 1992). To this end a number of—typically linguistic—strategies are employed to coordinate joint reference to objects and events in a communicative setting (e.g., Clark, 1992, 1996; Krauss & Fussell, 1996). Conversational coordination between speaker and addressee involves monitoring the *perspective of the addressee* (e.g., Fussell & Krauss, 1989a, 1989b; Schober, 1998), which contributes to the shape of the message production process. "Common ground" can be inferred from past conversations and supported by immediate surroundings and shared cultural background. Studies by Krauss and his colleagues (e.g., Fussell & Krauss, 1989a, 1989b) using a referential communication paradigm examine message design as a function of addressee characteristics. These types of studies illustrate how perspective taking influences the linguistic features of messages and how these in turn influence their communicative accuracy. It is not only the perspective of the addressee that is critical to successful communication. Considerable groundwork has to be done to achieve parity or intersubjectivity (Rommetweit, 1974; Schütz, 1962) in terms of the background knowledge shared by the interlocutors without which successful conversation cannot take place. In research terms this has meant a focus on processes that contribute to sharing a common ground (Clark & Wilkes-Gibbs, 1986), which has been regarded as a critical condition for successful communication.

In any purposeful complex task, it is not only the conventions noted for the coordination of a conversation that are sufficient but the additional coordination of joint activities that are given by the goal of the task. These have to do with who does what, when. Thus, what is required is not merely coordination at the dialogical level but also coordination of joint activities to achieve the goal of successful surgery. These are also driven by dialogue with a variety of correction practices to get back on course when events take unexpected turns.

The central theme driving this chapter is the necessity to establish equivalence or *parity* (cf. Liberman & Mattingly, 1985; Liberman & Whalen, 2000) between a sender and receiver for communication to be possible in the first place. So far, I have presented two sets of different processes by which parity is established. The first addressed in some length jointly recruited automatic processes underlying communication (i.e., *synchronization*) as an embodied grounding aspect of this process. The second, presented here briefly, is *coordination*, namely, the processes involved in purposeful human communication that establish equivalence in meaning and drive joint actions. Two final questions are addressed in this part. The first arises from the question of the differences between synchronization and coordination. The second has to do with how synchronization and coordination processes are interfaced. These are examined in the next two sections.

The Synchronization–Coordination Interface

How do synchronization and coordination interface? Obviously, human communication functions as an integral whole and not as a loosely connected set of processes. I turn to some features of dialogue and speech to illustrate this interface.

It takes the brain only a few seconds to put speech rate, accent, and message together for communication to occur. Speech is an incredibly fast process with an average production rate of 180–200 words per minute (approximately 333 msec per word); the upper range can go from fast (300 words per minute) to very fast (500 words per minute). We speak by accessing a lexicon with a volume between 20,000 and 60,000 (or more) words. Moreover, talk does not simply involve producing words. It requires choosing words from a lexicon to create sentences that are also linguistically structured. As Liberman and Whalen (2000) point out, an absolute requirement for particles in speech to be produced and perceived they have to be discrete, invariant and categorical—a consequence of the particulate principle (Abler, 1989, see below). A further constraint is inherent to the characteristics of the vocal tract and ear. Given the limitations of the vocal tract, the number of particles has to be small and put together in string form and these strings can "run considerable lengths. It is essential therefore, that the particles be produced and perceived rather rapidly if they are to be organized into the larger units of the language hierarchy. In fact, the consonants and vowels that are formed by the particles are delivered in speech at about 10 or 12 per second on average, and for short stretches the rate raises even higher" (Liberman & Whalen, 2000, p. 191). The point is that *perception* at these speeds is only possible because speech is *coarticulated*, thus production and perception are *synchronized* between producer and perceiver at the gesture level and not in the acoustic signal. Indeed, there is growing neuropsychological evidence providing provisional support for the notion of synchronization between producer and perceiver in speech. The evidence—however preliminary—relies on the notion that humans possess an "echo-neuron" system (cf. Rizzolatti & Craighero, 2004). An echo-neuron system refers to a neural system that synchronizes with the speech of another, in line with the motor theory of parity in speech perception (Liberman & Mattingly 1985; Liberman & Wahlen, 2000). For instance, Fadiga, Craighero, Buccino, and Rizzolatti (2002) presented participants with verbal and nonverbal stimuli (i.e., words, regular pseudowords, and bitonal sounds). In the middle of the words and pseudowords they had inserted either a double "f," which, when pronounced, requires slight tongue mobilization, or a double "r" requiring a tongue movement to be pronounced. When listening to words and pseudowords with "r" it was revealed that there was a significant increase of MEPs recorded from tongue muscles compared to the same stimuli with a double "f" as well as when listening to bitonal sounds. Watkins, Strafella, and Paus (2003) report similar results. Of course, as Rizzolatti and Craighero (2004) point out, these experiments—albeit less likely—do not exclude the alternative possibility that the echo-neuron system mediates the imitation of sounds. These findings lend support to the notion that an embodied grounding of speech and comprehension takes place via synchronization in a *coupled unit* of producer and perceiver and entails simultaneously and jointly recruited processes between producer and perceiver. This provides an anchor on the route to coordination, but it is still a long way away from purposeful, goal-driven communication via language use.

What is special about the evolutionary step introduced by symbolic vocalizations—speech—is that it furnished a novel possibility to human communication, namely, a combinatorial system. As Abler (1989) has pointed out, there is a distinct property of language, one that is also common to a number of natural systems. Abler draws attention to "Humbold's (1836) characterization of language, i.e. all systems 'make infinite use of finite media" whose "synthesis creates something that is not present *per se* in any of the associated constituents" (p. 1). Abler refers to this property as the *particulate principle*. "The creation of 'something that is not present per se in any of the associated constituents' involves the formation of at least a second level of organization in any system that conforms to Humbold's criteria . . . Human language involves phonemes at the first level, morphemes at the second level and phrase structures at the third level" (p. 3). This is the distinctive characteristic of human language. It is recursive. Importantly, as he points out, *organization at higher levels* (e.g., phrase structure) *tends to obscure lower-level constituents* (e.g., phonemes and phoneme composition).

Consequently, levels of organization have a propensity to act as shells, which enclose or hide their constituents. Translated into psychological terms, our attention and awareness during speech is driven by features regulating the dialogue, the communication goals that are pursued, and what is said and to be said, whereas "lower levels of organization" that act as scaffolds (phrase structure, morphemes, phonemes) for speech are used automatically and are not accessible and therefore outside consciousness.

The highest level of organization (at the dialogical level), "hide" the constituent levels, thus obscuring conscious access to them. These scaffolds entail particulars such as vocal gestures that make up speech (phrase structure, morphemes, phonemes) but also bodily movements, gestures, facial expressions, and their corresponding neural substrates, all of which are integrally matched to each other in communicative acts. All these modalities that are associated constituents, as suggested by the "particulate principle" (Abler, 1989), are recruited jointly and simultaneously by both producer and perceiver. It is not merely a matter of attention but the fact that the end product (synthesis) has a quality that is entirely different from the constituent parts. The direct analogy that illustrates this is, for instance, chemical compounds such as sand or water that are combinations of specific particulates (hydrogen, silicon, oxygen) that conceal their constituents. The constituents do not change character but retain their properties. However, the dif-

ferent syntheses produce compounds with distinct properties that are unique. Nevertheless, the constituent particles retain their qualities of distinctiveness and invariance and are categorical. Thus, it is inherent to the organization of communication that constituent levels of organization are not accessible. They are outside consciousness. The other reason is the one I mentioned earlier and has to do with the speed at which communication takes place. In contrast, the particular syntheses of these recursive constituents are a unique, nonreiterative, and consciously accessed "meaning."

Thus, while specific synchronization processes involved in speech facilitate the creative and unique syntheses manifested at the dialogical level, communication at the dialogical level (coordination) has also got to follow the parity principle. But now we are talking about parity at a consciously monitored level.

As I concluded in an earlier section, communication comes about in a *coupled unit* of producer and perceiver and entails simultaneously and jointly recruited processes between producer and perceiver. The processes are multimodal and occur by synchronization at the constituent levels of organization in communication, namely, recursive scaffolds of speech, but also in the case of the evolutionarily more ancient modalities of emotional and behavioral motor responses integral to communication.

Synchronization versus Coordination

Synchronization and coordination recruit distinctly different processes in terms of the *temporal frames* within which they operate. Synchronization fulfills an adaptive function by establishing neural, affective, and behavioral parity. With adaptive function I refer to the *continuous joint* behavioral and affective *monitoring* of a coupled unit of producer and perceiver that unfolds in continuous interaction. This is evident in the neural synchrony of motor movements and affect, as well as in the example of speech production and perception. If such monitoring would not be sensitive to immediate changes in the interaction then it would lose its adaptive function. Therefore, a significant feature of synchronization processes is that they operate in a *continuously situated* mode to monitor and establish parity.

An implication of the continuously situated operation mode is that synchronization processes have to be responsive to changes in very short temporal windows—otherwise they would lose their adaptive parity monitoring function. Indeed, one could argue that synchronization processes take place substantially below a 1,000-millisecond window,[8] which is one of the reasons (but not the only one) why synchronization processes are automatic and escape conscious access. A further distinctive feature of synchronization processes is that they are symmetrical in producer and perceiver.

Coordination in contrast is purposeful and goal driven and operates within much wider range of temporal windows. When cognitive activities are distributed across space and time and people, as they are with purposeful human communication, then language-driven coordination becomes an indispensable resource to structure and control actions. Any type of purposeful social interaction has a sequentially organized structure, which means that the coordination of the activities takes place over a temporal horizon. For a smooth and relatively flawless execution of joint action during purposeful social interaction it is crucial to ascertain that activities are coordinated and matched on at least two levels. One is within immediate communicative exchange but also across broader time intervals the range of which is defined by jointly pursued goals. Indeed, coordination runs over a substantial temporal horizon, as in the example of the heart surgery team or a variety of joint activities ranging from a dialogue to maintaining a relationship. The coordinating function of speech in dialogue is also very different. Compared to the symmetrical nature of synchronization processes coordination processes can take a wider range of dyadic formats, which have to do with the successful navigation of joint tasks as in the case of a dialogue or the example of the aforementioned heart surgery team. A further related feature of coordination processes is that they are purposeful and goal driven and consequently reflexive and consciously accessible. Coordinating activities frequently involves exchanging requests, instructions, corrections, and so on in order to maintain the smooth flow of joint activities, whereby such *correction* processes and deviations for coordinated action are consciously processed and instructions for corrections consciously produced. These processes are also situated processes; however, they operate within broader temporal windows.

CONCLUSIONS

Obviously, human communication, its nature, and its reach have been radically transformed over time. The crucial step for human communication was the evolution of gestural communication and speech as a result of two major changes in hominid vocal anatomy and physiology (e.g., Fitch, 2000; see note 7). The invention of writing in response for the need to record commercial transactions and administrative procedures in Mesopotamia approximately 6,000 years ago introduced a revolution in communication. This invention also meant that external devices could be used as aids for memory, cutting out intermediaries and distortions. The creation of different notations (alphabets, mathematics, music) and the introduction of simple devices, such as the space between words, radically changed the nature of the services that communication could be put into from advancing science to the reproduction and preservation of art to silent reading (Seanger, 1997). The invention of further technologies not only extended the communication reach but also transformed the nature of communication from the real and immediate (conversations, disputes, negotiations, etc.) to the removed (writing letters, voting, newspapers, films, theater, books), the magically removed (fantasies, dreams, daydreams), or the virtually removed (Internet) contexts. In short, the scope of human coordination is greatly expanded by the introduction of novel

tools and technologies. Thus the range of topics that can be covered under the social psychology of communication is vast. The focus of this chapter was on the biological, neural, psychological, and social foundations of the communication process with particular emphasis on synchronization processes as a core knowledge system, namely, the embodied grounding of communication that to our knowledge has not been addressed.

I tried to draw attention to the fact that human communication is not merely speech (e.g., Bavelas & Chovil, 2000). Language-based communication is about meanings and implications conveyed by articulatory gestures that are very important for coordination processes, but this is the tip of a *multimodal* communication iceberg that would not be possible without the cooperation of a range of automatic *neural and motor* processes that not only fulfill a continuous monitoring function by means of which parity is established but also provide scaffolds (among other things) for the production and comprehension of auditory messages. Face-to-face communication is composed of a simultaneously integrated set of audible and visible acts and any act of communication is a unified process resulting from the integration of information from multiple sensory modalities.

Thus, "language use"—located merely in terms of the product of speech—constitutes a crucial albeit very specific medium and modality for communication. While utterances in a dialogue may be the most salient features to the communication process, there are nevertheless a whole range of other modalities to communication aside from the production and perception of speech. These involve bodily movements (hand, arm, head, hip, leg, etc.) that accompany speech, the affective intonation of speech, and facial muscle activities involved in the expression of affect (*zygomatic major*, *corrugator supercilii* muscles, etc.), among other things. All these are finely integrated motor expressions along with communicative gestures and are not loosely or randomly occurring features of communication (e.g., Condon, 1982; Davies, 1982). This list is merely to draw attention to the fact that not only does human communication consist of *what is said* but that what is said (speech) is just a part of a multimodal expressive "whole." The communication modalities that are at the service of synchronization processes are prelinguistic and ancient in evolutionary terms. They display some continuity with primates. Other modalities such as modern language are—in evolutionary terms—recent modes of communication and are specifically human. In communication all modalities are integrated into a coordinated and complex whole.

There are a number of implications of the current formulation of synchronization processes as jointly activated. For one it treats communication as a "phenomenon" of a *coupled unit* and a phenomenon that comes about in terms of simultaneously recruited processes by the interlocutors to it, thus raising the analytic unit from that of an individual to a coupled unit. Conceptualizing communication as a process that has to be recruited simultaneously by two members involves thinking in terms of an analytic unit that is different from the traditional one. For historical and cultural reasons, the individual constitutes a prominent analytic focus and is the prevalent analytic unit in psychology and related disciplines. Such an analytic incision offers itself readily given the biological finitude of the individual. However, it does not necessarily lend itself as readily for conceptualizing what it means to be a "*social* species" in general and the analysis of communication in particular. Communication is a phenomenon that exists only when there is a *coupled unit* consisting of a producer and perceiver[9] and comes about in terms of processes recruited simultaneously by both producer and perceiver. Consequently, the proper analytic unit to communication is a coupled unit and jointly recruited processes.

Moreover, the current formulation suggests that the process of synchronization is a multimodal one serving multiple monitoring functions simultaneously. The present perspective introduces a different balance to the prevalent one that places a heavy emphasis on linguistically or symbolically driven communication. Language-driven communication—defined here as coordination processes—is the tip of the iceberg. For such purposeful communication to be successful hard work has to be done at the prereflexive level. Moreover, the argument derived from the particulate principle and its implication that higher levels of organization of communication (at the dialogical level) "hide" the constituent levels, thus obscuring conscious access to them, sheds a novel light on understanding a topic that is current, namely, the specific features of implicit cognitive processes. The distinctive flavor of approaching of what is implicit is that it comes from a perspective that is grounded on communication.

ACKNOWLEDGMENTS

NOTES

1. Others have suggested that chemosignals also have a significant role to play and that dance alone is insufficient to give other bees guidance (e.g., Sanoz, Laloi, Odoux, & Pham-Delegue, 2000; Wenner, Wells, & Johnson, 1969), although recent evidence suggests that dances provide the guidance to the vicinity of the source and chemosignals facilitate locating the precise source (Riley, Greggers, Smith, Reynolds, & Menzel, 2005).
2. The exception is learning by imitation.
3. There is, to my knowledge, only a brief reference to communication (Rizzollatti & Craighero, 2004, p. 183), while the theoretically provocative and stimulating accounts have been about the evolution of language (e.g., Arbib, 2005; Arbib & Rizzolatti, 1997; Rizzolatti & Arbib, 1998). Further theoretical speculations have been about what has been referred to as *shared intersubjective space* (e.g., Gallese, 2003).

4. There is a potential methodological issue with these two reports. This has to do with whether the observing subject's behavior is causally related to the movements of the executioner or the observed, or even to the anticipated object movements (as in the case of stacking blocks). The question is, Are the observers synchronizing with arm–finger movements or fixating on the endpoint of the object trajectory (Mataric & Pomplun, 1998)?

5. Thus, imitation is seen as different from *emulation* (cf. Mataric & Pomplun, 1998) where the observer's behavior may be casually related but not to the movement of the model but rather the observed object movement as in the case of stacking blocks. Emulation involves learning properties of the physical situation (Tomasello, 1990, 1998) rather than the movements themselves.

6. The plasticity of synchronization is demonstrated in the diverse studies with, for instance, monkeys whereby hearing specific sounds (e.g., peanut cracking and paper ripping) are sufficient to recruit the entire motor neuron sample involved in the action leading to the sound. See also the next section on the evolution of language. The flexibility of learning (as all the evidence with adults and monkeys suggests) synchronization is a very highly adaptive assimilative process, and acquisition of new forms is rapid. It is also noteworthy that synchronization as a process is also adaptively utilized in highly complex social interaction (e.g., syntactic priming), which indicates that the process has been adapted for the purposes of learning and executing more recent forms of communication.

7. I shall not discuss the issue of the evolution of language here for which there are diverse accounts (e.g., Aiello & Dunbar, 1993; Arbib, 2002, 2005; Corballis, 2004; Dunbar, 1996; Rizzolatti & Arbib, 1998; Rizzolatti & Craighero, 2004, *inter alia*). There is a neurophysiological account deriving from the research on mirror neurons, arguing for the gestural origins of language evolution (e.g., Arbib, 2002; Rizzolatti & Arbib, 1998) as well as models for the embodied grounding of language, which converge with the present argument on synchronization (e.g., Glenberg & Kaschak, 2002, 2003).

8. Most priming effects are successful well below the 1,000-millisecond margin. For instance, affective priming occurs within a short-lived window—preceding the target by 300 msec and succeeding it by maximally 150 msec (Fockenberg, Koole, & Semin, 2005). Synchronization of facial muscles with affective expressions takes place within 500 msecs (Dimberg et al., 2000, inter alia).

9. The nature of coupling has obviously undergone radical changes with the invention of revolutionary technologies such as writing, postal service, phone, video linking, Internet, and so on. These retain the embodied features of communication, but this subject is beyond the scope of this chapter.
